The synthesis of the 110 base template was carried out by ligation of three synthetic oligonucleotides, one of which contained the randomized sequence. A pool of 4^8 (=65536) different RNA molecules was generated by T7 transcription, and then subjected to four cycles of selection for DNA–polymerase binding by retention of RNA–protein complexes on nitrocellulose filters. After reverse transcription of the eluted RNA, PCR amplification, and transcription, the enriched RNA pool was used as the input for the next cycle of selection.[27] After the fourth selection/amplification cycle, no further change in the binding behavior of the remaining RNA with respect to wild-type RNA was observed. Two sequences predominated in the selected pool: the wild-type sequence AAUAACUC; and one other, AGCAACCU, which differs from the wild type at four positions. The four mutations are located in the part of the loop adjacent to the stem, and could allow the stem to be extended by two additional base pairs. The complexes of the two variants with T4 DNA polymerase exhibited the same dissociation constants ($K_d = 4.8 \times 10^{-9}$) in filter-binding assays. It is not yet clear if the protein binds equally well to two different structures, or if the two different sequences are able to form very similar tertiary structures in some unknown way.

3.3. Recognition of Double-stranded DNA(dsDNA) by RNA

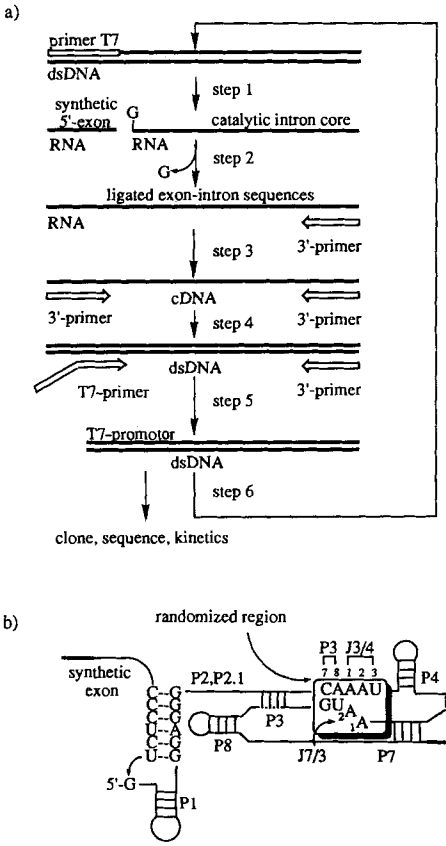
Single-stranded DNA and RNA can bind to DNA duplexes in the major groove, and can recognize specific sequences through the formation of T–AT and C^+–GC base triples. In order to explore more fully the rules of duplex DNA recognition, Pei et al.[28] used in vitro selection to isolate RNA sequences that could bind to a polypurine:polypyrimidine duplex DNA. The target duplex was attached to a thiol-Sepharose support through a disulphide linkage. Control experiments showed that an oligonucleotide complementary to the polypurine sequence was retained by the derivatized column matrix under high salt conditions, and was eluted under low salt conditions. A library of RNA molecules containing a random sequence region of 50 nts flanked by defined primer binding sites was then subjected to five cycles of selection for binding to the duplex DNA column. Any RNAs that might have bound to the thiol-Sepharose support itself were removed by negative selection on underivatized thiol-Sepharose. Sequencing of 17 clones from the final selected pool showed that most of these clones contained extensive polypyrimidine tracts that could be aligned with the sequence of the target duplex to form the expected T-AT and C^+-GC base triples. Surprisingly, many of the selected sequences contained "mismatched" base triples, or even substantial insertions of six to eight bases. Further selection experiments of this nature may clarify or expand the rules for the formation of stable triplex structures.

3.4. Structure and Function of Catalytic RNAs

The group I intron found within the pre-ribosomal RNA of *Tetrahymena* catalyzes its own removal to generate mature rRNA.[29] The first step in this self-splicing reaction consists of an S_N2 attack by the 3′-OH group of a free guanosine on the phosphate at the 5′-exon–intron junction. The phosphodiester bond between the intron and the 5′-exon is broken, and a new bond is formed between the guanosine and the intron. The 3′-OH group at the end of the 5′-exon then carries out a similar nucleophilic attack on the 3′-end of the intron. The intron is released and the two exon segments are ligated.[30] The structure of this RNA catalyst, its substrate-binding properties, and its mechanism of catalysis have been the subject of extensive experimentation over the last decade; in vitro selection promises to be quite useful in the study of this and other ribozymes.

3.4.1. Structure of the Tetrahymena ribozyme

Much of our knowledge of the structure of the *Tetrahymena* ribozyme has been deduced from a comparative analysis of the sequences of over 100 group I introns. This approach has been extraordinarily fruitful in providing evidence for the detailed secondary and tertiary structures of this RNA enzyme. Nevertheless, the phylogenetic approach is entirely dependent upon the availability of suitably divergent sequences. In order to avoid this limitation, Green



Scheme 6. a) Schematic representation of the selection strategy for the determination of functionally important interactions in the *Tetrahymena* ribozyme. Step 1: Transcription of double-stranded DNA (dsDNA) with T7 RNA polymerase. Step 2: Only the catalytically active variants can ligate the 5'-exon to the core. Step 3: Reverse transcription of ligated and unligated RNAs. Step 4: PCR amplification of the ligated exon–intron sequences, which have the 3'- and 5'-primer binding sites. Step 5: Nested PCR regenerates the starting intron sequence. Step 6: Return to Step 1 for the next selection cycle. b) The five and four nucleotide region that was randomized within the catalytic portion of the ribozyme. The annealing sequence of the synthetic exon is also shown.

et al.[31] have analyzed a derivative of the *Tetrahymena* ribozyme by in vitro selection.

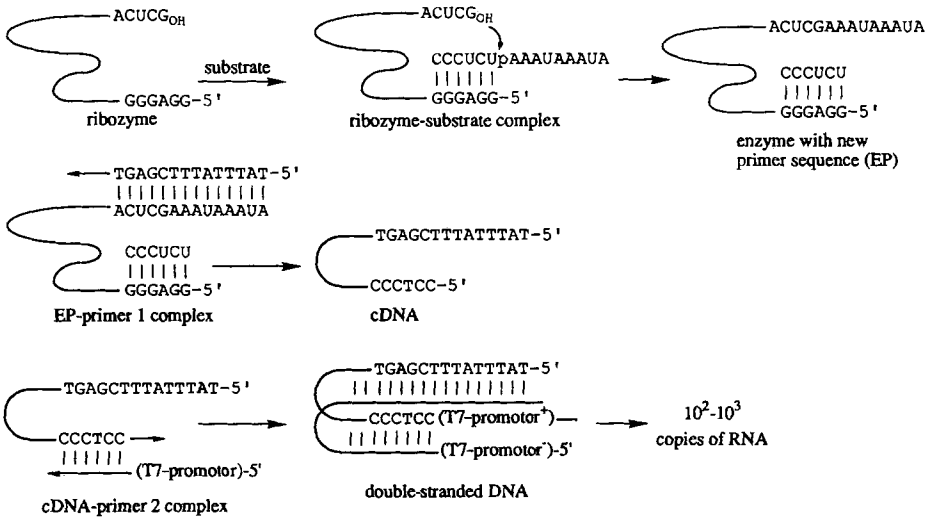
The selection procedure was based on the reverse of the cleavage reaction catalyzed by the ribozyme. A ribozyme was generated that corresponds to the product of the first splicing step, that is, the 5'-exon has been removed and the guanosine substrate covalently bound to the intron. The addition of a synthetic 5'-exon then allows reversal of the reaction: the exon becomes joined to the intron with concomitant release of free guanosine (Scheme 6).

The selection scheme takes advantage of the fact that exon ligation introduces new, unique sequences, which can be used as a primer binding site for PCR amplification; thus, only molecules which have taken part in a catalytic event can subsequently be amplified. After the initial PCR amplification of ligated RNAs, a second round of PCR is used to regenerate the starting intron sequence, including the guanosine that was cleaved during catalysis. In vitro transcription then regenerates RNA sequences that can be used in the next round of selection.

Two segments of four and five nucleotides within the wild-type intron, suspected on the basis of previous evidence to interact with one another,[32] were randomized.[33] Since the entire intron sequence was too long to synthesize chemically, the pool was generated by PCR amplification of a plasmid template by using primers containing the randomized sequences. After the pool of 4^9 (= 262144) different variants had been subjected to three cycles of selection and amplification, it showed half the control activity of the wild-type intron. Cloning of individual variants of the selected pool gave the wild-type sequence as the most common. In the remaining sequences, some positions were invariant, while others were quite variable. Two interesting positions did vary, but in a correlated manner; this suggests that these positions interact strongly with each other. With this information, hypotheses[34] about tertiary interactions between bases in the investigated region could be tested.

3.5. Selection for Altered Catalytic Properties

Robertson and Joyce recently reported an in vitro selection system for group I introns, similar to that described in the preceding section, but designed to select for variants with altered catalytic function.[35] Scheme 7 shows the selection strategy.



Scheme 7. Strategy of selection for the isolation of variants of the *Tetrahymena* ribozyme. DNA oligonucleotides were employed as substrates. The experiment was designed so that those forms of the ribozyme that could react best with the DNA substrate were selected.

The reaction being used can be viewed as the reverse of the second step of self-splicing (exon ligation). An added oligonucleotide, representing the ligated exons, is attacked by the 3'-OH of the ribozyme, which results in cleavage of the oligonucleotide and ligation of the 3'-half of the oligonucleotide to the ribozyme itself. This new 3'-sequence is only added to catalytically active variants of the ribozyme, and hence the complementary primer used to initiate reverse transcription can hybridize only to active molecules. The resulting cDNA is converted into dsDNA with a second primer; however, this DNA is not amplified by PCR, but amplification occurs as a result of the transcription step, during which T7 RNA polymerase synthesizes many copies of RNA from each DNA template. Although Robertson and Joyce attempted to select for a ribozyme variant that would preferentially cleave DNA rather than RNA, it appears that they have primarily obtained variants that have increased activity with both RNA and DNA substrates. Nevertheless, their approach is readily adaptable to selection over many sequential cycles, and the resulting ability to "evolve" novel ribozyme activities promises to be extremely interesting.

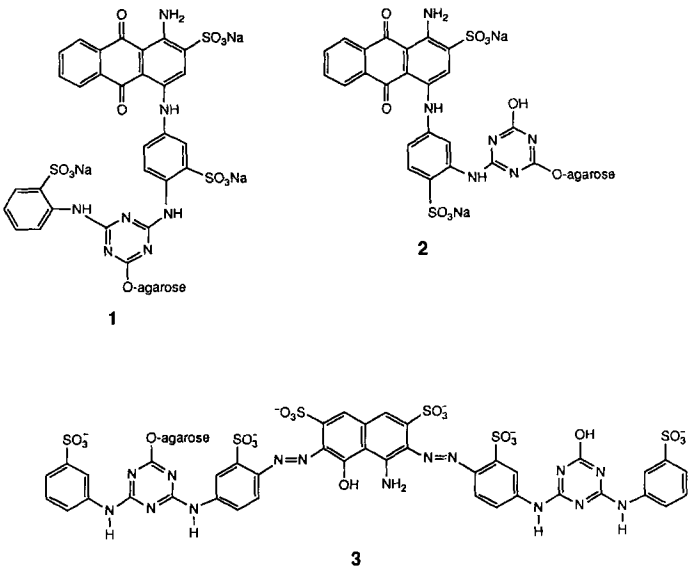
Self-replicating RNA molecules are thought to have played an important role in the early evolution of life.[36] The group I introns are of interest in this regard, because the chemistry of self-splicing is quite similar to the chemistry of existing RNA polymerases, although the substrates differ substantialy. Indeed, the catalytic abilities of the group I ribozymes have been used to demonstrate primitive replication like reactions.[37] Further modification of these ribozymes will be required to generate an RNA enzyme capable of efficiently and accurately copying another RNA molecule. In the absence of sufficient information to permit the rational design of such an RNA enzyme, the in vitro selection approach seems the most likely to lead to progress in this area.

3.6. Molecular Recognition of Small Substrates by Nucleic Acids

Ribozymes, like protein enzymes, have binding clefts and pockets that can very specifically recognize substrates.[38] The guanosine binding site in the *Tetrahymena* ribozyme[39] is an example of such substrate recognition, while interactions between drugs and DNA[40] and salt bridges between arginine and the phosphate backbone[24] are other examples of more or less sequence-specific nucleic acid/ligand interactions. The relative paucity of examples of small molecule recognition by nucleic acids has left open the question whether this sort of molecular recognition is general. The ability of nucleic acids to recognize small organic and even abiotic molecules has been addressed by in vitro selection experiments, as has the related but more subtle question of the probability of finding a sequence capable of such recognition in a pool of random sequences.

3.6.1. Selection for Substrate-Specific RNA Receptors

Ellington and Szostak used a completely random sequence of 100 base pairs, flanked by primer binding sites and the T7 promotor (see Scheme 3) for the selection of RNA receptors.[41] The pool contained more than 10^{13} different RNA molecules, which is larger than the number of possible antibodies in the mouse ($10^9 - 10^{10}$).[42] Affinity chromatography was used to select for RNA molecules capable of binding to dye molecules **1**–**3** covalently linked to agarose (Scheme 8). Such columns are commonly used for the purification of dehydrogenases by affinity chromatography because the dyes mimic the structure of NAD^+ and other cofactors.[43] The dyes are aromatic systems with many hydrogen-bond donors and acceptors and charged groups, all of which would seem to provide opportunities for strong interactions with RNA (Scheme 8).



Scheme 8. Structures of dye molecules used for the selection of specifically binding RNA molecules. **1**: cibacron blue 3G-A, **2**: reactive blue 4, **3**: reactive green 19.

Because bivalent cations can help RNA to fold into defined three-dimensional structures, the RNA pool was loaded onto each column in a buffer containing Mg^{2+} ions, and unbound species were washed off with the same buffer. Bound species were then eluted with ethylenediamine tetraacetic acid (EDTA) and amplified. After the first few rounds of selection, only a small fraction of the RNA was recovered in the EDTA wash, however, after five cycles of selection approximately 50% of the input RNA bound to the column and was recovered in the EDTA elution step. The total enrichment for binding molecules over the five cycles of selection was between 10^8 and 10^{10}. Dissociation constants for dye binding were determined by analytical affinity chromatography and found to be between 500 μM and 10 μM.

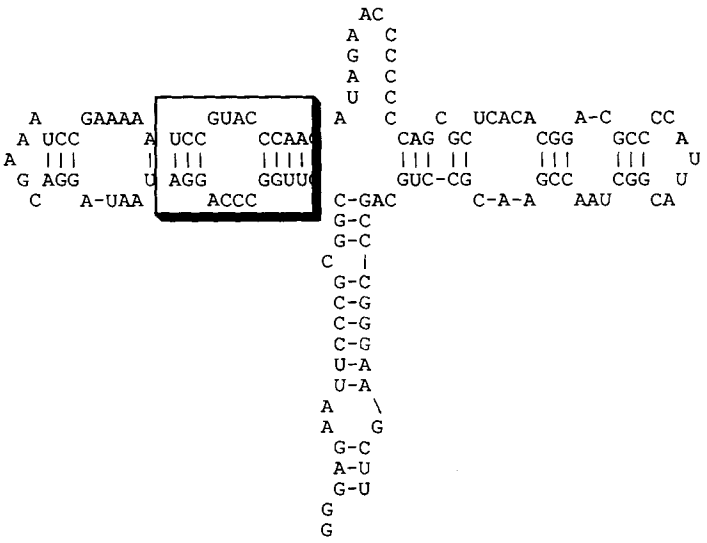
The pool of selected RNAs contained both dye-specific molecules and molecules that bound to agarose itself rather than to the dye ligand. The dye-specific RNA molecules bind only to the dyes with which they were selected[44] (Table 1).

The specificity observed in this study is remarkable because of the structural similarity of dyes **1** and **2**. In fact, the RNA-receptors show higher specificity than many proteins for these ligands.[45]

Table 1. Specificity of the binding of dye-specific RNAs on agaroses derivatized with dyes.

ararose derivatized with	RNA selected on dyes 1	2	3	oligo (dT)
	[% bound]			
1	63	1	1	6
2	8	85	1	5
3	7	1	73	6
oligo (dT)	7	7	4	61

To define the substrate-binding site on particular RNAs, templates for two of the clones were synthesized with a large number of mutations (85% wild type, 5% of each non-wild-type base, see Scheme 2b) and used to make new degenerate RNA pools, which were then reselected for dye-binding. Alignment of the sequences of the newly selected clones revealed conserved regions; these apparently represent the binding site. For the RNA that binds cibacron blue (**1**) these sequences could potentially form a stem–bulge–stem structure (Scheme 9).



Scheme 9. Possible secondary structure of the reactive blue 4-binding RNA B4-25. The sequences in the boxed area were conserved between functional variants of B4-25, and were also found in an independent clone (B4-45).

Can the method described here also be applied for smaller molecules that have fewer potential interaction sites? We have recently obtained an RNA pool that was selected on agarose derivatized with D-tryptophan. Remarkably, the binding of this pool is stereospecific[46]—the pool binds to D- but not to L-tryptophan agarose or other substrates. Analytical affinity chromatography of one clone revealed a K_D of 18 μM. This clone binds to L-tryptophan agarose with a K_D of greater than 12 mM, corresponding to a difference in the relative binding energies of $\Delta\Delta G = 3.8$ kcal mol^{-1}.

The finding that many RNA sequences are able to distinguish between **1** and **2** or between D- and L-tryptophan agarose shows that binding pockets similar to those found in proteins have been selected. Furthermore, many different sequence "solutions" exist for the problem of recognizing a particular structure.

All of the experiments described above were done with pools of RNA molecules. RNA, as opposed to DNA, was chosen because the existence of tRNA and RNA enzymes proves that RNA is capable of forming the complex three-dimensional structures required for molecular recognition. However, single-stranded DNA differs from RNA only in the lack of 2′-hydroxyls and in the presence of a 5-methylated version of uracil (i.e., thymidine), and so might also be capable of folding into complex shapes that can recognize other molecules. Selection experiments similar to those described above have recently been done with pools of single-stranded DNA molecules.[47] The pools were generated and amplified by asymmetric PCR, in which one primer acts more efficiently than the other; the result is an excess of one strand over its complement. Single-stranded DNAs that were able to bind to and discriminate between the various dye-agaroses described above were readily obtained. Interestingly, an RNA version of one of these DNA sequences did not bind its cognate dye-agarose, which suggests that RNA and DNA versions of the same sequence are nonequivalent in terms of molecular recognition.

4. Summary and Future Directions

We have discussed a number of applications of in vitro selection, ranging from the determination of protein binding sites on DNA and RNA, to the selection of improved and altered ribozymes and the synthesis and evaluation of novel nucleic acid receptors. In view of the tremendous effort that has gone into the design of molecules capable of molecular recognition,[48] it is perhaps ironic that the methods of molecular biology now allow the facile isolation of nucleic acids with just such properties, but without any knowledge on the part of the experimenter of the structure of these molecules or of how they bind and recognize their ligands. Pharmacological applications of these techniques are easy to imagine[49, 50] and it seems quite plausible that short oligonucleotides that inhibit the action of important proteins by binding could be isolated.[51]

Perhaps one of the most interesting scientific questions can now be approached: can RNAs or DNAs, selected for binding to ligands that mimic the transition state of a chemical reaction,[52] generate novel biocatalysts, similar to catalytic antibodies.[53] There exists thus the potential of finding chemical reactions experimentally that can be catalyzed by RNA (or DNA). This endeavour could help to test the plausibility of theories in which primitive life forms developed a complex metabolism based on RNA catalysis.[54]

5. Glossary

cDNA: short for "complementary DNA"; single-stranded DNA that has been synthesized by the reverse transcription of an RNA template.

Electrophoresis Mobility Shift Assay (EMSA) and band-shift electrophoresis: methods to detect the binding of a ligand (usually a protein or peptide) to a nucleic acid. Binding of the ligand influences the mobility of the polynucleotide in

the electric field; the nucleic acid migrates more slowly in the gel when bound to the ligand.

Env, gag, and pol: viral genes that are responsible for the replication of retroviruses; *env* encodes for the outer virus shell, *gag* the virus capsid, and *pol* the reverse transcriptase.

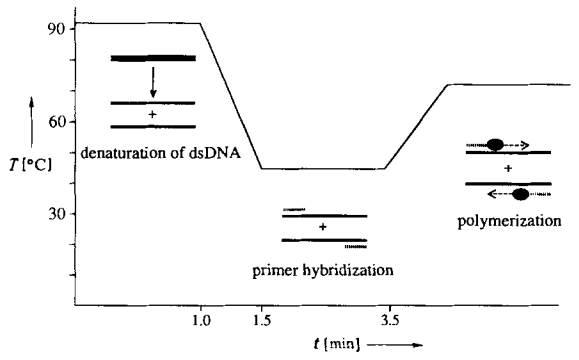
fos oncoprotein: the gene product of *fos*, an oncogene of the mouse osteosarcoma virus. It is a 55 kDa phosphoprotein and is found in the nucleus. *Fos* acts as a transcriptional activator for several growth factors and helps initiate their transcription by forming heterodimers with proteins such as the oncoprotein *jun*. The role of the *fos* oncoprotein in these regulatory processes is not yet understood in full detail (see, for example, M. J. Bishop, *Cell* **1985** *42*, 23).

Immunoprecipitation: a technique for the rapid isolation and purification of a target antigen in mixtures of proteins. The technique uses polyclonal or monoclonal immunoglobulins (Igs) that bind specifically to the protein of interest. The antibody/antigen complex is precipitated by binding to a secondary reagent, such as an anti-antibody coupled to a carrier matrix. Immunoprecipitation is extremely selective and sensitive: as little as 100 pg of a radiolabeled protein can be detected. Target proteins are normally precipitated from radiolabeled cell extracts (see, for example, D. J. Anderson, G. Blobel, *Methods Enzymol.* **1983**, *96*, 111).

In vitro translation: mRNAs that have been generated by in vitro transcription or have been extracted from mammalian cells can be translated in cell-free extracts to generate their encoded proteins (see for example, P. A. Krieg, D. A. Melton *Nature* **1984**, *308*, 203.).

Phylogenetic studies: phylogeny is the relationship between individuals, species, or population as a reflection of their evolutionary history. In phylogenetic studies, classifications are made on the basis of evolutionary similarities or differences, for example in DNA sequences, and relationships established.

Polymerase chain reaction (PCR): a technique that allows the amplification of DNA sequences. Applications range from genetics and disease diagnosis to forensic science. The key tool in PCR is the heat-stable DNA polymerase from the microorganism *Thermus aquaticus*, Taq–DNA polymerase. This enzyme has its optimal activity at 72 °C, but is stable at temperatures as high as 95 °C. A PCR cycle consists of three stages (see Scheme 10): a) Denaturation of double-stranded DNA into the two single strands (94 °C). b) Annealing of the primer sequences to the single-stranded templates. Primer binding sites have to be at least 18–20 bases long, but can be much longer. Depending on the length of the primer binding site, the annealing temperature can range from 40–60 °C. Primers are added to the PCR mix in large excess over the template. c) Synthesis of the complementary strands by Taq-DNA polymerase at 72 °C.



Scheme 10.

Every PCR cycle doubles the amount of template that was generated in the cycle before. After 20 PCR cycles ideally $2^{20} = 1{,}048{,}576$ copies of the input template are generated (for a brief and illustrative discussion of PCR, see H. Zinke, G. Gassen, Angew. Chem. **1990**, *102*, A–292; see also a) J. L. Marx, *Science* **1988**, *240*, 1408; b) K. B. Mullis, *Sci. Am.* **1990**, *262*, no. 4, p. 56; c) H. Ibelgaufts: *Lexikon Zytokine*, Medikon Verlag, München, **1992**, p. 66 ff.)

Serum Response Factor (SRF): a transcription factor that binds to the *c-fos* Serum Response Element (SRE), a multifunctional regulatory region of the *c-fos* promotor that responds to a variety of inducers (see: C. Norman, M. Runswick, R. M. Pollock, R. Treisman *Cell* **1988**, *55*, 989).

Zinc finger: a structural motif in various eukaryotic transcriptional regulatory proteins. Zinc fingers are about 30 amino acids in length. The motif contains histidine and cysteine residues whose side chains serve as ligands for a tetrahedrally coordinated Zn^{2+} ion. For specific DNA binding, several zinc finger domains within the protein chain are required. In the protein TFIIIA, for example, are about ten zinc fingers (see for example, helix-turn-helix, zinc finger, and leucine zipper motifs for eukaryotic transcriptional regulatory proteins: K. Struhl, *Trends Biochem. Sci. 14*, 137–140).

We are grateful to Hoechst AG and the Fonds der Chemischen Industrie (Liebig Stipend to M. F.) for the generous support of our work. We thank our co-workers and colleagues, David Bartel, Andrew Ellington, Rachel Green, Anusch Peyman, Mandana Sassanfar, and Charles Wilson for their contributions and discussions, and Jon Lorsch for help in writing the glossary.

[2] Even in a very good library of, for instance, 100 base-pair random sequences, only a small fraction of possible sequences are in fact present in the pool. That is not a result of the inefficiency of the chemical oligonucleotide synthesis: to have all possible permutations of a 100 base random sequence present in the pool, $4^{100} = 10^{60}$ different molecules would have to be made. This corresponds to no less than 10^{38} kg of DNA. At present automated oligonucleotide synthesis allows a complete coverage of all possible sequence permutations of 25 bases or less.

[4] At first sight, this idea seems to oppose the general direction of modern organic chemistry, where unique products are highly disirable. Here, the more different molecules we generate during the synthesis, the better. However, it is clear that clean reaction steps with as high yields as possible are necessary to maximize the yield of synthetic DNA. In the future, new methods for oligonucleotide synthesis that lead to very clean products, such as developed by Noyori et al., could prove to be very useful: Y. Hayakawa, S. Wakabayashi, H. Kato, R. Noyori, *J. Am. Chem. Soc.* **1990**, *112*, 1691; Y. Hayakawa, H. Kato, T. Nobori, R. Noyori, J. Imai, *Nucleic Acids Res. Symp. Ser.* **1986**, *17*, 97; Y. Hayakawa, H. Kato, M. Uchiyama, H. Kajino, R. Noyori, *J. Org. Chem.* **1986**, *51*, 2400. In addition, it may be desirable to use sequences as long as 400–1000 bases in length. Such sequences cannot be generated chemically, but could be accessible if defined restriction sites are built into the random oligonucleotides, to allow the ligation of several fragments. (D. P. Bartel, M. Famulok, J. W. Szostak, unpublished.)

[6] D. P. Bartel, M. Famulok, R. Green, J. W. Szostak, unpublished.
[7] One of the main problems in the synthesis of longer sequences (150–200 bases) is the increasing depurination that occurs with increasing chain length. (G. Remaud, X.-X. Zhou, J. Chattopadhyaya, M. Oivanen, H. Lönnberg, *Tetrahedron* **1987**, *43*, 4453; see also C. Tamm, E. Hodes, E. Chargaff, *J. Biol. Chem.* **1952**, *195*, 49; C. Tamm, H. Shapiro, R. Lipshitz, E. Chargaff, *ibid.* **1953**, *203*, 673). This can lead to branching of the DNA strand during the subsequent synthesis steps or to chain termination. Branched oligonucleotides are not amplifiable by PCR. One possibility for minimizing depurination is the use of the aprotic Lewis acid BF_3-methanol complex instead of the protic acid $Cl_2CHCOOH$ or Cl_3COOH, normally used to remove the dimethoxytrityl protecting group. (M. Mitchell, *Nucleic Acids Res.* **1990**, *18*, 5321).

[32] Phylogenetic comparisons of some group I introns show an interesting potential covariation: in 32 out of 35 group I introns, base pair 7 in the P3-stem (P3-7) is G-C, the second base in the region that connects P3 with P7 (J3/7–2) is A and the connecting region contains three bases. In the three remaining group I introns, P3-7 is G-C, J3/7–2 either U or G and J3/4 contains only two bases. On the basis of such phylogenetic data it seems plausible that nucleotides in this region interact with each other. S. Couture, A. D. Ellington, J. A. Doudna, R. Green, M. Hanna, U. Pace, J. On Quantifying Chirality

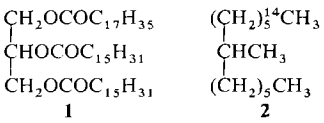
By Andrzej B. Buda, Thomas Auf der Heyde, and Kurt Mislow*

Since Pasteur's epochal discoveries a century and a half ago, the concept of chirality has continued to play a central role in chemistry and biochemistry. Can chirality be measured? It has long been known that molecular chirality can be given a quantitative meaning through functions specifically parametrized to match the magnitude of pseudoscalar observables. However, chirality is a property that is independent of its physical and chemical manifestations: for a system to be chiral, all that is required is the absence of improper rotations in the symmetry group of the system. This being the case, how can chirality be measured if the "system" is an abstract geometric figure, for example, a scalene triangle in the plane or an asymmetric tetrahedron in three-dimensional space? How does chirality vary as a function of pure shape? In this review we describe recent efforts designed to answer these and related questions.

1. Introduction

1-Stearoyl-2,3-dipalmitoylglycerin (**1**) exemplifies a class of enantiomerically pure triglycerides that exhibit no measurable optical activity in the visible and ultraviolet regions.[1] This result is readily understandable because the fatty acid residues in the 1- and 3-positions are "very similar... and hence the asymmetry of the molecule is very slight".[1b] Similar reasoning underlies the assertion that enantiomerically pure 7-methyl-[1-^{14}C]-tridecane (**2**) "would have zero rotation within experimental error on the most sensitive polarimeter now available".[2]



1

2

These examples, in which the "very slight" asymmetry in the structures of **1** and **2** is obviously the root cause for the observed optical inactivity of the samples, show that it is natural to attach a quantitative meaning to the chirality of molecular structures, and that the degree of chirality is manifested in the magnitudes of appropriate observables.[3, 4] By extension, it is possible to rank the chirality of closely related structures,[3] and to speak, for example, of 6-methyl-[1-^{14}C]-undecane and 8-methyl-[1-^{14}C]-pentadecane as being "more" and "less" chiral than **2**, respectively, with reference both to their molecular structures and to their chiroptical properties.[5]

In this review we explore some of the ways in which the chirality of molecular structures, more specifically of their geometric representations, may be placed on a quantitative basis. For the purposes of our discussion, we take the position that chirality is an inherent molecular property,[6] and we neglect problems arising from the parity-violating energy differences between enantiomers.[7, 8]

2. Measures of Geometric Chirality

2.1. From Abbé Haüy to Lord Kelvin

The story that culminates in Pasteur's momentous discovery of April 1848—the correlation of crystalline hemihedry with optical activity in the tartrates—begins with the observation of hemihedral facets in quartz ("quartz plagièdre") by Abbé René Just Haüy, the founder of modern crystallography.[9a] Following Biot's observation that the plane of linearly polarized light is rotated by passage through quartz and through certain organic liquids and solutions, Herschel[9b] recognized that hemihedry in quartz leads to the existence of two kinds of crystals, left-handed and right-handed, and that there is a causal relationship between the handedness of the crystals and their sense of optical rotation. Herschel's findings and concurrent studies by Biot and Fresnel prepared the ground for Pasteur's discovery[10] and for his demonstration that the optical activity of tartaric acid is a manifestation of molecular chirality ("dissymétrie moléculaire").[11]

From its historic roots in nineteenth-century science to the present day, chirality in chemistry has been associated with crystals and molecules. However, chirality is a general attribute of objects or figures, and does not depend for its definition on any connection to the material world and to the natural sciences, even though this connection is of the greatest importance.[12] It was left for Lord Kelvin to formulate a definition of chirality that gives explicit expression to the inherently abstract nature of the concept: "I call any geometrical figure, or group of points, *chiral*, and say it has *chirality*, if its image in a plane mirror, ideally realized, cannot be brought to coincide with itself."[13] Chirality is thus defined as the absence of reflection symmetry. As a property, it is attributable to objects regardless of whether they are models of molecules.

2.2. Classification of Chirality Measures

2.2.1. Degree of Chirality

We define as the "degree of chirality" of an object the value of a real-valued, continuous function that is zero

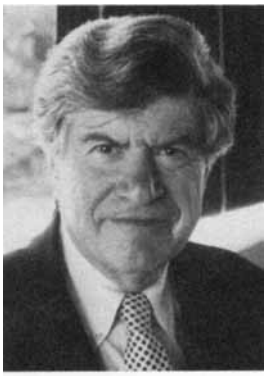
if, and only if, the object is achiral.[14] The degree of chirality is the measure of an absolute quantity, and its value is therefore the same for both enantiomorphs of the measured object.

In addition, like measures of symmetry for convex sets,[15] the degree of chirality of geometric figures should also be similarity invariant, because the chirality of such objects is measured by shape and not by size, and invariance under similarity transformations eliminates the factor of size.[16] Normalization of the function then renders it dimensionless in the interval [0, 1]. Thus, we see no reason for not applying measures of chirality to geometric figures as well as to geometric models of molecules and molecular ensembles.

2.2.2. *Classes of Measures for Chirality*

We recognize two general classes of measures: in the first, the degree of chirality expresses the extent to which a chiral object (or "chiroid"[13]) differs from an achiral reference object, while in the second it expresses the extent to which two enantiomorphs differ from one another. In chirality measures of the first kind the question to be answered is: how dissimilar are the chiroid and its achiral reference object? In chirality measures of the second kind (or "overlap measures") the question is: how dissimilar are the two enantiomorphs of a chiroid? The underlying concept is that of a "distance" measured between a chiral and an achiral object or between two enantiomorphous objects.[17] The following example may serve to illustrate the distinction between the two classes.

Consider a tetrahedron K and an achiral polyhedron P inscribed in K. Let $[K]$ and $[P]$ denote the volumes of the corresponding polyhedrons, and let P_{max} denote the inscribed polyhedron for which $R = [P]/[K]$ is at a maximum. Under this limiting condition, P_{max} fills K to its maximum capacity, that is, the unfilled volume of K is at a minimum. Clearly, K is achiral if, and only if, $P_{max} = K$ so that $R = 1$; otherwise K is chiral. The function $f(K) = \max_{P} \{[P]/[K]\}$ defined on the class of tetrahedrons then is a measure that is unity only for achiral tetrahedrons. Thus $\chi(K) = 1 - f(K)$, which expresses



Kurt Mislow was born in Berlin, Germany, in 1923. He obtained his B. S. degree at Tulane University (1944) and his Ph.D. at the California Institute of Technology (1947) with Linus Pauling. In 1964, after 17 years on the faculty of New York University, he joined Princeton University as the first incumbent of the Hugh Stott Taylor Chair of Chemistry. A member of the National Academy of Sciences and a Fellow of the American Academy of Arts and Sciences, he has been a Guggenheim Fellow twice, an Overseas Fellow of Churchill College at the University of Cambridge, a Fairchild Distinguished Scholar at Caltech, and has received numerous honors and awards, including the first Prelog medal of the ETH, Zürich, in 1986. Now Professor Emeritus at Princeton, he is continuing his exploration of stereochemical theory.

Andrzej B. Buda, born in Krosno, Poland, in 1953, studied chemistry at the Jagiellonian University in Kraków, where he received his Master's degree in 1977 and Ph.D. in 1982 with J. Mirek. After a year with E. Ōsawa in Hokkaido University, as a Fellow of the Japanese Ministry of Education, he returned to Kraków and was appointed Assistant Professor at the Jagiellonian University (1984–1986). In 1986 he joined K. Mislow's group at Princeton as a visiting research scientist, and in 1987 he went to the University of California at Los Angeles, where he was visiting scholar with K. N. Houk. He returned to Princeton in 1988, where he was appointed as a Research Staff Member. His scientific interests include dynamic stereochemistry, mechanisms of organic reactions, and electronic effects in nucleic bases during interactions of DNA with proteins, metals, and metal complexes.

Thomas Auf der Heyde was born in East London, South Africa, in 1958 and studied chemistry at the University of Cape Town (UCT), where be obtained his Ph.D. with L. R. Nassimbeni in 1988. Concomitant with his studies he worked as a research assistant to D. A. Thornton at UCT (1979–1980) and served as Lecturer in chemistry at the University of the Western Cape (UWC), where he is now an Associate Professor. While working for his Ph.D., he spent some months in 1984 and 1986 as a pre-doctoral fellow with H.-B. Bürgi in Berne, Switzerland. During a sabbatical/study-leave from mid-1989 to mid-1991 he spent six months with H.-B. Bürgi, four with F. H. Allen at the Cambridge Crystallographic Data Centre, and twelve in Princeton, working with his present co-authors. The dynamic stereochemistry of metal complexes remains the focus of his research interests.

the degree of chirality of K as a deviation from the achiral reference polyhedron P, is seen to be a measure of the first kind.

For a related measure of the second kind, consider again a tetrahedon K and its enantiomorph, K'. When K and K' are overlapped, $K^* = K \cap K'$ is a polyhedron inscribed in K and K'. Let K^*_{max} denote the intersection for which $R = [K^*]/[K]$ is at a maximum. Under this limiting condition, K^*_{max} fills K to its maximum capacity, and K is achiral if, and only if, $K^*_{max} = K$. The degree of chirality of K is now given by $\chi(K) = 1 - f(K)$, where $f(K) = \max_{K^*} \{[K^*]/[K]\}$, and where $\chi(K)$ expresses the extent to which K and K' differ from one another.[18]

The results for the two measures are the same if, and only if, $K^*_{max} = P_{max}$. In both systems, $f(K)$ cannot become zero (i.e., $\chi(K) \neq 1$), because it is always possible to inscribe an achiral polyhedron within any tetrahedron, or to overlap partially any pair of enantiomorphous tetrahedrons.

In Sections 2.3 and 2.4 we review salient results of work carried out at Princeton. We selected the tetrahedron as the principal target in our investigation of geometric chirality measures because of the historic role of the asymmetric (irregular) tetrahedron in stereochemistry.[19] At the focus of our investigation was the question: what is the most chiral tetrahedron? Evidently the answer would have to depend on the measure employed. As a first exploratory step we therefore applied several measures to the scalene triangle, whose special position as the asymmetric simplex in the Euclidean plane (E^2) parallels that of the asymmetric tetrahedron in three-dimensional space (E^3). The results of our quest for the most chiral triangle are described in the next section.

2.3. In Search of the Most Chiral Triangle

Section 2.3.2 describes two chirality measures of the first kind—those that express the "distance" of a chiral triangle from an achiral one[20]—while Section 2.3.3 describes two chirality measures of the second kind—those that express the "distance" between two enantiomorphous triangles.[21] But first we must provide a brief outline of symmetry and chirality in E^2; this is the subject of Section 2.3.1.

2.3.1. Chirality in the Euclidean Plane

Chirality is an extrinsic property; that is, its existence depends on the dimension of the space in which the object is embedded. Thus, objects that are enantiomorphs in E^n are superposable by proper rotations in E^{n+1}; for example, a scalene triangle is a chiroid in E^2 but not in E^3. There are two classes of point groups in E^2, cyclic (C_n) and dihedral (D_n). Figures in E^2 are chiral if, and only if, they belong to C_n, and achiral if, and only if, they belong to D_n. All chiroids in E^2 except those belonging to C_1 (the asymmetric group) have rotational symmetry with respect to a point at the center. A figure in E^2 that is symmetric with respect to inversion through a point is said to possess centric symmetry; centric symmetry is therefore the special case of rotational symmetry for which n is even. If, and only if, the figure is symmetric with respect to reflection through a line (axial symmetry), it belongs to D_n and is therefore achiral; if $n > 1$ the figure also has rotational symmetry. Accordingly, scalene, isosceles, and equilateral triangles belong to C_1, D_1, and D_3, respectively.

In chemistry, idealized models of chiral molecules distributed in monolayers or adsorbed on surfaces[22] are also said to possess "two-dimensional chirality".[23]

2.3.2. Deviation from Achirality

2.3.2.1. Geometric Chirality Products

In 1890, only 16 years after van 't Hoff's and LeBel's revolutionary proposals to extend the structural formulas of chemistry into three-dimensional space,[19] Guye[24] introduced the first algebraic function designed to correlate a pseudoscalar property, the optical rotation, with the molecular structure of a chiroid. Appropriately called "produit d'asymétrie", this was the first example of a chirality function in chemistry.[25] According to Guye, the chirality product P for a tetrahedral coordination skeleton, in which the bond angles subtended by the central carbon atom remain those of the regular tetrahedron (the "α-constraint", where α is the tetrahedral angle), is defined by Equation (a), where d_i is the distance of the molecular center of mass of the ith of six planes defined by each of the six edges and the center of the tetrahedron.

$$P(d) = \prod_{i=1}^{6} d_i \qquad \text{(a)}$$

$P(d)$ may also be expressed by Equation (b), where m_1, m_2, m_3, and m_4 are four masses at the vertices of the tetrahedron, separated by four distances, l_1, l_2, l_3, and l_4, from the central carbon atom.[26] If the four point-masses in Guye's model are taken to be all the same, then Equation (b) reduces to Equation (c), where $c = \left[\left(\sin\frac{\alpha}{2}\right)\Big/4\right]^6$.

$$P(m, l) = \left(\frac{\sin\frac{\alpha}{2}}{\sum_{i=1}^{4} m_i}\right)^6 \prod_{i>j}^{1-4} (m_i l_i - m_j l_j) \qquad \text{(b)}$$

$$P(l) = c \prod_{i>j}^{1-4} (l_i - l_j) \qquad \text{(c)}$$

$P(l)$ is a function of geometry alone and vanishes in all cases but one, that of the asymmetric tetrahedron. Geometric chirality products such as $P(l)$, which express the shape of geometric chiroids, are fully in accord with Ruch's theory.[27, 28] Thus, imagine a regular tetrahedron **t**, with center-to-vertex distances r, inscribed within a tetrahedron **T** whose chirality is given by $P(l)$, so that the center of **t** coincides with the center of **T** and the r's of **t** are coextensive with the l's of **T**. Because **t** is inscribed within **T**, $l - r \geq 0$. The four line segments, $l - r$, are therefore the geometric equivalents of ligands on a T_d permutation skeleton. Ruch[28b] had previously likened the ligand parameters λ to the diameters of spheres centered at the vertices of an achiral permutation

skeleton. The present construct, with $\lambda = l - r$, evokes a similar image.[29, 30]

These and related functions can also be rendered similarity invariant. However, the complexity of the resulting polynomials obscures basic features that are easily seen in the far more tractable polynomials of chirality products for triangles. A chirality product $P(e)$ for triangles [Equation (d)], where a, b, and c are the lengths of the sides, is not subject to the two-dimensional analog of the α-constraint, which is the constraint that none of the internal angles in the triangle can exceed $2\pi/3$ radians. Thus, Equation (d) encompasses all possible shapes of a triangle. In contrast, because of the α-constraint, Equations (a)–(c) cannot accommodate chiral tetrahedrons with C_2 or D_2 symmetry.

$$P(e) = (a - b)(b - c)(c - a) \qquad \text{(d)}$$

Division by abc transforms $P(e)$ into a similarity invariant function, $\chi(e)$ [Eq. (e)], which is bounded, normalized, and dimensionless in the interval $[-1, 1]$, and whose absolute value yields the degree of chirality for any triangle of defined shape.

$$\chi(e) = (1 - b/a)(1 - c/b)(1 - a/c) \qquad \text{(e)}$$

The shapes of triangles may be represented by points in an xy coordinate system in which side c opposite vertex C of a triangle ABC coincides with the x axis, and in which the center of c is fixed at the origin, with $c = 1$ so that the coordinates of A, B, and C are (1/2, 0), (−1/2, 0), and (x, y), respectively (Fig. 1). Accordingly, the coordinates of C define the shape of the triangle. We shall adhere to the labeling convention in Figure 1 throughout the following discussion.

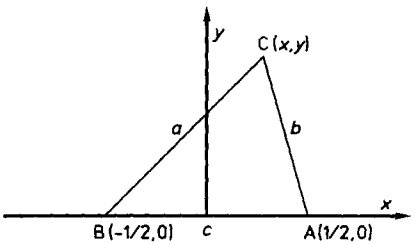


Fig. 1. Coordinate system and labeling convention for the shape space of triangles, in which a, b, and c, in that order, are arranged in a clockwise manner.

Points in the xy plane that represent isosceles triangles lie on one of three nodal curves, depending on whether $a = b$ [$x = 0$], $a = c$ [$(x + 1/2)^2 + y^2 = 1$], or $b = c$ [$(x - 1/2)^2 + y^2 = 1$]. Figure 2 shows two of the nodal curves as semicircles with radius $c = 1$, centered at $(-1/2, 0)$ and $(1/2, 0)$, that intersect the third nodal curve, the y axis, at $(0, \sqrt{3}/2)$, the point that represents the equilateral triangle. The three nodal curves divide the xy plane into six regions, each of which represents all chiral (scalene) triangles that have in common a given inequality of sides. The six regions fall into two sets representing enantiomorphous triangles: $\{c < a < b,\ a < b < c,\ b < c < a\}$ and $\{a < c < b,\ b < a < c,\ c < b < a\}$. However, because the shape of each scalene triangle is represented in three regions, and its enantiomorph in the other three, the six regions may be reduced to two, for example, those in which c is taken to be the longest side. All triangular shapes are then accommodated, without redundancy, within two regions, $a \leq b \leq c$ and $b \leq a \leq c$. In Figure 2 these regions are contained within a gothic arch whose apex is at $(0, \sqrt{3}/2)$ and which is bounded on two sides by arcs that belong to the two nodal semicircles and on the third by the x axis.[31] All isosceles triangles with $a = c$ or with $b = c$ are represented by points on the two arcs, while those with $a = b$ are represented by points on the y axis. All points that lie on the x axis represent degenerate triangles, that is, triangles whose three vertices are collinear and which are therefore excluded from the set of triangles under consideration. The shape space within the gothic arch is thus bounded on all three sides, but it is not closed at $y = 0$.

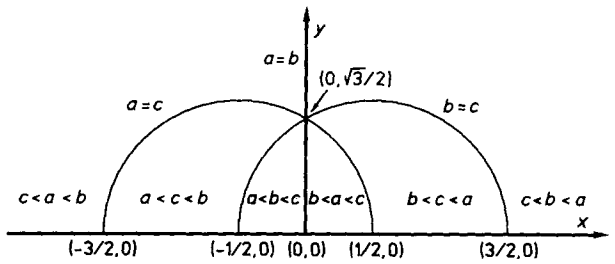

Fig. 2. The regions of shape space labeled according to the convention in Figure 1.

The dependence of $\chi(e)$ on triangular shape was explored by examining the behavior of the function as x varies for a given value of y within the bounds of the two arcs. Since $c = 1$, this corresponds to an examination of $\chi(e)$ as a function of triangular shape for all triangles with a given area $y/2$.

Figure 3 displays plots of $\chi(e)$ vs. x, computed for selected values of the altitude y. For each of the two enantiomorphous sets of triangles, $a < b < c$ and $b < a < c$, all values of $\chi(e)$ have the same sign, positive and negative, respectively, regardless of triangular shape. Within the conceptual framework developed by Ruch and coworkers,[28] $\chi(e)$ may therefore be characterized as a homochirality func-

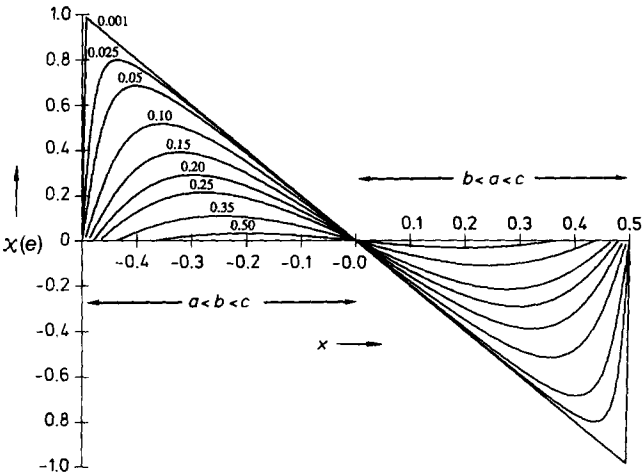

Fig. 3. Calculated plots of the chirality product $\chi(e)$ for triangles vs. x for the unique regions $\{a < b < c, b < a < c\}$ and several values of the altitude y. The altitudes are indicated by the numbers above the curves.

tion: the two sets are mutually heterochiral, all triangles within a given set are homochiral (i.e., chirally related), and the boundary between and around the two sets represents the set of achiral triangles.

For each value of y, $\chi(e)$ assumes a maximum value, χ_{max}, which is the same in magnitude but oppositely signed for the two sets. It is obvious on inspection of Figure 3 that with decreasing values of y, χ_{max} increases in magnitude and at the same time is shifted in the direction of the bounds at $x = \pm 1/2$. In the limit of $y = 0$, c is made up of two segments, a and b, so that $\chi(e) = -2x$ in the interval $(-1/2, 1/2)$. Thus $\chi(e)$ in the limit of $y = 0$ becomes a measure of one-dimensional chirality.

The magnitude of χ_{max} is negligible for values of y greater than 0.5, and becomes significant only for triangles that are extremely flat (i.e., for values of y close to zero) and extremely skewed (i.e., for values of x close to $\pm 1/2$). Within this domain, as the triangle becomes more chiral and more skewed, the vertex (C) representing the triangle with χ_{max} shifts towards the arched borders of the shape space. In the limit of $x = \pm 1/2$ and $\chi_{max} = \mp 1$, vertex C coincides with vertex A or vertex B. The most chiral triangle is therefore one that is infinitely flat and skewed, with an altitude y that is arbitrarily close to zero. Thus, paradoxically, the most chiral triangle is infinitely close to an achiral one.

2.3.2.2. *Symmetry Coordinates*

The problem of quantifying the distortion of a chemical molecule from a more symmetrical reference structure has been addressed by Murray-Rust, Bürgi, and Dunitz,[32] who set out to attach a quantitative meaning to statements of the type "the molecule has approximate T_d symmetry". In terms of their method, a given nuclear configuration is represented by a point in a multidimensional space spanned by a set of symmetry coordinates $\mathbf{S}_i$ for the more symmetric reference structure. The coordinates of the representative point are given by displacements along the $\mathbf{S}_i$'s, which are linear combinations of the internal coordinates that transform according to the irreducible representations of the molecular point group $\mathbf{G}$ of the reference structure; the origin of the space represents that reference structure. The magnitudes of these displacements then serve as the basis for quantifying the deformation of the observed configuration away from the reference structure.

This method is readily adapted to the problem of estimating degrees of chirality for triangles. A "conformation space" spanned by symmetry coordinates may be constructed, in which the choice of the three internal angles α, β, and γ as a basis set ensures similarity invariance, so that each point in this space represents the shape of a triangle, regardless of size. The achiral reference group, $\mathbf{G} = D_3$, is a two-dimensional group that is isomorphic with C_{3v}, in that the three σ_v elements in E^3 correspond to lines of reflection in E^2. The internal coordinates α, β, and γ transform as $A_1 + E$; three symmetry coordinates derived by standard methods[33] may be chosen as in Scheme 1, where Δ refers to the deviation from the angles in the reference structure, the equilateral triangle. However, the positive and negative deviations of the angles in the A_1 representation cancel out, since their sum must always remain zero. The conformation space of triangles is therefore adequately represented in terms of just the E coordinates.

$$\mathbf{S}_1(A_1) = (1/\sqrt{3})(\Delta\alpha + \Delta\beta + \Delta\gamma)$$
$$\mathbf{S}_{2a}(E) = (1/\sqrt{6})(2\Delta\gamma - \Delta\beta - \Delta\alpha)$$
$$\mathbf{S}_{2b}(E) = (1/\sqrt{2})(\Delta\beta - \Delta\alpha)$$

Scheme 1. Symmetry coordinates of the conformation space for triangles.

A projection of this space onto the plane defined by $\mathbf{S}_{2a}$ and $\mathbf{S}_{2b}$ is shown in Figure 4. The lines RP, PQ, and QR

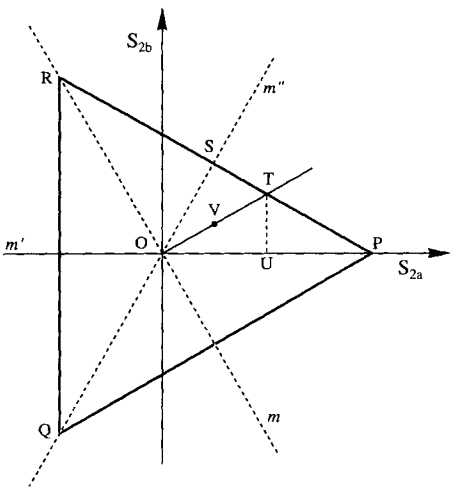

Fig. 4. Diagram of the conformation space for triangles. The dimensions of $\mathbf{S}_{2a}$ and $\mathbf{S}_{2b}$ are any angular measures. The space has symmetry $3m$, with O as the point of threefold rotation, and m, m', m'' representing the lines of reflection. Section OSP corresponds to one of the six asymmetric units. The significance of points S, T, U, and V is discussed in the text.

form the boundaries of the space and correspond to degenerate triangles with $\alpha = 0°$, $\beta = 0°$, and $\gamma = 0°$, respectively; the corners Q, R, and P correspond to degenerate triangles with $\alpha = 180°$, $\beta = 180°$, and $\gamma = 180°$, respectively. As in Section 2.3.2.1, degenerate triangles are excluded from the set of triangles under consideration. The space has symmetry $3m$; the point of threefold rotation, O, represents the equilateral triangle, while the three lines of reflection, m, m', and m'', which correspond to the coordinates $(\mathbf{S}_{2b} = -\sqrt{3}\ \mathbf{S}_{2a})$, $\mathbf{S}_{2b} = 0$, and $(\mathbf{S}_{2b} = \sqrt{3}\ \mathbf{S}_{2a})$, respectively, map isosceles triangles with $\alpha = \gamma$, $\alpha = \beta$, and $\beta = \gamma$, respectively. The points of intersection of these "achiral coordinates" with PQ, QR, and RP(S) represent degenerate triangles with $\alpha = \gamma = 90°$, $\alpha = \beta = 90°$, and $\beta = \gamma = 90°$, respectively. The three achiral coordinates divide the conformation space into six asymmetric units that correspond to the six permutations of α, β, and γ; for example, all triangles in asymmetric unit OSP have $\gamma \geq \beta \geq \alpha$, all triangles in asymmetric unit ORS have $\beta \geq \gamma \geq \alpha$, etc. In contrast to the shape space of triangles in Figure 2, all six asymmetric units in the conformation space of Figure 4 map triangles with the same handedness.[34]

A given chiral triangle is represented by a point C that lies in a general position—that is, not on any of the special positions mapped by the achiral coordinates—within any one of

the six equivalent asymmetric units. The degree of chirality of such a triangle is then gauged by the distance of C from the *nearest* point on an achiral coordinate. Since each asymmetric unit is bordered by two achiral coordinates, there will in general be two distances (d_1 and d_2) that need be considered. For example, in the asymmetric unit OSP the distances to the coordinates m' and m'' are $d_1 = (1/\sqrt{2})(\Delta\beta - \Delta\alpha)$ and $d_2 = (1/\sqrt{2})(\Delta\gamma - \Delta\beta)$, respectively. The degree of chirality **d** of the triangle is defined as the shorter of the two distances, that is, $\mathbf{d} = \min\{d_1, d_2\}$.

The location of the representative point for the most chiral triangle is obtained as follows. Consider, for example, the asymmetric unit OSP (Fig. 4): line OT (which corresponds to all triangles with $\beta = 60°$) is the bisector of angle SOP, and thus represents all geometries that are equidistant from the two achiral coordinates bordering this unit. The projections from point T onto the achiral coordinates are the suprema for perpendicular distances that can be realized within this asymmetric unit, and hence represent the upper bound for the displacement from achirality. It follows that the most chiral triangle corresponds to a point that is arbitrarily close to T, in other words, to a triangle that is infinitely flat and approachable only as a limit, with one angle of 60° (β), another (α) that is arbitrarily close to 0°, and a third (γ) that is arbitrarily close to 120°. The displacements d_1 and d_2 from U (the representative point for a triangle with $\alpha = \beta = 30°$ and $\gamma = 120°$) and S (see above) to T are given by the line segments $UT = (1/\sqrt{2})(\Delta\beta - \Delta\alpha)$ and $ST = (1/\sqrt{2})(\Delta\gamma - \Delta\beta)$, respectively, and are the same in magnitude. In both cases the displacement is accompanied by a total absolute angular change of 60°, with $d_1 = d_2 = \mathbf{d} = (1/\sqrt{2})(60°) \approx 42.4°$. This value defines the least upper bound (i.e. supremum) for **d** in the conformation space for triangles and allows normalization of **d** to the interval [0, 1].

It needs to be emphasized that the search for the point farthest from the achiral reference point and from the achiral boundaries, that is, for the point that is representative of the most chiral triangle, is not limited to the conformation space shown in Figure 4. For example, in the region of the shape space in Figure 2 that is labeled $b < a < c$, the point that is farthest from the achiral boundaries defined by $a = b$ and $a = c$ is located on the x axis, at (1/4, 0), and is representative of a degenerate triangle whose ratio of sides is 1:3:4. The most chiral triangle, which is arbitrarily close to this point, therefore differs in shape from the triangle close to T in Figure 4. As this example demonstrates, the shape of an extremal object given by a chirality measure of the first kind depends on the particular representation of the object space.

2.3.3. *Nonsuperposability of Enantiomorphs*

2.3.3.1. *Common Volumes*

This method was illustrated in section 2.2.2. by the example of overlapped tetrahedrons. Let T' denote the enantiomorph of a triangle T, taken to be a convex set with interior points, and let $T^* = T \cap T'$ denote the intersection resulting from the overlap of the two triangles in E^2. The problem of finding the most chiral triangle now becomes one of determining the conditions under which T^* assumes its maximum value, T^*_{max}. An analytical solution to this problem is far from trivial, considering the innumerable arrangements that are possible when two enantiomorphous triangles are superimposed; a priori, all that can be said is that T^*_{max} must be a polygon with 3, 4, 5, or 6 sides. Fortunately the problem becomes amenable to solution thanks to a theorem proved by Giering[35] that maximal overlap obtains only if both of two conditions are met: a) T^* must be axially symmetric, and b) the edges of T^* must be segments of all six sides of the two overlapped triangles. A measure of chirality that is in harmony with Giering's conditions is $\chi(T) = 1 - f(T)$, with $f(T) = \max_{T^*}\{[T^*]/[T]: T^* \text{ is axially symmetric and } T^* \subset T\}$ where $[T]$ and $[T^*]$ denote the areas of the corresponding polygons. The function $f(T)$ is similarity invariant, normalized in the interval [0, 1], and $f(T) = 1$ if, and only if, T is achiral.

To find the value of $\chi(T)$ for the most chiral triangle, that is, the supremum of the function, requires as a first step the systematic investigation of each class of polygonal intersections. Because Giering's second condition requires the edges of T^*_{max} to be segments of all six sides of the two overlapped triangles, triangular intersections are ipso facto excluded for all chiral triangles. Furthermore, it can be shown[21b] that only quadrilateral and pentagonal intersections, with a shared angle and a shared side, respectively, need be considered as candidates for $f(T)$. This analysis leads to Equation (f) for the unique geometry of a triangle T, with a given c/b or a given α, that corresponds to the lowest value of $f(T)$ for all possible intersections of T and its enantiomorph under conditions of maximal overlap, and to Equation (g) for the corresponding measure. In both equations, b and c are the two sides of T whose ratio is closest to unity and $b \leq c$, α is the angle subtended by vertex A (opposite side a), and for α the limits $1/2 \leq \cos\alpha < 1$ hold.

$$c/b = \sqrt{2\cos\alpha} \tag{f}$$

$$f(T) = \frac{2}{1 + \sqrt{2\cos\alpha}} \tag{g}$$

The value of $f(T)$ for the most chiral (i.e., least achiral) triangle obtains when $\alpha = 0$. It follows that the supremum of $\chi(T)$ can only be approached as a limit. At this limit, $c/b = \sqrt{2}$ [Eq. (f)], $f(T) = 2/(\sqrt{2}+1) \approx 0.828$,[36] and $\chi(T) = 1 - f(T) \approx 0.172$. The most chiral triangle is therefore infinitely flat, with an altitude h arbitrarily close to zero and with $c/b = \sqrt{2}$ and $a/b = \sqrt{2} - 1$ in limit $h = 0$. At the supremum the triangle would be completely flattened into a straight-line segment.

The small limiting value of $\chi(T)$ is particularly noteworthy, for it shows that the area of *any* triangle can be covered to the extent of *at least* 82.8% by overlapping the triangle with its mirror image in E^2.

2.3.3.2 *Hausdorff Distances*

The array of nuclear positions in a rigid molecular model may be represented by a discrete set of points in E^3. The

Hausdorff distance[37a] between sets is therefore a natural choice for a measure of chirality.

Consider two nonempty and bounded sets Q and Q'. Let $\delta(Q,q')$ denote the shortest distance between a fixed point $q' \in Q'$ and set Q; similarly, let $\delta(Q',q)$ denote the shortest distance between a fixed point $q \in Q$ and set Q'. Let $\rho(Q,Q') = \sup_{q' \in Q'} \delta(Q,q')$ and $\rho(Q',Q) = \sup_{q \in Q} \delta(Q',q)$. Then the Hausdorff distance between Q and Q' is given by $h(Q,Q') = h(Q',Q) = \max\{\rho(Q,Q'); \rho(Q',Q)\}$.[37b] If Q and Q' are geometric objects or sets of points in Euclidean space, the value of $h(Q,Q')$ depends on the relative orientations of Q and Q', and by varying the position of one with respect to the other by translation–rotations, it is possible to alter, and ultimately to minimize, $h(Q,Q')$ to $h_{min}(Q,Q')$, corresponding to the position of optimal superimposition.

Let Q' be the mirror image of Q. Then we define a similarity invariant Hausdorff chirality measure, $f(Q)$ [Eq. (h)], where $d(Q)$, the "diameter" of Q, is the maximum distance that can be realized between any two points of Q.

$$f(Q) = \frac{h_{min}(Q,Q')}{d(Q)} \qquad \text{(h)}$$

This function is normalized in the interval [0, 1] and it is zero if, and only if, Q is achiral.[38, 39]

Because the Hausdorff chirality measure for triangles is similarity invariant, the longest side can be assigned unit length without loss of generality. Hence, $f(Q) = h_{min}(Q,Q')$. Like other chirality measures of the second kind, the Hausdorff measure is combinatorial in character, that is, it requires an analysis of many different superimpositions of a given triangle T and its mirror image T'. In our approach to this problem[21c] we have resorted to a numerical analysis, in which a multidimensional hypersurface is explored in search of the global minimum corresponding to $h_{min}(Q,Q')$. The triangles are represented as physical objects in E^3 consisting of unit masses centered at the three vertices. A given triangle Q is placed with its center of mass (i.e., its centroid) at the origin of the Cartesian coordinate system, with the principal axes of inertia aligned along the axes of the coordinate system; this is done by diagonalizing the tensor of inertia and then using the eigenvectors to construct a rotational matrix for the triangle. The largest eigenvalue of the tensor of inertia is assigned to the z axis so that Q is located in the xy plane. This position of Q in the coordinate system is kept fixed throughout the minimization.

The superimposition of Q and Q' involves two variables, u and w, that describe the translation of Q' in the xy plane along the x and y axes, and a third, θ, that describes rotation about the z axis. Accordingly, $f(Q) = \min_{u,w,\theta} \{h(Q,Q',u,w,\theta)\}$. Rotations and translations of Q' relative to Q are carried out until $f(Q)$ is minimized as a function of u, w, and θ by the Broyden–Fletcher–Goldfarb–Shanno (BFGS) procedure.[40] In this manner, $f(Q)$ can be calculated for any given Q.

We showed in Section 2.3.2.1 that all chiral triangular shapes are represented in a construction in which two vertices, A and B, are located at (1/2, 0) and (−1/2, 0), respectively, while the third, C(x,y), maps into one of the two heterochiral regions labeled $a < b < c$ and $b < a < c$ in Figure 2. The most chiral triangle, corresponding to the supremum of $f(Q)$, must be located within one of these regions, and its enantiomorph within the other. We therefore explored the $a < b < c$ region by the grid method in a search for $\max\{f(Q) \equiv f(x,y)\}$. The results, displayed in Figure 5,

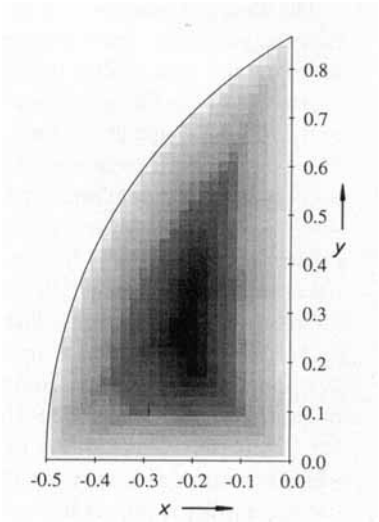

Fig. 5. Density plot of the Hausdorff chirality measure for triangles, evaluated on a 0.02 unit grid along the x and y axes. The values of the function are represented by different shadings: darker shadings indicate higher values. The shape space is the same as the region labeled $a < b < c$ in Figure 2.

show that there is only one relatively flat maximum located in the central portion of the region. Maximization by the BFGS procedure locates the point in the region with the largest value of $f(x,y)$. This point corresponds to the most chiral triangle: $f(x,y) \approx 0.196$, $\alpha \approx 21.5°$, $\beta \approx 44.2°$, $\gamma \approx 114.3°$. Orientations of Q' relative to Q that correspond to optimal overlap for this triangle are shown in Figure 6. Our calculations show that in all three orientations a line of reflection passes through the region of overlap, but that this line does not pass through the origin of the coordinate sys-

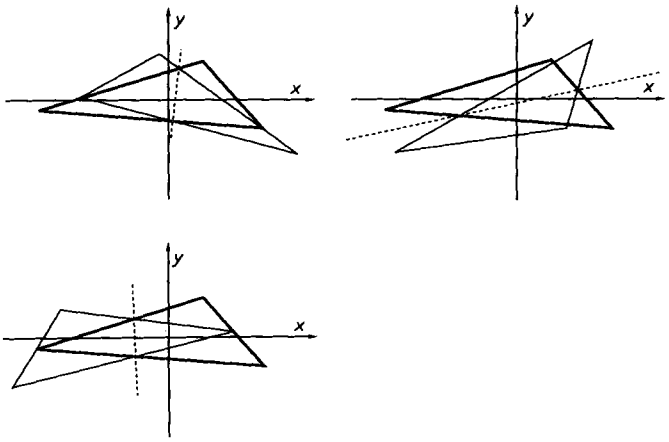

Fig. 6. Optimized orientations of Q' relative to Q for the most chiral triangle according to the Hausdorff measure, as determined by distances between vertices. The position of Q (heavy lines) in the xy plane remains fixed, with the centroid at the origin. The regions of overlap are axially symmetric. Lines of reflection are dashed. Degrees of chirality $f(Q)$ are 0.196 (top, left), 0.197 (top, right), 0.201 (bottom), that is, they are identical within the error limits of the calculation.

tem; the significance of this observation will be discussed in Section 2.3.4.

2.3.4. A Comparison of the Results

The principal conclusion of this study is that each chirality measure yields a different answer to the question: what is the shape of the most chiral triangle? Although three of the measures yield as the most chiral triangle one that is infinitely flat,[41] the shape at the limit differs with each measure. Thus, where both measures of the first kind described in Section 2.3.2 yield an ultimate triangle with the same ratio of sides (1:1:0), the ratios of internal angles are different (0°:0°:180° and 0°:60°:120°), and where the ratios of internal angles are the same (0°:0°:180°), the ratios of sides are different (1:1:0 and 1:3:4). The overlap measure described in Section 2.3.3.1 yields a triangle whose ratio of sides, $1:1/\sqrt{2}:(1-1/\sqrt{2})$, differs from that given by both measures in Section 2.3.2. As for the Hausdorff measure (Section 2.3.3.2), it is evident a priori that the most chiral triangle, which corresponds to $\max\{h_{min}(Q, Q')\}$, cannot be infinitely flat—as in fact it proves not to be—because, under conditions of optimal overlap, two infinitely flat enantiomorphous triangles are arbitrarily close to superposition and $h_{min}(Q,Q')$ is hence arbitrarily close to zero.

That triangular shape and degree of chirality depend on the measure may be further illustrated by the example of the most chiral right triangle (Table 1). According to the overlap measure described in Section 2.3.3.1, the shape of this triangle is given by $\arccos 2^{-1/3} \approx 37.5°$ and its degree of chirality by $(2^{1/3}-1)/(2^{1/3}+1) \approx 0.115$.[21a] Within the shape space defined by the gothic arch of Figures 2 (and 5), all right triangles are represented by points on a circle of radius 1/2 that is centered at (0, 0).[20a] The maximum degrees of chirality on this locus are 0.074 and 0.141 for the chirality product and the Hausdorff measure, respectively, and the corresponding shapes of the right triangles are given by $\alpha \approx 18.8°$ and 35.2°, respectively. In Figure 4, the most chiral right triangle in the asymmetric unit OSP lies at point V; according to this measure, the degree of chirality is $(1/\sqrt{2})(30°) \approx 21.2°$ and $\alpha = 30°$.[20b] Table 1 lists the degrees of chirality of the most chiral right triangles as fractions of the supremum on the values of the four measures. The four measures also yield different degrees of chirality for the right triangle with α fixed at 30° (Table 1).

Table 1. Comparison of four independent chirality measures for two defined right triangles.

Measure [Section]	Most chiral right triangle			Right triangle with $\alpha = 30°$	
	α	χ[a]	Rel. χ[b]	χ[a]	Rel. χ[b]
geometry [2.3.2.1]	18.8°	0.074	0.074	0.057	0.057
symmetry [2.3.2.2]	30.0°	0.500	0.500	0.500	0.500
overlap [2.3.3.1]	37.5°	0.115	0.669	0.073	0.423
Hausdorff [2.3.3.2]	35.2°	0.141	0.719	0.106	0.541

[a] Degree of chirality. [b] Degree of chirality relative to that of the most chiral triangle.

A fifth function, $\chi(\theta) = \sin 4\theta$, where θ is one of the acute angles in a right triangle, also meets all the conditions required of a chirality measure. This function achieves its maximum at $\theta = 22.5°$, while $\chi = 0.866$ for $\theta = 30°$; these values are to be compared with the corresponding entries in Table 1. The special significance of this function lies in the fact that it is one of a family of chirality measures that take the form $\chi(\theta) = \sin n\theta$ and that are continuous, normalized in the interval $[1, -1]$, oppositely signed for enantiomorphous objects, and that vanish if, and only if, the objects are achiral. For example, consider an array of two line segments of equal lengths, joined at their midpoints by a third line segment of finite length that is normal to both and that serves as an axis of rotation. The chirality of this array is a function of the torsion angle θ subtended by the two lines,[42] and its measure is $\chi(\theta) = \sin\theta$ if the lines are oriented and $\chi(\theta) = \sin 2\theta$ if they are not;[43] the latter may also be taken as a measure of helicity if one of a skew pair of nonoriented lines is the tangent of a cylindrical helix and the other is collinear with the screw axis.[42, 44]

The present work has revealed that the two overlap measures (Section 2.3.3) share at least two significant characteristics. First, according to the Hausdorff measure, the union of Q and Q' under conditions of optimal overlap is axially symmetric (Fig. 6). This meets the first of Giering's two conditions that were applied to the common volume measure (Section 2.3.3.1), which states that optimal overlap obtains only if the intersection, and hence the union, are axially symmetric. Our results suggest that *the union $K \cup K'$ of any object or set K and its mirror image K' is achiral under conditions of optimal overlap*. Further support for this conjecture comes from the results of the study reported in Section 2.4.2.

Second, in neither one of the two measures are the centroids of the two enantiomorphous triangles coincident under conditions of optimal overlap. In the case of the Hausdorff measure, because the line of reflection does not pass through the origin where the centroid of Q is located (see Fig. 6), it immediately follows that the centroid of Q' does not lie on the origin. In the case of the common volume measure, it is easily shown that for quadrilateral and pentagonal intersections of T and T' (with a shared angle and a shared side, respectively) the centroids do not lie on the line of reflection of T^*. In both measures, the centroids coincide only if the triangle is achiral.

2.4. In Search of the Most Chiral Tetrahedron

The construction of chirality measures for tetrahedrons is substantially more complex than that for triangles. First, while two independent parameters, for example two internal angles, suffice to define the shape of a triangle, five such parameters are required for a tetrahedron. Second, while C_1 is the only chiral group possible for triangles, three such groups (C_1, C_2, D_2) need to be considered for tetrahedrons.[45] We have therefore limited ourselves to the design of two measures, one of each kind.[21c] Sction 2.4.1 describes preliminary results obtained by use of the method of symme-

try coordinates, chosen because of its relationship to crystallographic analyses.[32] The Hausdorff measure described in Section 2.4.2 was chosen for several reasons. First, this measure is far easier to implement computationally than measures based on the fraction of overlapping volumes. Second, as noted before, the Hausdorff distance between sets of points in enantiomorphous geometric figures may be taken as an expression of the corresponding distance between nuclear positions of enantiomeric molecules—in contrast to measures based on overlapping volumes, which require the assumption of a uniform and continuous distribution of points within the model rather than the physically more realistic localization of matter in discrete regions. Finally, by use of the Hausdorff measure it may be possible, through the incorporation of chemical or physical parameters, to forge a connection to the world pseudoscalar observables.

2.4.1. Deviation from Achirality

Deformations of tetrahedral frameworks of carbon, specifically methane and the $C(C)_4$ fragment of neopentane, have received some attention in the past.[46] In all of these cases the focus was on the flattening of the T_d framework to a rectangular-planar (D_{2h}) or square-planar (D_{4h}) conformation. The former deformation may take place by means of a digonal twist involving two opposite edges, maintaining the D_2 symmetry of the tetrahedron, while the latter involves a compression along a C_2 axis that maintains D_{2d} symmetry.

Luef et al.[46c] used the symmetry coordinate approach to analyze angular distortions at the central carbon atom of the $C(C)_4$ fragment in some substituted spiro[4.4]nonanes. By contrast, we chose to describe the shape of a general tetrahedron by the set of twelve facial angles, three subtended at each vertex; the choice of this basis set ensures similarity invariance. Each angle may be denoted by a set of three numbers that specify the vertices that form it; for example, $\theta 123$ is the angle subtended at vertex 2 by vertices 1 and 3. For each angle we list the three vertices in an anticlockwise sense. This basis set transforms as $A_1 + E + T_2$. The six-dimensional conformation space for the tetrahedron may therefore be broken down into three subspaces of dimensionality one, two, and three, whose symmetries are 1, $3m$, and $\bar{4}3m$, respectively. The symmetry coordinates are given explicitly in Scheme 2.

As in the case of the triangles (Section 2.3.2.2), displacements along $\mathbf{S}_1$ will always be zero, since the sum of the angles for each face must always be 180°. Consequently we need only consider the E and T_2 subspaces of the conformation space. Moreover, for these spaces the value of the ideal facial angle (60°) cancels out in the expressions for the symmetry coordinates, so that the deviations (Δ) may be dropped, giving rise to the simplified expressions listed above.

We can probe the shape of the E subspace by holding displacements along the T_2 symmetry coordinates fixed at zero—as they would be for tetrahedrons with D_2 symmetry, for example—and then considering the maximal displacements that are possible ablong $\mathbf{S}_{2a}$ and $\mathbf{S}_{2b}$ (Fig. 7). The reaches of the E subspace that are available to such tetrahedrons are limited by the geometrical restrictions on the values that the facial angles can adopt. For example. a positive displacement along $\mathbf{S}_{2a}$ maps a compression of the tetrahedron along the C_2 axis passing through edges 12 and 34 that maintains D_{2d} symmetry: its maximum is reached when the edges become coplanar, that is, when angle $\theta 132$ (and the symmetry-equivalent angles $\theta 241$, $\theta 314$, and $\theta 423$) becomes 90°. A negative displacement maps a stretch along the same axis: its maximal value is reached when $\theta 132$ is 0°, that is, when the edges have been stretched apart to infinity. In the limit, these two conformations correspond to flattened (D_{4h}) and linear ($D_{\infty h}$) degenerate tetrahedrons, represented in Figure 7 by points Y and P respectively. Coordinate $\mathbf{S}_{2a}$ hence constitutes an achiral coordinate (m'). Two further such coordinates (lines m'' and m in Fig. 7) that map compressions and stretches along the other C_2 axes can be found

$$

Scheme 2. Symmetry coordinates of the conformation space for tetrahedrons.

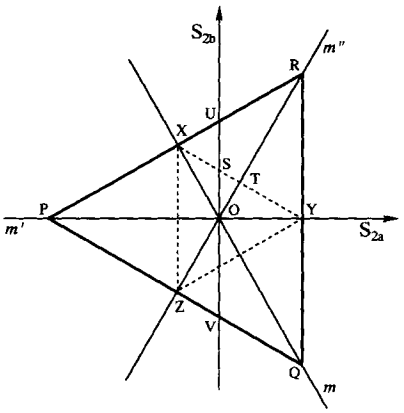

Fig. 7. Triangular *E*-subspace (PQR) of the conformation space for tetrahedrons. Lines m, m', and m'' are mirror lines, and the origin O represents a point of threefold rotation; the symmetry of the space is $3m$. ORX demarcates one of six asymmetric units, within which line OU maps D_2 tetrahedrons of increasing degrees of chirality. Triangle YZX traces the tetrahedral distortions that are mapped by the edges of the octahedral faces ABC of the T_2 subspace (Fig. 9). In terms of this construction, YZX can be visualized as one octahedral face, where m, m', and m'' represent mirror planes, point O a threefold axis, and section OTX an asymmetric unit.

displaced 120° and 240° from S_{2a}. The shape of the resulting two-dimensional conformation space is triangular ($3m$ symmetry), as it was in the case of the triangles (Fig. 4). Positive and negative displacements along S_{2b} map clockwise and anticlockwise digonal twists of edges 12 and 34 about their C_2 axis, such that the facial angle $\theta 132$ remains constant at 60°, with no attendant flattening or compression along this C_2 axis. Accordingly, the limiting conformations are rectangular-planar (D_{2h}) with edges in the ratio $1:\sqrt{3}$ (points U and V in Fig. 7). Similar coordinates for twists about the other two C_2 axes may be found displaced by 120° and 240°, but these are not illustrated in Figure 7. The edges of the subspace map degenerate tetrahedrons whose vertices are coplanar—when they are not colinear, as at the points P, Q, and R. Thus, segement RX, for example, maps the transformation of a linear ($D_{\infty h}$, point R) to a rectangular-planar (D_{2h}, point U) and finally a square-planar (D_{4h}, point X) degenerate tetrahedron; segment XP traces the reverse distortion.

By analogy to the triangles, the most chiral tetrahedron with D_2 symmetry will lie on the angle bisector between two adjacent achiral coordinates. When we consider the asymmetric unit ORX, for example, line OU is the bisector of the angle subtended by OR and OX, and the most chiral tetrahedron is situated at the point U. But, as before, the dimensionality reduces by one when this point is reached, so that the most chiral D_2 tetrahedron may once again be approached only as a limit. This limit takes the form of a planar rectangle whose sides are in the proportions $1:\sqrt{3}$, thereby yielding angles of 30°, 60°, and 90° in each of the four faces (Fig. 8, left). As was the case for the triangle, point U is displaced from the nearest achiral points on m and m'' by $d_1 = d_2 = \mathbf{d} = (1/\sqrt{2})(30°) \approx 42.4°$; this value once again defines the least upper bound, and allows for normalization of **d** to the interval [0,1].

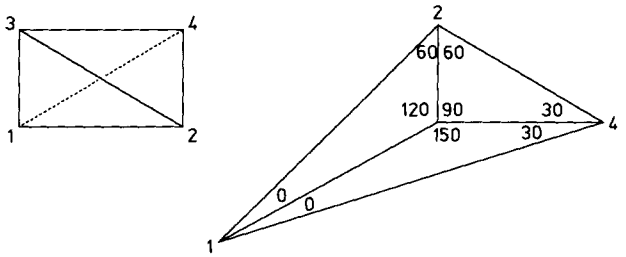

Fig. 8. Left: illustration of the limiting conformation for the most chiral D_2 tetrahedron with facial angles 30°, 60°, 90° according to the measure in Section 2.4.1. Right: schematic diagram of the limiting conformation for the most chiral C_1 tetrahedron, showing the limits to the values of the facial angles (see [47]). The representative point for this tetrahedron is situated at S in the E subspace (Fig. 7) and on the edge of AE in the T_2 subspace (heavy dot, Fig. 9).

As mentioned earlier, a displacement from the origin of the E subspace along S_{2b} int he direction of point U corresponds to a digonal twist of the tetrahedron about a C_2 axis; in other words, the more twisted the tetrahedron, the greater its degree of chirality. This result certainly makes intuitive sense in the extreme case of an infinitesimal deformation away from T_d symmetry: a tetrahedron with this symmetry is achiral, while one with even a miniscule twist of two opposite edges would be chiral; and the greater the twist, the greater the degree of chirality might appear to be. The result for the most chiral D_2 tetrahedron simply carries this reasoning to its logical extreme, and the apparently counterintuitive answer—that the most chiral tetrahedron is infinitely close to an achiral object—is a consequence of the fact that this method cannot deal with the collapse in dimensionality that occurs at the extreme.

For any tetrahedron whose displacement along S_{3a}, S_{3b}, or S_{3c} (Scheme 2) is not zero, the position of its representative point in the T_2 subspace will also need to be considered. The shape of this space will once again be determined by geometrical constraints that exist in tetrahedrons. Because of the tetrahedral symmetry of the subspace ($\bar{4}3m$), it might be supposed that its shape would be similarly tetrahedral. However, it turns out[21c] that the conformation space has an octahedral shape that can be viewed as constructed from a tetrahedron whose four vertices have been truncated at the midpoint of each edge (Fig. 9). In order to be consistent with its symmetry, the space may be imagined as a two-colored octahedron, with adjacent faces differently colored. In the context of such a perspective, the twofold axes of the subspace are visualized as the C_2 axes of a tetrahedron the midpoints of whose edges—bisected by the C_2 axes—represent the outer limits of the subspace. The mutually orthogonal symmetry coordinates spanning the space are coincident with these twofold axes: displacements along S_{3a}, S_{3b}, and S_{3c} map distortions of the tetrahedron that maintain C_{2v} symmetry. Similarly, the tetrahedron's C_3 axes are symbolized by the threefold axes of the colored subspace; these are coordinates along which real tetrahedrons with C_{3v} symmetry are found. Each pair of opposite faces of this octahedron maps either infinitely stretched tetrahedrons with three vertices coplanar and the fourth at an infinite distance (but possibly within the plane of the others), or infinitely flattened tetrahedra in which the fourth vertex is found within the triangular plane formed by the remaining three. For example, the face bound by the maximal positive displacements along each of S_{3a}, S_{3b}, and S_{3c} (face ABC in Fig. 9)

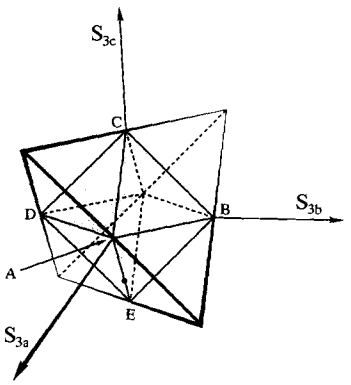

Fig. 9. Octahedral T_2 subspace of the conformation space for tetrahedrons. The symmetry coordinates may be thought of as the C_2 axes of a regular tetrahedron, and the octahedral subspace (shaded) can be constructed by truncating each of the vertices at the midpoints of the edges. In order to represent the $\bar{4}3m$ symmetry of the space, the octahedron must be viewed as two-colored, so as to yield adjacent faces with different colors. Each pair of opposite octants together contains six asymmetric units.

maps all degenerate tetrahedrons for which vertex 4 lies within the triangular plane formed by vertices 1, 2, and 3, while the face opposite it maps all those in which vertex 4 is at an infinite perpendicular distance to this plane.

Tetrahedral distortions that are mapped by the edges of the octahedral face ABC in the T_2 conformation space are represented in the E subspace by the edges of triangle YZX (Fig. 7). Each of the other octahedral edges map onto this triangle in a similar way, so that triangle YZX may be visualized as any one of the octahedral faces. In terms of this construction, mirror lines m, m', and m'' then represent the mirror planes (achiral coordinates) of the T_2 conformation space, which, together with the threefold axis through the center of the face (emerging perpendicularly from point O), define six asymmetric units in each octant of the octahedron. One such asymmetric unit is given by the section OTX (Fig. 7). However, since we are dealing with a two-color octahedron, opposite octants are not symmetry-equivalent. This implies that each such pair of octants *in combination* contains six asymmetric units, and each asymmetric unit takes the shape of a body constructed by joining two trigonal pyramids at a common vertex (which, in this case, is situated at the origin of the space). Depending on whether a particular tetrahedron is flattened or stretched along the C_3 axis, it will be represented in one or the other "half" of the asymmetric unit.

The representative point in T_2 space for the most chiral tetrahedron will have to be situated on the perimeter of the space (on one of the faces), since any position closer to the origin will also bring this point into closer proximity with the mirror planes that span the space and that intersect at the origin. Hence, with reference to the asymmetric unit OTX, when triangle YZX is viewed as a face of the T_2 conformation space, it will be obvious that the most chiral tetrahedron will once again be situated on the angle bisector (OU) between the coordinates m and m''. Point S is now seen to correspond to a point on one of the octahedral edges, at the outermost reaches of the subspace. Not unexpectedly, this yields a degenerate tetrahedron, which in this case is both planar and infinitely skewed. Figure 8 (right) illustrates this degenerate (C_1) tetrahedron schematically, while Figure 9 shows where in the T_2 subspace its representative point would be located.[47] In terms of this construction, triangle YZX could represent either face ABE, or face ADE (corner points are named in corresponding order). Note that each octahedral edge contains two such points, the total of 24 corresponding to the 24 possible permutations of the labels in the schematic illustration of the most chiral tetrahedron (Fig. 8). Point S is displaced by a distance $d_1 = d_2 = \mathbf{d} = (1/\sqrt{14})(15°) \approx 56.1°$ from its nearest achiral neighbors in the five-dimensional space spanned by the E and T_2 symmetry coordinates. This value again allows for normalization to the range [0, 1]. In terms of this approach, the most chiral D_2 tetrahedron ($\mathbf{d} = (1/\sqrt{2})(30°) \approx 42.4°$) is seen to be about 76% as chiral as the most chiral C_1 tetrahedron.

2.4.2. *Nonsuperposability of Enantiomorphs*

The Hausdorff chirality measure for tetrahedrons, $f(Q)$ as defined in Equation (h), like that for triangles (Section 2.3.3.2), requires a numerical analysis of many different superimpositions of a tetrahedron Q and its mirror image Q'. Each tetrahedron is represented as a physical object consisting of unit masses centered at the four vertices. A given Q is placed with its center of mass at the origin of the Cartesian coordinate system and the principal axes of inertia are aligned along the axes of the coordinate system. The enantiomorph Q' is generated by inversion of Q through the origin. The position of Q remains fixed throughout the calculations and the position of Q' is varied in relation to it.

For a tetrahedron, as for any object embedded in E^3, the value of $h(Q,Q')$ depends on six variables; three of them, u, v, and w, describe translations of Q' along the x, y, and z axes, respectively, and three others, ϕ, θ, and ω, define rotations around those axes. Determination of $f(Q)$ thus becomes a typical problem of searching for a global minimum on the multidimensional hypersurface and can be addressed by standard computational means, such as the BFGS procedure[40] that was successfully employed in the search for the most chiral triangle. This procedure is used to minimize $h(Q,Q')$ as a function of u, v, w, ϕ, θ, and ω [Eq. (i)], where $d(Q)$ is defined as in Equation (h).

$$f(Q) = \frac{\min\limits_{u,v,w,\phi,\theta,\omega} \{h(Q,Q',u,v,w,\phi,\theta,\omega)\}}{d(Q)} \qquad \text{(i)}$$

While all triangular shapes are uniquely represented by points within the two-dimensional shape space depicted in Figure 2, the shape space for tetrahedrons requires five dimensions. This space may be partitioned into asymmetric units in each of which every tetrahedral shape, without exclusions, is uniquely represented by exactly one point. However, asymmetric tetrahedrons, unlike asymmetric triangles, are chirally connected.[39] It follows that the set of points that represents achiral tetrahedra does not bisect an asymmetric unit into two heterochiral regions. Although an asymmetric unit in the shape space of tetrahedrons can be partitioned into two subsets, each of them containing the representation of one enantiomorph, one cannot assign a common sense of handedness to members of these subsets. This is in contrast to the regions in Figure 2, each of which represents a set of homochiral triangles (Section 2.3.2.1). The same applies to chiral tetrahedrons with C_2 or D_2 symmetry, since such figures can be continuously deformed into asymmetric (C_1) shapes.[48]

The shape space of a general tetrahedron with vertices A, B, C, and D is defined as follows. First, because $f(Q)$ is similarity invariant, the size of the tetrahedron can be constrained by setting one edge (AB) equal to unity, without loss of generality. All other edges are constrained to be no longer than AB, so that $d(Q) = 1$. Let Z denote the intersection of two unit spheres centered at A, $(x + 0.5)^2 + y^2 + z^2 = 1$, and at B, $(x - 0.5)^2 + y^2 + z^2 = 1$. To satisfy the constraint on length specified above, the other two vertices, C and D, must also belong to Z. Every tetrahedron can be oriented in the Cartesian coordinate system in such a way that if two vertices (A and B) are placed on the xy plane, the other two vertices (C and D) are located in a second plane, parallel to the xy plane and at some height h above it. Figure 10 depicts Z truncated on the positive side of the z axis by that second

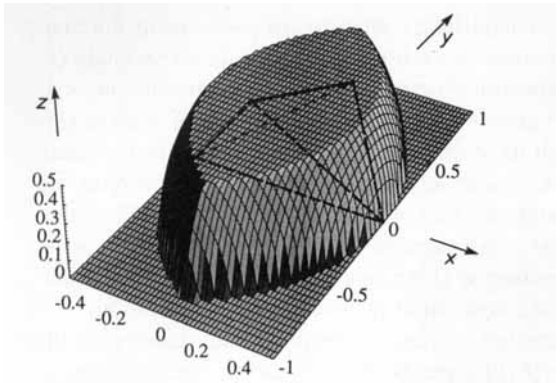

Fig. 10. Intersection of two unit spheres centered at (-0.5, 0, 0) and (0.5, 0, 0) and truncated by a plane parallel to the xy plane that intersects the z axis at 0.5. This defines a domain that contains the vertices of a general tetrahedron ABCD with vertices A and B at the centers of the spheres and C and D located in the plateau at $z = 0.5$.

plane, while Figure 11 shows the projection along the z axis of the same truncated intersection. At any particular height h, $0 < h \leq \sqrt{3}/2$, the plateau consists of the intersection Δ of two overlapping circles $(x + 0.5)^2 + y^2 = 1 - h^2$ and $(x - 0.5)^2 + y^2 = 1 - h^2$. Both C and D are contained in Δ. To eliminate redundancies in Δ, C is restricted to the quadrant of Δ that is bounded by the positive segments of the x and y axes, D is restricted to the intersection of Δ and a circular domain bounded by a circle $(x - x_C)^2 + (y - y_C)^2 = 1$ (see Fig. 11), and the y coordinate of D is lim-

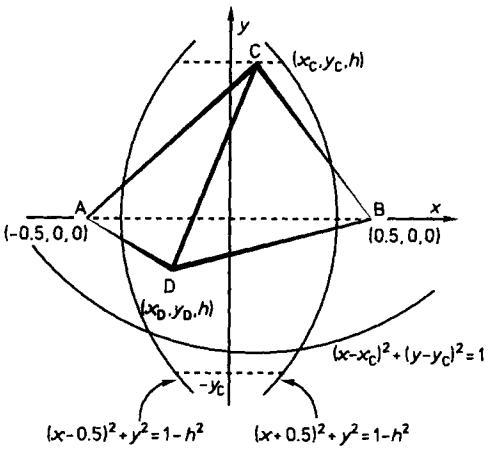

Fig. 11. Projection of Figure 10 along the z axis.

ited to the interval $y_C > y_D \geq -y_C$. The shape of a tetrahedron is therefore fully defined by a set of at most five shape coordinates (h, x_C, y_C, x_D, y_D); the actual number of independent parameters is a function of the tetrahedron's symmetry.

For any D_2 tetrahedron, symmetry requires that the lengths of the AB and CD edges both equal unity. From this constraint it follows that the shape of such a tetrahedron is fully determined by just two independent variables, h and x_C. To find the most chiral D_2 tetrahedron, $\mathbf{Q}_a$, therefore requires locating the point in the asymmetric unit that corresponds to $f(\mathbf{Q}_a) = \max \{f(Q_a) \equiv f(h, x_C)\}$. This two-dimentional space is easily explored by the grid method, and calculations show that there is only one maximum within the asymmetric unit. This maximum, localized by the BFGS procedure, corresponds to the most chiral D_2 tetrahedron, $f(\mathbf{Q}_a) = 0.221$, whose faces have internal angles of 35.1°, 60.5°, and 84.4°. Figure 12 shows three optimal overlaps of

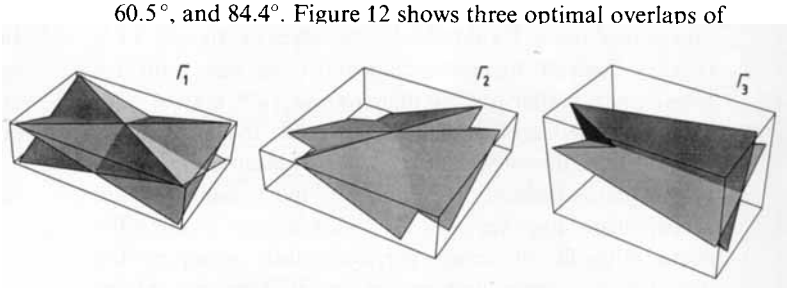

Fig. 12. Unions (Γ) of the most chiral D_2 tetrahedron, $\mathbf{Q}_a$, and its enantiomorph, $\mathbf{Q}'_a$, according to the Hausdorff measure. Γ_1 has D_{2h} symmetry. Γ_2 and Γ_3 have D_{2d} symmetry. The shape of each union is visualized by two interpenetrating solid tetrahedrons, although their Hausdorff chirality measures are determined by the distances between vertices.

$\mathbf{Q}_a$ with its mirror image $\mathbf{Q}'_a$ that are characterized by the same value of $f(\mathbf{Q}_a)$ but that differ in the geometry of the union, $\Gamma_a = \mathbf{Q}_a \cup \mathbf{Q}'_a$. One union, Γ_1, has D_{2h} symmetry with the three twofold axes of $\mathbf{Q}_a$ collinear with the three symmetry-related twofold axes of $\mathbf{Q}'_a$, while the other two, Γ_2 and Γ_3, have D_{2d} symmetry and can be obtained from Γ_1 by 90° rotations of $\mathbf{Q}'$ around one of the three axes.[49]

While C_2 symmetry does not require the CD edge to be equal in length to AB, vertices C and D must be related to each other by a twofold axis that is perpendicular to the xy plane and that passes through the origin of the coordinate system. The shape of a C_2 tetrahedron is therefore fully determined by a set of three independent variables, h, x_C, and y_C. The most chiral C_2 tetrahedron, $\mathbf{Q}_b$, localized by the BFGS procedure, has $f(\mathbf{Q}_b) = 0.252$; its shape is characterized by internal angles $\theta 312 = 45.6°$, $\theta 132 = 34.7°$, $\theta 134 = 38.0°$, and $\theta 314 = 83.4°$, with the C_2 axis bisecting edges 12 and 34. As in the case of $\mathbf{Q}_a$, our calculations show that there are three different unions, $\Gamma_b = \mathbf{Q}_b \cup \mathbf{Q}'_b$, that are characterized by the same value of $f(\mathbf{Q}_b)$; one of the three has C_{2v} symmetry with the twofold axes of the enantiomorphs collinear and their centroids superposed, while the other two have C_s symmetry.

For C_1 symmetry there are no constraints, so that all five independent shape variables must be taken into account in the search for the most chiral C_1 tetrahedron, $\mathbf{Q}_c$. The Monte Carlo procedure was used initially to search the asymmetric unit for regions characterized by high values of $h(Q,Q')$, and the final search by use of the BFGS method localized the point corresponding to $\mathbf{Q}_c$, $f(\mathbf{Q}_c) = 0.255$. The shape of $\mathbf{Q}_c$ differs only slightly from that of $\mathbf{Q}_b$. Once again, the same value of $f(\mathbf{Q}_c)$ is represented by more than one union, $\Gamma_c = \mathbf{Q}_c \cup \mathbf{Q}'_c$, all with C_s symmetry.

Our calculations provide strong support for the conjecture (Section 2.3.4) that the union of an object and its mirror image is achiral under conditions of optimal overlap. Furthermore, the observed trend of an increase in $f(\mathbf{Q})$ with a decrease in symmetry parallels results obtained by the method of symmetry coordinates (Section 2.4.1).

3. Other Chirality Measures

Our efforts to develop measures of chirality, described in Sections 2.3 and 2.4, grew from the seeds of ideas that were planted in 1976.[3] The last few years have witnessed a resurgence of interest in this subject, and in what follows we select for discussion several studies that were carried out independently of, and contemporaneously with, our own, and that illustrate the great variety of approaches that may be employed.

3.1. Kuz'min's Method

As discussed in Section 2.3.2.1, the chirality product of a molecular model, as conceived by Guye[24, 26] and by Ruch et al.,[27, 28] is a product of differences between appropriately chosen ligand parameters. This function, which vanishes for achiral objects, is a chirality measures of the first kind. It is therefore of interest to note that a product function recently developed by Kuz'min et al.[50] is a chirality measure of the second kind.

In Kuz'min's scheme, the model of a molecule, M, is represented by a rigid body consisting of a set of point masses, m_i. This object is placed with its center of mass at the origin of a reduced system of coordinates, with the principal axes of inertia aligned along the axes of a Cartesian coordinate system. If M has a plane of symmetry, the center of mass must lie in that plane, which also contains two of the principal axes of inertia, and if M has an axis of symmetry of any order, the center of mass must lie on that axis, which is also one of the principal axes of inertia.[51] If, in such a coordinate system, a rotation–reflection (improper rotation) operation, S_n, is performed on M, then S_n can be a symmetry or covering operation only if M is achiral; if M is chiral, S_n will generate the nonsuperposable enantiomorph, M'. The degree of chirality of M can therefore be gauged by some function of r_i, the distance between corresponding points m_i and m_i' in M and M'. Keeping in mind the expression for moments of inertia, Kuz'min has defined a function of r_i as the "level of dissymmetry", LD [Eq. (j)].

$$LD = \sum_i m_i r_i^2 \qquad (j)$$

Thus, LD $\neq 0$ if M is chiral, and the larger the value of LD, the greater the degree of chirality of M.

Each S_n performed on M, except for S_2 (central inversion), generates the three LD's that correspond to the three improper rotation axes aligned along the principal axes of inertia. For example, pure reflection, S_1, generates $LD^{S_1^x}$, $LD^{S_1^y}$, and $LD^{S_1^z}$. The exception is LD^{S_2}. The "dissymmetry function", DF, defined as the geometric mean of the ten LD's that result from operations ranging from S_1 to S_6, is expressed in Equation (k), where LD_n for $n = 1, 4$, and 6 stands for $(LD^{S_n^x})$ $(LD^{S_n^y})$ $(LD^{S_n^z})$, and, for $n = 2$, $LD_2 = LD^{S_2}$.

$$DF = [(LD_1)(LD_2)(LD_4)(LD_6)]^{1/10} \qquad (k)$$

The reason for truncating the DF at LD_6 is based on the practical consideration that compounds whose symmetry is S_n with $n > 6$ are quite rare, but Equation (k) could always be expanded to include LD_n's with $n > 6$ should the need arise. Kuz'min et al. have reported several chemical applications of their function.[52]

A limitation on the applicability of Kuz'min's approach that is significant in principle, though not in practice, arises from the fact that in spherical tops all three principal moments of inertia are equal, and the choice of the three principal axes of inertia is therefore rendered arbitrary.[51] As a consequence, the approach fails with objects having T, O, or I symmetry.[50b] Similar limitations apply to symmetric tops. It must also be borne in mind that the numerical values of the LD's, and hence of the DF's, are obtained by computational methods that do not entail optimization of the relative spatial positions of the enantiomorphs. One constraint imposed by the method is that the centers of masses of the enantiomorphs are both located at the origin of the reduced system of coordinates. However, as was noted in section 2.3.4, according to either the Hausdorff or the common volume measure, the centroids of enantiomorphous triangles do not coincide under conditions of optimal overlap. This observation suggests the possibility that optimal overlap may not be achieved under the constraints imposed in Kuz'min's method.

3.2. Hel-Or's Method

The difference in behavior between chiral and achiral two-dimensional objects under rotation is the basis for an attempt by Hel-Or et al.[53] to develop a measure of chirality. In E^2 a statically achiral object under rotation about a point on the mirror line acquires "dynamic chirality" and exists in two enantiomorphous states that are characterized by the sense of rotation, clockwise or anticlockwise.[54] The two states are symmetry-equivalent and therefore exhibit the same scalar properties. On the other hand, a statically chiral object under rotation exists in two states that are characterized by the fixed sense of chirality of the object combined with the sense of rotation. These two states are symmetry-nonequivalent and may be expected in general to exhibit different scalar properties. The difference in scalar properties, zero for rotating achiral objects and nonzero for rotating chiral objects, might therefore be taken as the basis for a chirality measure of the first kind.

The computational scheme invented by Hel-Or et al. to actualize this difference may be illustrated by the following example. Imagine two objects, an achiral one shaped like the capital letter M and a chiral one shaped like the capital letter F, embedded in a plane full of tiny two-dimensional particles. When rotated in the plane about a point on its mirror line, the M-shaped object will scoop up the same number of particles whether the rotation is clockwise or anticlockwise. In contradistinction, the F-shaped object will scoop up more particles when rotated in one direction than in the other. The difference in collected particles after rotation, appropriately normalized, gauges the chirality of M and F. For the enantiomorph of F in E^2, the measure is the same in magnitude but opposite in sign. Note that, as this example demonstrates, the difference between chiral and achiral objects is discussed by comparison of their states before and after (not

during) the rotation; what is gauged is therefore static rather than dynamic chirality.

An interesting comparison with our work is possible through an analysis of L-shaped objects in which the ratio of legs, a/b, is allowed to vary. The chirality of such an object in E^2 achieves its maximum somewhere within the achiral bounds of $a/b = 1$ and a/b (or b/a) $= 0$, and in Hel-Or's computational scheme this maximum is located in the neighborhood of $a/b = 0.5$.[53a] If we think of the L-shaped object as a right triangle lacking a hypotenuse, we find that a value of about 0.5 as a ratio of sides falls well within the range of values (0.34–0.76) calculated for the most chiral right triangle by the five independent measures discussed in Section 2.3.4.

As regards applications to chemistry,[53b] stringent limitations are placed on molecular representations because Hel-Or's measure works only for simply connected binary shapes,[53a] such as the M-, F-, and L-shaped objects discussed above. More significant in our view is the fact that this measure is incapable of "telling right from left" whenever enantiomorphous shapes are chirally connected;[28b] as noted above,[38] a chiral zero is bound to occur in such a case and corresponds to a chiral object collecting the same number of particles under clockwise and anticlockwise rotations. However, chirality is a symmetry property, and a measure of chirality can therefore be zero if, and only if, the object is achiral. Because this condition is not always fulfilled, Hel-Or's measure fails to qualify as a measure of chirality in the general case.

3.3. Mezey's Method

A chirality measure of the first kind has been devised by Mezey[55] and is based on his approach to molecular shape analysis.[17b] The measure requires the assessment of shape chirality in an object at various levels of resolution. For example, consider three closed curves in the plane ("Jordan curves") J_1, J_2, and J_3, within the interiors of which are inscribed "interior filling animals", $A(J,n)$ (Fig. 13).[56] Figure 13 shows several stages in the stepwise increase in resolution. At the lowest levels the results are clearly unsatisfactory: for $n = 3$ all three curves are approximated by the same $A(J,3)$ even though the curves are all different, and for $n = 5$ all three curves are approximated by chiral $A(J,5)$'s even though J_3 is achiral. However, with an increase in n and progressively higher levels of resolution, the shape of the perimeter of $A(J,n)$ is increasingly constrained to approximate the shape of the surrounding curve. Mezey has shown that for each chiral curve there exists a critical level of resolution that is defined by a finite cell number, n_0, the "chirality index", above which all interior filling animals are chiral.[57] The chirality index then becomes an inverse measure of the chirality of the curve, in the sense that the more pronounced the chirality of the shape, the lower the requisite minimum level of resolution and hence the smaller the value of n_0.

The upper and lower bounds of n_0 are well defined. The upper bound, $n_0 = \infty$, obtains only for achiral Jordan curves, for example J_3 in Figure 13, since the number of cells of the interior filling animal exceeds any finite threshold. The lower bound, $n_0 = 4$, corresponds to the perimeter J_4 of

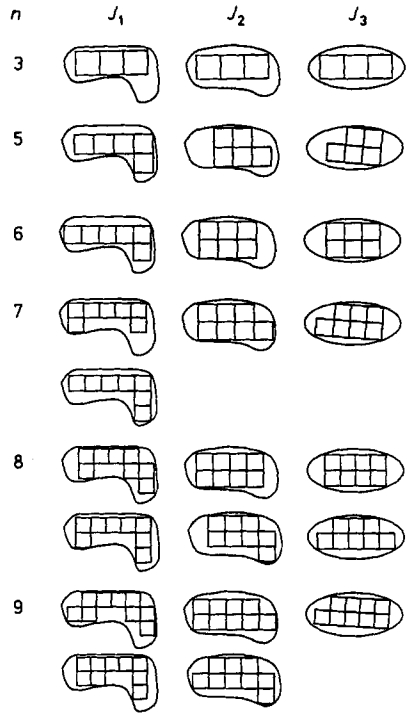

Fig. 13. The n-cell interior filling animals of three curves, J_1, J_2, and J_3, for selected values of n. Curves J_1 and J_2 are chiral, whereas ellipse J_3 is achiral (adapted from [55b]).

"Tippy", the 4-cell animal with C_2 symmetry, since no achiral $A(J,n)$ with $n > 4$ can be inscribed in J_4.[55d] On this basis a "degree of chirality", $\chi(J)$, may be defined [Eq. (l)] whose bounds, 0 and 1, correspond to the upper and lower limits of n_0, respectively.

$$\chi(J) = \frac{1}{n_0 - 3} \qquad \text{(l)}$$

The function $\chi(J)$ is unique among the chirality measures discussed in this review because n_0 can only assume integral values and $\chi(J)$ is therefore not continuous.[58]

The technique for shape characterization described for curves in E^2 is easily extended to three-dimensional bodies; the role of animals are now played by polycubes—cubes joined to one another by shared faces—and the chirality of boundary surfaces are now assessed by the use of interior filling polycubes.[55b, c] All else remains the same, and Equation (l) still applies: as before, the outer bounds on the chirality index are $n_0 = \infty$ for achiral bodies and $n_0 = 4$ for the three-dimensional analog of "Tippy", that is, the C_2-symmetric polycube with $n = 4$.

The concept underlying Mezey's measure is appealing, but there remains the problem of implementation. While the upper and lower bounds of n_0 are well defined, how are the numerical values of n_0, and hence of the degree of chirality, determined in the general case? As a specific example, consider a comparison of J_1 and J_2 in Figure 13: on visual inspection the chirality of J_1 seems more evident than that of J_2; stated differently, the shape of J_2 seems closer to that of the achiral ellipse J_3 than the shape of J_1. Accordingly, the chirality of J_1 should manifest itself at a lower level of resolution than that of J_2, and one would therefore be justified

in expecting a smaller value of n_0 for J_1 than for J_2. In harmony with this qualitative visual ranking, Harary and Mezey have asserted[55b] that $n_0 = 8$ and 15 for J_1 and J_2, respectively. However, this assertion is unsupported by any evidence that all interior filling animals with $n > 8 (J_1)$ and $n > 15 (J_2)$ are chiral. Indeed, the value of n_0 in the general case is a priori unknown, and the levels of resolution that need to be tested before such evidence can be supplied in order to determine n_0 with complete confidence are therefore also a priori unknown. In practice, of course, one can get around this difficulty by setting some upper limit—chosen arbitrarily or on some extraneous grounds, such as computational convenience—to the level of resolution, and then estimating some confidence level for the resulting numerical value of n_0.

4. Scope and Limitations of Chirality Measures

We have seen that there are many ways to approach the problem of quantifying chirality, and that there is great diversity among individual chirality measures. In this section we offer some remarks on the general applicability of these measures.

4.1. Characteristics of the Two Classes

We shall show that chirality measures of the first kind, which depend on the quantification of deviations from achirality, are severely limited in scope because of the need for an achiral reference object. We begin our analysis with examples taken from the realm of chemistry.

In keepint within the spirit of Kelvin's definition (Section 2.1), our discussion so far has focused on applications of chirality measures to geometric objects. As chemists we naturally entertain the hope that such objects might also serve as iconic models[59] of molecules, but geometric objects are rigid entities and thus are limited to the representation of rigid or quasi-rigid[60] structures. Yet there is no dearth of nonrigid (i.e., flexible or fluxional) molecules, whose portrayal by the point group formalism on the fast-exchange time scale "at the very least is a step removed from reality".[61] For such molecules, "dynamic models"[62] in the form of reaction graphs or supergroups[63] are the more appropriate representations.[64] While overlap measures are not affected by molecular nonrigidity—for every chiral structure in conformation space there exists a corresponding enantiomorph—serious difficulties are introduced in the choice of an achiral reference structure for chirality measures of the first kind. These difficulties become acute when "chemical achirality"[65] refers to an achiral ensemble composed of chiral molecules—dubbed "molecular Euclidean rubber gloves"[66]—that undergo rapid enantiomerization *exclusively* through chiral pathways;[67] they become insuperable when the structures to be modeled exhibit topological chirality.

Structures are said to be topologically chiral if the molecular graphs of their enantiomorphs are nonhomeotopic, that is, if they cannot be interconverted by continuous deformations in E^3.[66, 68, 69] Examples are the Simmons–Paquette K_5 molecule,[70] Walba's 3- and 4-rung THYME Möbius ladders,[71] Sauvage's catenane composed of two interlocked oriented rings[72] and his molecular trefoil knot,[73] and the DNA knots and linked loops that are among the subjects of "biochemical topology".[74] It follows that such molecular graphs are incapable of attaining rigidly achiral presentations by continuous deformations in E^3,[75] in contradistinction to the graphs of molecular "Euclidean rubber gloves".[76] The absence of homeotopic achiral comparison standards for intrinsically achiral graphs that have topologically chiral embeddings (e.g., Sauvage's trefoil knot) and the absence of *any* achiral comparison standards for intrinsically chiral topological embeddings (e.g. Walba's 3-rung THYME Möbius ladder) means that the corresponding continuous chirality functions cannot attain a value of zero. It follows that chirality measures of the first kind are ruled out for topologically chiral structures. In contrast, the absence of an achiral zero has no effect on the general applicability of chirality measures of the second kind, since all conceivable conformations (presentations) of molecules with topologically chiral embeddings are matched by their enantiomorphs and may thus be assigned degrees of chirality by such measures.[77] It is clear that this conclusion is general and applies not only to molecules but also to abstract objects regardless of whether they are models of molecules.[78]

While measures of the second kind therefore have a significantly broader range of application than those of the first kind, they too have their limitations. Thus, in measures of common volumes (Sections 2.2.2 and 2.3.3.1) the intersection of the enantiomorphous objects must have the same dimension as the objects themselves; if this condition is not fulfilled, the measures cannot be applied. For example, the degree of chirality of one-dimensional figures in E^3 (e.g. Möbius ladders, knots, rigid helices) or in E^2 (e.g. triangles with no interior points, spirals), or of two-dimensional figures in E^3 (e.g. Möbius strips) cannot be determined by these measures. However, the Hausdorff measure is not limited in the same way; for this reason, and because it is applicable to continuous sets as well as to sets of discrete points, the Hausdorff chirality measure has emerged as the general method of choice for the quantification of chirality.

4.2. Dependence of Ranking on Measure

Molecules may be unambiguously ranked as relatively "more" or "less" chiral according to an agreed criterion,[3] but the ranking depends on the nature of the chosen criterion. The same applies to the ranking of abstract geometric figures. For example, consider two right triangles, A and B, with $\alpha = 18.8°$ and $30°$, respectively, and their degrees of chirality χ as calculated by various measures. According to the measure described in Section 2.3.2.1, A ($\chi = 0.074$) is more chiral than B ($\chi = 0.057$) (see Table 1), whereas according to the measure described in Section 2.3.2.2, B ($\chi = 0.500$) is more chiral than A ($\chi = 18.8/60 = 0.313$). Such reversals in the rank ordering of chiral figures are direct consequences of differences in the functions that express the degree of chirality; see also Section 2.3.4. In short, *the ranking of objects according to degree of chirality generally depends on the particular function that is chosen as the chirality measure.*

From all that has been said, it should be abundantly clear that there is no unique answer to the question: what is the shape of the most chiral member in a given class of objects. Nevertheless, it seems reasonable to assume that, regardless of which measure is chosen, maximal chirality of an object is attainable in general only when all constraints on the shape of the object are relaxed. The evidence so far fully supports this assumption. Thus, for each of the four independent measures in Section 2.3, the degree of chirality of the most chiral right triangle is less than that of the most chiral general triangle (Table 1). As another example, according to each of the two independent measures in Section 2.4, the degree of chirality of the most chiral tetrahedron increases with a decrease in symmetry from D_2 to C_1. The last result suggests that *the most chiral figure (object) in E^n is invariably the least symmetric.*

5. Summary and Future Prospects

Every geometric figure—and every rigid molecular model—is either chiral or achiral, and no figure is both; the set of all figures is thus partitioned into two disjoint, complementary subsets.[5,8] Nevertheless, within the domain of chiroids it is possible to measure degrees of chirality and to rank chiroids as "more" or "less" chiral, depending on the measure. As we have defined them, chirality measures are real-valued and continuous functions that are zero if, and only if, the object is achiral and that should ideally be similarity invariant. We find that these measures fall into two categories: those that gauge the extent to which a chiroid differs from an achiral reference object (measures of the first kind) and those that gauge the extent to which two enantiomorphs differ from one another (measures of the second kind).

In this review we have described some of the many chirality measures that might in principle be devised. Our principal conclusions are that measures of the second kind have, in general, a significantly wider range of application than those of the first kind, that chirality rank depends on the measure, that the bounds of each chirality measure are dictated by the nature of the function so that the shape of the most chiral object in a given class differs from measure to measure, that maximum chirality is associated with minimum symmetry, and that the union of an object and its mirror image is achiral under conditions of optimal overlap.

Efforts to quantify chiral shapes have so far been limited to geometric figures and to rigid models of molecules; future work might be devoted to broadening the scope of these studies by addressing related problems in dynamic and topological chirality. Beyond this, there remains the daunting challenge of bridging the gap between the results of chiral shape analysis and the world of experimental observables. There has been no shortage of precedent for this type of correlation: beginning with Guye's "produit d'asymétrie" in 1890 and continuing to the present day, great ingenuity has been expended in the design of chirality functions to model pseudoscalar physical and chemical properties. Although these models have so far found rather limited utility, it may not be naive to expect that the type of approach described in this review will eventually prove useful in correlating molecular shape with properties arising from molecular chirality.

We thank Victor Klee (Seattle) and Paul Mezey (Saskatoon) for helpful discussions, Viktor Kuz'min (Odessa) for permission to cite unpublished results from his laboratory, and the National Science Foundation (U.S.A.) for support of this work. T. Auf der Heyde thanks the University of the Western Cape for leave of absence, and the Foundation for Research Development (South Africa) for financial assistance.

In this paper we pointed out that it is "permissible to speak of degrees of chirality, and to compare molecules or molecular ensembles by the use of expressions such as 'more' or 'less' chiral or achiral."

[4] In addition to optical rotatory power (rotationai strength), chiral discriminations between enantiomers or between enantiotopic groups may also be expressed on the scale of a numerically valued variable. These discriminations result from the differential interaction of enantiomers or of enantiotopic groups (which are necessarily incorporated in an achiral molecule) with a chiral environment (reagent, solvent, surface, field, etc.); examples include different reaction rates with a chiral reagent (e.g. an enzyme), NMR chemical shift differences in a chiral solvent or in the presence of a chiral shift reagent, and different rates of elution from a chiral column. Symmetry arguments suffice to explain the existence of chiral discriminations, but separate theoretical models appropriate to each type of observation are required to account for their magnitude and direction. For partial overviews, see S. F. Mason, *Molecular Optical Activity and the Chiral Discriminations*, Cambridge University Press, Cambridge, **1982**; *Asymmetric Synthesis Vol. 1: Analytical Methods* (Ed.: J. D. [5] Even if all three compounds are to all appearances optically inactive (i.e., "crypto-active" [1c]), the model still demands different levels of optical activity below the operational null [3].

[6] In this view, enantiomers are time-dependent molecular states with very long tunneling times, that is, kinetically stable states and therefore individually (separately) observable. Beginning with Hund's "Paradoxon der optischen Isomeren" [F. Hund, *Z. Phys.* **1927**, *43*, 805], the quantum-mechanical treatment of molecular structure has raised issues that profoundly affect theories of molecular chirality. Most notable among these is the radical proposition, advanced by Woolley, that if nuclear and electronic motions are not separated (i.e., in the absence of the Born-Oppenheimer approximation), *isolated* molecules in stationary (time-independent) quantum states are spherically symmetric and thus lack all of the features that are associated with molecular shape, including chirality. However, the question becomes moot if the model of the molecule is based on observations of bulk matter, that is, of molecules in a many-body environment. See "Quantum Theory and Molecular Structure": R. G. Woolley, *Adv. Phys.* **1976**, *25*, 27; "Must a Molecule Have a Shape?": R. G. Woolley, *J. Am. Chem. Soc.* **1978**, *100*, 1073; "Natural Optical Activity and the Molecular Hypothesis": R. G. Woolley, *Struct. Bonding (Berlin)* **1982**, *52*, 1. For commentary on these ideas, see, inter alia, L. [7] The parity-violating weak neutral current perturbation lifts the degeneracy of space-inverted enantiomers, for example, D- and L-alanine; an *exact* degeneracy exists only between a chiral molecule and its mirror image composed of antiparticles, such as D-alanine and L-"anti"-alanine or D-"anti"-alanine and L-alanine. Barron [8a] has emphasized that this parity-violating energy difference, which is of the order of 10^{-18} kcal mol^{-1}, obtains only for systems whose sense of chirality is invariant to time reversal, that is, for systems that are able to support time-even pseudoscalar observables. As he has noted, the helical sense of a spinning sphere that is translating along its spin axis, or of a circularly polarized photon or a longitudinally polarized electron, is also invariant to time (i.e., motion) reversal. In contrast, the sense of chirality of a cone spinning about but not translating along its axis is reversed by time reversal.

Geison, J. A. Secord, *Isis* **1988**, *79*, 6.

[11] According to a principle attributed to F. E. Neumann [A. V. Shubnikov, V. A. Koptsik, *Symmetry in Science and Art*, Plenum, New York, **1974**, p. 334; J. D. Donaldson, S. D. Ross, *Symmetry and Stereochemistry*, John Wiley, New York, **1972**, p. 132], the properties of a system are invariant with respect to its symmetry operations. In a famous aphorism by Curie [P. Curie, *J. Phys. Theor. Appl. Ser. 3*, **1894**, *3*, 393], "c'est la dissymétrie qui crée le phénomène," that is, observable phenomena result from a lowering of the symmetry (desymmetrization) of the system. Thus, all manifestations of chirality originate from a single source: the absence of improper rotations in the symmetry group that describes the system under observation.

[12] The classic text by Gardner [a) M. Gardner, *The Ambidextrous Universe*, Basic Books, New York, **1964**; 2nd ed.: Charles Scribner, New York, **1979**, b) *The New Ambidextrous Universe*, 3rd ed., Freeman, New York, **1990**] remains the premier popularization of the left-right dichotomy in Nature.

[13] W. T. Kelvin, *Baltimore Lectures on Molecular Dynamics and the Wave Theory of Light*, C. J. Clay, London, **1904**, pp. 439, 618–619; see also L. L. Whyte, *Nature (London)* **1957**, *180*, 513; *ibid.* **1958**, *182*, 198; *Leonardo* **1975**, *8*, 245. From Kelvin's definition it follows that the chirality of an object is a function of the object's *shape*. Thus, to achieve chirality it is not sufficient to assign different labels to parts of an achiral object. For example, an irregular tetrahedron is chiral, but a regular tetrahedron in which the four different vertices are distinguished by different indices (labels) is not.

[14] Any function that does not satisfy this conditio sine qua non fails to qualify as a measure of chirality. An egregious example is a recently proposed "chirality measure" [D. Avnir, A. Y. Meyer, *J. Mol. Struct. (Theochem)* **1991**, *226*, 211] that gives "chirality values" for achiral halogenated normal alkanes: not only are these values not zero but they are even higher than the "chirality values" of the corresponding chiral halogenated alkanes!

[18] a) The "common volume" measure of chirality exemplified here is a straightforward extrapolation of Kitaigorodskii's proposal [A. I. Kitaigorodskii, *Organic Chemical Crystallography*, Consultants Bureau, New York, **1961**, p. 230] that the resemblance in the shapes of two molecular models M and M' may be gauged by superimposition of M on M' in such a way that the nonoverlapping volumes equal some minimum value Δ: "If the overlapping volumes add up to τ, then $\varepsilon = 1 - \Delta/\tau$ is the degree of molecular isomorphism". If M and M' denote enantiomorphous chiroids, the fraction of nonoverlapping volumes under conditions of maximal overlap beomes a measure of the degree of chirality. b) See also B. Chion, J. Lajzerowicz, D. Bordeaux, A. Collet, J. Jacques, *J. Phys. Chem.* **1978**, *82*, 2682; G. Gilat, L. S. Schulman, *Chem. Phys. Lett.* **1985**, *121*, 13; G. Gilat, *J. Phys. A.: Math. [27] Ruch et al. [28] have defined a function $\chi(\lambda)$ with reference to a model in which a set of n ligands is partitioned among the n sites of an achiral permutation skeleton, such as a regular tetrahedron, and in which λ is a transferable, ligand-specific, scalar parameter with a physical dimension, for example polarizability, or with geometrical properties.

[28] a) E. Ruch, I. Ugi, *Theor. Chim. Acta* **1966**, *4*, 287; E. Ruch, A. Schönhofer, I. Ugi, *ibid.* **1967**, *7*, 420; E. Ruch, A. Schönhofer, *ibid.* **1968**, *10*, 91; E. Derflinger in *Chirality – From Weak Bosons to the α-Helix*, (Ed.: R. Janoschek) Springer, Berlin, **1991**, p. 34.

[29] Only five tetrahedral symmetries, T_d, C_{3v}, C_{2v}, C_s, and C_1 are possible for $P(I)$ under the α-constraint. These are the same five symmetries that result from different ligand partitions on a regular tetrahedral permutation skeleton.

[30] In a construct used by Boys to model optical rotatory power [S. F. Boys, *Proc. R. Soc. London A*, **1934**, *144*, 675], four spheres are brought into mutual contact so that their centers form the vertices of a tetrahedron, the length of each edge of which is equal to the sum of the radii of two spheres. Boys remarked that the variables "were termed the radii of repulsion of the radicals, but rather than representing any exact physical quantity they must be regarded more as parameters used to express the shape of the molecule". For any given symmetry, this shape is obviously different from that of Ruch's model in which the same four spheres are centered at the vertices of a regular tetrahedron; the shape of this model is given by a different chirality product.

[31] Gothic arches based on the same geometric design can be found in windows of the cathedral of Reims built during 1211–1221. See B. Artmann, *The Mathematical Intelligencer* **1991**, *13*, 44.

[34] This difference arises from the labeling convention adopted in Figure 1. Consider, for example, applying the labels a, b, and c to the sides of a given scalene triangle, with $a < b < c$. When the labels a and b are transposed, the sense of cyclic directionality (orientation) of the labels is reversed. Therefore, in order to preserve the same orientation of labels for both inequalities, $a < b < c$ and $b < a < c$, as required by the convention, enantiomorphs of the triangle will have to be considered. The two segments of the shape space (Fig. 2) in which the representative points for the enantiomorphs will be found hence represent enantiomorphous triangles labeled in the same sense.

[35] O. Giering, *Elemente der Mathematik* **1967**, *22*, 5.

[36] The same bound was found by Nohl [W. Nohl, *Elem. Math.* **1962**, *17*, 59] for centric convex sets in E^2, with equality for a special class of parallelograms, and by Bondensen and Dou [A. Bondensen, J. Dou, *Crux Mathematicorum*, **1989**, (3), pp. 78–87], who proved that any triangular piece of paper of area 1 can be folded once so that, when placed on a table, it will cover an area of less than $2 - \sqrt{2}$. We are grateful to Professor J. C. Fisher (Regina) for drawing our attention to this proof.

[37] a) F. Hausdorff, *Set Theory*, transl. by J. R. Aumann et al., Chelsey, New York, **1957**, pp. 166–168. b) The following formulation of Hausdorff's definition was suggested to us by Professor V. Klee (Seattle). The Hausdorff distance $h(Q,Q')$ between sets Q and Q' is the smallest number δ that has the following two properties: 1) each spherical ball of radius δ centered at any point of Q contains at least one point of Q'; 2) each spherical ball of radius δ centered at any point of Q' contains at least one point of Q.

[38] Rassat [A. Rassat, *C.R. Acad. Sci. Ser. 2* **1984**, *299*, 53] has proposed a classification of geometric figures A as right- or left-handed, depending on which of two Hausdorff distances, $h_{min}(A,B)$ or $h_{min}(A,B')$ in our notation, is the smaller, where B and B' are the enantiomorphs of an arbitrarily chosen reference figure (such as a chiral tetrahedron). If A is achiral, $\delta h_{min} = h_{min}(A,B) - h_{min}(A,B') = h_{min}(A,B) - h_{min}(A',B) = 0$, where A' is

the mirror image of A. However, δh_{min} may also zero if A is chiral. Such "chiral zeros" are bound to occur whenever two enantiomorphs are chirally connected [28b, 39]. In such a case it is difficult to see how Rassat's scheme can be of any use in assigning a sense of chirality to A, since nothing less than a change to a different set of arbitrarily chosen reference enantiomorphs is required to lift the "cryptochirality" [3] of A. It follows from the existence of chiral zeros that the achirality of A is a sufficient but not a necessary condition for $\delta h_{min} = 0$, and that δh_{min} is therefore in general unsuitable as a chirality measure.

[39] Asymmetric tetrahedrons, in Ruch's simile [28b], are potato-like, since an asymmetric tetrahedron (or any four points asymmetrically distributed in E^3) and its mirror image are chirally connected. That is, connecting paths exist by which the enantiomorphs can be interconverted by continuous deformation without ever passing through an achiral shape. An important corollary follows: *concepts like "left-handed" and "right-handed" with reference to asymmetric tetrahedra are meaningless.* Indeed, because the tetrahedron is the simplex in E^3, every such classification is meaningless (or at best arbitrary) for any object in E^3 in the absence of well-defined constraints. In contrast, all scalene triangles are partitioned into heterochiral sets (Section 2.3.2.1).

[40] W. H. Press, B. P. Flannery, S. A. Teukolsky, W. T. Vetterling, *Numerical Recipes*, Cambridge University Press, Cambridge, **1986**. See also C. G. Broyden, *J. Inst. Math. Its Appl.* **1970**, *6*, 222; R. Fletcher, *Comput. J.* **1970**, *13*, 317; B. Goldfarb, *Math. Comput.* **1970**, *24*, 23; D. F. Shanno, *ibid.* **1970**, *24*, 647.

[41] An extremal triangle corresponding to the supremum of the functions described in Sections 2.3.2.1, 2.3.2.2, and 2.3.3.1 does not exist, and is only approached in the limit. This finding is consistent with the noncompactness of the space of similarity invariant triangles. Grünbaum [15] has pointed out that the space of similarity invariant convex sets is noncompact; see also B. A. deValcourt, *Isr. J. Math.* **1966**, *4*, 65. Thus, the range of measures defined on such sets is bounded but may not be closed, and it follows that the bounds of the measures may not be attainable.

[42] T. Damhus, C. E. Schäffer, *Inorg. Chem.* **1983**, *22*, 2406.

[43] These measures are qualitatively correlated to the rotational strength, as given by the coupled oscillator model [8b], of a system consisting of two diatomic molecules arrayed as described above; homonuclear molecules are then modeled by nonoriented lines and heteronuclear molecules by oriented lines.

[44] A different measure of helicity is given by the volume of a cylinder on the surface of which is inscribed one complete turn of a helical thread [J. H. Brewster, *Top. Curr. Chem.* **1974**, *47*, 29]. If L denotes the height of the cylinder, that is, the pitch of the helix, and D the length of the thread, then, according to Brewster's analysis, the volume of the cylinder is at a maximum when $L = D/\sqrt{3}$. Maximum helicity is therefore achieved when the angle of rise is $\arcsin 3^{-1/2} \approx 35.3°$.

[45] Of the five chiral subsymmetries of T_d, two (C_3 and T) cannot be realized by a tetrahedron [V. Prelog, G. Helmchen, *Helv. Chim. Acta* **1972**, *55*, 2581].

[47] Edge AE of the T_2 conformation space maps degenerate tetrahedrons for which, first, vertex 1 is infinitely far from vertices 2, 3, and 4 (face ABE in Fig. 9), and, second, vertex 3 is contained within the tetrahedral face formed by vertices 1, 2, and 4 (face ADE).

[48] If the constraints of D_2 or C_2 symmetry are not relaxed, interconversion of enantiomorphs unavoidably requires passage through an achiral shape. The set of achiral shapes then constitutes a boundary that separates two heterochiral classes, and it becomes possible to describe such tetrahedrons as "left-handed" or "right-handed" with reference to an arbitrarily chosen coordinate system. See also [39].

[49] Rotation about the third axis yields a union that corresponds to a local minimum with a much larger value of $h(Q,Q')$ (0.44).

[56] A lattice "animal" is a graph consisting of n square cells that are joined to one another by shared edges. The number of animals with intrinsically different (i. e., symmetry-nonequivalent) shapes is 1, 1, 2, 5, and 12 for $n = 1, 2, 3, 4$, and 5, respectively. Among the five animals with four cells, two are chiral, and among the twelve animals with five cells, six are chiral. An n-cell animal $A(J,n)$ inscribed in a Jordan curve J is said to be "interior filling" if, and only if, no animal of the same cell size and with more than n cells can be inscribed in J [55b].

[57] Let $a(J)$ denote the interior area of any chiral Jordan curve J. There exists a maximal achiral subset S of J whose area, $a(S)$, can be inscribed in J. Since J is chiral, some area, $a(J) - a(S)$, must be left over. By sufficiently reducing the size of the cells, interior filling animals $A(J,n \geq n_0)$ can therefore always be generated whose areas $a(A)$ are larger than $a(S)$, that is, $a(J) \geq a(A) > a(S)$. It follows that all such animals are chiral [55d].

[58] Kelvin's definition of chirality (Section 2.1), when analyzed from an algebraic point of view, also implicitly contains a proposition for a noncontinuous measure of chirality, $k(Q)$. This can be paraphrased as follows: if any geometrical figure or set of points, Q, can be brought to coincide with its mirror image, then $k(Q) = 0$ (object is not chiral); otherwise $k(Q) = 1$ (object is chiral). The implications of this "black-and-white" or binary approach to chirality have been discussed *in* [3].

[64] The time-average symmetry, as given by the molecular symmetry (MS) group [63a], may sometimes be isomorphic to the point group of an intuitively appealing time-average structure at the fast exchange limit, as in the case of NH_3 (D_{3h}) or cyclohexane (D_{6h}). However, such convenient coincidences cannot always be counted on. For example, the MS groups of ethane and PF_5 appropriate to the fast exchange limit are isomorphic to $D_3 \times D_3$ (order 36) and $S_5 \times S_2$ (order 240), respectively. Neither group corresponds to the symmetry of any conceivable conformation of these molecules [J. Reisse, R. Ottinger, P. Bickart, K. Mislow, *J. Am. Chem. Soc.* **1978**, *100*, 911].

[65] As defined by Ugi et al. [63c], a molecule is "chemically achiral" if each momentary geometry of the molecule can be superposed on its mirror image by using the rotations, translations, *and* intramolecular motions that can occur under the given observation conditions. Chemical achirality is thus a special case of "stochastic achirality" [3].

[75] This conclusion is valid regardless of whether such graphs are "intrinsically achiral", that is, topologically equivalent (homeomorphic) to achiral embeddings in E^3 (as is the case with knots and links, all of which are homeomorphic to unknotted and unlinked rings), or "intrinsically chiral", that is chiral in all embeddings (like Möbius ladders with an odd number of differentiated rungs). See [66] and [69b].

[76] These graphs *can* attain rigidly achiral presentations by continuous deformation in E^3, even if the presentations correspond to conformations that are unrealistic from a chemical point of view: questions of internal energy are totally disregarded. For example, in the enantiomerization of asymmetric phosphoranes [67d], a planar molecular graph is required for achiral Pabcde.

[77] The sharp differentiation between the two classes of chirality measures confirms that "it is good not to forget the distinction between metrical chirality and the deeper topological chirality" [12b, p. 163].

[78] In this connection we need to comment on an intriguing notion by Walba that classes of molecular graphs may be ranked "by degree of chirality, from most chiral to least chiral" [66]. Walba's "topological hierarchy of molecular chirality" consists of six classes, "three resolvable and three non-resolvable." In our view, the energetics of racemization have no bearing on the degree of chirality of the molecule undergoing racemization, and Walba's scheme may therefore be reduced to four classes: molecular graphs that are topologically and intrinsically chiral, topologically chiral and intrinsically achiral, topologically achiral with no rigidly achiral presentations (e.g. the knot known as 8_{17} [69b], a "topological rubber glove" [66] that has not yet been realized at the molecular level), and topologically achiral with rigidly achiral presentations (all formally achiral molecules, as well as formally chiral molecules such as Nabc, Cabcd, and "molecular Euclidean rubber gloves"). Whatever the merits of this classification might be, Walba's ranking is not a numerical function and is therefore not a measure of chirality.

What subscribers and authors have to say about Angewandte Chemie:

Jean-Marie Lehn, Université Louis Pasteur, Strasbourg:

"I consider Angewandte Chemie as one of the top not only chemical but scientific journals... It presents the highly effective combination of well chosen, exciting and thorough review articles, reflecting timely topics that cover a very broad range in science, with short but informative communications reporting specific advances of particular interest for chemistry. It is also carefully produced and nicely presented, which adds to the reading pleasure."

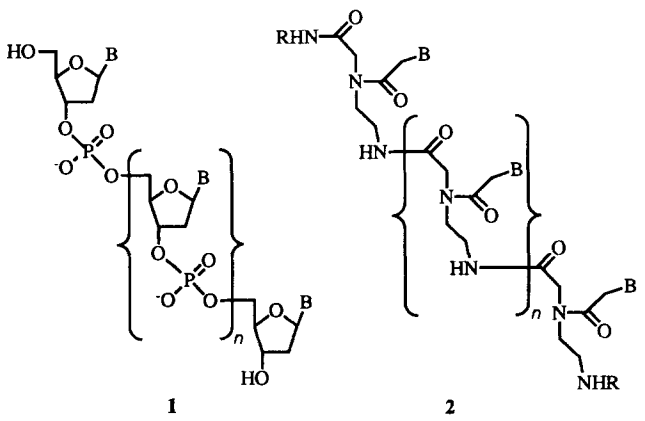
Peptide Nucleic Acids (PNAs)—Unusual Properties of Nonionic Oligonucleotide Analogues

By *Chris Meier*, and *Joachim W. Engels**

There is no molecule more important in the molecular processes in living systems than the DNA double helix. All fundamental functions of life are established by this molecule: the storage, the transfer (replication), as well as the translation (expression) of the genetic information. This is based on the order of only four constituents (nucleosides): deoxyadenosine (dA), deoxyguanosine (dG), thymidine (T), and deoxycytidine (dC). Two nucleosides, dA and T, as well as dG and dC, form Watson–Crick base pairs by association through hydrogen bonds which leads to a double helix in the case of the polymer DNA. For many years the DNA double helix has been a main research topic for chemists because of its uniqueness and importance, as well as its relatively simple construction.

Single-stranded nucleic acids of $n = 3-100$ nucleosides are called oligonucleotides **1** (Scheme 1). Oligomers such as **1** with a defined sequence may be prepared synthetically.



Scheme 1. **2a**, $n = 6$; **2b**, $n = 8$; **2c**, $n = 10$.

They serve as models of the DNA double helix because of their ability to form complementary sequences with oligonucleotides under formation of relatively short double helices, and their physical and biological characteristics are studied. Noncovalent and reversible binding of synthetic oligonucleotides **1** is not restricted to oligomers bearing deoxyriboses (DNA) but is also possible with ribose-containing oligonucleotides (RNA) under duplex formation as well as with a complementary sequence in an intact DNA double helix under triple helix formation.[1] The fact that an oligonucleotide with a definite sequence of 17 nucleosides (17mer oligonucleotide) would find statistically only one exact complementary sequence within the human genome shows the enormous potential of synthetic oligonucleotides. The facile access to **1** as well as several applications (e.g., the application as primers or starter oligonucleotides for the polymerase chain reaction (PCR) amplification technique) were made possible by the introduction of automated oligonucleotide synthesis.[2]

It is not surprising that a new application of oligonucleotides has been recently explored: the development of pharmaceuticals as gene blockers where either the DNA double helix (triple helix formation) or mRNA (double helix formation, antisense approach) are the targets for binding.[3, 4] The advantage of these concepts over present methodologies is obvious. Several regions of the genome of a virus or a cancer cell must be transcribed into mRNA and expressed as proteins for the duplication of these organisms. Many protein molecules are produced from one mRNA copy. If one is able to inhibit the transcription process by triple helix formation or to bind the mRNA copy by an antisense oligonucleotide with a complementary sequence, it could be possible to treat diseases on the DNA or RNA level and not by inhibition of proteins (enzyme blockers). For this purpose unmodified oligonucleotides are not applicable because of their instability to oligonucleotide-degrading enzymes (endo- and exonucleases) and their bad membrane permeation properties. In order to increase nuclease stability as well as improve transport behavior, several modifications were introduced. As analogues of the sugar/phosphate backbone mono- or dithiophosphate, methylphosphonate, phosphotriester oligonucleotides, and nonphosphate nonionic analogues like formacetal-, carbamate-, sulfoxido-, and sulfone-linked species were intensively studied.[5]

A total turn away from this concept of substituting the phosphodiester linkage by isosteric groups was published recently by Egholm, Burchardt, Nielsen, and Berg.[6a, b] They made use of a widely distributed natural polymer as a backbone analogue—the peptides: Taking a monomeric building block that consisted of an amino acid (2-aminoglycine) bearing the nucleobase (thymine) attached with a defined spacer (methylenecarbonyl), they polymerized this monomer according to the Merrifield method of peptide synthesis and obtained a peptide nucleic acid (PNA, **2**; Scheme 1).[6c] The monomeric building block **3** used in the Merrifield synthesis was prepared as follows: Thymine **4** was treated with α-bromomethylacetate **5** in DMF in the presence of potassium carbonate followed by aqueous saponification and DCC-mediated esterification with pentafluorophenol (Pfp) to yield α-thyminylpentafluorophenylacetate **6**. Nucleophilic substitution of **6** by *N*-(*N'*-Boc-aminoethyl)glycine (*N'*-BocAeg, **7**)/triethylamine in DMF and subsequent esterification (Pfp/DCC) gave the Pfp-active ester **3** (Boc-Taeg-OPfp) of the monomer (Scheme 2). **3** was oligomerized under conditions of the "single-coupling protocol"[7] in 30% DMF/methylene chloride on a 4-methylbenzhydrylamino solid support. The yield per step was determined by quantitative ninhydrin analysis (>99%). The cleavage of **2** from the solid support was achieved by treatment with anhydrous HF.

This approach, amazingly simple upon first glance, has some advantages over the applications of modified oligonu-

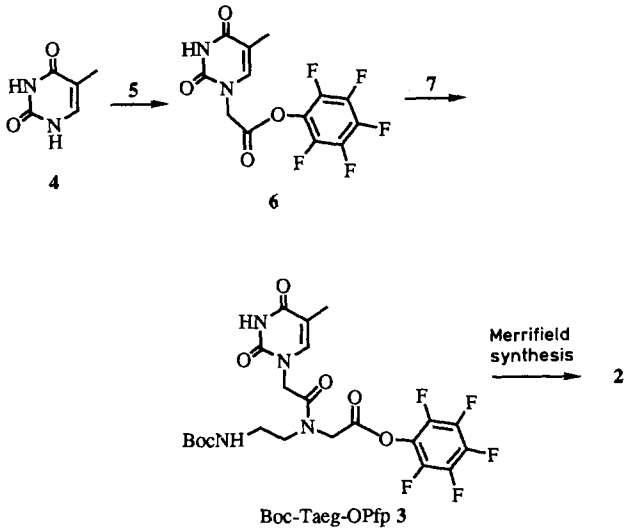

Scheme 2. **5** = methyl α-bromoacetate, **7** = *N*-(*N'*-Boc-aminoethyl)glycine. For details of the synthesis of **2** see text.

cleotides studied so far. Nonionic oligonucleotides are stable to nucleases. In aqueous medium, complexes of nonionic species with unmodified oligonucleotides are much more stable than their ionic counterparts. It is possible to synthesize larger amounts of PNAs **2** according to the Merrifield methodology while the synthesis of modified oligonucleotides is limited by the capacities of the oligonucleotide synthesizers. The synthetic method for PNAs may also allow access to not only PNAs with an achiral peptide backbone but also those with a chiral backbone. The controlled introduction of stereochemistry into methylphosphonates, phosphotriesters, and phosphothioates[8] has been achieved only in the last case. Stereochemical nonuniform products result in complex, not verifiable hybridization properties. In addition, the flexibility of the described peptide backbone is significantly less than that of a phosphodiester backbone because of the two amide bonds per monomeric unit. A disadvantage of PNAs **2** is perhaps the limited membrane transport relative to oligonucleotides because of the lack of active transport mechanisms. The metabolic pathways of **2** inside cells are also not known.

The authors used molecular modeling in their selection of the described monomeric building block. A monomer with six bonds (2-aminoglycine) as well as a spacer with two bonds separating the nucleobase from the backbone fulfilled the requirements for the optimal binding of **2** to a B-DNA single-strand oligonucleotide with formation of a double helix. These structural requirements were proposed recently by Weller et al. independently from the work of Nielsen et al.[9] In Weller's studies, also based on molecular modeling, the formation of helical peptide structures with simultaneous base stacking is clearly dependent on the monomer size.[9] The calculated optimal distances are not surprising, however, because these are also found in a natural DNA strand (see Scheme 1). Nielsen et al. synthesized hexa-, octa-, and decamers (**2a**, **2b**, and **2c**, respectively) of the thymine-containing monomer. **2a–c** were capped at the *C*-terminus by a lysine residue to avoid self-association. This would also increase the interaction (attractive effects) with an unmodified oligonucleotide, because at physiological pH value the amino group of the lysine side chain is protonated. Modifications at the *N*-terminus are possible as was shown by the introduction of the intercalator acridine. As in analogous compounds acridine causes an increase in association with single- or double-stranded DNA.

Some very astonishing results were obtained from the binding studies. The hybrid of the lysine–thymine decamer PNA **2c** with a dA decamer has an extremely high melting point T_m of 72 °C (ca. 50 °C higher than the T_m value of a dA/T decamer hybrid)! Additionally, the increase of the T_m value of 10 °C per monomer unit is unusually high. As expected, the T_m value dropped by the same value when mismatches were introduced. The introduction of acridine at the *N*-terminus caused an increase of the T_m value by 13 °C. One has to wonder if electrostatic interactions coupled with the formation of hydrogen bonds provide sufficient explanation for these observations or if other unnoticed contributions are responsible for these enormous hybridization capabilities. On the other hand, the hybridization of oligo(dA) with oligo(T) has always been exceptional, and one should wait for sequence-specific studies.

Another interesting feature of **2c** was revealed in hybridization studies with a DNA double strand containing a T_{10}/dA_{10} fragment. It seemed that lysine–thymine$_{10}$ PNA **2c** displaced the T_{10} strand from the complementary dA_{10} strand and did not form a triple helix as one might have expected and as the authors had originally intended.[6a] This conclusion was convincingly supported by enzymatic and chemical degradation experiments.

Despite these positive properties of PNAs **2** described for the first time by Nielsen et al., the results pose other questions that are important for the use of **2** as antisense oligonucleotide analogues with mRNA as target. First of all there is the question of the binding properties of a 17mer PNA that are essential for a sequence-specific recognition. A rough extrapolation of the T_m value of the 10mer would result a value of approximately 140 °C for the 17mer. Thus it is difficult to consider a reversible binding at body temperature. Additionally, there is the question if such an oligomer would be able to bind specifically to a complementary sequence. Even eight (!) mismatches in the 17mer do not reduce the T_m value to below body temperature (37 °C). In UV titration experiments of the formed duplexes the authors found a 2:1 ratio of PNA:DNA. This puzzling result points to the possible formation of a triple helix. Another question is how an oligomer designed for DNA would behave with RNA as a result of the different structural types of these molecules. The former shows a B-DNA type conformation whereas the latter has an A-DNA type conformation. Are the PNAs able to allow the conformational changes necessary? The stability of **2** to nucleases is obvious, but what about its stability to proteases or peptidases? Investigations of the use of PNAs instead of backbone-modified oligonucleotides may give new exciting results. Small changes in the natural phosphate/sugar backbone (methylphosphonates or phosphothioates) cause great changes in the hybridization properties of oligonucleotides. However, the results presented by Nielsen et al. suggest that extensive modifications may change the hybridization capabilities in an apparently more controllable fashion. The paper points out one thing very clearly: the search for new DNA analogues as antisense reagents sup-

plies new, surprising, and unpredictable insights on the interaction of these compounds with unmodified oligonucleotides. The data presented also show that computer modeling is a helpful tool in the design of new DNA analogues.

Synthetic Models for Iron–Oxygen Aggregation and Biomineralization

By *Karl S. Hagen**

Iron, the most abundant transition element in the earth's crust, plays a major role in biological systems primarily because of its rich redox chemistry, and to a lesser extent the structural and magnetic properties of its various mineral forms. A streamlined biological apparatus for handling free iron is imperative, since free Fe(II) ions will react with dioxygen to form highly reactive and destructive radicals, whereas uncomplexed Fe(III) ions form insoluble iron hydroxide under physiological conditions. The iron-storage protein ferritin, made up of 24 subunits forming a shell approximately 70 Å in diameter which can contain up to 4500 iron atoms, is primarily responsible for solubilization and storage of excess Fe(III).[1] The structure of the hydroxo(oxo)iron core of ferritin is not well-defined and is variable in composition. The best information is obtained under low phosphate concentrations for which considerable long-range order, resembling that of the mineral ferrihydrite, is detected by X-ray diffraction and electron microscopy. The variable phosphate component in the core is thought not to play a dominant structural role, although phosphate may play a significant role in binding to isolated iron ions, small aggregates, or the surface of large crystallites.

Iron oxides have a rich mineral chemistry, and more than twenty years ago stable, soluble nanoparticles averaging 70 Å in diameter were prepared by hydrolytic polymerization of iron(III).[2] Yet the chemistry of molecular iron–oxygen clusters has been dominated by the fundamental oxo-bridged diiron(III) unit[3] and the trinuclear basic iron carboxylates. The crystal structure determination in 1981 of a binuclear iron–oxygen species in hemerythrin and the discovery of related oxo-bridged bimetallic centers in other proteins has revived the study of iron–oxygen chemistry. An extensive chemistry of binuclear model complexes has been developed, and larger Fe_4, Fe_6, Fe_{11}, and Fe_{16} aggregates,[4] predominantly ligated by bridging carboxylato ligands, have been characterized.

However, the precipitation process of iron hydroxide oxides remains ill-defined, and unlike the rich polyoxoanion chemistry of early transition metal ions, no molecular polyiron(III) species containing only aqua, hydroxo, or oxo ligands has been crystallized. The inability of high-spin Fe^{III} ions to strongly polarize and stabilize terminal oxo ligands favors the uncontrolled growth of polyiron complexes. Therefore the formation of molecular aggregates necessarily relies on multidentate or bulky organic capping ligands. A few model studies of the basic aggregation process are now available to aid our understanding of the molecular basis of polymer growth. This report highlights the advances in this field culminating in a recent report in this journal[11] on the largest polyiron aggregates isolated and crystallographically characterized to date.

The electronic spectroscopy of ferritin indicates octahedral coordination about the high-spin iron(III) ions. Therefore aggregates are best conceptualized as a construction of FeL_6 octahedra which share vertices, edges, or faces (L = H_2O, OH^-, O^{2-}, phosphate, or donor atoms from amino acid side chains). The $Fe_2(\mu\text{-O})$ unit in **1**[3] has the simplest structure in which two octahedra share a vertex at oxygen.[*] Dibridged cores $Fe_2(\mu\text{-OR})_2$ as in **2**[3b] (where

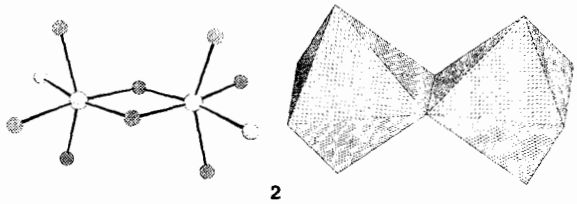
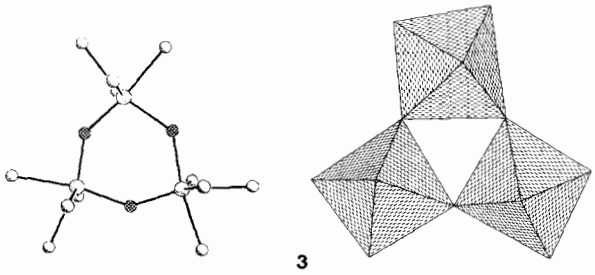
[*] In the structures of **1**–**11** depicted here, only the central skeletons of the polyiron compounds are shown for reasons of clarity. Atom representations are: Fe dotted, O cross-hatched, (carboxylate O atoms in **9** are white), N partially shaded circles. The same perspectives are presented for ball-and-stick and polyhedral drawings except for those of **5** where orthogonal views are depicted.



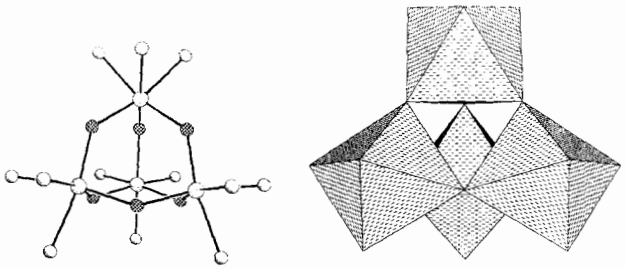
2

R = H or alkyl or aryl groups) are also known. The only structurally characterized trinuclear iron complex without carboxylate bridges contains the planar $Fe_3O_2(OH)$ core in **3**[5] in which tetradentate ligands block all but two coordination sites at the octahedral iron center. Use of tridentate



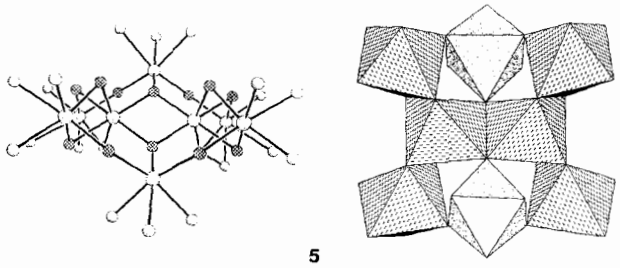
3

facially coordinating ligands affords the "three-dimensional" core $Fe_4O_2(OR)_4$ in compounds of type **4** in which a fourth octahedron caps the three octahedra arranged like



4

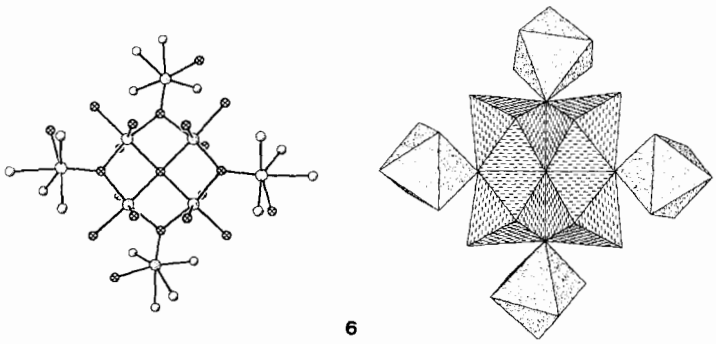
those in **3**.[6] This core may be prepared by the hydrolysis of [Fe(tacn)Cl_3] (tacn = 1,4,7-triazacyclononane). Further hydrolysis affords the octanuclear Fe–O aggregate



5

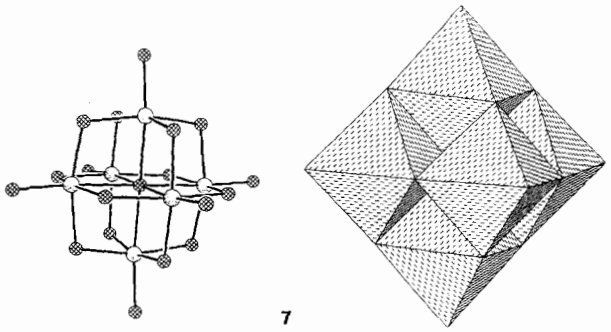
$[Fe_8O_2(OH)_{12}]^{8+}$ in **5**[7a] which, for the first time, contains two discrete layers of close-packed ligand atoms (O and N) with Fe(III) ions in octahedral holes. This is also the first compound containing the Fe_3O unit which does not have bridging carboxylate groups.

Subsequent growth in iron–oxygen aggregates can be viewed either from variation in the role of bridging oxo ligands or increasing nuclearity. An example of the former is the introduction of the μ_4-O unit as in the $[Fe_8(\mu_4\text{-}O)(\mu_3\text{-}O)_4]^{14+}$ core in **6**.[7b] This results in a compact core with four



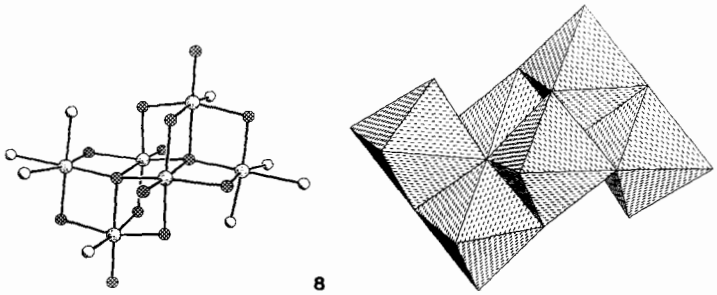
6

central octahedra sharing a common vertex and each sharing two edges with neighbors. This central core is a fragment of the alkoxido(oxo)hexaferrate $[Fe_6(\mu_6\text{-}O)(\mu\text{-}OR)_{12}(OR)_6]^{2-}$ in **7**,[7b] a structural motif common to early transition-metal polyoxoanions.[8] The next step in polyoxoanion growth is a



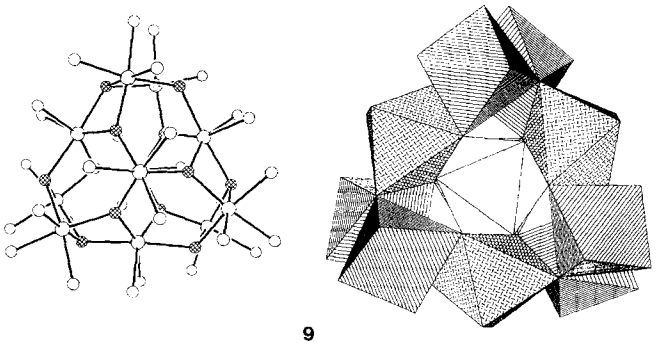
7

fusion of two hexametalates to the decametalates, $[M_{10}O_{28}]^{n-}$, a fragment of which is seen in the hexairon oxo alkoxide, $[Fe_6(\mu_4\text{-}O)_2(\mu\text{-}OR)_8(OR)_4(tren)_2]^{2+}$ **8**[7c] (tren = tris(2-aminoethyl)amine). The coordination of terminal amine ligands has presumably prevented the full decametalate structure from forming.



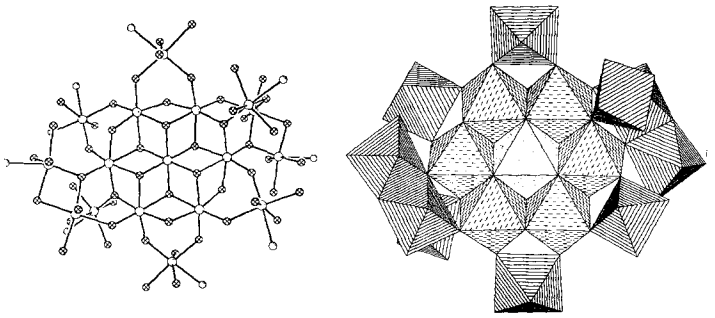
8

An example of Fe–O aggregates with higher nuclearity is the carboxylate $[Fe_{11}O_6(OH)_6(O_2CPh)_{15}]$ shown in **9**.[4a] The bidentate carboxylate ligands dictate the overall geome-

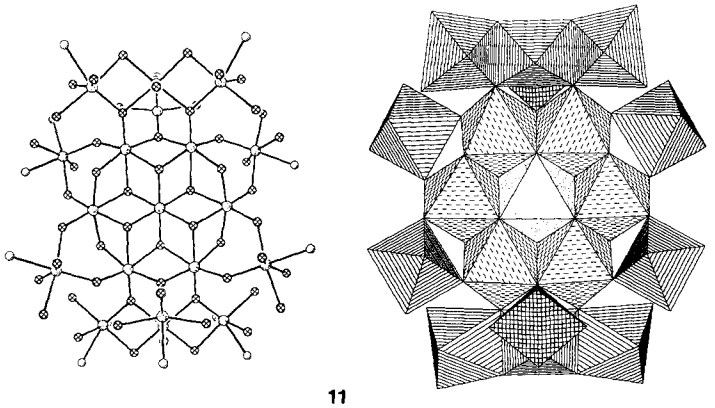


9

try and prevent layered structures from forming. Such aggregates may represent the structures of amorphous iron oxides which are present in ferritin and a prerequisite for subsequent nucleation and crystal growth.[10] The largest iron–oxygen aggregates crystallized to date are **10** and **11** (H_3heidi = $N(CH_2COOH)_2(CH_2CH_2OH)$).[11] They are excellent models for the incipient stages of the biomineralization of layered iron oxides. The Fe_7O_{12} cores are clearly



10



11

$[Fe_{17}(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_6(\mu\text{-}OH)_{10}(heidi)_8(H_2O)_{12}]^{3+}$ **10**
$[Fe_{19}(\mu_3\text{-}O)_6(\mu_3\text{-}OH)_6(\mu\text{-}OH)_8(heidi)_{10}(H_2O)_{12}]^{+}$ **11**

fragments of the layered AX_2 structural type and are surrounded by less highly structured shells made up of eight and ten iron atoms capped and bridged by the tetradentate ligand heidi.

These synthetic models shed light on two basic aggregation processes: the formation of soluble aggregates with high nuclearity related to well-defined polyoxometalates of the early transition metals, and the formation of insoluble layered minerals such as goethite. They lay the groundwork for the synthesis of models of technologically important iron(II) oxides[12a] and the mixed-valence mineral magnetite, which has recently been synthesized in ferritin.[12b]

Artificial Replication Systems

By *Siegfried Hoffmann**

"It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material"—rarely has anything fascinated Science as much as the "hallowed" structure of DNA, born in that classical understatement of Watson and Crick, but also of Franklin and Wilkins. From the chemical side, however, the euphoria was mingled with a little melancholy and dismay. The chemists had loved proteins too much to be able to devote due attention to the nucleic acids. Schrödinger's "aperiodic crystal", which revealed in its enchanting statics a wealth of dynamics inconceivable before its discovery (Fig. 1), had, beginning with Miescher and Altmann, remained largely the domain of nonchemists and chemical outsiders.[1]

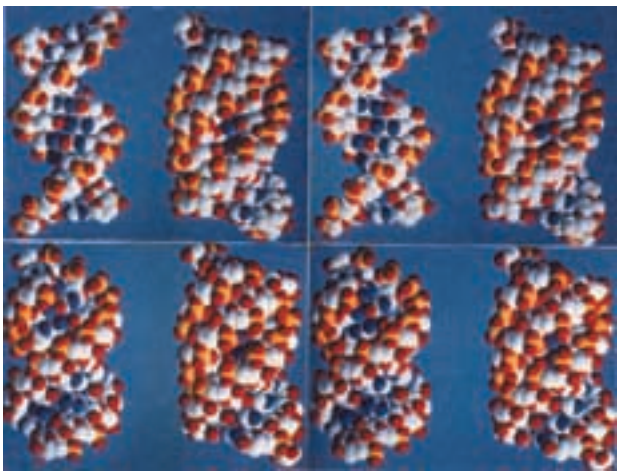

Fig. 1. Stereo representations of DNA and RNA duplex and triplex systems. (Top: DNA; bottom: RNA. Left triplex, right duplex).

Todd sought to answer for chemistry in a landmark appeal: "The use of one molecule as a template to guide and facilitate the synthesis of another...has not hitherto been attempted in laboratory synthesis, although it seems probable that it is common in living systems. It represents a challenge which must, and surely can, be met by organic chemistry".[2] And the grand concept indeed appeared to be portentous. Quite soon, Schramm et al.[3] aroused enthusiasm with the "nonenzymatic synthesis of polysaccharides, nucleosides and nucleic acids, and the origin of self-replicating systems". There it stood, diagnosed by hybridization techniques and portrayed by electron microscopy; the first nucleic acid to be generated in vitro, in the form of a polyadenylic acid, and, of course, the first attempt at an artificial matrix reaction, the polycondensation of uridylic acid onto the orienting $(A)_n$ matrix. Was this the breakthrough that would lead chemistry not only into the wonderland of biology, but also rapidly to ordered macromolecular organizations in its own dominions?

[*] Professor Dr. S. Hoffmann
Institut für Biochemie der Universität Halle-Wittenberg
Weinbergweg 16a, D-O-4050 Halle (FRG)

Schramm's dramatic experiments had to push the natura standards optimized by evolution back into the high erro phase of a prebiotic beginning. Purely artificial template experiments that evaluated all the interactive possibilities of both covalent and noncovalent nature, however, were devoid of even this possible relationship to evolutionary development. The first great "chemical" departure into the temptations of such matrix reactions[4] ran aground on innumerable difficulties. The dominant element in scientific progress came to be not the tremendous variety of chemical matrices and the distant aim of building systems capable of self-replication. Rather, fascination with the effortless elegance of the natural prototypes stimulated the vanguards of chemistry and biology in their campaign of molecular penetration of biological systems. Rapid scientific breakthroughs were achieved which had never been thought possible. The golden age of molecular biology had begun.[4]

Oparin and Haldane's heirs, Eigen and Kuhn, gave these events a time perspective, and with their "information" also described the vector of the "Grand Process" of evolution.[5] With this, however, a multitude of rival problems, which had been simmering in the collective unconscious, resolved themselves out of the complexity of the original goals of template experiments. Self-replication, mutation, and metabolism (as prerequisites for selection) made up the list of criteria; through these, information and its origin, evaluation, processing, and optimization had governed the evolutionary history of prebiotic and biotic systems.

In connection with Spiegelman's initial experiments, Eigen and Schuster, Joyce, and others attempted to "bring to life" the theoretical premises behind the laboratory realities of enzyme-catalyzed RNA replication and evolution experiments. Orgel's groups, by contrast, exerted themselves to transform diverse matrix relationships into artificial, enzyme-free nucleic acid formation.[5] When Altman and Cech raised RNA to the throne of an archaic informational and functional omnipotence—confirming earlier speculations by Crick, Orgel, and Woese—it amounted to a late justification of the toil and trouble of this "nucleic acids first" route. "A tRNA looks like a nucleic acid doing the job of a protein", Crick once observed. Now, self-splicing RNA complexes, polymerase activities, ribozymes and hypothetical RNAsomes afforded unusual insights into the genotypical and (!) phenotypical complex behavior of a single nucleic acid species.[6] And with the supposedly greater understanding of this "RNA-world", fresh impetus was given even to the purely chemical approaches, once so promising and now almost forgotten. As "bioid" successors to Decker, these now attempted to work through evolutionary conceptions in classical chemical systems. Once again—but more strongly and at a higher level—a "Kuhn" period of divergent evolution of matrix approaches between molecular biology and classical chemistry had begun.

Three self-replicating systems are representative and exemplary for the wealth of variety of this creative outburst, and clarify, with their different degrees of abstraction, one of the dynamic scientific peripheries of our times (Fig. 2–

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0808-1013 $ 3.50+.25/0

4).[7-9] Through elucidation of the static and dynamic principles of replicative information systems, all three endeavor to gain insight into both the transitional stages between chemical and biological evolution and the possibilities of artificial development of their chemical duplication.

After innumerable attempts to explain the matrix relationships of mono- and oligonucleotides to orienting and catalytic oligo- and polynucleotide templates, here, first, are two self-replicating nucleic acid models (Fig. 2): a DNA-analogous hexamer system by von Kiedrowski et al.[8a, c-f] and an RNA-analogous tetrameric assembly from the Orgel group.[8b] The earlier of these, in concept and realization,

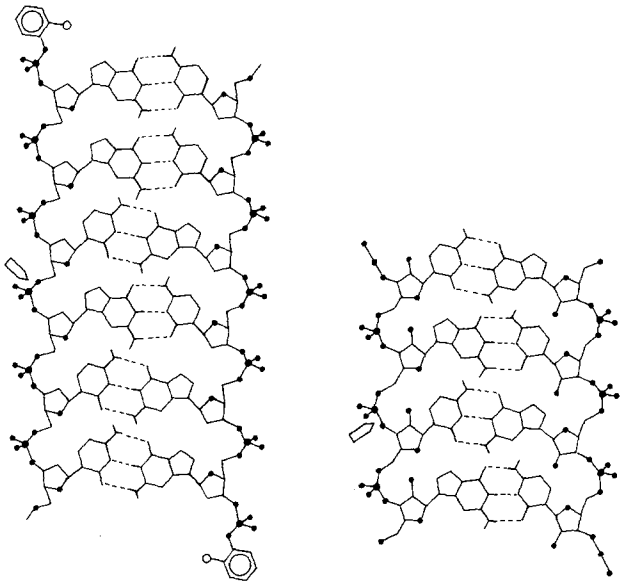

Fig. 2. Self-replicative oligonucleotide matrix systems with self-complementary G/C sequences developed by Kiedrowski et al. (left) and Zielinski and Orgel (right). The bond formed in ligation (carbodiimide method) is marked with an arrow. Left: hexa(3'-deoxyribo)nucleotide matrices with 3'-5'-phosphoester [8a] or 3'-5'-phosphoamidate bonds [8e] in the ligation region; other sugars are 3'-5'-phosphoester linked; 5'-hydroxy groups are alkyl-protected, 3'-phosphate residues are protected as 2-chloro-1-phenoxy derivatives. Right: tetranucleoside triphosphoamidate matrices with 3'-amino-3'-deoxyriboses and 3'-azido modification of the sugar moiety in the 3'-position [8b].

was von Kiedrowski's first successful model hexadeoxyribonucleotide duplex,[8a] which became a leitmotif in the detailed treatment of growth kinetics, and anticipated later self-replicating "minimal systems" in many ways (Fig. 3). By using the ligation of oligonucleotides, he exploited their higher cooperativity to attain increased stability of the matrix duplex and the ternary formation complex. The choice of a palindromic system reduced the complexity of biological replication experiments to a simplified kinetic measurement of its identical (since self-complementary) matrix components. In this way he could obtain direct proof for self-replication, demonstrating the autocatalytic behavior of his system. The surprising square root law of matrix growth kinetics with its ideal case of a parabolic reaction course, derived from the hexadeoxynucleotide duplex, confirmed slightly later by the Zielinski-Orgel system,[8b] and finally also verified in the Rebek dimer assembly,[9, 8d-f] was recognized as autocatalytic system behavior of self-replicative oligonucleotide templates under isothermal conditions. Lat-

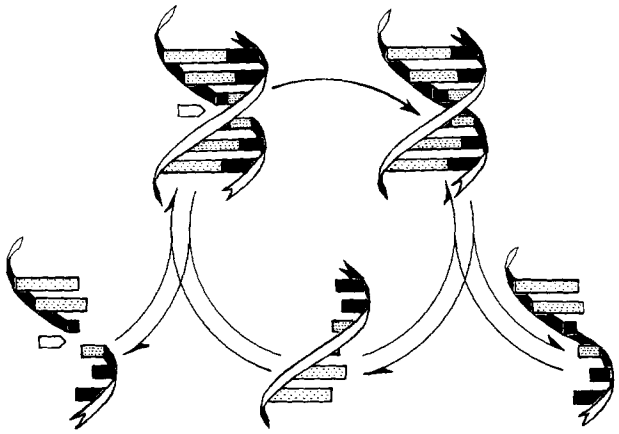

Fig. 3. Self replication diagram for an autocatalytic matrix synthesis, modified from ref. [8f].

er functional and reactive refinements overcame the difficulties remaining in the first approach,[8a] in which the autocatalytic reaction channel was too heavily disguised by the noninstructed, spontaneous synthesis. A hexameric system constructed from two trimeric blocks by phosphoamidate coupling reveals sigmoidal growth behavior and stands out for its extraordinary "autocatalytic efficiency".[8e, f]

The patterns of autocatalysis with respect to parabolic and exponential reaction courses can by now be derived from the thermodynamic and kinetic data of the matrix partners and their reactivities. The findings closely affect the conclusions of Eigen's evolution experiments concerning the decision criteria for mutant selection and coexistence, and offer quite new views, with "autocatalytic co-operation" between competitive species.[8, 9] Basic questions of prebiotic behavior patterns can for the first time become the object of detailed experimental study, separate from "enzyme-catalyzed" evolution experiments with RNA and DNA systems. While studying more complex autocatalysis patterns, von Kiedrowski et al.—extremely aptly—diagnosed modulation of molecular recognition as an operational deficit of earlier self-replicating artificial nucleic acid systems with regard to exponential reaction courses, and identified it as an ideal aim for future models. On its way to the nucleoprotein system, evolution must have had a similar view of the problem when, in Lucretius's "eternal game"[5a] (Fig. 5), it endowed nucleic acids, which are somewhat inefficient in this respect, with proteins experienced in phase and domain regulation control to achieve an ideal milieu for directing modulations of recognition.

Matrix growth kinetics as known for oligonucleotides are followed even by a drastically abstracted artificial replication system developed by Rebek's group (Fig.4). After all that has gone before, this seems to augur a fresh departure for the far horizons of artificial chemical evolution systems. The dimer assembly developed from host-guest relationships combines the interactive and cognitive possibilities of native nucleic acid matrices with the more general biopolymer relationships of the amide bond formation involved in the matrix reactions.[9] When Rebek et al., who have in the meantime sought to stimulate the competition and selection behavior of their self-replicating species by "chemical" mutations, state that one of their main aims is artificial peptide

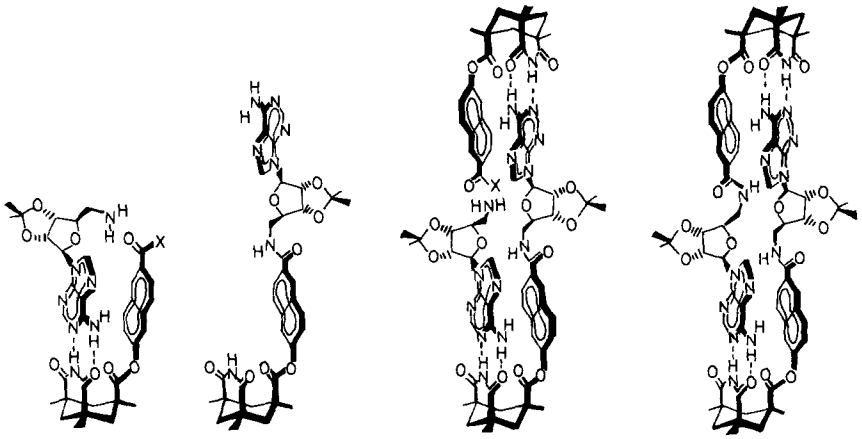

Fig. 4. Self-replicating matrix system of Rebek et al. [9]; the acyl component of the ligation bond is activated in various manners.

synthesis on a nucleic acid matrix, it is slightly reminiscent of the very beginnings. Long before computer simulations fitted protein β-pleated sheets snugly into the minor groves of DNA duplexes and shallow grooves of RNA duplexes to allow modeling of early stages of nucleation of the nucleoprotein system with the mutual polymerase activities for the two grand partner structures,[5i-k] Todd had already—along with his "template"-vision—suggested hypothetical peptide syntheses as one of his "Perspectives in Organic Chemistry". He proposed that the amino acid building blocks of the nascent peptide chain might be activated as common "mixed anhydrides" of the nucleic acid phosphates, and suitably localized stereoelectronically by the orienting matrix—an early view of evolution, developed by human rationality,[2] without regard for the actual biological complexity.

It is, indeed, just this complexity which for today's chemistry provides provocation and stimulation, intimidation and temptation, love, hate and fate together. The systems presented here still remain utterly outclassed by even the most primitive life forms, such as RNA-viruses. The possibility of describing natural selection behavior according to quasi-species distributions in the extreme multidimensionalities of sequence spaces is, for artificial systems, at best a very distant utopia. However, independently of the respective chemical character, basic patterns of autocatalytic activities once again make the original image of that "notionally reduplicative" DNA double helix the center of hopeful expectations. With all its early primitivity, but also with its promising inherent potential of "minimal models of self-replication", chemistry is throwing down the gauntlet to biological complexity in what must be the most decisive region of evolutionary formative processes, and in doing so is gaining new qualities.

Kuhn divergences generate a tremendous number of new matrix and replication variations,[10] and from this breadth develop an impressive depth of impending convergences. The successors to elite nucleic acid templates were surprisingly the apparently simplified amidinium–carboxylate matrices.[8a, 10f] However, in the attempt to simplify generalizing principles as far as possible, the desirable operational modes, astoundingly, become accessible. The dramatically abstracted amidinium–carboxylate systems, which nevertheless cover certain aspects of complex protein–nucleic acid interactions, prove to be susceptible to modulation of molecular recognition and even delight their examiners with exponential growth kinetics. Detailed aspects, such as the possibilities of coordination in native nucleic acid assemblies, make themselves independent in helicates whose structures reflect the relationship between our life process and its basic matrices. Matrix studies of triplex systems (cf. Fig. 1) model possible regulation strategies of nucleic acid organization and at the same time bridge the gap to basic, hysteretic mechanisms of information processing in more highly condensed systems. The paths of chemistry—from the chemical bond to the chemical system, from molecularity to supramolecularity, from statics to dynamics—are united with the spatial–temporal coherences of phase and domain regulations from physics in the asymmetries and nonlinearities of the "Life Sciences",[11] affording processes which are stabilized by their own dynamics. From the earliest preludes (Fig. 5) to the unknown intimacies of nucleation of the nucleoprotein system, up to today's complex evolutionary character, only the half-way adequate complexity of the scientific approach might provide sufficient simulation potential to approximate the Grand Process.

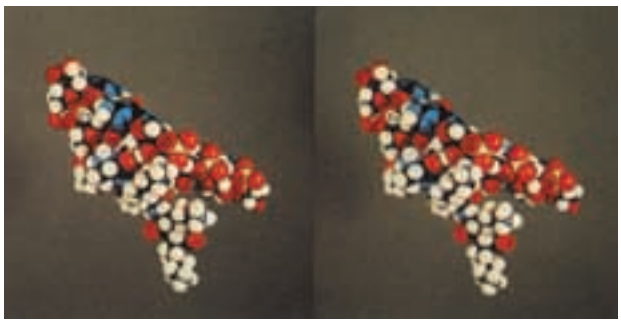

Fig. 5. Quacumque inter se possent congressa creare—Lucretius. (Translation: Whatever they would be able to do stems from their coming together.) [5a]

And finally, there is also the "evolution" of an individual scientific life's work,[12] which itself follows decisive stages of the Grand Process: the exploration of early chemical requirements, the development of prebiotic ligand systems, the fixation into the ordered structures of "inorganic" matrix patterns and, finally, the liberation of their inherent wealth of design and information into the order–disorder dialectics of today's nucleoprotein system. Using basic hexose structures, the actual successes of evolution, a never attempted, or perhaps

only forgotten, "evolutionary step" is now taking place—once again in the area of replicative nucleic acid systems.

But this is another whole story—and another great game.

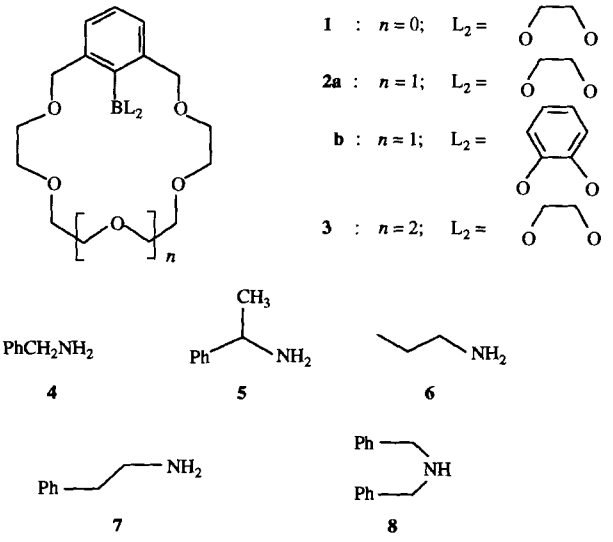
Molecular Recognition of Primary Amines by Three-Point Binding with Boron-Containing Host Molecules**

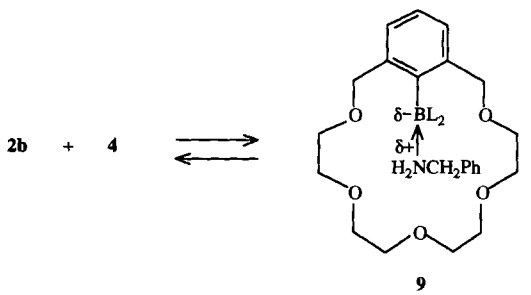
By *Manfred T. Reetz,* Christof M. Niemeyer, Marcus Hermes,* and *Richard Goddard*

Host molecules capable of showing pronounced molecular recognition of primary amines RNH_2 have not been synthesized to date.[1, 2] Crown ethers, for example, form only weak and unselective interactions with amines.[1] The corresponding ammonium ions $RNH_3^{\oplus}$ are bound more strongly by suitable crown ethers, but generally the degree of selectivity here is also quite low.[1] The latter is hardly surprising because the $RNH_3^{\oplus}$/crown ether complexes, which are held together by hydrogen bonds, are structurally so arranged that the groups R are too remote from the framework of the host molecule.[3, 4] The formation of adducts with Lewis acids,[5] for example with trialkyl boranes leading to reversible formation of adducts $R_3N \cdot BR'_3$,[6] is a quite different type of amine complexation. The dissociation constants of these equilibria depend, among other factors, on the number and size of the groups R in the amine.

We describe here a new concept in molecular recognition in which host molecules containing a Lewis acid metal center[2b, 4, 7] and at least two donor sites selectively bind primary amines via three-point binding (Scheme 1). If the amine RNH_2 forms a reversible dative bond with the metal center, it takes on the character of an ammonium ion. This should permit the formation of hydrogen bonds with the donor positions situated spatially nearby, thereby leading to synergistic effects.

To test this concept experimentally we synthesized the boron-containing crown ethers **1**–**3**[8] and allowed them to react with the amines **4**–**8**. Treatment of host **2b**, for example, with a stoichiometric amount of benzylamine **4** in dichloromethane leads to a spontaneous reaction with formation of the adduct **9**. Especially the ^{11}B and ^{13}CNMR spectra indicate the existence of a dative B–N bond and formation of hydrogen bonds between the amine hydrogen atoms and the crown ether.[9] Only the secondary amine **8** appears to be an exception, since the ^{13}CNMR signals of the crown ether carbon atoms do not indicate any participation in the sense of hydrogen bonds.





The crystal structure analysis[10] of the host/guest molecule **9** provides conclusive proof of the postulated three-point binding (Fig. 1, left). In particular, the space-filling representation[11] (Fig. 1, right) shows the strong embracement of the guest by the host. Figure 1 (right) suggests the possibility of a high degree of molecular recognition with respect to different amines RNH_2. In 1:1:1 competition experiments with the host **2b** and two different amines at room temperature, the ratio of the two possible host/guest compounds is not easy to determine by NMR spectroscopy because of rapid exchange processes. However, the ratio could be measured at −30 °C by integration of the appropriate ^1HNMR signals. Accordingly, the host **2b** shows a very

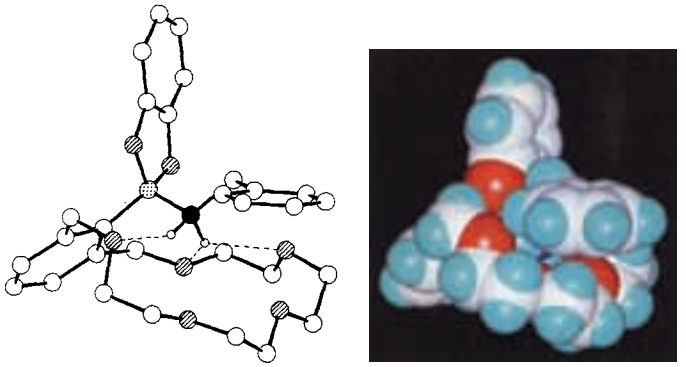

Fig. 1. Left: Crystal structure of **9**; boron, dotted; carbon: white; oxygen: hatched; nitrogen: black (only hydrogen atoms attached to nitrogen are shown). Right: space-filling portrayal of **9** [11]. Carbon: white; oxygen: red; nitrogen: dark blue; hydrogen: light blue; boron: concealed.

sensitive response to steric factors. For example, in the case of benzylamine/methylbenzylamine or benzylamine/dibenzylamine pairs (**4**/**5** or **4**/**8**), benzylamine is bound exclusively. Of particular significance is the selectivity in the competition between two α-unbranched primary amines, for example, **6** versus **4** and **7** versus **4**. (**4** vs. **5** = >98:<2; **4** vs. **8** = >98:<2; **6** vs. **4** = 90:10; **7** vs. **4** = 80:20.)

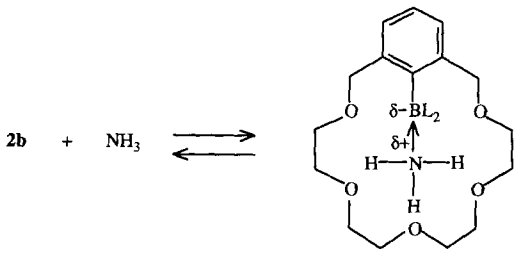
Synergism as the result of three-point binding could also be demonstrated with the hosts **1**, **2a**, and **3**. The binding constants K for the reaction of these hosts with benzylamine **4** were determined by the NMR titration method[12] at room temperature.[13] The data collected in Table 1 point to a distinct dependence of the values of K on the ring size of the crown ether (cf. positions 1–3). In fact, when the existence of

Table 1. Binding constants K for the equilibrium host + benzylamine $\overset{K}{\rightleftharpoons}$ host/benzylamine at 23 °C in CCl_4.

Position	Host	K
1	**1**	795
2	**2a**	30
3	**3**	6
4	phenylboronic acid glycol ester/ benzo[18]crown-6	1.3
5	phenylboronic acid glycol ester	0.3

a three-point interaction is assumed, Corey–Pauling–Koltun (CPK) models show that benzylamine fits distinctly better into the smaller crown ether. To what extent preorganization[1] also plays a role cannot be answered at present, because the conformation of the neutral host molecule is unknown. Control experiments with phenylboronic acid glycol ester as the host (Table 1; position 5) and phenylboronic acid glycol ester/benzo[18]crown-6 as the host system[14] (position 4) are also revealing: although the boron centers of the respective boronic acid esters are sterically less shielded than in the hosts **1**–**3**, the binding constants K are considerably *smaller*. This result also shows that the boron compounds **1**–**3** are not conventional Lewis acids.[5,6]

Finally, several experiments were conducted with anhydrous ammonia. For example, the host **2b** reacts with NH_3 to form the adduct **10**, in which strong four-point binding may be operative. The ammonia molecule is not displaced by the addition of a 100% excess of benzylamine. The binding constants for the reaction of ammonia with the hosts **2a** (K = 310) and **3** (K = 27) at room temperature demonstrate that NH_3 is actually bound more strongly than benzylamine (**2a**: K = 30; **3**: K = 5.8) or *n*-propylamine (**2a**: K = 132; **3**: K = 7.6). This observation is in contrast to that for conventional boron compounds such as $(CH_3)_3B$ which bind ammonia *less* strongly than they do primary amines.[6]



10

The selectivities described here are without precedence in molecular recognition. All experimental findings are in agreement with the synergism outlined in Scheme 1. It remains to be seen whether a high degree of enantioselective recognition is possible for racemic amines on the basis of chiral hosts containing boron or other σ-bound metal centers.

[9] The ^{11}B NMR signal (CD_2Cl_2, BF_3-etherate as external standard) of the host **2b** ($\delta = 30$) is shifted upfield ($\delta = 9$) by the addition of benzylamine. In the ^{13}C NMR spectrum of the adduct **9**, the signals of the benzylic C atoms, for example, are shifted down field, cf. [4].

[10] Crystallographic data for **9** · 0.5 toluene ($C_{29}H_{36}BNO_7 \cdot 0.5C_7H_8$, M_r 567.5): triclinic, space group $P\bar{1}$ [no. 2], $a = 10.648(1)$, $b = 11.760(1)$, $c = 13.755(2)$ Å, $\alpha = 67.66(1)$, $\beta = 73.60(1)$, $\gamma = 87.29(1)°$, $Z = 2$, $\rho_{calcd} = 1.24$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.80$ cm^{-1}. Measurements were made with an Enraf–Nonius CAD4 diffractometer ($Mo_{K\alpha}$ radiation, $= 0.71069$ A, graphite monochromator, $T = 297$ K); 9275 reflections, 8825 independent, 5907 with $I > 2\sigma(I)$ considered as observed. Solution by direct methods and refinement with SHELX-76, $R = 0.074$, $R_w = 0.094$ ($w = 1/\sigma^2(F)$); all non-hydrogen atoms isotropic; hydrogen atoms attached to N and O atoms localized and refined (isotropic), the others calculated and fixed. Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft for wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-56138, the names of the authors, and the full journal citation.

[11] For the generation of the space-filling presentation given in Figure 1, the crystallographic data were employed on a Silicon Graphics computer.

[12] The equilibrium constants were obtained mathematically by a nonlinear two parameter fit of chemical shift (δ) and the logarithm of the binding constants ($\lg K$) according to the method of least squares. We thank Dr. H.-J. Buschmann, Textilforschungsanstalt Krefeld, for providing a computer program to evaluate the titration results.

[13] In a typical titration experiment 500 µL of a 0.15 M solution of the host in CCl_4 (with 5 vol.% C_6D_6) was prepared, and various equivalents of benzylamine stock solution (in the same solvent mixture) added in portions. Eight measurements were made in the range guest:host = 0.2–6. The duration of the experiments did not exceed 2 h, because in some cases slow deborylation of the host molecule was observed with a large excess of amine after ca. 6 h. The values of K given arise from the shifts of the ^{1}H NMR signals of the glycol units attached to boron. Inaccuracies arise in particular in the determination of the concentration of the host. An uncertainty of ±5% leads to a maximum derivation of ±10% in $\lg K$.

Effect of Torsional Strain and Electrostatic Interactions on the Stereochemistry of Nucleophilic Additions to Cyclohexanone and Related Systems**

By *Yun-Dong Wu, Kendall N. Houk,** and *Michael N. Paddon-Row**

Recently, Frenking, Köhler, and Reetz[1] offered a frontier molecular orbital rationalization of the well-known preference for small nucleophiles to attack cyclohexanones from the axial direction.[2] We show here that the torsional effects identified by Felkin et al.[3] provide an explanation not only of the stereoselectivity of nucleophilic addition to cyclohexanone, but to other cyclic ketones as well. The LUMO extensions identified by Frenking et al. are a simple consequence of the geometry of the transition structure, and are maximized in the direction *trans* to the bond best eclipsed with the C–O π orbitals. In addition, we show that electrostatic interactions can also have a profound effect on stereoselectivity when polar substituents are present.[4, 5]

[**] This work was supported by the U.S. National Science Foundation and the Australian Research Council. We thank the Pittsburgh Supercomputer Center for a grant of computing time.

Kobayashi et al. observed that nucleophilic additions to 1,3-dioxan-5-one (**1**) occur more by axial attack than those to cyclohexanone, while nucleophilic additions to 1,3-dithian-5-one (**7**) proceed predominantly by equatorial attack.[6, 7] These results were rationalized by Felkin's torsional effects based on structural features of these ketones,[8] an interpretation which was supported by force-field modeling of the transition state.[4b, c]

We have now calculated the axial and equatorial transition structures for the reactions of lithium hydride with **1** and **7**. The structures were fully optimized with the 3-21G or the 3-21G* (d orbitals on sulfur) basis set,[9] and the energies were further evaluated with MP2/6-31G*(sp)[10] calculations (Table 1).

Table 1. Absolute [Hartree] and relative energies [kcal mol^{-1}] of the transition structures of the reactions of 1,3-dioxan-5-one (**1**), 1,3-dithian-5-one (**7**), and cyclohexanone with lithium hydride.

	6-31G*//3-21G	315.90968	315.90700	1.7
	MP2/6-31G*//3.21G	316.88236	316.88028	1.3

[a] The 6-31G* basis set here is the 6-31G* with a set of diffuse s and p orbitals on the hydride ion. [b] Always based on the transition structure of the axial attack.

Figure 1 shows the optimized structure of **1**, and axial and equatorial transition structures (**3** and **5**, respectively) for LiH addition. The six-membered ring of **1** is quite flat, as indicated by a flap angle of 156° and a ring O-C-C-C dihedral angle of 27°. The corresponding values for cyclohex-

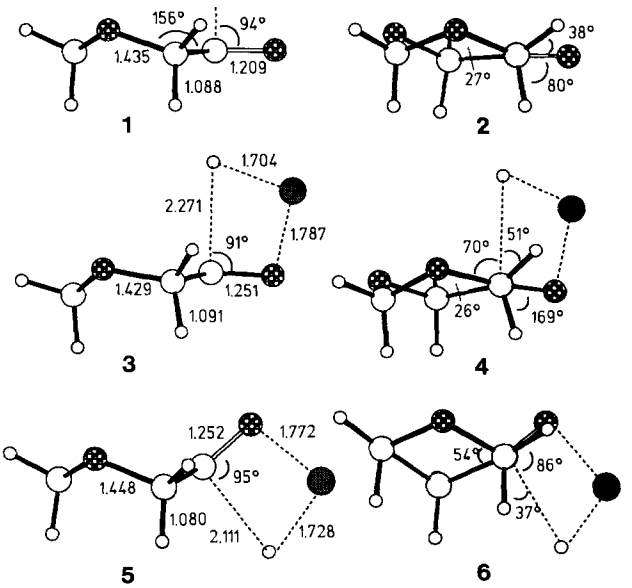

Fig. 1. Calculated structures of 1,3-dioxan-5-one (**1**), the axial (**3**) and equatorial (**5**) transition structures of the addition of lithium hydride to **1**, and Newman projections of the same structures (**2**, **4**, and **6**, respectively) along the C4–C5 bonds. Important structural parameters are also shown.

anone are 130° and 54°, respectively.[4a] This flattening is caused by the short ring O–C bonds. The axial transition structure **3** achieves a staggered conformation about the C4–C5 bond without ring distortion. However, a partially eclipsed arrangement of the substituents exists in the equatorial transition structure **5** despite major ring distortions, as indicated by a 27° increase in the ring O-C-C-C dihedral angle.

The structures of **7** and the axial (**9**) and equatorial (**11**) transition structures for LiH addition are given in Figure 2. The long S–C bonds and small C-S-C angles cause the six-membered ring to be significantly puckered (flap angle 120°, S-C-C-C dihedral angle 68°. As a result, the O=C–C–H_{eq}

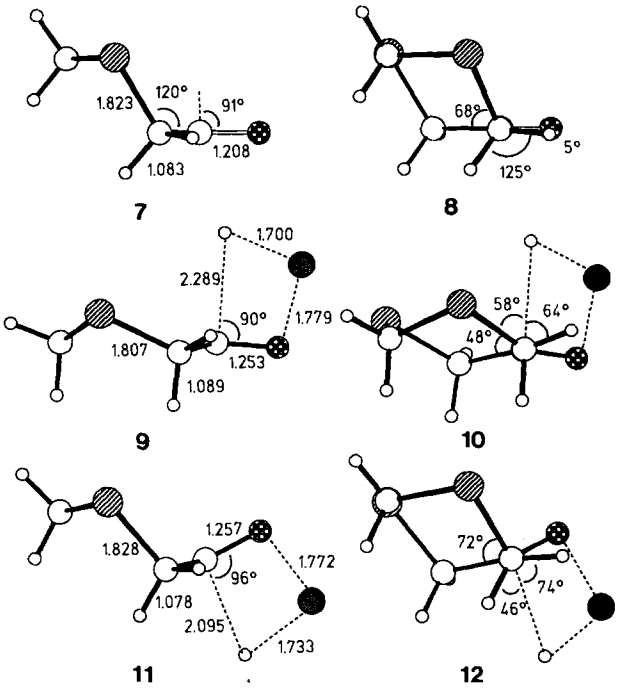

Fig. 2. Calculated structures of 1,3-dithian-5-one (**7**), the axial (**9**) and equatorial (**11**) transition structures of the addition of lithium hydride to (**7**), and Newman projections of the same structures (**8**, **10**, and **12**, respectively) along the C4–C5 bonds. Important structural parameters are also shown.

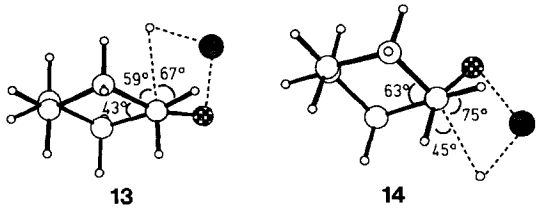
moiety is distorted on the opposite face (compare to **1**). This calculated structure is very similar to the crystal structure of 2-phenyl-1,3-dithian-5-one determined by X-ray structural analysis.[8] While there is no ring distortion in the equatorial transition structure, significant ring flattening occurs in the axial transition structure, as indicated by a 20° decrease in the S-C-C-C dihedral angle.

Removal of LiH from the transition structures and recalculation of energies of the isolated distorted ketones provides a qualitative estimate of the ring strain contribution to stereoselectivity (see below).[1, 4] The ketone moiety of **3** is 2.5 kcal mol^{-1} more stable than that of **5**, reflecting the lack of distortion in **3**. The ketone moiety in the axial transition structure **9** is less stable than that in equatorial transition structure **11** by 1.2 kcal mol^{-1}, reflecting the ring distortion in **9**.[11]

Why are the axial transition structures calculated (see Table 1) for the reactions of **1** and **7** with LiH to be disfavored by 1.5 and 8 kcal mol^{-1}, respectively? There is significant electrostatic repulsion between the negative hydride ion and the lone pairs of the respective oxygen and sulfur atoms in the axial transition structures: the hydridic hydrogen atom is quite negatively charged (H, −0.5 e, 6-31G*(sp)); the H^-–O distances in **3** (and the H^-–S distances in **9**) are only about 3.3 Å; a simple Coulomb's Law calculation using point charge interactions (− 0.6 e on O) gives repulsion of about 3 kcal mol^{-1} for each H^-–O interaction. Therefore, significant electrostatic repulsions are expected in the axial transition structures. These electrostatic interactions are less significant with lithium aluminum hydride in solution, and the axial addition to **1** becomes favorable. In the case of **7**, both torsional and electrostatic effects work against the axial addition, resulting in a large preference for the equatorial addition. For the reaction of 2-phenyl-1,3-dithian-5-one,[6] the two observed products are both likely to be derived from an equatorial attack of the nucleophile, the major transition state having the phenyl substituent equatorial and the less populated transition state having it axial. The degree of stereoselectivity is roughly equal to the relative stability of the two conformations of the reactant.[12]

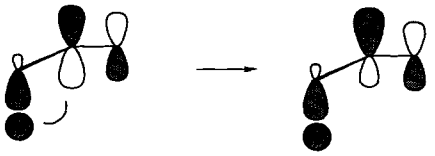
Electrostatic effects of the type involved here have also been shown for other cases. We proposed that electrostatic effects cause stereochemical variations in nucleophilic additions to cyclohexanone and acetaldehyde derivatives with polar substituents.[4a, 5c] For example, a fluorine substituent at C3 of cyclohexanone causes increased axial attack of the nucleophile due to increased positive charge at the C3 position, which gives stabilizing coulombic interactions with the nucleophile approaching from the axial direction.[13]

It is necessary to reiterate our version of the Felkin torsional strain theory[3] for the preference of axial addition to cyclohexanone by small nucleophiles,[4] as Frenking et al. misinterpreted our argument.[1] For equatorial addition, in order to form an ideal staggered transition structure, ring strain would have to be introduced; to reduce or avoid this ring strain, the equatorial transition structure is forced to adapt a partially eclipsed conformation. The overall result is a balance between the two types of strain. For the cyclohexanone–LiH reaction, calculations give an ideal staggered axial transition structure (**13**) but a partially eclipsed equatorial transition structure (**14**) in which the ring strain is largely avoided,[14] but only at the expense of eclipsing strain involving the attacking nucleophile.[15]



Torsional effects and orbital interactions are not mutually exclusive. Earlier, we described the secondary orbital interactions which cause the attack of nucleophiles, radicals, and electrophiles on unsaturated centers to occur in a staggered fashion with respect to allylic bonds.[16] The LUMO extensions in cyclohexanone identified by Frenking et al. are a direct consequence of geometrical distortion. As shown in Scheme 1, the LUMO interacts with the most eclipsed allylic bond in an antibonding fashion. This leads to an extension of the LUMO in the direction *trans* to the allylic bond. In cyclohexanone, the ring distortion causes the C–H bond to

be more eclipsed with the π orbitals (≮ O-C-C-H, 115°) than the C–C bond is (≮ O-C-C-C, 127°), resulting in orbital distortion in the axial direction.[1, 17] On the other hand, ring distortions in dithianone and in benzocycloheptenone are opposite to that in cyclohexanone.[18] This geometrical distortion causes equatorial orbital extension,[19] and equatorial addition of hydride ion is favored.[18]



Scheme 1. The antibonding interaction indicated (left) leads to the extension of the LUMO in the direction *trans* to the allylic bond (right).

What role, if any, do orbital interactions involving the antiperiplanar C–O, C–S, C–C, and C–H bonds have?[20] The β C–O or β C–S bonds in the axial transition structures are about 0.02 Å shorter than the corresponding bonds in the equatorial transition structures. However, the C–C bonds in the axial transition structure of the cyclohexanone–LiH reaction are also shorter by about 0.02 Å. These bond length variations reflect the geometrical differences in the axial and equatorial transition structures, and do not support the argument of significant differences in hyperconjugative interactions by antiperiplanar C–O, C–S, C–C, and C–H bonds.

In summary, we demonstrate that torsional strains, and electrostatic effects in the presence of polar substituents, are most responsible for the stereoselectivity of nucleophilic additions to cyclohexanone and related systems. Orbital interactions due to the inherent difference in C–C, C–H, C–O, and C–S bonds are less important. We also point out that LUMO extension and small pyramidalizations of sp^2 centers[4a] are a direct consequence of geometrical distortions.

[10] A set of diffuse s and p orbitals was added to the hydride ion.
[11] The 6-31G* and MP2/6-31G* energies of the ketone moieties are (in Hartree): 379.51067 and 380.54766 in **3**; 379.50198 and 380.54374 in **5**; 1024.82766 and 1025.76654 in **9**; 1024.82760 and 1025.76839 in **11**.
[12] R. J. Abraham, W. A. Thomas, *J. Chem. Soc.* **1965**, 335.
[13] A thorough discussion can be found in [4a]. Frenking et al. [1] suggested a change in 2s(C) coefficient in the C-O π* orbital by a 3-F substituent at C3 to be responsible for the increased axial addition, although the change is very small.
[14] The energy difference between the cyclohexanone moiety in the two cyclohexanone–LiH transition structures is basis set dependent. It is 0.0, 0.8, −0.3, and 0.2 kcal mol^{-1} with the 3-21G, 6-31G*//3-21G, MP2/6-31G*//3-21G, and MP3/6-31G*//3-21G calculations. Similar basis set dependence is also found for dioxanone and dithianone systems and for relative energies of transition structures.
[15] This strain can be roughly estimated by the calculations on the transition structure of acetone–LiH reaction. A 15° rotation of the two methyl groups away from the transition structure position in either direction causes about 1 kcal mol^{-1} increase in energy.

The Reaction of $[Cp_2^+Nb_2(B_2H_6)_2]$ ($Cp^+ = \eta$-$EtMe_4C_5$) with Sulfur: Stabilization of the Tetrathioborato Ligand in Novel Sulfido Niobium Clusters

By *Henri Brunner, Günther Gehart, Bernd Nuber, Joachim Wachter,** and *Manfred L. Ziegler*

The structural chemistry of binary boron–sulfur compounds is characterized by the formation of rings either in isolation or linked to chains, in which boron usually has the coordination number three.[1] In contrast the coordination number four is not often found. Tetrathioborates with corner-linked BS_4 tetrahedra occur in the layer structures of heavy metal thioborates.[1] However, monomeric $M[H_nB(SH)_{4-n}]$ ($n = 0-3$) compounds could only be proven by spectroscopy in solution in the form of their alkali metal salts because they are easily polymerized.[2] Hitherto tetrathioborates have not been observed as ligands in organometallic chemistry. Herein we report the first tridentate, triply bridging tetrathioborato ligand.

The surprisingly stable diboranato complex **1** was chosen as the starting material. The synthesis of **1** had been mentioned previously ten years ago, however, without specific details being given.[3] We have have recently studied **1** systematically with regard to its method of formation, structure, and spectroscopic properties.[4] The two (unstable in the free state) B_2H_6 dianions, which are arranged as bridges perpendicular to the (formal) Nb–Nb double bond are characteristic of **1**. The reaction of **1** with sulfur in decane at 170 °C affords the neutral, diamagnetic complex **2** in yields of up to 26%. The boiling temperature of *o*-xylene (144 °C)

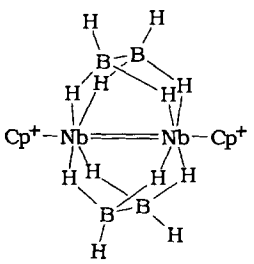
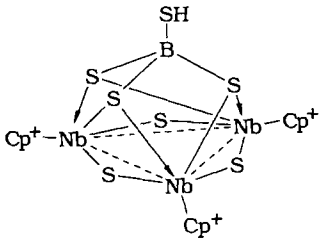
is the lowest temperature at which **2** is still formed. However, under these conditions the preparation of complex **3** (20–45% yield) predominates, which differs from **2** in that it contains an additional S atom. Elemental analyses and FD mass spectra strongly indicate the stoichiometry $[Cp_3^+Nb_3S_nBH]$ ($n = 7$ and 8, respectively) of **2** and **3**. The IR spectra show weak absorptions at 2560 (**2**) and 2550 cm^{-1} (**3**); ν_{SH} bands of diorganoborosulfanes occur in a similar region of the spectrum.[5] The ^1H NMR spectra provide interesting information about the different symmetry characteristics of **2** and **3**: whereas all Cp^+ ligands are equivalent in **2**, they are split in a ratio of 2:1 in **3**. The ^{11}B NMR spectrum of **2** shows a sharp signal at $\delta = 1.9$ ($h_{1/2} = 20$ Hz)[6] and thus lies in a similar region ($\delta = -0.6$) as that observed for $[B(SH)_4]^-$.[2]



1



2

A crystal structure analysis has so far only been carried out for **2**[7] (Fig. 1), and this shows that the molecule consists of an equilateral Nb_3 triangle whose edges are spanned by the corners of a BS_4 tetrahedron. The sulfido ligands bridge

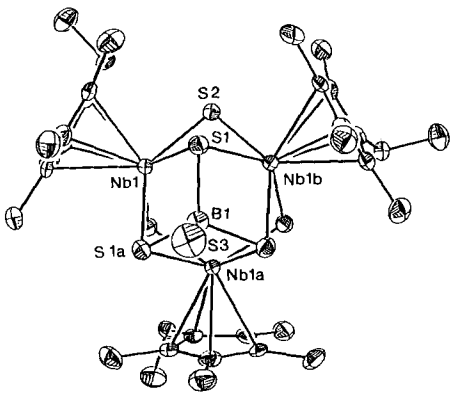


Fig. 1. Structure of **2** (ORTEP). Selected distances [Å] and angles [°]: Nb1-S1 2.554(4), Nb1-S2 2.396(4), Nb1-Nb1a 3.157(3), S1-B1 1.929(10), S3-B1 1.884(22); S1-Nb1-S1a 72.5(1), S1-Nb1-S2 80.7(1), Nb1-S1-Nb1-b 76.5(1), Nb1-S2-Nb1b 82.7(1), Nb1-S1-B1 90.8(5), S1-B1-S1a 102.8(7), S1-B1-S3 115.5(6).

the Nb–Nb edges on the "underside" of the molecule. The threefold metal-substituted ligand which is derived from $B(SH)_4^-$ is bound to the Nb_3 unit with normal Nb–S distances (average 2.554(4) Å). In contrast the Nb–S distances to the S^{2-} bridges are approximately 0.16 Å shorter. They are also shorter than the values found so far in cyclopentadienylsulfidoniobium complexes.[8] Whereas the average B–S distances are similar to those found in BS_4 tetrahedra, the angles at B1 differ from ideal tetrahedral angles by $\pm 6°$. The localization of the proton on S3 is not possible because of a disorder about the threefold axis through B1–S3. The organization of the molecules in the columnlike unit cell (c is almost 100 Å!) to give layers is peculiar. These layers are built up from BS_4 tetrahedra which lie opposite one another in such a way that the B1–S3 vectors are arranged parallel to the threefold axis and all the S3 atoms are in the same plane. Disordered solvent molecules (Et_2O) are situated approximately in this same layer (Fig. 2). The shortest intermolecular contacts between non-hydrogen atoms of the single molecules are not less than 4.0 Å.

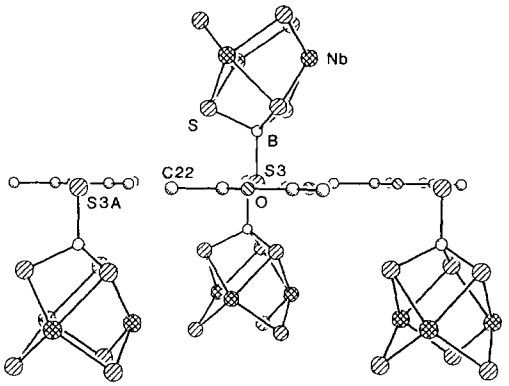

Fig. 2. Section of the unit cell of **2** with the view perpendicular to the trigonal axis. Symmetry related molecules lying opposite each other are shown without the Cp^+ ligands; the distorted ether molecules are shown in the side view. Selected distances: S3···S3A 6.98, S···C22 4.02, S3···C22 4.67 Å.

The tridentate tetrathioborato ligand of **2** acts as a 12e donor, and when the 30e of the cyclopentadienyl and sulfido ligands as well as the 2e of the Nb_3^{13+} core are added, a total of 44 valence electrons is obtained for **2**. Thus, **2** is isoelectronic with $[Cp_3^*Nb_3(\mu\text{-}Cl)_3(\mu\text{-}O)_3]^+$ ($Cp^* = C_5Me_5$),[9] which above all has an effect on the Nb–Nb bonds: from the MO calculations carried out for $[Cp_3^*Re_3(\mu\text{-}O)_6]^{2+}$[10] it was deduced that the cluster orbital with the lowest energy ($1a_1'$ symmetry) is of a strongly bonding character and should be delocalized over the Nb three-membered ring. Its occupation with the two electrons of the Nb_3^{13+} core leads to the formation of equal M–M bonds of the formal bond order 2/3. This is indicated by the Nb–Nb distances of 3.157(3) Å which are between bonding and nonbonding interactions.[9, 12]

The structure of **3** remains unclear. If the framework of **2** is considered as a basis for that of **3**, the eighth S atom must be arranged in such a way that only two Cp^+ ligands are equivalent. μ_3-S or S_2 ligands in all their varieties of coordination could then be conceivable, such as in multinuclear cyclopentadienylsulfidoniobium complexes.[8] Attempts to interconvert **2** and **3** by the directed removal and addition of sulfur, respectively, have so far been unsuccessful.

Experimental Procedure

The violet solution obtained from **1** (391 mg, 0.72 mmol) and S_8 (372 mg, 1.45 mmol) in decane (50 mL) was refluxed for 15 h, whereby the color of the solution had already changed to red-brown after 1 h. The decane was then distilled off and the residue was taken up in toluene and the suspension was filtered over SiO_2. The red filtrate was subsequently chromatographed on SiO_2 (column 30 × 3 cm). A series of small quantities of firstly an unknown compound, then **3** (15%), and **2** (18–26%) were eluted with a toluene/pentane mixture (3:1). Recrystallization was achieved from Et_2O (**2**) or Et_2O/pentane 10:1 (**3**) and this afforded analytically pure substances (correct C, H, S analyses). **2**: ^1H NMR (250 MHz, $CDCl_3$): $\delta = 1.13$ (t, $^3J(H,H) = 7.6$ Hz, 9H; CH_3), 2.11 (s, 36H; CH_3), 2.48 (q, $^3J(H,H) = 7.6$ Hz, 6H; CH_2); FD-MS (toluene) m/z 962.6 ($M^{\oplus}$); **3**: ^1H NMR (250 MHz, $CDCl_3$): $\delta = 1.13$ (t, $^3J(H,H) = 7.6$ Hz, 3H; CH_3), 1.14 (t, $^3J(H,H) = 7.6$ Hz, 6H; CH_2), 2.09 (s, 12H; CH_3), 2.10 (s, 12H; CH_3), 2.20 (s, 6H; CH_3), 2.18 (s, 6H; CH_3), 2.44 (q,

^3J(H,H) = 7.6 Hz, 4H; CH_2), 2.58 (q, ^3J(H,H) = 7.6 Hz, 2H; CH_2); FD-MS (toluene): m/z 994.1 ($M^{\oplus}$).

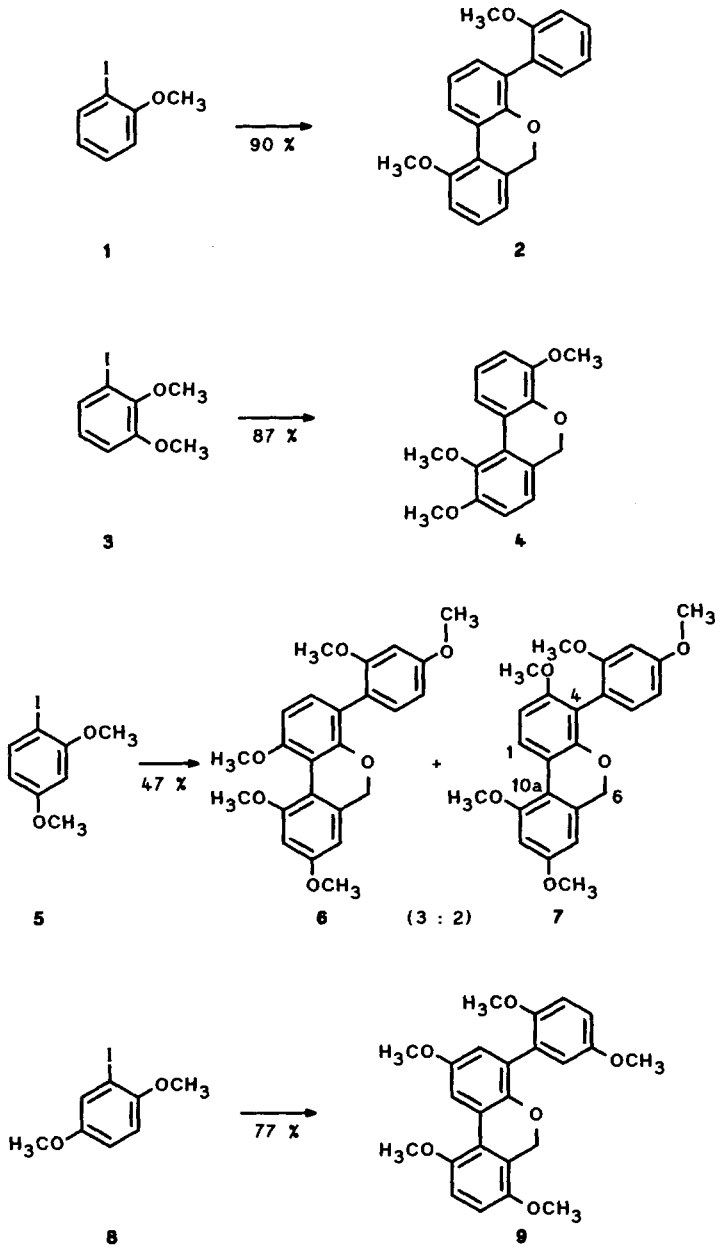
Palladium-Catalyzed C-H Activation of Methoxy Groups: A Facile Synthesis of Substituted 6*H*-Dibenzo[*b*,*d*]pyrans**

By *Gerald Dyker**

Transition metal catalyzed reactions have proved themselves particularly efficient in the synthesis of annelated ring systems.[1] Palladium-catalyzed coupling reactions of aryl halides with alkenes,[2] alkynes,[3] and, intramolecularly, with arenes,[4] have been well characterized and have found numerous applications in organic synthesis. In several cases, domino processes have been observed, in which polycyclic products are formed from several molecules of simple synthetic building blocks.[5] We now report a new domino coupling reaction, where for the first time a palladium-catalyzed CH-activation at a methoxy group occurs.

ortho-Iodoanisole **1** is condensed with palladium catalysis to give a 90% yield of the substituted 6*H*-dibenzo[*b*,*d*]pyran **2**, a colorless, crystalline solid (m.p. 135°C).[6] In order to investigate the generality of this annelation, and to clarify the regiochemical course of the reaction, a series of readily available 1-iodo-2,*n*-dimethoxybenzenes ($n = 3-6$)[7] were transformed under the reaction conditions described above (Scheme 1). In the case of 1-iodo-2,3-dimethoxybenzene (**3**),



Scheme 1. Synthesis of dibenzopyrans **2**, **4**, **6**, **7**, and **9**. Reaction conditions: 4 mol% $Pd(OAc)_2$, K_2CO_3, nBu_4NBr, dimethylformamide, N_2, 3 d, 100 °C.

the condensation product **4** was obtained (87% yield, m.p. 119°C), which originates from only two molecules of the starting compound. Clearly, a crucial position for the third condensation step is blocked.

1-Iodo-2,4-dimethoxybenzene (**5**), on the other hand, affords a 47% yield of the regioisomeric annelation products **6** and **7** in a 3:2 ratio (71% yield with respect to unrecovered

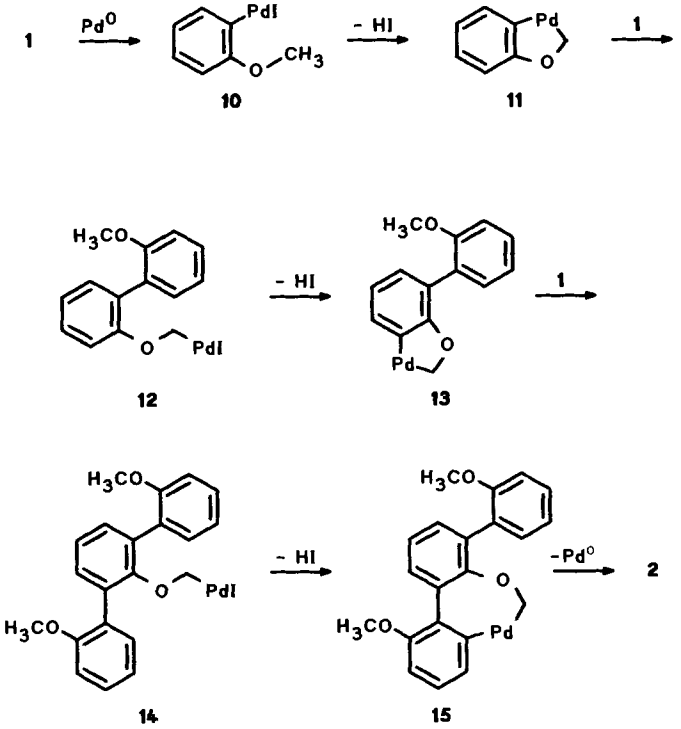
[**] Transition metal catalyzed annelation reactions, Part 2. This work was support by the Fonds der Chemischen Industrie with a Liebig Scholarship, and by Bayer AG, Monheim, with chemicals and glassware. Part 1: G. Dyker, *Tetrahedron Lett.* **1991**, *32*, 7241–7242.

starting material). A pure sample of **7** was obtained after several recrystallizations from ether/pentane to constant melting point (m.p. 162–163°C). Because of the C4–C1′ chirality axis, the methylene protons of the CH_2-6 group in the pyran ring of **7** are diastereotopic, and give rise to an AB signal in the ^1H NMR spectrum (geminal coupling constant 12.9 Hz). The ^1H NMR spectrum of **6** reveals only a singlet corresponding to two protons for this methylene group. Since the methoxy group in position 3 is absent in **6**, the C4–C1′ axis is not a chirality element in this molecule, due to the reduced steric hindrance on the NMR timescale. The methylenoxy bridge on the C10a–C10b axis ought to lead to a reduction in the atropic isomerization threshold,[4, 8] relative to the analogous di-*ortho*-substituted, but unbridged derivative.

Condensation of 1-iodo-2,5-dimethoxybenzene (**8**) leads regioselectively to **9** as the sole product isomer, in 77% yield (m.p. 134–135°C). Reaction of 1-iodo-2,6-dimethoxybenzene returns only the starting material, in 95% yield. A coupling product could not be detected. It is possible that stabilized palladium complexes are formed which lead to interruption of the catalytic cycle, and this is currently being investigated.[9]

By using the condensation reaction of **1** as an example, a possible mechanism has been developed which is in accord with the experimental findings (Scheme 2). The decisive reaction step is suggested to be the cyclometallation of the aryl Pd^{II} iodide **10** to the five-membered ring compound **11**, involving an intramolecular C-H activation[10]. Pd^{IV} complexes as additional reactive intermediates are an interesting explanation both for this reaction step and for the formation of **12** from **11**. Recently, evidence that the oxidative addition of Pd^{II} compounds to C–H and C–halogen compounds proceeds via Pd^{IV} intermediates with subsequent reductive elimination to the Pd^{II} complexes (i.e. Pd^{II}–Pd^{IV}–Pd^{II} cycles) has been documented in detail.[11]



Scheme 2. Possible reaction mechanism for the domino coupling reaction of **1** to afford **2**.

The cyclometallation of **12** with dehydrohalogenation ought, by contrast, to yield a five-membered ring (**13**). Repeated addition of **1** to give the symmetric intermediate **14**, cyclometallation to the heptacyclic compound **15**, and subsequent reductive elimination lead to the condensation product **2**.

The C-H activation of methoxy groups described here represents a new reaction principle for palladium-catalyzed processes. The simple and efficient synthesis of substituted 6*H*-dibenzo[*b*,*d*]pyrans is the first application. The intramolecular palladium-catalyzed C-H activation of other neighboring groups is one target of our continuing studies, as is the development of cross couplings based on this reaction principle.

Experimental Procedure

A mixture of 2 mmol of **1**, **3**, **5**, or **8**, 0.08 mmol of $Pd(OAc)_2$, 8 mmol of K_2CO_3, and 2 mmol of nBu_4NBr in 10 mL of dimethylformamide was stirred for 3 d at 100 °C under nitrogen in a closed flask. After addition of 50 mL of water, the mixture was extracted three times with ether, the organic phase filtered through silica gel, and the solvent removed by evaporation. The products were isolated by flash chromatography (silica gel, petroleum ether/ether, 4/1), and crystallized from ether/pentane.

Selected spectroscopic and analytical data:[6]

2: ^1H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 3.78 (s, 3H; 2′-OCH_3), 3.92 (s, 3H; 10-OCH_3), 4.93 (s, 2H; H-6), 6.75 ("d", "J" = 7.4 Hz, 1H; H-7), 6.93 ("d", "J" = 8.3 Hz, 1H; H-9), 6.98 ("d", "J" = 8.5 Hz, 1H; H-3′), 7.01 (m, 1H; H-5′), 7.10 ("t", "J" = 7.7 Hz, 1H; H-2), 7.20 (dd, ^3J = 7.5, ^4J = 1.7 Hz, 1H; H-3), 7.22 ("t", "J" = 7.9 Hz, 1H; H-8), 7.26 (m, 1H; H-6′), 7.33 (m, 1H; H-4′), 8.39 (dd, ^3J = 7.9, ^4J = 1.7 Hz, 1H; H-1); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 55.57 (q; OCH_3), 55.62 (q; OCH_3), 68.85 (t; C-6), 110.89 (d; C-3′), 111.34 (d; C-9), 117.17 (d; C-7), 119.24 (s; C-10a), 120.41 (d; C-5′), 121.08 (d; C-2), 122.32 (s; C-10b), 127.42 (s; C-4), 127.68 (s; C-1′), 128.05 (d; C-1), 128.32 (d; C-8), 128.67 (d; C-4′), 130.52 (d; C-3), 131.40 (d; C-6′), 135.03 (s; C-6a), 152.77 (s; C-4a), 156.61 (s; C-10), 157.00 (s; C-2′).

4: ^1H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 3.73 (s, 3H; OCH_3), 3.89 (s, 3H; OCH_3), 3.90 (s, 3H; OCH_3), 5.00 (s, 2H; H-6), 6.85 (d, ^3J = 8.2 Hz, 1H; H-8), 6.89 (dd, ^3J = 8.0, ^4J = 1.4 Hz, 1H; H-3); 6.90 (d, ^3J = 8.2 Hz, 1H; H-7), 7.01 (t, ^3J = 8.0 Hz, 1H; H-2), 8.08 (dd, ^3J = 8.0, ^4J = 1.4 Hz, 1H; H-1).

6: ^1H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 3.76 (s, 3H), 3.82 (s, 3H), 3.83 (s, 3H), 3.89 (s, 3H), 3.94 (s, 3H), 4.76 (s, 2H; H-6), 6.38 (d, ^4J = 2.4 Hz, 1H), 6.52–6.56 (m, 3H), 6.74 (d, ^3J = 8.6 Hz, 1H; H-2), 7.15 (d, ^3J = 8.6 Hz, 1H; H-3), 7.16 (d, ^3J = 8.2 Hz, 1H; H-6′).

7: ^1H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 3.76 (s, 3H), 3.77 (s, 3H), 3.82 (s, 3H), 3.84 (s, 3H), 3.91 (s, 3H), 4.85 (d, ^2J = 12.9 Hz, 1H; H_A-6), 4.88 (d, ^2J = 12.9 Hz, 1H; H_B-6), 6.28 (d, ^4J = 2.4 Hz, 1H), 6.50 (d, ^4J = 2.4 Hz, 1H), 6.55–6.60 (m, 2H; H-3′, H-5′), 6.70 (d, ^3J = 8.9 Hz, 1H; H-2), 7.12 (d, ^3J = 8.1 Hz, 1H; H-6′); 8.26 (d, ^3J = 8.9 Hz, 1H; H-1).

9: ^1H NMR (400.1 MHz, $CDCl_3$, TMS): δ = 3.75 (s, 3H), 3.76 (s, 3H), 3.77 (s, 3H), 3.83 (s, 3H), 3.87 (s, 3H), 5.02 (s, 2H; H-6), 6.78 (d, ^3J = 9.0 Hz, 1H), 6.79 (d, ^4J = 3.1 Hz, 1H; H-3), 6.82–6.94 (m, 4H), 8.02 (d, ^4J = 3.1 Hz, 1H; H-1).

Carbene Osmium Complexes by Double Metalation of Alkoxylalkyl- and Aminoalkylphosphanes**

By *Helmut Werner,* Birgit Weber, Oliver Nürnberg,* and *Justin Wolf*

Dedicated to Professor Ekkehard Winterfeldt on the occasion of this 60th birthday

Since the first synthesis of a carbene metal complex by Fischer and Maasböl,[1] a wide variety of substrates have been employed to generate metal-bound carbenes.[2] In the extensive literature, however, there is no single report to date which illustrates that a compound of the general composition $[L_nM{=}CHX]$ (X = OR, NR_2, etc.) is formed from a suitable precursor CH_3X and a transition metal compound. We report here[3] that such a conversion succeeds with high efficiency with osmium as the metal center if the CH_3O or CH_3N group to be metalated is part of an alkoxylalkyl- or aminoalkylphosphane molecule.

Recently, we described that $[RuCl_2(PPh_3)_3]$ reacts with alkoxyalkylphosphane **1** by ligand exchange to give the octahedral complex $[RuCl_2(\eta^2\text{-}\mathbf{1})_2]$. If the osmium complex **2**[5] is treated with **1** under similar conditions (benzene, 80 °C, 45 h), a small amount of a yellow solid is isolated with a composition corresponding to **3a** [Eq. (a)]. Because of the

$$[OsCl_2(PPh_3)_3] \;\xrightarrow[C_6H_6,\ \Delta,\ 45\ h]{\mathbf{1}}\; [OsCl_2(=CHOCH_2CH_2P\mathit{i}Pr_2)(\eta^2\text{-}\mathbf{1})] \quad \text{(a)}$$

2 **3a**

$\mathbf{1} = \mathit{i}Pr_2PCH_2CH_2OMe$

unsatisfactory yield of **3a** (16%), we attempted to prepare this complex directly from $OsCl_3 \cdot 3H_2O$ and **1**. This reaction provided almost quantitatively (80% yield with regard to $OsCl_3 \cdot 3H_2O$) a lemon-yellow crystalline product **3b** with the same analytical composition as **3a** [Eq. (b)]. The ^{1}H NMR

$$OsCl_3{\cdot}3H_2O \;\xrightarrow[\mathit{i}PrOH,\ \Delta,\ 2\ d]{\mathbf{1}}\; [OsCl_2(=CHOCH_2CH_2P\mathit{i}Pr_2)(\eta^2\text{-}\mathbf{1})] \quad \text{(b)}$$

3b

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347), the Fonds der Chemischen Industrie, and Degussa AG.

spectra of both compounds, **3a** and **3b**, reveal a signal in the low-field region which is split due to P–H coupling into a doublet at $\delta = 15.50$ and 15.46, respectively, thus indicating the presence of a =CHOR unit.[2c,6] In the ^{13}C NMR spectrum of **3b** a signal at $\delta = 247.33$ characteristic of a carbene moiety appears in a position very similar to that of cyclic oxycarbene complexes with the structural unit $Os{=}\overline{CCH_2CH_2CH(R)O}$.[7] The ^{31}P NMR spectra of both **3a** and **3b** show two doublets with a small P–P coupling which confirms the *cis* position of the two phosphorus atoms. These and other selected spectroscopic data for the new compounds are summarized in Table 1.

Table 1. Selected spectroscopic data (without ^{1}H and ^{13}C NMR data for the CH_2 and *i*Pr groups). ^{1}H NMR spectra at 400 MHz (at 60 MHz for **3a** only), ^{13}C NMR spectra at 100.6 MHz (at 22.5 MHz for **10** only), ^{31}P NMR spectra at 162.0 MHz for **3b** and **5**, at 36.2 MHz for **3a**, **8**, **9**, and **10**.

3a: ^{1}H NMR ($CDCl_3$): $\delta = 15.50$ (d, J(PH) = 4.0 Hz, Os=CH), 3.80 (s, OCH_3); ^{31}P NMR ($CDCl_3$): $\delta = 15.37$ and -19.00 (both d, J(PP) = 10.3 Hz)

3b: ^{1}H NMR (C_6D_6): $\delta = 15.46$ (d, J(PH) = 3.6 Hz, Os=CH), 3.79 (s, OCH_3); ^{13}C NMR ($CDCl_3$): $\delta = 247.33$ (t, J(PC) = 17.05 Hz, Os=C), 59.80 (s, OCH_3); ^{31}P NMR ($CDCl_3$): $\delta = 20.95$ (d, J(PP) = 10.1, $J(^{187}Os^{31}P) = 266$ Hz), -15.13 (d, J(PP) = 10.1, $J(^{187}Os^{31}P) = 228$ Hz)

5: ^{1}H NMR ($CDCl_3$): $\delta = 13.14$ (d, J(PH) = 4.2 Hz, Os=CH), 3.23, 2.80, and 2.40 (each s, NCH_3); ^{13}C NMR ($CDCl_3$): $\delta = 212.99$ (d, J(PC) = 7.6 Hz, Os=C), 50.59 and 49.69 (both s, NCH_3); ^{31}P NMR ($CDCl_3$): $\delta = 16.33$ (d, J(PP) = 7.3, $J(^{187}Os^{31}P) = 280$ Hz), -18.95 (d, J(PP) = 7.3, $J(^{187}Os^{31}P) = 274$ Hz)

8: ^{1}H NMR (C_6D_6): $\delta = 3.41$ (s, OCH_3); ^{13}C NMR (C_6D_6): $\delta = 185.25$ (s, CO_2Me), 55.03 (s, OCH_3); ^{31}P NMR (C_6D_6): $\delta = 2.75$ (s)

9: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1915 (OsCO), 1710 (CO_2Me, free), 1615 (CO_2Me, coord.); ^{1}H NMR ([D$_8$]toluene): $\delta = 3.53$ and 3.52 (both s, OCH_3); ^{31}P NMR ($CDCl_3$): $\delta = 24.80$ and 9.59 (both d, J(PP) = 290.2 Hz)

10: ^{1}H NMR ([D$_8$]toluene, 60 °C): $\delta = 7.38$ and 6.95 (both m, C_6H_5), 3.52 (s, OCH_3), 2.64 (t, J(PH) = 5.9 Hz, Os=C*H*Ph); ^{13}C NMR (C_6D_6): $\delta = 297.11$ (t, J(PC) = 22.0 Hz, Os=*C*=CHPh), 109.31 (t, J(PC) = 6.1 Hz, Os=C=*C*HPh), 53.25 (s, OCH_3); ^{31}P NMR ([D$_8$]toluene): $\delta = 2.56$ (s) at 40 °C; $\delta = 9.51$ and -2.93 (both d, J(PP) = 332 Hz) at -80 °C.

The stereochemistry of **3b** is established by the X-ray structure analysis.[8] It confirms (Fig. 1) that one of the alkoxyalkylphosphane ligands is converted by double metalation of the methoxy group into a carbene unit, which is

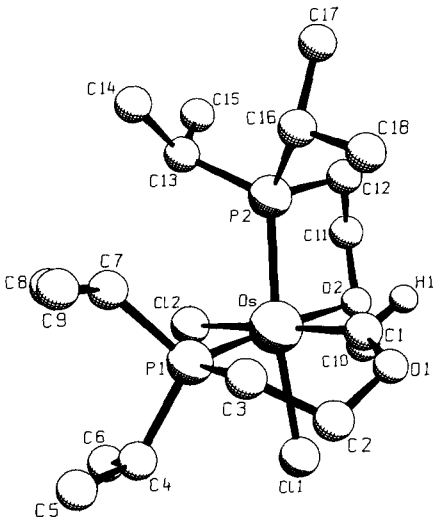

Fig. 1. Crystal structure of **3b**. Selected bond distances [Å] and angles [°]: Os-C1 1.83(1), Os-P1 2.256(3), Os-P2 2.336(3), Os-Cl1 2.466(4), Os-Cl2 2.495(3), Os-O2 2.297(8), C1-O1 1.34(1), C2-O1 1.42(2); P1-Os-O2 176.5(3), P2-Os-Cl1 167.3(1), C1-Os-Cl2 167.4(3), Os-C1-O1 138.8(9).

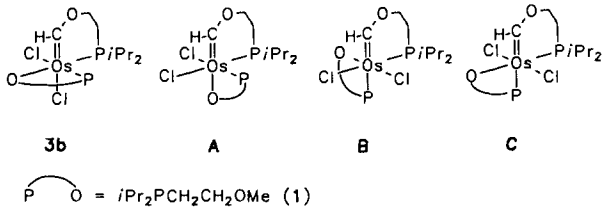
 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0808-1025 $ 3.50+.25/0

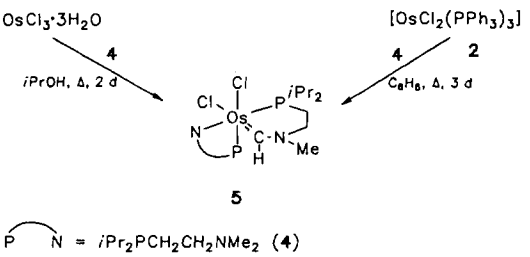
part of a six-membered chelate ring system. The intact alkoxyalkylphosphane ligand is coordinated to the metal center at P and O. The Os–C1 distance is significantly shorter than that in related carbene osmium complexes such as $[OsCl(=CH_2)(NO)(PPh_3)_2]$ (1.92(1) Å) and $[OsCl_2(=CHPh)(CO)(PPh_3)_2]$ (1.94(1) Å),[6] both of which also contain two phosphane ligands.

For $[OsCl_2(=CHOCH_2CH_2PiPr_2)(\eta^2\text{-}1)]$ there are three more possible stereoisomers besides **3b**—**A**, **B**, and **C** which are all chiral (Scheme 1). The question of which of the isomers **A**, **B**, or **C** corresponds to the complex **3a** is still open. Remarkably, in the single crystal of **3b** used for the X-ray structural analysis only one enantiomer is present, which according to the designation for octahedral complexes not containing two cisoid bidentate or three bidentate ligands has the *A* configuration (corresponding to the *S* configuration for tetrahedral compounds).[9] The enantiomeric purity of the crystal could be due to packing effects or, alternatively, could originate from the mechanism of the reaction of $OsCl_3 \cdot 3H_2O$ with **1**. We assume that the formation of **3a** and **3b** occurs via hydridometal intermediates, and that an insertion of the metal into the C–H bond of a OCH_3 group is the primary step. In this context we note that in the reaction of the olefin iridium compound $[IrCl(C_8H_{14})_2]_2$ with **1**, the metallated hydridoiridium complex $[IrHCl(CH_2OCH_2CH_2PiPr_2)(\eta^2\text{-}1)]$ is formed nearly quantitatively.[10]



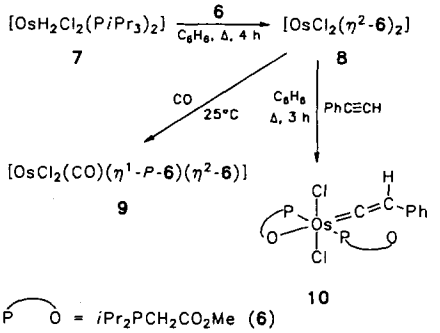
Scheme 1.

The reaction of $OsCl_3 \cdot 3H_2O$ with aminophosphane **4** proceeds in moderate yield (40–50%) to the carbene complex **5**, and that of **2** with **4** in good yield (70–75%). In the reaction of $OsCl_3 \cdot 3H_2O$ with **4**, several by-products are formed which could not as yet be completely separated from **5**. By comparing the ^1H, ^{13}C, and ^{31}P NMR data of **5** and **3b** we conclude that the compounds are structurally related.



Scheme 2.

An osmium complex of the general type $[OsCl_2(\eta^2\text{-}iPr_2P\text{-}Y)_2]$ (Y = heteroatom unit), originally expected as the product of the reaction of **2** and **1**, is accessible with the methyloxycarbonylphosphane **6**. Compound **8** is isolated in 90% yield after a mixture of **7**[11] and **6** in hexane is heated at 110 °C for 4 h (Scheme 3). Surprisingly, the reaction of **8** with CO leads to a monocarbonyl and not to a dicarbonyl metal complex (isolated yield of **9**: 77%); the reaction of **8** and phenylacetylene affords vinylidene–osmium derivative **10** quantitatively. The Os=C distance in **10** is 1.802(6) Å, comparable with the Os=C bond length in **3b**.[3]



Scheme 3.

In toluene at room temperature compound **10** exists in two rapidly converting isomeric forms as is apparent from the broadening of the ^1H NMR signals. The free energy of activation $\Delta G^{\neq}$ for the "open-and-close mechanism" (i.e. the simultaneous cleavage and formation of one Os–O bond) is 53 kJ mol^{-1} (T = 288 K).[12] The carbonyl complex was found to be rigid at room temperature on the NMR timescale; owing to the large P–P coupling (290 Hz) of the signals in the ^{31}P NMR spectrum there is no doubt that the two nonequivalent phosphane ligands are *trans* to each other.[13]

Experimental Procedure

3b: A suspension of 413 mg (1.18 mmol) of $OsCl_3 \cdot 3H_2O$ in 20 mL of 2-propanol was treated with 870 µL (4.70 mmol) of **1** and heated for 48 h at reflux. After the solution was cooled, it was concentrated to 2 mL, and 25 mL of ether was added. The yellow solid that precipitated was filtered off and recrystallized twice from methanol/ether. A second fraction of **3b** was isolated from the filtrate; yield 576 mg (80%); m.p. 132 °C.

5: A solution of 214 mg (0.37 mmol) of **2** in 10 mL of benzene was treated with 234 µL (1.10 mmol) of **4** and heated for 72 h under reflux. After the solution was cooled, the solvent was removed and the brown oily residue stirred with 10 mL of hexane to give a pale yellow solid; yield 166 mg (71%) m.p. 176 °C.

8: A suspension of 119 mg (0.20 mmol) of **7** in 15 mL of hexane was treated dropwise with 120 µL (0.61 mmol) of **6** and heated for 4 h at 110 °C in a sealed tube. After the solution was cooled, orange crystals started to precipitate. To enhance the precipitation, the reaction mixture was concentrated to 2 mL. The orange crystalline solid was filtered off and washed with ether; yield 118 mg (90%); m.p. 69 °C.

10: A solution of 93 mg (0.145 mmol) of **8** in 5 mL of benzene was treated with 32 µL (0.29 mmol) of phenylacetylene and heated for 3 h at reflux. After the solution was cooled, the solvent was removed and the residue stirred with a small amount of hexane to give a salmon-colored solid; yield 103 mg (96%); m.p. 154 °C.

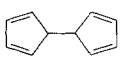
Double Open-Edged P_{10} Dihydrofulvalene as a 16-Electron Donor Ligand**

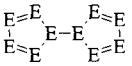
By *Otto J. Scherer,* Bernd Höbel,* and *Gotthelf Wolmershäuser*

Since the discovery of the stabilization of P, As, and several other P_n and As_n molecules by complexation approximately 20 years ago, it has become clear—especially in very recent times—that no limit has yet been placed on the structural variety of such acyclic, cyclic, and polycyclic P_n and As_n ligands.[1] Whereas theory predicts polycyclic molecules as being the most stable isomers for P_5 to P_{11},[2] the *cyclo*-E_n molecules (E = P, As; $n = 4–6$), isovalent with the carbocyclic $(CH)_n$ π systems, can also be stabilized by coordination.[1]

Starting from **1** and E_4 (E = P, As) we have now been able to synthesize E_n building blocks of this type, namely, P_{10} and As_{10} (structure type **B**). These are analogous to the dihydrofulvalene **A** and are coordinated in an open-edged form as ligand in the tetranuclear rhodium complexes **2** [Eq.(a)].



A ($C_{10}H_{10}$)



B (E_{10}; E = P, As)

Complexes **2a**, **b** form black crystals which can be handled in air for a short time. These crystals dissolve well in hexane and are even more soluble in benzene and dichloromethane.

$$[Cp''Rh(CO)_2]\ \mathbf{1} \xrightarrow[190\,°C,\ 3\ h]{E_4,\ decalin} \begin{matrix}[(Cp''Rh)_2(E_5\text{–}E_5)(RhCp'')_2]\quad \mathbf{2a, b}\\ +\\ [\{(Cp''Rh)(\mu,\eta^2\text{:}\eta^2\text{-}E_2)\}_2]\quad \mathbf{3a, b}\end{matrix} \qquad (a)$$

a: E = P, **b**: E = As; Cp'' = 1,3-tBu$_2$C$_5$H$_3$

The X-ray structure analysis[3] (Fig. 1) shows that the polycyclic Rh_4P_{10} framework of **2a** is centrosymmetric and also that the all-phophorus analogue of dihydrofulvalene P_{10}[4] (structure type **B**) is arranged so that the Rh atoms can achieve the 18 valence electron configuration; formally, Rh 2 receives the four π electrons of the double bonds P2–P 3 and P 4–P 5 [2.143(2) and 2.148(2) Å, respectively], and Rh 1 has the pair of nonbonding electrons on P 1 at its disposal, as well as a bonding electron pair as a result of the opening (oxidative addition) of the P 3–P 4 edge [2.624(2) Å]. Thus,

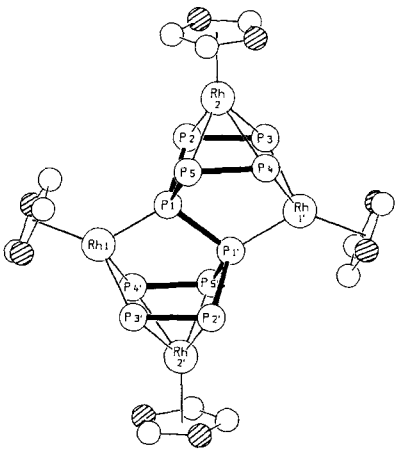


Fig. 1. Crystal structure of **2a**. Selected bond lengths [Å] and bond angles [°]: P1-P1' 2.184(2), P1-P2 2.192(1), P1-P5 2.193(1), P2-P3 2.143(2), P4-P5 2.148(2), P3 ··· P4 2.624(2), Rh1-P1 2.209(1), Rh1-P3' 2.329(1), Rh1-P4' 2.325(1), Rh2-P2 2.406(1), Rh2-P3 2.435(1), Rh2-P4 2.443(1), Rh2-P5 2.401(1), Rh1-Cp'' (center) 1.95, Rh2-Cp'' (center) 1.90; P1'-P1-P2 101.7(1), P1'-P1-P5 102.2(1), P1'-P1-Rh1 111.0(1), P2-P1-P5 91.2(1), P1-P2-P3 100.2(1), P2-P3-P4 96.7(1), P3-P4-P5 96.9(1), P4-P5-P1 99.5(1), P3-Rh1'-P4 68.6(1), P3-Rh2-P4 65.1(1), Rh1'-P3-Rh2 112.6(1), Rh1'-P4-Rh2 112.4(1), P1-P2-Rh2 93.5(1), P1-P5-Rh2 93.6(1), P2-Rh2-P5 81.4(1). ⊘ = CtBu.

P_{10} functions as a 16-electron donor ligand. The structure of the [Rh 2,P 3,P 2,P 5,P 4,Rh 1'] fragment differs only slightly from the analogously constructed binuclear complex **4**[5] (for **2a** one has to imagine that P 2 is connected to P 5, Fig. 1). The Rh 1–P 1 distance (2.209(1) Å) is similar to the Rh–P

$[Cp'Rh(\mu,\eta^4\text{:}\eta^1\text{:}\eta^1\text{-}P_4)Rh(CO)Cp']$ **4**, Cp' = C_5Me_4Et $\quad$ $[(Ph_3P)_2Rh(\mu\text{-}Cl)]_2$ **5**

$[\{CpCr(CO)_2\}_5(P_{10})]$ **6**, Cp = C_5H_5 $\quad$ BaP_{10} **7** $\quad$ Cu_4SnP_{10} **8**

distances of 2.200(2) and 2.213(2) Å found in the binuclear complex **5**.[6] The average value of the P–P distances (2.17 Å) in **2a** is significantly shorter than that for the same distances

in complex **6** (2.22 Å), the polycyclic P_{10} framework of which is constructed from a P_7 norbornane with a P_2 bridge and one terminal P atom.[7] The P_{10} ion in the polyphosphide **7** [$\bar{d}$(P–P) = 2.21 Å] forms the two-dimensional infinite polyanion $^2_\infty[P^{2-}_{10}]$ by the linkage of pentagons of phosphorus atoms arranged in tubes in one direction;[8] the polyphosphide **8** [$\bar{d}$(P–P) = 2.18 Å] has a P^{6-}_{10} framework with a structure analogous to adamantane.[9] The four-membered rings Rh 2-P 2-P 1-P 5 (sum of angles = 359.7°) and Rh 2-P 3-Rh 1′-P 4 (358.7°) in **2a** are almost planar. The plane P 3-P 4-P 5-P 2 is almost parallel with the C_5 plane of the Cp″ ligand at Rh 2 (deviation 1.1°), whereas for the P 1′-P 3-P 4 plane and the C_5 plane of the Cp″ ligand at Rh 1′ the deviation is greater (5.6°).

The structure of the P_{10} framework of **2a** was also established from an analysis of the P,P-COSY 45 NMR spectrum.[10] According to the most recent theoretical studies[2b] the P_8 cuneane framework with a P_2 bridge is considered to be the most stable framework for the calculated P_{10} isomers. All indications from the X-ray structure data[3] obtained for **2b** were in agreement with an As_{10} framework analogous to the P_{10} ligand of **2a**.[11] To our knowledge neither the polyarsenide ions corresponding to the polyphosphides **7** and **8** nor other As^{n-}_{10} polyarsenide ions are known.

For the E_4 unit of the complexes **3a, b** we propose a $(\mu, \eta^2{:}\eta^2\text{-}E_2)_2$ ligand, which has already been confirmed by X-ray structure analyses.[12]

Experimental Procedure

2a, 3a: A solution of P_4 (1.5 g, 12.1 mmol) in decalin (75 mL) was allowed to react with **1** (1.04 g, 3.09 mmol) and the mixture was stirred under reflux for 3 h. After the removal of the solvent in vacuum the dried residue was transferred to a column (20 × 1.5 cm) packed with Al_2O_3 (3% H_2O) and petroleum ether. With petroleum ether/toluene (10:1) a yellow-orange fraction was obtained from which **3a** (47 mg, 4.5%) was isolated as an orange powder. With petroleum ether/toluene (1:1) pure **2a** (384 mg, 35%) was eluted, which after recrystallization from hexane gave black, rectangular crystals.

2b, 3b: 200 mL of a boiling solution of As_4 in decalin (about 12 mg As_4 per mL, ca. 8 mmol) was allowed to react with **1** (1.1 g, 3.27 mmol). The reaction and work up was carried out analogously to **2a, 3a**. With petroleum ether/toluene (10:1) a violet fraction was eluted from which **3b** (280 mg, 20%) was isolated as a brown powder. A 5:1 mixture of the same solvents led to a beige-brown fraction which after the removal of the solvent in vacuum afforded brown $[Cp''_2Rh_2As_6]$ (53 mg, 3%) [13]. With a 1:1 mixture a red-brown fraction was eluted from which pure **2b** (517 mg, 34%) could be isolated. After recrystallization from benzene thin, black, diamond-shaped crystals were obtained.

[13] For this molecule we propose a structure analogous to $[Cp^*_2Co_2As_6]$ with a single open-edged As_6 Dewar benzene ligand [12c].

Stepwise Synthesis of Binuclear Photoactive Complexes with a Bridging 3,4-Dihydroxyphenylterpyridine Ligand**

By *Christine A. Howard* and *Michael D. Ward**

The ability of polypyridyl complexes of ruthenium(II) to act as photosensitizers is well established.[1] Recently attention has turned to the incorporation of 'light-harvesting' ruthenium centers into large molecular assemblies containing covalently attached quenching groups, so that energy or electron transfer from the chromophore to the accepting group is intramolecular and not dependent on collision of the two species in solution.[2] These covalently attached quenching groups may be organic electron donors or acceptors such as phenothiazines[3] or viologens,[4, 5] energy-accepting groups such as anthracene,[3] or inorganic complexes such as $[Ni(cyclam)]^{2+}$.[6] One aim of this type of work is the synthesis of large molecular assemblies—photochemical devices—which mimic biological photosynthesis by efficient intramolecular transfer of energy from the excited state 'antenna' to a reaction center. The reaction center then uses the energy in a catalytic process. Despite this interest, synthetic methods for the preparation of heteropolynuclear complexes incorporating photoactive groups are scarce.

The successful synthesis of multicomponent supramolecular assemblies of this type may be achieved by the *stepwise*

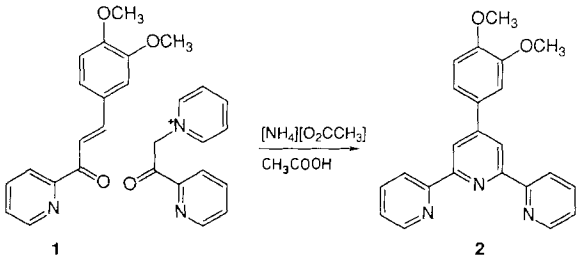
[**] This work was in part supported by the Nuffield Foundation. We thank Dr. J. Maher for assistance with the EPR spectroscopy and Dr. M. Murray for the two-dimensional NMR spectra.

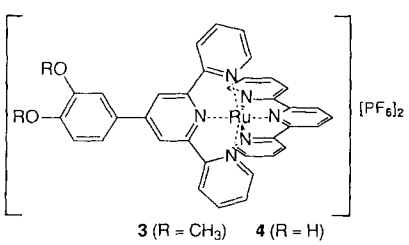
synthesis of heteropolynuclear complexes with a 'complexes as ligands' approach, in which a metal complex is prepared which contains a vacant, externally directed binding site. A second complex fragment may then be attached to the vacant site, allowing the stepwise buildup of polynuclear species from individual building blocks whose properties are known. We have recently prepared some derivatives of $[Ru(bpy)_3]^{2+}$ (bpy = 2,2'-bipyridine) containing externally directed pyridyl or phenol ligands for this purpose.[5] We now wish to describe the synthesis of **4**, a derivative of $[Ru(terpy)_2]^{2+}$ (terpy = 2,2':6',2''-terpyridine), in which the terpy ligand has a 3,4-dihydroxyphenyl substituent, and the syntheses and properties of binuclear complexes **5** and **6** prepared by subsequent attachment of a second metal center to the catechol binding site.

The key component in these syntheses is the ligand 3,4-dimethoxyphenylterpyridine (**2**), prepared in 42% yield by reaction of **1** with *N*-[2-(2-pyridyl)-2-oxoethyl]pyridinium iodide in the presence of ammonium acetate and refluxing glacial acetic acid (Scheme 1) in a standard Kröhnke-type pyridine synthesis.[7] The ligand was purified by isolation as



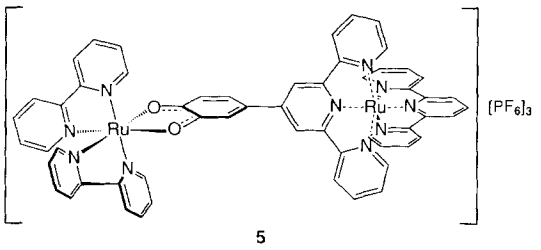
Scheme 1. The synthesis of 3,4-dimethoxyphenylterpyridine (**2**) is carried out in glacial acetic acid under reflux.

its Fe^{II} complex and subsequent demetalation,[8] followed by recrystallization from ethanol.[9] Chalcone **1** was in turn prepared in 63% yield by condensation of 2-acetylpyridine with 3,4-dimethoxybenzaldehyde in aqueous ethanol/KOH at room temperature. Reaction of **2** with $[Ru(terpy)Cl_3]$ in ethylene glycol at reflux followed by addition of aqueous KPF_6 gave the mixed-ligand complex **3** in 75% yield; it was purified by chromatography on silica with an acetonitrile/aqueous KPF_6 mixture as eluent. Reaction of **3** with BBr_3 in CH_2Cl_2 at room temperature[10] resulted in near-quantitative removal of the methoxy protecting groups, thus unmasking the secondary catechol binding site *after* initial formation of the ruthenium complex **3**.



3 (R = CH_3) **4** (R = H)

The binuclear ruthenium complex **5** was prepared by reaction of **4** with $[Ru(bpy)_2Cl_2]$, under the same conditions as required for the formation of the analogous mononuclear complex $[Ru(bpy)_2(sq)]^+$ (sq = the monoanionic semiquinone ligand arising from one-electron oxidation of catechol)[11] followed by precipitation with KPF_6. Complex **5** was obtained in 40% yield after purification by preparative thin-layer chromatography (TLC) on alumina plates with acetonitrile/toluene (2:1) as eluent. As in $[Ru(bpy)_2(sq)]^+$, the catecholate ligand oxidizes to the semiquinone oxidation state on exposure to air: **5** therefore contains a trication and is paramagnetic; the EPR spectrum shows a single, sharp resonance at $g = 2.00$. This precludes its characterization by



5

NMR spectroscopy, but its fast atom bombardment (FAB) mass spectrum shows a peak centered at m/z 1088 which corresponds to the mass of the binuclear cation of **5** and has the appropriate isotopic pattern.

A cyclic voltammogram of **5** (Fig. 1) shows that all three redox processes are reversible ($\Delta E_p = 60-90$ mV at scan rates up to 500 mVs^{-1}; $i_{p,a} \approx i_{p,c}$). The first two processes

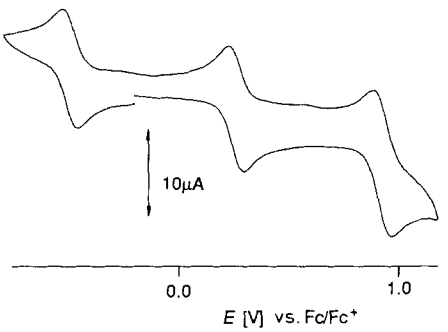


Fig. 1. Cyclic voltammogram **5** in CH_3CN at a scan rate of 0.2 Vs^{-1}.

($E_{1/2} = -0.51$ and $+0.26$ V vs. ferrocene/ferrocenium (Fc/Fc^+)) correspond respectively to the catecholate/semiquinone and semiquinone/benzoquinone redox couples of the bridging ligand. The analogous ligand-based redox processes in $[Ru(bpy)_2(sq)]^+$ are also reversible and occur at -0.69 and $+0.16$ V (vs. Fc/Fc^+);[12] the shifts of 100–200 mV of these waves to more positive potentials in **5** may be simply ascribed to the presence of a second cationic metal center nearby, which electrostatically destabilizes the oxidized forms of the catecholate. The third process ($E_{1/2} = +0.94$ V vs. Fc/Fc^+) has no counterpart in the voltammogram of $[Ru(bpy)_2(sq)]^+$, and is assigned to the Ru^{II}/Ru^{III} couple of the bis(terpyridyl)ruthenium center (the redox potential of $[Ru(terpy)_2]^{2+}$ under the same conditions was $+0.90$ V vs. Fc/Fc^+).

Part of the UV/VIS spectrum of complex **5** is shown in Figure 2, which compares the spectrum of **5** with the sum of the spectra of the mononuclear counterparts $[Ru(bpy)_2(sq)]^+$ and $[Ru(terpy)_2]^{2+}$ at the same concentration. There is a significant increase in the width of the metal-to-ligand charge transfer (MLCT) band at 480 nm, but the biggest difference

is in the Ru^{II}–semiquinone MLCT band. In $[Ru(bpy)_2(sq)]^+$ this occurs at 889 nm ($\varepsilon = 6400\ dm^3mol^{-1}cm^{-1}$); in **5** it has shifted to 967 nm and become about three times more intense ($\varepsilon = 20000\ dm^3mol^{-1}cm^{-1}$), indicating that the semiquinone fragment in **5** is a better electron acceptor than that in $[Ru(bpy)_2(sq)]^+$ due to its attachment to the $[Ru(terpy)_2]^{2+}$ fragment (i.e. a simple substituent effect).

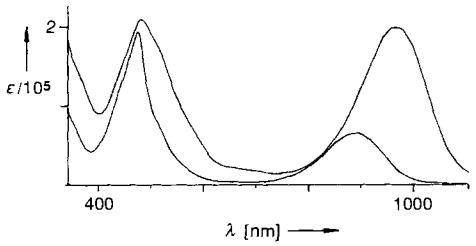

Fig. 2. UV/VIS spectrum of **5** in CH_3CN (upper trace) and the sum of the spectra of $[Ru(bpy)_2(sq)][PF_6]$ and $[Ru(terpy)][PF_6]_2$ at the same concentration (lower trace).

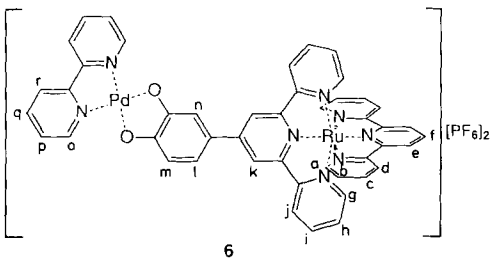
The binuclear Ru–Pd complex **6** was prepared by reaction of **4** with one equivalent of $[Pd(bpy)Cl_2]$ and three equivalents of KOH in methanol at room temperature under N_2 (Scheme 2). The resulting purple precipitate was purified (30% final yield) by preparative TLC on alumina plates with acetonitrile/toluene (2:1) as eluent. In **6**, as in the mononuclear analogue [Pd(bpy)(cat)][12] (cat = dianion of catechol), the catecholate ligand does not oxidize. The ^1H NMR spectrum shows eighteen signals in the region of the aromatic protons; these were assigned[13] with the help of a two-dimensional COSY spectrum and by comparison of the spectrum with the spectra of **4** and [Pd(bpy)(cat)]. The FAB mass spectrum shows a peak centered at *m/z* 936, which corresponds to the mass of the binuclear cation and has the appropriate isotopic pattern.



Scheme 2. The letters correspond to the labeling of the protons that was used for the assignment of the ^1H spectrum [13].

The cyclic voltammogram shows an irreversible oxidation at +0.18 V vs. Fc/Fc^+, which is characteristic of the [Pd(bpy)(cat)] fragment,[12, 14] and a reversible oxidation at +0.93 V vs. Fc/Fc^+ corresponding to the Ru^{II}/Ru^{III} couple. The UV/VIS spectrum of **6** is shown in Figure 3, which compares the spectrum of **6** with the sum of the spectra of the mononuclear counterparts $[Ru(terpy)_2]^{2+}$ and [Pd(bpy)(cat)] at the same concentration. The most striking difference is in the ligand-to-ligand charge transfer (LLCT) band (catecholate–bipyridine). In [Pd(bpy)(cat)] this absorption occurs at $\lambda_{max} = 535$ nm ($\varepsilon = 1300\ dm^3mol^{-1}cm^{-1}$); in **6** this band has moved only slightly ($\lambda_{max} = 524$ nm) but has increased in intensity by over an order of magnitude ($\varepsilon = 19000$), resulting in a beautiful and very strong wine-red color in solution. The catecholate fragment in **6** is evidently more electron-rich than the catecholate in [Pd(bpy)(cat)]; this may be ascribed to the fact that it is attached to the π-acidic terpyridine ligand, which contains electron density accepted from the ruthenium ion, and is in interesting contrast to the apparently enhanced electron-accepting nature of the semiquinone fragment in **5**.

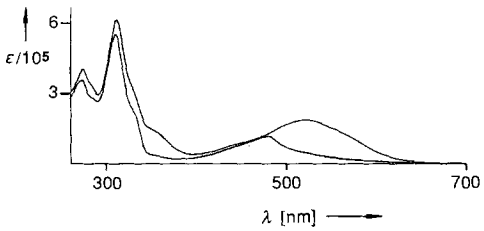


Fig. 3. UV/VIS spectrum of **6** in dimethylformamide (upper trace) and the sum of the spectra of [Pd(bpy)(cat)] and $[Ru(terpy)_2][PF_6]_2$ at the same concentration (lower trace).

The LLCT excited state of [Pd(bpy)(cat)] is quenched by triplet O_2 in solution giving singlet O_2.[15] Since singlet O_2 reacts with 2,2,6,6-tetramethyl-4-piperidinol to give a stable nitroxide radical, the efficiency of the production of singlet O_2 under irradiation may be determined. This is achieved by measuring the intensity of the EPR signal of the nitroxide radical as a function of irradiation time in an O_2-saturated solution of the palladium complex to which 2,2,6,6-tetramethyl-4-piperidinol has been added.[12] Comparison of [Pd(bpy)(cat)] with **6** showed that **6** is about 50% more efficient as a photocatalytic producer of singlet O_2.

In conclusion, we have developed a straightforward new method for the stepwise synthesis of polynuclear complexes which contain a $[Ru(terpy)_2]^{2+}$ chromophore. Unmasking the second coordination site after formation of the first complex allows the efficient, unambiguous preparation of heterobinuclear complexes with strong electronic interactions between the two fragments.

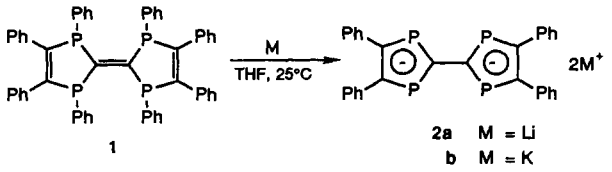
Tetraphosphafulvalene Dianions: Isoelectronic Species of Tetrathiafulvalene Dications

By *Nicole Maigrot, Louis Ricard, Claude Charrier,* and *François Mathey**

Recently, we described the synthesis of the first tetraphosphafulvalenes.[1] Our ultimate aim was to prepare charge-transfer (CT) complexes of the tetrathiafulvalene–tetracyanoquinodimethane type and to study their electrical conductivity. However, for this purpose tetraphosphafulvalenes themselves are useless since they incorporate four pyramidal phosphorus atoms that prevent the stacking of such species. We report herein the selective cleavage of the four exocyclic P–C bonds, a crucial step for the formation of tetraphosphacycles which can be stacked.

The reaction of the octaphenyl derivative **1** with an excess of lithium or potassium in THF at room temperature afforded a single phosphorus-containing product **2** (Scheme 1). The



Scheme 1. M is added in excess.

resonance frequency for **2** in the ^{31}PNMR spectrum ($\delta \approx 170$) lies in the same range as those of 1,3-diphospholide ions.[2] We were able to obtain crystals of **2b** suitable for an X-ray structural analysis from a mixture of ether and 1,2-dimethoxyethane[3] (Fig. 1). The two diphospholyl rings are coplanar (maximum deviation 0.010(3) Å) and aromatic. The length of C1–C1′ bond that links the two five-membered rings [1.482(5) Å] corresponds to a normal single bond between two sp^2 hybridized carbon atoms. The P–C bonds are between 1.748(3) and 1.761(3) Å long and are thus similar in length to those found in the lithium phospholide Li(tmeda)PC$_4$Me$_4$.[4] The C3–C4 bond (1.401(4) Å) is longer than a localized C=C bond; however, it is similar in length to the corresponding bond in the previously mentioned lithium phospholide.[4] The most intriguing feature of this structure is the position of the potassium ions relative to the central tetraphosphafulvalene unit. Instead of pentahapto coordination of the metal as in Li(tmeda)PC$_4$Me$_4$,[4] the potassium ions in **2b** are shared by the two 1,3-diphospholyl units. These are positioned on both sides of the cycle at a distance of 2.82 Å and can be viewed as bis η^2-coordinated to the two P2–C1 and the two P5–C1 bonds. The K–P distances are close to the sum of the covalent radii (K + P = 3.37 Å). If we consider a K$_2$(dme)$_4$ unit (dme = dimethoxyethane) sandwiched between two tetraphosphafulvalene planes, in addition to the four "terminal" oxygen atoms, two oxygen atoms of two DME molecules (022,022*) bridge the two potassium ions so that each of the potassium ions is heptacoordinated (Fig. 2). The dianion contains a center of symmetry, and the ions are arranged in infinite chains produced by translation of the unit cell along the *b* axis of the crystal.

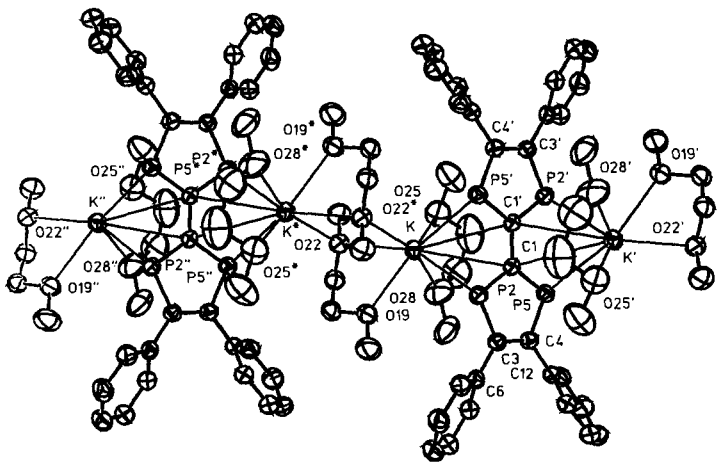


Fig. 1. Crystal structure of **2b** [3]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances [Å] and angles [°]: K-K′ 4.604(1), K-P2 3.267(1), K-P5 3.393(1), C1-C1′ 1.482(5), C1-P2 1.748(3), C1-P5 1.753(3), P2-C3 1.761(3), C3-C4 1.401(4), C4-P5 1.761(3); P2-K-P5 60.51(2), C1-C1′-P2 123.7(3), C1-C1′-P5 121.1(3), P2-C1-P5 115.2(1), K-P2-C1 82.7(1), K-P2-C3 120.2(1), C1-P2-C3 96.3(1), P2-C3-C4 116.1(2), C3-C4-P5 116.3(2), K-P5-C1 81.5(1), K-P5-C4 122.2(1), C1-P5-C4 96.1(1).

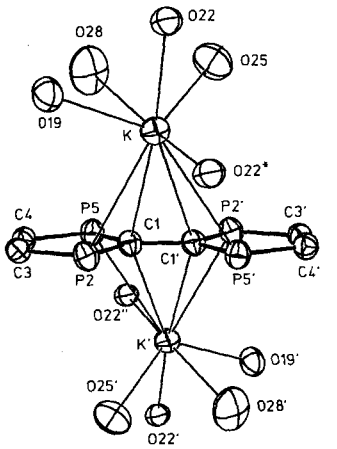

Fig. 2. The coordination sphere of a potassium ion in a crystal of **2b**.

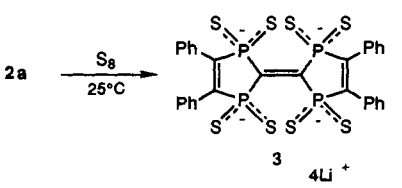
The reaction of **2a** with an excess of sulfur led to the expected lithium tetrakis(dithiophosphinate) **3**[5] (Scheme 2) whose structure was established by X-ray crystal structure analysis[6] (Fig. 3). Both the aromaticity of the rings and the



Scheme 2. Sulfur is added in excess.

planarity of the whole tetraphosphafulvalene unit in **3** are lost and the central C1–C1′ bond clearly has double-bond character. Two tetrahedral trisaqua acetonato lithium ions and one doubly charged di-μ^2-aqua-tetrakis-η^1-aqua dilithium ion serve as the counter ions.

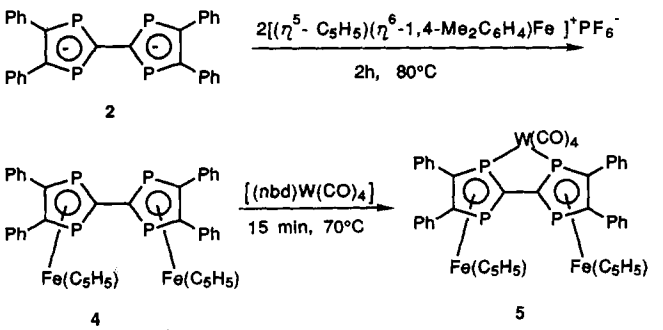
Important bond distances [Å] and angles [°]: S1-P2 1.977(5), S2-P2 1.993(5), S3-P5 1.957(5), S4-P5 2.003(5), P2-C1 1.89(1), P2-C3 1.82(1), P5-C1 1.85(1), P5-C4 1.81(1), C1-C1' 1.34(2), C3-C4 1.33(1), C4-C12 1.51(2), C3-C6 1.49(2); S1-P2-S2 118.8(2), S1-P2-C1 111.7(4), S1-P2-C3 107.9(4), S2-P2-C1 112.3(4), S2-P2-C3 106.3(4), C1-P2-C3 97.4(5), S3-P5-S4 117.2(2), S3-P5-C1 113.2(4), S3-P5-C4 107.1(5), S4-P5-C1 113.0(4), S4-P5-C4 105.9(4), C1-P5-C4 98.1(5), P2-C1-P5 106.7(6), P2-C1-C1' 123.7(8), P5-C1-C1' 129.5(8), P2-C3-C4 116.9(9), P2-C3-C6 116.8(7), C4-C3-C6 126.0(1), P5-C4-C3 117.7(9), P5-C4-C12 118.3(8), C3-C4-C12 124.0(1). The four phosphorus atoms and the C1-C1' double bond are coplanar. The dihedral angle between this plane and the P2-C3-C4-P5 mean plane is 20.37 ± 0.58°.

Additional characterization of **2a** was provided by its reaction with (η^5-cyclopentadienyl)(η^6-*p*-xylene)iron hexafluorophosphate.[7] The resulting η^5-complex **4**[8] is very sensitive toward oxidation, but it could be characterized after chelation with the [W(CO)$_4$] fragment (→ 5) (Scheme 3).[9]



Scheme 3. nbd = norbornadiene.

Dianions such as **2** are isoelectronic with tetrathiafulvalene dications. We are currently studying the electrochemistry of **2**.

Experimental Procedure

2a: The P–Ph bonds of tetraphosphafulvalene **1** (810 mg, 1 mmol) were cleaved under an argon atmosphere by stirring with lithium containing 1% of sodium (47 mg, 6.6 mmol) in freshly distilled dry THF (15 mL). The cleavage was complete after 3 h. The phenyllithium by-product was destroyed by addition of anhydrous NH_4Cl (200 mg, 4 mmol).

2b was prepared by stirring the tetraphosphafulvalene **1** (470 mg, 0.55 mmol) with potassium (150 mg, 3.8 mmol) in freshly distilled dry DME (10 mL). The reaction was complete after 3 h. The phenylpotassium by-products formed insoluble polymers which were eliminated by filtration under an argon atmosphere. The solution was concentrated (5 mL) and 5 mL of dry ether was added. Pale yellow crystals of **2b** were obtained after one week at −18 °C.

3: To the solution of **2a** was added an excess of sulfur (270 mg, 8.4 mmol). The reaction mixture was stirred for 15 min and filtered. The solvent was evaporated and the residue extracted with 4 × 30 mL of diethyl ether. The evaporation of ether yielded a pasty yellow residue which was crystallized from acetone. Yield 35%.

4: To a solution of dianion **2a** was added [Cp(η^6-1,4-$Me_2C_6H_4$)Fe]PF_6 (820 mg, 2.3 mmol). The reaction mixture was heated at 80 °C for 2 h, concentrated to 5 mL, and quickly chromatographed on a silica gel column (20 g, l = 8 cm, ∅ = 26 mm) with dichloromethane as eluent. After evaporation of the solvent, the product was again chromatographed on silica gel (100 g, l = 21 cm, ∅ = 36 mm) with hexane/toluene (50/50) as eluent. A deep red crystalline product was obtained. Yield 30%. Compound **4** proved to be unstable on standing and in solution.

5: Crude **4** was allowed to react in situ with [(nbd)W(CO)$_4$] (700 mg, 2.1 mmol). The reaction mixture was heated at 70 °C for 15 min. After concentration to 5 mL, the solution was quickly chromatographed on silica gel (20 g, l = 8 cm, ∅ = 26 mm) with toluene as eluent. After evaporation, the residue was once more chromatographed on silica gel (100 g, l = 21 cm, ∅ = 36 mm) with toluene as eluent. A red-orange crystalline compound was thus obtained in 34% yield.

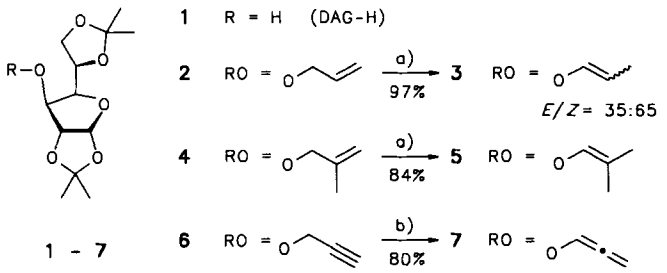
Diacetoneglucose as Auxiliary Group for the Asymmetric Hetero-Diels–Alder Reaction with Nitrosoalkenes**

By *Thomas Arnold, Beate Orschel,* and *Hans-Ulrich Reissig**

Dedicated to Professor Ekkehard Winterfeldt on the occasion of his 60th birthday

In our search for efficient optically active auxiliaries for the asymmetric hetero-Diels–Alder reaction,[1] we recently came across diacetoneglucose (DAG-H, **1**). With this easily accessible[2] and cheap sugar derivative,[3] enol ethers and allenyl ethers can be readily prepared, which undergo cycloaddition reactions with nitrosoalkenes[4] in high diastereomeric excesses. The resulting optically active dihydro-1,2-oxazines attract much attention as a versatile building blocks in synthesis.[5]

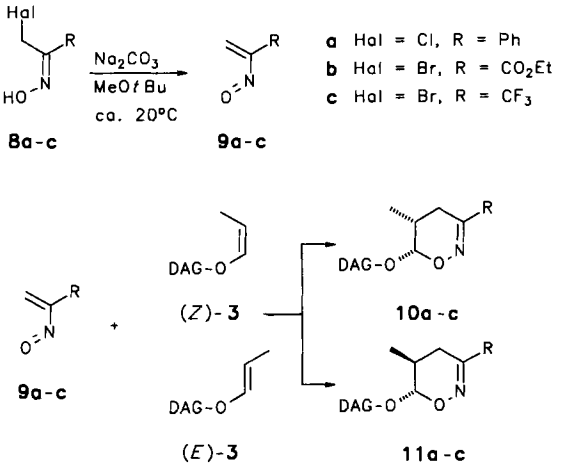
Enol ethers **3** and **5** were prepared from the allyl ethers **2** and **4**, respectively, which can be readily obtained from **1** and the appropriate allyl halide under phase-transfer conditions[6] (Scheme 1). $[Fe(CO)_5]$-catalyzed isomerization[7]



Scheme 1. Compound **2** from **1** and allyl bromide according to [6]; **4** analogously from **1** and 3-chloro-2-methyl-1-propene (KOH, [18]crown-6, THF, 20 °C, 3 days), 63%; **6** from **1** and propargyl bromide (NaOH, nBu$_4$NI, THF, 20 °C, 4 days), 92%; a) $[Fe(CO)_5]$ (0.12 or 0.20 equiv, xylene, 135 °C, 8 or 15 h); b) KOtBu (1.75 equiv, toluene, 110 °C, 1 h).

gave the enol ethers **3** and **5** in satisfactory overall yields. A disadvantage, however, is the E/Z mixture of **3** that forms with this catalyst, but the isomers can be at least partially separated by chromatography.[8] The optically active allene derivative **7** can be obtained from the propargyl ether **6** through standard procedures without difficulty.[9]

The highly reactive nitrosoalkenes **9a–c** were generated in situ from the α-halooximes **8a–c** with sodium carbonate.[4] Scheme 2 summarizes the trapping reactions for **9** with the 1-propenyl ethers (*Z*)-**3**/(*E*)-**3**. In each of these exploratory experiments, the ethers were used as a mixture with varying Z/E ratios (Table 1), and the products were the dihydro-1,2-oxazines **10a–c** and **11a–c**. It is important that the (*E*)-enol ether reacts considerably faster than the (*Z*)-enol ether with **9** (see Table 1).[10] Therefore, for an appropriate **9**/**3** ratio, (*Z*)-**3** can be recovered in highly enriched form and again treated with **9** in a second cycle. Thus a confident assignment of the isolated dihydrooxazines **10** and **11** to *cis*/*trans* isomeric cycloadducts or diastereomers with respect to the auxiliary is possible.[11] In Scheme 2 only the major diastereomers of **10** and **11** are presented.

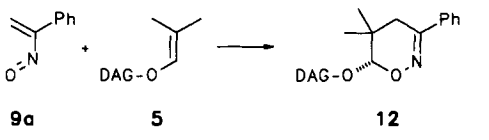


Scheme 2. Asymmetric [4 + 2] cycloadditions of nitrosoalkenes **9** with (*Z*)-**3**/(*E*)-**3** (for an experimental procedure see [1e]). **a**, Hal=Cl, R=Ph; **b**, Hal=Br, R=CO_2Et; **c**, Hal=Br, R=CF_3.

Table 1. Diastereomeric ratios (dr) in reactions of (*Z*)-**3**/(*E*)-**3** with nitrosoalkenes to give dihydro-1,2-oxazines **10**/**11**.

(*Z*)-**3**/(*E*)-**3**	**9**	yield [%]	**10**	**11**
20:80	**a**	52	2:0	98:0
94:6	**a**	54	73:19	8:0
			dr = 79:21/ > 95:5	
92:8	**b**	33	61:14	25:0
			dr = 81:19/ > 95:5	
70:30	**c**	65	76:6	16:2
			dr = 93:7/ ≈ 90:10	

The cycloadditions of the nitrosoalkenes **9a–c** with (*Z*)-**3** proceed with good diastereoselectivity (dr = 79:21 to 93:7, see Table 1). The selectivity increases with increasing reactivity of the heterodiene (**9a** < **9b** < **9c**).[12] The reactions of the (*E*)-enol ether (*E*)-**3** with **9a** and **9b** yields the dihydrooxazines **11a** and **11b**, respectively, in diastereomerically pure state, whereas with **9c** the minor isomer of **11c** constitutes 10% of the product mixture. Therefore, as in earlier examples,[1e] the substantially more reactive (*E*) olefin shows a distinctly higher selectivity than the (*Z*) olefin; only with **9c** are the diastereomeric ratios of **10** and **11** approximately equal. The selectivity of the reaction between isobutenyl ether (**5**) and nitrosostyrene (**9a**), which forms dihydrooxazine **12**, lies between that of (*Z*)-**3** and (*E*)-**3**.



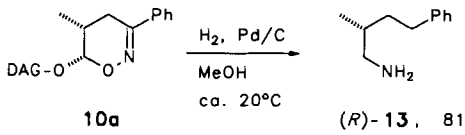
dr = 88:12, 60%

The absolute configurations given for **10**, **11**, and **12** are based on a crystal structure analysis[13] of the major diastereomer of **10a**, which was obtained pure after chromatography (m.p. 106–109 °C, $[\alpha]_D^{20}$ +57.7, c=1.00 in $CHCl_3$). That the configurations of **10a** and **11a** must be different at C5 of the heterocycle, and thus the same at C6 because of the stereospecific course of the cycloaddition,[10] follows from the hydrogenolysis of these cycloadducts. In

[*] Prof. Dr. H.-U Reissig, Dipl.-Ing. T. Arnold, Dipl.-Ing. B. Orschel Institut für Organische Chemie der Technischen Hochschule Petersenstrasse 22, D-W-6100 Darmstadt (FRG)

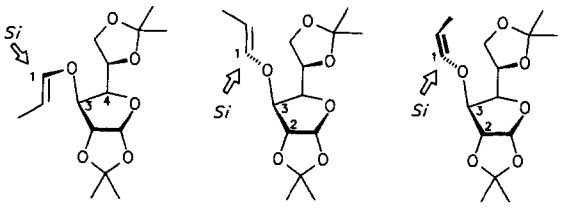
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Vereinigung von Freunden der Technischen Hochschule Darmstadt.

this reductive nitrogen transposition,[14] the *cis* adduct **10a** yields the primary amine (*R*)-**13** ($[\alpha]_D^{20}$ +15.5, *c*=2.00 in $CHCl_3$), whereas **11a** affords the enantiomer (*S*)-**13** ($[\alpha]_D^{20}$ −15.9, *c* = 1.11 in $CHCl_3$). The enantiomeric excess of (*R*)-**13** was determined to be >90% by NMR spectroscopy, with the aid of a shift reagent.



10a (*R*)-**13**, 81%

Our results show that predominantly or exclusively the *Si* side (with reference to C1) of the enol ether is attacked by **9a**. For (*E*)-**3** this means that a back side approach to the reactive conformation **A** and a front side approach to **B** (Scheme 3) must be considered above all others. Although in **B** the diastereotopic sides of the olefin should be more clearly differentiated, reactive conformation **A** may also be plausible, because here the repulsion between the dioxolane group at C4 and the propenyl unit is less than in **B**.[15] Besides, the cycloaddition will profit from a stronger electronic activation of the double bond in the s-cisoid conformation **A**.[16] The difference in the sides in **A**, however, is less pronounced, in particular if an *exo* transition state is involved.[17] Nevertheless, the back side of **A** should be more "open" to attack than the front side.[18]



A C-1/O cisoid C-1/O/C-3/C-4 *anti*

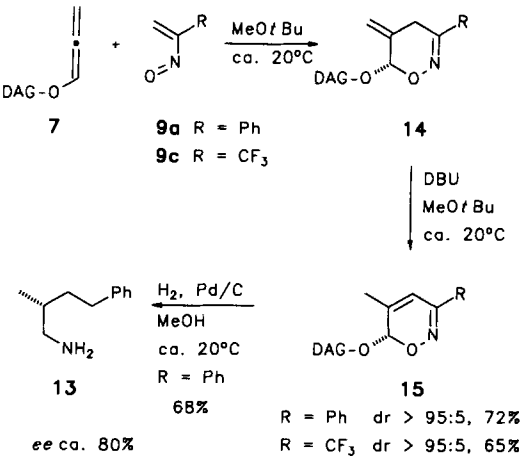
B C-1/O transoid C-1/O/C-3/C-2 *anti*

C C-1/O *gauche* C-1/O/C-3/C-2 *anti*

Scheme 3. Reactive conformations **A**–**C** of (*E*)-**3** and (*Z*)-**3**.

For (*Z*)-**3** a similar consideration of models is even more difficult, but a reactive conformation corresponding to **A** is hardly feasible. In retrospect, the results can be explained with a *gauche* conformation **C**, in which the propenyl unit is turned slightly forward, and a front side attack of **9a**. The lower selectivity of (*Z*)-**3** might be due to the poorer differentiation between the sides in **C** or the participation of other reactive conformations.

The mechanistic interpretation proposed for (*E*)-**3** can also be applied to the allene derivative **7** (Scheme 4), which yields the labile primary adducts **14** with the nitrosoalkenes **9a** and **9c** (dr about 90:10). These alkenes are transformed into the stable conjugated 6*H*-1,2-oxazines **15**, which after chromatography are obtained diastereomerically pure in good overall yields. The assignment of the configuration at C6 is based on the results with the enol ether **3**, but mainly on the transformation of **15**, R=Ph, into the primary amine **13**. Here the first step can be assumed to be a hydrogenation of the CC double bond from the side opposite to the bulky DAG group. The intermediate is probably **10a**. The optical rotation of **13** ($[\alpha]_D^{20}$ +12.4, *c* = 2.00 in $CHCl_3$), which corresponds to an enantiomeric excess of about 80%, shows that the asymmetric induction in this hydrogen addition is good, but not perfect.



Scheme 4. Reactions of **9** with the allenyl ether **7**. DBU = diazabicycloundecene.

The results presented here demonstrate that using the cheap diacetoneglucose as optically active auxiliary[20] gives surprisingly high diastereoselectivities in hetero-Diels–Alder reactions. The enol ethers and the allene derivative containing this group are expected to gain in general significance (e.g., for other cycloadditions or reactions with electrophiles); furthermore, the optically active dihydro-1,2-oxazines obtained here are interesting intermediates, as exemplified by the synthesis of the primary amines (*R*)-**13** and (*S*)-**13** in high enantiomeric purity.

[11] The isomeric ratios refer to the crude products and were determined by ^1H and ^{13}C NMR spectroscopy (±5% error). The quoted yields refer to purified products after chromatography and, if possible recrystallization. Satisfactory elemental analyses and the expected spectral data were obtained for all compounds.
[12] With increasing electron-withdrawing property of group R, the LUMO energy of the nitrosoalkenes decreases (H.-U. Reissig, unpublished MNDO calculations) and the reactivity toward electron-rich olefins increases; see also [4d].
[13] We thank Prof. Dr. H. J. Lindner (Technische Hochschule Darmstadt) for the structure determination. Details will be published in a full paper.
[14] For details on the mechanism of this six-step transformation, which most probably proceeds with retention of configuration at the nonparticipating stereogenic center, see [5b].
[15] Similar preferential conformations were found by X-ray analysis for 3-*O*-alkylated diacetoneglucose derivatives (for example, I. W. Krajewski, P. Głuzinski, Z. Urbanczyk-Lipkowska, A. Banaszek, K. Vangehr, P. Luger, *Carbohydr. Res.* **1984**, *125*, 203–216). We thank one referee for this hint and other critical comments.
[16] See D. Bond, P. von R. Schleyer, *J. Org. Chem.* **1990**, *55*, 1003–1013, and references cited therein.
[17] Whether an *exo* or an *endo* transition state is involved in these cycloadditions cannot be deduced from the products. Earlier studies on a model compound ([10]) indicate that an *exo* transition state should dominate. An *endo* approach to the nitrosoalkenes should, however, result in a greater side differentiation. For a similar discussion see [1f].
[18] Fixation of the conformation by Lewis acids, as discussed for similar auxiliaries [19], should not play a role here, because even the sodium ions present exert no influence: If Et*i*Pr$_2$N is used as base to generate **9a**, similar diastereomeric ratios are obtained from (*Z*)/(*E*)-**3** for **10a**/**11a** as when Na_2CO_3 is used as base.

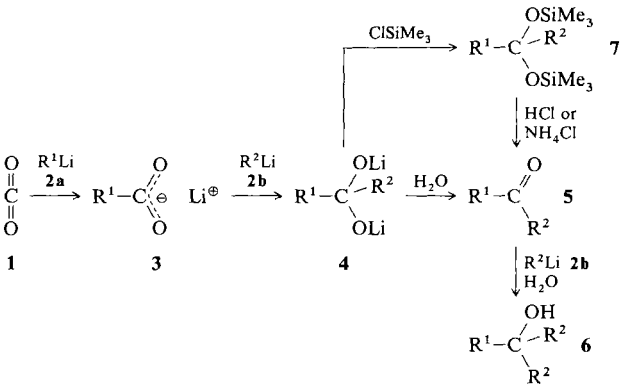
A One-Pot Synthesis of Ketones and Aldehydes from Carbon Dioxide and Organolithium Compounds**

By *Guido Zadel* and *Eberhard Breitmaier**

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

Besides the old textbook examples such as the carboxylation of Grignard compounds to carboxylic acids,[1] and the Kolbe–Schmitt conversion of phenol to salicylic acid,[2] there are only a few more recent preparative applications of carbon dioxide;[3] one is the introduction of a carbamate protecting group to nitrogen heterocycles.[4]

We report here a new method of synthesizing ketones and aldehydes from carbon dioxide, in which CO_2 (**1**) reacts as an electrophile with an alkyllithium compound R^1Li **2a**. If after



the excess carbon dioxide is removed, another alkyllithium compound R^2Li **2b** or lithium hydride (**2b**, R = H) is added in aprotic media (Table 1) and the reaction mixture is hydrolyzed, for example with aqueous hydrochloric acid or ammonium chloride, then symmetric ($R^1 = R^2$) or unsymmetric ketones **5** or aldehydes (**5**, R = H) are formed.

Table 1. Results of the syntheses of ketones and aldehydes.

Starting materials		Results		Conditions	
R^1 in **2a**	R^2 in **2b**	product	yield [%][a]	solvent	workup
Ph	prop-2-enyl	**5a**	78	ether	Me_3SiCl
*t*Bu	Ph	**5b**	92(83)	pentane, ether	NH_4Cl
*t*Bu	2-pyridyl	**5c**	65(54)	pentane, THF	HCl
Ph	[b]	**5d**	88	ether	Me_3SiCl
Ph	2-furyl	**5e**	68(44)	ether	Me_3SiCl
3-pyridyl	Bu	**5f**	58	ether, hexane	HCl
1-naphthyl	Ph	**5g**	88	THF, ether	NH_4Cl
cyclohexyl	Me	**5h**	93(37)	THF	HCl
Ph	Ph	**5i**	89	ether	HCl
Bu	H	**5j**	54	hexane	Me_3SiCl
3-pyridyl	H	**5k**	72	1,2-dimethoxyethane	HCl
mesityl	H	**5l**	45	1,2-dimethoxyethane	Me_3SiCl
*t*Bu	H	**5m**	51	pentane	Me_3SiCl
cyclopropyl	H	**5n**	43	THF	Me_3SiCl

[a] The values in parentheses refer to the results from the addition of **2b** before **2a**.

[**] This research was supported by the state of Nordrhein-Westfalen and the Fonds der Chemischen Industrie.

Besides the ketones or aldehydes, the tertiary alcohols **6** may be isolated before the reaction has gone to completion. They arise during the alkaline hydrolysis by addition of the alkyllithium compound **2b**, present in excess, to the already formed ketone **5**. If a series of samples are taken from an equimolar mixture of phenyllithium (**2b**, R^2 = Ph) and lithium-2,2-dimethylpropanoate (**3**, R^1 = *t*Bu, prepared in situ from 2-chloro-2-methylpropane, lithium, and carbon dioxide), and the concentrations of pivalophenone (**5b**), 2,2-dimethyl-1,1-diphenylpropanol (**6**, R^1 = *t*Bu, R^2 = phenyl), and pivalic acid are measured, it is apparent that the yield of ketone increases with time (Table 2). After the reaction is complete, tertiary alcohols **6** are formed only if more R^2Li is added during the workup (Table 2, last line). This experiment also supports the reaction sequence that Gilman et al.[3c] sketched out for the reaction of phenyllithium with carbon dioxide to give benzophenone: CO_2 (**1**) adds to the first alkyllithium compound **2a**; the resulting lithium carboxylate **3** reacts with the second alkyllithium compound **2b** or with lithium hydride (**2b**, R^2 = H) to give the dilithiated acetal or ketal **4**; hydrolysis leads to ketone (or aldehyde) **5**.

Table 2. Product distribution (GC analysis) as related to the reaction time for the reaction of **3**, R^1=*t*Bu, and **2b**, R^2=Ph, with workup in concentrated ammonium chloride solution.

Reaction time at reflux [h]	Products [%] ketone	alcohol	acid
0.5	29	25	44
1	32	25	41
2	37	26	35
3	55	16	26
4	63	10	22
5	70	7	19
10	91	0	7
24	92	0	6
24 [a]	53	33	7

[a] After 24h, 1 equiv **2b**, R^2 = Ph, was added.

The undesired formation of alcohols can be suppressed if the dilithiated acetals **4** are converted into the trimethylsilylacetals **7** by treatment with chlorotrimethylsilane. Compounds **7** are then hydrolyzed with aqueous hydrochloric acid.

The reaction lends itself to the synthesis of ketones and aldehydes with almost any substitution pattern, even those that are accessible conventionally only with difficulty. ^{13}C-labeled ketones and aldehydes can be prepared (from ^{13}C carbonate). Varying the reaction conditions according to Table 2 also opens the way to specific tertiary alcohols.

Experimental Procedure

Ketones and aldehydes: Dried powdered CO_2 (**1**, 132 g) was suspended in approximately 50 mL of solvent (Table 1) under argon in an apparatus with an additional gas inlet into the reaction mixture. A solution of the alkyllithium compound **2a** (0.05 mol) in 30 mL of solvent was cooled to −40 °C and added dropwise over 10 min; the reverse procedure leads primarily to symmetric ketones. After all the CO_2 had reacted or gone into solution, the reaction mixture was stirred for 1 h at −10 °C, heated 10 to 15 min at reflux, and then flushed free of CO_2 with argon (monitored with $Ba(OH)_2$).

Ketones: The reaction mixture was cooled to 0 °C, a solution of the alkyllithium compound **2b** (0.06 mol, 1–1.5 M solution) was added dropwise over 1 min, and the reaction mixture was then heated at reflux for 5 h (suspensions were heated for 10 to 24 h). The extent of reaction can be monitored titrimetrically according to ref.[5].

In situ variation: Alternatively, alkyllithium **2b** was prepared in situ by the addition of the haloalkane (0.06 mol) to lithium (0.06 mol, 0.48 g) over 30 min; the reaction mixture was heated for 5 to 10 h as previously described.

Aldehydes: After all of the CO_2 had been removed (monitored with $Ba(OH)_2$; metal hydrides and CO_2 form explosive mixtures![6]), the reaction mixture was cooled to −40 °C, and lithium hydride (**2b**, R^2=H, 0.065 mol, 0.48 g) was added. The reaction mixture was carefully allowed to warm to room temperature and then stirred for 12 h, or in the case of slower reactions, heated for 12 to 24 h at reflux.

Workup: The reaction mixture was pipetted in 2 mL aliquots into cold hydrochloric acid (1 N, 130 mL) or into saturated aqueous NH_4Cl solution (50 mL) for the hydrolysis. (The reversed procedure leads to the tertiary alcohols.) Alternatively, the reaction mixture was cooled to 0 °C and treated with chlorotrimethylsilane (15 mL). The reaction mixture was warmed and then quenched with hydrochloric acid (1 N, 50 mL) (Table 1). For both methods of hydrolysis the phases were separated, and the aqueous phase was extracted with ether. The collected organic phases were washed with NaCl solution, dried over $MgSO_4$, filtered, and distilled or recrystallized. The purity and identity of the known carbonyl compounds (Table 2) were determined by gas chromatography and ^1H NMR spectroscopy.

The Pentagonal Bipyramid as Fundamental Structure for Compounds with the Coordination Number Seven**

By *Ali-Reza Mahjoub, Thomas Drews,* and *Konrad Seppelt**

Tetrahedrons and octahedrons are the commonest polyhedral shapes for molecules with the coordination numbers 4 and 6.[1] In the case of coordination number 5 the principle geometry is the trigonal bipyramid, at least for homoleptic compounds. Here, however, it must be borne in mind that a square-pyramidal structure often has only marginally higher energy, which leads to the known intramolecular rearrangements.[2] A molecule AB_7 has three potential ideal geometries: the pentagonal bipyramid, (1:5:1 structure), the capped octahedron (1:3:3 structure), and the capped trigonal prism (1:4:2 structure) (Fig. 1). The theoretical treatment of this structural problem—considering the electrostatic ligand repulsions as the only determining factor—shows that the 1:3:3 structure is energetically most favorable, followed by the 1:4:2 and 1:5:1 structures.[3] This theoretical study, however, also reveals that these three structures inter-

convert through changes in angles almost without activation energy, and the pentagonal bipyramid and the capped trigonal prism are saddle points only a little higher on the energy surface.[3]

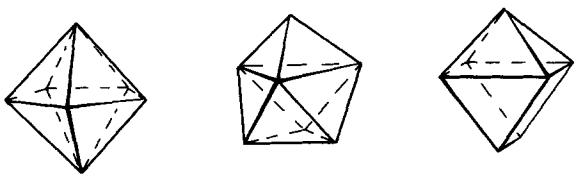

Fig. 1. The three polyhedrons of homoleptic compounds with coordination number 7 that are lowest in energy: pentagonal bipyramid (left), capped octahedron (center), capped trigonal prism (right).

A very small selection of compounds with the coordination number 7 are known whose structures are minimally affected by other effects. If the choice is limited to compounds of the main group elements to minimize the influence of d orbitals, and if, moreover, complications due to nonbonding electron pairs and lattice energy are to be avoided, the only remaining possibility is IF_7. In the gaseous state this is, without doubt, pentagonal bipyramidal,[4] although the structural data is imprecise. In particular, the important question of whether this homoleptic molecule has strict D_{5h} symmetry or whether it shows certain systematic deviations (puckering) cannot be answered at present. The electron diffraction data suggest a nonideal structure. The structure of IF_7 in the crystal has likewise not been unambiguously elucidated. In the solid state a complicating factor is the plastic phase containing disordered molecules, which transforms into an ordered phase only at $-120\,^{\circ}C$.[5]

We set ourselves the goal of solving the structural problem of substances with coordination number 7 by looking at tellurium compounds, of which TeF_7^- is already known.[6] The possible distortion of a fundamental structure by interionic interactions was to be decreased by the use of the large $(CH_3)_4N^+$ ion as counterion. The existence of $(CH_3)_4N^+TeF_7^-$ was demonstrated by the ^{125}Te and ^{19}F NMR spectra in CH_3CN.[6c, d] However, since all seven fluorine atoms are magnetically equivalent, the molecule is fluctional in solution. Studies with vibrational spectroscopy suggest, in analogy to IF_7, a pentagonal bipyramidal structure.[6c, d]

Large single crystals of $(CH_3)_4N^+TeF_7^-$, prepared from $(CH_3)_4N^+F^-$ and TeF_6, are easily grown, but are severely disordered because of the almost spherical shape of cation and anion.[7] This disorder can be restricted to (parts of) the anion by particularly slow crystal growth. The crystal structure analysis shows very clearly the presence of a pentagonal bipyramidal structure with shorter axial Te–F bond lengths than equatorial ones, but also the distinct distortion of the equatorial flourine atoms from a perfect planar arrangement (Fig. 2). The fourfold disorder of these fluorine atoms throws doubt on their positions; thus an equatorial fluorine atom in Figure 1 represents only the electron density of 21/4 electrons in the vicinity of the 52 electrons of the tellurium atom.

To prove conclusively the important statement on nonplanarity of the equatorial positions in the pentagonal bipyramid, the system was modified. Substituted tellurium(VI) fluorine compounds such as CH_3OTeF_5,[8] *trans*-[9] and *cis*-$(CH_3O)_2TeF_4$,[8] $(CH_3)_2NTeF_5$,[10] *cis*-$[(CH_3)_2N]_2TeF_4$,[10] $F_5Te(O)_nTeF_5$ ($n=1$,[11] 2[12]), and TeF_5Cl[13] were also allowed to react with $(CH_3)_4N^+F^-$ [Eq. (a) and (b)]. In two cases ^{19}F and ^{125}Te NMR spec-

$$CH_3OTeF_5 + F^- \longrightarrow CH_3OTeF_6^- \xrightarrow{25\,^{\circ}C} CH_3F + TeF_5O^- \qquad (a)$$

$$trans\text{-}(CH_3O)_2TeF_4 + F^- \longrightarrow trans\text{-}(CH_3O)_2TeF_5^- \xrightarrow{>0\,^{\circ}C} \text{decomposition} \qquad (b)$$

troscopy revealed sevenfold coordination. In all other cases only decomposition to TeF_5^-, TeF_7^-, and $TeOF_5^-$ was observed.

In the ^{125}Te NMR spectrum the anion $CH_3OTeF_6^-$ shows coupling to six equivalent fluorine atoms as well as to three protons; therefore this anion is also fluxional (Fig. 3). Because of the distortion of the high symmetry by the methoxy group, the compound $(CH_3)_4N^+CH_3OTeF_6^-$ crystallizes without disorder or twinning (Fig. 4). The methoxy group is

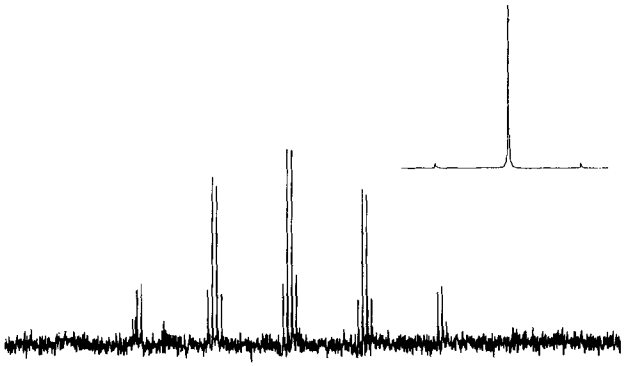

Fig. 3. ^{125}Te NMR spectrum of the $CH_3OTeF_6^-$ ion in CH_3CN at $-10\,^{\circ}C$. $\delta = -332.8$. The inset shows the ^{19}F NMR spectrum.

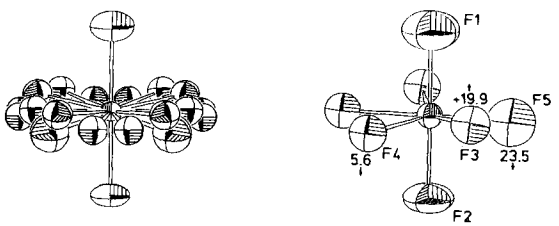

Fig. 2. Crystal structure of the TeF_7^- ion. Left: fourfold disordered model; right: one possible arrangement. Te–F1 178.8(16), Te–F2 179.1(17), Te–F3 186.1(21), Te–F4 183.2(20), Te–F5 190.3(39) pm. The numbers at the equatorial fluorine atoms give the distance in pm from the ideal equatorial plane.

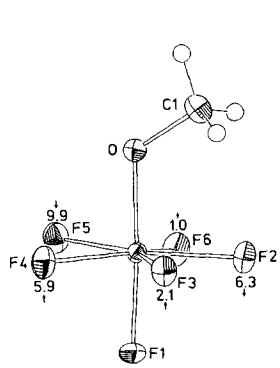

Fig. 4. Crystal structure of the $CH_3OTeF_6^-$ ion. The numbers at the equatorial fluorine atoms give the distance in pm from the ideal equatorial plane. Te–F1 182.2(3), Te–F2 190.9(2), Te–F3 192.3(2), Te–F4 191.2(2), Te–F5 190.5(2), Te–F_6 191.6(2), Te–O 185.8(3) pm; O-Te-F1 176.7(1), Te-O-C1 121.7(3)°.

in an axial position, in complete accord with the electron pair repulsion model: this position enables better space filling. The deviation of the O-Te-F_{ax} angle of 180 °C can, without doubt, be explained by the bent structure of the methoxy group. Again the equatorial Te–F bonds are longer than the axial bond, and the equatorial fluorine atoms lie distinctly off the ideal plane. This structural analysis is precise enough for the latter statement to be valid.

The crystal structure analysis of *trans*-$(CH_3O)_2TeF_5^-$ shows the oxygen atoms in the biaxial position (Fig. 5), as expected from the preceding discussion. Interestingly, in the solid state the anion occurs in both the *syn* and the *anti* conformation with respect to the methoxy groups. In both cases the equatorial fluorine atoms deviate from the ideal plane, and in slightly different ways, influenced here also by the orientation of the methoxy groups. The latter also determine the deviation from linearity of the vertical axis of the molecule.

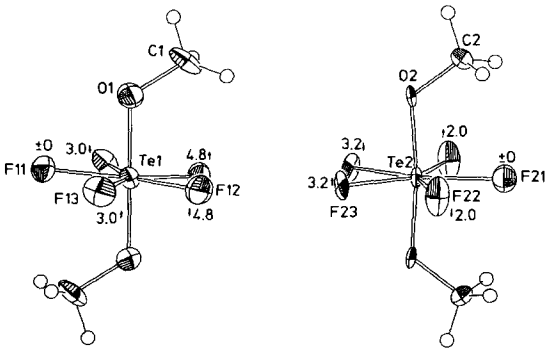

Fig. 5. Crystal structure of the two *trans*-$(CH_3O)_2TeF_5^-$ ions. The numbers at the equatorial fluorine atoms give the distance in pm from the ideal equatorial plane. Left: Te1–F11 192.1(5), Te1–F12 191.8(3), Te1–F13 192.6(3), Te1–O1 187.2(4) pm; O1-Te1-O1′ 180.6(2), Te1-O1-C1 119.6(4)°. Right: Te2–F21 196.3(4), Te2–F22 193.5(3) Te2–F23 194.0(3), Te2–O2 184.7(4) pm, O2-Te2-O2′ 172.8(2), Te2-O2-C2 124.1(3)°.

For *trans*-$(CH_3O)_2TeF_5^-$ it is not possible to prove that the anion is fluctional from NMR spectroscopy, because all fluorine atoms are equivalent by symmetry, if free rotation about the tellurium–oxygen bond is assumed.

The following preliminary structural principles for compounds with coordination number 7 can be deduced:

1) The fundamental structure of a homoleptic compound with coordination number 7 is the pentagonal bipyramid in which the bonds to the axial substituents are shorter than those to the equatorial ones. In the case of nonidentical ligands, smaller substituents take up equatorial positions.

2) When identical or very similar substituents are present, the pentagonal bipyramid is never rigid, with the exception of IOF_6^-: in this case the oxygen atom avoids an equatorial position because of the substantial double-bond character of the iodine–oxygen bond and therefore hinders the intramolecular exchange processes.[7]

3) An ideal pentagonal bipyramid is never achieved. That is, as a result of the repulsion among the spatially confined equatorial positions, this part of the molecule is distorted from planarity. The slightly greater repulsive energy of a pentagonal bipyramid compared with that of the capped octahedron can thus be accommodated while the highest symmetry is still approximately maintained. The highest possible symmetry has the arrangement that requires the fewest parameters to describe it: an (ideal) pentagonal bipyramid requires two, a capped octahedron five, and a capped trigonal prism five. As the highest symmetric arrangement is also the commonest for compounds with 5 (trigonal bipyramid) and 8 (square Archimedean antiprism[7]) as coordination number, this construction principle seems to be general.

Experimental Procedure

TeF_6, CH_3OTeF_5 [8], *trans*- [9] or *cis*-$(CH_3O)_2TeF_4$ [8], were condensed into a Teflon FEP tube that contained $(CH_3)_4N^+TeF^-$ [14] partly dissolved in CH_3CN. Crystals of $(CH_3)_4N^+F_7^-$ were obtained by heating to +40 °C and slow cooling over weeks to −18 °C. $(CH_3)_4N^+CH_3OTeF_6^-$ was dissolved at room temperature and cooled to −18 °C within a few hours to prevent decomposition. $(CH_3)_4N^+$-*trans*-$(CH_3O)_2TeF_5^-$ crystallizes from relatively concentrated solutions in the form of large, rectangular, colorless crystals. In each case a suitable crystal was placed on a CAD-4 diffractometer ($Mo_{K\alpha}$, graphite monochromator) with a special apparatus [15].

$(CH_3)_4N^+TeF_7^-$: $a = 894.7(1)$, $c = 623.1(1)$ pm, $V = 498.8 \times 10^6$ pm^3, −158 °C. *P4/nmm* (no. 129), $Z = 2$. In the range $2° < \theta < 35°$, 2479 measured reflections ($\pm h$, $+k$, $+l$, ω-2θ scan), 652 independent reflections, 620 reflections with $F \geq 3\sigma(F)$, $\mu = 31.49$ cm^{-1}, full matrix, equatorial fluorine atoms isotropic, fourfold disordered, other atoms anisotropic. SHELXS, $R = 0.062$, $Rw = 0.046$. The calculation with the twinning program SFLS [16] (*Pmmn*, no. 59) with remaining twofold disorder according to the twinning law (010)(−100)(001) yields no other results. For other physical properties see ref. [5c,d].

$(CH_3)_4N^+CH_3OTeF_6^-$: $a = 853.4(2)$, $b = 628.7(2)$, $c = 2002.5(7)$ pm, $\beta = 94.25(2)°$, $V = 1071.4 \times 10^6$ pm^3, −154 °C, $P2_1/c$, $Z = 4$. In the range $2° < \theta < 25°$, 2125 measured reflections, ω-θ scan, $\pm h$, $+k$, $+l$, 1870 independent reflections, 1621 reflections with $I \geq 3\sigma(I)$, $\mu = 29.2$ cm^{-1}, full matrix, SHELXS, $R = 0.027$, $Rw = 0.020$, all atoms anisotropic. ^{19}F NMR (CH_3CN): $\delta = 14.2$, singlet; ^{125}Te NMR: $\delta = -332.8$, (H_6TeO_6/H_2O), $J(Te,F) = 2630$ Hz, septet, $J(Te,H) = 148$ Hz, quartet. Raman (cryst.) $\tilde{\nu}$[cm^{-1}] = 956(s), 950(s), 846(w), 760(w), 760(vs), 674(w)m 630(w), 597(s), 581(w, Sch), 566(w), 527(w), 458(m), 379(m), 325(w), 206(w); IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1229, 1014(w), 955(m,Sch), 947(s), 842(m), 630(m), 459(m) cm^{-1}.

$(CH_3)_4N^+$-*trans*-$(CH_3O)_2TeF_5^- \cdot 2CH_3CN$: $a = 1448.1(4)$, $b = 1764.5(3)$, $c = 2693.9(9)$ pm, $V = 6883.3 \times 10^6$ pm^3, −145 °C, *Ibca* (no. 73), $Z = 16$. In the range $2° < \theta < 25°$, 4774 measured reflections, 2996 independent reflections, 2702 reflections with $F \geq 3\sigma(F)$, $\mu = 31.49$ cm^{-1}, full matrix, SHELXS, $R = 0.044$, $Rw = 0.035$, all atoms anisotropic. ^{19}F NMR (CH_3CN): $\delta = 10.3$, singlet; ^{125}Te NMR: $\delta = -304.3$, $J(Te,F) = 2422$ Hz, sextet, $J(Te,H) = 148$ Hz, septet.

Semiconductor-Catalyzed Photoaddition of Cyclic Enol Ethers to 1,2-Diazenes**

By *Ronald Künneth, Christian Feldmer,* and *Horst Kisch**

Suspensions of inorganic semiconductors such as TiO_2 and CdS have in recent years found increased application as photocatalysts in the synthesis of organic compounds. Potentially useful preparative reactions include oxidations,[1] reductions,[2] cyclodimerizations,[3] and isomerizations,[4] which usually lead to known products. We now show that ZnS and CdS powder photocatalyze the linear addition of cyclic enol ethers to 1,2-diazenes to afford hitherto unknown hydrazine derivatives.

On irradiation ($\lambda \geq 290$ nm) of a suspension of ZnS in a solution of 1,2-diphenyldiazene and 3,4-dihydro-2*H*-pyran (3,4-DHP) in methanol, the initially deep orange mixture decolorizes completely. The major reaction is an addition of 3,4-DHP to the diazene, in which the hydrazines **1** are formed (Scheme 1). Only after 20% conversion can 1,2-diphenylhydrazine be detected as minor product. As soon as all the 1,2-diphenyldiazene has been converted, the dehydrodimerization of the excess 3,4-DHP starts with simultaneous hydrogen evolution, in analogy to the known reaction of 2,5-dihydrofuran (2,5-DHF).[5] In addition the product **1a** decomposes on longer exposure times. The yield of **1a**, determined by HPLC at the end of the reaction, is 65%, but after isolation and two recrystallizations it decreases to 30%. When the reaction is performed without addition of ZnS, only a *cis/trans* isomerization of the diazene component takes place.

Analogous to 1,2-diphenyldiazene, 1,2-di-*p*-tolyldiazene and 1-*tert*-butyl-2-phenyldiazene react to form the adducts **1b** and **1c**, respectively. When 3,4-DHP is replaced by 2,3-dihydrofuran or 2,5-DHF, **1d** is isolated in 20% yield. According to HPLC, linear addition products are also obtained with 4,7-dihydro-1,3-dioxepin and cyclohexene. However, if 4,5-dihydro-2-methylfuran is used, 1,2-diphenylhydrazine forms as major product beside traces of the addition product. Saturated ethers like THF or 1,4-dioxane, on the other hand, are completely inert and induce no reaction.

The structure of the products is deduced from mass spectrometric data, as well as one- and two-dimensional ^{1}H and ^{13}C NMR spectra (see Table 1). The ^{13}C NMR signals of the enol ether group in **1a** have typical chemical shifts (δ = 148.3, 99.2); the coupling of the protons at C5 (for numbering see Scheme 1) with those on C1 and C4 are obtained unambiguously from the ^{1}H–^{1}H COSY spectra, which show that the new C-N bond is formed regioselectively at the C1 position of the substrate R_3H. Furthermore, in the reaction of 1-*tert*-butyl-2-phenyldiazene the addition of 3,4-DHP occurs regioselectively at the phenyl-substituted nitrogen atom; this follows from the chemical shift of the NH protons (δ = 3.17). In **1a**, **1b**, and **1c** the resonance signal of this proton is in the δ range of 5.35 to 5.62.

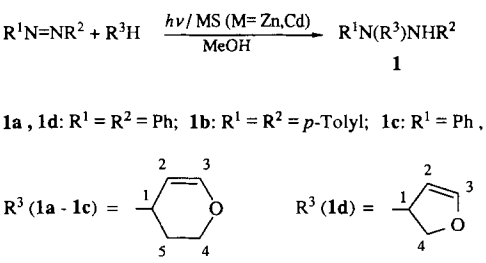
CdS	70	44	65	75

[a] $CDCl_3$, 67.7 MHz. [b] $CDCl_3$, 270 MHz. [c] In cm^{-1}. [d] Yields in %; determination by HPLC.

For all described reactions, CdS can also be used instead of ZnS as heterogeneous catalyst. Since CdS absorbs visible light sufficiently ($\lambda_{bg} \geq 516$ nm), a tungsten lamp ($\lambda \geq 350$ nm) was employed for the irradiation in this case. Within 48 h about 10 mmol of 1,2-diphenyldiazene was converted in the presence of 2 mmol CdS.[6]

The reaction presented here can be explained with the simplified catalytic cycle sketched in Scheme 2. The electron promoted to the conduction band by irradiation of the semiconductor (e^-) drifts to the surface and reduces the diazene to the hydrazyl radical (R^1–$\dot{N}$–NH–R^2). In accord with this step are the findings that protic solvents are essential for the reaction, that the reduction of water is inhibited by the pres-



Scheme 1.

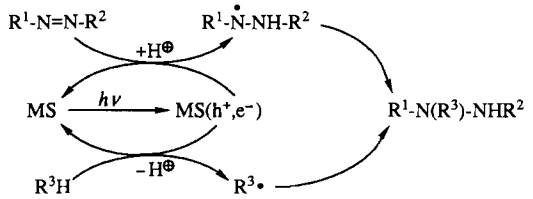
ence of the diazene, and that 1,2-di-*p*-tolyldiazene, which is more difficult to reduce, reacts more slowly than 1,2-diphenyldiazene. The hole in the valence band (h^+) that is created at the same time oxidizes the ether via an intermediate radical cation to an allyl-stabilized radical $^{\bullet}R^3$. Recombination of R^1–$\dot{N}$–NHR^2 with $^{\bullet}R^3$ affords the final product **1**. The intermediacy of the radical $^{\bullet}R^3$ is deduced from the formation of the dehydrodimers R^3–R^3 as side products. Regioisomeric products, which could arise from the allyl rearrangement of the dihydropyranyl radical, have not been detected.



M= Zn, Cd

Scheme 2. Postulated photocatalysis cycle.

The proposed mechanism is supported by the irradiation ($\lambda \geq 290$ nm) of a dilute solution of 1,2-diphenyldiazene and benzophenone in 3,4-DHP. This reaction also affords the addition product **1a** regioselectively in a yield of 30% according to HPLC. In the excited triplet state, benzophenone, which functions as sensitizer in this system, abstracts an H atom from 3,4-DHP.[7] The benzhydryl radicals that result react with 1,2-diazenes to afford the corresponding hydrazyl radicals,[8] which recombine with the dihydropyranyl radicals to form **1a**.

The overall reaction corresponds to an addition of an allylic C–H bond of a cyclic enol ether to a diazene group, a reaction type that was hitherto known only for electron-poor diazenes like azodicarboxylic acid esters.[9] Thus, we have shown for the first time that two different organic substrates can be coupled to form a linear addition product on the irradiated surface of a semiconductor.

Experimental Procedure

All manipulations were conducted under an inert atmosphere of N_2 with dry, N_2-saturated solvents. ZnS and CdS were prepared according to [10] and [11]. General procedure: 1,2-diphenyldiazene (0.5 g, 2.74 mmol), ZnS (0.5 g, 5.13 mmol), 3,4-DHP (3.00 mL, 33.2 mmol), and MeOH (85.0 mL) or 1,4-dioxane/H_2O (70.0/15 mL) were suspended in an ultrasound bath in a Pyrex immersion lamp apparatus for 15 min and thereafter irradiated with a Hg high-pressure lamp (Phillips HPK 125 W) until no more diazene could be detected by thin-layer chromatography (about 15 h). ZnS was filtered off, and evaporation to dryness (25 °C) yielded a yellow oil. **1a** and **1d**: white solids after two recrystallizations from MeOH (yield: 30 and 20% respectively); **1b** and **1c**: after column chromatography (Al_2O_3/petroleum ether) **1b** was isolated (40%) as a pale yellow oil that yields a white solid on crystallization from petroleum ether (10%). **1c** is isolated as colorless oil (30%).

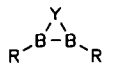
Bis(trisyl)oxadiborirane**

By *Peter Paetzold,* Laurence Géret-Baumgarten,* and *Roland Boese*

Dedicated to Professor Hermann Stetter on the occasion of his 75th birthday

As ab initio calculations show,[1] the diboriranes **1a**–**4a** (R = R′ = H) have a tendency to contract the B–B distance and open the H-B-B angle with increasing electronegativity of Y. This behavior is similar to that of the corresponding heterocyclopropanes and disiliranes.



1, Y = BR′
2, Y = CR_2'
3, Y = NR′
4, Y = O

In the case of the azadiborirane **3**, experimental crystal structure determinations are only available for two derivatives with amino groups bonded to boron.[2, 3] Since the electronic effect of these substituents is strong, a comparison with theoretical predictions makes little sense. An alkyl derivative (**3b**, R = R′ = *t*Bu) proved to be disordered in the crystal.[4] We have now prepared the first oxadiborirane, title compound **4b**, by initially converting the chloroborane **5** into the diboryl oxide **6** [Equation (a)] and, subsequently, **6** into **4b** through reduction with Na/K alloy [Equation (b)].

The colorless crystalline product **4b** shows only one NMR signal in C_6D_6 for each of the atoms H, B, and C.[5] For the structure of the parent compound **4a** determined by ab initio methods, an NMR shift of $\delta(^{11}B) = 67.0$ has been calculat-

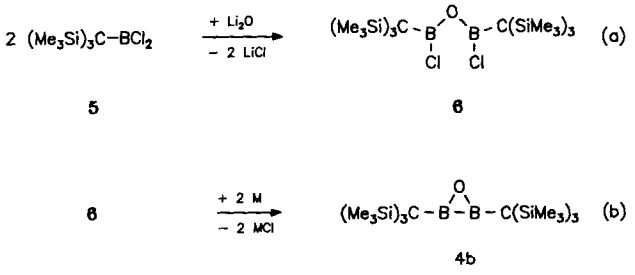
[**] Trisyl = tris(trimethylsilyl)methyl.



ed[6] by the IGLO method, which agrees well with the measured value for **4b** of 65.7. The X-ray crystal structure analysis of **4b**[7] confirms the three-membered ring structure with an almost linear C–B–B′–C′ moiety (Fig. 1). The O atoms are disordered about the crystallographic C_2 axis and are therefore found with half the electron density on each side of the B–B′ bond. This disorder leads to centrosymmetry, which—as the isotropic dislocation parameters show—is strictly valid for the $C(SiMe_3)_3$ groups. The same parameters indicate such a strong displacement of the ring atoms out of the ring plane that an exact description of the ring geometry becomes impossible.

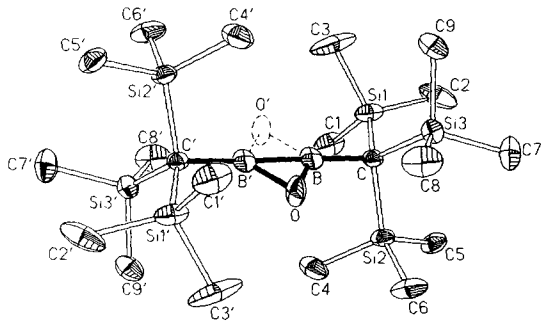


Fig. 1. Molecular structure of **4b** in the solid state. The ellipsoids correspond to 50% probability of electron occupation, hatched and unhatched atoms are equivalent by crystallographic centrosymmetry, the disordered oxygen atom is drawn as an ellipse with dashed outline, and the hydrogen atoms are omitted for clarity. Selected distances [Å] and angles [°] (standard deviations in parentheses): B-B′ 1.601(7), B-O 1.545(5), B′-O 1.510(6), B-C 1.544(4); O-B-B′ 57.4(3), B-O-B′ 63.2(3), C-B-O 120.2(3), C-B-B′ 177.7(3).

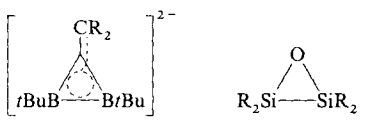
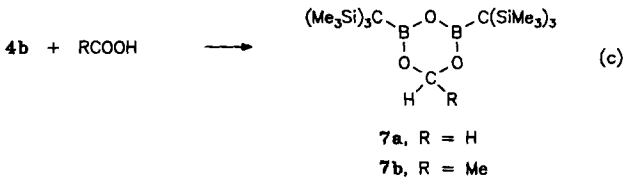
In spite of disorder in the region of the B–B′ bond, this bond length can be determined with satisfactory accuracy to 1.60 Å. It is almost as short as the B–B bond in anion **A** (1.58 Å; R = $SiMe_3$),[8] which is—to our knowledge—the shortest B–B bond measured up to now. It is noteworthy, in



A **B**

this context, that B–B bond lengths are scattered over a wide range; the B7–B8 distance in $B_{10}H_{14}$ of 2.01 Å,[9] for example, is still considered bonding. The B–B bond distance calculated for **4a** of 1.594 (3-21G) or 1.562 Å (MP2/6-31G*[6]) is close to that measured for **4b**. Theory[1] draws a picture of a diborane(2), RB=BR, that is bridged by an O atom in analogy to an olefin bonded side-on by a transition metal ("σ-bridged π bonding"). In oxadisilirane **B** (R = Mes), which is related to three-membered rings of type **4** through the diagonal relationship in the periodic system, a Si–Si distance of 2.23 Å is found,[10] which is closer in length to a double bond than to a single bond, each of these bond lengths being found in a typical range, in contrast to B–B bonds. Certainly, the short B–B and Si–Si distances of oxadiborirane and oxadisilirane can also be accurately described by a model with bent bonds and no π interaction.[11] The remarkably long B–O distances of 1.545 and 1.510 Å in **4b** do not agree well with those calculated for **4a** (1.409[1] or 1.403 Å[6]) and prove to be drastically longer than the 1.32 Å measured for the open-chain compound, $(RO)_2B–B(OR)_2$ ($(RO)_2$ = $–OCMe_2–CMe_2O–$), that can be used for comparison. Because of the disordered O atoms, the C-B-B′ and B-B′-C′ angles of **4b** (177.7 and 182.3°, respectively) can only be compared with the values of 173.9°[1] and 175.2°[6] calculated for **4a**, insofar as these angles accurately reflect the tendency toward linearization of the chain R–B–B–R on passing from **1** to **4**; the corresponding angles for unknown three-membered ring compounds of type **1** where R = R′ are expected to be 150°.

The oxadiborirane **4b** proves to be quite inert. In contrast to the azadiboriridine **3b** (R = R′ = *t*Bu), it reacts neither with CO,[12] nor with RN_3 (R = Pr, Bu),[13] BH_3,[14] or EtB≡N*t*Bu,[15] and not even with alkynes RC≡CR (R = Et, Me_3Si), whose reaction with the B–B bond of diborane(4) derivatives is considered typical. It is inert even towards O_2 and H_2O. Attempts to cleave the O atom reductively with phosphanes PR_3 (R = Me, Ph) as acceptors left **4b** intact. The only reaction that we could find for **4b** is the oxidative addition of formic or acetic acid in the ratio 1:1 according to Equation (c), in which the crystalline products **7a**, **b** are ob-



7a, R = H
7b, R = Me

tained in yields of 82 or 71%, respectively.[16] Unexpectedly, not the acidic proton, but the carboxyl C atom is oxidizing.

Experimental Procedure

Bis[chloro{tris(trimethylsilyl)methyl}boryl] oxide **6**: Li_2O (0.17 g) was added to a solution of **5** (3.57 g) [17] in THF (30 mL). The mixture was stirred for 10 h at room temperature before the solvent was removed in vacuo, the residue dissolved in pentane (20 mL), and LiCl filtered off. At −80°C **6** crystallized (3.10 g, 95%, m.p. 198°C) [18]. The same product was obtained with a similar procedure from **5** and $NaOSiMe_3$ in the ratio 2:1 (75%).

Bis[tris(trimethylsilyl)methyl]oxadiborirane **4b**: A solution of **6** (3.10 g) in hexane (30 mL) was heated under reflux in the presence of Na/K alloy (3 mL) for 10 h. The excess alloy and alkali-metal salts were filtered off, and the filtrate was evaporated to dryness. Sublimation at 120°C/0.005 Torr afforded **4b** (1.55 g, 57%, m.p. 242°C).

troscopy shows only the intense $S_0 \rightarrow S_2$ transition. Likewise, normally no information can be gleaned from fluorescence spectroscopy about the energetic situation of S_1 in long-chain polyenes such as β-carotene.

Experiments showed that shorter polyenes containing fewer than nine double bonds generally fluoresce from the first singlet state S_1, a state forbidden for absorption, whereas longer carotenoids containing more than eight π bonds, such as β-carotene, show an anti-Kasha emission from the S_2 state.[11] We now report the synthesis of novel, modified carotenoids with nine and eleven π bonds, for which dual fluorescence (that is, emission from the S_1 and the S_2 state) occurs, and thus the energetic level of S_1 can be determined at least approximately.

In the planning of the synthesis of modified, sufficiently photostable carotenoids, we were first guided by the idea of substituting the saturated ethano fragments in lycopene by conjugatively stabilizing carbonyl groups (oxalyl fragments). To achieve this we linked two C_4 end components with a C_n central component (dialdehydes **1**–**4**) according to the synthesis principle $C_4 + C_n + C_4 = C_{n+8}$. As shown in Figure 1, the diones **7**–**10** and the tetrones **11**–**14** can be obtained in this way (Table 1). Whereas the color of the diones **7**–**10**

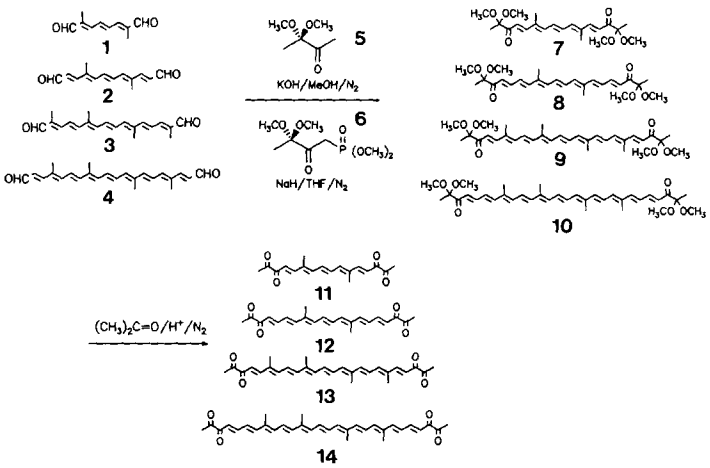

Fig. 1. The synthesis of tetramethoxydiapocarotenediones **7**–**10** and diapocarotenetetrones **11**–**14**. Compounds **5** or **6** may be used to provide the carbonyl groups.

Dual Fluorescence of Novel Modified Carotenoids**

By *Hans Bettermann,* Martin Bienioschek, Hans Ippendorf,* and *Hans-Dieter Martin**

Carotenoids are counted among the most important and also most numerous naturally occurring chromophores.[1, 2] In the photosynthesis of higher plants, algae, and bacteria they assume a dual role: a) they absorb energy as accessory pigments (antenna function); thus they aid in energy transfer and b) they quench the triplet state of various chlorophylls or remove reactive or excited oxygen species.

The key to the understanding of the energy transfer processes in carotenoids is a knowledge of their lowest excited states, in particular the states S_1 (2^1A_g), S_2 (1^1B_u), and T_1 (C_{2h} symmetry assumed). Unfortunately little is known about the energy of S_1 and T_1, in spite of intensive spectroscopic investigations:[3–10] conventional absorption spec-

14: M.p. 240 °C, MS(70 eV): m/z 484 (M^+), UV/VIS($CHCl_3$): λ[nm](ε) = 549 (112000), 580 (110000)

[a] All compounds have the correct elemental analysis. The compounds were purified by column chromatography, and their purity tested by thin-layer chromatography.

varies from yellow to dark red, the tetrones **11**–**14** are orange to reddish blue. The photostability of the diones **7**–**10** at radiant flux densities in the order of 10^{22} photons $cm^{-2}s^{-1}$ is good enough for spectroscopic studies (see Experimental), but the tetrones **11**–**14** proved unexpectedly to be not persistent enough under the same conditions. In the following, therefore, the results of fluorescence spectroscopy on diones **8** and **9** will be described in detail.

In the absorption spectra of unsubstituted all-*trans* polyenes, or those with identical substituents as end groups, the visible transition with lowest energy is the $S_0 \rightarrow S_2$ band, since the $S_0 \rightarrow S_1$ transition is symmetry forbidden and therefore cannot be detected in conventional absorption spectroscopy. The S_1 state of all-*trans* polyenes (point group C_{2h}), like the ground state, belongs to the symmetry species A_g. This was confirmed by two-photon spectroscopy.[10] The substitution of terminal double bonds in polyenes by carbonyl groups changes the position of the absorption bands by only a few nanometers. The additional $n \rightarrow \pi^*$ states cannot influence the fluorescence because, as experience shows, they are substantially more hypsochromic (about 300–400 nm).

Figure 2 shows the absorption spectra of compounds **8** and **9** in chloroform at room temperature. That the vibronic structure of the $S_0 \rightarrow S_2$ absorption band arises from at least two vibrational progressions follows from the second derivative. However, only the C–C stretching vibrational progressions (**8**: 1218 cm^{-1}, **9**: 1172 cm^{-1}) are unambiguously determinable. The two clearly visible vibronic bands in the spectrum of **8** are assigned to the transitions $0 \rightarrow 1$ (484 nm, 20640 cm^{-1}) and $0 \rightarrow 2$ (457 nm, 21856 cm^{-1}); the $0 \rightarrow 0$ transition lies at 19422 cm^{-1} (515 nm). This is in accord with the position of the origin of the fluorescence ($0 \rightarrow 0$ transition) of **8** and the only slight shift of the $0 \rightarrow 0$ transition in absorption and fluorescence for carotenoids such as β-carotene.[11] Also in agreement with the origin of the fluorescence spectrum to be discussed later, the first visible vibronic transition in the spectrum of compound **9** at 18868 cm^{-1} (530 nm) is, however, assigned to the $0 \rightarrow 0$ transition of the C–C stretching vibrational progression.

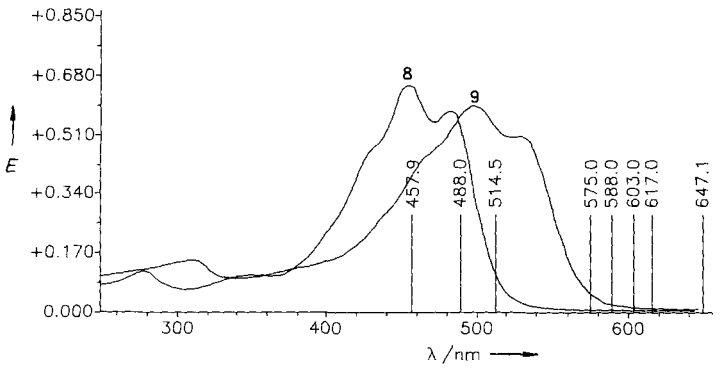

Fig. 2. Absorption spectra of compounds **8** (8.2×10^{-6} M) and **9** (6×10^{-6} M), dissolved in chloroform. E = extinction.

Figure 3 shows the fluorescence spectra of **8** and **9**. Each have two fluorescence maxima (**8**: 18492 cm^{-1}, 540 nm and 13600 cm^{-1}, 735 nm; **9**: 17492 cm^{-1}, 571 nm and around 13500 cm^{-1}, 740 nm). The less intense fluorescence signals overlap with the Raman signals of the solvent and the substance under investigation. The two maxima are the result of different emission transitions. The maximum at higher energy is assigned to the $S_2 \rightarrow S_0$ emission and that at lower energy to the $S_1 \rightarrow S_0$ emission. This dual fluorescence is supported by the following findings:

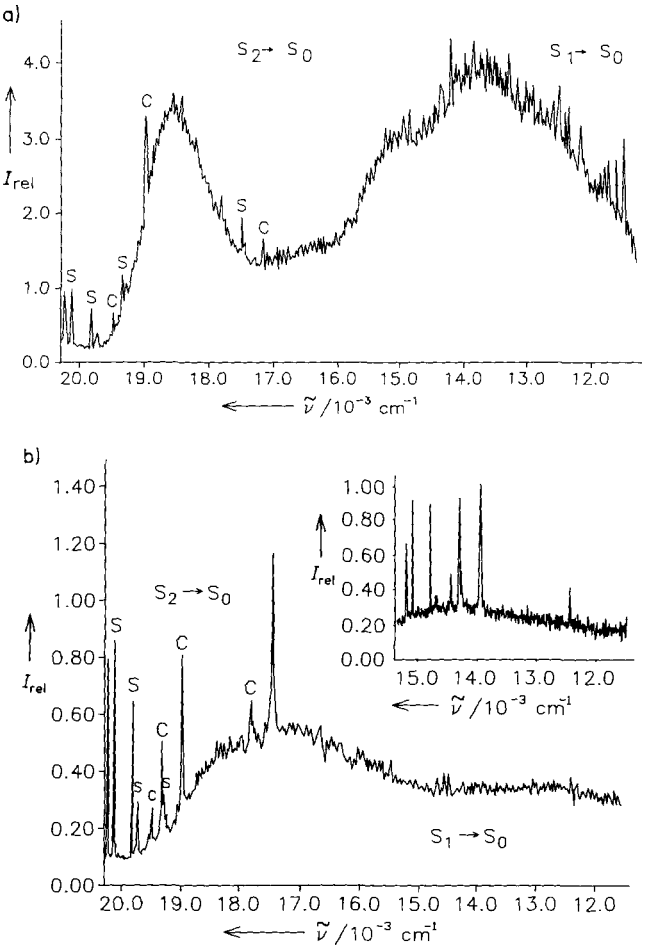

Fig. 3. Fluorescence spectra of **8** (a) and **9** (b) in chloroform (10^{-5} M, excitation wavelength λ_{ex} = 488.0 nm). C: Raman signals of the compound under investigation; S: Raman signals of the solvent. The inset in (b) shows the $S_1 \rightarrow S_0$ fluorescence of **9** in chloroform (10^{-3} M) after excitation with a krypton ion laser (λ_{ex} = 647.1 nm)

- On excitement with frequencies smaller than the $S_0 \rightarrow S_2$ absorption, the fluorescence at lower energy can be observed separately. If **8** is excited with light of wavenumbers 17391 (575), 17007 (588), 16584 (603), and 16207 cm^{-1} (617 nm), the red-shifted luminescence band appears, irrespective of the energy of the excitation irradiation. This proves that the fluorescence is from a single state. Likewise **9** shows one luminescence on excitement beyond the $S_0 \rightarrow S_2$ absorption band determined from the UV/VIS spectrum; its maximum lies at approximately 14000 cm^{-1} (714 nm; inset in Fig. 3b). The Raman signals in the spectra of both compounds show a distinct resonance enhancement, which confirms the direct excitement into the S_1 state.
- For small concentrations (10^{-7}–10^{-8} M) the long-wavelength emission band is missing. This concentration dependence indicates that the two fluorescence emissions do not proceed from the same excited state. The nonlinear concentration dependence of the ratio of the two emission bands excludes the simultaneous presence of excimer and monomer fluorescence. Presumably the different concentration dependence of the $S_1 \rightarrow S_0$ and $S_2 \rightarrow S_0$ fluorescence is attributable to different intermolecular radiationless deactivation.

The $S_2 \rightarrow S_0$ fluorescence band of **8** does not show the mirror image of the $S_0 \rightarrow S_2$ absorption band. This points to different geometries for the S_0 and S_2 states. The $0 \rightarrow 0$ transition of the $S_2 \rightarrow S_0$ fluorescence is found in the range 19200–19500 cm^{-1} (520–512 nm), while the $0 \rightarrow 0$ transition of the $S_1 \rightarrow S_0$ fluorescence can be assigned to the band at 16200 cm^{-1} (617 nm) on the grounds of the fluorescence excitation spectra.

The origins ($0 \rightarrow 0$ transitions) of the $S_2 \rightarrow S_0$ and the $S_1 \rightarrow S_0$ fluorescence of compound **9** are estimated to be 19000 ± 200 and 15200–15400 cm^{-1}, respectively.

Dual fluorescence in linear conjugated polyenes was hitherto observed only for all-*trans*-tetradecaheptaene[11] and fucoxanthin (nine conjugated π bonds).[12] In condensed phases the long-chain polyenes show $S_2 \rightarrow S_0$ fluorescence preferentially, whereas $S_1 \rightarrow S_0$ emission occurs for short-chain polyenes. This general observation is related to the exponential decay of the nonradiative deactivation rate when the $S_1 \rightarrow S_2$ energy difference increases.[13] For short-chain polyenes with smaller $S_1 \rightarrow S_2$ energy differences (e.g., 4900 cm^{-1} for dodecahexaene[11]), predominantly the $S_1 \rightarrow S_0$ fluorescence is observed.

Known compounds that emit from an S_1 and an S_2 state mostly have a large energy difference between these two states (e.g., 14000 cm^{-1} for azulene[14]). The dual fluorescence observed here for compound **8**, which has a small $S_1 \rightarrow S_2$ energy difference (3000–3300 cm^{-1}) is precisely for this reason very remarkable.

In the longer chain carotenoid **9** the $S_1 \rightarrow S_2$ difference was measured to be 3400–4000 cm^{-1}. This is in accord with the fact that $\Delta E(S_2\text{–}S_1)$ increases with increasing chain length.[11] Since for β-carotene (eleven π bonds) $\Delta E(S_2\text{–}S_1)$ is not known exactly, but is thought—not uncontested—to lie at approximately 3500 cm^{-1},[15] it is interesting to note that the carotenoid **9** (likewise containing eleven π bonds) yields an experimental value in this range.

Experimental Procedure

The emission spectra were generated with excitation from an argon ion laser (488.0 nm, 250 mW), a krypton ion laser (647.1 nm, 300 mW), and a dye laser (Rhodamin 6G, 575, 588, 603, and 617 nm), and measured with a grating spectrometer (Jarrell-Ash, model 25-400; Czerny-Turner double monochromator, 1 m focal length; Peltier-cooled photomultiplier RCA C31034 combined with a photon counter [16]). The measurements were performed with a constant mechanical slit width. The spectral slit width was 9 cm^{-1} (488.0 nm) and 6 cm^{-1} (647.1 nm). The spectra were recorded with a scan speed of 300 $cm^{-1}min^{-1}$ (100 $cm^{-1}min^{-1}$ for excitement with the dye laser) at a step size of 2.25 cm^{-1} (1 cm^{-1} for excitement with the krypton ion laser and the dye laser).

The samples were measured in a rotating cuvette to avoid local heating by the focused laser beam [17]. Since the path of the focused beam was tangential to the inner wall of the cuvette, the fluorescence signals could not be reabsorbed. The luminescence was observed at an angle of 90° to the excitation beam. The signal detection and processing was computer-controlled [18]. The spectra were corrected as follows:

- At the same time that the data was recorded, a photodiode measured the laser power to make fluctuations visible.
- The spectra were corrected to account for the spectral sensitivity curve of the monochromator/detector system.
- The decrease in intensity of the exciting light due to the absorption by the sample solution was compensated by normalization of the spectra with a Raman signal of the solvent.

To monitor the photochemical stability of the samples, UV/VIS spectra were recorded before and after each measurement on a diode-array spectrophotometer (Hewlett-Packard, Model 8452A). After 30 min irradiation (λ_{ex} = 488.0 nm, 250 mW, 10^{-5} M solution) the photochemical conversion was 4%.

Ten-Membered Ring Enediynes with Remarkable Chemical and Biological Profiles**

By *K. C. Nicolaou*, Erik J. Sorensen, Robert Discordia, Chan-Kou Hwang, Robert E. Minto, Kamal N. Bharucha,* and *Robert G. Bergman**

We report the synthesis and study of a novel series of ten-membered ring enediynes[1, 2] with geminal dimethyl groups flanking the enediyne moiety as protecting devices.[3] These compounds, which are analogues of more complex anticancer antibiotics, exhibit novel rates of cycloaromatization and DNA-cleaving properties.

The critical steps in the synthesis of molecules **2**–**4** (Scheme 1) from dialdehyde **1**[4] are illustrated in Scheme 1; additional details of the synthesis and characterization will be provided in the full account of this work. The configurations of the conformationally rigid compounds **2** and **3** were assigned by NMR spectroscopy with chiral shift reagents and confirmed by X-ray crystallographic analysis of the *trans* isomer **2** (Fig. 1).

Molecular modeling studies suggested a nearly orthogonal arrangement of the two carbonyl groups in dione **4**, an inference supported by its IR spectrum, which showed a C=O band at $\tilde{\nu}_{max} = 1708$ cm^{-1} (see Table 1). The ^1H NMR spec-

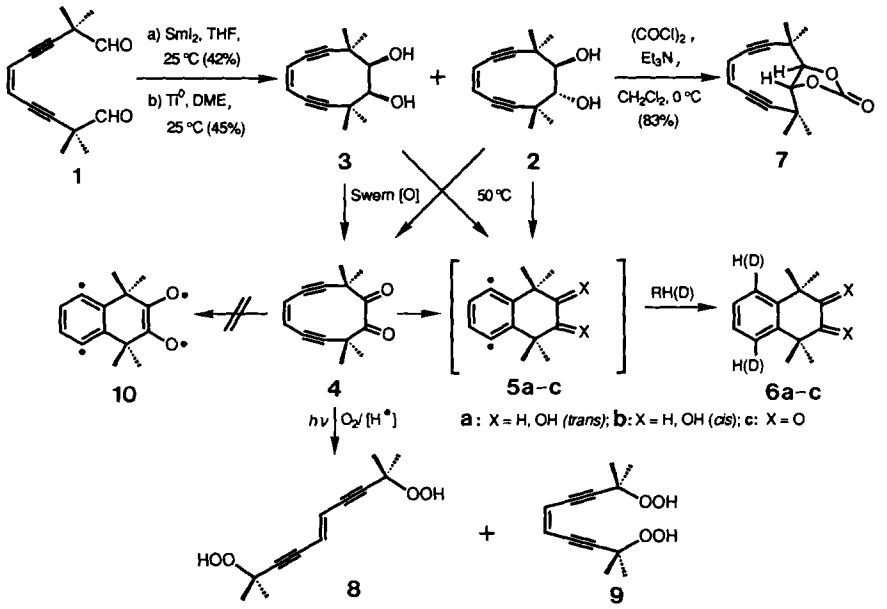

Scheme 1. Synthesis and chemistry of ten-membered ring enediynes **2**–**4**. Under reaction conditions a, **2** and **3** were formed in a 20:1 ratio; under reaction conditions b (slow addition of **1** to Ti°), in a 1:2.6 ratio. For important data of compounds **2**–**4** and **7** see Table 1.

trum of **4** is temperature dependent and suggests that an exchange process involving interconversion of two degenerate ring conformations occurs. Two sharp resonances for the methyl groups at $\delta = 1.62$ and 1.43 observed below $-60\,^{\circ}C$ coalesced to a singlet at $-3.0\,^{\circ}C$. An Arrhenius plot provided $\Delta H^{\neq} = 12.9\ kcal\,mol^{-1}$ and $\Delta S^{\neq} = +3.2\ cal\,K^{-1}\,mol^{-1}$ as thermodynamic parameters for this interconversion.

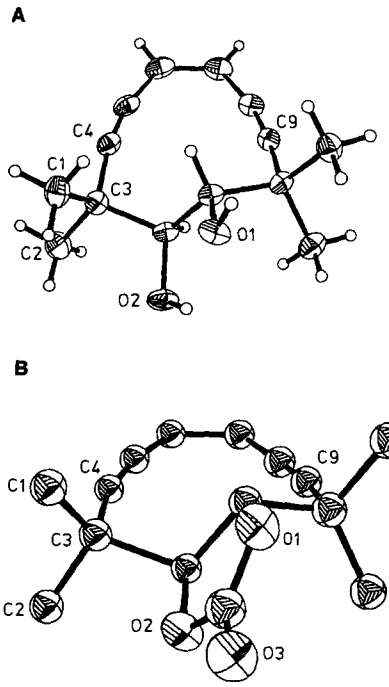

Fig. 1. ORTEP representation of compounds **2** (A) and **7** (B). The C4–C9 distances are 3.422 and 3.424 Å, respectively.

Thermal cycloaromatization of **2** at temperatures ranging from ambient to 105 °C in 1,4-cyclohexadiene/THF gave 50–75% isolated yields of **6a**. In [D_8]THF, a mixture of [D_2]**6a** (55%) and products resulting apparently from coupling with solvent-derived radicals (45%) were formed. The rate laws of this reaction were found to be first order in **2** and independent of the solvent, concentration of **2**, and concentration of hydrogen atom donor ($\Delta H^{\neq} = 30.2\ kcal\,mol^{-1}$ and $\Delta S^{\neq} \approx 9.7\ cal\,K^{-1}mol^{-1}$ temperature range 60–105 °C). Interestingly, the *cis* isomer **3** cyclized faster in [D_8]toluene ($t_{1/2} \approx 4$ h at 50 °C) than the *trans* isomer **2** ($t_{1/2} \approx 22$ h at 50 °C); **6a** was obtained in 49% yield in both cases. Significantly higher temperatures (75–100 °C) were required to convert dione **4** to the bicyclic aromatic diketone **6a**. CIDNP (Chemically Induced Dynamic Nuclear Polarization) was observed when the cyclization of **2** was carried out in the probe of an NMR spectrometer between 70 and 100 °C in [D_8]THF, [D_6]acetone, or [D_3]MeCN. Kaptein's rules[5] suggest that **2** cyclizes via singlet diradical **5a**, in agreement with earlier results for acyclic enediyne systems.[6]

Carbonate **7**, a crystalline solid (Fig. 1 B), interested us since we expected the second ring to act as a "locking device" that would prevent cycloaromatization. Indeed **7** proved to be completely stable at 100 °C for several hours.

Dione **4** was subjected to UV irradiation in the presence of 1,4-cyclohexadiene in an attempt to generate the oxygen-

4: $R_f = 0.20$ (petroleum ether; SiO_2); 35–51% yield; IR (neat) $\tilde{\nu}_{max} = 2984, 2937, 2197, 1708\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$) $\delta = 5.79$ (s, 2H, olefinic H), 1.55 (br.s, 12H, CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) $\delta = 200.9, 122.8, 101.6, 85.8, 43.2, 25.1$; HRMS: *m/z* calcd for $C_{14}H_{14}O_2(M)$, 241.0994, found 241.0995

7: $R_f = 0.35$ (5% ether in petroleum ether); 83% yield; m.p. = 132–134 °C; IR($CHCl_3$) $\tilde{\nu}_{max} = 2978, 2924, 2197, 1805\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$) $\delta = 5.87$ (s, 2H, olefinic H), 4.64 (s, 2H, 2 C*H*OC), 1.43 (s, 6H, CH_3), 1.24 (s, 6H, CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) $\delta = 154.0, 123.0, 103.2, 84.4, 84.0, 36.3, 26.1, 18.4$; HRMS: *m/z* calcd for $C_{15}H_{16}O_3Na$ (M + Na) 267.0997, found 267.0988, HRMS: *m/z* calcd for $C_{15}H_{16}O_3H$ (M+H) 245.1178, found 245.1170

and carbon-centered "multiple warhead" tetraradical **10**, a potentially powerful species for DNA damage. In the event, however, none of the products expected to arise from **10** were formed. Instead, the two novel dihydroperoxides **8** and **9** were isolated in 22 and 10% yield, respectively. The same transformations were also effected, although less cleanly, by thermolysis in the presence of hydrogen atom donors. Quite intriguing is the possibility of the intermediacy of a dioxetene[7] which is presumed to eject the equivalent of ethenedione,[8] perhaps as two carbon monoxide molecules.[9]

Compounds **2** and **3** caused significant DNA cleavage when incubated with φX174 supercoiled DNA at pH 8.5 and 50 °C (Fig. 2). Interestingly, dione **4** caused only slight DNA damage under the same conditions, whereas hydroperoxides **8** and **9** showed, as expected, quite strong DNA-cleaving activities. Based on the chemistry of these systems we presume that whereas the ten-membered ring enediynes **2** and **3** may exert their DNA-cleaving power by cyclization to an aromatic diradical, the open-chain enediynes **8** and **9** may operate by an entirely different mechanism involving the generation of oxygen-centered radicals.

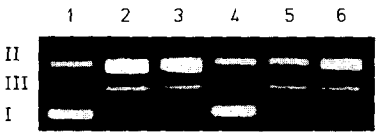

Fig. 2. Interaction of supercoiled DNA with enediynes **2**–**4**, **8**, and **9**. φX174 DNA was incubated for 48 h at 50 °C with the enediynes in buffer (50 mM Tris-HCl, pH 8.5) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; Lane 2: DNA + *cis* diol **3** (5000 μM); Lane 3: DNA + *trans* diol **2** (5000 μM); Lane 4: DNA + dione **4** (5000 μM); Lane 5: DNA + *trans* enediyne **8** (5000 μM); Lane 6: DNA + *cis* enediyne **9** (5000 μM). I–III stand for form I, form II, and form III DNA, respectively.

The described chemistry demonstrates a highly convergent route to conjugated cyclic enediynes, some fascinating stereochemical effects of rigid ten-membered ring systems, the introduction of new "locking devices" to stabilize labile enediynes, and the DNA-cleaving action of a number of new enediynes.

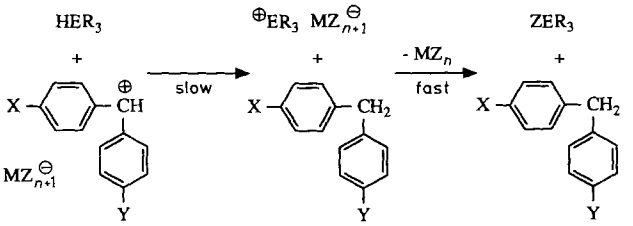
Kinetics of Hydride Transfers from CH, SiH, GeH, and SnH Groups to Carbenium Ions**

By *Herbert Mayr** and *Nils Basso*

Dedicated to Professor George A. Olah on the occasion of his 65th birthday

Hydrides of the group IV elements are important hydrogen sources in radical and ionic reductions.[1–4] While homolytic fissions of these element–hydrogen bonds have been studied intensively,[5] the current kinetic data on ionic hydride-transfer reactions[6–8] do not allow a direct comparison of the reactivity of these compounds toward hydride acceptors. We now report on the kinetics of the reactions of triphenylmethane and of trisubstituted germanes and stannanes with diarylcarbenium ions, and we compare these data with the recently published rate constants for the hydride abstractions from silanes.[6] Because of the huge differences in reactivity, not all experiments could be carried out with the same hydride acceptor; We used linear free energy relationships for a quantitative comparison of these reducing agents.

The recently described photometric method for determining the kinetics of the reactions of diarylcarbenium ions with silanes[6d] was also employed here for the investigation of element hydrides with the general formula HER_3. Since the nature of the counterion (trifluoromethanesulfonate (OTf^-) or $TiCl_5^-$) was found not to affect the rates of the reactions of the bis-*para*-methoxy-substituted benzhydryl cation (p-$MeOC_6H_4)_2CH^+$ with tributylgermane and triphenylstannane, we conclude that under the selected reaction conditions, the counterion is not involved in the rate-determining step, as previously reported for silanes (Scheme 1).



Scheme 1.

In analogy to the reactions of diarylcarbenium ions with alkenes, the reactions of free and paired carbenium ions have identical rates, resulting in a second-order rate law [Eq. (a)], where $[Aryl_2CH^+]$ is the sum of the concentrations of free and paired carbenium ions.

$$d[Aryl_2CH^+]/dt = -k_2[Aryl_2CH^+][HER_3] \quad (a)$$

When the rate constants listed in Table 1 are plotted against the rate constants of the reference reaction previously used, $Aryl_2CH^+$ + 2-methyl-1-pentene,[9] almost parallel lines are obtained (Fig. 1), indicating that the relative reac-

tivities of these element hydrides are almost independent of the electrophilicities of the hydride abstractors (constant selectivity relationship according to Ritchie).[9c, 10] Intersections of these lines may be observed, however, when a very wide range of reactivity is considered: The bis(*para*-dimethylaminophenyl)carbenium ion (*p*-$Me_2NC_6H_4)_2CH^+$, which is 5 to 10 orders of magnitude less electrophilic than the other carbenium ions examined in this study, reacts 11.5 times more slowly with $HGenBu_3$ than with $HSnPh_3$, while $HGenBu_3$ is three to eight times more reactive than $HSnPh_3$ toward the carbenium ions shown in Figure 1.

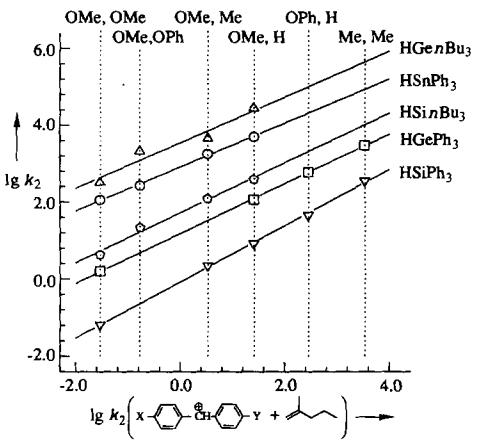

Fig. 1. Correlation of the reactivities (CH_2Cl_2, $-70\,^\circ C$) of substituted diarylcarbenium ions (*p*-XC_6H_4)(*p*-YC_6H_4)CH^+ (*para* substituents X and Y on the upper edge of the graph) versus several hydride donors HER_3 and 2-methyl-1-pentene (reference reaction [9c]).

When these small differences in slopes are neglected, a reactivity scale of hydride donors can be given, which is conveniently based on the reactivities toward the mono-*para*-methoxy-substituted benzyhydryl cation $AnPhCH^+$ (An = *p*-$MeOC_6H_4$) (Table 2). The k_2 value for $HSnnBu_3$ is calculated from the relative reactivities of $HSnnBu_3$ and $HSnPh_3$ toward (*p*-$Me_2NC_6H_4)_2CH^+$. The corresponding rate constant for $HCPh_3$ is derived from the relative reactivities of $HCPh_3$ (Table 1) and $HSiPh_3$ toward (*p*-$ClC_6H_4)_2CH^+$. The latter value, $\lg k_2[HSiPh_3 + (p\text{-}ClC_6H_4)_2CH^+, 70\,^\circ C] = 5.39$, is extrapolated from the correlation of $\lg k_2$ ($HSiPh_3$) with pK_{R^+} of the particular hydride abstractors.[6d]

Table 2 indicates that the decrease of the enthalpy of homolytic bond dissociation (C − H ≳ Si − H > Ge − H > Sn − H) is associated with an acceleration of the hydride and of the hydrogen radical abstractions. Whereas in radical reactions the triphenyl-substituted compounds are generally somewhat more reactive than the trialkyl-substituted ones, in ionic reactions the ratio $k_2(HEBu_3)/k_2(HEPh_3)$ grows with the size of the core atom from less than 1 for HCR_3 to a value of approximately 400 for $HSnR_3$. This trend may be explained by the decreasing ability of the phenyl group to donate π electrons as the size of the central atom increases. The considerably greater influence of the nature of the core atom on the rates of the ionic reactions (compared with the radical reactions) may be caused by the decrease of the ionization potential in the series $R_3C^\bullet$ to $R_3Sn^\bullet$ as well as by a more productlike transition state of the ionic reactions.

Table 2. Comparison of the rates of hydride abstractions to the rates of H$^\bullet$ abstraction from HER_3 and the corresponding bond dissociation energies (BDE).

[RuO(dppz)(tpy)]$^{2+}$: a DNA Cleavage Agent with High DNA Affinity**

By *Nishi Gupta, Neena Grover, Gregory A. Neyhart, Weigen Liang, Phirtu Singh*, and *H. Holden Thorp**

The development of new DNA cleavage agents is of interest for the designing of synthetic restriction enzymes,[1] for an understanding of the structure of DNA,[2] and for pharmaceutical applications.[3] We have recently directed our efforts at investigating functional metal complexes that initiate DNA cleavage by unusual mechanisms,[4] and have reported efficient cleavage of DNA by the dicationic complex **1**[5] (bpy = 2,2′-bipyridine, tpy = terpyridine). **1** was generated via oxidation of **2** [Eqs. (a) and (b)].[6]

$$\underset{\mathbf{2}}{[Ru^{II}OH_2(bpy)(tpy)]^{2+}} \rightleftharpoons [Ru^{III}OH(bpy)(tpy)]^{2+} + e^- + H^+ \quad (a)$$

$$[Ru^{III}OH(bpy)(tpy)]^{2+} \rightleftharpoons \underset{\mathbf{1}}{[Ru^{IV}O(bpy)(tpy)]^{2+}} + e^- + H^+ \quad (b)$$

The DNA cleavage with **1** can be effected either stoichiometrically by addition of **1** to the DNA or electrocatalytically by application of a potential of 0.8 V to a solution of DNA and **2**.[5] In attempts to increase the binding affinity of these agents, we have now prepared the dicationic complex **3** (dppz = dipyridophenazine, see Scheme 1).

$[RuOH_2(dppz)(tpy)]^{2+}$ **3** $[Ru(bpy)_2(dppz)]^{2+}$ **4**

The planar dppz ligand imparts high DNA affinity to the complex **4**.[7] Studies with topoisomerase showed that **4** unwinds DNA by 30°, strongly implicating an intercalative binding mode. Complex **4** has very attractive photophysical properties, but does not exhibit DNA cleavage reactivity. Complex **3** also exhibits a high DNA affinity while retaining the DNA cleavage reactivity of the $Ru^{II}OH_2/Ru^{IV}O$ functionality. Furthermore, the X-ray crystal structure of this complex shows extensive π-stacking of the planar dppz ligand (see Fig. 3), which may provide insight into the high DNA affinity of dppz complexes.

Reaction of $Ru(tpy)Cl_3$ with dppz in the presence of triethylamine affords the complex [RuCl(dppz)(tpy)]Cl. Treatment of an aqueous solution of this complex with $AgClO_4$ leads to the precipitation of **3**-$(ClO_4)_2 \cdot H_2O$, in the form of black crystals suitable for X-ray structure analysis. The complex exhibits a typical $Ru^{II} \rightarrow py(\pi^*)$ metal-ligand charge transfer (MLCT) absorption band with $\lambda_{max} = 482$ nm ($\varepsilon = 12000\ M^{-1}cm^{-1}$). In aqueous solution, the complex is oxidized sequentially to the dicationic Ru^{IV} complex [Eqs. (c) and (d)].

$$\mathbf{3} \rightleftharpoons [Ru^{III}OH(dppz)(tpy)]^{2+} + e^- + H^+ \quad (c)$$

$$[Ru^{III}(dppz)(tpy)]^{2+} \rightleftharpoons \underset{\mathbf{5}}{[Ru^{IV}O(dppz)(tpy)]^{2+}} + e^- + H^+ \quad (d)$$

At pH 7, $E_{1/2}(Ru^{III}/Ru^{II}) = 0.56$ V and $E_{1/2}(Ru^{IV}/Ru^{III}) = 0.62$ V (SCE), compared to 0.49 V and 0.62 V in the case of the complex **2**.[6] The pK_a value of the aqua ligand in **3** is 8.6 compared to a pK_a of 9.7 in **2**.[6] The structure of **3** is shown in Figure 1.[8] The coordination about the Ru center is very similar to that in both $[Ru^{II}OH_2(tmen)(tpy)]^{2+}$ (tmen = *N*,*N*,*N*′,*N*′,-tetramethylethylenediamine)[9] and **2**.[10] Thus, incorporation of the strongly intercalating dppz ligand has not altered the electronic properties of the $Ru^{II}OH_2$ functionality that are vital to the DNA cleavage reactivity.

Complex **3** binds very strongly to DNA. We have determined the binding constants for a series of complexes related to **2** using an electrochemical method based on the cyclic voltammetric currents for the Ru^{III}/Ru^{II} redox pairs of the complexes with and without DNA.[9] When the complex is

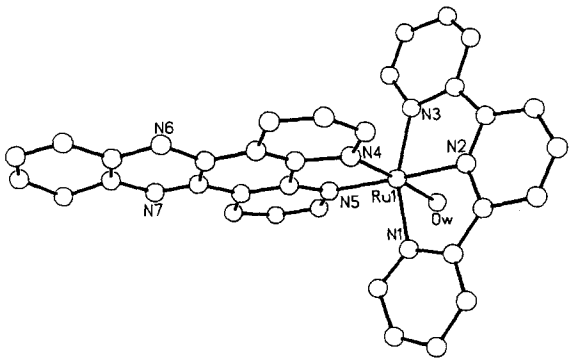

Fig. 1. Structure of **3** in the crystal (counterion ClO_4^-). Hydrogen atoms have been omitted for clarity; unlabeled atoms are carbon. Selected bond lengths [Å] and angles [°]: Ru-N1 2.047(29), Ru-N2 1.998(20), Ru-N3 2.039(28), Ru-N4 2.022(26), Ru-Ow 2.168(24), N1-Ru-N3 159.3(9), N4-Ru-Ow 174.4(8).

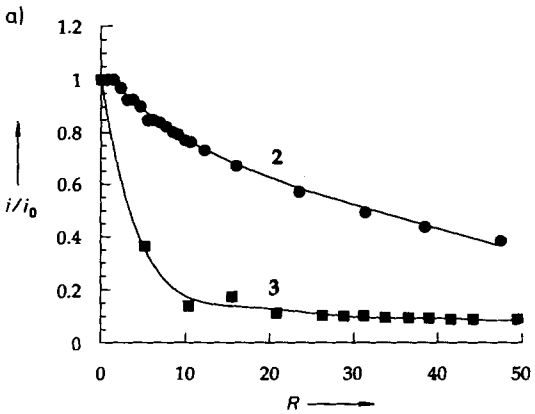
bound to DNA, a decrease in current is observed because the diffusion coefficient of the bound complex is much smaller than the diffusion coefficient of the free complex; the binding constant can therefore be determined using equations developed by Bard et al.[11] As a result of the change in diffusion coefficient, a drop in current as a function of added DNA is observed, as shown for **2** ($K_b = 15000\ M^{-1}$) in Figure 2a. For complex **3**, the drop in current is so rapid that a binding constant cannot be determined (Fig. 2a). In addition, the binding is also too strong for determining K_b by equilibrium dialysis, even at a buffer ionic strength of 50 mM.[12] Based on the electrochemical and equilibrium dialysis experiments, we can estimate a lower limit of $K_b \geq 10^6\ M^{-1}$ for the complex **3**.[7]



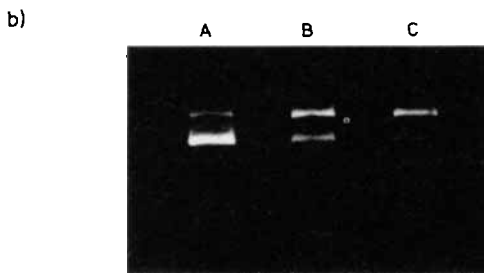


Fig. 2. a) Plots of voltammetric current for **2** (●) and **3** (■) as a function of the DNA concentration. R = [DNA-nucleotide phosphate]/[Ru complex]. i_0 Current measured in the absence of DNA; i current measured after addition of DNA. b) 1% Agarose gel showing the results of electrophoresis of supercoiled ϕX174 DNA (A) alone, (B) after electrolysis at 0.8 V for 3 h in the presence of 40 mM **2**, (C) after electrolysis at 0.8 V for 10 h with 40 mM **3**.

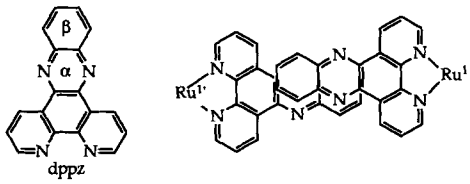
Identical observations were made in the equilibrium dialysis of **4**, and the same conclusions were drawn.[7] However, with the present complex, rapid conversion of superhelical DNA (form I) into circular DNA with single strand breaks ("nicked circular DNA" form II) occurs upon incubation of the DNA with **5** (data not shown). Indeed, optical spectroscopy shows that the dppz ligand dramatically increases the efficiency of the thermal reaction. Under identical conditions, the reaction of calf thymus DNA with **1** is 85% complete after 6.5 min, while the reaction of **5** with calf thymus DNA is 85% complete in 10 s.[13] This increased efficiency of the stoichiometric reaction is no doubt a result of the high affinity of the dppz ligand for the DNA. Cleavage is also realized upon electrolysis of the DNA at 0.8 V in the presence of **3** (Fig. 2b). The longer electrolysis time required for **3** results from the effect of the high binding affinity on the rate of oxidation of **3** to **5** and is not related to the efficiency of the cleavage reaction itself, as we have discussed in detail in Ref. [9]. Complex **3** is not as effective a photophysical probe as **4**, because replacement of a pyridine ligand by an aqua ligand apparently deactivates the MLCT excited state quite efficiently.

Some insight into the high binding affinity of dppz complexes can be gained from consideration of the X-ray crystal structure of **3**. There are two unique Ru centers (Ru1 and Ru2) that are related to the other two Ru centers by an inversion center. In the pair Ru1 and Ru1′, it is evident that ring α (the nitrogen ring) of the Ru1-complex is stacked directly above the ring β of the Ru1′ complex and vice versa.



Scheme 1. Superposition of two molecules of **3**.

The distance between the ring planes of the two ligands is 3.51 Å, similar to the base-pair stacking distance in DNA[14] and the intercalator-base pair stacking distance in crystal

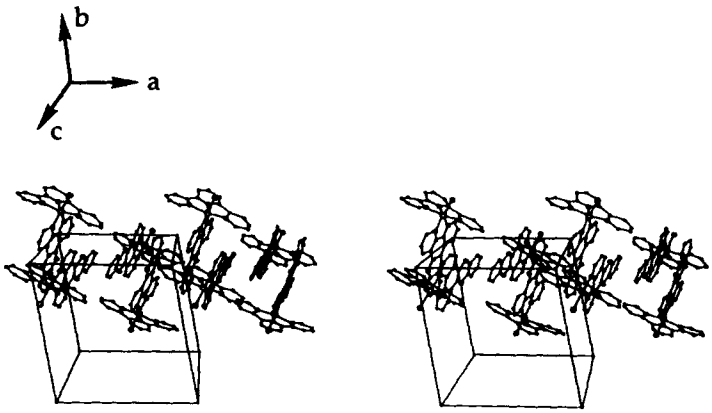


Fig. 3. Stereodiagram of the packing of **3** in the crystal. ClO_4^- counterions and hydrogen atoms are omitted for clarity.

structures of oligonucleotide-intercalator complexes.[15] A similar two-ring overlap pattern has been observed in the case of stacked acridine orange intercalators in the crystal structure of a Pt complex attached to the acridine intercalator by a long alkyl linker.[16] An infinite π-stacking interaction therefore exists throughout the crystal, as illustrated in the stereodiagram in Figure 3. Thus, it appears that the dppz ligand has an innate propensity for π-stacking that is no doubt responsible for the high DNA binding affinity of **3** and **4**. Observations of π-stacking interactions in the crystal structures of more conventional organic intercalators such as acridine orange[16] and phenanthridinium salts[17] are common.

[12] Equilibrium dialysis was performed according to: A. M. Pyle, J. P. Rehmann, R. Meshoyrer, C. V. Kumar, N. J. Turro, J. K. Barton, *J. Am. Chem. Soc.* **1989**, *111*, 3051.
[13] Complex **5** was prepared by electrolysis of **3** at 0.8 V in phosphate buffer (pH 7). $[RuO(bpy)(tpy)]^{2+}$ was prepared as described in Ref. [9]. Rate data were measured by optical spectroscopy at $\lambda = 406$ nm, where the kinetics of oxidation by $Ru^{IV}O^{2+}$ are known to be first-order [5]. Experimental conditions for the kinetic measurements: 0.8 mM DNA, 0.08 mM $Ru^{IV}O^{2+}$, 50 mM phosphate buffer, pH 7. The change in absorption with time can described in terms of a first order rate equation. The measurements were carried out on a Cary 14 spectrometer. The experimental conditions for electrocatalytic cleavage were identical to those described in Ref. [5]. None of the cleavage results is affected upon treatment with base.

Empty Octahedral Hexazirconium Clusters with Only Ten Electrons, $[Zr_6X_{14}(PR_3)_4]$**

By *F. Albert Cotton,* Xuejun Feng, Maoyu Shang,* and *William A. Wojtczak*

The existence of compounds comprised of octahedral Zr_6 clusters with bridging halogen atoms on all edges and one additional bond to each zirconium atom along a four-fold axis of the $[Zr_6X_{12}]$ unit was first reported many years ago.[1] Several years later it was realized[2] that these compounds, all prepared by high-temperature reactions, contain an additional atom (e.g. Be, B, C, N, and even a transition metal atom) in the center of the octahedron. The idea then took hold[3] that the central atom, and the electrons it could contribute to the Zr_6 cluster bonding, were essential to the stability of such $[Zr_6X_{12}]X_6$ systems. However, the report[4] in 1988 of $[Zr_6Cl_{12}(PMe_2Ph)_6]$, which was made in an entirely different way, at low temperature and in solution, showed that an empty cluster with 12 electrons can be stable. We are still seeking a better preparative method for such compounds, and in the course of doing so, we have found that empty Zr_6 clusters with even fewer electrons (ten) can be prepared. Herein we report on the results of the crystal structure analyses and the $^{31}P\{^1H\}$-NMR spectra of the new clusters **1**–**4**, as well as on SCF-Xα-SW molecular orbital calculations on the model compound $[Zr_6Cl_{14}(PH_3)_4]$.

$[Zr_6Cl_{14}(PMe_3)_4] \cdot 2CH_2Cl_2$ **1** $[Zr_6Cl_{14}(PEt_3)_4] \cdot 2CH_2Cl_2$ **2**
$[Zr_6Cl_{14}(PPr_3)_4] \cdot 2C_6H_6$ **3** $[Zr_6Br_{14}(PMe_3)_4] \cdot 2CH_3CN$ **4**

The new compounds **1**–**4** were synthesized by reduction of ZrX_4 (X = Cl or Br) with two equivalents of $(n\text{-}C_4H_9)_3SnH$[5] in benzene (CH_2Cl_2 for **1**). The reduction was allowed to proceed for a period of 36 h, during which time a dark colored precipitate collected on the bottom of the reaction vessel. The addition of one equivalent of phosphane immediately solubilized the precipitate, furnishing a deep-red solution, which afforded very air- and moisture-sensitive crystals upon layering. The $^{31}P\{^1H\}$-NMR spectrum of dissolved crystals of **2** shows a singlet at $\delta = 21.27$ ($\Delta\nu_{1/2} = 31.4$ Hz at 20 °C, 81 MHz). The singlet shifts downfield by $\Delta\delta \approx 1$ over the temperature range −40 °C to 60 °C, which is consistent with weak temperature-dependent paramagnetism arising from a diamagnetic ground state having some access to a paramagnetic excited state at higher temperature. This will be discussed further in the context of our theoretical calculations. The direction of the peak shift is undoubtedly dependent on the particular spin transfer mechanism. The ^1H-NMR spectrum of **2** shows two broad peaks corresponding to protons of the ethyl group of the bound phosphane ligand and gives no indication of the existence of a hydridic proton within the cluster; however, the line-broadening effect arising from the weak paramagnetism of the compound precludes any definitive statement in this regard.

The compounds **1**–**4** were characterized by X-ray crystallography,[6] pertinent crystallographic parameters are listed

in Table 1, important molecular dimensions in Table 2. Figure 1 shows a molecule of **1** as viewed along its Cl_t–Zr_{ax} bond. It should be noted that all hydrogen atoms of **1** were found from a Fourier map that followed the anisotropic refinement of the non-hydrogen atoms. The hydrogen atoms (including the hydrogens on the CH_2Cl_2 of crystallization were positionally refined with fixed thermal parameters of 1.3 B_{eqv} of the corresponding carbon atom. Compound **1** resides on a crystallographic inversion center in the monoclinic space group $P2_1/n$. In order to determine whether adequate electron density exists at the center of the Zr_6 cluster to support the hypothesis that *any* atom is there, we attempted to refine a hydrogen atom with fixed coordinates at (0,0,0). The thermal parameter of the aforementioned hydrogen atom grew very large after only a few refinement cycles by the least-square method ($B > 50$ Å^2).

Table 2. Selected distances [Å] and angles [°] for clusters **1**–**4**. X_t = terminal halogen atom, X_b = bridging halogen atom (X = Cl, Br). The terminal halogen atoms are bound to the Zr atoms designated as Zr_{ax}.

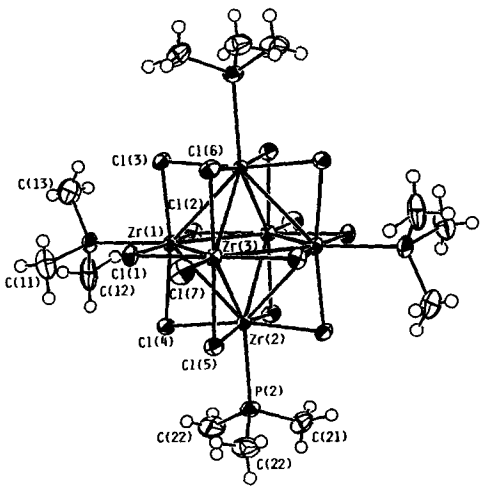

Fig. 1. **1** viewed along the Zr_{ax}–Cl_t bond. Hydrogen atoms have been given arbitrary thermal parameters and heavy atoms are represented by their ellipsoids at the 50% probability level.

The two distinct sets of Zr–Zr bond lengths (eq–eq, ax–eq) in the $[Zr_6X_{14}(PR_3)_4]$-type clusters suggest that a small but real tetragonal distortion exists, in which the Zr_{ax}–Zr_{eq} bond lengths are longer than the Zr_{eq}–Zr_{eq} bond lengths. This phenomenon has been observed previously[7] in solid-state clusters of the composition $[Zr_6X_{14}Z]^{n+}$ and may be attributed to the chemical inequality of the Zr_{ax} and Zr_{eq}, positions resulting from the disparate electron donor ability of the terminal ligands. The bromo complex, **4**, contains slightly longer Zr–Zr bonds than its chloro analogue. This trend has also been observed in the edge-sharing bioctahedral complexes of the elements of group IV and has been attributed to greater ligand–ligand repulsive forces of the larger halogen atoms.[8] The Zr–Zr bond lengths of the compounds **1** to **3** lie in the range 3.167–3.450 Å recently reported for centered zirconium hexanuclear clusters, with cluster based electron counts between twelve and eighteen, that were obtained by dissolution of solid-state phases.[9] Further comparison between our clusters **1**–**4** and those just mentioned is unjustified, since large differences exist with respect to ligand environments, electron counts, and the presence of interstitial atoms.

Our ten-electron clusters can, however, be compared with the twelve-electron cluster **5**.[4] The average Zr_{eq}–Zr_{eq} bond

$[Zr_6Cl_{12}(PMe_2Ph)_6]$ **5**

length of 3.319(6) Å in **3** is 0.096(9) Å longer than the Zr–Zr distance in **5**. The lengthening of the Zr-Zr-bond is not surprising, considering that removal of two electrons that are Zr_6 core bonding from the t_{1u} HOMO of **5** is required for formation of the ten-electron cluster **3** (cf. **8** in Fig. 2). The commensurate enlargement of the Zr_6 cage in **3** can be gauged from the Zr_{eq}–Center radius of 2.346(1) Å, compared to 2.279(2) Å in **5**. The degree of bond lengthening is small, since the bond order changes only from 0.5 (**5**) to 0.42 (**3**), respectively.

$[Zr_6Cl_{14}(Ph_3)_4]$ **6** $[Zr_6Cl_{14}(Ph_3)_4H]$ **7** $[Zr_6Cl_{12}(Ph_3)_6]$ **9**

Molecular orbital calculations were carried out by the SCF-X_α-SW method for the C_{4v}-symmetric clusters **6** and **7**. The latter compound was assumed to be structurally the same as the former except for having a hydrogen atom at its center. For comparison, a compound of similar structure (D_{3d} symmetry) but with twelve metal cluster electrons, **8**,[4] was also calculated. Figure 2 shows the MO diagram for the upper valence orbitals in these molecules. For all three molecules, the MOs in the energy range between −9 and −11 eV are mostly metal-ligand(terminal) bonding, while the higher energy orbitals are predominantly metal-metal

bonding and accommodate all metal cluster electrons. The $7a_1$ orbital in **7** provides the bonding between the metal atoms and the centered atom and is correlated to the $18a_1$ orbital in **6**, as indicated by the asterisks in Figure 2. Three pairs of nearly degenerate MOs in **8** (right-hand column in Fig. 2), each of which correlates to a level of *t*-symmetry of the octahedral $Zr_6Cl_{12}P_6$ framework, are labeled accordingly. Upon lowering the symmetry to C_{4v}, the levels are split.

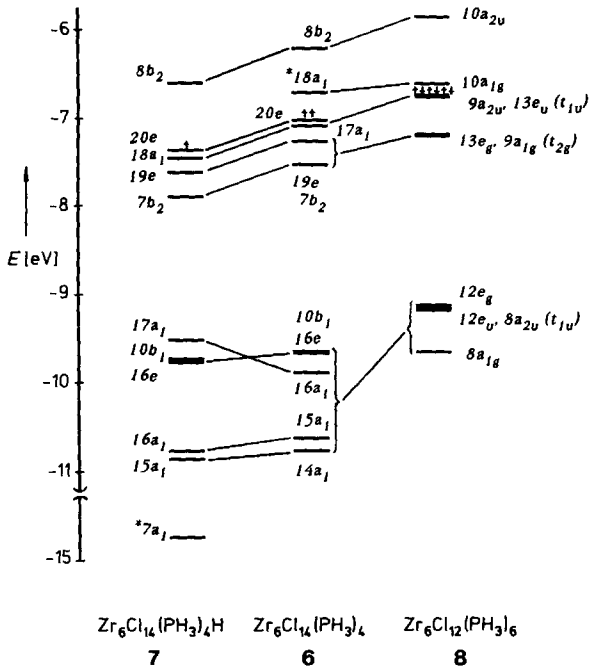

Fig. 2. Molecular orbital diagram of the upper valence orbitals for **6**–**8**.

According to the electronic structures shown in Figure 2, the compound we are concerned with $(Zr_6Cl_{14}(PH_3)_4)$ should be strongly paramagnetic, whether it contains a hydrogen atom at the center or not. Paramagnetism is absolutely unavoidable in the case of the hydrogen-centered model compound **7** since it contains an odd number of electrons. However, as indicated by the $^{31}P\{^1H\}$-NMR spectra recorded at various temperatures, compound **2** exhibits only very weak temperature-dependent paramagnetism, which suggests that it should have a closed-shell electronic configuration in the ground state. Thus, the possibility that the compound has a centered hydrogen atom can be eliminated. The NMR result shows that the calculation for **6** has not correctly predicted the exact ordering of the closely-spaced MOs in the HOMO-LUMO region (middle column of Fig. 2). This is not surprising in view of the very similar energies of the $17a_1$, $20e$ and $18a_1$ orbitals. The calculation may have overestimated the metal-ligand(terminal) antibonding contribution in the $18a_1$ orbital (see Fig. 3, left). Orbitals of the same character in other systems such as $[Zr_6Cl_{18}]^{4-}$,[10, 11] have been found to be much lower than the t_{2g} level. Noticing also the strong metal-metal bonding character with the d_{z^2} orbitals of all metal atoms pointing towards the center of the Zr_6 cage, it is then possible that the $18a_1$ orbital actually lies lower than the $17a_1$ orbital. Furthermore, if there is a larger splitting between the $17a_1$ and the $20e$ orbitals, there could be a closed-shell electronic configuration with the $17a_1$ and $20e$ orbitals as the HOMO and LUMO, respectively. The $17a_1$ and $20e$ orbitals have the same metal-metal bonding character (Fig. 3, right). The splitting between the two is caused by differences in metal-ligand(terminal) antibonding character of the orbitals. In the $17a_1$ orbital, the antibonding is between the metal atoms and the chlorine atoms, while in the $20e$ orbital it is between the metal and the phosphorus atoms. Because of this, the other possibility of a closed shell configuration by reversing the order of these two orbitals seems unlikely.

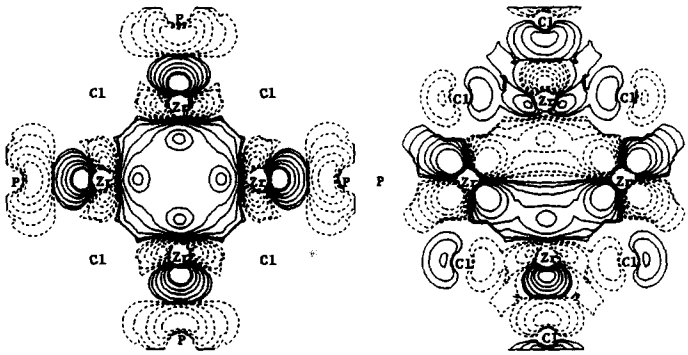

Fig. 3. Molecular orbital contour plots for the $18a_1$ orbital (left) and the $17a_1$ orbital (right) of **6**.

We are currently attempting to synthesize other hexanuclear clusters, for example, $[Zr_6Cl_{12}L_6]$, as well as investigating other synthetic routes for clusters of elements of Group IV.

Experimental

All operations were carried out under an argon atmosphere using standard vacuum-line and Schlenk techniques. The solvents were freshly distilled under nitrogen from the appropriate drying reagent and the reactants were used as received from the supplier.

Synthesis of **1**–**4**: ZrX_4 (X = Cl, 0.466 g, 2.0 mmol; X = Br, 0.822 g, 2.0 mmol) was reduced with $(nC_4H_9)_3SnH$ (1.05 mL, 4.0 mmol) in 20 mL of benzene (20 mL of CH_2CL_2 for **1**) for 36 h. The resulting red-brown precipitate (dark blue for X = Br) was washed with two 10-mL portions of fresh solvent to remove excess $(nC_4H_9)_3SnH$, followed by addition of 20 mL of fresh solvent. One equivalent of PR_3 (R = Me; 0.20 mL, 2.0 mmol, R = Et; 0.29 mL, 2.0 mmol, R = Pr; 0.40 mL, 2.0 mmol) was added dropwise. The precipitate was solubilized immediately, producing a deep-red/brown solution. The benzene was removed from **2** and **4** under vacuum, and CH_2Cl_2 and CH_3CN were added, respectively. The solutions were filtered through 2 cm of Celite and layered with 25 mL of hexane (for **1**, **2**, and **3**) and 25 mL of Et_2O for **4**. Red crystals separated out within one to two weeks. The yields of crystalline material isolated ranged from 10–20% for **1**–**4**.

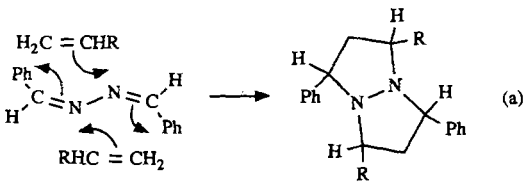
An Organometallic Analogue of the "Criss-Cross" Cycloaddition Reaction**

By *Colleen Kelley, Lisa A. Mercando, Michael R. Terry, Noël Lugan, Gregory L. Geoffroy,* Zhengtian Xu,* and *Arnold L. Rheingold*

Azines have been known since 1917[1] to undergo consecutive [3 + 2] cycloaddition reactions with 1,3-dipolarophiles to give bicyclic products having fused five-membered rings [Eq. (a)], a transformation that is commonly known as the criss-cross reaction.[2] Electron-rich azines typically require



electron-deficient alkenes as partners and often need elevated temperatures and prolonged reaction times. In contrast, azines with electron-withdrawing CF_3 substituents react with a variety of substrates, including electron-rich olefins.[2, 3] We report herein the first examples of organometallic analogues of this criss-cross cycloaddition involving benzalazine and vinylidene or carbyne complexes.

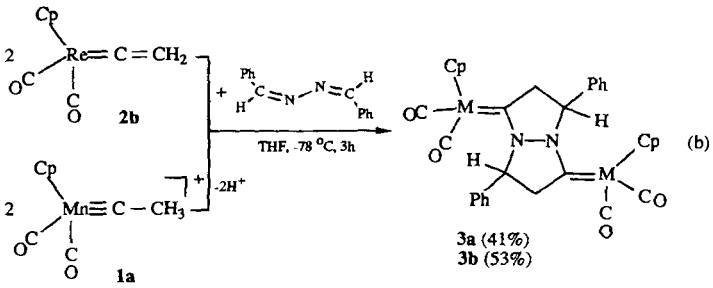
It has been found that the ethylidyne complexes **1** undergo deprotonation to form the new vinylidene complexes **2**.

$[Cp(CO)_2M{\equiv}C{-}CH_3]BCl_4$ **1** $[Cp(CO)_2M{=}C{=}CH_2]$ **2**

a, M = Mn; **b**, M = Re

This deprotonation may be accomplished by treating complexes **1** with Et_3N, although the rhenium complex **1b** is sufficiently acidic to deprotonate spontaneously upon dissolution in CH_2Cl_2 or THF. Vinylidene complexes analogous to **2a, b** with organic substituents on the β-carbon are known,[5] but the unsubstituted derivatives **2a, b** have not been previously described. However, **2a** has been proposed as a reaction intermediate.[6] The complexes **2a, b** have been spectroscopically characterized, but they cannot be isolated since upon warming to 22 °C they rapidly decompose, with formation of the μ-vinylidene complexes $[\{Cp(CO)_2M\}_2(\mu\text{-}C{=}CH_2)]$.[6, 7] Consequently, they must be generated and studied at low temperature.

The criss-cross cycloaddition product **3b** was formed upon addition of benzalazine to the vinylidene complex **2b** [Eq. (b)]. IR monitoring indicates a clean transformation without



detectable by-products, and **3b** was isolated as a solid and was spectroscopically characterized. A similar reaction occurs between the carbyne complex **1a** and *two* equivalents of benzalazine to give the analogous product **3a**, with the second benzalazine equivalent necessary to deprotonate the intermediate formed between **1a** and the azine. The ORTEP drawing of **3a** (see Fig. 1[8]) shows the fused five-membered rings to be nearly planar [max. deviation = 0.17 Å at C(20)] as is the entire bridging ligand (dihedral angle [C(15)-N(1)-N(2)-C(17)]-[C(20)-N(1)-N(2)-C(18)] = 171.5°). The Mn–

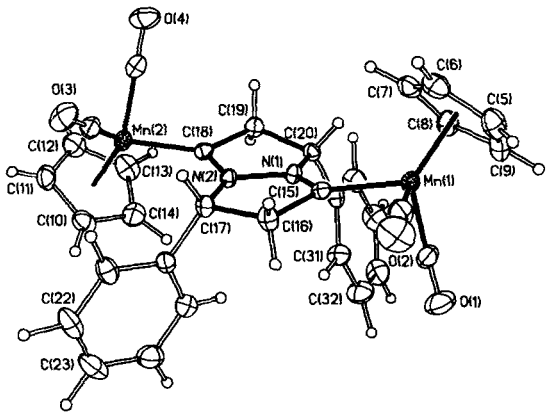


Fig. 1. An ORTEP drawing of **3a**. Selected bond lengths [Å]: Mn(1)-CP(1), 1.791(4); Mn(2)-Cp(2), 1.782(4); Mn(1)-C(15), 1.945(3); Mn(2)-C(18), 1.936(3); N(1)-N(2), 1.438(3); N(1)-C(20), 1.472(4); N(1)-C(15), 1.312(4); N(2)-C(17), 1.473(4); N(2)-C(18), 1.306(4).

C(carbene) bond lengths of 1.945(3) and 1.936(3) Å lie in the typical range.[9] The planes defined by the carbene carbon atoms and their attached carbon and nitrogen substituents do not bisect the CO–Mn–CO angle, as often found for $[Cp(CO)_2Mn{=}CRR']$ carbene complexes,[9] but instead

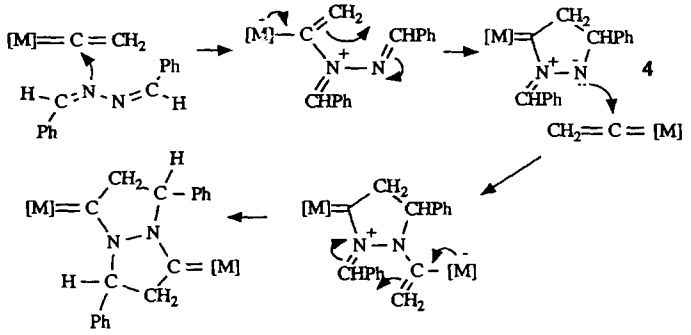
appear to be oriented so as to minimize steric interactions. The two benzylic carbons of the bridging organic ligand are both chiral, and thus the molecule could be present as a pair of enantiomers or in the *meso* form. However, NMR data indicates only the formation of a single spectroscopically detectable stereoisomer, and the crystal structure shows it to be the *RR*/*SS* pair with the two phenyl groups on the same side of the fused five-membered rings.

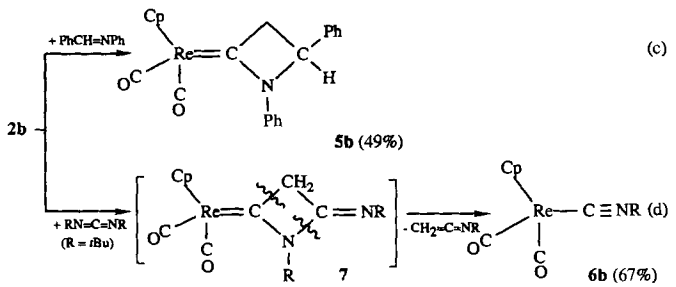
The reaction mechanism proposed for the formation of **3b** resembles that which has been established for organic analogues of this criss-cross reaction[2] (Scheme 1). The α-



Scheme 1. Proposed mechanism for the formation of **3b**; [M] = $Cp(CO)_2Re$.

carbon of vinylidene complexes is known to be electrophilic,[5] and the cycloaddition reaction is most likely initiated by addition of the azine nitrogen to this carbon in **2b**. Cyclization then ensues to give **4**, an organic analogue of which is known.[3a] Addition of the nucleophilic nitrogen of **4** to a second equivalent of **2b** with subsequent cyclization would give **3b**. The carbyne complex **1a** is believed to react in a similar fashion but with deprotonation of the methyl substituent occurring *after* the initial addition of the azine nitrogen to the carbyne carbon.[10]

Vinylidene complex **2b** also undergoes [2 + 2] cycloaddition with PhN=CHPh to give the carbene complex **5b** [Eq. (c)], a reaction which has precedent in the cycloaddition of



imines with vinylidene iron complexes.[11] A novel transformation of vinylidene complexes is that with **2b** and *t*BuN=C=N*t*Bu to form the isocyanide complex **6b** [Eq. (d)].[12] This reaction represents a net metathesis of the vinylidene C=C bond with the N=C bond of the carbodiimide and may proceed via the intermediate carbene complex **7**, which could undergo a retro-cycloaddition to give the observed products. For the addition of $C_6H_{11}N{=}C{=}NC_6H_{11}$ to $[(CO)_5Cr{=}C(OH)CH_3]$, in which a chromium analogue of **7** could be isolated, a vinylidene complex was proposed as intermediate.[13]

The above reactions demonstrate that the vinylidene complex **2b** is a highly reactive species, and in particular the criss-cross cycloaddition with benzalazine indicates that this complex is a potent 1,3-dipolarophile which should be capable of undergoing cycloadditions with a variety of other substrates. Interestingly, the manganese vinylidene complex **2a** does not readily react with benzalazine and *t*BuN=C=N*t*Bu, implying a decreased electrophilicity of the vinylidene α-carbon in **2a** compared to that in the rhenium complex **2b**. However, the much more electrophilic carbyne complex **1a** does react rapidly with each of these substrates to give, after treatment with Et_3N, the analogous complexes **3a**, **5a**, and **6a**. Thus, in the manganese reactions deprotonation must be accomplished after substrate addition, but in the rhenium case it occurs before addition.

Experimental

Dissolution of $[Cp(CO)_2Re{\equiv}CCH_3][BCl_4]$ in CH_2Cl_2 at −50 °C gave immediate deprotonation to yield gaseous HCl (the vapors turned litmus paper red) and complex **2b**, (detected by IR). A two-fold excess of benzalazine was added, the mixture was stirred for 1 h at 0 °C, the solvent was removed under vacuum, and the residue was chromatographed on neutral alumina to afford a yellow band of PhCH=NN=CHPh [eluent: CH_2Cl_2/hexane (1:1)] as well as a yellow band of **3b** [eluent: CH_2Cl_2/hexane (3:1); 53% yield]. To prepare **3a**, a two-fold excess of benzalazine was added to a −50 °C THF solution of $[Cp(CO)_2Mn{\equiv}CCH_3]BCl_4$, and the solution was stirred at −50 °C for 3 h followed by warming to 22 °C and evaporation of solvent under vacuum to afford a red oil which was chromatographed on neutral alumina to give first a yellow band of PhCH=N−N=CHPh [eluent: CH_2Cl_2/pentane (1:1)] followed by a yellow band of **3a** (eluent: 100% CH_2Cl_2; 41% yield). **2a**: IR (CH_2Cl_2, ca. −50 °C): $\tilde{\nu}$ [cm^{-1}] = 1998, 1935 (CO), 1623 (C=C); **2b**: IR (CH_2Cl_2, ca. −50 °C): $\tilde{\nu}$ [cm^{-1}] = 1990, 1915 (CO), 1629 (C=C); ^1H NMR (300 MHz, CD_2Cl_2, −10 °C): δ = 2.32 (s, 2H, CH_2), 5.48 (s, 5H, Cp). **3a**: ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.38-6.99 (Ph), 5.34 (dd, J = 10.2, 2.4 Hz, C*H*Ph), 4.03 (s, Cp), 3.34 (dd, 1H, J = 18.4, 10.2 Hz, CH_2), 3.10 (dd, J = 18.4, 2.4 Hz, CH_2). $^{13}C\{^1H\}$ NMR (75.5 MHz, CD_2Cl_2, 25 °C): δ = 245.5 (Mn = C), 233.95, 232.89 (CO), 140.6-126.8 (Ph), 84.0 (Cp), 66.25 (*C*HPh), 59.26 (CH_2). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 1926, 1858 (CO). MS (FAB): m/z = 612 ($M^{\oplus}$). **3b**: ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.8-6.7 (Ph), 4.91 (s, 5H, Cp), 4.03 (dd, J = 7.5, 2.4 Hz, C*H*Ph), 1.85 (dd, 1H, J = 16.6, 7.5 Hz, CH_2), 1.81 (dd, 1H, J = 16.6, 2.4 Hz, CH_2). $^{13}C\{^1H\}$ NMR (75.5 MHz, CD_2Cl_2, 25 °C): δ = 228.3 (Re = C), 206.9, 206.5 (CO), 148.2-125.9 (Ph), 87.5 (Cp), 38.3 (*C*HPh), 22.6 (CH_2). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 1926, 1847 (CO).

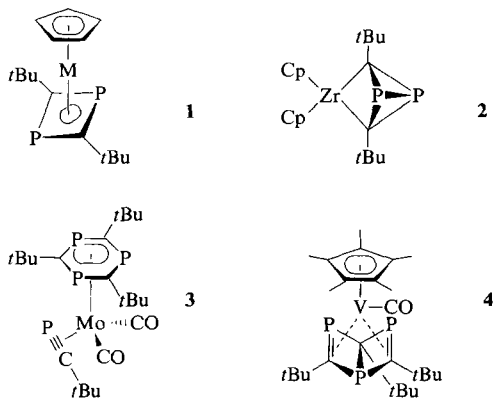
Spirocyclization of a Stable Phosphaalkyne with Aluminum Trichloride—Key Reaction for the Production of Triphospha Dewar Benzene Derivatives**

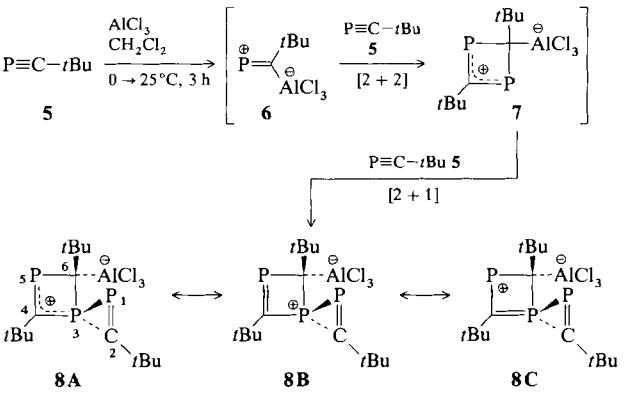
By *Bernhard Breit, Uwe Bergsträsser, Gerhard Maas,* and *Manfred Regitz**

Dedicated to Professor Günter Maier on the occasion of his 60th birthday

The organometallic chemistry of phosphaalkynes received considerable impetus from cyclooligomerization reactions, in which their metal complex fragments were incorporated into the products.[1] Significant milestones along this route include the cyclodimerization of *tert*-butylphosphaacetylene **5** to give the 1,3-diphosphacyclobutadiene complexes **1** (e.g., with cyclopentadienylrhodium[2] or -cobalt fragments[3]), the unusual linkage of **5** to the tricyclic zirconium complex **2**,[4] and finally the cyclotrimerization of **5** to give the molybdenum compound **3** of 1,3,5-triphosphabenzene,[5] as well as the Dewar isomer **4** with vanadium as the central metal atom.[6] Whereas in the case of **2** the true phosphaalkyne dimer was used successfully as a building block for cyclic phosphorus–carbon compounds,[7] cleavage reactions of the metal complex fragments of the other complexes have so far been unsuccessful.



Herein we report for the first time a spirocyclotrimerization of the phosphaalkyne **5**[8] in the presence of aluminum trichloride. In dichloromethane this reaction occurs highly selectively (≥95%) in a 3:1 molar ratio and gives betaine **8** with the incorporation of the Lewis acid. First indications of a cyclooligomerization were provided by the ^{1}H NMR spectrum, which showed three different *tert*-butyl groups (Table 1), and the ^{31}P NMR spectrum, in which the three observed absorptions lie at completely different δ values



[Table 1; $\delta = -80.1$ (P3), 261.4 (P1), 417.9 (P5)]. The two latter absorptions indicate that the reaction product still has

Table 1. Selected physical data for the spirocyclic betaine **8** as well as for the tetracycles **12** and **13** [a].

8; ^{1}H NMR: $\delta = 1.34$ (dd, ^4J(P,H) = 0.7, 0.8 Hz, 9H, *t*Bu), 1.43 (d, ^4J(P,H) = 1.2 Hz, 9H, *t*Bu), 1.59 (pseudo-t, ^4J(P,H) = 0.9 Hz, 9H, *t*Bu); ^{13}C NMR: $\delta = 31.9$ (s, C(CH_3)$_3$), 33.8 (pseudo-t, ^3J(P,C) = 9.2 Hz, C(CH_3)$_3$), 34.9 (dd, ^3J(P,C) = 12.2 Hz, ^4J(P,C) = 12.5, 4.5 Hz, C(CH_3)$_3$), 41.1 (d, ^2J(P,C) = 8.4 Hz, *C*(CH_3)$_3$), 43.6 (pseudo-t, ^2J(P,C) = 2.0 Hz, *C*(CH_3)$_3$), 48.1 (d, ^2J(P,C) = 3.0 Hz, *C*(CH_3)$_3$), 202.9 (d, ^1J(P,C) = 65.4 Hz, P = C), 245.9 (dd, ^1J(P,C) = 68.2, 81.7 Hz, P = C); ^{31}P NMR: $\delta = -80.1$ (d, ^1J(P,P) = 214.5 Hz, P3), 261.4 (dd, ^1J(P,P) = 214.5 Hz, ^3J(P,P) = 18.0 Hz, P1), 417.9 (d, ^3J(P,P) = 18.0 Hz, P5).

[**] Phosphorus Compounds, Part 58. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. Part 57: M. Birkel, J. Schulz, U. Bergsträsser, M. Regitz, *Angew. Chem.* **1992**, *104*, 870; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 879.

two phosphaalkene units;[9] the relatively high-field position of the third phosphorus signal (P3) lies approximately in the range of phosphirenium ions.[10] The signals due to the heteronuclei P1 and P3 are each split by a $^1J(P,P)$ coupling of 214.5 Hz to give doublets, which indicates that they are direct neighbors; P1 has an additional P,P coupling of 18.0 Hz, and this splits the resonance signal of P5.

Finally characteristic low-field absorptions for two phosphaalkyne carbons occur in the ^{13}C NMR spectrum of **8** at $\delta = 202.9$ and 245.9, which have $^1J(P,C)$ couplings (Table 1). The signal for the C6 atom in the four-membered ring cannot be observed. This has to be considered as good evidence for the C6 atom being a direct neighbor of the aluminum atom.[11]

The final confirmation of the constitution of the phosphaalkyne/aluminum trichloride compound **8** was achieved by an X-ray crystal structure analysis (Fig. 1).[12] The bond

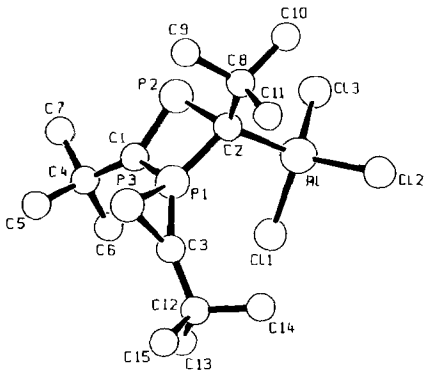

Fig. 1. Structure of **8** (SCHAKAL plot). Selected distances [Å] and angles [°]: P1-C1 1.77(1), P1-C2 1.80(1), P2-C1 1.70(1), P2-C2 1.91(1), C2-Al 2.02(1), P1-P3 2.108(4), P1-C3 1.74(1), P3-C3 1.68(1); C1-P1-C2 90.8(5), P3-P1-C1 122.8(4), P3-P1-C2 128.1(4), P3-P1-C3 50.8(3), C1-P1-C2 90.8(5), C1-P1-C3 131.6(5), C2-P1-C3 133.0(5), P1-P3-C3 53.3(3), P1-C3-P3 75.9(4), P1-C2-P2 85.0(5), C2-P2-C1 89.4(5), P2-C1-P1 93.1(5). Torsion angles [°]: C1-P1-C2-P2 9.4(4), C1-P2-C2-P1 −9.7(4), C2-P2-C1-P1 9.9(4), C2-P1-C1-P2 −10.5(5), P3-P1-C1-C4 −54.0(1.1), C3-P1-C1-C4 10.3(1.2). The second independent molecule is different from the one depicted here especially with regard to the torsion angles in the four-membered ring (which are 1.2–1.4° smaller than the ones given above) as well as the bonds C1–C4, C2–Al, and C3–C12.

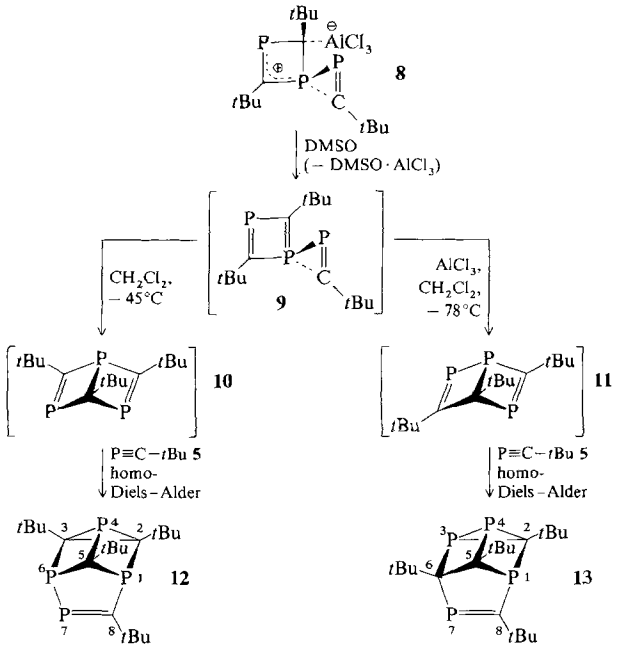
lengths P2–C1 (1.70 Å) and P1–C1 (1.77 Å) justify the formulation of the key product **8** as the resonance hybrid **8B** ↔ **8C** with an almost delocalized P=C bond and positive charge on the heteroatom in accordance with **8A**. Both values for the bond lengths are above the average values for open-chain phosphaalkenes (1.67 Å[13]), but are a long way from being within the range of single P–C bonds. The four-membered ring is no longer planar (see torsion angles in the legend to Fig. 1). The P3–C3 distance is within the expected range (1.68 Å); for the $W(CO)_5$ complex of a 2*H*-diphosphirene the P=C bond length was found to be 1.634 Å,[14] and for a 1*H*-diphosphirene with a donor substitutent at the phosphaalkyne unit it was 1.702 Å.[15]

With regard to the mechanism it may be assumed that the title reaction is initiated by the addition of the Lewis acid at the carbon atom of the phosphaalkyne **5** (→ **6**) in keeping with the polarization of the P≡C bond.[16] Starting from **6** the [2+2] cycloaddition of a second equivalent of the phosphaalkyne **5** occurs to give the dimeric complex **7**,[17] in which the phosphorus has electrophilic character. The final [2+1] cycloaddition with the third equivalent of **5** leads to the formation of the product (→ **8**).

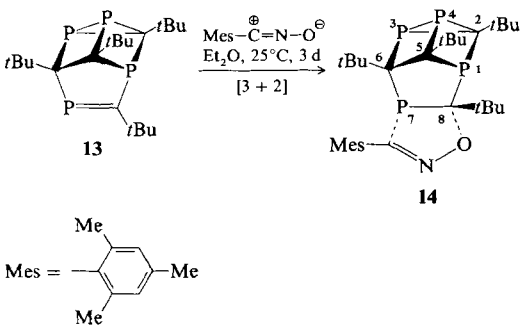
If the aluminum chloride substituent in betaine **8** is removed by the addition of the Lewis base dimethyl sulfoxide, the spirocyclic $\lambda^5\sigma^4,\lambda^3\sigma^2$ diphosphete **9** is generated, which cannot be isolated. Even at −45 °C (CH_2Cl_2) after the P–P bond breakage in the diphospirene ring, **9** rearranges to the 1,3,5-triphospha Dewar benzene **10**, which also cannot be isolated. If the phosphaalkyne **5** is added as a trapping



reagent for **10** before the release of **9**, the tetraphosphatetracycle **12** (37%) is formed by a homo-Diels–Alder reaction. However, with an excess of aluminum trichloride, and at −78 °C (CH_2Cl_2), the same experiment leads to the constitutional isomer **13** (38%). Under these conditions the rearrangement of **9** occurs with the breakage of the P–C bond to give the 1,2,5-triphospha Dewar benzene **11**, which is also trapped by a homo-Diels–Alder reaction (→ **13**). The role of the aluminum chloride (or its DMSO adduct) during the rearrangement reaction at present remains unexplained. Both processes are highly selective and allow the desired formation of the hitherto unknown phosphaalkyne cyclotetramers.

In the ^1H NMR spectra of **12** and **13** the signals for four *t*Bu groups are found for each compound. These signals are partly split by $^4J(P,H)$ couplings of 0.9–2.0 Hz (Table 1). The position and splitting of the ^{31}P NMR resonance signals of the two isomers prove the constitutions; for **12** the high-field position of the phosphorus atom P4 of the three-membered ring at $\delta = -160.0$[18] as well as the low-field absorption of P7 ($\delta = 417.1$) are characteristic. The latter resonance signal is split by $^1J(P,P)$ coupling of 264.8 Hz, which also occurs for P6 ($\delta = 134.3$). Naturally for P1 ($\delta = 111.5$) three $^2J(P,P)$ couplings (33.1, 32.9, 16.6 Hz) are found. In **13** the resonance signals $\delta = -174.4$ and −147.3 [$^1J(P,P) = 83.0$ Hz] are assigned to the diphosphirane unit.[18] The $\lambda^3\sigma^2$ phosphorus atom P7 ($\delta = 399.0$) is not coupled with another heteronucleus. P1 ($\delta = 64.6$) shows only one $^2J(P,P)$ coupling of 31.2 Hz. The position and splitting of the carbon resonance signals in the ^{13}C NMR spectra (Table 1) are in agreement with the structures **12** and **13**.

Chemically the existence of the P=C bond of **13** can be proven by the reaction with mesitylnitriloxide. The regio- and stereospecific [3 + 2] cycloaddition affords quantitatively crystalline **14** [colorless crystals with m.p. 184°C (from *n*-pentane)]. The break up of the phosphaalkene unit in **13** is indicated by the considerable high-field shift of the absorption of P7 in the ^{31}P NMR ($\delta = 75.6$) as well as of C8 in the ^{13}C NMR spectrum ($\delta = 108.6$, ^1J(P,C) = 53.4, 37.4 Hz).



The crystal structure analysis[12] confirms the constitution of the cycloadduct **14** (and thus also the precursor **13**) (Fig. 2). The P–C distances in the polycycle are worthy of note, since they vary greatly between 1.807 (P2–C4) and 1.927 Å (P4–C2).

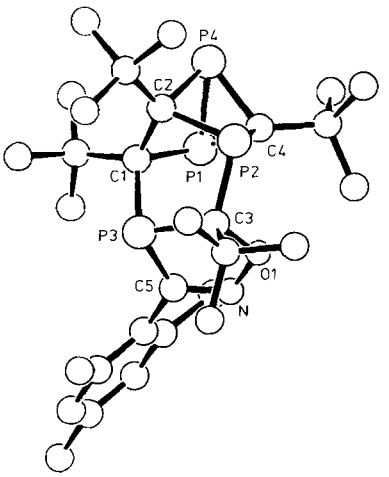


Fig. 2. Structure of **14** (SCHAKAL plot). Selected distances [Å] and angles [°]: P4-P1 2.179(3), P3-C1 1.886(7), C2-C1 1.596(9), P2-C4 1.807(7), P3-C5 1.854(7), N-C5 1.261(8), P4-C2 1.927(7), P2-C3 1.895(7); O1-C3 1.960(8), P1-C1 1.914(7), O1-N 1.396(7), P1-C4 1.845(7), P4-C4 1.866(7), P2-C2 1.876(7), P3-C3 1.836(7); C1-P1-P4 81.4(2), C4-P1-C1 95.5(3), C3-P2-C4 103.9(3), C2-P4-P1 78.2(2), P3-C1-P1 115.1(3), C2-C1-P3 106.6(4), P4-C4-P1 71.9(3), P4-C2-P2 88.4(3), C1-C2-P4 98.4(4), C4-P1-P4 54.5(2), C2-P2-C4 83.2(3), C3-P2-C2 101.2(3), C3-P3-C1 98.0(3), C4-P4-P1 53.6(2), C2-P4-C4 80.2(3), C2-C1-P1 95.1(4), P2-C4-P1 111.8(4), P4-C4-P2 92.4(3), C1-C2-P2 103.3(4), P3-C3-P2 106.9(3).

Experimental Procedure

8: To a suspension of aluminum trichloride (0.67 g, 5.0 mmol) in dichloromethane (5 mL) a solution of the phospaalkyne **5** (1.50 g, 15.0 mmol) [8] in dichloromethane (5 mL) was added dropwise and stirred at 0 °C (air and moisture exclusion). After 1 h the solution was allowed to warm to 25 °C and stirred for a further 2 h. The solution was concentrated under vacuum at 25 °C/10^{-3} mbar, whereby **8** remained as a spectroscopically pure (^{31}P NMR) red-brown oil. Yield after recrystallization from toluene: 2.06 g (95%) yellow crystals; m.p. 134 °C (decomp).

12: To a solution of betaine **8** (1.47 g, 3.4 mmol) in dichloromethane (10 mL) the phosphaalkyne **5** (0.34 g, 3.4 mmol) [8] and dimethyl sulfoxide (0.80 mL, 11.3 mmol) each in dichloromethane (5 mL) were added dropwise one after the other and stirred at −45 °C (air and moisture exclusion). Over a period of 6 h the mixture was allowed to warm up to 25 °C and then stirred for a further 18 h after which it was concentrated under vacuum at 25 °C/10^{-3} mbar. Extraction of the residue with *n*-pentane (5 × 10 mL) and concentration of the solution afforded spectroscopically pure (^{31}P NMR) **12** as a red oil. Yield: 0.50 g, (37%). Middle-pressure chromatography on silica gel with *n*-pentane was possible but with large losses of the product.

13: To a solution of betaine **8** (1.16 g, 2.7 mmol) and aluminum chloride (0.59 g, 4.4 mmol) in dichloromethane (10 mL), the phosphaalkyne **5** (0.26 g, 2.6 mmol) [8] and dimethyl sulfoxide (0.62 mL, 8.7 mmol) each in dichloromethane (5 mL) were added dropwise one after the other and stirred at −78 °C (air and moisture exclusion). Workup as for **12** afforded **13** as a yellow oil. Yield: 0.39 g (38%). Column chromatography on silica gel (inert gas) with *n*-pentane is possible, but involves great losses.

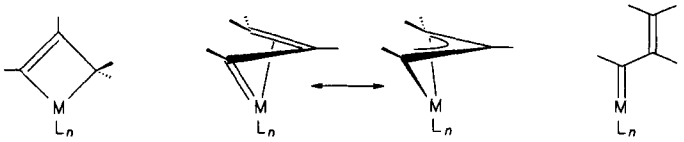
Cyclopentadienyl Cobalt Complexes of Cobaltapentalenes: Products Formed by Reaction of (μ-Cyclopentadienylidene) Cobalt Complexes with Silylalkynes**

By *Hubert Wadepohl,* Wolfgang Galm, Hans Pritzkow,* and *Andreas Wolf*

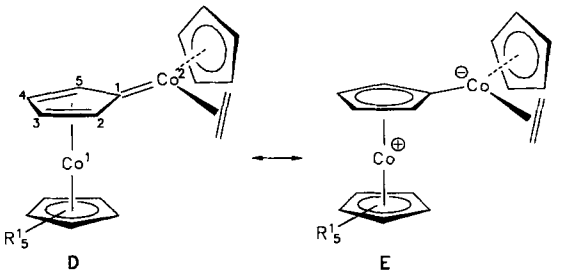
Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Coupling reactions of metal-carbene complexes with alkynes are very important in chemical syntheses.[1] Depending on the isolobal character of the relevant metal fragment, metallacyclobutenes **A** or η^3-vinylcarbene complexes **B** are postulated as intermediates in these mechanistically still largely unexplained reactions.[2] In the Dötz reaction[3] (that is, the reaction of certain Fischer carbenes with alkynes) **B** or an η^1-vinylcarbene complex **C** derived from the latter is carbonylated by a CO ligand. The resulting vinylketene complex can then react further, depending on the starting materials and the reaction conditions, to form one of numerous possible types of products. Carbene complexes of the Schrock type react with alkynes—with the insertion of the alkynes into the M=C bonds—only as far as stage **C**.[4]



A B C

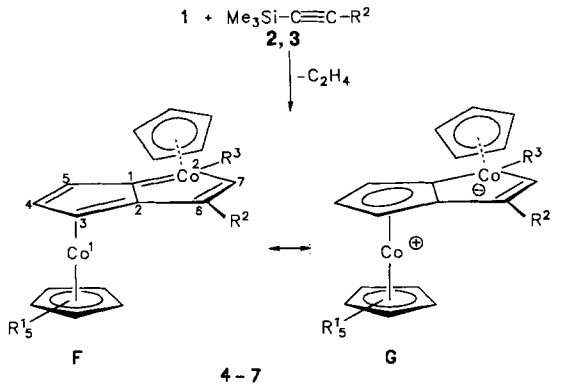
The μ-cyclopentadienylidene dicobalt complexes **1** can be described by the limiting structures **D** (carbene complex) and **E** (zwitterion).[5] With alkynes they do not react by insertion of the alkyne into the Co2–C1 bond.



D E

1a, R^1 = H
1b, R^1 = Me
1c, R^1_5 = Me_4Et

Turquoise **1a** decomposes in the presence of but-2-yne, hex-3-yne, bis(*tert*-butyl)acetylene, diphenylacetylene, or bis(benzo-1,2-dioxaborolyl)acetylene at temperatures above 50 °C after a short time to form dark products that could not be characterized. Bis(trimethylsilyl)acetylene **2a**, on the other hand, reacts readily with the complexes **1** at 45 °C in a very unusual reaction to form the binuclear complexes **4** with a cobaltabicyclic ring system as ligand (Scheme 1). With



F 4–7 G

Scheme 1. **2a**, R^2 = $SiMe_3$; **2b**, R^2 = $SiEt_3$; **2c**, R^2 = $SiMe_2tBu$; **3**, R^2 = *t*Bu; **4a**, R^1 = H, R^2 = R^3 = $SiMe_3$; **4b**, R^1 = Me, R^2 = R^3 = $SiMe_3$; **4c**, R^1_5 = Me_4Et, R^2 = R^3 = $SiMe_3$; **5a**, R^1 = H, R^2 = $SiEt_3$, R^3 = $SiMe_3$; **5a'**, R^1 = H, R^2 = $SiMe_3$, R^3 = $SiEt_3$; **6a**, R^1 = H, R^2 = $SiMe_2tBu$, R^3 = $SiMe_3$; **6a'**, R^1 = H, R^2 = $SiMe_3$, R^3 = $SiMe_2tBu$; **7a**, R^1 = H, R^2 = *t*Bu, R^3 = $SiMe_3$.

bis(triethylsilyl)acetylene, **1a** does not react under similar conditions; decomposition occurs above 60 °C. The unsymmetrically substituted bis(silyl)alkynes **2b, c** react with **1a** to give nonseparable mixtures of the stereoisomers **5a**, **5a'** and **6a**, **6a'**, respectively. In both cases smaller amounts of the complex **4a** with two trimethylsilyl groups in the cobaltabicyclic system are also formed. Only the product **7a** with the trimethylsilyl group on the cobalt atom is obtained regioselectively from **1a** and **3**.

The constitution of the novel blue-violet binuclear complexes **4–7** can be derived from the NMR spectra.[6] The singlet resonance signals displaced far downfield (δ = 9.9–11.1) for the metal-enyl hydrogen atom 7-H as well as the broadened downfield ^{29}Si NMR signals ($\delta \approx 30$–40) of the silyl groups on the cobalt atoms are especially characteristic. ^{13}C NMR signals for the quaternary carbon atoms C1 bound to the cobalt atom are not observed at all. The "car-

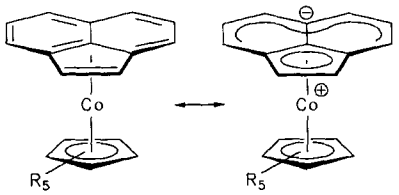
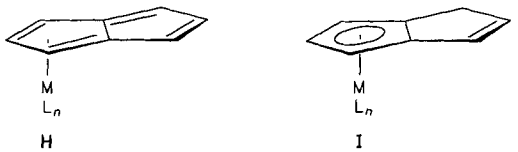
bene" carbon atoms are not detectable in the starting materials **1** either.[5, 7]

The complexes **4**–**7** can be described by limiting structures such as **F** with η^4-bonding of the metallabicyclic ring system to the $CpCo^1$ group ($Cp = \eta^5$-C_5H_5) as well as by zwitterionic formulations such as **G**. In the latter case the bicyclic system should be η^5-coordinated to the $[CpCo]^+$ group. A charge separation such as in **G** then appears to be energetically favorable if at the same time partial structures that resemble the cobaltocenium cation are possible. This becomes clear, for example, in **1** (limiting structures **D**↔**E**) and the mononuclear complexes $[(C_5R_5)Co$(acenaphthylene)] (**8**, R = H, Me),[8] both of which should be formulated



8a, R=H
8b, R=Me

with considerable zwitterionic contributions. **4**–**7** are related to π complexes of pentalene (**H**) on the one hand and to π complexes of dihydropentalenyl (**I**) on the other by the isolobal series $CpCoR \leftrightarrow d^7\text{-}ML_4 \leftrightarrow CH$ and $[CpCoR]^- \leftrightarrow d^8\text{-}ML_4 \leftrightarrow CH_2$ respectively. To our knowledge, at the present time only the latter are known, however, they have η^5-dihydropentalenyl ligands.[9]



H I

Insight into the bonding is provided by an X-ray structural analysis of **4c**.[10] The carbacyclic five-membered ring of the cobaltapentalene ligand is bonded through all five carbon atoms to the $[(\eta^5\text{-}C_5Me_4Et)Co]$ fragment (Fig. 1). The bond between Co1 and C1, which is slightly displaced (0.07 Å) from the C2-C3-C4-C5 plane, is, at 2.206(6) Å, longer than the bonds between Co1 and the carbon atoms C2–C5. This indicates a transition to the η^4-coordination, as is also found for the cyclopentadienylidene ligand in the binuclear complexes of type **1** (d(Co1–C1) = 2.186(6) (**1a**[11]), 2.204(5) Å (**1b**[11]), d(Co1-C2 to C4) = 1.98–2.04 and 1.99–2.06 Å (**1b**). It is striking that, in the planar CoC_4 five-membered ring, both of the endocyclic Co–C bonds starting from Co2 are very short and almost equal in length (1.88 Å). This value is comparable to the bond lengths Co2–C1 in **1** (**1a**: 1.866(6) Å,[11] **1b**: 1.872(5) Å[11]). The length of formal Co–C(sp^2) single bonds, for example in the cobaltacyclopentadienes (cobaltoles) $[(\eta\text{-}C_5H_4R)(PPh_3)Co(C_4H_4)]$ (R = H, COOMe),[12] lies between 1.93 and 1.95 Å. The C6–C7 bond is shorter than the remaining C–C bonds in the cobaltapentalene. Overall, the structural data indicate that several limiting structures such as **F** and **G** have to be taken into account in a qualitative description of the bonding in the dicobalt complexes **4**–**7**.

Compared to the extremely air- and moisture-sensitive starting compounds **1**, **4**–**7** are much less reactive. They are

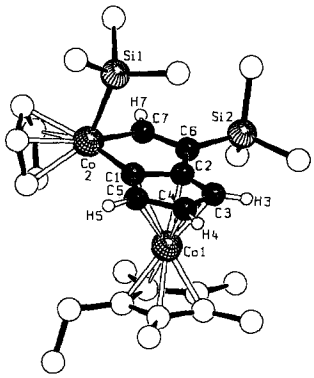


Fig. 1. Molecular structure of **4c**. Hydrogen atoms of the Cp, CH_3, and C_2H_5 groups are not shown. Selected bond lengths [Å] and angles [°] with standard deviations given in parentheses: Co1-C1 2.206(6), Co1-C2 2.106(6), Co1-C3 2.007(7), Co1-C4 1.981(7), Co1-C5 2.049(6), Co2-Si1 2.281(2), Co2-C1 1.883(6), Co2-C7 1.877(7), C1-C2 1.462(8), C1-C5 1.433(8), C2-C3 1.410(9), C2-C6 1.459(8), C3-C4 1.428(10), C4-C5 1.410(10), C6-C7 1.379(9); C5-C1-C2 105.0(5), C2-C1-Co2 114.7(4), C1-C2-C3 109.1(5), C1-C2-C6 113.6(5), C2-C3-C4 107.9(6), C3-C4-C5 107.9(6), C1-C5-C4 109.9(6), C1-Co2-C7 81.9(3), Co2-C7-C6 122.0(5), C2-C6-C7 107.7(5), C5-C1-Co2 140.2(5).

only moderately air-sensitive, can be chromatographed on silica gel, and can be distilled or sublimed without decomposition under vacuum (oil pump) at about 100 °C. They do not react with CO, even under pressure (30 bar, room temperature). The high stability of the cobaltabicyclic system is also shown by the fact that hydrogenation of the formal C6–C7 double bond over a Pd/C catalyst is not possible (1 bar H_2, room temperature).

The mechanism of formation of **4**–**7** can only be surmised at the present time. We believe that oxidative addition of the silylalkyne to the electron-rich Co2 in **1** is probably one of the first reaction steps.[13] The σ-alkynyl group that is thus formed could attack the cyclopentadienylidene ligand at C2, from which a [1,3] hydride shift to the enylic position (C7) would be possible.

Experimental

1b: A solution of [Cp*Co(cyclopentadiene)] (580 mg, 2.33 mmol) [14] and $[CpCo(C_2H_4)_2]$ (440 mg, 2.44 mmol) [15] in petroleum ether (ca. 40 mL) was transferred to a 250 mL reaction flask, a slight vacuum was applied, and the solution was left to stand at room temperature. The flask was flushed daily with argon and slightly re-evacuated. After four days the deep-green reaction solution was decanted off from the crude product which was recrystallized from toluene at −20 °C. Yield 230 mg (25%) of dark-green **1b**. M.p. 152 °C; correct C,H analysis.

^{1}H NMR (200 MHz, [D$_8$]toluene) δ = 1.2 (m, 2H, C_2H_4), 1.40 (s, 15H, Cp*), 3.0 (m, 2H, C_2H_4), 3.49 (br.s, 2H, CH), 3.85 ("t", 2H, CH), 4.67 (s, 5H, Cp); ^{13}C{^{1}H} NMR (50 MHz, [D$_8$]toluene, assignment by J-modulation test) δ = 9.8 (C_5Me_5), 31.7 (C_2H_4), 79.4 (CH), 84.0 (Cp), 85.4 (CH), 90.7 (C_5Me_5); MS (EI, 70 eV) m/z 382 (10 [$M - C_2H_4$]$^+$), 260 (16, [Cp*Co(C_5H_6)]$^+$), 259 (100, [Cp*CoCp]$^+$), 258 (23, [Cp*Co(C_5H_4)]$^+$), 189 (18, [Cp_2Co]$^+$), 133 (8, [Cp*-2H]$^+$), 124 (18, [CpCo]$^+$), 59 (6, Co$^+$).

1c: Preparation from [(C_5Me_4Et)Co(cyclopentadiene)] [14] and $[CpCo(C_2H_4)_2]$ analogous to **1b** (yield 55%).

4a: A solution of **1a** (400 mg, 1.2 mmol) and **2a** (200 mg, 1.2 mmol) in toluene (20 mL) was heated in a slight vacuum for three hours at 45 °C. After the reaction solution was concentrated by evaporation to about 5 mL, the solution was chromatographed on silica gel (eluent toluene). After the solvent was removed from the violet eluate, 440 mg (78% yield) of solid **3a** was isolated. Correct C,H analysis; MS (EI, 70 eV) m/z 482 (32, M^+), 409 (8, [M − $SiMe_3$]$^+$), 285 (42, [M − $SiMe_3$ − CpCo]$^+$), 189 (42, [Cp_2Co]$^+$), 124 (12, [CpCo]$^+$), 73 (30, [$SiMe_3$]$^+$).

4b: is obtained in a similar manner to **4a**, from **1b** and **2a** (yield 69%).

4c: A solution of **1c** (650 mg, 1.5 mmol) and **2a** (280 mg, 1.6 mmol) in toluene (40 mL) was heated in a slight vacuum for five hours at 60 °C. After the reaction mixture was concentrated to 5 mL by evaporation, the solution was chromatographed twice on silica gel (eluent toluene). After the solvent was removed

from the violet eluate, 680 mg (80% yield) of pure **3c** was obtained and was recrystallized from cyclopentane at −78 °C; yield 590 mg (69%); m.p. 124–126 °C, correct C,H analysis; MS (EI, 70 eV) *m/z* 566 (46, M^+), 493 (14, $[M - SiMe_3]^+$), 442 (13, $[M - CoCp]^+$), 369 (100, $[M - CoCp - SiMe_3]^+$), 273 (19, $[(C_5Me_4Et)CoCp]^+$).

5a, **5a′** (mixture of isomers): obtained similarly to **4a**, from **1a** and **2b**; yield 68% (mixture of **5a**, **5a′** and a small amount of **4a**).

6a, **6a′** (mixture of isomers): obtained similarly to **4a**, from **1a** and **2c**: yield 82% (mixture of **6a**, **6a′** and a small amount of **4a**).

7a: obtained similarly to **4a** from **1a** and **3** (yield 83%).

Synthesis of (2-Arylindol-3-yl)acetamides as Probes of Mitochondrial Steroidogenesis—A New Mechanism for $GABA_A$ Receptor Modulation**

By *Alan P. Kozikowski,* Dawei Ma, Elena Romeo, James Auta, Vissilios Papadopoulos, Gulia Puia, Erminio Costa*, and *Alessandro Guidotti*

Binding studies,[1] molecular biological studies,[2] and steroid biosynthesis studies[3] have revealed the presence in the central nervous system (CNS) of a structurally and functionally distinct class of benzodiazepine binding sites located on the outer mitochondrial surface. These receptors bind benzodiazepines and non-benzodiazepine derivatives such as imidazopyridines (Alpidem) and other ligands including the endogenous peptide DBI. This peptide is present in the peripheral and CNS cells that contain this mitochondrial receptor[4]; it binds with high affinity (10^{-8} M) and stimulates mitochondrial steroidogenesis in vitro.[5] In order to adhere to the classical nomenclature that names a receptor from the endogenous ligand, we have termed this receptor the mitochondrial DBI receptor (MDR).[5] This MDR is thus to be distinguished from the neuronal benzodiazepine binding sites located predominantly on the extracellular domain of the type A receptor for γ-aminobutyric acid ($GABA_A$ receptor), sites which when occupied serve to modulate the GABA-dependent conformational transitions in the associated chloride ion channel.[6]

Neurosteroid precursors are synthesized in mitochondria under the regulation of the mitochondrial benzodiazepine receptors. The glial cells probably constitute the most important steroidogenic cells in the brain, and evidence indicates that they produce pregnenolone and perhaps[7] dehydroepiandrosterone sulfate, 3α-hydroxy-5α-pregnan-20-one (3α-OH-DHP), and 3α,21-dihydroxy-5α-pregnan-20-one (THDOC).[4] These steroids bind with high affinity to sites probably located on the transmembrane domain of the heterooligomeric integral membrane protein functioning as the $GABA_A$ receptor, thereby modulating the responsiveness of the $GABA_A$ receptor. These MDR receptors would therefore appear to offer an intriguing new, but indirect, pharmacological approach to modulation of the $GABA_A$ receptor complex (Fig. 1).

At present, the isoquinolinecarboxamide PK11195 is the only compound known to possess high affinity for the MDR without binding to other known neurotransmitter recep-

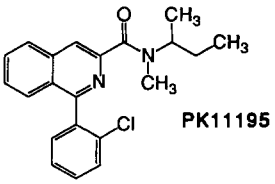
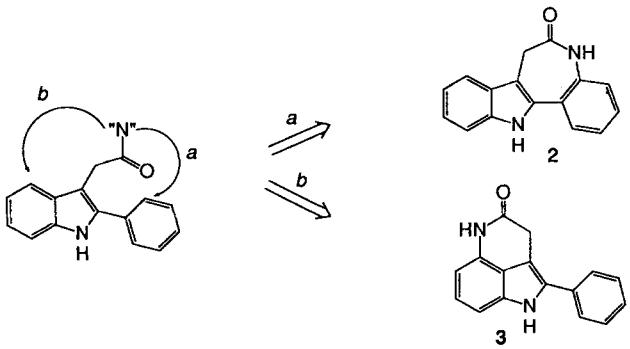
tors.[8] This compound, however, fails to cause marked behavorial effects in rats,[9] probably because either it acts as a partial agonist of the MDR, or it has some other action in the biosynthesis or release of neurosteroids. In an effort to discover agonists that exhibit high affinity and selectivity for these mitochondrial receptors, thereby permitting the determination of their role and therefore the role of steroidogenesis in CNS function, we have synthesized a novel class of (3-indolyl)acetamides possessing these desired properties.

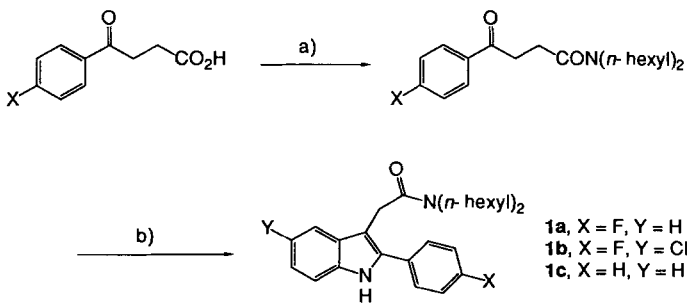


Of the many diverse (2-arylindol-3-yl)acetamides we prepared molecule **1a**, possessing a 2-*para*-fluorophenyl substituent and two *n*-hexyl substituents on the amide nitrogen atom, proved to be one of the most potent and efficacious. This compound was readily prepared by a five-step protocol (Scheme 1). The starting keto acid was obtained from the CN^--catalyzed addition of *p*-fluorobenzaldehyde to acrylonitrile,[10] followed by hydrolysis of the nitrile group. Next, the acid was transformed into the amide via its mixed anhydride (Scheme 1a), and the oxoamide was treated with phenylhydrazine to furnish the corresponding hydrazone. A Fischer indole synthesis promoted by zinc chloride[11] then gave crystalline **1a** in an overall yield of 70% (Scheme 1b). Compound **1a** has a K_i value of 4.4 ± 0.15 nM for the MDR as measured by the displacement of [^{3}H]4′-chlorodiazepam from rat cerebellar glial cell membranes, and a K_i value of 5.0 ± 1.6 nM as measured by the displacement of [^{3}H]PK11195. Compound **1b**, an analogue of **1a** with a chloride substituent on the indole unit, has a K_i value of 2.3 ± 0.9 nM for the MDR, whereas analogue **1c** lacking halogens has a K_i value of 9.7 ± 0.6 nM. In order to gain further insights as to the structural characteristics of these molecules relevant to their high affinities for the MDR, we also synthesized inter alia two conformationally rigid analogues of **1c**. In these molecules the amide group is linked either to the *ortho* position of the phenyl substituent (**2**) or to the 4 position of the indole ring (**3**) (Scheme 2). Syntheses of

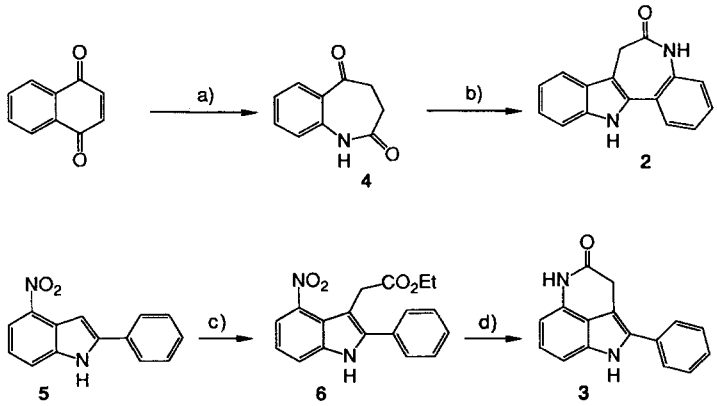


Scheme 2. Two possibilities for fixing the conformation of (2-phenylindol-3-yl)acetamides.

2 and **3** are presented in Scheme 3. Compound **2** was prepared by Fischer indole synthesis of the γ-oxolactam **4**, which is readily obtained from naphthoquinone by reaction with sodium azide in sulfuric acid followed by catalytic hydrogenation in analogy to ref. [12]. Analogue **3** was available from indole **5**, which was prepared according to the Bergman



Scheme 1. Synthesis of the MDR-selective (2-arylindol-3-yl)acetamides by the Fischer indole reaction. a) EtOCOCl, Et_3N, THF, −40 °C → −20 °C, 30 min, addition of HN(*n*-hexyl)$_2$, → room temperature (RT). b) 1. *p*-$YC_6H_4NHNH_2$, 100 °C, 30 min; 2. $ZnCl_2$, 170 °C, 5 min (65–85% overall).



Scheme 3. Synthesis of conformationally rigid analogues of the MDR-selective (2-phenylindol-3-yl)acetamide **1c**. a) 1. NaN_3, H_2SO_4, 0 °C → 10 °C, 3 d; 2. Pd/C, 1 atm H_2, $CHCl_3$ (9% overall). b) 1. $PhNHNH_2$, benzene, reflux, 30 min; 2. $ZnCl_2$, 170 °C, 5 min (85%). c) 1. $H_2C{=}NMe_2^+Cl^-$, CH_2Cl_2; 2. Me_2SO_4, NaCN, MeOH, RT, 18 h (57% overall); 3. HCl, EtOH, H_2O, reflux, 18 h (87%). d) 1. 1 atm H_2, Pd/C, EtOH (96%); 2. toluene, reflux, 72 h (69%).

protocol.[13] **5** was converted to its gramine derivative and then to the 3-indolylacetonitrile by reaction with dimethyl sulfate and sodium cyanide. The nitrile was converted in turn to ethyl ester **6** and the nitro group reduced to an amine group by hydrogenation over Pd/C. Heating the aminoindole derivative in toluene at reflux then furnished the required lactam **3**. In our experiments neither **2** nor **3** was capable of displacing the binding of [^{3}H]4′-chlorodiazepam, thus suggesting the importance of other conformations of the amide unit to MDR affinity.[14]

Further details of the biological properties of the new ligands **1** will be reported separately. We wish to note here, however, that **1a** failed to bind to a wide variety of other receptor systems[15] thus establishing its selectivity, and moreover, electrophysiological experiments failed to show any direct action on GABA-gated chloride ion currents in cortical neurons.[16] Furthermore, **1a** was found to produce an increase in pregnenolone formation in glial cells[3] with an EC_{50} of about 3 nM. In behavioral experiments with rats, compound **1a** was found to increase the number of entries and the time spent in the open arms of the elevated plus maze[17] in a dose-dependent fashion (0.57 to 1.1 $\mu mol\,kg^{-1}$), allowing the conclusion that such compounds can reduce fear of novelty (neophobia) without causing sedation.

In summary, the novel, structurally simple, and readily modifiable 3-indolylacetamides[18] reported herein may herald a new direction in the development of modulators of GABAergic receptor function by binding to MDR with stimulation of neurosteroid production. These compounds are of added interest in view of a recent report that pregnenolone and steroids metabolically derived from it possess memory-enhancing effects.[19]

Dependence of the Reactivity of Ag and Ni Clusters Deposited on Solid Substrates on the Cluster Size

By *C. N. Ramachandra Rao*,* *Venugopal Vijayakrishnan*, *Asok Kumar Santra*, and *Menno W. J. Prins*

The structure and properties of metal clusters are currently subjects of intense research.[1] Many fundamental aspects of metal clusters need to be understood, such as the dependence of the metallicity of the clusters on the size. Another important question, the variation of the reactivity of the metal clusters with size, has been examined in studies on alkali metal clusters in the gas phase.[2] We are interested in investigating how the reactivity of transition metal clusters deposited on solid substrates varies with cluster size, since such a study is relevant to heterogeneous catalysis. For this purpose we have examined the interaction of O_2 with Ag clusters deposited on graphite as well as the interaction of H_2S and CO with Ni clusters deposited on graphite or Al_2O_3 by employing X-ray and UV photoelectron spectroscopy (XPS and UPS). We have also employed Bremsstrahlung isochromat spectroscopy (BIS) and Auger electron spectroscopy for the characterization of the clusters. This study has revealed that the cluster size strongly determines the reactivity of Ag clusters towards O_2 and of the Ni clusters towards H_2S and CO, that is, the cluster size indeed plays an important role in heterogeneous reactions.

Ag and Ni were deposited on the solid substrate in situ at room temperature under ultrahigh vacuum (UHV) conditions in the preparation chamber (base pressure ca. 10^{-10} Torr) of the electron spectrometer (VG-ESCA3 Mk II). The metals were vaporized by means of resistive heating of high purity samples wound around a tungsten filament as described elsewhere.[3] Polycrystalline graphite was annealed at 600 K and sputtered with 6 kV Ar ions to produce an amorphous surface and remove the surface contaminants. The Al_2O_3 substrate was prepared in situ by surface oxidation of a pure Al foil in the preparation chamber. The final oxide film was approximately 20 Å thick. Charging effects of the Al_2O_3 film were marginal and were corrected for. We quantified the sizes of the clusters by comparing the intensity of the signal for the transitions of the metal core level I_M (Ag,

$3d_{5/2}$; Ni $2p_{3/2}$) to the intensity of the signal for transitions of the core level of the support I_S (S 1s for graphite and O 1s for Al_2O_3). The surface coverage θ, estimated by the method of Carley and Roberts,[4] was 4.8×10^{13} and 6.3×10^{13} atoms per cm^2, respectively, for the smallest of clusters of Ag and Ni studied. These values correspond to a mean cluster radius of 5–9 Å as estimated by the method of Wertheim and Di-Cenzo.[5] The clusters were exposed to purified O_2, CO, or H_2S in the preparation chamber (1 Langmuir = 10^{-6} Torr s).

We examined the variation of the shift in the Ag $3d_{5/2}$ binding energy ΔE (relative to 368.2 eV, the value for bulk silver) with the cluster size (or I_{Ag}/I_C) before studying the interaction of O_2 with the clusters. The results (Fig. 1 top) show that ΔE increases markedly with the decrease in the cluster size, especially when $I_{Ag}/I_C < 3$. The value of ΔE for the smallest Ag cluster is approximately 0.6 eV; the kinetic energy of the Auger electrons [Ag ($M_4N_{45}N_{45}$) line] at this cluster size also shifts by −1.2 eV relative to the value of silver metal. The marked change in ΔE occurring around $I_{Ag}/I_C \approx 3.0$ indicates a stage at which metallic screening

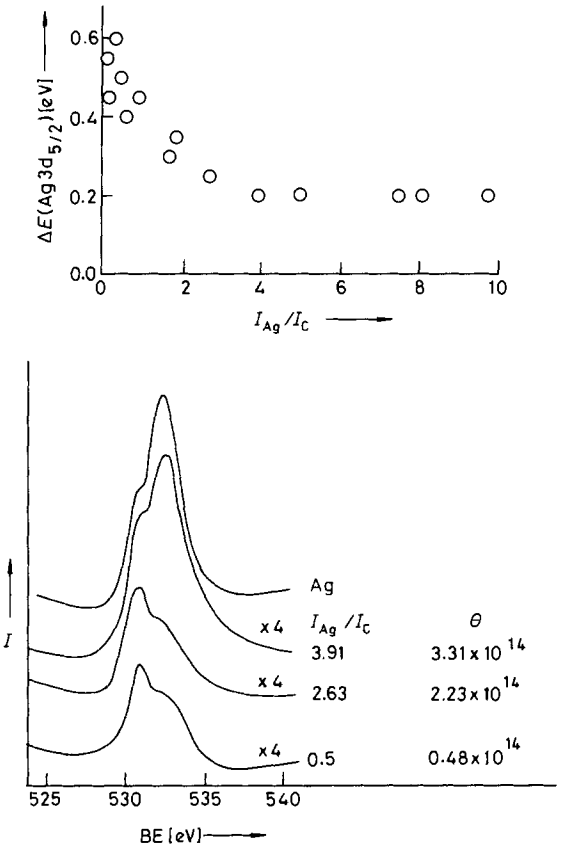

Fig. 1. Top: Variation in the shift of $3d_{5/2}$ binding energy of Ag clusters deposited on graphite relative to the bulk metal with I_{Ag}/I_C. Bottom: Change in the O 1s spectra of Ag clusters exposed to 500 L O_2 at 80 K. I = relative intensity, θ = surface coverage, number of atoms per cm^2.

becomes negligible. The variation of ΔE in Figure 1 is therefore a manifestation of the metal–insulator transition that occurs with decreasing cluster size. We have obtained further confirmation of such a transition by BIS measurements which show the emergence of new states close to the Fermi energy E_F with increase in cluster size.

In Figure 1 bottom, typical O 1s spectra of Ag clusters exposed to 500 L O_2 at 80 K are shown. We see that the intensity of the O 1s signal at 530.5 eV attributed to dissociated atomic oxygen (O) decreases with increase in cluster size relative to the signal due to molecular oxygen (O_2) (532.5 eV). We verified that the 532.5 eV feature was not due to OH species. On bulk Ag, the adsorbed oxygen species at 80 K is known to be predominently O_2.[6, 7] It appears that small clusters favor dissociation of O_2. The proportion $O:O_2$ on large clusters ($I_{Ag}/I_C > 3$) is close to that on bulk Ag. Furthermore, the temperature dependence of the intensity ratio of the O 1s signals $I(530)/I(532)$, that is, the ratio $O:O_2$, is dependent on cluster size. $I(530)/I(532)$ is temperature independent between 80 and 300 K for small values of I_{Ag}/I_C but shows a marked dependence for the bulk silver metal as well as for large clusters. This interaction of O_2 with Ag dependent on cluster size is remarkable.

The interaction of H_2S with Ni clusters deposited on graphite shows a definite size dependence. H_2S adsorbed on Ni clusters or bulk Ni at 80 K (500 L) gives rise to two signals at 164.5 eV and 162.0 eV due to H_2S and S^{2-}, respectively. When the temperature is increased to 150 K, the major sulfur species is S^{2-} in all the cases, but the ratio of H_2S to S^{2-} shows a temperature dependence which varies with cluster size. In Figure 2 we have plotted the intensity ratio of the signals for the core-level transitions $I_{S^{2-}}(T)/I_{S^{2-}}(300)$ versus temperature for different cluster size.

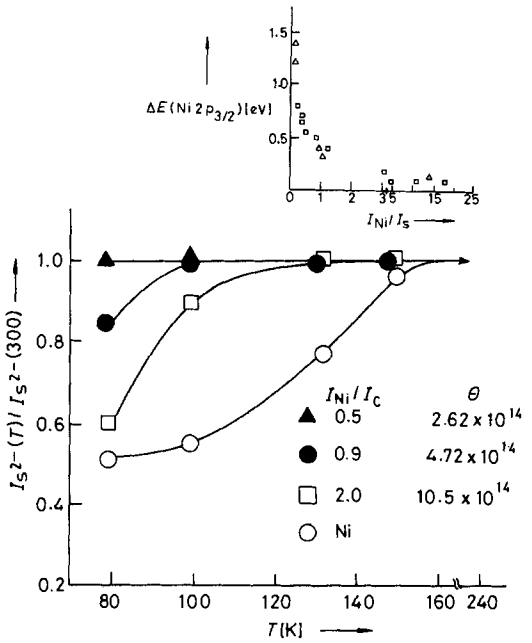

Fig. 2. Variation of the normalized intensities of the signals for the core-level transitions of S^{2-} with temperature for different sizes of Ni clusters deposited on graphite (for θ see Fig. 1). The inset shows the variation in the shift of the $2p_{3/2}$ binding energy of Ni clusters relative to the bulk metal with I_{Ni}/I_S. □ = Nickel on graphite; △ = nickel on Al_2O_3.

The inset shows the variation of the shift in the Ni $2p_{3/2}$ binding energy relative to the value for bulk nickel (852.9 eV). This demonstrates how metallic screening decreases with the decrease in cluster size, especially when $I_{Ni}/I_C \leq 1$. For the smallest clusters we examined, the kinetic energy of the Auger electrons [Ni ($L_3M_{45}M_{45}$) line] decreases by −1.4 and −2.8 eV (relative to the bulk metal) on graphite and Al_2O_3,

respectively. From Figure 2 we see that when the clusters are small ($I_{Ni}/I_C < 1$), the proportion of S^{2-} is essentially independent of temperature, but the temperature dependence becomes more marked with the increase in the cluster size. This observation suggests that on small Ni clusters, H_2S dissociates to the maximum extent possible even at the lowest temperature, whereas in the case of larger clusters, the extent of dissociation is dependent on temperature.

We have studied the interaction of carbon monoxide on Ni clusters deposited onto an Al_2O_3 substrate by means of He II UPS. Figure 3 shows the difference spectra of CO absorbed on Ni clusters of different sizes.

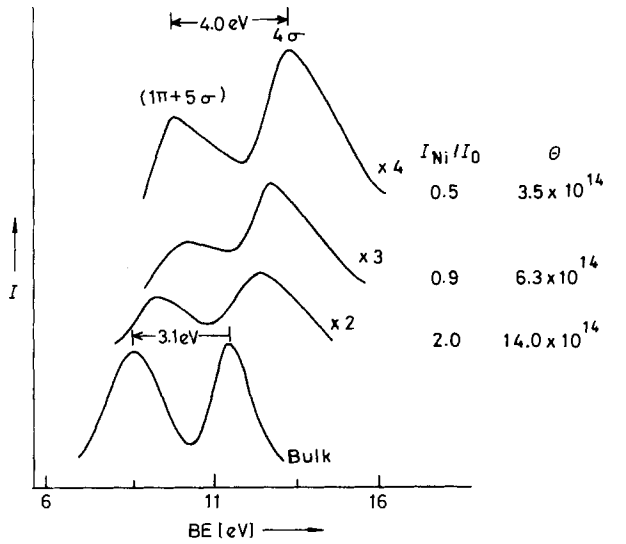

Fig. 3. He II difference spectra of CO adsorbed (at 50 L) on Ni clusters (Al_2O_3 substrate) for various cluster sizes. The asymmetry of the bands arises because of the low intensity of the signal and the background signal due to the Al_2O_3 support.

A shift in the Co valence band closer to the E_F is evident with increasing cluster size. This shift is due to the increasing relaxation of the highest excited states of the CO molecule which depends on the density of Ni clusters and therefore on their size. More importantly, the size of the separation between the $(1\pi + 5\sigma)$ and the 4σ bands of the adsorbed CO varies with the cluster size. On bulk nickel this is around 3 eV. The separation increases with the decrease in the cluster size reaching a value of ≈ 4.0 eV for the smallest cluster size we studied ($I_{Ni}/I_O \approx 0.5$). We consider this to be due to the weakening of the C–O bond as a result of the increasing interaction between CO and Ni with decreasing cluster size.[8]

The present investigation shows that small clusters of Ag and Ni are more reactive than the bulk metal, a conclusion that finds support from an earlier study on the chemisorption of Cl_2 on Cu, Ag, and Pt clusters[9, 10] and of CO on Pt clusters.[11] What is noteworthy in the present study is that the dependence of reactivity on cluster size becomes marked at a stage where metallic screening becomes weak, signifying the onset of a metal–insulator transition. The cluster regime where the reactivity is enhanced seems to correspond to one where the clusters are not really metallic. This observation is of relevance to heterogeneous catalysis in which the metals dispersed on oxide supports generally consist of clusters of 100–200 atoms.

A Simple Method for the Replacement of the OH Group in Free Carboxylic Acids by the Phosphonium Ylide Group**

By *Hans Jürgen Bestmann,** *Roman Dostalek,* and *Bernd Bauroth*

Bis(trimethylsilyl)methylenetriphenylphosphorane **3**[1] can be prepared readily and in larger amounts[2] from the reaction of the monosilylated ylide **1**[1, 2] with trimethylbromo- or -iodosilane **2** to the corresponding salt of **3** followed by deprotonation, best conducted with sodium(bistrimethylsilyl)amide.[3] The oxidation of **3** with the adduct of ozone and triphenylphosphite, **4**, leads to bistrimethylsilylketone **5**.[4]

We have now treated **3** with the free carboxylic acids **6** and observed that acyl ylides **9** are formed besides hexamethyl-

[**] This research was supported by the Volkswagen Stiftung.

disiloxane (**10**). We assume that the phosphonium salts **7** arise primarily from **3** and **6**. The carboxylate anion desilylates the phosphonium ion leading to **1** and the trimethylsilyl ester **8**, which react to give **9** and **10**.[2]

The reaction thus allows the replacement of the OH group of the free carboxylic acid by the ylide function in a one-pot procedure without the initial preparation of an acid chloride, a thiol ester,[5] or an acylimidazole.[6] Dicarboxylic acids **11** are converted to bisacyl ylides **12**. Free amino acids may also be employed in the reaction as shown in Table 1. This method allows access to α-aminoacyl ylides such as **9k** and **9l** for the first time. Reactions with *O*-protected tartaric acids and monomethyl ester tartrate derivatives lead to undefined elimination products.

Table 1. Monoacyl ylides **9** [a] and bisacyl ylides **12** [a] prepared from monocarboxylic acids **6** and dicarboxylic acid **11**, respectively.

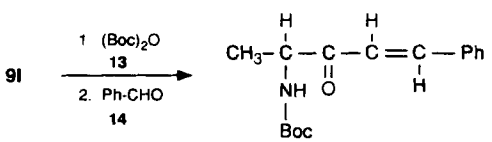
[a] All new compounds **9** and **12** provided correct elemental analyses and clean spectra. Our data for known compounds are identical to those in the literature. [b] $[\alpha]_D = +18.4$ ($c = 1.6$ in CH_2Cl_2). [c] Treated with oxalic acid.

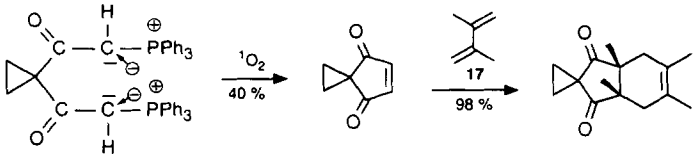
Compound **9l** (prepared from alanine and **3**) is attacked by Boc anhydride **13** (Boc = *tert*-butoxycarbonyl) at the amino group (98% yield); the subsequent reaction with benzaldehyde **14** provides the *N*-Boc-protected merucathinone **15** in 88% yield. The preparation of the free base (isolated as the oxalate) from **15** is known.[8] It is a component of Catha edulis Forsk., a wide-spread drug in Yemen and eastern



15

Africa.[9] The measurements of the optical rotation of **15** provided an *ee* of 78.5% (in comparison to the literature value[8]: *ee* ≧ 98%). A determination of the enantiomeric excess of **9k** by means of ^1H NMR spectroscopy with shift reagents did not succeed. Thus we could not prove if the partial racemization occurred in the reaction of alanine with **3** or in the Wittig reaction.

To test the synthetic potential of the bisacyl ylides **12**, compound **12q**, prepared from (*Z*)-1,2-cyclopropane dicarboxylic acid, was oxidized with singlet oxygen.[10] The resulting spirobicyclic cyclopentenedione derivative **16**, produced in 40% unoptimized yield, was treated with dimethylbutadiene **17**. The formation of the product **18** demonstrated the dienophilic character of **16**. A potential application of **16** is in the synthesis of prostaglandins with a spirocyclic cyclopentane ring.



12q **16** **18**

Experimental Procedure

9, **12**: 30 mmol of bis(trimethylsilyl)methylenetriphenylphosphorane **3** was dissolved in 120 mL of THF. 30 mmol of the appropriate monocarboxylic acid **6** or 15 mmol of the dicarboxylic acid **11** were added to the solution at room temperature. The reaction mixture was stirred for 30 min at room temperature and then heated at reflux for ca. 3–4 d. After the reaction was complete, the solvent was removed under aspirator pressure. The residue was recrystallized from ethyl acetate or toluene (diethyl ether was added if necessary). Addition of diethyl ether to the mother liquor allowed the isolation of a second fraction, which in the most cases is only slightly impure.

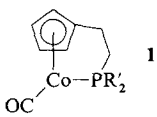
Inhibition of the [2+2+2] Cyclization by the Formation of Chelates: Alkyne and Vinylidene Complexes with Cyclopentadienylcobalt(I)**

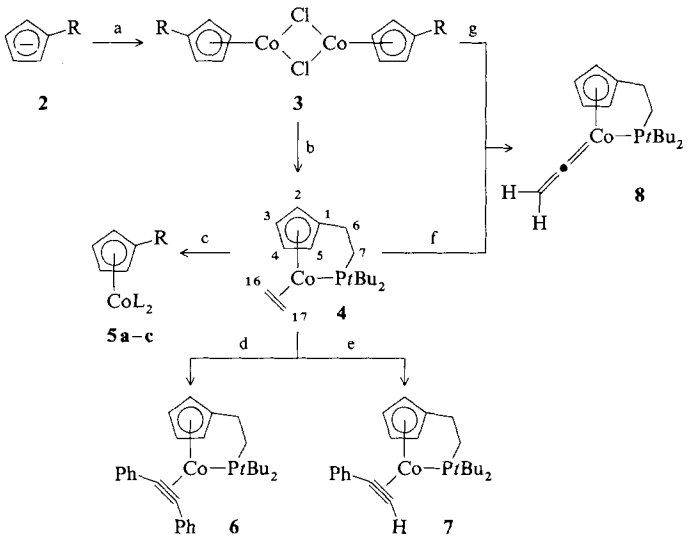
By *Holger Butenschön*,* *Ralf T. Kettenbach*, and *Carl Krüger*

The reactivity of cyclopentadienylcobalt(I) complexes as well as many of their derivatives substituted on the cyclopentadienyl ligand has been investigated intensively, particularly with regard to the cyclotrimerization of alkynes to arenes and also their [2+2+2] cocyclization with a large variety of other unsaturated substrates.[1] With the use of $\eta^{5:1}$-[(phosphinoalkyl)cyclopentadienyl]cobalt(I) chelate complexes such as **1** and **4** these reactions are almost completely prevented by the phosphinoalkyl groups.[2] We have now found that this is a good precondition for obtaining alkyne complexes with cyclopentadienylcobalt(I) fragments which for the first time also contain alkynes whose triple bond is arranged terminally. Furthermore, with the formation of the previously unknown cyclopentadienyl-vinylidene cobalt(I) complexes a reaction type hitherto not observed for cyclopentadienylcobalt(I) compounds has become possible.[3] The vinylidene complex **8** is available in just a few steps in high yield (Scheme 1).



1

Since the carbonyl complexes **1** (R′ = Ph, *i*Pr, *t*Bu) readily available from the reaction of lithium [phosphinoethyl]-cyclopentadienides with [ICo(CO)$_4$][4] have proven to be not very reactive,[2] the corresponding ethene complex **4** was prepared according to the method of Kölle et al.[5] For this the anion **2**[2] was treated with cobalt(II)chloride to give the paramagnetic dimer **3** (74%). Treatment of a solution of **3**



Scheme 1. R=$CH_2Ch_2PtBu_2$; a) $CoCl_2$, THF, −30 → 20 °C, 20 min, then 20 °C, 1 h, 74%; b) 1% Na/Hg, ethene, THF, −55 °C, 1 h, 93%; c) L_2, THF, 20 °C, **5a**: L_2 = cycloocta-1,5-diene, 4 d, 82%, **5b**: L_2 = 1,2-bis(diisopropylphosphino)ethane, 40 h, 93%, **5c**: L_2 = 2,2′-bipyridyl, 18 h, 88%; d) diphenylethyne, THF, 20 °C, 14 h, 83%; e) phenylethyne, THF, 0 °C, 14 d, 98%; f) ethyne, pentane, 20 °C, 18 h, 20%; g) 1% Na/Hg, ethyne, THF, −50 °C, 1 h, then 20 °C, 2 h, 88%.

and introduction of ethene afforded compound **4** in 93% yield (red-black crystals, m.p. 115 °C, spectroscopic data see Table 1). The ^{1}H NMR spectrum of **4** is temperature dependent and indicates a hindered rotation of the ethene ligand about the metal–olefin axis. The activation energy of **4** is 62 kJ mol^{-1} estimated from the coalescence temperature. It lies within the range also observed for the barrier to rotation of other ethene complexes.[6]

All spectroscopic data are in complete agreement with the structure of **4**. The mass spectrum of **4** is only slightly different from that of **1** (R′ = *t*Bu) since the ethene and CO ligands, respectively, (both *m/z* 28) are the first to be lost, in both cases the same fragment ions are formed. The crystal structure of **4** is shown in Figure 1.[7] The cobalt atom is in a distorted trigonal-planar environment if the centers of the Cp (D1) and C_2H_4 ligands (D2) as well as the P atom are considered as coordination sites. The dihedral angles C1-C6-C7-P (36°) and C6-C7-P-Co (29°) indicate a torsion of the ethene bridge by which the formation of tetrahedral angles at C6 [110.6(2)°] and C7 [110.9(2)°] is made possible. The distance from the cobalt atom to the carbon atom C1 [2.057(3) Å] is only slightly shorter than the distance to the other C atoms of the cyclopentadienyl ligand, probably because of the chelate bridge.

Compound **4** is significantly more reactive than **1** (R′ = *t*Bu). Ligand exchange reactions with bidentate ligands at 20 °C with the loss of ethene lead to the chelate complexes **5** in high yields. In these complexes the di-*tert*-butylphosphinoethyl substituent of the cyclopentadienyl ligand is no longer bound to the cobalt atom (^{31}P NMR). Compound **5a**

had previously been obtained by the irradiation of **1** (R′ = *t*Bu) in cycloocta-1,5-diene in 42% yield.[2]

Whereas the η^2-alkyne complex **6** was obtained in only 39% yield by the reaction of **1** (R′ = *t*Bu) with diphenylethyne under photochemical conditions, **4** afforded **6** in 83% yield at 20 °C with the loss of ethene. Compound **4** reacts with phenylethyne at 0 °C to give the η^2-alkyne complex **7** (98%), which is the first cyclopentadienylcobalt(I) complex of an alkyne with a terminal triple bond. Unexpectedly, the reaction of the ethene complex **4** with ethyne at 20 °C does not yield the η^2-ethyne complex but **8**, the first vinylidene complex of a cyclopentadienylcobalt(I) compound,[8] in 20% yield. The identity of **8** was confirmed from the spectroscopic data; the chemical shift of the vinylidene carbon atom C10 (δ = 303.7) is particularly characteristic for the compound. Analogously to the formation of other vinylidene complexes it may be assumed that the η^2-ethyne complex occurs as an intermediate during the formation of **8**.[8] [(Phosphinoalkyl)cyclopentadienyl]vinylidene cobalt(I) complexes such as **8** are interesting as precursors for the rare cobalt–carbene complexes, which should be accessible by addition of nucleophiles.[8] To make this preparation feasible in worthwhile quantities, firstly higher yields from the preparation of the vinylidene complexes were necessary. In order to achieve this the synthetic route was shortened. Thus, the dimer **3** was not initially converted into the ethene complex **4** but was immediately treated with sodium amalgam and ethyne to give **8** (yield 88%). As a result **8** is available in amounts which allow further investigations, especially on the formation of cobalt–carbene complexes. At present we are investigating whether **7** can also be rearranged in order to establish whether the method can be extended to the synthesis of substituted vinylidene complexes.

Table 1. Spectroscopic data of the compounds **4**, **5b**,**c**, **7**, and **8** [a].

4: ^{1}H NMR (400 MHz, 300 K, [D$_8$]toluene): δ = 1.06 (d, 18H, CH$_3$, $^3J_{P,H}$ = 11.4 Hz), 1.81 (m, 2H, 6-H), $^3J_{P,H}$ = 19.0 Hz), 1.87 (m, 4H, 7-H, 16-H or 17-H, $^2J_{P,H}$ = 7.0 Hz), 2.27 (m, 2H, 16-H or 17-H, $\sum J_{16,17}$ = 9.0 Hz), 3.50 + 5.39 [AA′BB′ system, 4H, 2(5)-H, 3(4)-H, $\sum J_{2(5),3(4)}$ = 4.0 Hz]; (400 MHz, 353 K, [D$_8$]toluene): δ = 1.09 (d, 18H, CH$_3$, $^3J_{P,H}$ = 11.4 Hz), 1.84 (m, 2H, 6-H), 1.97 (m, 2H, 7-H), 2.02 (m, 4H, 16-H, 17-H), 3.46 + 5.38 [AA′BB′ system, 4H, 2(5)-H, 3(4)-H].

8: IR ([D$_8$]THF): $\tilde{\nu}$ = 1606 cm^{-1} (m, vinylidene C=C); ^{1}H NMR (400 MHz, [D$_8$]THF): δ = 1.33 (d, 18H, CH$_3$, $^2J_{P,H}$ = 12.6 Hz, 2.08 (m, 2H, 6-H, $^3J_{6,7}$ = 7.4 Hz, $^3J_{P,H}$ = 19.3 Hz), 2.09 (d, 2H, 10-H, $J_{P,H}$ = 9.6 Hz), 2.80 (m, 2H, 7-H, $^2J_{P,H}$ = 7.8 Hz), 4.49 [m, 2H, 2(5)-H or 3(4)-H, $\sum J_{2(5),3(4)}$ = 3.8 Hz], 5.03 [m, 2H, 2(5)-H or 3(4)-H]; ^{13}C NMR (100.6 MHz, [D$_8$]THF): δ = 25.8 (dt, C-6), 30.1 (dq, C-9), 36.6 (d, C-8), 41.0 (dt, C-7), 80.0 [d, C-2(5)], 81.6 [d, C-3(4)], 106.2 (dt, C-11), 112.3 (d, C-1), 303.7 (d, C-10); ^{31}P NMR (81 MHz, [D$_8$]THF): δ = 111.7; MS (70 eV): m/z (%) 322 (14) [$M^{\oplus}$], 296 (51), 254 (13), 240 (47), 184 (100), 137 (44), 59 (33), 57 (16).

[a] All new compounds were completely characterized by spectroscopy (^{1}H, ^{13}C, ^{31}P NMR, IR) and spectrometry (MS, and high-resolution MS) as well as by correct elemental analyses.

Experimental Procedure

All operations were carried out under argon.

3: In a Schlenk tube with a magnetic stirring bar, a solution of **2** (1.95 g, 15.1 mmol) in THF (120 mL) which had been previously cooled to −30 °C was added to cobalt(II) chloride (7.35 g, 30.1 mmol). The red suspension was stirred for 20 min, during which time its temperature warmed from −30 °C to 20 °C and subsequently for a further hour at 20 °C. The THF was removed under vacuum, the residue taken up in diethyl ether (2500 mL), and filtered through a P4 frit (under an argon atmosphere). The red-violet ether solution was cooled to −78 °C for the crystallization. This afforded **3** (7.33 g, 11.4 mmol, 73%) as black-violet plates, m.p. 192 °C (decomp).

4: In a 1000 mL three-necked flask with gas inlet tube, magnetic stirrer and two gas inlets with taps, ethene is introduced into a solution of (6.8 g, 10.2 mmol) **3** in THF (400 mL) at −55 °C. After 10 min, sodium amalgam (301.5 g, 1%, 152 mmol Na) was pipetted into the cooled, red-violet solution. The mixture was stirred for 1 h and warmed to 20 °C. The mud-brown mixture was filtered through a P4 frit, the red filtrate was concentrated to 20 mL and cooled to −78 °C. This afforded **4** (6.15 g, 19 mmol, 93%) as red-black crystals, m.p. 115 °C (decomp).

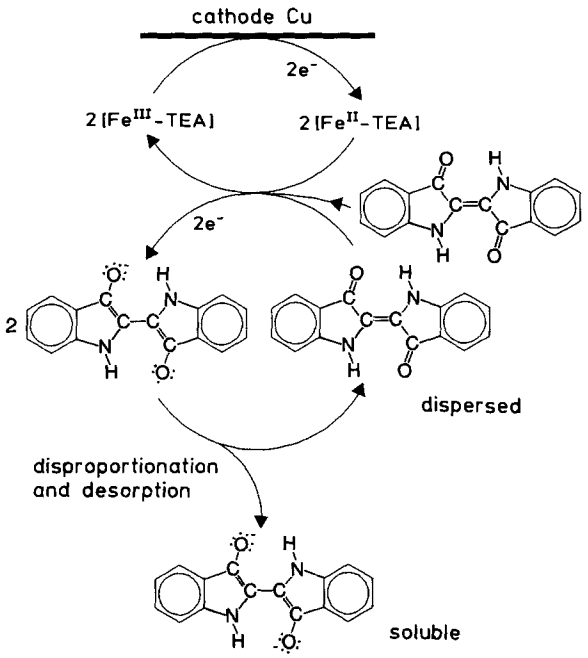
Reduction of Dispersed Indigo Dye by Indirect Electrolysis**

By *Thomas Bechtold,* Eduard Burtscher,* Angelika Amann*, and *Ortwin Bobleter*

The reduction of indigo, which is insoluble in water and alkaline solution, to the disodium salt of leuco-indigo, which is soluble in alkaline solution, is crucial to the application of indigo as a textile dye. This reduction is carried out in alkaline media with an excess of the reducing agent with a sufficiently negative redox potential. Because of the economic importance of this dye technology, a multitude of reducing agents have been examined (for instance, $Na_2S_2O_4$, sulfinic acid derivatives, organic hydroxycarbonyl compounds).[1] The reducing agents currently in use have the disadvantage of not being reversible, that is, the reducing agents cannot be recovered and the process baths cannot be recycled. Numerous mediators for the indirect electrochemical reaction of organic substances in homogenous solvent system have been described.[2] Investigations of reversible reducing agents led to the development of a procedure for indirect electrolysis: Coordination compounds of iron(II) and iron(III) salts and triethanolamine (TEA), which are stable in alkaline medium, were employed as mediators for the reduction of dispersed systems.[3]

Triethanolamine can form complexes with iron(II) as well as iron(III) ions in aqueous alkaline solvent systems that are stable enough,[4] so that iron concentrations up to 0.1 mol L^{-1} in aqueous sodium hydroxide ($c = 1$ mol L^{-1}) are possible. As was previously shown with cyclic voltammetry, a reversible charge transfer to the complexes can be achieved on HMDE electrodes (HMDE = hanging mercury drop electrode).[5] The cathodic peak potential E_{pc} of the coordination compounds for the transition Fe^{II}/Fe^{III} in aqueous alkaline solution is -1055 mV (vs. Ag/AgCl/3 mol L^{-1} KCl).

With this reversible redox system as a mediator, the finely dispersed indigo dye can be reduced by indirect electrolysis. The course of the reaction is summarized along the lines of the reaction model for the direct electrochemical reduction of anthraquinone-2-sulfonate[6] in Scheme 1.



Scheme 1. Course of the indirect electrochemical reduction of finely dispersed indigo with triethanolamine–iron coordination compounds in dilute sodium hydroxide solution.

The triethanolamine–Fe^{III} complexes generated in situ are reduced at the cathode (-1050 to -1100 mV vs. Ag/AgCl/3 mol L^{-1} KCl) to the corresponding Fe^{II} complexes. Since the reduction potential of the Fe^{II} complexes is low enough for a reduction of indigo, one electron is transferred from the Fe^{II} complex to the surface of the dispersed dye particle. The dye radical anion formed initially disproportionates with formation of leuco-indigo dianions, which are soluble in alkaline solution, and reoxidized indigo molecules. The dianion is desorbed from the surface of the dye particle and goes into solution. Whereas indigo is colored blue in the oxidized form, the reduced form provides yellow solutions with an absorption maximum at 410 nm. The extent of reaction can be followed either by photometric methods, or the indirect electrolysis can be monitored by a redox titration of the electrolyte with $K_3[Fe(CN)_6]$. The results of the potentiometric analyses are presented in Figure 1. The complete reduction of the dye is evident after electrolysis for 130 to 150 min.

The increase in the amount of dye dianions ($E = -710$ mV vs. Ag/AgCl/3 mol L^{-1} KCl) with increasing electrolysis times and the increase of the potential to the redox potential of the Fe^{II}/Fe^{III} complexes after complete reduction of the dispersed indigo are clearly recognizable. The current yields calculated from the experimental data are around 50–55%. It is important in estimating the current yields to take into account that the experiments were conducted in an electrolysis cell under air. Back-oxidation processes on the liquid–air interface thus lead to an apparent reduction of the current yield. Control experiments were

Höchsterstrasse 73, A-6850 Dornbirn (Austria)

[**] This research was supported by the Fonds zur Förderung der Wissenschaftlichen Forschung (Austria) and the Verein zur Förderung der Forschung und Entwicklung in der Textilwirtschaft Vorarlberg.

conducted in the absence of dye in the same electrolysis cell in which the current yields had been determined by a manganometric titration of the Fe^{II} ions produced; current yield in the range of 80–90% were obtained without inert gas atmosphere. The concentration of the reduced mediator at the time of the measurements was thus approximately 0.008 mol L^{-1}, which corresponds to 60–70% of the starting complex (0.012 mol L^{-1}).

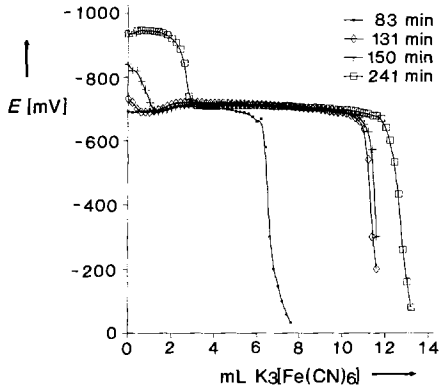

Fig. 1. Titration curves of the potentiometric determination of the extent of reaction with 0.01 mol L^{-1} $K_3[Fe(CN)_6]$. Samples: 5 mL catholyte at four different reaction times.

The solutions obtained after the complete reduction of indigo can be used directly for textile dyeing processes. Experiments with cotton textiles gave comparable results in terms of the depth and location of color to those obtained with the use of conventional reduction agents such as $Na_2S_2O_4$.

Experimental Procedure

For the preparation of 1 L of electrolyte, iron(III) sulfate (6 g, 0.012 mol) was dissolved in about 100 mL of water and treated with a mixture of triethanolamine (40 g, 0.268 mol), NaOH (10 g, 0.25 mol), and 50 mL of water. After the iron(III) hydroxide that had initially precipitated had dissolved, water was added to make a total volume of 1000 mL. The solution was filtered (0.45 μm membrane filter) to remove small amounts of undissolved hydroxides. The mediator solution thus obtained was used as both catholyte (ca. 950 mL) and anolyte (ca. 50 mL). To the catholyte solution was added indigo (5 g, 0.019 mol, technical grade, BASF) and a dispersion agent (0.5 g naphthalenesulfonic acid condensation product, Setamol WS, BASF). The electrolysis was conducted in a cylindrical cell at room temperature; the anode and the cathode were separated by a ceramic diaphragm.

The cathode was a Cu electrode with a surface of 500 cm^2; a stainless steel wire with a surface of 6 cm^2 served as the anode. The cathodic potential was regulated from −1050 to −1100 mV vs. Ag/AgCl/3 mol L^{-1} KCl, in order to avoid the undesired formation of hydrogen. The current density at the start of the electrolysis was 1 mA cm^{-2} and decreased as the reaction proceeded to 0.4 mA cm^{-2}. The catholyte solution was stirred with a magnetic stirrer. The concentration of sodium hydroxide in the anolyte was kept constant by addition of sodium hydroxide solution.

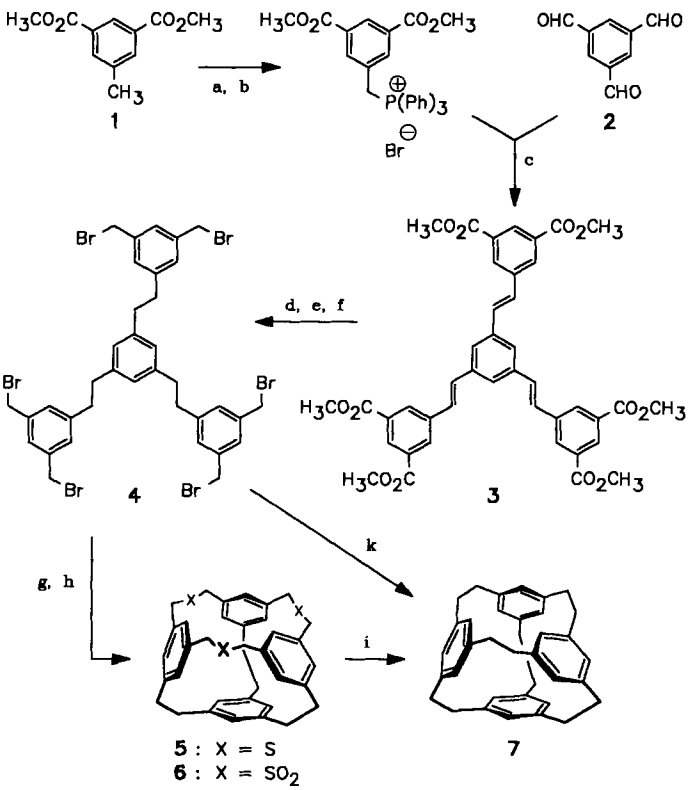
$C_{36}H_{36}$—Tetrahedral Clamping of Four Benzene Rings in a Spherical Hydrocarbon Framework

By *Fritz Vögtle,* Jens Gross, Christian Seel,* and *Martin Nieger*

Molecules with a spherical shape and a closed surface are of topical interest: the first preparation of fullerenes has rapidly led to the development of a new field of science;[1] guests encapsulated in the interior of carcerands are totally isolated from the environment, and thus are considered to be in a new state of matter;[2] and aesthetically appealing platonic hydrocarbons like dodecahedrane continue to present a challenge for synthetic chemists.[3] Our intention was to synthesize, based upon experiences in cyclophane and host/guest chemistry,[4] a nearly spherical hydrocarbon as a potential π ligand with a largely (but not completely) closed surface and intramolecular cavity.

Starting from dimethyl 5-methylisophthalate (**1**),[5] the key compound **4** for the cyclization reaction is available in six steps. Bromination with *N*-bromosuccinimide (NBS) (a in Scheme 1), phosphorylation (b), and threefold Wittig reaction (c) with the trialdehyde **2**[6] lead to the "tristilbene" **3** as a mixture of isomers. These are converted into the



Scheme 1. a) NBS, azobisisobutyronitrile (AIBN), CH_2Cl_2, *hv*, reflux, 69%; b) PPh_3, $CHCl_3$, 2 h reflux, 99%; c) Li, MeOH/THF, argon, 12 h at room temperature, 64%; d) 3 bar H_2, Pd/C (5%), toluene, 99%; e) $LiAlH_4$, THF, argon, 2 h reflux, then Ac_2O, 4 h reflux, 89%; f) HBr/acetic acid (30%), 8 h at 60 °C, 77%; g) dilution principle, 3 equiv $Na_2S \cdot 9H_2O$, 20 equiv Cs_2CO_3, benzene/EtOH (1:1), argon, 16 h reflux, 18%; h) 12 equiv *m*-chloroperoxybenzoic acid, $CHCl_3$, 24 h at room temperature, 73%; i) 10^{-2} Torr, 570 °C, 45%; k) dilution principle, 15 equiv PhLi, THF/ether, argon, 8 h at room temperature; 11%.

Institut für Anorganische Chemie der Universität Bonn

hexabromide **4** by hydrogenation (d), reduction of the ester and acetylation (e), and treatment with hydrogen bromide/acetic acid (f). The well-established sulfide cyclization reaction with sodium sulfide[4a] provides the macrotricyclic phane **5** in 18% yield (g). The pyrolytic desulfurization reaction (SO_2 extrusion) (i)[7] of the trisulfone **6**, which is easily available by oxidation (h), leads to the heptacyclic hydrocarbon **7** in amounts of 25 mg.[8] However, the threefold intramolecular Wurtz coupling of **4** with phenyllithium (k) turned out to be the better alternative since twice the amount of **7** can be synthesized more conveniently and in less time.

The high symmetry of the spheriphane **7**, a tetramer of 1,3,5-trimethylenebenzene, is proved by spectroscopy: The ^{1}H NMR spectrum shows only one signal for the aromatic and benzylic protons, respectively, and the ^{13}C NMR spectrum has only three signals.[9] Even at temperatures lower than $-90\,^\circ$C the molecular skeleton is flexible enough not to hinder the twisting of the ethano bridges about the C_3 symmetry axes, so no splitting of the signals is observed.[10]

The X-ray structure analysis of the 1:1 adduct of chloroform and **7** exhibits (exclusively)[11] a *P*-helical conformation of the spherical molecular framework (Fig. 1).[12] The

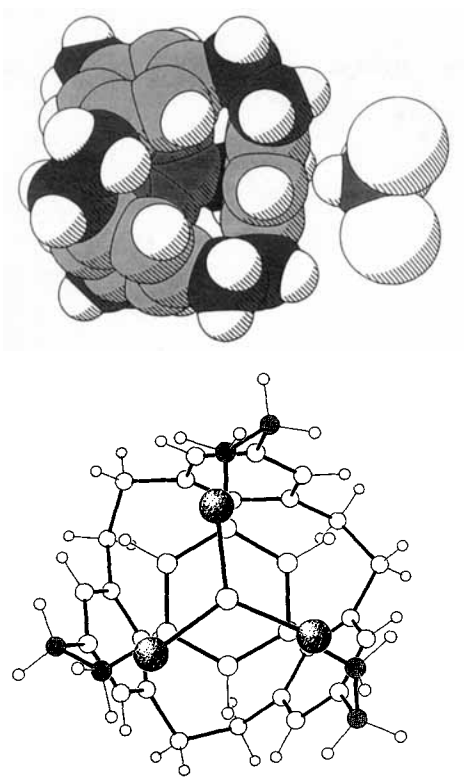

Fig. 1. Crystal structure of the 1:1 adduct of chloroform and **7**. Top: This perspective shows the coordination of the chloroform molecule to one of the benzene rings and the compact shape of the spheriphane. Bottom: Looking at the $CHCl_3$ molecule along the symmetry axis reveals the chiral twist of the hydrocarbon skeleton. The carbon atoms of three ethano bridges are hatched to elucidate the *P* helix.

centroids of the four benzene rings form a tetrahedron slightly compressed (4 pm) along the C_3 symmetry axis. The radius of the intramolecular cavity is 284 pm (average distance of the arene centroids from the center of the molecule; taking the van der Waals radii into account, the value is about 114 pm), and thus there is enough space for the inclusion of metal cations like Ag^+[13] and Ga^+.[14] (For comparison, the radii of C_{60} and dodecahedrane are approximately 351 pm[15] and 216 pm,[16] respectively.) The "windows" on the surface formed by [2.2.2]metacyclophane subunits are 386 pm in diameter (about 180 pm in consideration of the van der Waals radii). The solvent molecule lies on the symmetry axis and is bound by attractive hydrogen–π interactions to one of the benzene rings.[17] The ideal distance between the $CHCl_3$ carbon atom and the arene centroid in the chloroform–benzene complex has been calculated to be 336 pm.[18] In the adduct of **7** this value is distinctly shorter: only 323 pm (227 pm for the $CHCl_3$ hydrogen atom). The chlorine atoms are placed in a nearly eclipsing position above the quarternary carbon atoms; the deviation is 5.9° (Fig. 1 bottom).

In complexation experiments with silver triflate (trifluoromethanesulfonate) in THF a 1:1 complex precipitated readily.[19] The colorless solid is insoluble in solvents of low polarity like dichloromethane but dissociates into its components in methanol/dichloromethane mixtures. In contrast to this, the silver triflate complexes of [2.2.2]paracyclophane[13a] and [2$_6$](1,2,4,5)cyclophane (deltaphane)[13b] are readily soluble in chloroform and THF. The structure of $7 \cdot AgO_3SCF_3$ could not be determined spectroscopically, so it is uncertain if the cation is inside the cavity or faces one of the [2.2.2]metacyclophane windows as in the deltaphane complex.[20]

Attempted dehydrogenation of **7** with palladium/charcoal (10%) at 500 °C did not lead to significant reaction, whereas dehydrogenations at higher temperatures as well as treatment in an $AlCl_3$/NaCl melt at 140 °C caused decomposition.[21] Reduction reactions with platinum as a catalyst in dioxane/ethyl acetate (2:1) yield derivatives of **7** with successively hydrogenated benzene rings up to perhydrogenated $C_{36}H_{60}$.

The new synthetic strategy allows the preparation of similar concave hydrocarbons with larger molecular frameworks by use of longer bridges or building blocks containing more arene units. Such molecules are of interest as potential host compounds with hydrophobic cavities.[22]

[19] Correct C,H,Ag-analysis.
[20] In the deltaphane and [2.2.2]paracyclophane complexes the anion is coordinated to the silver ion. In the case of the complex of **7** the low solubility might be caused by the naked triflate anion if the Ag^+ ion is encapsulated inside the cavity.
[21] Investigations with mass spectrometry indicate the formation of naphthalene, anthracene, and phenanthrene derivatives.
[22] We have already synthesized heteroanalogous spheriphanes containing three ether or amino bridges, respectively, and will report on them elsewhere.

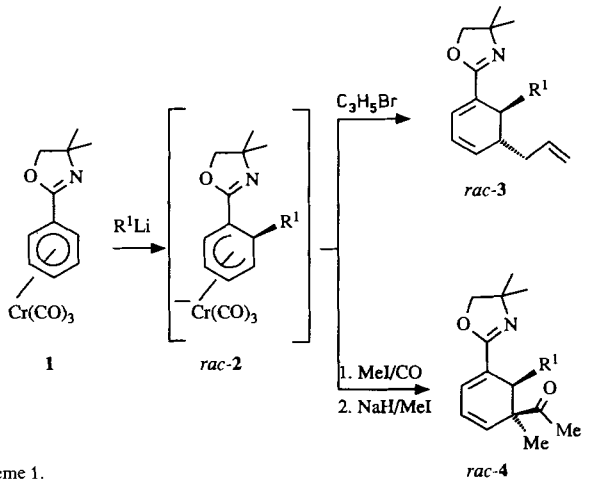
Diastereoselective Synthesis of Substituted Cyclohexadienes from Enantiomerically Pure Tricarbonyl(2-phenyl-4,5-dihydrooxazole)chromium Complexes**

By *Ernst Peter Kündig,* Alberto Ripa,* and *Gérald Bernardinelli*

The one-pot transformation of arenes into regio- and stereoselectively *trans*-disubstituted dihydroarenes can be carried out efficiently via the readily accessible $Cr(CO)_3$ complexes.[1, 2] Absolute stereochemical control would be highly desirable in order to extend the synthetic utility of this transformation. We here show that this can be realized.

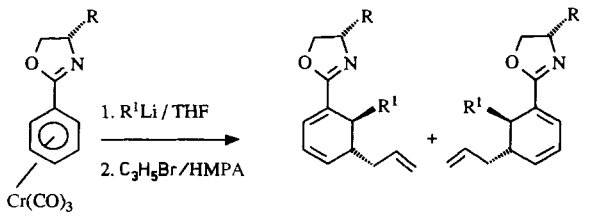
Chiral 4,5-dihydrooxazoles have been used extensively in asymmetric synthesis.[3] Meyers et al. reported the sequential addition of a nucleophile and an electrophile to naphthalene[4a–d] and pyridine derivatives[4e, f] activated by σ-bound chiral 4,5-dihydrooxazoles. While this constitutes a useful methodology and provides access to regio- and stereoselectively substituted dihydronaphthalene and dihydropyridine derivatives, extension to benzene and its derivatives failed.[5]

Recently, we found that the tricarbonyl(2-phenyl-4,5-dihydrooxazole)chromium complex **1** undergoes regioselective *ortho*-addition of C-nucleophiles under lithium coordination control.[6] Subsequent reactions of the anionic intermediate *rac*-**2** with primary C-electrophiles yielded the regio- and stereoselectively substituted cyclohexadienes *rac*-**3** or *rac*-**4**, the distribution of which strongly depended on the electrophile and on the reaction conditions (Scheme 1).[7]



Scheme 1.

An asymmetric version of this methodology was conceived based on a chiral dihydrooxazole. We anticipated that the addition of a C-nucleophile could be preferentially directed to one of the resulting diastereotopic *ortho* positions of the complexed arene.[8] The data reported here confirm this hypothesis and show that the absolute configuration of the two new stereogenic centers can be easily controlled with the enantiomerically pure complexes **5** and **6** derived from L-valinol and L-*tert*-butylglycinol.[9]



Scheme 2. R^1 = alkyl, vinyl, phenyl; HMPA = hexamethylphosphoric triamide.

Low-temperature sequential addition of alkyl-, vinyl-, or phenyllithium and allyl bromide to **5** or **6** afforded the cyclohexadienes **7** and **8** (Scheme 2, Table 1). MeLi (→**7a**, **8a**), *n*BuLi (→**7b**, **8b**) and vinyl lithium (→**7c**, **8c**) added to **5**

[**] We thank the Swiss National Foundation for support of this work.

with the same high level of diastereoselectivity (up to 92% *de*), whereas PhLi gave a ca. 4:1 mixture of **7d** and **8d**.[10]

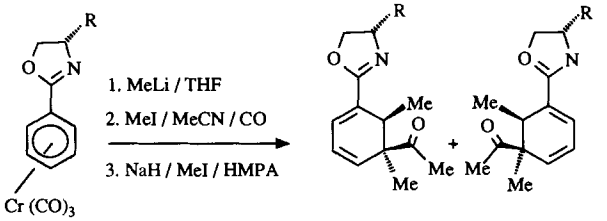
The already high diastereoselectivity could be further improved with complex **6**, which contains a sterically more demanding dihydrooxazole group. MeLi (→**7e**, **8e**) and *n*BuLi (→**7f**, **8f**) afforded a single detectable diastereoisomer; and PhLi (→**7g**, **8g**) also added with considerably improved selectivity.[10]

Table 1. Sequential diastereoselective addition of organolithium reagents and allyl bromide to complexes **5** and **6**.

R	R^1Li	Product 7, 8	Yield [%] [a]	7:8 [b]
*i*Pr	MeLi	**a**	61	96:4
*i*Pr	*n*BuLi [c]	**b**	54	95.5:4.5
*i*Pr	VinylLi [d, e]	**c**	48	95.5:4.5
*i*Pr	PhLi [f]	**d**	60	81:19
*t*Bu	MeLi	**e**	69	≥99:1
*t*Bu	*n*BuLi	**f**	62	≥99:1
*t*Bu	PhLi [f]	**g**	51	95.5:4.5

[a] Ketone products were also formed in 10–25% yield; see Ref. [7]. [b] Determined by 400-MHz ^{1}H NMR and HPLC. [c] Reaction run in THF/toluene (1:10) at −90 °C. [d] Generated in situ from MeLi and tetravinyltin. [e] Reaction run at −90 °C. [f] Reaction run in THF/toluene (1:5) at −80 °C.

The same level of asymmetric induction by the two auxiliaries was obtained in the tandem addition of MeLi and MeI, followed by a second alkylation with MeI. This afforded **9a** (R = *i*Pr) and **9b** (R = *t*Bu) in 54 and 58% yield, and with 90 and 98% *de*, respectively (Scheme 3).



5, 6	[%]	9a-b		10a-b
5, 9a, 10a: R = *i*Pr	54	95	:	5
6, 9b, 10b: R = *t*Bu	58	>99	:	1

Scheme 3. HMPA = hexamethylphosphoric triamide.

The result of a single-crystal X-ray analysis of **9a** is shown in Figure 1.[11] It establishes the relative configuration of the two new stereogenic centers with respect to that of the auxiliary. For a mechanistic interpretation (see Scheme 4) let us

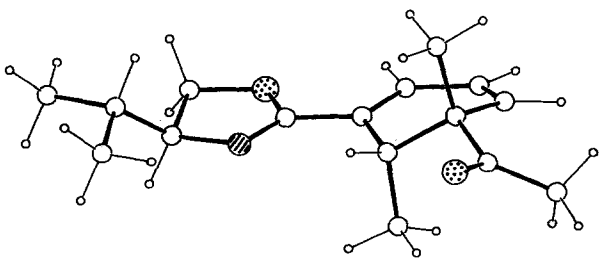


Fig. 1. Crystal structure of **9a**. Dotted spheres are O, shaded N, white C, and small white H atoms.

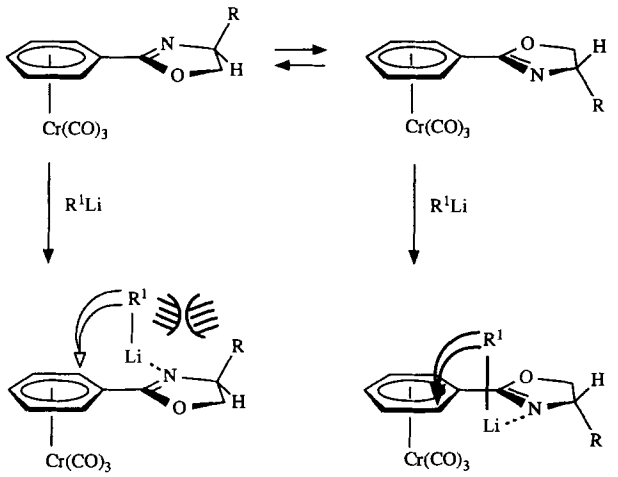
first consider the two rotamers. Models, and, more definitively, the X-ray structure of **5**, show that in the *syn*-rotamer the isopropyl group is located far away from the [Cr(CO)$_3$] group. There is no steric interaction between these two fragments and it is therefore unlikely that one of the rotamers of **5** and **6** is strongly favored. In fact, the X-ray structure of **5** shows the presence of both the *syn*- and the *anti*-rotamer in the unit cell (ratio 1:1).[12] Next we recall that it is well documented that nucleophiles add to the *exo* face of arene tricarbonyl chromium complexes[1c, 2, 13] and that both imine and oxazoline groups very efficiently direct nucleophiles to the *ortho*-position of the arene.[4, 6, 7] Based on these observations, we assume that lithium coordination to the nitrogen atom precedes nucleophilic addition as shown in Scheme 4.[14] Product stereochemistry then reflects a transi-



Scheme 4. Left: Coordination controlled by the Li atom in the *anti*-rotamer; right: in the *syn*-rotamer.

tion state in which the R substituent of the chiral auxiliary is *syn* to the metal fragment. In the *anti* rotamer, the lithium coordination controlled addition of the C-nucleophile would lead to a very congested transition state because of strong steric interactions between the R and R^1 groups (as usual, the organolithium reagents are represented as monomers, even though aggregates may be the reacting species[15]). These interactions become more important with the size of R, and this readily accounts for the higher induction by the *tert*-butyldihydrooxazole in **6** compared to the isopropyl analogue **5**.

In conclusion, the first examples of a highly regio- and diastereoselective introduction of two or three C substituents across a benzene double bond have been achieved via the combined activation of the arene by σ-bound and π-bound groups.

Experimental

7e: To a stirred solution of complex **6** (63 mg, 0.186 mmol) in 1.9 mL of dry THF was added dropwise MeLi (133 μL of a 1.67 M ether solution, 0.223 mmol, 1.2 equiv.) at −90 °C under N_2. The solution was slowly warmed to −78 °C (3 h) and dry HMPA (323 μL) and allyl bromide (161 μL, 10 equiv., distilled from P_2O_5) were added. The solution was slowly warmed to room temperature and stirred for about 15 h. Excess of electrophile and THF were evaporated in vacuo. The residue was dissolved in ether (30 mL) and washed with water (2 × 10 mL), and brine (10 mL). The combined aqueous phases were extracted with ether (3 × 10 mL). The combined organic phases were dried ($MgSO_4$), exposed to sunlight until colorless (decomplexation), filtered through celite, and evaporated. Flash-chromatography (SiO_2, hexane:ether 3:1) afforded 33.2 mg of **7e** (69%) ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS) δ = 0.89 (s;

9H; $C(CH_3)_3$), 1.03 (d, $^3J(H,H) = 7.3$ Hz, 3H; CH_3), 1.89–2.03 (m, 1H; CH), 2.07–2.17 (m, 2H; CH_2), 2.87 (bq, $^3J(H,H) = 7.3$ Hz, < 1 Hz, 1H; CH), 3.91 (dd, $^3J(H,H) = 6.7$, 10 Hz, 1H; CH), 4.08–4.18 (m, 2H; CH_2), 4.91–5.03 (m, 2H; $=CH_2$), 5.69–5.80 (m, 1H; =CH), 5.94 (dd, $^3J(H,H) = 5.5$, 9.6 Hz, 1H; =CH), 5.99 (dd, $^3J(H,H) = 5.1$, 9.6 Hz, 1H; =CH), 6.56 (d, $^3J(H,H) = 5.1$ Hz, 1H; =CH); IR (CH_2Cl_2): $\tilde{\nu}$[cm^{-1}] = 1650, 1612; MS (70 eV): *m/z* 259 ($M^{\oplus}$, 20%), 218 ($M^{\oplus} - C_3H_5$, 100); $[\alpha]_D^{20} = -512.4$ (*c* = 0.835, $CHCl_3$).

9a: A pressure resistant Schlenk tube was used for this reaction. To a stirred solution of complex **5** (78.7 mg, 0.2419 mmol) in 2.5 ml of dry THF was added dropwise MeLi (177 μL of a 1.62 M solution, 0.290 mmol, 1.2 equiv.) at −90 °C under N_2. The solution was slowly warmed to −78 °C over a period of 3 h. MeI (150 μL, 10 equiv., distilled from P_2O_5) and dry MeCN (2.5 mL) were added and the mixture cooled to liq. N_2 temperature. The reaction vessel was evacuated, warmed to −78 °C and further reaction carried out under CO (4 bar). The solution was slowly warmed to room temperature and stirred for about 15 h. Volatiles were removed in vacuo. The residue was dissolved in dry THF (8 mL), cooled to −78 °C and cannulated into a dispersion of NaH (29 mg of a 60% oil dispersion, 3 equiv., prewashed with dry pentane) in dry THF (2 mL) at the same temperature. After 30 minutes MeI (10 equiv.) and dry HMPA (420 μL) were added. The temperature was brought to 20 °C over a 4 h period. After work-up, flash-chromatography (SiO_2, hexane:ether = 2:1 to 1:2) afforded 34.2 mg (54%) of **9a**. M.p. 71 °C; ^1H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 0.86$ (d, $^3J(H,H) = 6.7$ Hz, 3H; CH_3), 0.88 (d, $^3J(H,H) = 6.8$ Hz, 3H; CH_3), 0.96 (d, $^3J(H,H) = 6.8$ Hz, 3H; CH_3), 1.23 (s, 3H; CH_3), 1.80–2.00 (m, 1H; CH), 2.21 (s, 3H; CH_3), 3.07 (q, $^3J(H,H) = 6.7$ Hz, 1H; CH), 3.97–4.30 (m, 3H; CH, CH_2), 6.01 (dd, $^3J(H,H) = 5.4$, 9.8 Hz, 1H; =CH), 6.37 (bd, $^3J(H,H) = 9.8$ Hz, 1H; =CH), 6.59 (bd, $^3J(H,H) = 5.4$ Hz, 1H; =CH); IR (CH_2Cl_2): $\tilde{\nu}$[cm^{-1}] = 1707 (C=O); MS (70 eV): *m/z* 218 ($M^{\oplus} - C_2H_3O$, 47%), 133 (100); $[\alpha]_D^{20} = -316.8$ (*c* = 1.12, $CHCl_3$). The diastereomeric ratio **9a**:**10a** was determined by HPLC analysis of the crude mixture (Silica-spheri 5 μm, 250 × 10 mm column; hexane:AcOEt = 3:1, 5 ml min^{-1}; UV detector at 280 nm); R_t = 8 min (**9a**) and 10 min (**10a**).

Strain-Activated Formation of a Triple-Layered Phane**

By *Henning Hopf,* Bernhard Witulski, Peter Bubenitschek,* and *Peter G. Jones*

The ease with which [2.2]paracyclophane and its homologues with more than two bridges undergo cycloadditions, substitutions, and rearrangements is strongly dependent upon how much strain is released in these processes.[1, 2] One strain-relieving reaction was reported in 1966 in which the parent hydrocarbon [2.2]paracyclophane was isomerized with a Lewis acid to [2.2]metaparacyclophane.[3] This type of reaction was shown in the following years to be typical also for cyclophanes with multiple bridges.[1, 4] In a study designed to accomplish an analogous isomerization with [2.2](2,5)furanoparacyclophane (**1**), we were surprised to observe that in the presence of Lewis acids (MX_n) this heterophane gave a dimer in good yield that rearranged to the triple-layered structure **5**, identified by spectroscopic (see *Experimental Procedure*) and X-ray crystallographic data.[5] Aluminum chloride or titanium chloride in dichloromethane at 0 °C afforded the best yields (60 and 64%, respectively), whereas milder acids such as zinc(IV) chloride and ether–boron tri-

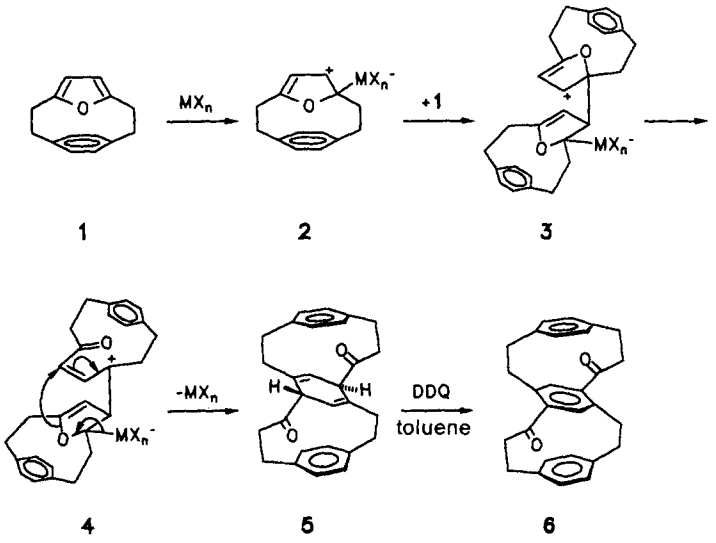
[**] Cyclophanes, Part 37. This work was supported by the Fonds der Chemischen Industrie, the BASF Aktiengesellschaft, and the Deutsche Forschungsgemeinschaft.–Part 36: H. Hopf, T. Laue, M. Zander, *Angew. Chem.* **1991**, *103*, 441–442; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 432–433.



Scheme 1. A possible mechanism for the Lewis acid catalyzed formation of **5** from **1**.

fluoride failed to cause dimerization; instead the starting material **1** could be recovered unchanged.[6]

The central 1,4-cyclohexadiene moiety of **5** is predisposed to aromatization, which can be induced by heating (110 °C, 5 h) with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to produce the triple-layered arene **6** (yield 50%, unoptimized). Definitive proof for the structure of **6** was obtained from the X-ray structure analysis[5] seen in Figure 1.

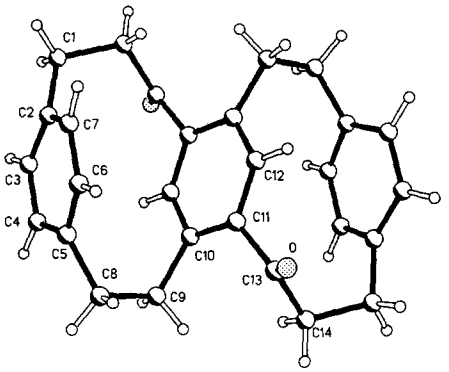


Fig. 1. The crystal structure of **6**. The radii are arbitrary. Only the asymmetric unit is numbered. This numbering system was also used in the assignment of the NMR signals of **5** and **6**.

A mechanism for this novel reaction, which builds layered compounds, is unknown; the sequence of steps proposed in Scheme 1, however, seems plausible at present:[7] initial activation of furan **1** with the Lewis acid leads to complex **2**. Electrophilic attack of this complex on a second molecule of **1** results in a dimer **3** that then releases its internal strain by undergoing ring opening to complex **4**. Subsequent loss of the catalyst molecule and further release of strain (opening of the "lower" phane system) give rise to the stabilized product **5**. The importance attached to stress reduction in this interpretation of the mechanism[5] gains support from the observation that 2,5-dimethylfuran, serving as an "unstrained half" of **1**, gave no identifiable products under our experimental conditions.[8]

Additional studies should show whether the reaction described here can be used as a general method for synthesizing multilayered compounds by starting from precursors containing appropriately substituted furan units as reaction initiators.[7] In all events, diketones **5** and **6** offer readily accessible starting materials for triple-layered systems

Experimental Procedure

5: A solution of **1** (500 mg, 2.5 mmol) [9] in dichloromethane (20 mL) was added dropwise to a cooled (0 °C) suspension of $AlCl_3$ (340 mg) in dry dichloromethane (70 mL) and the mixture stirred for 5 h at 0 °C. Next, the mixture was diluted with 1 N HCl (30 mL), extracted with dichloromethane, washed until neutral, and dried with magnesium sulfate. The solvent was removed and the product mixture purified by column chromatography (SiO_2, dichloromethane); fraction 1: 50 mg (10%) **1**, fraction 2: 320 mg (64%) **5**. Physical and spectroscopic data: m.p. 276 °C (colorless needles from $CHCl_3$/pentane); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3020 (w), 2975 (m), 2935 (m), 2849 (m), 1691 (s), 1507 (m), 1432 (m), 1346 (m), 1161 (m), 1082 (s), 1041 (m), 895 (m), 848 (m), 814 (s); ^{1}H NMR (400.1 MHz, $CDCl_3$, internal TMS): δ = 6.90 (s, 2H), 6.81 (AB pattern, J = 7.9 Hz, 1H, arene H), 6.69 (AB pattern, J = 7.9 Hz, 1H, arene H), 4.31 (s, 1H, 12-H), 3.09 (s, 1H, 11-H), 2.92–2.73 (m, 3H), 2.48 (ddd, J_1 = 13.3, J_2 = 10.7, J_3 = 4.6 Hz, 1H), 2.32 (m, 1H), 2.11 (m, 2H), 1.96 (m, 1H, 1-CH_2, 8-CH_2, 9-CH_2, 14-CH_2); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 211.0 (br.s, C13), 140.5 (s), 138.9 (s), 130.4 (s, C2, C5, C10), 129.9 (d), 129.6 (d), 128.4 (d), 128.0 (d, C3, C4, C7, C6), 123.7 (br.d., C12), 54.4 (d, C11), 43.9 (t, C14), 40.0 (t, C9), 32.9 (t), 32.7 (t, C1, C8).

6: A solution of **5** (200 mg, 0.51 mmol) in dry toluene (50 mL) was added to DDQ (347 mg, 1.53 mmol), and the reaction mixture was heated for 5 h at 110 °C. After the solvent was removed, the residue was dissolved in dichloromethane and filtered through alumina III/N. Separation by column chromatography [alumina III/N, dichloromethane/hexane: 6/6 (v/v)] yielded 110 mg of **6** (50%) [5]. Physical and spectroscopic data: m.p. > 300 °C (colorless prisms from $CHCl_3$/pentane); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3017 (m), 2973 (m), 2953 (m), 2944 (m), 2930 (s), 2859 (m), 2835 (m), 1681 (s), 1650 (m), 1643 (m), 1502 (m), 1444 (s), 1439 (s), 1427 (m), 1377 (m), 1332 (m), 1228 (m), 1177 (s), 1096 (m), 1050 (s), 924 (s), 888 (s), 807 (s), 724 (m); ^{1}H NMR (200.1 MHz, CD_2Cl_2, internal TMS: δ = 6.90–6.7 (br.m, 4H, outer benzene rings), 4.92 (s, 1H, 12-H), 3.0–2.7 (br.m, 8H, -CH_2-). The width of the signal in the ^{1}H NMR spectrum is an indication of the mobility of the rings in **6**, a subject for future study.

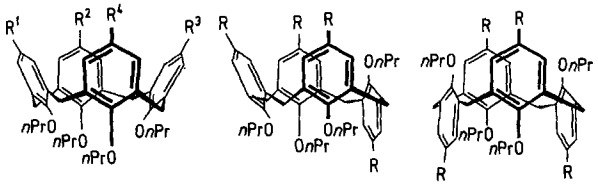
Nitrocalix[4]arenes as Molecules for Second-Order Nonlinear Optics**

By *Erik Kelderman, Lode Derhaeg, Gerard J. T. Heesink, Willem Verboom, Johan F. J. Engbersen, Niek F. van Hulst, Andre Persoons,* and *David N. Reinhoudt**

Organic molecules with π electron systems and unsymmetric charge distributions are promising for use in nonlinear optics (NLO), for example for frequency-doubling of laser light and electro-optic switching.[1-3] In the molecules investigated so far the "NLO-phore", that is the structural unit responsible for the nonlinear optical properties, consists of one single π electron system with one or more electron donors and/or acceptors (D-π-A molecules). Extension of the conjugated system increases the nonlinear hyperpolarizability β, but unfortunately this is accompanied by a shift of the charge-transfer absorption band (CT band) to longer wavelength, thereby restricting the applicability in frequency-doubling.[1-5] Here we describe a novel class of compounds which combine more D-π-A systems resulting not only in an increased hyperpolarizability, and dipole moment, but also in a shift of the CT bands to shorter wavelengths.

Calix[4]arenes are cyclophanes that consist of four phenol moieties connected by methylene bridges.[6] Functionalization of these phenols allows the combination of four D-π-A units within a single calix[4]arene molecule. These calix[4]arenes can be present in four idealized conformations[6-9] with different relative orientations of the intramolecular NLO-phores (Scheme 1).



cone | *paco* | *1,3-alternate*

1a, $R^1=R^2=R^3=R^4=t$Bu
1b, $R^1=R^2=R^3=R^4=NO_2$
1c, $R^1=R^2=R^3=R^4=H$
4, $R^1=NO_2$ $R^2=R^3=R^4=H$
5, $R^1=R^3=NO_2$ $R^2=R^4=H$
6, $R^1=R^2=NO_2$ $R^3=R^4=H$

2a, R = *t*Bu
2b, $R=NO_2$

3a, R = *t*Bu
3b, $R=NO_2$

Scheme 1.

In the *cone* conformer (e.g. **1**) the four oxygen atoms of the phenol hydroxyl groups are all on the same side of the calix, whereas in the partial cone (*paco*) conformer (e.g. **2**) only three are. The *1,2-* and *1,3-alternate* conformers (e.g. **3**) have idealized point and radial symmetry, respectively. The different conformers are not interconvertible[7b] when the hydroxyl groups are alkylated by groups larger than 2-hydroxyethyl.[10] *n*-Propylation of *para-tert*-butylcalix[4]arene[6] in *N,N*-dimethylformamide (DMF) at room temperature for 5 days with sodium hydride as a base afforded only **1a** in 93% yield. However, when the reaction was carried out in refluxing benzene with potassium *tert*-butoxide as a base, a 1:1 mixture of **2a** and **3a** in an overall yield of 70% was obtained. The *paco* (**2a**) and *1,3-alternate* conformers (**3a**) could be isolated by crystallization of the crude mixture from chloroform/methanol and chloroform/hexane, respectively. Subsequent *ipso* nitration[11] of **1a**–**3a** afforded the desired tetranitrocalix[4]arenes **1b**–**3b** in 70% yield. The mononitro- **4**, 5,17-dinitro- **5**, and the 5,11-dinitrocalix[4]arene **6** were obtained by reaction of tetrapropoxycalix[4]arene[12] **1c** with nitric acid in dichloromethane and subsequent separation of the mixture of nitrocalix[4]arene products by column chromatography.

To determine the influence of the different orientations of the D-π-A dipoles in the tetranitrocalix[4]arenes[13] on the hyperpolarizability β we have studied the *cone*, *paco*, and the *1,3-alternate* conformers **1b**, **2b**, and **3b**, respectively, by electric field induced second harmonic generation (EFISH).[14] The data obtained for **1b**–**3b** are summarized in Table 1.

Table 1. Hyperpolarizability in the direction of the field-induced *z* axis β_z, dipole moment μ, and the wavelength of the longest wavelength absorption for the nitrocalix[4]arenes **1b**–**6** and the reference compounds **7** and **8**.

	$\beta_z \times 10^{30}$ [esu]	μ [D]	λ_{max} [nm]
1b	30	13.8	291
2b	27	6.7	291
3b	0	0	291
4	16	4.5	308
5	15	7.8	302
6	20	8.7	307
7	12	4.6	302
8	–	–	288

Compound **1b** has a β_z value of 30×10^{-30} esu, about 30% of the value of the reference compound 4-methoxy-4′-nitrostilbene (MONS),[14a] which has a more extended π system. Moreover **1b** has a large dipole moment of 13.8 D. The *paco* conformer **2b** also has a comparably high β_z value, but its dipole moment is only 6.7 D. As expected, the centrosymmetric *1,3-alternate* conformer **3b** exhibits no frequency-doubling of 1064 nm laser light (Nd:YAG laser).

In order to examine whether the β_z values of the four individual D-π-A units are additive, we synthesized a series of *cone* nitrocalix[4]arenes besides **1b** with NO_2 groups in various numbers and positions (**4**, **5**, and **6**) and compared their β values and UV spectra with the reference compounds 4-nitroanisole (**7**) and 2,6-dimethyl-4-nitro-1-*n*-propoxybenzene (**8**).[3,15] The β_z value of the mononitrocalix[4]arene **4** is slightly greater than that of 4-nitroanisole (**7**). Surprisingly, 5,17-dinitrocalix[4]arene **5** has almost the same β_z value. The conformational flexibility of the four aromatic rings in the *cone* conformers and the intramolecular repulsion of the charged D-π-A systems might explain the relatively low β_z value of **5**. In addition, the local field factor $F(\omega)$, which describes the influence of the electrostatic field in the neigh-

[**] This investigation was supported by the Netherlands Foundation of Chemical Research (SON) and the Foundation for Fundamental Material Research (FOM) with financial aid from the Netherlands Organization for Scientific Research (NWO). We wish to thank J. M. Visser, J. L. M. Vrielink, T. W. Stevens, and A. M. Montanaro-Christenhusz for recording the IR, UV-VIS, and mass spectra and for performing the elemental analyses.

borhood of the NLO-phore on β [Eq. (a)], is expected to be lower for two cofacial D-π-A aromatic rings.[1, 2] In Equation (a), $\Delta\mu$ is the difference between the dipole moment in the ground and first excited state and f is the oscillator strength of the CT band. 5,11-Dinitrocalix[4]arene **6**, on the other hand, has a slightly higher β_z value than **5**. This may be due to a more parallel and noncofacial orientation of the D-π-A moieties in **6**. The larger dipole moment of 8.7 D, possibly due to reduced dipole-dipole repulsion in **6**, lends further support.

$$\beta_{CT} = \frac{3e^2\hbar^2 F(\omega) f \Delta\mu}{2m} \qquad \text{(a)}$$

From these results it can be concluded that the D-π-A moieties in the calix[4]arenes **1b** and **4**–**6** do not behave as completely independent NLO-phores. This is also in line with the UV spectra. The λ_{max} values of the nitrocalix[4]arenes **1b** and **4**–**6** show a remarkable trend when compared to the reference compound 2,6-dimethyl-4-nitro-1-*n*-propoxybenzene (**8**). The longest wavelength band of **4** (λ_{max} = 308 nm) is shifted bathochromically by 20 nm relative to that of **8** (λ_{max} = 288 nm). This difference must be due to interactions with the other aromatic rings of the calix[4]arene. Remarkably, with increasing numbers of nitro substituents, the λ_{max} values for the CT band of the nitrocalix[4]arenes in the cone conformation decrease slightly, whereas the μ values and the β_z values increase. A λ_{max} of shorter wavelength indicates a more restricted electron transfer from the ground state to the first excited state ($F(\omega)$). According to Equation (a), a lower $F(\omega)$ will cause the β_z value to decrease, and this effect may contribute to the nonlinear increase of β_z with an increase in the number of strong dipoles in a calix[4]arene molecule.

The large dipole moment of **1b** (13.8 D) in combination with the preorganized framework of the four NLO-phores can be used to orient **1b** in a polymeric methylmethacrylate (PMMA) matrix by corona-poling with a strong DC electrical field.[16] For a film with 4.5 wt % of **1b** the degree of orientation[17] $\cos^3\theta$ obtained was 0.28, whereas a similar film with 2 wt % of poled *N*,*N*-dimethylaminonitrostilbene (DANS) gave the much lower $\cos^3\theta$ value of 0.02 under identical conditions. In Equation (b), N is the density of molecules with nonlinear optical properties in the film, and F is the local field factor.[18]

$$\langle\cos^3\theta\rangle = \frac{2d_{33}}{NF\beta_z} \qquad \text{(b)}$$

The NLO efficiences d_{33} of poled films with 4.5 and 25 wt % of **1b** were initially 0.21 and 1.1 pmV^{-1}, respectively. Measurements over a period of two months showed a decrease of the d_{33} value to 60% of the initial value, that is to 0.13 and 0.65 pmV^{-1}, respectively. These values were attained in about one week and did not change thereafter. For comparison, the d_{33} of a film with 2 wt % of DANS had decreased to 30% of the initial value of 0.21 pmV^{-1} after one week and was inactive after one month.[19]

The high stability of the film of **1b** is probably a result of the bulkiness of the calix[4]arene skeleton, the restricted rotation of the individual D-π-A moieties, and the complexation of the methyl groups of the polymer backbone with this molecule.

In conclusion, this new class of NLO compounds possesses a unique combination of four nonconjugated D-π-A dipoles in one molecule. These compounds combine high β_z, and μ values with relatively low λ_{max} values. The low λ_{max} values make them suitable for frequency-doubling 820 nm emission from diode lasers to blue laser light at 410 nm.[4, 5] The high μ value of the tetranitrocalix[4]arene **1b** enables a high degree of orientation upon poling in a polymeric matrix. Further functionalization leading to extended π electron systems with high β_z values and the synthesis of polymerizable calixarenes with high dipole moments are currently under investigation.

Experimental Procedure

All new compounds were fully characterized by ^{1}H and ^{13}C NMR spectroscopy, mass spectroscopy, elemental analysis, UV-VIS and IR spectroscopy.

General procedure for *ipso* nitration of the *tert*-butylcalix[4]arenes **1a**, **2a**, and **3a**: To a solution of calix[4]arene **1a**, **2a**, and **3a** (3.00 mmol) in a mixture of CH_2Cl_2 (30 mL) and glacial acetic acid (30 mL) was aded 100% HNO_3 (10 mL, ca. 240 mmol) at 0 °C. The reaction mixture was stirred at room temperature until the black–purple color had discharged and subsequently poured into water (200 mL). The aqueous layer was extracted with CH_2Cl_2 (2 × 50 mL). The combined organic layers were washed with water (2 × 50 mL), dried over $MgSO_4$, and concentrated. Recrystallization of the crude reaction products from methanol gave analytically pure compounds.

^{1}H NMR spectroscopic data of **2b** and **3b** (conditions: 250 MHz, $CDCl_3$, 25 °C, TMS): **2b**: δ = 8.23, 8.15 (s, 4H; ArH), 7.89, 7.11 (d, 4H, J = 2.7 Hz; ArH), 4.1–3.3 (m, 16H; $ArCH_2Ar$ and OCH_2), 2.2–1.8 (m, 8H; CH_2CH_3), 1.2–1.1 (m, 9H; CH_3), 0.62 (t, 3H, J = 7.5 Hz; CH_3). **3b**: δ = 7.96 (s, 8H; ArH), 3.80 (t, 8H, J = 7.3 Hz; OCH_2), 3.74 (s, 8H; $ArCH_2Ar$), 2.0–1.9 (m, 8H; CH_2CH_3), 1.05 (t, 12H; CH_3).

Procedure for nitration of calix[4]arene **1c**: To a solution of **1c** (1 g, 1.7 mmol) in a mixture of CH_2Cl_2 (100 mL) and acetic acid (4 mL) was added 65% nitric acid (1 mL, 25 mmol, 15 equiv) whereupon the mixture was stirred for 0.5 h at room temperature. The reaction was stopped by the addition of water (100 mL), and the product mixture was extracted with CH_2Cl_2 (3 × 25 mL). The combined organic layers were washed with water (3 × 25 mL), saturated sodium bicarbonate solution (3 × 25 mL), and water (3 × 25 mL), dried over $MgSO_4$, and concentrated. The reaction mixture consisted mainly of mononitrocalix[4]arene **4** (30%) and traces of 5,17-dinitrocalix[4]arene **5** and 5,11-dinitrocalix[4]arene **6**. The same reaction with **1c** for 3 h afforded **5** and **6** in 30% and 10% yields, respectively. The products were separated by column chromatography SiO_2/CH_2Cl_2.

4: M.p. 192–193 °C; ^{1}H NMR: δ = 7.25 (s, 2H; ArH-NO_2), 7.0–6.8 (m, 6H; ArH), 6.22 (s, 3H; ArH), 4.47 and 3.20 (ABq, 4H, J = 13.7 Hz; $ArCH_2Ar$), 4.42 and 3.16 (ABq, 4H, J = 13.5 Hz; $ArCH_2Ar$), 4.0–3.7 (m, 8H; OCH_2), 2.0–1.8 (m, 8H; CH_2CH_3), 1.1–0.9 (m, 12H; CH_3), ^{13}C NMR: δ = 161.2, 157.0, 155.6 (s, ArC-O), 142.4 (s, ArC-NO_2), 76.8, 76.5, 76.4 (t, OCH_2), 30.9, 30.8 (t, $ArCH_2Ar$), 23.2, 22.9 (t, CH_2CH_3), 10.4, 10.3, 10.0 (q, CH_3).

5: M.p. 185–186 °C; ^{1}H NMR: δ = 7.42 (s, 4H; ArH), 6.74 (s, 6H; ArH), 4.47 and 3.25 (ABq, 8H, J = 13.7 Hz; $ArCH_2Ar$), 4.0–3.8 (m, 8H; OCH_2), 2.0–1.8 (m, 8H; CH_2CH_3), 1.2–0.9 (m, 12H; CH_3); ^{13}C NMR: δ = 161.7, 156.1, 142.3, 136.1, 134.0 (s, ArC), 128.7, 123.2, 122.9 (d, ArC), 77.1, 76.7 (t, OCH_2), 30.8 (t, $ArCH_2Ar$), 23.1, 22.9 (t, CH_2CH_3), 10.1, 10.0 (q, CH_3).

6: M.p. 151–152 °C; ^{1}H NMR: δ = 7.5–7.4 (m, 4H; ArH-NO_2), 6.6–6.5 (m, 6H; ArH), 4.6–4.4 and 3.3–3.1 (3 ABq, 8H, J = 13.7 Hz; $ArCH_2Ar$), 4.0–3.7 (m, 8H; OCH_2), 1.9–1.8 (m, 8H; CH_2CH_3), 1.0–0.9 (m, 12H; CH_3); ^{13}C NMR: δ = 162.2, 156.4 (s, ArC-O), 142.5 (s, ArC-NO_2), 31.1, 30.8 (t, $ArCH_2Ar$), 23.3, 23.2 (t, CH_2CH_3), 10.3, 10.2 (q, CH_3).

The EFISH measurements are described in ref. [14].

Poled films were prepared in a clean room facility with dust class 1000 and at 20 °C and 5% humidity. A solution of **1b** (4.5 wt %)/PMMA (M = 33000) in chloroform was spun on pyrex glass yielding thin films with thicknesses in the range of 0.25–1 μm. The film was orientated by corona-poling with a field of 8 kV at 110 °C for 15 min and allowed to cool to room temperature while the high voltage was maintained. The SHG efficiency of the film was measured at 1064 nm against a sample of α-quartz as reference to determine the absolute d_{33} value.

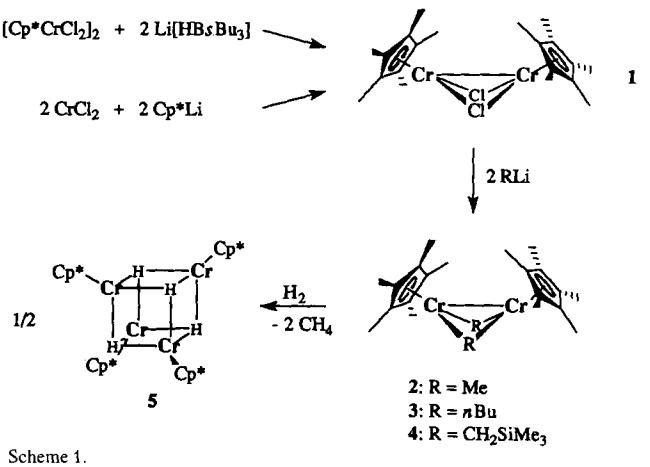
[18] The local field factor ($F = 2.5$) was determined from refractive index measurements ($n = 1.45$) on the film. Because of the low dispersion of the material, the refractive indices at both wavelengths are approximately equal. The number density of the film with 4.5 wt% of **1b** is about $4.5 \times 10^{-25}\ m^{-3}$.
[19] Hampsch et al. measured a d_{33} value of $0.4\ pm\ V^{-1}$ for a film with 4.5 wt% of DANS; this is in good agreement with our results. H. L. Hampsch, Jianyang, G. K. Wong, J. M. Torkelson, *Macromolecules* **1990**, *23*, 30640.

[{Cp*Cr(μ_3-H)}$_4$]—a Paramagnetic Chromium Hydride with a Cubane Structure**

By *Robert A. Heintz, Brian S. Haggerty, Hong Wan, Arnold L. Rheingold*, and *Klaus H. Theopold**

During the course of our exploration of paramagnetic organometallic complexes of chromium(III)[1] many attempts at preparing hydride complexes have come to naught. However, we have now discovered a novel class of electron-deficient alkylchromium(II) compounds, which undergo efficient hydrogenolysis to yield unusual paramagnetic chromium hydrides.[2] Herein we report the synthesis, structural characterization, and some unusual magnetic properties of the latter.[3]

Addition of two equivalents of Li[HB*s*Bu$_3$] to a solution of [(Cp*CrCl$_2$)$_2$] (Cp* = C$_5$Me$_5$) in THF yielded the reduction product [{Cp*Cr^{II}(μ-Cl)}$_2$] (**1**) instead of the desired complex [{Cp*Cr^{III}(H)Cl}$_2$]. Alerted to the stability of this rather simple starting material for organometallic compounds with divalent chromium,[4] we found that **1** may also be prepared in reasonable yield (65%) directly from Cp*Li and CrCl$_2$ (Scheme 1). The X-ray crystal structure determination revealed that **1** is a dinuclear complex with pseudo C_{2v} symmetry and a Cr–Cr distance of 2.642(2) Å. The effective magnetic moment (μ_{eff}) of this compound is temperature dependent and gradually rises to 2.0 μ_B per dimer at room temperature, consistent with some degree of metal–metal bonding.



Scheme 1.

Complex **1** was easily alkylated and thereby yielded a series of extremely electron-deficient alkylchromium(II) complexes of the type [Cp*Cr(μ-R)]$_2$ **2**–**4** (Scheme 1). The methyl complex **2** was structurally characterized by X-ray diffraction. As expected, the substitution of the 3-center/4-electron chloride bridges with the 3-center/2-electron methyl bridges causes a dramatic decrease in the Cr–Cr distance (2.263(3) Å).[5] The greater strength of the metal–metal interaction is also evident in the magnetic behavior of **2**; μ_{eff} for the dinuclear complex only reaches 0.92 μ_B at room temperature. Finally, the muted reactivity of the compound supports the presence of a strong metal–metal bond. Complex **2** is thermally stable up to 100 °C in solution and does not react with ethylene under mild conditions; although **2** is eventually cleaved by bis(dimethylphosphino)ethane (dmpe) to produce the known [Cp*Cr(dmpe)CH$_3$],[1b] the reaction is very slow (several hours at room temperature). **2** is one of the few chromium(II) complexes thought to exhibit multiple Cr–Cr bonds despite the absence of binucleating ligands akin to carboxylates.[6]

In our experience alkylchromium(III) complexes have largely resisted hydrogenolysis; in contrast **2** reacted slowly with H_2 at room temperature to generate methane and a black paramagnetic precipitate. Elemental analysis and IR spectroscopy of the solid indicated the presence of Cp* ligands. Well-formed crystals of this material were eventually grown from hot toluene; however, only a rough crystal structure could be obtained due to disorder that likely resulted from an unresolvable superlattice.[7] This problem was finally overcome when the EtMe$_4$C$_5$ ligand was used instead

[**] This work was supported by the National Science Foundation (CHE-9096251) and the University of Delaware. We thank Prof. H. Hope (University of California at Davis) for obtaining a low-temperature X-ray diffraction data set of [{Cp*Cr(μ_3-H)}$_4$], and Prof. G. Hadjipanayis (University of Delaware) for the use of his SQUID.

of Cp*. The result of an X-ray structure determination is shown in Figure 1;[8] the products of the hydrogenation of **2** and **2'** (with $EtMe_4C_5$ ligand) are tetranuclear chromium hydrides of the formulas $[\{Cp^*Cr(\mu_3\text{-}H)\}_4]$ (**5**) and $[\{(\eta^5\text{-}EtMe_4C_5)Cr(\mu_3\text{-}H)\}_4]$ (**5'**), respectively (the heavy atom cores of **5** and **5'** were essentially identical). Each molecule of **5'** has a crystallographic mirror plane passing through the positions of the atoms Cr2, Cr3, H2, and H3. The basic framework of the complex is an essentially regular cube, whose corners are occupied alternately by Cr and H atoms. The average Cr–Cr distance of 2.715 Å is long by comparison to those of the complexes **2** and **1**; the distribution of the sixteen available d-electrons over six equal metal–metal interactions probably precludes significant multiple metal–metal bonding. The Cr–Cr distance is also greater than the Co–Co distance in the isostructural complex $[\{CpCo(\mu_3\text{-}H)\}_4]$ (2.467 Å).[9] This "saturated" complex has been assigned a metal–metal single bond[10] and thus **5'** (and **5**) may best be described as lacking metal–metal bonds. The hydride ligands were located by the X-ray structure analysis and their positions refined. While X-ray structural parameters of hydrogen atoms are of necessity uncertain, there is no doubt that the hydride ligands are capping the four faces of the Cr_4 tetrahedron.

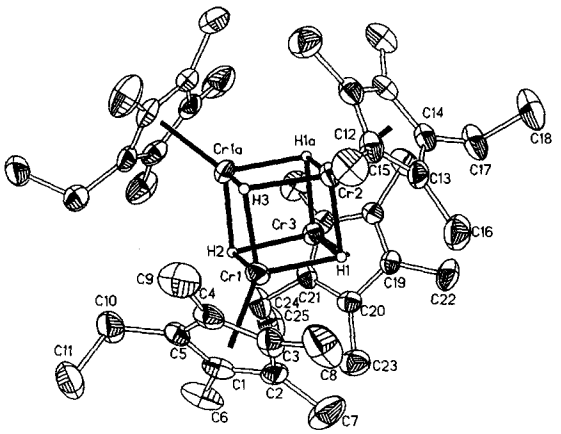

Fig. 1. The molecular structure of $[\{(EtMe_4C_5)Cr(\mu_3\text{-}H)\}_4]$ (**5'**). Selected distances [Å] and angles [°]: Cr1-Cr1a 2.722(2), Cr1-Cr2 2.715(1), Cr1-Cr3 2.716(2), Cr2-Cr3 2.703(2), average Cr-H 1.969 (1.894–2.014), average Cr-C 2.267; average H-Cr-H 92.7 (88.9–94.3).

Mindful of the extreme variability of metal–metal distances in polynuclear chromium compounds and the ongoing discussion of Cr–Cr bonding in such complexes,[6b] we have investigated the magnetic behavior of **5**. Figure 2 depicts the results of measurements of the magnetic susceptibility of complex **5** with a Faraday balance. Somewhat surprisingly, the complex exhibits almost ideal Curie-type paramagnetism.[11] The effective magnetic moment is constant from room temperature down to 15 K ($\mu_{eff} = 5.7\ \mu_B$, or 2.85 μ_B per chromium atom). This value is ambiguous: it can either be interpreted as resulting from complete lack of any exchange interaction between the four Cr^{II} ions ($S = 1$, spin-only moment 2.83 μ_B) or as μ_{eff} of a complex with a ground state of high spin multiplicity ($S = 2$, augmented by an orbital contribution) caused by accidental degeneracy of MOs. Evidence for the latter, more probable, explanation was provided by saturation magnetization measurements[12] on **5** at high magnetic field ($H < 55$ kOe) and $T = 4.0$ K. Under these conditions, the magnetic moment of the sample, induced by aligning all of the spin moments, was that expected for a system of four unpaired electrons per Cr_4 molecule.

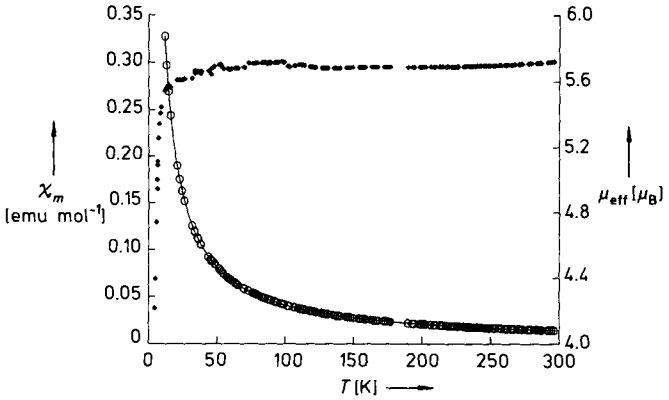

Fig. 2. Temperature dependence of the molar magnetic susceptibility (χ_m, corrected for diamagnetism and temperature-independent paramagnetism, open circles) and the effective magnetic moment (μ_{eff} per Cr_4 cluster, filled squares) of **5**. The line represents the fit of χ_m data with the Curie–Weiss law [11].

The electronic spectrum of the **5** is dominated by a very intense absorption below 400 nm; in addition, there are two discernable shoulders of much lower extinction at approximately 480 and 980 nm. While the low solubility of **5** precludes characterization by NMR spectroscopy in solution, its analogue **5'** exhibits a distinct ^1H NMR spectrum in C_6D_6 attributable to the $EtMe_4C_5$ moiety ($\delta = 7.9$ (6H), 7.2 (6H), 3.4 (2H), 1.1 (3H), full width at half-maximum (fwhm): 18–65 Hz); the resonance signals are broad but are still within the normal range of chemical shifts. To our surprise, even a ^{13}C NMR spectrum of **5'** exhibiting the seven expected resonance signals could be obtained ($\delta = 119.7$, 114.7, 111.0, 94.0, 91.7, 84.5, 37.9). Various attempts to record mass spectra of **5** (EI, FAB, laser desorption) yielded only spectra with the fragmentation patterns of the known $[\{Cp^*Cr(\mu_3\text{-}O)\}_4]$;[13] the considerable air-sensitivity of **5** and **5'** probably explains this observation. To enable the assignment of any Cr–H vibrations in the IR spectrum, $[D_4]$ **5** and $[D_4]$ **5'** were prepared; however, the largely featureless solid-state IR spectra of the deuterides do not differ significantly from those of the hydrides. Corroborating evidence for the presence of hydrido ligands in **5**, **5'** came from protonation reactions of these complexes. Addition of an excess of gaseous HCl to solutions of **5'** liberated 5.9 equivalents of H_2 (measured with a Töpler pump) leaving a quantitative yield of $[\{(EtMe_4C_5)Cr^{III}Cl_2\}_2]$. Two equivalents of H_2 were formed in the apparent oxidation of four Cr^{II} ions to Cr^{III} ions, and the additional H_2 presumably resulted from proton–hydride combination. Complex **5** could not be reduced even in the presence of a mixture of potassium metal and the [222] cryptand;[14] however, **5** is rapidly oxidized by air and by $AgBF_4$. None of the compounds reported herein catalyze the polymerization of ethylene in homogeneous solution. Further experiments are under way in our laboratory.

The chemistry of paramagnetic organometallic chromium compounds now encompasses hydrides too. We are investigating their range of stability, physical properties, and reactivity characteristics.

Experimental Procedure

1: Cp*Li (1.0 g, 7.0 mmol) was added to a stirred suspension of $CrCl_2$ (0.87 g, 7.7 mmol) in 50 mL of THF. After the mixture was stirred for 12 hours the

solvent was evaporated, and the residue was extracted with pentane. Concentration and cooling of the green–brown solution to −30 °C yielded 1.01 g of **1** (2.27 mmol, 65%). ^{1}H NMR (C_6D_6): δ = 10.8 (br s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2959 sh, s), 2909 (s), 2857 (s), 1441 (m), 1377 (s), 1069 (w), 1022 (m), 799 (w), 523 (w); correct elemental analysis for $C_{20}H_{30}Cl_2Cr_2$.

2: 2.0 equivalents of MeLi (1.4 M in Et_2O) were added to a THF solution of **1** (prepared in situ as above). Evaporation of THF and extraction with pentane gave a brown solution, which was filtered and concentrated. Cooling to −30 °C for approximately 15 h yielded 0.85 g of **2** (2.1 mmol, 60%). ^{1}H NMR (C_6D_6): δ = 14.9 (br s, 3H), 2.51 (s, 15H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2960 (sh, s), 2909 (s), 2857 (s), 1435 (m), 1375 (s), 1165 (w), 1111 (w), 1022 (w), 937 (m), 824 (w), 475 (w); correct elemental analysis for $C_{22}H_{36}Cr_2$.

5: A solution of **2** (0.80 g, 2.0 mmol) in pentane (50 mL) was placed in a 500 mL flask fitted with a needle valve. The solution was degassed and the flask backfilled with H_2 (1 atm). After the mixture was stirred at room temperature for 6 days, the solution was filtered to yield a black solid **5**, which was washed with pentane and dried (0.51 g, 0.68 mmol, 68%). IR (KBR): $\tilde{\nu}$[cm^{-1}] = 2982 (m), 2903 (s), 2852 (s), 1435 (m), 1370 (s), 1020 (m), 550 (s), correct elemental analysis for $C_{40}H_{64}Cr_4$.

[7] Crystal data for **5**: dark brown, M_r = 752.9, triclinic, $P\bar{1}$, a = 10.617(5), b = 10.845(17), c = 17.895(17) Å, α = 83.00(3), β = 82.53(3), γ = 67.33(2)°, V = 1879.3(8) Å^3, Z = 2. Axial photographs taken along the c axis revealed interlayer streaks suggesting the presence of a superlattice. Attempts to determine the relationship of the superlattice to the one reported were unsuccessful. The intensity of the reflections defining the superlattice were orders of magnitude weaker than the sublattice data. Solution and refinement of the sublattice data was terminated due to extreme light-atom disorder. However, a tetrahedral Cr_4 core with Cr–Cr distances of 2.61–2.74 Å was unambiguous.

[8] Crystal data for **5'**: $C_{44}H_{72}Cr_4$, dark brown, M_r = 809.0, orthorhombic, *Pnma*, a = 15.412(4), b = 17.195(4), c = 16.221(3) Å, V = 4298.7(14) Å^3, Z = 4, ρ_x = 1.250 g cm^{-3}, $R(F)$ = 0.0494 for 1958 observed ($3\sigma F_0$) data, max. 2θ = 45°. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW, on quoting the full journal citation.

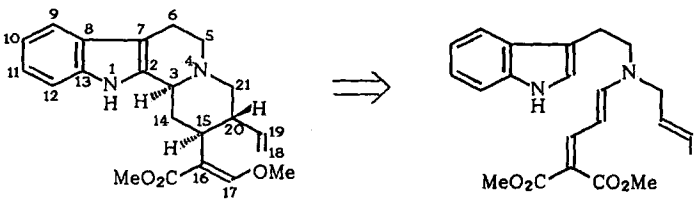
A Short Diastereoselective Entry to Indole Alkaloids of the Corynanthe Type by the Intramolecular Ene Reaction**

By *Lutz F. Tietze** and *Jürgen Wichmann*

Dedicated to Professor Ekkehard Winterfeldt on the occasion of his 60th birthday

Pericyclic reactions, primarily the Diels–Alder reaction,[1] are widely employed in natural product synthesis. The ene reaction[2] has not been utilized to the same extent, possibly because of its higher activation energy. However, much milder reaction conditions have been developed—activation of the enophile by introducing electron-withdrawing groups[3] and the use of Lewis acids[4]—which make the ene reaction very attractive nowadays. Therefore, it is astonishing that this reaction has not been applied to the synthesis of indole alkaloids, which make up an intensively examined field of natural product synthesis.[5] The *trans*-specific formation of six-membered ring systems by intramolecular ene reactions by means of enophiles with two electron-withdrawing groups at the terminal position[3] should provide a short route to indole alkaloids of the corynanthe group according to the retrosynthetic analysis shown for corynantheine (**1**) in Scheme 1.



1 **3a**

Scheme 1. Retrosynthesis of corynantheine (**1**).

We report here on a short and highly diastereoselective synthesis of the *trans*-indolo-[2,3-*a*]-quinolizidine framework by a sequential Pictet–Spengler[6] intramolecular ene reaction starting from **3a** and **3b**. Compounds **3** were obtained from **2**[7] by alkylation with 1-bromo-2-butene and 1-bromo-3-methyl-2-butene, respectively (Scheme 2). The one-pot, double cyclization was accomplished without the isolation of intermediates **4** by treatment of **3** with trifluoro-

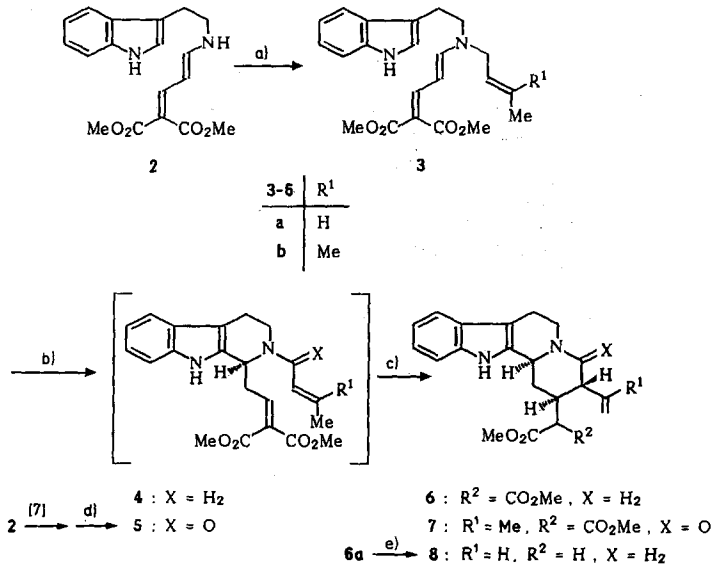
[**] Intramolecular Ene and Related Reactions, Part 10. This work was supported by the Fonds der Chemischen Industrie.—Part 9: L. F. Tietze, J. R. Wünsch, *Synthesis*, **1990**, 985.

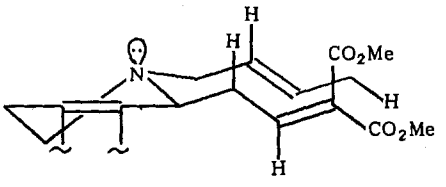
acetic acid (TFA) followed by $SnCl_4$[8] to give the *trans*-indolo-[2,3-*a*]-quinolizidines **6**. When **3** was allowed to react with only trifluoroacetic acid, **4** was obtained in 63–66% yield. Thus, it was not possible to carry out a double cyclization with a Brønsted or a Lewis acid alone. Surprisingly, $SnCl_4$ was the only one of the common Lewis acids which could promote the intramolecular ene reaction.



Scheme 2. a) $BrCH_2$–CH=CR^1–Me, $LiNiPr_2$, THF, −78 → 20 °C, 12 h; 60% (**3a**), 76% (**3b**). b) 1.5 equiv TFA, CH_2Cl_2, 20 °C, 24 h. c) 1.2 equiv $SnCl_4$, 20 °C, 24 h; 42% (**6a**), 47% (**6b**). d) Me–R^1CH=CH–COCl, pyridine, CH_2Cl_2, 0 → 20 °C, 12 h; 74% (**5b**). e) LiI · $3H_2O$, Me_2SO, 180 °C, 2.5 h; 65%.

In a similar transformation, **5b**, which was obtained from **2** by cyclization[7] followed by acylation with 3-methylbutenoyl chloride, was converted with $SnCl_2$ into **7** in 65% yield. In contrast, **5a** did not react under these conditions, presumably because of the low energy of the HOMO of the ene moiety.

The intramolecular ene reactions of **4a**, **4b**, and **5b** are highly diastereoselective, leading to only the respective desired diastereomers **6a**, **6b**, and **7** which have the same relative configurations at the stereogenic centers as the corynanthe alkaloids. We assume that the transition structure has an *exo*-*E*(ene)-*anti*-orientation with a chair-type arrangement of the tether as shown in Scheme 3. As pointed out



Scheme 3. Postulated transition structure of the intramolecular ene reaction of **4a**.

earlier,[9] the excellent stereocontrol may be a result of the conformation fixed by the 1,3-allylic strain,[10] which is due to the disubstituted enophile terminus (sp^2 geminal effect[3c]).

The configuration and conformation of the compounds **6a**, **6b**, and **7** have been determined by NMR spectroscopy. 3-H of **6a** and **6b** resonates at $\delta = 3.14$ and 3.18, respectively, clearly proving the existence of a *trans*-quinolizidine unit. The axial orientation of 3-H, 15-H, and 20-H in **6a** (and **6b**) can be deduced from the three large couplings of $J = 11-12$ Hz for the signal of 14-H_{ax} at $\delta = 1.72$ (1.64 for **6b**) and from the two large couplings of $J = 11$ Hz for 21-H_{ax} at $\delta = 2.13$ (2.28 for **6b**). A similar argument holds for **7**.

The ene product **6a** was transformed into the known methyl corynantheate (**8**) by demethoxycarbonylation.[11] Compound **8** is an intermediate often used in the synthesis of corynantheine (**1**), dihydrocorynantheine, corynantheol, and dihydrocorynantheol.[5a, 12]

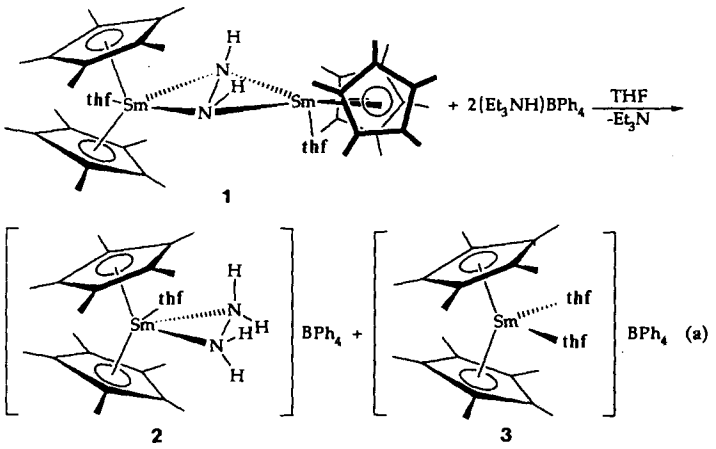
Synthesis and Structure of a Mononuclear η^2-Hydrazine Complex by Protonation of an $[N_2H_2]^{2-}$ Complex**

By *William J. Evans,* Gabriele Kociok-Köhn,* and *Joseph W. Ziller*

One of the models for the fixation of dinitrogen in biological systems is the coordination of N_2 to a metal center followed by subsequent protonation of the N_2 ligand to give N_2H_x compounds ($x = 1-4$) and ultimately NH_3.[1] Although model complexes of several of these N_2H_x ligands have been characterized,[2] they are generally not prepared by the sequence of protonation reactions thought to occur in the biological systems. We report here a rare example of a structurally characterized η^2-hydrazine complex prepared by protonation of a $(N_2H_2)^{2-}$ complex.

The starting material **1** of the reaction (a) is prepared in quantitative yield by the addition of THF to complex **4**.[3]



$[\{C_5Me_5)_2Sm\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HNNH})]$ **4**

Complexes **1** and **4**[3] have been characterized by elemental analysis, NMR spectroscopy,[4] and X-ray structural analysis.[5] **1** is unusual in that it retains the overall structure of **4** despite the addition of two THF molecules (Fig. 1); this demonstrates the remarkable ability of the $[(C_5Me_5)_2Sm]_2$ unit to coordinate a variety of ligand sets and sizes.[6]

The reaction of **1** with two equivalents of $(Et_3NH)BPh_4$ in THF leads to the formation of complex **2** with side-on coordination of the hydrazine ligand and to the previously characterized tetrahydrofuran complex **3**[7] [Eq. (a)]. Complex **2** was characterized by elemental analysis, NMR spectroscopy,[4] and X-ray structural analysis (Fig. 2).[5] Apparently, the η^2-hydrazine ligand is strongly attached to the samarium atom, since the ligand remains coordinated when solvent is removed under vacuum from a solution of **2** and also when **2** is recrystallized from THF/toluene. Complex **2** can also be made from **4** and $(Et_3NH)BPh_4$ in toluene. The protonation is reversible in that **2** reacts with $[\{(C_5Me_5)_2Sm(\mu\text{-H})\}_2]$ in hexane to regenerate **4**.

Complex **2** is unusual both with regard to its synthesis and structure. With one exception,[2e] all previously characterized hydrazine complexes were prepared from hydrazine rather than from N_2H_2 metal complexes. In addition, most structurally characterized hydrazine complexes are either $\mu\text{-}\eta^1\text{:}\eta^1\text{-}MNH_2NH_2M$ compounds or mononuclear complexes, MNH_2NH_2.[2b, 8] The exceptions are $[(tripod)Co(\eta^2\text{-}N_2H_4)]^{2+}$ (prepared from $[(tripod)Co(\eta^2\text{-}N_2H_3)]^+$, tripod $= MeC(CH_2PPh_2)_3$),[2e] and $[(C_5Me_5)Me_3W(\eta^2\text{-}H_2NNH_2)]$-OTf (prepared from H_2NNH_2); the structure has been determined but not yet reported.[2a]

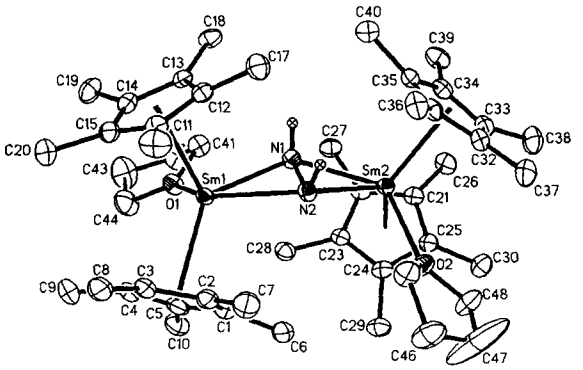


Fig. 1. Crystal structure of **1** (ORTEP) with probability ellipsoids drawn at the 50% level. Selected distances [Å] and angles [°]: Sm1-N1 2.456(4), Sm1-N2 2.413(4), Sm2-N1 2.417(4), Sm2-N2 2.459(4), Sm1-O1 2.522(4), Sm2-O2 2.507(4); Sm-C(ring) average 2.82(4), N1-N2 1.484(6), Cp_1^*(center)-Sm-Cp_2^*(center) average 125.8.

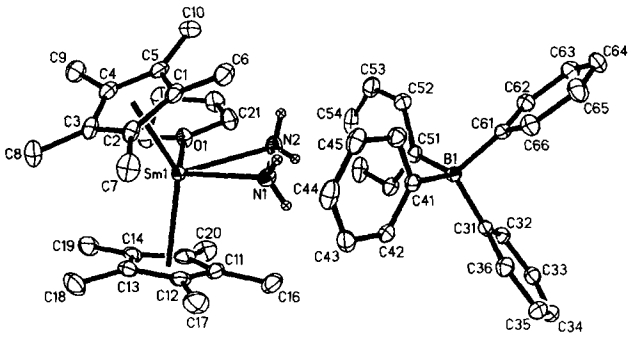

Fig. 2. Crystal structure of **2** (ORTEP) with probability ellipsoids drawn at the 50% level. Selected distances [Å] and angles [°]: Sm1-N1 2.492(2), Sm1-N2 2.523(2), Sm1-O1 2.470(2), N1-N2 1.471(3); Sm1-C(ring) average 2.73(2); Sm1-N1-N2 74.1(1), Sm1-N2-N1 71.8(1), N1-Sm1-N2 34.1(1), N2-Sm1-O1 80.8(1); Cp_1^*(center)-Sm1-Cp_2^*(center) 138.9.

The N–N distances in **1** and **2** (1.484(6) and 1.471(3) Å, respectively) are in the expected range for single bonds.[9] The Sm–N distances in **1** are intermediate between typical Sm–NR_2 and Sm ← NR_3 bond lengths.[10] The longer Sm–N distances in **2** are consistent with Sm ← NR_3 bonds, in which the NR_3 ligand is bound to a cationic samarium center. The hydrogen atoms shown in Figures 1 and 2 were located in both X-ray structural analyses.

The existence of these complexes and the reaction sequence shown in Equation (a) demonstrate that the organolanthanide unit $(C_5Me_5)_2Sm$ provides an interesting metallic environment with which to study transformations of nitrogen-containing substrates relevant to nitrogen fixation.[11] Since no redox chemistry occurs in the Sm^{III} reactions, these organosamarium complexes provide the opportunity to study how protons can be transferred between nitrogen substrates without concomitant redox processes.

Experimental Procedure

Complex **1** was prepared under nitrogen in a glovebox by addition of THF to $[(C_5Me_5)_2Sm]_2(HNNH)$ [3] followed by removal of solvent by rotary evapora-

Irvine, CA 92717 (USA)

[**] This work was supported by the National Science Foundation (USA) and by the Deutsche Forschungsgemeinschaft (postdoctoral fellowship for G. K.-K.).

tion. Complex **2** was prepared by the addition of a suspension of $(Et_3NH)BPh_4$ (75.9 mg, 0.18 mmol, from $(Et_3NH)Cl$ and $NaBPh_4$) in 5 mL of THF to a stirred orange-yellow solution of **1** (90 mg, 0.09 mmol) in 7 mL of THF. The reaction was stirred overnight and the solvent was removed by rotary evaporation to leave a dark orange product. This was washed with 5 mL of toluene to remove oily by-products and left a 2:1 mixture (by NMR spectroscopy of **2** and **3** (110 mg). Complex **2** was separated by recrystallization from THF: toluene (4:1).

Reduction of a Boron–Nitrogen 1,3-Butadiene Analogue: Evidence for a Strong B–B π-Bond**

By *Afarin Moezzi, Ruth A. Bartlett,* and *Philip P. Power**

A recurring theme in inorganic and organometallic chemistry is the, often close, structural analogy that is drawn between organic compounds and their inorganic and organometallic counterparts.[1] Perhaps the most well-known case involves the boron–nitrogen compounds which frequently possess physical properties and structures that are very similar to their organic analogues.[2] One illustration of the B–N, C–C relationship involves the diboron species of the general formula $R(R'_2N)BB(NR'_2)R$ (R = alkyl or aryl groups) which may be regarded as substituted 1,3-butadiene analogues.[3–5] Their structures[6, 7] show that the π-interaction is localized exclusively in the B–N bonds and that the B–B bonds are single and ca. 1.7 Å long. Generally, there is a large angle (> 60°) between the coordination planes at the boron atoms, whereas the angle between the boron and nitrogen planes is ca. 0°. Recent work in this laboratory has shown that it is possible to doubly reduce the related tetraaryl diboron species B_2Ar_4 to give the substituted ethene analogue $[B_2Ar_4]^{2-}$, which has a B–B bond length of 1.636(11) Å and an almost planar B_2 (*ipso*-C)$_4$ core.[8] This result is in agreement with an earlier prediction of the existence of a B–B multiple bond in the hypothetical species $[B_2H_4]^{2-}$.[9] In this paper we provide independent evidence for the presence of strong boron–boron double bonds in these dianions via the reduction of the butadiene analogue **1** to give the dianion **2**.

$Ph(Me_2N)BB(NMe_2)Ph$ **1** $[\{(Et_2O)Li\}_2\{Ph(Me_2N)BB(NMe_2)Ph\}]$ **2**

$Br(Me_2N)BB(NMe_2)Br$ **3**

Compound **1**[10] was synthesized by the reaction of **3**[11] with two equivalents of LiPh in hexane. The X-ray crystal structure analyses[6] of **1** and **3** revealed average B–N lengths of 1.399 Å (**1**) and 1.36 Å (**3**) and B–B lengths of 1.714(4) Å (**1**) and 1.682(16) Å (**3**). Moreover, the angles between the planes at the boron atoms are large (88.7° for **1** and 83.7° for **3**). In short, the structures display the features that are consistent with a B–N 1,3-butadiene analogy for **1** and **3**. Reduction of **1** with excess Li powder occurs readily in Et_2O/THF solution, from which red crystals of the product **2** can be obtained after suitable work-up.[12] The X-ray crystal structure[13] of **2** is illustrated in Figure 1. Each asymmetric unit in the cell contains two half molecules, which, therefore, possess a center of inversion. The B_2N_2 (*ipso*-C)$_2$ array is planar and the B–B distances in the molecules are 1.623(8)

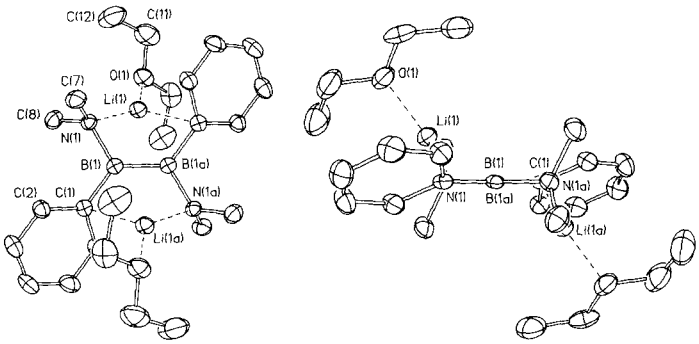

Fig. 1. Two views of one of the molecules of **2**; H atoms are omitted for clarity. Selected distances [Å] and angles [°], with the corresponding parameter for the second molecule in brackets, are: B(1)-N(1) 1.560(5) [1.562(5)], B(1)-B(1a) 1.631(9) [1.623(8)], B(1)-C(1) 1.595(6) [1.591(6)], Li1···O(1) 1.920(7) [1.916(7)], Li1···N(1) 1.978(7) [1.977(7)], Li1a···C(1a) 2.251(7) [2.249(8)], Li(1)···B(1) 2.281(8) [2.251(8)], Li-B(1a) 2.337(8) [2.304(8)]; N(1)-B(1)-C(1) 114.2(3) [114.9(3)], N(1)-B(1)-B(1a) 119.4(4), C(1)-B(1)-B(1a) 126.4(4). Angle between B(1) N(1) C(1) plane and the plane of the C(1) ring = 31.5°.

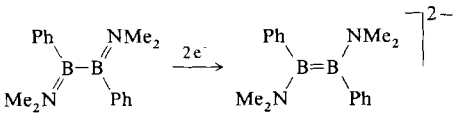
and 1.631(9) Å, which are significantly shorter than those observed in the precursor. The most important features of the structure, however, are the long B–N bond lengths (1.560(5) and 1.562(5) Å) and the orientation (ca. 90° angle) of the NMe_2 groups with respect to the core, which show that the B–N π-interactions have been destroyed in the reduction process. In effect, the formation of the B–B π-bond proceeds at the expense of B–N π-bond rupture. The solvation of the Li^+ ions by ether, the nitrogen lone pair, and the *ipso* carbon atom also provide impetus for reduction.[14] The ^{11}B-NMR spectrum of **2** displays a broad singlet at $\delta = 33$, whereas the corresponding peak for **1** appears at $\delta = 49.3$. The upfield shift upon reduction is indicative of an increase in the electron density at the boron centers in spite of the elimination of strong π-donation by the NMe_2-substituents. The structural and spectroscopic data thus indicate that the reductive process may be represented schematically as in Scheme 1.[15]



Scheme 1. Schematized reduction.

The electronic absorption spectrum of **2** in Et_2O displays an intense peak at 320 nm. If this is taken to be indicative of the $\pi \rightarrow \pi^*$ transition of the B–B π-bond than an energy difference of ca. 90 kcal mol^{-1} between the π and π^* levels may be estimated. The energy of the π-bond is probably less than half of this value, perhaps in the region of 40 kcal mol^{-1}. If this estimate seems high in view of the ca. 0.09 Å difference between the B–B distances in **1** and **2**, it should be borne in mind that the presence of two negative charges in close proximity may give rise to Coulombic repulsion which lengthens the bond. The B–B distance (1.859(8) Å) found in the compound $[Li_2\{(Me_3Si)_2CB(Mes)(Mes)BC(SiMe_3)_2\}]$,[16] which has a single bond between two negatively charged boron atoms, suggests that B–B π-bond formation results in a shortening of ca. 0.23 Å rather than the 0.09 Å with respect to the precursor **1**. This difference in length which is similar to that observed between H_3CCH_3 (1.54 Å) and H_2CCH_2 (1.34 Å) supports the presence of a strong B–B π-bond.

Experimental

Under anaerobic and anhydrous conditions, a solution of **1** (0.485 g, 1.8 mmol) in diethyl ether (25 mL) and tetrahydrofuran (10 mL) was added dropwise to a suspension of lithium powder (0.07 g, 10 mmol) in diethyl ether (10 mL). Stirring for 3 h at room temperature afforded a deep-red solution. The solvents were removed under reduced pressure and the residue was extracted with diethyl ether (25 mL). Filtration and reduction of the solution volume to 10–12 mL followed by cooling overnight in a freezer (−20 °C) furnished deep-red crystals of **2** in 70% yield (0.54 g). M.p. = 105–110 °C; ^{11}B NMR (96.25 MHz, Et_2O): $\delta = 33$; ^{1}H NMR (300 MHz, C_6D_6): $\delta = 0.99$ (t, 12H), 2.55 (s, 12H), 3.11 (q, 8H), 7.3 (m, 10H), UV/VIS (Et_2O): $\lambda_{max} = 320$ nm.

Synthesis of (*R*)- and (*S*)-2-*tert*-Butyl-6-trifluoromethyl-1,3-dioxin-4-ones, Transformations into 3-Hydroxy-3-(trifluoromethyl)alkanoates, and Surprising Differences in the Reactivity of CH_3- and CF_3-Substituted Compounds**

By *Markus Gautschi* and *Dieter Seebach**

For many years[1] we have been engaged in the preparation and investigation of chiral, trifluoromethyl-substituted compounds.[2] Our interest in these systems has grown as we continue to be fascinated by their surprising reactivity, and because we expect that our results will finally lead to a better understanding of inter- and intramolecular interactions of fluoro-substituents in organic compounds. In addition, the reactions we have performed and the compounds we have synthesized during these investigations should find application in the development of new agrochemicals and pharmaceuticals.[3] As in the case of non-fluorinated chiral building-blocks, simple compounds with one, or at most, two stereogenic centers are predicted to have greatest potential.

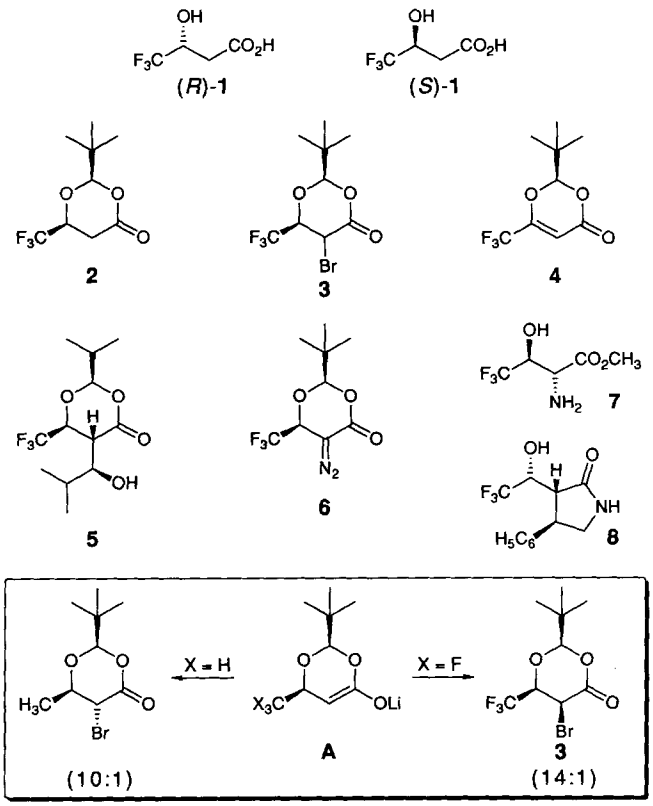
[**] Part of the planned Ph.D. thesis by M. G., ETH Zürich

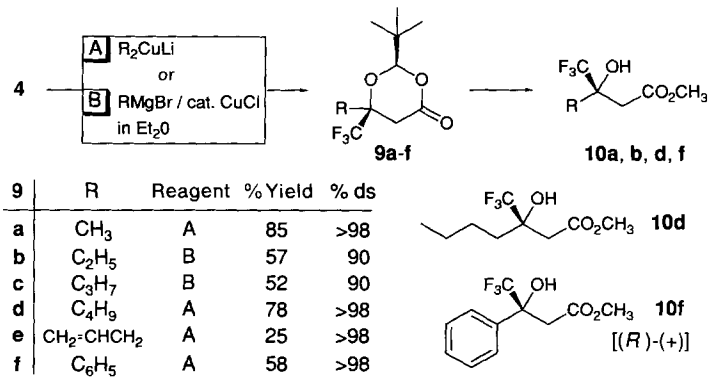
When we attempted to transform the (*S*)- and (*R*)-trifluorohydroxybutanoic acids **1** (Scheme 1), which are accessible on a large scale by separation of the enantiomers,[1a] into the chiral trifluoroacetylacetic acid derivatives **4** and *ent*-**4**, we observed that bromination of the corresponding dioxanones with *N*-bromosuccinimide (NBS),[4] which had been possible in the case of other β-hydroxy acids, was not successful due to the low reactivity of the trifluoromethyldioxanone **2** towards this reagent. On the other hand,



Scheme 1. Starting materials **1** and products from the Li-enolate **A** of **2** [generated using *t*BuLi or $LiN(SiMe_3)_2$(LHMDS), THF, −78 °C] and electrophiles. **2** → **3** → **4**: see *Experimental*.—**5** (m.p. = 123 °C): 66% from **2**, LHMDS (Li hexamethyl disilazamide), 10 Me_2CHCHO, under transacetalization.—**6** (m.p. = 91 °C): 56% from **2**, LHMDS, $TosN_3$.—**7** (m.p. = 117 °C): 57% from **2**, *t*BuLi, Boc-N=N-Boc (*tert*-butoxycarbonyl), then HCl/MeOH, then H_2/PtO_2; comparison with the coupling constants of trifluorothreonine and -*allo*-threonine, respectively [7].—**8** (m.p. = 164 °C, main diastereoisomer): from *ent*-**2**, *t*BuLi, nitrostyrene (95%, 66% ds), then H_2/Raney-Ni/EtOH/70 °C. The assignments of configuration are based on NMR measurements (see *Experimental*).

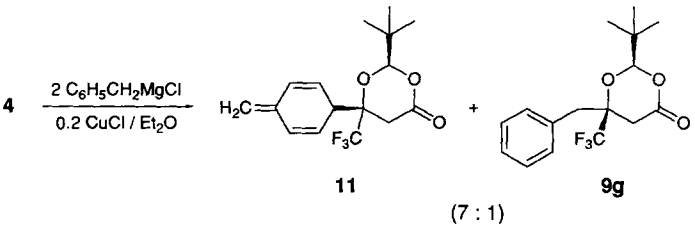
the 5-bromodioxanone **3**, obtained via bromination of the Li-enolate **A** of **2**,[5] led, on treatment with base, to the desired dioxin-4-one **4** (46%) in contrast to the non-fluorinated analogue[6a] (see Scheme 1 and *Experimental*). The enolate of **2** also reacts with other "fast"[8] electrophiles, see products **5**–**8**. Surprisingly, inversion of the stereochemical course of the bromination is observed on switching from the CH_3- to the CF_3-derivative, the *trans*-configurated CH_3- and the *cis*-configurated CF_3-compounds being formed, respectively (see legend and box in Scheme 1).[6b] The enolate of **2** reacts with both aldehydes (→ **5**) and azodicarboxylate (→ **7**), leading to *trans*-products, whereas with nitrostyrene the *cis*-product results (**8**).

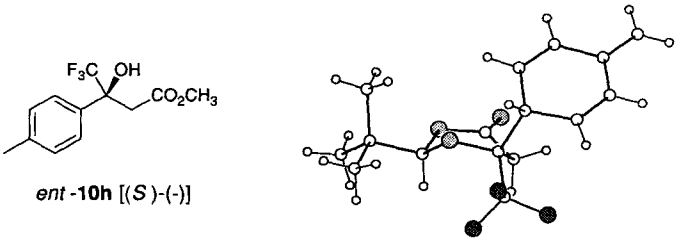
Like non-fluorinated dioxin-4-ones,[9] **4** is an excellent acceptor for cuprates or CuCl-doped Grignard reagents: addition with relative topicity *like* (*trans* to the *tert*-butyl group) occurs, and the 6,6-disubstituted dioxanones **9** are formed. These are transformed, almost quantitatively, into the hydroxytrifluoromethyl-substituted carboxylic esters **10** upon treatment with methanolic HCl (Scheme 2). Up to this point, the CF_3-substituted dioxacyclohexenone behaved in an "inconspicious" manner. Doubly surprising was the reaction with benzylmagnesium chloride (Scheme 3): In essen-

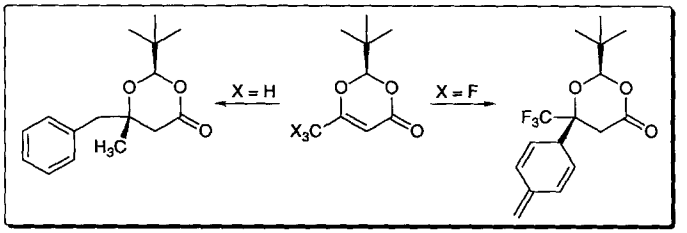


9	R	Reagent	% Yield	% ds
a	CH_3	A	85	>98
b	C_2H_5	B	57	90
c	C_3H_7	B	52	90
d	C_4H_9	A	78	>98
e	CH_2=$CHCH_2$	A	25	>98
f	C_6H_5	A	58	>98

Scheme 2. Reactions of the Michael-acceptor **4**. The yields refer to samples obtained after chromatography performed on the crude products **9** from 5 mmol-scale reactions, the diastereoselectivities were determined by NMR spectroscopy of the crude products; the indicated configuration follows from NOE measurements on **9a** and **9f**, and from a comparison of the $[\alpha]_D^{RT}$ values of the dioxanones **9** (**a**–**e** dextrorotatory, **f** levorotatory, all $c \approx 1$ in EtOH). **9** → **10**: HCl/MeOH/RT (**10a**,**b**,**d** levorotatory, **f** dextrorotatory, $c \approx 1$ in EtOH).







Scheme 3. Reactions of **4** with benzylmagnesium chloride and proof of the structure of **11**. Separation of **11** and **9g** by flash chromatography (SiO_2; pentane/Et_2O 4:1; RT). **9g**: m.p. = 78.5 °C; $[\alpha]_D^{RT}$ +2.8 (c = 1.0, EtOH).—**11**: m.p. = 104 °C; $[\alpha]_D^{RT}$ −131.4 (c = 1.05, EtOH).—*ent*-**10h** (from **11**, MeOH/HCl): 94%, b.p. = 75 °C/0.2 torr; $[\alpha]_D^{RT}$ −8.8 (c = 1.02, EtOH).—The X-ray crystal structure analysis was performed by V. Gramlich, T. Bremi, and F. Kühnle within the crystallography course (WS1991/92) at ETH-Zürich; **11** exists in a boat conformation, which is unusual for dioxanones [10]; further details concerning the crystal structure analysis may be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW, on quoting the full literature citation of this paper.

tially quantitative yield a 7:1 mixture of the isomers **11** and **9g** is formed (67 and 10% of the pure products were isolated, respectively). The main product turned out to have arisen from a 1,5-addition of the benzylic nucleophile with relative topicity *unlike* (*cis* to the *tert*-butyl group), as proven by aromatization of **11** to *ent*-**10h** and X-ray crystallographic analysis of **11**. For comparison, the non-fluorinated dioxin-4-one (**4**, CH_3 instead of CF_3) was treated with benzylmagnesium chloride under identical conditions. This led to the isolation of 60% "normal" product (**9g**, CH_3 instead of CF_3) and 36% of starting material (see box in Scheme 3).[11] The inversion of the regio- *and* stereochemical course of the reaction on going from the methyl- to the trifluoromethyl-dioxin-4-one must be due to a change in the reaction mechanism.[12] Investigations concerning the mechanism are in progress.

Experimental

3: To a cooled (−78 °C) solution of dioxanone **2** (11.31 g, 50 mmol) in 200 mL THF, under argon, was added 36.2 mL (55 mmol) of a 1.52 M solution of *t*BuLi in hexane such that the reaction temperature did not rise above −70 °C. The yellow enolate solution was added via teflon cannula to a precooled (−78 °C) solution of 2.85 mL (55 mmol) of bromine in 125 mL of THF. Work-up (80 mL sat. aq. NH_4Cl, Et_2O, drying over $MgSO_4$), and recrystallization of the sublimed (60 °C/0.01 torr), crude product (15.15 g, 98%) from pentane, afforded 12.1 g (75%) of **3** as a colorless crystalline solid. M.p. = 82.0–83.5 °C; $[\alpha]_D^{RT}$ −30.5 (c = 1.0, EtOH); ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.03 (s, *t*Bu); 4.54 (d, ^3J(H,H) = 5.6 Hz, H-C(5)); 4.71 (dq, ^3J(H,H) = 5.6 Hz, ^3J(H,F) = 5.6 Hz, H-C(6)); 5.29 (s, H-C(2)); the relative configuration was assigned by NMR-comparison with the analogous non-fluorinated *cis*- and *trans*-bromides, as well as with numerous other *cis*/*trans*-isomeric pairs of the same type [6, 9, 13] and by NOE-measurements.

4: To an ice-cold solution of 1.52 g (5 mmol) of dioxanone **3** in 30 mL Et_2O, under argon, was added 1.5 mL (9.6 mmol) of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), rapidly. The resulting colorless suspension was stirred for 15 min (0 °C), quenched with 30 mL of 2 M HCl, and then extracted with Et_2O. The combined ethereal extracts were dried ($MgSO_4$) and concentrated. Distillation (bulb to bulb, 30 °C/10 torr) furnished 690 mg (62%) of **4** as a colorless, crystalline solid; m.p. = 32–33 °C; $[\alpha]_D^{RT}$ −141.9 (c = 1.04, $CHCl_3$); IR ($CHCl_3$): $\tilde{\nu}$[cm^{-1}] = 2980 m, 1750 s, 1420 s, 1405 s, 1365 s, 1280 s, 1270 s, 1200 s, 1170 s, 1095 s; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 1.10 (s, *t*Bu); 5.22 (s, H-C(2)); 5.94 (s, H-C(5)); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): δ = 23.76 (CH_3); 34.70 (C); 98.81 (CH); 108.37 (CH); 117.98 (q, $^1J_{CF}$ = 273.4 Hz); 157.81 (q, $^2J_{CF}$ = 39.0 Hz); 160.24 (CO); ^{19}F NMR (282.2 MHz, $CDCl_3$, TMS): δ = −73.89 (s); MS: m/z 225 ([M + 1]$^{\oplus}$, 0.1), 57 (76); correct C,H,F analysis. Enantiomeric purity of **4** > 99% (GC-analysis, Chrompack CP-Cyclodextrin-β-2,3,6-M-19 WCOT fused silica column, 50 m × 0.25 mm; 1.1 bar H_2, 40 °C, 0.7°/min).

[5] For these reactions the enolate was directly generated from **2** using *t*BuLi. This laboratory scale practical method of generating enolates can be applied, in our experience, to many other carbonyl compounds. For a discussion of salt- and amine-free Li-enolates see section 4 (Scheme 10) in D. Seebach, *Angew. Chem.* **1988**, *100*, 1685–1715; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 1624–1654.

[6] a) As observed earlier [J. N. Kinkel, U. Gysel, D. Blaser, D. Seebach, *Helv. Chim. Acta* **1991**, *74*, 1622–1635], the HBr-elimination from 5-bromo-1,3-dioxan-4-ones normally does not occur. Under the reaction conditions used for the step **3** → **4**, the nonfluorinated analogue of **3** is mostly decomposed! The increased acidity of H-C(6) in **3**, due to the CF_3-group, must be responsible for this difference in reactivity. b) It is not possible, without further investigations, to explain this inversion. For example, the CF_3-group might interact in a special way with the electrophile (bromine) or lead to a changed reactive conformation of the enolate **A** [compare the discussion in: J. Zimmermann, D. Seebach, T.-K. Ha, *Helv. Chim. Acta* **1988**, *71*, 1143–1155].

Synthesis of Cubane-like and Double Cubane-like Tungsten-Copper-Sulfur Clusters from the "Butterfly" Cluster $[Cu_2S_3W(O)(PPh_3)_3]$**

By *Shaowu Du, Nianyong Zhu, Pengcheng Chen,* and *Xintao Wu**

The tetrathiometalate anions $[MoS_4]^{2-}$ and $[WS_4]^{2-}$, which have proven to be useful and versatile reagents,[1] play a key role in bioinorganic chemistry.[2–3] Since cubane or double cubane-like clusters with cores $\{MoFe_3S_4\}$,[4] $\{NiFe_3S_4\}$[5] and $\{VFe_3S_4\}$,[6] or $\{MoFe_3S_4S_4Fe_3Mo\}$, respectively,[7] have model character for the active sites of some enzymes, they have received much attention. The anion $[MoS_4]^{2-}$ has been claimed to be the most effective antagonist[3] of copper metabolism. Extensive research has been carried out on $[MoS_4]^{2-}/Cu^I$ and $[WS_4]^{2-}/Cu^I$ complexes.[1, 8] The cubane-like series of Mo–Cu–S and W–Cu–S clusters have been completed as $\{M_3CuS_4\}^{5+}$,[9] $\{M_2Cu_2S_4\}^{4+}$,[10] and MCu_3S_3X,[11] in which the first two were synthesized from the homometallic trinuclear clusters $[M_3S_4\{S_2P(OCH_2CH_3)_2\}_4(H_2O)]$[12] and dinuclear complexes $[M_2S_4(SCH_2CH_2S)_2]^{2-}$[13] (M = Mo, W). In this communication, the heterometallic butterfly cluster $[Cu_2S_3W(O)(PPh_3)_3]$ **1**[14] was used as a reactive fragment in the designed synthesis of W–Cu–S clusters, in which the coordinatively unsaturated μ_2-sulfido atoms with lone-pair

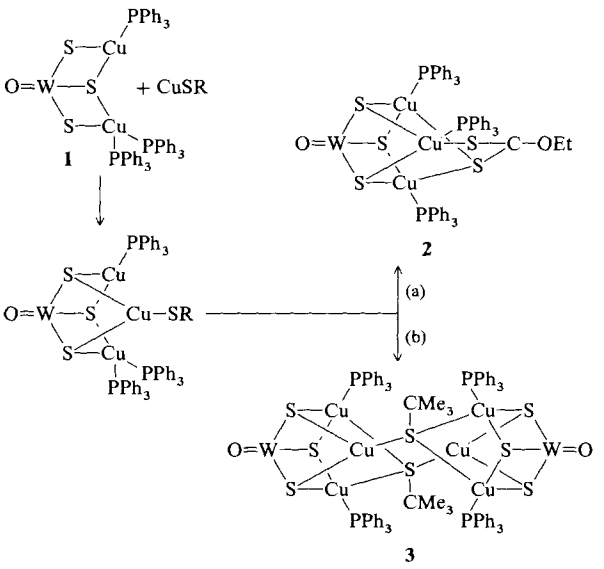
electrons have a high affinity for metal complexes with unsaturated sites or with easily displaceable ligands.

The cubane-like cluster **2** [Eq. (a)] was obtained by reaction of **1** and $[Cu(S_2COEt)]$ in the molar ratio 1:1, while the double cubane-like cluster **3** [Eq. (b)] was isolated from the reaction of equimolar amounts of **1** and $[Cu(SCMe_3)]$. Both compounds were characterized by elemental analysis, IR, UV/VIS spectroscopy, and by a single-crystal X-ray structure analysis.[15]

$$\underset{\mathbf{1}}{[Cu_2S_3W(O)(PPh_3)_3]} + Cu(S_2COEt) \longrightarrow \underset{\mathbf{2}}{[Cu_3S_3W(S_2COEt)(O)(PPh_3)_3]} \quad (a)$$

$$2\underset{\mathbf{1}}{[Cu_2S_3W(O)(PPh_3)_3]} + 2Cu(SCMe_3) \longrightarrow \underset{\mathbf{3}}{[Cu_6S_6W_2(SCMe_3)_2(O)_2(PPh_3)_4]} \quad (b)$$

Possible pathways for the reactions are shown in Scheme 1. Presumably, depending upon the thiolate complex employed, the reaction can proceed in one of two ways: a monodentate thiolate ligand will lead to dimerization of the starting compound to give a double cubane-like cluster; a bidentate dithiolate ligand causes the formation of a cubane-like cluster. This assumption was subsequently confirmed by the synthesis of the clusters $[Cu_3S_3W\{S_2P(OEt)_2\}(O)(PPh_3)_3]$, $[Cu_6S_6W_2(SCH_2CH_2OH)_2(O)_2(PPh_3)_4]$, and $[Cu_6S_6W_2(SCH_2CHMe_2)_2(O)_2(PPh_3)_4]$.



Scheme 1. Possible pathways of the reactions (a) and (b). R = CMe_3, C(S)OEt.

The compound **2** crystallizes in the space group $P\bar{1}$ with two molecules per unit cell. Figure 1 shows one of the two independent molecules. The structure is similar to that of the cluster $[Cu_3S_3W(Cl)(O)(PPh_3)_3]$,[11b] except that the chloride ion is replaced by a triply-bridging bidentate dithiocarbonato ligand $EtOCS_2^-$. The bridging mode of the bidentate dithiocarbonato ligand is unusual.[16] Such bridging is known in the case of thiocarbamates of the type $R_2NC(O)S^-$, e.g. in $[M(Pr_2mtc)]_6$ (M = Cu,[17a] Ag;[17b] Pr_2mtc = *N*,*N*-dipropylmonothiocarbamate), but so far has not been reported for dithiocarbonates(1-) as ligands.[16]

3 crystallizes in the space group $P\bar{1}$ with one molecule per unit cell (Fig. 2). The crystallographic inversion center

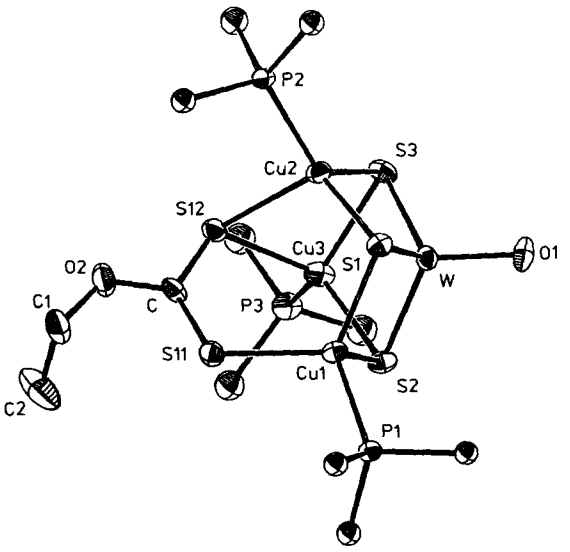


Fig. 1. ORTEP drawing of **2** (thermal ellipsoids at the 30% probability level). Selected bond lengths [Å] and angles [°]: W-Cu(1) 2.798(2), W-Cu(2) 2.721(2), W-Cu(3) 2.736(2), W-S (average) 2.246(3), W-O(1) 1.752(7), Cu(1)-S(1) 2.321(3), Cu(1)-S(2) 2.322(3), Cu(1)-S(11) 2.312(3), Cu(1)-P(1) 2.277(3), Cu(2)-S(1) 2.290(3), Cu(2)-S(3) 2.353(3), Cu(2)-S(12) 2.536(3), Cu(2)-P(2) 2.224(3), Cu(3)-S(2) 2.287(3), Cu(3)-S(3) 2.352(3), Cu(3)-S(12) 2.457(3), Cu(3)-P(3) 2.213(3), S(11)-C 1.67(1), S(12)-C 1.69(1), O(2)-C 1.36(1); S(1)-Cu(1)-S(2) 102.0(1), S(1)-Cu(1)-P(1) 116.7(1), S(3)-Cu(2)-S(12) 89.1(1), S(3)-Cu(2)-P(2) 124.3(1), S(3)-Cu(3)-S(12) 91.0(1), S(3)-Cu(3)-P(3) 124.0(1), Cu(2)-S(12)-Cu(3) 78.5(1).

overlaps the center of the molecule. The molecule consists of two cubane-like $[Cu_3S_3W(SCMe_3)(O)(PPh_3)_2]$ units linked by two triply bridging $SCMe_3$ groups. This kind of μ_3-coordination of Me_3CS^- is rare in organothiolato transition metal complexes.[18] The structure of **3** is similar to that of the double cubane-like cluster $[Cu_2S_8Mo_6(H_2O)_{18}]^{8+}$[19] in which the molybdenum is in a low oxidation state.

Our findings demonstrate once again the high tendency of formation of transition metal-copper-sulfur clusters and their structural variants. The driving force for the reactions studied is the preferred formation of μ_3S compared to μ_2S moieties in the presence of soft metal centers, which corresponds to the formation of the prismane type cage $[CuP(Ph_3)_4(MoOS_3)_2]$ from two halves of it, that means from the butterfly type species $[Cu_2(PPh)_3(MoOS_3)]$.[14] Subunits of M–Cu–S complexes seem to be suitable for the synthesis of various molecular structures. Whereas the synthesis of transition-metal clusters like **2** and **3** with sulfido-bridges by "spontaneous self-assembly" reactions from simple inorganic reagents is highly unlikely, in some cases smaller clusters can be used as building blocks in cluster synthesis.

Experimental

2: A mixture of 0.20 g (0.165 mmol) of **1** and 0.032 g (0.17 mmol) of $Cu(S_2COEt)$—obtained from 2.0 g of CuI in saturated KI solution (30 g KI in 30 mL H_2O) and 1.7 g KS_2COEt (in 10 mL H_2O) as a yellow precipitate, which was washed with saturated KI solution, water, ethanol and ether—was dissolved in 15 mL CH_2Cl_2 and stirred for 3.5 h. The orange reaction solution was then filtered and the filtrate treated with 60 mL diethyl ether. This solution was allowed to stand for about 12 h at ca. 5 °C and 0.15 g of pure red crystals were obtained (yield: 65 %); satisfactory C,H,Cu,P,S analysis.

3: A mixture of 0.20 g (0.165 mmol) of **1** and 0.027 (0.18 mmol) of $Cu(SCMe_3)$—obtained by reaction of 5.0 g $Cu(NO_3)_2 \cdot 3H_2O$ with 5 mL $HSCMe_3$ and 5 mL NEt_3 in 50 mL ethanol as a yellow precipitate, which was washed with ethanol and ether—was dissolved in 30 mL of CH_2Cl_2 and stirred for 25 min. The orange-red solution was filtered and the filtrate was treated with 30 mL of diethyl ether. The filtrate was allowed to stand for ca. 12 h at 5–10 °C, orange crystals were obtained. The orange-red crystals that separated out were recrystallized from 25 mL of CH_2Cl_2 solution by gaseous diffusion of diethyl ether. Yield: 0.10 g (55 %); satisfactory C,H,P,S analysis.

Docking of a Second Functional Protein Layer to a Streptavidin Matrix on a Solid Support: Studies with a Quartz Crystal Microbalance

By *Hiroshi Ebato, James N. Herron, Wolfgang Müller, Yoshio Okahata, Helmut Ringsdorf,** and *Peter Suci*

The specific interaction of streptavidin[1] with biotinylated lipids at the air/water interface leads to the formation of optically anisotropic two-dimensional streptavidin crystals.[2–4] This perfectly ordered matrix of the protein streptavidin, with two of its original four binding sites remaining free, can be functionalized in various ways with biotinylated subunits.[2] Recently, it has been shown by Ward et al. that it is possible to detect the binding of biotinylated moieties to unspecifically adsorbed avidin and streptavidin layers with a quartz crystal microbalance (QCM) for biosensor applications.[5] In the study presented here, the possibility of using a streptavidin film, specifically bound via biotin to a solid support, as a template for docking a second functional protein layer was explored. A quartz crystal microbalance[6] was utilized to study both the interaction of streptavidin with biotinlipid membranes and the docking of biotinylated anti-fluorescyl-antibody fragments (Fab fragments)[7] to streptavidin.

Previous monolayer experiments with biotinlipids at the air/water interface revealed that it is necessary to have sufficient mobility and free space around the biotin headgroups of the lipids for proper binding of the ligand.[3, 4] One would expect, that on a solid support, mobility and access of the

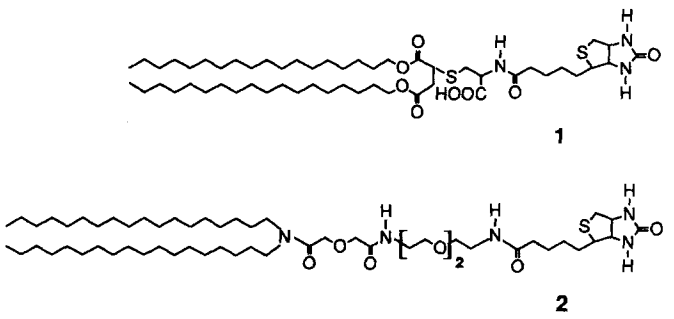
biotin headgroups will be even more important and hence biotin lipids with a short (**1**) and a long (**2**) hydrophilic spacer were compared in the studies. For all the experiments presented below, three monolayers of the corresponding lipids mixed with L-α-dipalmitoylphosphatidylethanolamine (L-α-DPPE) in varying amounts were deposited by means of the Langmuir–Blodgett (LB) technique on the gold electrode of a QCM. All measurements with the QCM were performed in buffer solution (50 mmol phosphate, pH = 7.5).



1

2

As expected the spacer length plays an important role in the docking process of streptavidin on solid supports. The frequency change observed with the long spacer lipid **2** (5 mol-% in DPPE[8]; Fig. 1 filled circles) is strongly dependent on the protein concentration up to the saturation of the membrane, which occurs between 2.5×10^{-7} and 3.5×10^{-7} M streptavidin in the buffer solution. The resulting saturation frequency change of 65 Hz is in agreement with the frequency change expected for a monolayer of streptavidin as predicted by the Sauerbrey equation (in air).[9] In contrast to this, for the biotin-free (pure DPPE) membrane and the membrane with 5 mol-% of the short spacer lipid **1**, a maximum frequency change of only 15 Hz is found (Fig. 1 open circles, triangles). With the pure DPPE membrane, a specific interaction with the biotin ligand is excluded, and therefore the frequency changes produced can be assumed to result from nonspecific adsorption of streptavidin to the membrane surfaces. Apparently, sufficient spacer length between the biotin-headgroup and the membrane-forming alkyl chains of the biotinlipids can compensate for the reduced mobility and close packing of the headgroups on the surface and allow proper binding of a streptavidin layer.

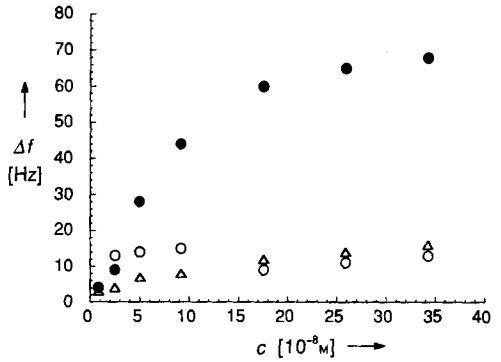


Fig. 1. Interaction of streptavidin with different lipid membranes, measured via the change in resonance frequency Δf of a quartz crystal microbalance as a function of the streptavidin concentration c. ○: pure DPPE membrane; △: DPPE with 5 mol-% of biotinlipid **1**; ●: DPPE with 5 mol-% of biotinlipid **2**.

This is confirmed by experiments to determine the amount of biotinlipid needed for a total protein coverage of the surface in mixed DPPE/**2** layers. It could be shown (Fig. 2) that with approximately 1 mol-% of **2** in the DPPE matrix the saturation frequency change of 65 Hz is already found.

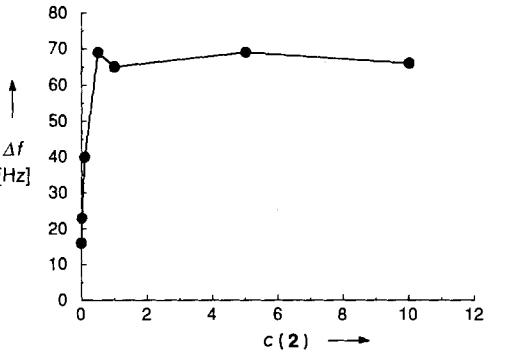

Fig. 2. Dependence of the change in resonance frequency on the content (c in mol-%) of biotinlipid **2** in the membrane.

When the biotinlipid **2** content was increased further no difference in the equilibrium frequency change was observed, even when the content was 10 mol-%, indicating that under these conditions no further protein can be induced to adsorb once the surface is saturated.

The protein used for the docking of a second protein layer to the streptavidin matrix is a Fab fragment of a monoclonal antifluorescyl antibody (clone 4-4-20).[7] Two different biotinylation procedures of the Fab were used: the results presented in Figure 4 were obtained with a Fab fragment biotinylated nonspecifically with an amino-reactive reagent (BioFab) (see *Experimental*); the measurements presented in Figure 5, on the other hand, were performed using a Fab fragment specifically monobiotinylated in the hinge region via a disulfide bridge (Fab') (see *Experimental*). This results in formation of a layer structure (Fig. 3), in which the antigen-binding sites face the adjacent solution.

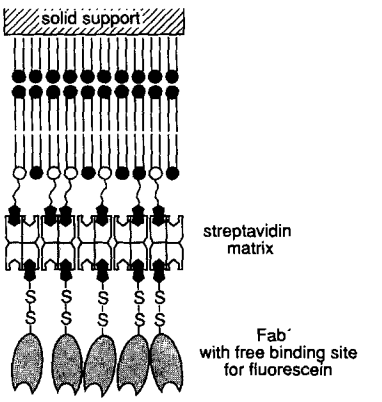

Fig. 3. Schematic representation of the docking of a Fab fragment which was specifically biotinylated in the hinge region to a two-dimensional streptavidin layer. The Fab' layer can serve as a matrix for further binding of fluorescein-containing molecules.

Figure 4 shows the course of the streptavidin interaction with time with a biotinlipid-containing membrane (5 mol-% of lipid **2** in DPPE) before and after addition of the Fab- and BioFab-fragments.

Binding of streptavidin (5×10^{-7} M) to the biotinlipids is very fast and the equilibrium frequency change of 65 Hz described above is reached after six minutes. The streptavidin covered membrane was rinsed with buffer, transferred into a fresh buffer solution and incubated with streptavidin a second time to see whether washing affects the coverage of the surface. No frequency change could be detected during this process, indicating that the streptavidin layer is tightly bound to the membrane surface. The surface was then washed as before and now incubated with non-biotinylated Fab (1.8×10^{-7} M). No significant frequency change was detected indicating no or only a negligible amount of nonspecific adsorption. Thereafter 3.5×10^{-8} M of biotinylated Fab was added to the buffer; this resulted in a slow but significant frequency change reaching saturation at 55 Hz relative to the original saturation frequency change (Fig. 4), pointing to a dense packing of the Fab molecules onto the streptavidin layer, as already shown with ellipsometry measurements at the air/water interface.[10]

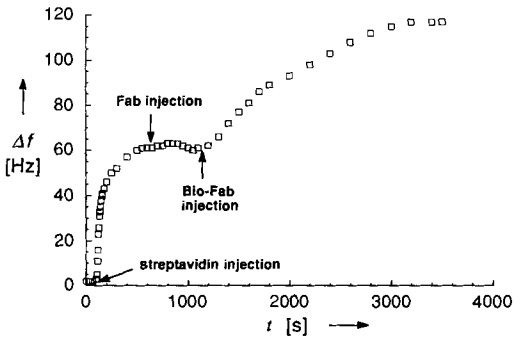

Fig. 4. Course of streptavidin binding with time to a lipid membrane containing 5 mol-% of lipid **2** and interaction of non-biotinylated antifluorescyl-Fab and biotinylated antifluorescyl-Fab with a streptavidin matrix.

It was interesting to see whether the same extent of binding could be attained using the site-specifically monobiotinylated Fab fragment. The results of these docking experiments are presented as a binding curve in Figure 5. This specific

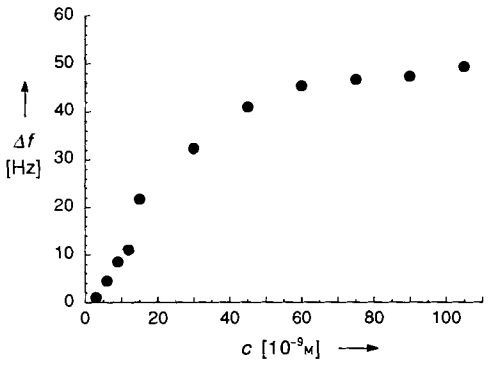

Fig. 5. Binding of a site-specifically monobiotinylated Fab fragment (Fab') to a streptavidin matrix as monitored with the QCM (each symbol represents averaged data of three independent measurements).

interaction leads to an increasing frequency change with increasing Fab' concentration, reaching again a saturation value of 50 Hz for a Fab' concentration of 1×10^{-7} M. As before, the control experiment with non-biotinylated Fab fragment resulted in no detectable frequency change (not shown).

In conclusion it has been shown that the QCM is able to differentiate between specific binding and nonspecific adsorption of streptavidin to different biotinlipid membranes. Employing this first streptavidin layer as a template, docking of monoclonal antibody Fab (biotinylated by two different methods) was followed using the QCM. In general, surface bound, highly organized protein matrices, having a vast variety of binding specificities, can be constructed using this method.

Experimental

The resonance frequency of the quartz crystal of the QCM is sensitive to the mass bound to the surface of the gold electrode, although in liquids the relation between adsorbed mass and frequency change may be quite complex [11]. In air, the frequency change expected from a quantity of adsorbed mass is given by the Sauerbrey equation [9]. Thus, in principle, the QCM technique allows one to quantify the binding process of proteins to various membranes. Furthermore, the course of the interaction with time can be followed in real time. The experimental setup used by us has already been described elsewhere [6]. The crystals used in the experiments had a resonance frequency of 9 MHz.

LB-deposition of the lipid membranes was performed at a speed of 1 cm/min and a surface pressure of 40 mN m^{-1} ($T = 22$ °C) from the solid analogous phase of the lipid monolayer. This resulted in a close packing and low lateral mobility of the lipids on the support. For the mixed membranes (DPPE/biotinlipid) adequate amounts of chloroform solutions of the corresponding lipids were mixed prior to spreading. For the measurements the crystal was immersed in buffer solution (50 mmol phosphate buffer, pH 7.5). The starting frequency (f_0) and the change in resonance frequency of the crystal ($\Delta f = f_0 - f(t)$) was monitored as a function of the protein concentration in the buffer solution.

The nonspecific biotinylation of the Fab fragment was performed with 6-(6-(biotinoyl)amino)-hexanoylamino)hexanoic acid succinimidyl ester (B-1606 Molecular Probes, Inc., Eugene, OR 97402, USA). The selective biotinylation of the Fab' fragment in the hinge region was achieved with *N*-(6-(biotinamidohexyl)-3-(2-pyridyldithio)propionamide (21341 Pierce, Rockford, IL 61105, USA) via formation of a disulfide bridge.

Biotinlipid **1** was synthesized as described earlier [12].

Biotinlipid **2** was synthesized in the following way [13]: 4 g (6.3 mmol) of *N,N*-dioctadecyldiglycolic acid monoamide (DODA-GSA) was refluxed with 1.1 g (6.8 mmol) of carbonyldiimidazole in 30 mL of dry THF for 2 h to yield the corresponding imidazole-active ester. The resulting solution was then added dropwise to a stirred solution of 8 g (54 mmol) of 1,8-diamino-3,6-dioxaoctane in 50 mL of dry THF. The reaction was monitored by TLC ($CHCl_3$/MeOH: 5/1). After completion (20 min), the solvent was evaporated off and the residue taken up in $CHCl_3$, extracted with water to remove the excess of diamine, and purified by chromatography to yield 2.8 g of 1-*N,N*-dioctadecyl-14-amino-5-oxo-3,9,12-trioxa-6-azatetradecanoic acid amide (DODA-EO_2-NH_2). 300 mg (0.39 mmol) of DODA-EO_2-NH_2 and 133 mg (0.39 mmol) of *N*-hydroxysuccinimidobiotin were dissolved in 10 mL of dry DMF and allowed to react at room temperature until no DODA-EO_2-NH_2 could be detected by TLC ($CHCl_3$/MeOH: 10/1). The solvent was removed by evaporation in vacuo; the residue was then taken up in $CHCl_3$ and purified by chromatography to yield 220 mg of pure **2**. Its structure was confirmed by elemental analysis and ^{1}H NMR spectroscopy (400 MHz).

[8] Since LB-transfer of the homogeneous lipid mixtures was performed in the solid condensed state of the monolayer at 40 mN/m the space required for one lipid molecule is approximately 40 Å^2. 5 mol-% biotinlipid content will thus result in approximately seven biotinlipid molecules on an area convered by two streptavidin molecules (5000 Å^2).
[9] G. Sauerbrey, *Z. Phys.* **1959**, *155*, 206. According to the Sauerbrey equation the change of resonance frequency of a piezo quarz crystal is proportional to the change in mass on the electrode surface. For the crystals used here, calibration revealed that a frequency change of 1 Hz corresponds to a mass increase of 1.05 ± 0.01 ng. The gold electrode has a diameter of 4.5 mm resulting in a sensitive area of 15.9 mm^2. A monolayer coverage with streptavidin (2500 Å^2 per molecule) should thus result in a frequency decrease of 63 Hz. But due to the electrode surface roughness this can only be a rough estimation.

A Remarkable Change in Framework Cation Positions upon Lithium Exchange: the Crystal Structure of $LiMnPO_4(OH)$

By *Miguel A. G. Aranda,* J. Paul Attfield* and *Sebastian Bruque*

In the search for new battery materials, molecular sieves, and ionic conductors and exchangers, reactions involving the insertion or exchange of lithium into the channels or interlamellar spaces of precursor structures are of great interest.[1, 2] We have recently reported the synthesis and structure of a new material, manganese(III) arsenate hydrate $MnAsO_4 \cdot H_2O$,[3] which undergoes a topotactic lithium exchange reaction with solid $LiNO_3$ to give $LiMnAsO_4(OH)$.[4] This reaction is accompanied by an unusual switch in the framework geometry as the Jahn-Teller distortions of the MnO_6 octahedra change although the topology is unaltered. In this communication we describe the analogous lithium exchange reaction of $MnPO_4 \cdot H_2O$ to give $LiMnPO_4(OH)$, which is accompanied by a different, remarkable change in the framework, as the Mn^{3+} cations are displaced to alternative octahedral sites within the $PO_4(OH)$ sublattice.

$LiMnPO_4(OH)$ was prepared in the form of a microcrystalline powder by solid-state reaction of $MnPO_4 \cdot H_2O$ with $LiNO_3$. The use of low temperatures and long reaction times furnished a sufficiently crystalline material for crystal structure determination from laboratory X-ray powder diffraction data to be successful (see *Experimental*). A restrained Rietveld[5] refinement of the $MnPO_5$ framework and the Li position was performed, and although the remaining H atom was not located, bond valence calculations[6] showed that it is attached to O(3), as are those in $MnPO_4 \cdot H_2O$[7] and $LiMnAsO_4(OH)$,[4] confirming the formulation as a phosphate hydroxide rather than as a hydrogen phosphate oxide.

Polyhedral[8] representations of the structures of $MnXO_4 \cdot H_2O$ (X = P, As), $LiMnAsO_4(OH)$ and $LiMnPO_4(OH)$ are shown in Figures 1a, 1b and 1c, respectively.

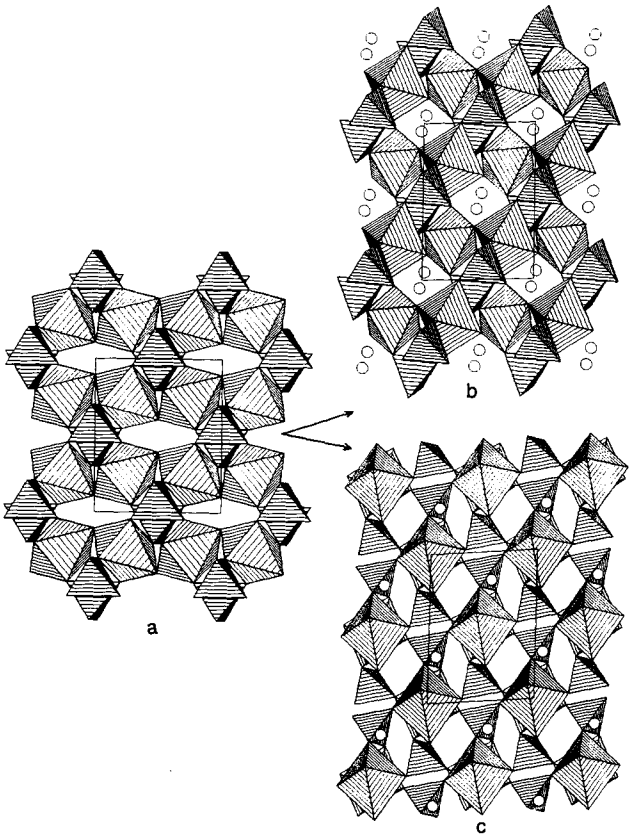

Fig. 1. Polyhedral near-(001) views (*b* axis vertical) of a) $MnXO_4 \cdot H_2O$ (X = P, As), b) $LiMnAsO_4(OH)$, and c) $LiMnPO_4(OH)$ with lithium atoms shown as open circles. Hydrogen atoms are not included.

In the first two structures, the MnO_6 octahedra are linked via opposite vertices by H_2O or OH^- groups to form infinite zigzag chains in the [101] direction that are interconnected by XO_4 tetrahedra, resulting in a three-dimensional framework. This encloses small channels parallel to the *c*-axis into which the hydrogen atoms project in $MnXO_4 \cdot H_2O$ (X = P, As), and in which the lithium ions are located in $LiMnAsO_4(OH)$. In the $LiMnPO_4(OH)$ structure, the MnO_6 octahedra are also linked through opposite vertices by OH^- groups to give infinite zigzag chains, but these now lie in the [001] direction. This structural rearrangement is due to a migration of the manganese atoms from the octahedral sites at 1/4 ,1/4 ,0 and related positions in $MnXO_4 \cdot H_2O$ to alternative octahedral holes in the channels at 0, 0, 0 and equivalent positions. Remarkably, this change in Mn positions results in little change to the cell parameters or the coordinates of the other atoms (Table 1). The two possible octahedral sites in the $MnXO_4 \cdot H_2O$ structure type are shown in Figure 2. The vacant sites in $LiMnPO_4(OH)$ are also connected to form channels in which the lithiums reside, but these run in a [101] direction rather than [001] in the starting material. This re-

[a] Sites that are equivalent in the monoclinic $MnXO_4 \cdot H_2O$ structures (X = P, As) are labeled (a) and (b). [b] *B* = isotropic temperature factor.

arrangement of the manganese sublattice results in only slight displacements and distortions of the phosphate groups (Table 1 and Fig. 1c).

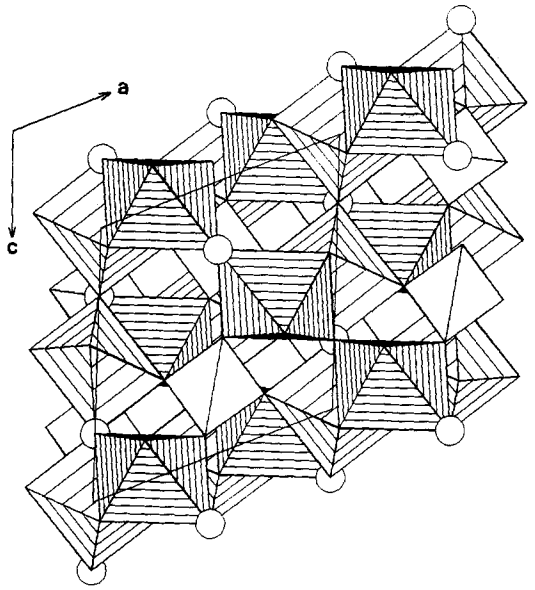

Fig. 2. A polyhedral (010) view showing the Mn sites occupied in the two different structures of $AMnPO_4(OH)$. The MnO_6 octahedra are shaded heavily/lightly for A = H/Li. The XO_4 tetrahedra are unshaded and the oxygens of the water molecules that link the octahedra into chains in both structures are shown as open circles.

Comparison of the bond distances in $MnPO_4 \cdot H_2O$ and $LiMnXO_4(OH)$ (X = P, As) (Table 2) shows a surprising change in the Jahn-Teller distortions of the MnO_6 octahedra that arise from the $t_{2g}^3 e_g^1$ electronic configuration of a high-spin Mn^{III} ion. In $MnPO_4 \cdot H_2O$, the manganese environment shows the well known [4 + 2] elongated tetragonal distortion with four short bonds to phosphate oxygens and two long bonds to the shared water molecules. The Mn atoms in $LiMnAsO_4(OH)$ are [2 + 2 + 2] coordinated with two short and two long Mn–OAs bonds plus two further intermediate Mn–OH bonds (Table 2) due to the previously reported switch in Jahn-Teller modes.[4] In $LiMnPO_4(OH)$, the distortions of the MnO_6 octahedra are intermediate between the [4 + 2] and the [2 + 2 + 2] types. The coordination geometries in the two lithium derivatives are remarkably similar considering that different Mn sites are occupied. In both cases, the Mn–OH bonds have shortened drastically from ca. 2.30 Å in the μ-aqua bridges to ca. 1.98 Å in the μ-hydroxo bridges in the two inequivalent $Mn(a)O_6$ and $Mn(b)O_6$ octahedra. This change decreases the Mn–Mn distance in the chains of octahedra from 3.976 and 4.048 Å in $MnXO_4 \cdot H_2O$ (X = P, As) to 3.561 and 3.636 Å in $LiMnXO_4(OH)$ (X = P, As). The Li^+ ions in $LiMnPO_4(OH)$ are irregularly coordinated in the channels parallel to the [101] direction, with contacts to five arsenate oxygen atoms and one hydroxy oxygen atom; the Li–Li distance is 3.14(3) Å.

Table 2. Mn–O distances [Å] in $MnPO_4 \cdot H_2O$ [7] and $LiMnXO_4(OH)$ (X = P, As [4])

$MnPO_4 \cdot H_2O$		$LiMnXO_4(OH)$	X = P	As
Mn-O(1)	1.886(3)	Mn(a)-O(1a)	2.142(5)	1.908(8)
		Mn(b)-O(1b)	2.292(5)	1.821(9)
Mn-O(2)	1.909(3)	Mn(a)-O(2b)	1.944(5)	2.104(9)
		Mn(b)-O(2a)	1.938(6)	2.168(9)
Mn-O(3)	2.284(3)	Mn(a)-O(3)	1.985(6)	1.966(11)
		Mn(b)-O(3)	1.978(6)	2.026(10)

The different structural changes produced for X = P and As when the $MnXO_4 \cdot H_2O$ compounds undergo lithium exchange under the same reaction conditions to give $LiMnXO_4(OH)$ reflect the size of the channels and differing flexibilities of the XO_4 groups in the starting materials. The arsenic compound, with wider channels, undergoes the exchange reaction without changes in the framework topology, although the switch in the Jahn-Teller modes due to the loss of H^+ from the framework strains the arsenate group.[4] Such strain cannot be tolerated by the phosphate analogue, and the exchange of H^+ for Li^+ is accompanied by a migration of the manganese atoms to a different set of octahedral holes that give a new framework topology, although with similar local coordination geometries, which can more easily accommodate the lithium ions.

Experimental

$MnPO_4 \cdot H_2O$ was synthesized hydrothermally as previously described[9]. An intimate mixture of solid $LiNO_3$ and $MnPO_4 \cdot H_2O$ in a 4:1 molar ratio was heated at 200 °C for 4 weeks in air, and the product was washed with dilute nitric acid and water and dried at 60 °C. Chemical analysis of the yellow-brown residue showed it to be $LiMnPO_4(OH)$. Mn, P, Li and H_2O were analyzed as described elsewhere[4, 10]. Obtained (and calculated for $LiMnPO_4(OH)$) results: Li:P and Mn:P ratios 0.95 (1.0) and 1.02 (1.0), respectively; Mn oxidation state + 3.1 (3.0), and H_2O content ≈5.4% (5.2%).

Structure Determination: X-ray powder diffraction data were collected for $LiMnPO_4(OH)$ (Siemens D501 automated diffractometer, θ–2θ geometry, flat-plate sample, graphite-monochromated $Cu_{K\alpha}$ radiation, $13 < 2\theta < 130$ °C (2θ), step size = 0.02°, counting time per point = 25 s).The pattern was indexed [11] on a *C*-centered triclinic cell similar to that of $LiMnAsO_4(OH)$ (see Table 1) [4]. However, all attempts to refine the crystal structure of $LiMnPO_4(OH)$ by the Rietveld method using the atomic coordinates of $LiMnAsO_4(OH)$ as starting model were unsuccessful. Therefore an ab initio structure solution was attempted with 81 structure factors obtained from a limited data range [$16 < 2\theta < 54°$] using Le Bail's method [12]. The Mn(a) and Mn(b) positions were derived from

a Patterson map and a difference Fourier map revealed the phosphorus position. A trial framework was then constructed from these heavy-atom coordinates and oxygen positions taken from the structure of $LiMnAsO_4(OH)$. Atomic positions, usual profile parameters and isotropic temperature factors were refined using the GSAS program [13] giving a good fit. A difference Fourier map revealed the lithium position, but the hydrogen position was not located. The final refinement with restraints in the P–O bonds (to maintain a reasonable PO_4 geometry) converged at $R_{wp} = 0.079$, $R_p = 0.062$ and $R_F = 0.053$. In this final refinement, the isotropic temperature factors of each type of atoms were constrained to have the same value to avoid correlations. Results of the refinement are given in Table 1. Further details of the crystal structure investigation may be obtained from Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CS-56 602, the names of the authors, and the journal citation.

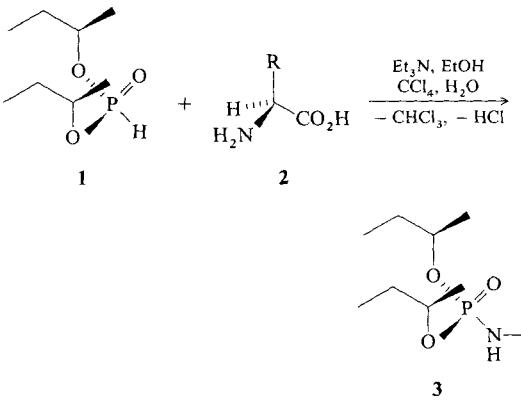
The ^{31}P-NMR Spectroscopic Determination of the Enantiomeric Excess of Unprotected Amino Acids**

By *Ron Hulst, N. Koen de Vries,* and *Ben L. Feringa**

The increasing use of natural and synthetic amino acids and their derivatives for the modification of proteins and as chiral building blocks or chiral ligands in numerous asymmetric syntheses[1] demands new methodologies for the fast and accurate determination of the enantiomeric excess (*ee*) of these compounds. The enantiomeric purity of amino acids is routinely analyzed by gas or liquid chromatography through the use of chiral stationary phases and various (in situ) derivatizing techniques.[2]. A number of methods exist for the determination of the enantiomeric excess of amino acid derivatives by NMR spectroscopy, employing chiral[3] or achiral[4] derivatizing agents. Similar methods for *free amino acids* are scarce, mainly due to the low solubility in organic solvents[5] or to the lack of proper chiral derivatizing agents. We now report a simple and efficient ^{31}P-NMR method for the determination of the enantiomeric excess of unprotected amino acids which is based on the use of phosphonate **1** as new chiral derivatizing agent.

The reagent **1** is readily prepared from (*S*)-2-butanol and PCl_3.[6] All amino acids examined thus far react with **1** quantitatively in a few hours at room temperature providing phosphonic amides **3**. The formation of diastereomeric phosphonic amides **3** is most conveniently carried out using aqueous ethanolic solutions of amino acids **2** and reagent **1** dissolved in CCl_4 employing triethylamine as base.[7]



It should be emphasized that aqueous solutions of the amino acids can be analyzed following this methodology and, in particular, by using **1** that no purification of the adducts **3** is necessary, thus allowing rapid *ee* determination. Typical results of the ^{31}P-NMR analyses are summarized in Table 1.

Table 1. ^{31}P-NMR data of the phosphonic amides **3** prepared from amino acids and from chiral amines and alcohols and **1**, recorded in C_6D_6 [a].

[**] We thank Dr. J. H. Kamphuis and Dr. B. Kaptein for the synthesis of the α-alkylated amino acids.

other hand, a singlet is observed in each case for the enantiomerically pure compounds **3**. Figure 1 shows the ^{31}P-NMR spectra of an amino acid at different *ee* values.

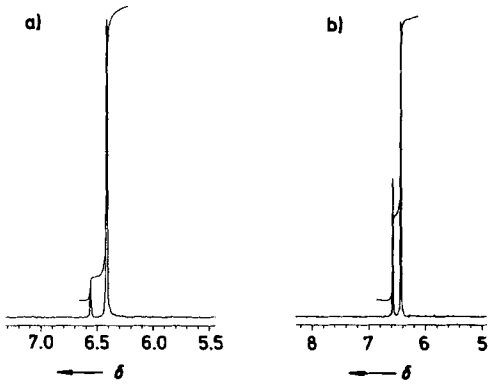

Fig. 1. Noise-decoupled ^{31}P-NMR spectrum of **3** (R = Me) in C_6D_6. a) 82% *ee*. b) 40% *ee* for the (*S*)-enantiomer of **2**.

Though diastereomeric peak separations have also been observed in the ^{1}H-NMR spectra the phosphorus–proton long range coupling gives rise to rather complex spectra.

Phosphonic amides **3** form stable complexes with water, alcohols, and ethyl acetate. After normal workup, 0.5 equivalents of H_2O are complexed which can be removed by heating at 60 °C under high vacuum. Removal of the complexed water results in nearly doubling of the chemical shift differences of the diastereomers of **3** (Table 1).

Some typical results of the *ee* determinations performed on partially enriched compounds are listed in Table 2 together with the *ee*'s determined by the known α-chloropropionyl chloride method[5] and by rotation measurements. These results clearly show that the enantiomeric purities obtained via the different methods are in excellent agreement and that no racemization or kinetic resolution occurs during phosphonic amide formation.

Table 2. Comparison of the *ee* values, those for samples with known enantiomeric composition determined ^{31}P-NMR spectroscopically by rotation [8], and by the α-chloropropionyl chloride method [5] [a].

Entry [b]	Ratio of enantiomers

1	76.40:23.60	76.35:23.65	76.40:23.60
2	73.45:26.55	74.10:25.90	74.10:25.90
15	70.80:29.20	70.10:29.90	70.50:29.50

[a] Estimated errors: ^{31}P-NMR 2%, polarimetry 3%, ^{1}H-NMR 2%. [b] Numbering of entries as in Table 1.

1 is not only suitable as derivatizing reagent for the determination of the enantiomeric excess of unprotected amino acids but can also be used in the case of α-alkylated amino acids (Table 1, entries 10–14), amino acid esters and amides, chiral amines, and alcohols. Typical examples are given in Table 1.

The new method has some unique features and several advantages over existing methods. To our knowledge this is the first ^{31}P-NMR method to be reported for the determination of the *ee* of free amino acids using facile in situ derivatization and broad solvent tolerance including aqueous solutions; the chiral derivatizing agent **1** is readily prepared, and excellent results are obtained with α-alkylated amino acids and their derivatives. Furthermore, the method compares favorably with currently available NMR techniques for amino acids in view of the large shift differences and the possibility of using phosphorus nuclei besides other nuclei.

Experimental

(*S,S*)-*O,O*-Di-*s*-butylphosphonate **1** was synthesized according to known literature procedures [6].

Synthesis of phosphonic amide **3**: A suspension of amino acid (1.0 mmol) in Et_3N (0.4 mL), H_2O (0.2 mL) and ethanol (0.5 mL) was cooled to 0 °C and treated dropwise with a solution of the phosphonate **1** (1.15 mmol) in CCl_4 (0.5 mL) and the mixture stirred at 20 °C for 2 h. The reaction was quenched by acidifying the mixture to pH 2 with 10% HCl solution. After extraction of the mixture with EtOAc (3 × 5 mL) the combined EtOAc phases were washed with water (5 mL) and dried (Na_2SO_4). The solvent was then removed by evaporation and the oily residue used as such for the *ee* determination. The phosphonic amides were purified by crystallization from EtOAc/petroleum ether or column chromatography on silica gel, providing white solids or oils.

With other substrates such as amino acid esters, the use of water as cosolvent may be omitted. When alcohols are used, addition of a catalytic amount of *N,N*-dimethylaminopyridine is recommended or alternatively the potassium alkoxides can be used.

The ^{31}P-{^{1}H}-NMR spectra were recorded on a Varian VXR 300 spectrometer operating at 121.42 MHz; the chemical shifts are given relative to those of $(NPCl_2)_3$ (δ = 19.91).

A Diels–Alder Route to [5]- and [6]-Helicenes**

By *Nikolaos D. Willmore, Longbin Liu*, and *Thomas J. Katz**

Before the discovery of the transformation in Scheme 1 (X = H),[1] the only easy route to carbocyclic helicenes was the photocylization of stilbenes,[2] a procedure that suffers two severe limitations: the solutions irradiated must be very dilute,[3] thus restricting the scale on which reactions can be performed, and functional groups that perturb or depopulate the reactive excited state must be absent.[4] The synthesis

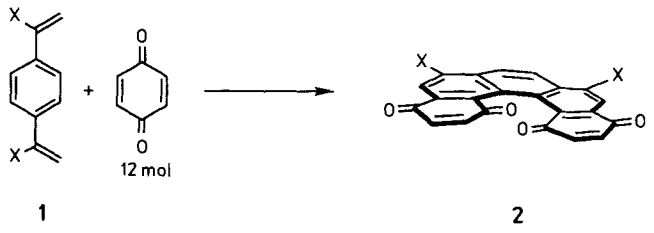
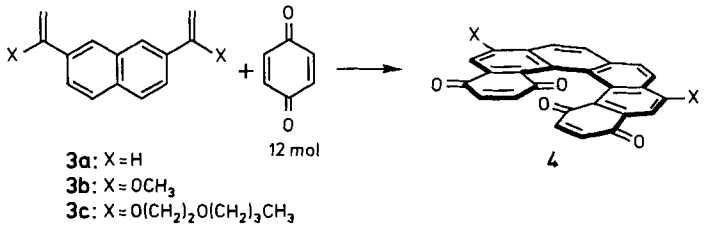
of [5]-helicenebis(quinone) **2** according to Scheme 1 is therefore noteworthy because it is very simple, proceeds without irradiation, and affords an interesting functionalized helicene from cheap reagents. The low yield (17%) is inconse



Scheme 1. Synthesis of [5]-helicenes. Reaction conditions: refluxing toluene containing an acidic or basic catalyst.

quential since large quantities of the product are prepared with little effort and little cost. The same cannot be said of the next higher homologue (Scheme 2), for the starting compound 2,7-divinylnaphthalene, unlike *p*-divinylbenzene, is not a cheap commercially available chemical. Its synthesis requires effort,[5] and the low yield of **4** (X = H), found here to be only 6%,[7] is in this case detrimental. We report herein how higher yields can be achieved.

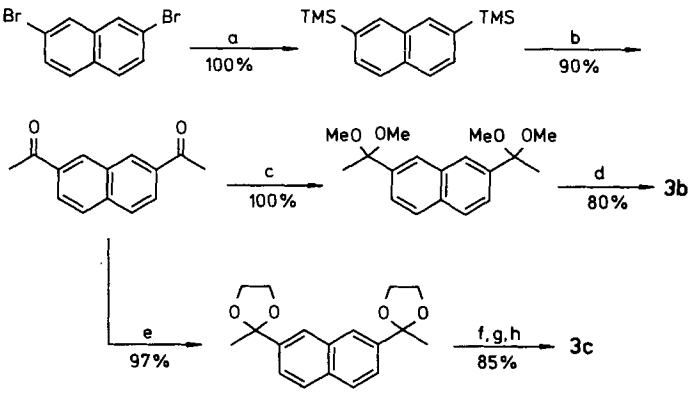


Scheme 2. Synthesis of [6]-helicenes.

This problem is solved by substituting the 1-positions of the vinyl groups in divinylarenes by alkoxyls. Thus, when, for example, X in Scheme 2 is OCH_3, the yield is 47%. When it is $O(CH_2)_2O(CH_2)_3CH_3$, the yield is 45%.[8] No other product is isolated. Accordingly, since bis(enol ethers) are easily synthesized, [6]-helicenes can be prepared in this way in very much larger quantities than by conventional photocyclization of bis(stilbenes). Similar principles apply to [5]-helicenes, the yield in Scheme 1 tripling (to 50%) when X is changed from H to $OC_{12}H_{25}$.[9]

The structures of **2** (X = $OC_{12}H_{25}$), **4b**, and **4c** were determined with the help of spectroscopic data.[10] Of the symmetrical structures for **4b** and **4c** required by the ^1H and ^{13}CNMR's, those with four linearly-fused rings are excluded by the proton spectra, which exhibit, at $\delta > 5$, two pairs of doublets and one singlet, not one pair of doublets and three singlets. For **2** (X = $OC_{12}H_{25}$) the structures with linearly and angularly fused rings are distinguished by the complexity of the resonances of the OCH_2 proton resonances, at *ca.* $\delta = 4.34$. They imply that the ring-system itself is chiral. Similar evidence, confirming structure **4c**, is the splitting of the analogous resonance signals into two clear sets ($\delta = 4.48$ and 4.56).

1 (X is $OC_{12}H_{25}$) was prepared from the corresponding ester and Tebbe's reagent,[11] and **3b** and **3c** according to the procedure shown in Scheme 3. Noteworthy are the syntheses of the enol ethers. While **3b** and **3c** could be made satisfactorily by treating the corresponding acetals with $(CH_3)_3SiOSO_2CF_3$ and $(iPr)_2NEt$ in CH_2Cl_2,[14] we found $(CH_3)_3SiCl$ superior to the silyl triflate because it costs 1/50th as much. The use of benzoic acid plus pyridine was modeled on a method of Newman et al.,[15] while the use of NaI and Et_3N was adopted from methods used to make silyl enol ethers.[16]



Scheme 3. Synthesis of **3b** and **3c**. Reagents and conditions: a) trimethylsilyl chloride (TMSCl) (3 mol), *n*BuLi (2.75 mol), THF (0.5 M), $-78 \rightarrow -20\,^{\circ}C$; b) $(CH_3CO)_2O$ (2.2 mol), $AlCl_3$ (4.4 mol), CH_2Cl_2, 0 °C [12]; c) $HC(OMe)_3$ (5.5 mol), MeOH (0.5 M), *p*-TsOH (0.1 mol); d) TMSCl (5.4 mol), $PhCO_2H$ (0.1 mol), pyridine (0.7 M), 65 °C, 1 h; e) $(HOCH_2)_2$ (3 mol), *p*-TsOH (0.1 mol), PhH (0.5 M), reflux; f) TMSCl (5.4 mol), NaI (5.4 mol), Et_3N (5.8 mol), CH_3CN (0.5 M), reflux; g) K_2CO_3 (1.6 mol), MeOH (0.25 M), ambient temperature; h) *n*BuBr (4 mol), KOH powder (8 mol), DMSO (0.5 M), ambient temperature, 1.5 h [13].

It is remarkable that of the styrene derivatives used during the past 65 years as diene components of Diels–Alder reactions,[17] only a single example seems to have been the enol ether of an acetophenone.[18, 19] Yet the reactivities of other styrenes are not comparably great. The beneficial effects of alkoxy substitution were seen to disappear when the substituents, instead of being on the double bonds, were on the benzene-rings.[20, 21] This implies that Diels–Alder reactions of acetophenone enol ethers could be especially useful in synthesis. Our findings described illustrate this by showing how the combination of such enol ethers with *p*-benzoquinone can be used to construct helicenes rapidly, on a large scale, without much effort, and in decent yields.

Experimental

4c: Benzoquinone (6.8 g, 63 mmol) and **3c** (2.0 g, 4.8 mmol) in toluene (49 mL) were stirred and refluxed for 48 h under nitrogen (not more than 1 atm). The residue, after removal of solvent, was boiled for one minute with 10% THF in benzene (ca. 100 mL), cooled to room temperature, and passed through a column of silica gel (∅ = 1 inch), using more 10% THF in benzene to wash the product through. Two flash chromatographic separations with this solvent and one with 10% ethyl acetate in benzene furnished 1.4 g (a 45% yield) of pure **4c**, a deep-red solid, m.p. 152–166 °C, soluble in many organic solvents.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Quanta. A Handbook of Concepts. 2nd Edition. By *P. W. Atkins*. Oxford University Press, Oxford, 1991. 434 pp., hardcover £ 50.00.—ISBN 0-19-855572-5; paperback £ 25.00.—ISBN 0-19-855573-3

The reader immediately becomes aware that this is no ordinary textbook when he or she looks for the list of contents and fails to find one. The concepts of quantum mechanics have been subdivided into a large number of easily digestible morsels, ranging in alphabetical order from "Ab initio", through "Frontier orbitals" and "Ligand field theory", to "Zero point energy". The lengths of the articles vary from a few lines (e.g., for "Rydberg level") to several pages (as for "Molecular orbital theory"). Mathematical formulas have been almost entirely excluded from the main text. Where formulas are really unavoidable, as when explaining the terms "Laplacian" and "Overlap integral", they are given in boxes distinguished by coloring. Atkins is well known for his clear didactic presentations and the excellent standard of illustrations in his textbooks, and here again one is not disappointed. The author has a remarkable ability to present complex situations using simple diagrammatic aids. Thus the fundamentals of quantum mechanics are explained mainly in a visual form, which is very appropriate for the chemist accustomed to the diagrammatic language of chemistry (see R. Hoffmann, P. Laszlo, *Angew. Chem.* **1991**, *103*, 1; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1). Cross-references to other articles in the book enable one to quickly read up all the material on a particular subject area. However, some familiarity with the basic language of quantum mechanics would be useful—though not essential—if one is not to lose one's way when searching for information on particular concepts. Finally, a comprehensive index provides a good means of access to the contents of the book.

The paragraphs headed "Further information" at the end of each article are very useful. Instead of a comprehensive bibliography, which can often be quite laborious to search, a short commentary is provided, giving references to material for further reading. This enables readers to search the literature in a way that suits their own level of knowledge.

In this second edition the small errors in the first have been largely eliminated. In the article "Alternant hydrocarbon" propene is wrongly given as an example instead of the allyl radical. The orbital diagrams in the article "Woodward-Hoffmann rules" seem confusing compared with the explanations given in other textbooks. However, the manner of presentation is, in the end, a matter of personal preference.

The standard of production is remarkably good for a book in this price bracket. In this respect it stands out from the flood of books that are poor value for money because the camera-ready texts vary in print quality and layout (a situation that must be blamed not on the authors but on the publishers). Two-color printing is used throughout, but the use of color for emphasis has been applied sparingly. Many of the figures are printed in the broad margin, which makes for an easily readable text and also invites browsing. The book is pleasing to handle and use, both with regard to its outward form and its content.

Although this book is, of course, not a substitute for a textbook on quantum mechanics, it can be strongly recommended as an aid to finding one's way around the field and as a reference manual to use in conjunction with other reading.

Chirality and Optical Activity in Organometallic Compounds. Edited by *V. I. Sokolov*. Gordon and Breach, New York, 1990. VIII, 145 pp., hardcover $ 110.00.—ISBN 2-88124-714-1

"Optically active compounds" and "chirality" are terms that were, until not very long ago, associated only with organic chemistry. Only gradually did it come to be appreciated that the principles of asymmetry could be carried over to organometallic compounds, if one surrounded a metal center with chiral organic ligands, or constructed it in such a way as to form a chiral center. The field then developed very rapidly and in many different directions. V. I. Solokov correctly recognized that there was a need for a systematic treatment of the stereochemistry of organometallic compounds. He has restricted his treatment to transition metals, a fact that is not obvious from the title.

The book is divided into four chapters. After an introduction to the basic concepts of chirality in organometallic compounds, a chapter by A. P. Klyagina establishes a relationship between optical activity and electronic structure, based on the theoretical analysis of circular dichroism (CD) spectra. The book concludes with a description of various structural types of chiral and optically active organometallic compounds and their applications in organic synthesis.

Although the theoretical treatment of CD spectra forms an important part of the book, it is a preliminary to the main core, centered on the description of classes of compounds in Chapter 3. It is undoubtedly difficult to make a representative selection from the great wealth of complexes that have a metal atom as a chiral center, but even so, the choice of examples here seems rather strange. Except for the classic example of $[CpMn(NO)(CO)PPh_3][PF_6]$, the opportunity to sketch the historical development of this field of chemistry has been missed, and that would certainly have been useful as an aid to understanding the subject. Instead of this the reader is expected to refer to an inappropriately large number of original papers. Important stereochemical reactions are introduced by means of examples, but tetragonal-pyramidal complexes are treated much too briefly and their intramolecular dynamics are not covered at all. In contrast, planar chiral complexes and chiral metal clusters are treated in great detail.

Applications to organic synthesis have been confined to stoichiometric reactions, which is appropriate since most asymmetric catalysts do not contain organometallic groups. However, at the end of the book is a list, covering 1 ½ pages, of reactions that are catalyzed asymmetrically by optically inactive organometallic compounds. Surely one could have done even better by starting from the phenomenon of optical induction in metal complexes with chiral centers (unfortunately not mentioned), and progressing from this to the transfer of chirality from the optically active ligand of an organometallic catalyst onto the coordination center, and thence to a state-of-the-art analysis of mechanistic studies. This is a case where less quantity would have meant better quality.

Despite these criticisms one should not overlook the fact that the book is a first attempt at a clear and up-to-date presentation of a very heterogeneous body of knowledge (the literature coverage extends up to 1989). The wealth of detailed information that it contains will make it a valuable resource for the specialist.

Joachim Wachter
Institut für Anorganische Chemie
der Universität Regensburg (FRG)

The Green Flame: Surviving Government Secrecy. By *A. Dequasie*. American Chemical Society, Washington, DC (USA), 1991. XII, 220 pp., hardcover $ 22.95.—ISBN 0-8412-1857-9

This is a most unusual and unconventional book that virtually defies categorization. The title refers to the bright green flame that occurs when pyrophoric boron hydrides ignite in air, as well as to the youthful, green naiveté of the scientists and engineers who worked with them, and the cover of the book is quite appropriately colored green. Yet if one is seeking the kind of chemical and technical information contained in such monographs as Alfred Stock's *Hydrides of Boron and Silicon* (Cornell University Press, 1933), William Gerrard's *The Organic Chemistry of Boron* (Academic Press, 1961), William N. Lipscomb's *Boron Hydrides* (W. A. Benjamin, 1963), or Herbert C. Brown's *Boranes in Organic Chemistry* (Cornell University Press, 1972), one will be disappointed. This is not a systematic treatise on boron hydrides, although some of the chemistry of these intriguing compounds is discussed, along with pertinent chemical equations. Rather it is the anecdotal, personal reminiscences of a sexagenarian recalling his activities and adventures as a young (23–29 years old) chemical engineer working from 1953 to 1960 for the U.S. Government on secret research to develop a boron-based jet and rocket super fuel for the Army's Project Hermes and Navy's Project Zip.

The writing career of the author, who received his B.S. in chemical engineering in 1950 from the University of Pittsburgh and who spent the period 1951–1953 as a writer in the U.S. Army Chemical Corps, is as unconventional as this, his third, book. Dequasie's previous books are *The Dragonslayers* (Carlton, 1972), a medieval satire, and *Thirsty* (Walker, 1983), a western novel. In 1983 he received the Medicine Pipe

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0808-1096 $ 3.50+.25/0

Award of the Western Writers of America, of which he is a member. His writing skills are evidenced by the entertaining and easygoing style of his latest book, which, despite the inclusion of many chemical engineering details, is readily accessible to the general reader.

The 13-chapter book begins with the author's acceptance of an assignment on a classified government project without knowing what the job was and having been misled as to where the work was to take place (he thought that he would be employed at Olin Mathieson's Niagara Falls plant, but instead he was assigned to the same company's boron fuels pilot plant at the Malta Rocket Test Station at Malta, New York). Dequasie managed pilot plants and assisted in the design of the first commercial plant until the project, which consumed about a billion dollars (as measured in 1990 dollars) in the construction alone for eight plants was abandoned on August 10, 1959, shortly before production was to begin in earnest. The project was terminated because of excessive costs but primarily because boric oxide, one of the combustion products of boron fuels, is a solid, which caused problems of erosion and deposits in the engines and produced less thrust than if the combustion product were a gas. This unsurmountable defect should have been recognized before the project was even begun.

The boron hydrides not only ignited spontaneously in air, but they possessed nerve-gas toxicity, making gas masks routine equipment for project workers. Boron hydride poisoning, nicknamed "the goodies", was also rumored to cause sterility or impotence. Furthermore, in combination with solvents and other substances, boranes were explosive, and eight persons were killed in explosions during the course of the project. Dequasie strikingly recounts these "hazards at every turn" and other chemical and engineering challenges along with quotidian problems such as testing valves, filling cylinders, changing vacuum pump oil, scaling up reactions, cleaning pots, and dealing with broken pipes, toxic exposures, shock waves, and the like. He also discusses at length after-hours activities such as snowball fights, pinochle and drinking parties, girl-chasing, dating, swimming, fishing, camping, canoeing, hiking, cooking, flying lessons, social clubs, ball games, explorer scout leadership, and bachelor life in general. In his own words, the book is "not a documentary about high-level administrative decisions [but]...the story of the project as lived by front-line, hands-on people." The 56 illustrations consist of snapshots of project workers, plant maps, documents, newspaper articles, scenery, buildings, equipment, airplanes, and even a groundhog. A 10-page (2 columns per page) index adds to the utility of the volume.

As those of us who have worked under government security clearance can testify, work on such projects carried out during the cold war era was complicated by the stringent secrecy imposed by concerns with national security. In keeping with the subtitle of his book, Dequasie fully considers these problems. He makes extensive use of hundreds of newspaper and technical magazine articles and recollections of his project colleagues to reinforce his own memories, and he uses recently declassified documents to, in his own words, "fill in things I had not known." He speculates on the possible existence of spies and sabotage but leaves the ultimate decision about these to the reader.

Although the boron hydrides were an expensive failure as aircraft fuels, this engaging story of the boron fuels project is much more than a history of chemical engineering or a secret government project. It vividly captures the life and vibrancy of an era. It can also serve as a cautionary tale, for Dequasie declares that "today's chemists, engineers, and budding scientists still in school should be aware of the lessons learned by our experience. This book is designed to help others to avoid repeating our mistakes."

George B. Kauffman

Band Theory of Solids. An Introduction from the Point of View of Symmetry. By *S. L. Altman*. Oxford Science Publications/Clarendon Press, Oxford, 1991. XIV, 286 pp., hardcover £ 37.50.—ISBN 0-19-855184-3

In this book S. L. Altman is concerned with the electronic properties of solids, with special reference to symmetry principles. In the preface the author explains that the book is intended partly for solid state physicists; however, he has also aimed to examine chemical aspects of solid state theory and to provide solid state chemists with an introduction to the field. Leaving aside the question of the appropriate readership, the author here offers a survey, written at a very advanced level, of symmetry aspects of the band structures of solids. For solid state physicists at least, the book provides an easier introduction to the subject than, for example, Ziman, Kittel, or Lax. However, the author is perhaps too optimistic in believing that it will find general acceptance among theoretical solid state chemists. In order to reach a quantitative understanding of the symmetry properties of solids and their band structures, it is essential to work through a textbook such as this one. However, in the opinion of this reviewer it is questionable whether chemists will accept this approach. It seems more probable that solid state chemists will look for an easier, qualitative, way into this field, and will be content to leave it at that. Even at this level one can find suitable review articles. Nevertheless, it is to be hoped that in future chemists will become increasingly involved in the area of solids, and will be prepared to acquire the necessary working knowledge.

Altman's book is divided into 14 chapters. At the end of each chapter there are exercise problems, the solutions to which are discussed in detail in the appendix. There are over 80 problems altogether, with a steadily increasing level of difficulty. Nearly all the chapters are well constructed from a learning standpoint, and they enable the reader to get to grips with a field that is by no means easy, and demands some ability to deal with abstract concepts.

Chapter 1 is easily understandable, and explains the basic principles of the model of free electrons in solids. The wave vector $\boldsymbol{k}$ is introduced, and the significance of the Fermi energy and Fermi surface is explained. The density of electronic states and energy bands are also discussed. Chapter 2 gives a very short introduction to the elements of group theory (19 pp.). Unfortunately this part of the book is too brief to meet the needs of an introductory text. The book would be more easily understood by readers who already have some knowledge of group theory. In the opinion of this reviewer, the very condensed introduction to group theory is the only negative aspect of the book. Chapter 3 deals with space groups, covering such important topics as the Bravais lattice and the definition of the Seitz operators for handling point symmetry and translational symmetry in solids. Chapters 4 and 5 then introduce reciprocal lattices, Brillouin zones, and the Bloch functions for solids. The derivation of energy bands from the Bloch functions is also explained. Chapter 6 returns to the theme of Chapter 3 with a discussion of ways of representing space groups. The effects of

 © *VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992* *0570-0833/92/0808-1097 $ 3.50+.25/0*

symmetry operations in a space group on the corresponding Bloch functions are discussed in detail. Some applications of this are then described in Chapter 7. Chapter 8 is concerned mainly with energy bands in metals, semiconductors, and insulators, and with how they are affected by the symmetry of the lattice. This general theme is continued in Chapter 9. Chapter 10 describes theoretical methods based on band structure. Regrettably, however, Altman does not go into detail regarding the more recent approaches that are of such great importance for solid state calculations; examples of these are linearized muffin-tin calculations and density functional methods, which in recent years have at last made it possible to handle systems of chemical interest. However, perhaps these topics are outside the scope of an introduction. The remaining four chapters deal with selected subject areas in the general field of condensed matter. Chapter 11 is mainly concerned with lattice vibrations and electrical conductivity, and also touches on electron–phonon coupling. Chapter 12 discusses instabilities and their dependence on characteristic solid-state properties such as dimensionality. Here Altman analyzes the physical causes of the so-called Peierls instabilities. The next chapter looks at analogies between band models and representations of the electronic wave-function in real space. The book ends with a review of surface states and localized defect states.

To summarize, S. L. Altman has here written a very good book on symmetry in solids. The material in the individual chapters is very concentrated, and considerable effort is needed to work through them. The main emphasis is on explaining group theoretical methods, rather than on covering the whole range of potential applications. From the chemistry standpoint, the book will only be of interest to specialists in solid state theory.

Cytochromes C. Evolutionary, Structural and Physicochemical Aspects. (Springer Series in Molecular Biology). By *G. R. Moore* and *G. W. Pettigrew*. Springer, Berlin, 1990. XVI, 478 pp., hardcover DM 168.00.—ISBN 3-540-50852-X

The book reviewed here is the second monograph written by Moore and Pettigrew on the subject of cytochromes C. The first one, "Cytochromes C. Biological Aspects", was published in 1987 in the same series. Although cytochrome C is only one of many hemoproteins of importance in energy metabolism, it serves here as an example for describing the many different physical methods used to analyze structure and function of hemoproteins. The physicochemical fundamentals of hemoprotein structures and the spectroscopic methods used to determine them, such as NMR, EPR, CD, MCD, fluorescence, phosphorescence, Mössbauer and X-ray spectroscopies, are all described in great detail. Examples of actual results are discussed and summarized in the form of tables. A further chapter lists all the known amino-acid sequences of cytochrome C variants. The molecular geometries and crystal structures are treated in great detail, including variants in which the central atom is changed or the amino-acids are modified. The chapter on evolution includes detailed discussions of the problems of phylogenetic trees, the molecular clock, and the theory of random genetic drift, as well as questions such as that of genus and species in bacteria, or the theory of endosymbionts to explain the formation of mitochondria and chloroplasts. A further chapter deals with the redox potentials of cytochromes C, and here too the explanation of the physicochemical fundamentals is thorough and lucid. The final chapter gives a very detailed and thorough treatment of the question of electron transfer mechanisms.

The authors have shown a commendable awareness of the need to relate the large amount of published work on cytochrome C to the basic physicochemical principles, and to summarize the findings in useful generalizations. The book is intended primarily for specialists, but also provides the less experienced student with the basic knowledge needed to embark on the study of hemoproteins. Consequently it will still remain an up-to-date work of reference ten years hence. The book is indispensable for the libraries of biophysics departments and those engaged in research on energy metabolism.

Nucleoside Synthesis. Organosilicon Methods. (Ellis Horwood Series in Organic Chemistry.) By *E. Lukevics* and *A. Zablocka*. Ellis Horwood, New York, 1991. 496 pp., hardcover $ 221.95.—ISBN 0-13-812652-6

The chemistry of nucleosides, nucleotides, and nucleic acids is currently a rapidly growing area of research. It soon became clear from studies of the structure and biological function of these natural products that synthetically modified species would have an enormous biological potential. Synthetic analogues of nucleosides, nucleotides, and nucleic acids are nowadays used as antimetabolites in biochemistry and medicine. Examples are antiviral agents such as the nucleoside analogues 3′-azidothymidine (AZT, which has anti-HIV activity) and acyclovir (with anti-Herpes-simplex activity), the antitumor agent 5-fluoridine, and the use of "antisense-RNA" and "antisense-DNA" as gene blockers. Since biologically active nucleoside analogues are now so widely used, methods for synthesizing them are of great importance.

One approach is by chemical modification, using a naturally occurring nucleoside as a precursor. However, the scope for introducing such modifications is rather limited, owing to the lability of the β-glycosidic linkage that is already present. Another method is to build up the aromatic heterocycle by using an *N*-glycosylated derivative as a precursor, but this method can only be considered in special cases because of the considerable amount of synthetic work required. The most important method, and the one that allows most scope for modifications, is the glycosylation of the aglycone component using an appropriate carbohydrate derivative. A special variant of this is the silyl method, in which the glycosylation is carried out using a silylated heterocycle, and this method is the subject of the book reviewed here. The first part of the book is devoted to a thorough discussion of the synthetic aspects, and the second part contains a survey, in the form of tables, of glycosylations that have so far been carried out using a silylated heterocycle (2549 examples in all!). The book is completed by indexes listing the heterocycles and carbohydrate derivatives that are covered, and a bibliography containing 1056 references.

The first part is divided into six chapters. The first of these gives a brief summary of the conventional methods of nucleoside synthesis, including the Hilbert–Johnson method, the Fischer–Helferich method, and the fusion and nitromethane methods. Transglycosylation reactions are also briefly discussed. Surprisingly, however, there is no mention of another modern method whereby the glycosidic linkage is formed from the aromatic heterocycle and the carbohydrate component by a phase transfer reaction in the presence of a base; this is one of the few methods that does not require the use of metal halides as catalysts, which is a crucially important advantage for analogues that are to be used in biological systems. The yields are no worse than with the silyl method. Chapter 1 ends with some examples of nucleoside syntheses in which the heterocycle is built up from *N*-glycosylated carbohydrates. Chapter 2 introduces the method using glycosylation of silylated heterocyclic arenes. First the reagents used for the silylation of the heterocycle are described, followed by a detailed discussion of the possible reaction mechanisms. From this it quickly becomes apparent that the method is closely related to the Hilbert–Johnson method. The mechanisms are also considered from the standpoint of reactions using carbohydrate derivatives (halogenoses on p. 32, and 1-*O*-acyloxy- and 1-*O*-alkyloxy sugars on p. 39). The influences of solvent and of catalyst (e.g., $AlCl_3$, $TiCl_4$, $SnCl_4$, or trimethylsilyltriflate, p. 41) are discussed, as also are the effects of substituents in the heterocycle with regard to the α/β anomer ratio of the glycosidic linkage and the reaction yield. The advantages of the silyl method compared with the conventional glycosylation methods are also explained. Chapter 3 describes various syntheses that lead to modified pyrimidine nucleosides and their aza and deaza analogues, and discusses the factors influencing them. Chapter 4 then gives corresponding data for nucleosides formed from bicyclic heteroarenes, and also deals with the purine nucleosides and their *N*-isomers. Chapter 5 contains a detailed description of nucleosides derived from other heterocyclic bases. These latter three chapters use selected examples to discuss all the factors that influence the course of the reaction. For example, pages 58 and 59 summarize, in the form of text and tables, data on the reaction of a β-D-glucopyranosyl bromide with 2,4-bis(trimethylsilyl)thymine under nine different sets of reaction conditions. Also reactions performed by the silyl method are frequently compared with the conventional methods (e.g., on p. 59). In the glycosylation of bicyclic *N*-heteroarenes (Chapters 4 and 5) one is interested in controlling not only the anomeric configuration but also the regioselectivity in relation to the nitrogen atom of the heterocycle. Ways of achieving this are described using various examples (e.g., p. 174). Chapter 6 adds a brief discussion of methods for synthesizing nucleotides.

I feel that the usefulness of the book could have been improved by a clearer subdivision of the material. It would have been desirable to make a clear distinction between nucleosides containing only a pyrimidine ring and those containing only a purine ring, and to have one chapter dealing with aza, deaza, and *N*-isomeric analogues of pyrimidine and purine nucleosides (see Sections 3.8 and 3.9, and Sections 4.2 to 4.8), together with nucleoside analogues derived from other heterocyclic bases.

The authors have succeeded in their aim of presenting an overview of this variant of the glycosylation method, which has now come very much into favor because it is easy to carry out. This easily readable and well illustrated book is a worthwhile purchase for everyone concerned with the synthesis of nucleoside analogues, as it contains a useful and remarkably comprehensive collection of data on the silyl method. Regrettably, however, the astronomically high price will mean that it reaches only a limited readership.

Chris Meier
Institut für Organische Chemie
der Universität Frankfurt am Main (FRG)

Essential Molecular Biology. A Practical Approach. Vols. 1 and 2. (The Practical Approach Series.) Edited by *T. A. Brown*. IRL Press at Oxford University Press, Oxford, 1991. Vol. 1: XIX, 299 pp., paperback £ 22.50.—ISBN 0-19-963111-7; Vol. 2: XX, 296 pp., paperback £ 22.50.—ISBN 0-19-963113-1

The rapid advances that have occurred in the techniques of molecular biology during the last decade have brought about a quantum leap in virtually every biologically-orientated area of research, especially since the basic techniques of cloning can, in principle, be mastered by anyone. Consequently, there is now a wide and growing demand for introductory textbooks on molecular biological methods that are experimentally orientated and easily understandable. Alongside "Maniatis", the excellently written and well-proven standard work in this field, a crop of new textbooks and manuals is now springing up like mushrooms. The continuing rapid pace of progress, which is also apparent from the growing number of new or modified reagents and techniques, means that these publications will soon become outdated.

In the two volumes reviewed here, which belong to the successful "Practical Approach" series on modern techniques of bioscience, the editor offers another introduction to practical methods in molecular biology, aimed at beginners and non-specialists. Volume 1 ("Molecular Cloning") explains the underlying principles and the basic techniques needed for carrying out experiments on DNA cloning. These include microbiological techniques for handling bacteria and phages, methods for purifying DNA and RNA, analytical and preparative methods for electrophoretic separation of nucleic acids, and procedures for generating, transforming, and selecting recombinant DNA using suitable combinations of cloning vectors and host bacteria. Building on this groundwork, Volume 2 ("Recombinant DNA") gives a comprehensive description of the relevant procedures for genome analysis. After describing the preparation of gene banks in lambda and cosmid vectors or in the form of cDNA, an account is given of the techniques commonly used for investigating the structure of a cloned gene; these include identification by labeling, immobilization, and hybridization of the nucleic acid, multiplication by means of the polymerase chain reaction (PCR), and DNA sequencing by the didesoxy method. Lastly the volume explains procedures for investigating the cellular expression by DNA–protein interactions or RNA transcript analysis.

The background knowledge and practical advice on experimental procedures is generally presented in such a straightforward and detailed way that even lay readers will understand the basis of the techniques, what they aim to achieve, and how they can be adapted to design appropriate experiments for individual scientific problems. Also in many cases the reader is referred to more advanced or specialized techniques. Finally, the beginner will benefit from the valuable expert advice regarding the most suitable materials to work with, and especially from the detailed troubleshooting guidance, since locating potential sources of error often presents difficulties for the inexperienced. Each chapter concludes

with a detailed and well-balanced list of references to more advanced literature.

Apart from the variations in level of treatment and amount of detail that are usual in a multi-author work, the presentation of the subject matter is commendably thorough. Also, from 1991 the volumes in this series have changed their appearance: the layout has been considerably altered to provide a better subdivision of the material and improved clarity. Important statements in the text are shown with emphasis. Experimental procedures are clearly separated from the rest of the text; each includes a list of the materials and reagents needed, safety precautions, cross-references to other related procedures in the same volume, and useful hints regarding special circumstances.

The appendices include a list of some important *E. coli* host strains, culture and buffer media, DNA- and RNA-modifying enzymes, restriction patterns for individual vectors, and addresses of commercial suppliers (although these do not always include those of the parent companies). The appendix listing the various safety points connected with work in molecular biology is *far* too brief to be useful. In contrast to this, there is an excellent appendix containing general information on essential laboratory equipment; this will be especially valuable in helping those who must first decide whether or not their research environment is adequate to allow experimental work in molecular biology.

A picture tells more than a thousand words—this old saying applies especially to "do-it-yourself" introductions aimed at a general readership. Comparing these two volumes with the standard that has been set by "Maniatis" reveals their only serious weakness, namely that figures and sketches are rather infrequent. For example, a reaction sequence involving a steplike or flush scission of DNA is conveyed so much more clearly and succinctly by a small reaction scheme diagram than by a description in words alone, even when the latter uses very descriptive technical terms such as "sticky end" and "blunt end"!

To summarize, these volumes live up to their claim that the reader with no previous experience is led step by step, by means of easily understandable introductory explanations and exact detailed descriptions, into a fascinating new world of experimentation. At this affordable price, therefore, Volume 1 can be recommended for both students and teachers as an accompaniment to a technique-orientated practical course (subject to the reservation mentioned above regarding the scanty provision of diagrams). The two-volume set is recommended for everyone who wishes to become familiar with the experimental methods of recombinant DNA work—and who finds "Maniatis" too expensive or too unwieldy.

Synthetic Approaches toward Molecular and Polymeric Carbon Allotropes

By François Diederich* and Yves Rubin

Life on earth is based on compounds that have carbon frames and backbones. Today, chemists have added to the world of biomolecules and biopolymers approximately 10^7 different synthetic molecules and polymers, the structures of which also depend on the formation of strong, stable carbon–carbon bonds. Although the stability of carbon–carbon bonds has been recognized for more than a century, the two natural modifications graphite and diamond were, until recently, the only allotropic forms of carbon on earth that were available in macroscopic quantities and were structurally well characterized. With the synthesis of macroscopic quantities of buckminsterfullerene (C_{60}) and the higher fullerenes (C_{70}, C_{76}, C_{78}, etc.) and the exploration of the fascinating properties of these all-carbon spheres, this situation has completely changed. In the coming decades, the design, preparation, and study of novel molecular and polymeric allotropic forms of carbon will be a central topic in chemistry. Research in this area will dramatically advance the fundamental knowledge on carbon-based matter and, as already illustrated by the ongoing work on C_{60}, generate unprecedented technological perspectives. This review surveys synthetic organic-chemical approaches toward the preparation and study of all-carbon molecules and polymers that differ from the familiar networks of graphite and diamond as well as from the fullerenes. We will also discuss the ongoing research on fullerenes with a particular focus on the synthetic approaches to these all-carbon spheres and their transition metal complexes.

1. Introduction

Until recently, graphite and diamond were the only two structurally well characterized carbon allotropes available in macroscopic quantities (Scheme 1). The technological importance of these networks is enormous.[1] Graphite is used as a solid lubricant, in pencils, as a moderator in nuclear reactors, and, most importantly, as a reinforcement material in carbon fiber composites.[2] Diamond is mostly known for its hardness and its high refractive index. It is used in the jewelry industry and in drilling heads for the extraction of crude oil. More recently, diamond thin films have attracted great interest for use in electronic devices and in protective coating of tools and materials.[3, 4] A whole variety of other, yet unprepared all-carbon network polymers have been predicted to exhibit interesting material properties. This was a

strong incentive for us to initiate a research program for the synthesis of novel molecular and polymeric forms of carbon.[5-7]

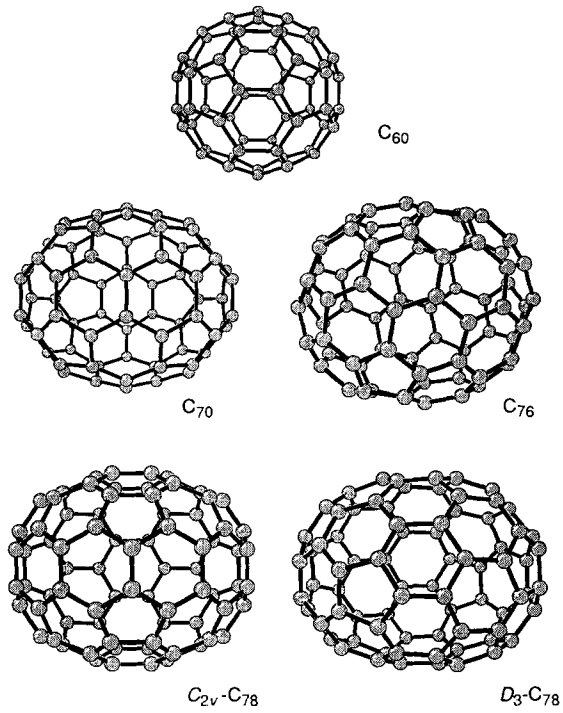
Additional interest in the structures and properties of new carbon allotropes is derived from their potential relevance to combustion processes and soot formation.[8, 9] Also, all-carbon molecules are believed to be present in carbon-rich stars and interstellar dust and, therefore, have been of tremendous interest to astronomers and astrophysicists during the past two decades.[10, 11] Whereas carbon is the fourteenth most abundant element on earth, it has the sixth highest abundance in the cosmos.[12] It is therefore not so surprising that the first preparation of macroscopic quantities of C_{60}, the third allotropic form of carbon, was been reported by a team of astronomers led by Wolfgang Krätschmer and Donald Huffman (see Scheme 2).[13] In 1990, these researchers reported the isolation of C_{60} from soot produced by resistive heating of graphite under an inert atmosphere. The now well-established cagelike structure of C_{60} with the shape of a truncated icosahedron had been predicted in 1985 by Kroto, Smalley, et al. at Rice University to account for the exceptional stability of the C_{60} species in carbon cluster beams produced by the laser vaporization of graphite.[14] In honor of Buckminster Fuller, the American architect renowned for his geodesic domes, these researchers gave the name "buckminsterfullerene" to C_{60}. Although other scientists had previously predicted that C_{60} would be a stable, soccerball-shaped molecule,[5, 15] it was only after the 1985 communication by the group at Rice University that a broad range of chemists and physicists became interested in theoretical calculations to predict the structure and properties of buckminsterfullerene.[11, 16-18] The predicted IR spectrum[19] for C_{60} proved to be crucial to its discovery. When Krätschmer et al. recorded the IR spectrum of their soot, they detected four distinct absorptions at 1429, 1183, 577, and 528 cm^{-1} superimposed on a broad background absorption.[20] A comparison with the frequencies that had been previously calculated for C_{60} (1600 ± 200, 1300 ± 200, 630 ± 100, and $500 \pm 50\ cm^{-1}$) showed that the soot contained significant amounts of this carbon sphere.

Prior to the landmark study on C_{60} by the group at Rice University, experiments in 1984 at Exxon Research Laboratories on the abundances of carbon clusters generated by the laser vaporization of graphite provided the surprising observation that only even-numbered clusters were present in the C_{40} to C_{200} ion range.[21] Kroto, Smalley, et al. explained the abundance of these even-numbered species in 1985 by evoking the formation of an entire family of carbon cages containing a central cavity called the fullerenes.[22] They defined fullerenes as all-carbon molecules with the composition C_{20+2m}, which take the form of hollow closed nets composed of twelve pentagons and m hexagons. The ellipsoidal fullerene C_{70}, initially reported by the Rice University group as the second most prominent carbon cluster besides C_{60},[14] was also found by Krätschmer, Huffman, et al.[13] as the second most abundant carbon cage in their soot. A series of other higher fullerenes have now been isolated and characterized either in pure form[23, 24] or as mixtures.[25, 26] Diederich, Whetten, et al. characterized in pure form the next higher members of the fullerene family beyond C_{60} and C_{70}—the chiral D_2-symmetric molecule C_{76}[23] and the isomeric C_{2v}-C_{78} and D_3-C_{78} molecules (Scheme 2)—and determined their structures by ^{13}C NMR spectroscopy.[24] The ongoing fullerene research has recently been the subject of a

François Diederich was born in Ettelbruck in the Grand-Duchy of Luxembourg on July 9, 1952. He studied chemistry at the University of Heidelberg and obtained his Diplom in 1977 and his doctoral degree in 1979 for work with Heinz A. Staab. After postdoctoral research with Orville L. Chapman at the University of California at Los Angeles from 1979 to 1981, he became a research associate at the Max-Planck-Institut für medizinische Forschung in Heidelberg. Following his Habilitation at the University of Heidelberg in 1985, he joined the faculty at UCLA where he advanced in 1989 to full professor of organic chemistry. Since April 1992, he has been a professor of organic chemistry at the ETH Zürich. He is a recipient of the Otto-Hahn-Medaille of the Max-Planck-Gesellschaft, the Camille Dreyfus Teacher-Scholar Award, and the Arthur C. Cope Scholar Award of the American Chemical Society. His research interests are the chemistry of all-carbon molecules and network polymers, molecular recognition, and the general area of supramolecular chemistry.

Yves Rubin was born on March 9, 1963 in Yverdon, Switzerland. He received his Diplom in chemistry in 1987 from the University of Fribourg with Albert Gossauer and Alexander von Zelewski as thesis advisors. From 1987 to 1991, he was a doctoral student with François Diederich at UCLA, working on syntheses of all-carbon molecules and networks and on the isolation and characterization of fullerenes C_{60}, C_{70}, and C_{84}. After receiving his Ph.D. degree, he became a postdoctoral fellow with Ronald Breslow at Columbia University, working on the development of organic ferromagnets. He won the Saul Winstein Dissertation Award at UCLA and was awarded a postdoctoral fellowship from the Schweizerischen Nationalfonds zur Förderung der wissenschaftlichen Forschung. Since July 1992, he has been an assistant professor of organic chemistry at UCLA and recently received a Dreyfus New Faculty Award. His research interests include the total synthesis of C_{60} and functionalized derivatives and the preparation and study of organic materials.

number of reviews.[11, 16–18] We take a different approach in this article, summarizing synthetic approaches to C_{60} and surveying fullerene transition metal complexes as part of a general chapter on transition metal complexes of all-carbon molecules.

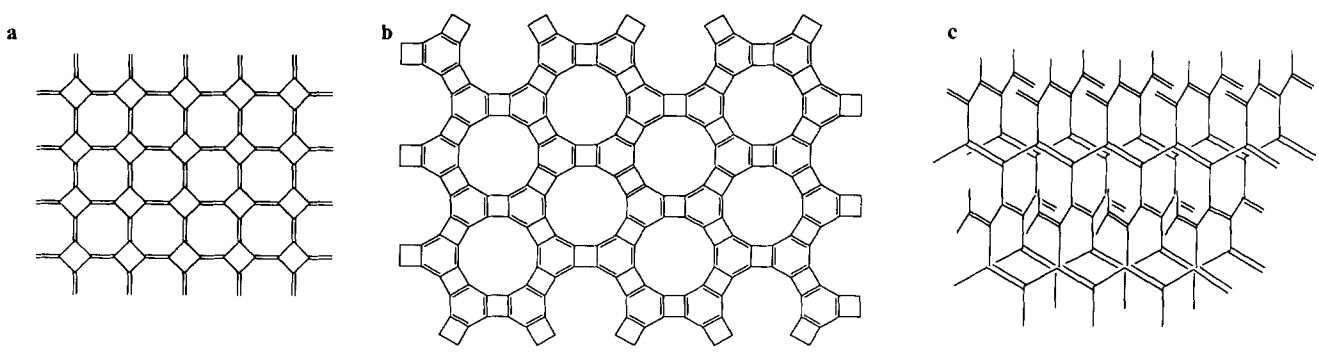


Scheme 2. Molecular structures of the five fullerenes isolated in pure form.

Long before the discovery of C_{60} and the subsequent development of fullerene chemistry, the assembly of carbon atoms into all-carbon molecules and polymers had already been the subject of a large body of experimental and theoretical work. In 1942, Hahn, Strassmann, et al. detected by mass spectrometry the formation of carbon ions from C_1^+ to C_{15}^+ in the vapor obtained by electrical discharge between graphite electrodes.[27] Subsequent mass spectrometric analyses led to the discovery of even larger carbon ions ranging up to C_{21}^+.[28] With the advent of laser vaporization techniques in the early 1980s, all-carbon molecules and ions became the subject of intensive experimental and theoretical studies.[29–33] Molecules and ions of sizes ranging from C_2 to $> C_{600}$ have been detected in the supersonic beams produced by the laser vaporization of graphite[21] and other carbon-rich materials,[34] and a variety of theoretical investigations have been useful in assigning structures to these species. Ion cyclotron resonance experiments have been particularly valuable for generating mass-selected ion beams of significant lifetime, allowing the study of both physical and chemical properties of these ions. Alternatively, the spectral properties of some of the smaller carbon ions produced by the vaporization of graphite or the photolysis of acetylene have been studied in low-temperature matrices. A comprehensive review of the gas-phase and matrix studies on carbon molecules and ions until April 1989 has been provided by Weltner and Van Zee.[29] For the smaller molecules C_2 through C_9,[35] linear chain structures, and for compounds as small as C_3, cyclic structures also have been discussed.[36] The consensus among the theoreticians is that the larger molecules C_{10} through C_{29} should have monocyclic structures, and experimental results could be interpreted consistently with these hypothesized structures.[37] Special stability was predicted by Roald Hoffmann in Extended Hückel calculations for the neutral cycles with $[4n + 2]$ atoms that are aromatic closed-shell systems, such as C_{14}, C_{18}, and C_{22}.[38] Carbon molecules in the range from C_{30} to C_{40} are, by comparison, very reactive.[39] Above C_{40}, fullerene structures become abundant.[40]

A variety of imaginative and practical, as well as impractical, structures can be found in the literature for two-dimensional (2-D) and three-dimensional (3-D) all-carbon networks that differ from graphite and diamond. As early as 1946 in a work on amorphous carbon and carbon combustion, Riley[8, 41] proposed a new 3-D network composed of interconnecting hexaphenylbenzene subunits. A variety of interesting 2-D nets were proposed in 1968 by Balaban et al.[42] Scheme 3 shows two of these interesting structures which, in more recent work by the same author,[12] were complemented with other 2-D and 3-D all-carbon structures. Carbon networks have also been of particular interest to Hoffmann et al.[7, 43] Scheme 3c shows their proposed three-dimensional, possibly metallic net in which infinite polyene chains run along two dimensions with no conjugation in the third dimension.[44, 45]

The most significant early efforts towards the synthesis of all-carbon molecules were initiated in 1981 by Orville Chapman at the University of California, Los Angeles (UCLA). At that time, Chapman was convinced of the high stability of the soccerball structure for C_{60}.[46] These efforts, which extended between 1981 and 1990, are documented in four



Scheme 3. Representative 2-D (a,b) and 3-D (c) carbon networks. Networks a and b were suggested by Balaban et al. [42], network c by Hoffmann et al. [43].

UCLA Ph.D. theses, and some of the synthetic approaches are discussed below. In 1986, Diederich et al. started a research program exploring the preparation of new carbon allotropes different from the fullerene structures through rational chemical synthesis.[47] This review article gives an overview of the progress in these studies directed to the synthesis of all-carbon rods, rings, nets, and spheres.

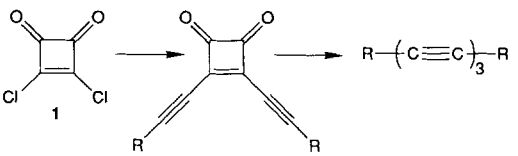
2. Polyynes as Precursors to Molecular Carbon Rods

An intriguing aspect of carbon chemistry is the preparation of infinite one-dimensional rods constituted of alkyne units (Scheme 4).[30c] Such infinite linear polyynes, which

Scheme 4. Infinite one-dimensional polyyne.

have been called "carbyne" or "chaoite",[48,49] are expected to be one-dimensional conductors, and calculations predict an unusual variety of soliton and polaron states.[50] Reports on their preparation are controversial: materials obtained by oxidative polycondensation of acetylenes, dehydrochlorination of polyvinylidene chloride $(CHCl)_x$,[51] or contact heating of pyrolytic graphite at temperatures of 2700–3000 K led only to ill-defined materials with poorly reproducible structural characteristics.[48,52] The stability of carbyne, which is predicted to prefer the acetylenic form $\cdot C-(C\equiv C)_n-C\cdot$ over the cumulenic form $:C=(C=C)_n=C:$,[50] should be substantially affected by chain-to-chain polymerizations, for example Diels–Alder-type cyclizations or $[n+m]$ cycloadditions between cumulene units.[53]

Materials approaching carbyne are the extended linear polyynes incorporating up to 16 conjugated acetylene units prepared by Walton et al.[54] Whereas stable solutions of $H(C\equiv C)_{12}H$ could still be obtained by deprotection of the corresponding bis(triethylsilyl) derivative, the longer polyynes were only stable when protected with two bulky Et_3Si end-groups. When we became interested in a systematic synthetic approach towards linear polyynes $X-(C\equiv C)_x-Y$ with thermally or photochemically removable end-groups X and Y for the generation of unsubstituted C_x species, we found that there were very few procedures for the preparation of such oligomers.[55,56] Long-chain polyynes were usually constructed in tedious stepwise procedures by multiple Cadiot–Chodkiewicz,[57] Eglinton–Glaser,[58] or Hay[59] coupling reactions starting from terminal mono- or diynes. No convenient general method for the preparation of linear polyynes with an odd number of C≡C bonds existed. Therefore, we developed a general method for the preparation of symmetrically and unsymmetrically substituted polyynes starting from readily available 3,4-dichloro-3-cyclobutene-1,2-dione (**1**).[60] As shown in Scheme 5, the new synthetic sequence makes use of the acetylene synthon, 3-cyclobutene-1,2-dione, which readily loses its two carbonyl groups in pyrolytic or photolytic reactions.[61–63]



Scheme 5. Synthesis of polyynes with an odd number of C≡C bonds.

Despite the extensive amount of work reported on squaric acid and its derivatives,[61,64,65] no 3,4-dialkynyl-3-cyclobutene-1,2-diones, the key intermediates in the new polyyne synthesis, had previously been prepared. Using organotin[66] and organocopper[67] compounds, we developed two methods to prepare these colored compounds in good to high yields (Table 1).[60,68,69] The structure of the bis(phenylethynyl) derivative **2a** was determined by X-ray crystallography. Since the majority of the 3,4-dialkynyl-3-cyclobutene-1,2-diones showed poor volatility and thermal instability, they could not be subjected to conventional flash vacuum pyrolysis (FVP)[70] for the extrusion of the two carbonyl groups to give the linear polyynes. Therefore, we developed solution-spray flash vacuum pyrolysis (SS-FVP) as a potentially general method for the preparative-scale pyrolysis of thermally sensitive compounds with high molecular

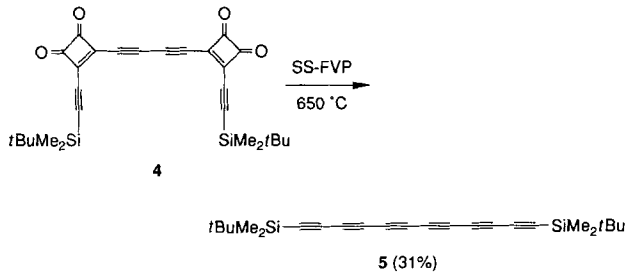
weights.[60] In this procedure, solutions of the 3,4-dialkynylcyclobutene-1,2-diones **2a–i** in benzene were introduced by capillary tubing as aerosols[71] into a hot pyrolysis tube made of quartz glass and filled with quartz rings. The triynes and pentaynes **3a–i** were obtained in good to excellent yields by this method (Table 2). The reaction could even be applied to convert the bis(cyclobutenedione) **4** into the hexayne **5** (31% yield, Scheme 6). As in Fowler's "solvent-assisted sublimation" method,[72] the sublimation of the solid substrate into the gas phase during SS-FVP is assisted by the flash evaporation of benzene.



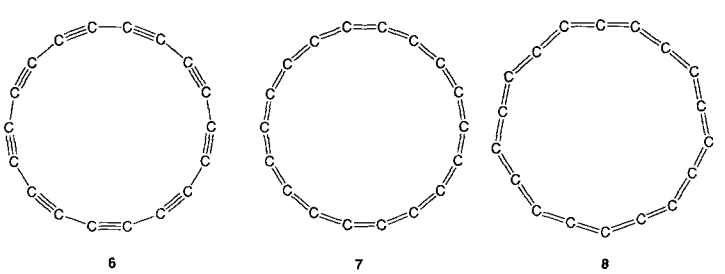
Scheme 6. Preparation of the hexayne **5**.

This new method for the preparation of symmetrically and unsymmetrically protected linear polyynes should greatly facilitate the generation of longer molecular carbon rods through oxidative coupling reactions and provide us with an entry into the study of linear C_x species of various sizes. Also, the topochemical[73] or the thermal polymerization of suitable polyyne derivatives in the solid state could lead to ladder polymers[74] exhibiting, among other characteristics, bulk spin alignment[75] or non-linear optical properties.[76]

3. The Cyclo[*n*]carbons

3.1. Definitions and Structural Predictions

As a first target in our synthetic approach towards all-carbon molecules, we chose the cyclic polyyne C_{18} **6** (Scheme 7).[47] This compound belongs to the novel class of monocyclic molecules which we call the cyclo[*n*]carbons. As in the [*n*]annulenes,[77, 78] *n* defines the number of carbon atoms that are connected to form the monocyclic structure. A distinctive aromatic stabilization might be among the potentially interesting properties of cyclo[18]carbon (**6**), since



Scheme 7. Calculated structures for C_{18}.

two perpendicular systems of conjugated π orbitals exist, one in-plane and one out-of-plane, with $[4n + 2]$ π-electrons each.

Extended Hückel[38] and semiempirical MNDO calculations[32, 37b] predict an energetic preference for a monocyclic structure of C_{18} over a linear one. These predictions were further refined by ab initio molecular orbital calculations. Interestingly, conflicting results were obtained at different levels of theory.[47, 79a] Results of SCF calculations with a 3-21G or larger basis set suggest that the cyclic acetylenic D_{9h} structure **6** with alternating bond lengths represents the ground state geometry and is more stable than the cumulenic D_{18h} and D_{9h} structures **7** and **8**. However, optimization at the MP2 level including valence electron correlations[79a] produced an opposing prediction and favored the D_{18h} structure **7** over **6** and **8** (Table 3). This discrepancy should eventually be resolved when cyclo[18]carbon is synthesized.[79b]

Table 3. Relative energies, bond lengths, and bond angles of optimized structures **6–8** of cyclo[18]carbon [47, 79a].

Method	Basis set	Structure		
		6	**7**	**8**
Relative Energies [kcal mol^{-1}]				
SCF	3-21G	0.0	53.8	37.6
	[4s3p1d]	0.0	68.7	35.2
	[5s4p3d2f]	0.0	71.5	
36-MP2 [a]	[4s3p1d]	54.6	0.0	108.8
72-MP2 [b]	[5s4p3d2f]	85.7	0.0	
Bond Lengths [Å]				
SCF	3-21G	1.362 (C–C) 1.199 (C≡C)	1.265	1.271
	[4s3p1d]	1.375 (C–C) 1.194 (C≡C)		1.277
36-MP2	[4s3p1d]		1.277	
Bond Angles [°]				
SCF	3-21G	160	160	170.4 149.6
	[4s3p1d]	160		175
36-MP2	[4s3p1d]		160	

[a] Thirty-six valence electrons were correlated.[b] Seventy-two valence electrons were correlated.

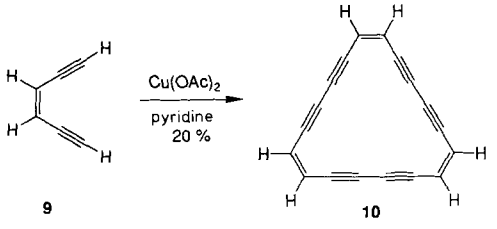
A variety of data predict that the cyclic polyyne structure **6** should not have unusual strain-related instability and should be isolable at room temperature. Strain in the monocyclic structures **6–8** results mainly from the distortions of bond angles from the ideal value of 180° to ≈160°. This distortion of the bonding of an acetylenic or allenic C atom requires about 4 kcal mol^{-1}, leading to a predicted total strain of 72 kcal mol^{-1}.[80] Several stable strained cycloalkynes with C≡C–C angles around 160° and even as small as 145.8°[81] have been reported; the reader is referred to excellent reviews on this subject.[82, 83] Finally, a computational assessment of the stability of **6** shows that the energy change for the isodesmic reaction summarized in Equation (a) is

$$\mathbf{6} + 2HC{\equiv}CH \longrightarrow HC{\equiv}C{-}(C{\equiv}C)_7{-}C{\equiv}CH + HC{\equiv}C{-}C{\equiv}CH \quad (a)$$

76 kcal mol^{-1}, far less than the energy of about 130 kcal mol^{-1} required to cleave a C–C single bond joining two acetylene units.

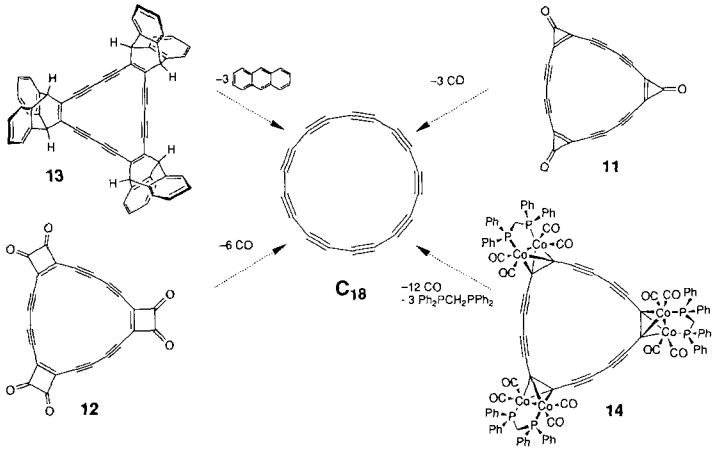
3.2. Synthetic Approaches to Cyclo[18]carbon

The strategies which we pursued to synthesize cyclo[18]carbon were all based on the same retrosynthetic analysis. By oxidative coupling of (*Z*)-3-hexene-1,5-diyne (**9**), Sondheimer and Okamura obtained in 1967 exclusively the yellow trimer **10** (Scheme 8).[84, 85] In analogy, we intended



Scheme 8. The Sondheimer synthesis of hexadehydro[18]annulene **10** [84].

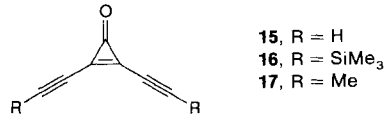
to synthesize "hexadehydroannulene" structures similar to **10** but with suitable leaving groups instead of the six peripheral hydrogen atoms. Thus, C_{18} would be generated in the final step of the synthesis by extrusion of the functional groups. The four routes pursued are shown in Scheme 9.



Scheme 9. The four synthetic routes to cyclo[18]carbon (the acetylenic structure **6** is shown).

3.2.1. The Cyclopropenone Route to C_{18}

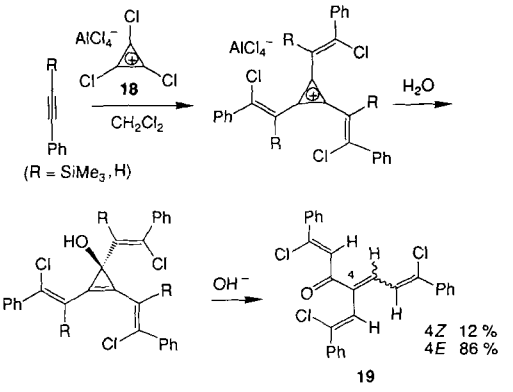
Cyclopropenones, like 3-cyclobutenediones, are known to eliminate carbon monoxide readily in pyrolytic[62b, 82b] and photolytic processes[63] to form acetylenes. Therefore, one route to C_{18} departed from **15** which, upon oxidative cyclization, could yield **11** and ultimately, by extrusion of three CO molecules, cyclo[18]carbon (Scheme 9). Whereas dialkynylcyclopropenones such as **15**–**17** (Scheme 10) were not



15, R = H
16, R = $SiMe_3$
17, R = Me

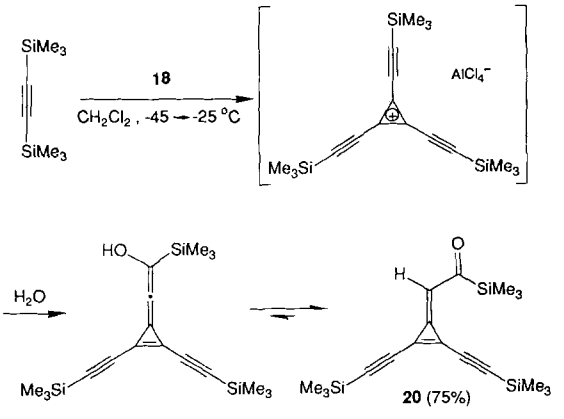
Scheme 10. Dialkynylcyclopropenones **15**–**17**.

known,[86] a great variety of other disubstituted cyclopropenones had previously been prepared by the reaction of arenes,[87] alkynes,[88] or alkenes[88, 89] with trichlorocyclopropenylium salts, generated from tetrachlorocyclopropene and a Lewis acid such as aluminum chloride. We hoped to



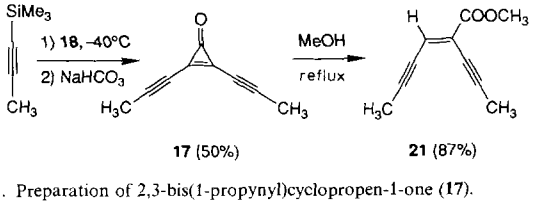
Scheme 11. Reaction of **18** with phenylacetylene derivatives. The dinitrophenylhydrazone derivative of **19** was characterized by X-ray crystallography.

prepare 2,3-dialkynylcyclopropenones in the reaction of alkynyltrimethylsilanes with trichlorocyclopropenylium tetrachloroaluminate (**18**)[90] as the electrophile in analogy to the reaction of alkynyltrimethylsilanes with acyl halides to give alkynylketones.[91] Schemes 11–13 show some of the



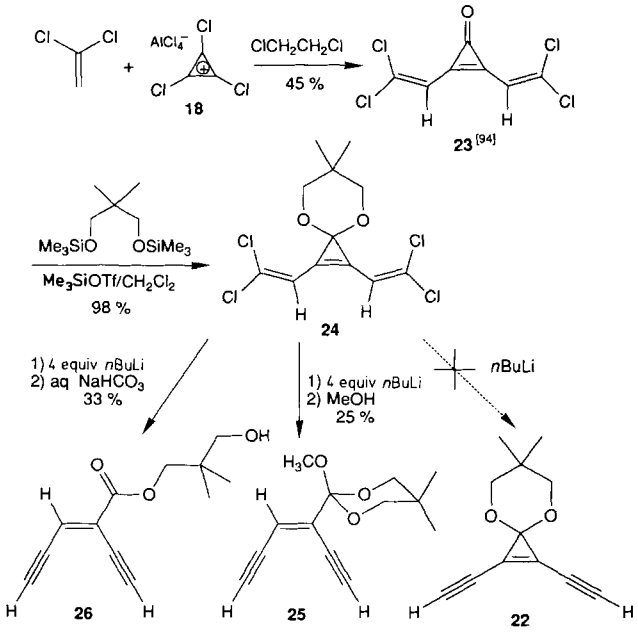
Scheme 12. Reaction of **18** with bis(trimethylsilyl)acetylene.

surprising results obtained in these studies.[68b] The only 2,3-dialkynylcyclopropenone that we were able to prepare was the bis(1-propynyl) derivative **17** (Scheme 13). This compound reacts readily with methanol to give the enediyne **21**.[92]



Scheme 13. Preparation of 2,3-bis(1-propynyl)cyclopropen-1-one (**17**).

In a variation of the cyclopropenone route to C_{18}, we tried to obtain the protected derivative **22** which subsequently would be cyclized to the trimer and finally deprotected to give **11** (Scheme 14).[93] As a precursor to **22**, ketal **24** was prepared in nearly quantitative yield from **23**.[94] However, all attempts to transform **24** into **22**[95] led to the opening of the cyclopropene ring.[96]



Scheme 14. Attempted preparation of ketal **22**. OTf = OSO_2CF_3.

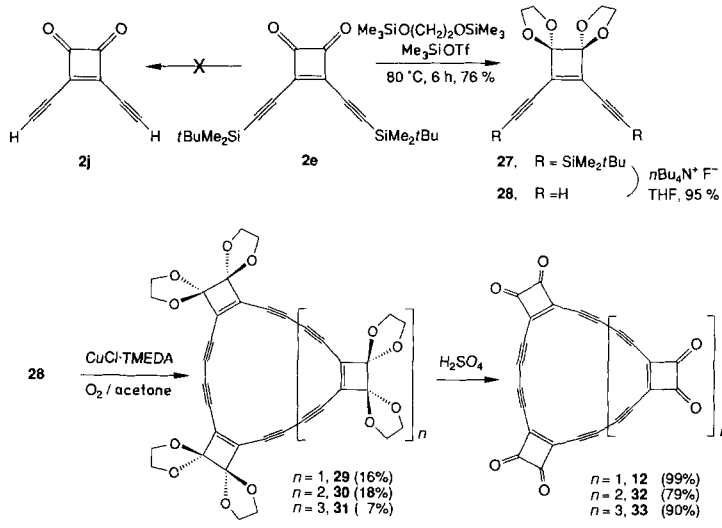
The cyclopropenone route to cyclo[18]carbon is very short and elegant. However, the chemistry of 2,3-dialkynylcyclopropenones must first be developed before this pathway can be further pursued. At present, the bis(1-propynyl) derivative **17** remains the only known member of this class of compounds.

3.2.2. The 3-Cyclobutene-1,2-dione Route to Cyclo[18]carbon

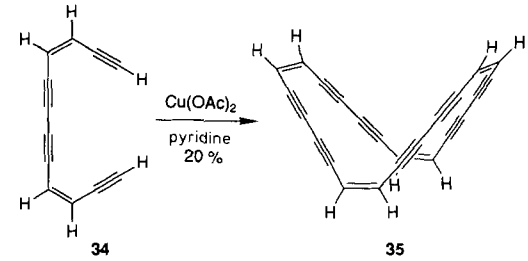
3.2.2.1. Cyclobutene-Annelated Dehydro[n]annulenes: Surprisingly Stable [4n + 2] and [4n]π Electron Perimeters

The direct approach to **12**, the macrocyclic precursor in the cyclobutenedione route to cyclo[18]carbon (Scheme 9), required the oxidative cyclization of the diethynyl derivative **2j** (Scheme 15). However, all attempts to prepare this compound, for example by deprotection of the silyl-protected derivatives **2d–f**, failed presumably due to the extreme reactivity of **2j** as a Michael acceptor. Instead, the diketal **27** was formed from dione **2e** under unusually forcing conditions.[68b] Compound **27** readily afforded the diethynyl derivative **28**, which was cyclized under Hay coupling[59] conditions to yield the three cyclobutene-fused dehydroannulenes **29–31** in good overall yield.

The comparison of the macrocycles **29–31** and the parent dehydroannulenes **10** and **35** prepared by Sondheimer et al.[84, 97] shows a pronounced effect of the cyclobutene annelation on the structure and reactivity of the macrocycles (Schemes 8, 15, and 16). The oxidative coupling of **9** exclusively led to the formation of the trimer **10**, a planar diatropic highly unstable hexadehydro[18]annulene which explodes at approximately 85 °C. The octadehydro[24]annulene **35**, prepared by dimerization of **34**, is a nonplanar, cyclooctatetraene(COT)-like shaped atropic compound and is also highly unstable, with a tendency to explode upon heating. In



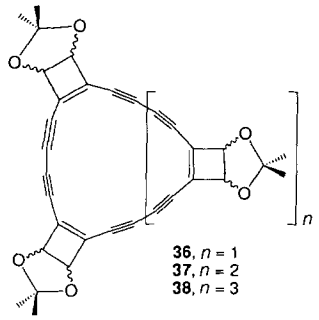
Scheme 15. Synthesis of the carbon oxides **12**, **32**, and **33**.



Scheme 16. The Sondheimer preparation of octadehydro[24]annulene **35** [97].

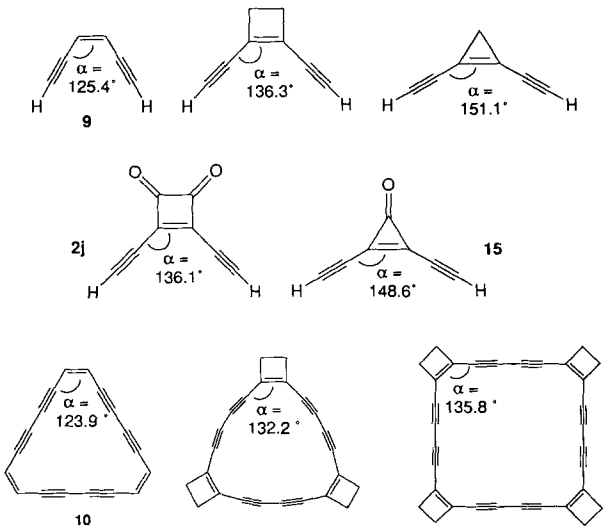
sharp contrast, oxidative coupling of **28** led to the three compounds **29–31**; the tetramer **30** was formed with the best yield. ^{1}H NMR and UV/VIS spectroscopic analysis show that the pale-yellow trimer **29** has a planar diatropic 18 π-electron perimeter and the orange-red tetramer **30** a planar paratropic 24 π-electron perimeter, whereas the bright-yellow pentamer **31** (30 π-electrons) is a conformationally more flexible, atropic system.[68, 98] All three macrocycles are stable compounds at room temperature and when exposed to air. The fusion of cyclobutene rings particularly stabilizes the planar [24]annulene perimeter and is majorly responsible for the preferred formation of tetramer **30** in the oxidative coupling reactions. Investigations on a second series of cyclobutene-fused dehydroannulenes (**36–38**) provided similar results (Scheme 17).[68b]

Computational studies with the MM2 force field[99] and semiempirical AM1[100] molecular orbital calculations reproduce the size and conformational preferences of the macrocycles observed by Sondheimer et al. and by us.[98]



Scheme 17. Dehydroannulenes **36**–**38**.

Some of the computational results are shown in Scheme 18. Steric rather than electronic (e.g. $[4n + 2]$ vs. $[4n]$ π-electrons) factors determine the structural preferences. The calculations show that, with its C=C–C angle α of 125.4°, the parent enediyne **9** is best converted into a planar trimer (ideal angle $\alpha = 120°$) or a nonplanar COT-type tetramer (ideal angle $\alpha \approx 120°$), but not into a planar tetramer with an ideal angle α of 135°. In contrast, the diethynylcyclobutene unit **28**



Scheme 18. C=C–C bond angles α at enediyne units calculated by AM1.

with its large C=C–C angle α of 136.1° is accommodated in a nearly strain-free way in the planar tetramer ($\alpha = 135.8°$), whereas its incorporation into the planar trimer **29** generates considerable angle strain and bending of the diacetylene units as is illustrated by the X-ray crystal structure of **12** (Fig. 1).

The increased stability of the cyclobutene-fused derivatives **29**–**31** compared to the parent compounds **10** and **35** is a result of enhanced rigidity of the ring skeleton in the annelated systems. It is well recognized in annulene chemistry that, besides the absence of transannular steric interactions or angle strain, the rigidity of the ring skeleton is an essential structural prerequisite for stability.[101–104] Rigidity and planarity can be imposed on annulene perimeters by annelation to arenes.[105] However, the more effective benzenoid delocalization is superposed on the annulenoid delocalization, and the diatropism of the $[4n + 2]$ π-electron perimeter of the annulene is weakened. In the extreme case of kekulene,[106] a perfectly stable planar molecule with an inner [18]annulene and an outer [30]annulene perimeter, all experimental evidence shows that macrocyclic delocalization is overwhelmed by benzenoid aromaticity.[107] Annulenes can be stabilized without disturbing the macrocyclic delocalization by bridging the perimeter to enforce rigidity and planarity.[108–111] The rigidity of annulenes also increases upon introduction of acetylene units into the π-electron perimeters.[77, 112] Also, a large number of annulenes including the porphyrins and analogues[78, 102, 113, 114] are made planar and stable by the five-membered aromatic heterocycles such as pyrrole and furan that are integrated into the macrocyclic π-electron system.

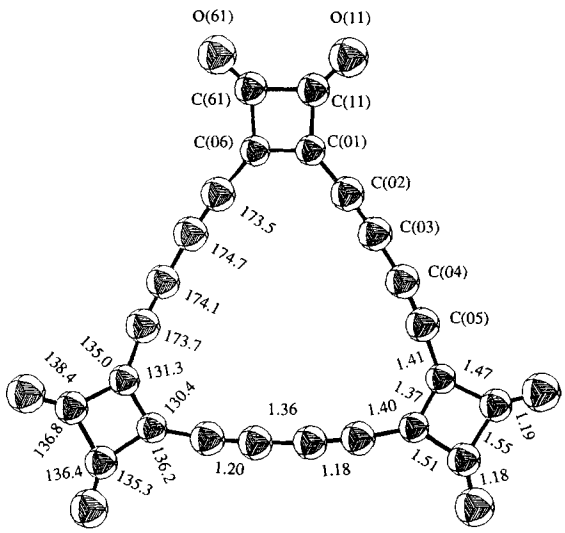


Fig. 1. X-ray crystal structure of the carbon oxide $C_{24}O_6$ **12**. Important distances [Å] and bond angles [°] are noted.

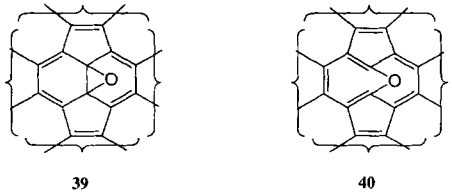
The enhanced kinetic stability of the cyclobutene-fused dehydroannulenes **29**, **30**, **36**, and **37**, compared to the parent systems **10** and **35**, can be explained by the fact that the bending and out-of-plane distortions normally required to reach transition states are energetically more difficult in the former rigid systems.[98, 111] This previously unrecognized stabilization through annelation with small cycloalkenes does not alter the macrocyclic π system. Mills–Nixon effects,[115] that is, the localization of double bonds in aromatic systems as a result of strain caused by annelation to small rings, have not been found to be very effective in benzenoid and annulenoid systems.[116] It will be interesting to see how fusion with small cycloalkenes affects structures and stabilities in other series of annulenes.[117–119]

3.2.2.2. The Higher Carbon Oxides $C_{8n}O_{2n}$: Direct Precursors to Cyclo[n]carbons

The removal of the ketal protecting groups in **29**–**31** to form the corresponding carbon oxides proved to be exceptionally difficult and could only be achieved by dissolution of the compounds in concentrated sulfuric acid.[69] The particular sensitivity of the products formed also required unusual workup conditions. Dilution of the sulfuric acid solu-

tions with water led to instant polymerization of the product. Therefore, the sulfuric acid solutions were extracted with 1,2-dichloroethane and the organic layer neutralized with powdered $CaCO_3$ to give the carbon oxides $C_{24}O_6$ (**12**), $C_{32}O_8$ (**32**), and $C_{40}O_{10}$ (**33**) in high yields. Solutions of these compounds in 1,2-dichloroethane are orange-yellow (**12**), red (**32**), and yellow (**33**). The X-ray crystal structure of oxide **12** was obtained (see Fig. 1) and reveals appreciable strain within the perfectly planar annulene perimeter. The three higher oxides of carbon **12**, **32**, and **33** are extremely sensitive to nucleophiles, which induce polymerization through initial Michael addition. Also, they undergo rapid Diels–Alder reactions with dienes, for example furan, leading to strained derivatives that subsequently polymerize. Although these carbon oxides are stable at room temperature, they explode above 80 °C.

Other oxides of carbon, molecules of the composition C_xO_y, have recently attracted much attention, although the total number of compounds in this interesting class still remains rather small.[120–122] In the series of the linear cumulene-type oxides (C_nO_2),[123], a new stable member with an odd number of carbon atoms, 1,2,3,4-pentatetraene-1,5-dione (O=C=C=C=C=C=O, C_5O_2),[124] has been added to the well known derivatives CO_2 and carbon suboxide C_3O_2. Members of the series with an even number of carbon atoms have long defied experimental detection.[125] Calculations predict that they have a triplet ground state, which would explain the high reactivity of these molecules.[125, 126] The synthesis of the first cumulenic carbon oxide with an even number of C atoms, 1,2,3-butatriene-1,4-dione (O=C=C=C=C=O, C_4O_2), was recently accomplished in an argon matrix[125] as well as in the gas phase.[126] As large molecules of composition C_xO_y, the fullerene oxides have been under intensive investigation. Compound $C_{70}O$, an oxide of D_{5h}-C_{70},[25a] as well as $C_{60}O$[127] are isolated as by-products of the fullerenes when the resistive heating of graphite is done in a He atmosphere containing residual amounts of oxygen. Compound $C_{70}O$ is also formed by burning graphite rods doped with La_2O_3 for the production of endohedral lanthanum compounds.[128] Electrochemical oxidation of C_{60} was reported to generate a mixture of $C_{60}O_n$ ($n = 1-4$).[129] Pure $C_{60}O$ has been prepared by photooxidation of C_{60} in benzene[130] and by reaction of the fullerene with 2,2-dimethyldioxirane.[131] The ^{13}C NMR data of $C_{60}O$ strongly support the epoxide structure **39** over the oxo-bridged annulene structure **40** (Scheme 19).[132] With the further developments in the chemistry of the fullerenes and carbon allotropes in general, we will undoubtedly also see a rapid increase in the number of oxides as well as sulfides[122f, 133] of carbon that are prepared.



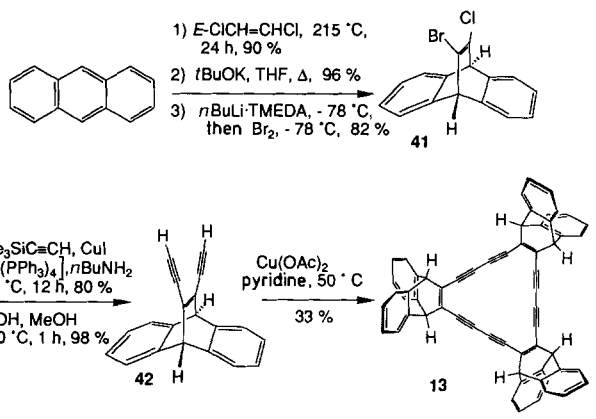
39 **40**

Scheme 19. Epoxide (**39**) and oxo-bridged annulene (**40**) structures for fullerene oxides.

The good availability of gram quantities of **12**, **32**, and **33** now allows systematic investigations of the transformation of these compounds into the cyclocarbons C_{18}, C_{24}, and C_{30}, respectively. Laser desorption Fourier transform (FT) mass spectra of these compounds show a remarkable ease of successive losses of two CO molecules to give C_{18}, C_{24}, and C_{30} ions.[69] Preliminary IR spectroscopic investigations of **12** isolated in a matrix suggest that the photolytic extrusion of six CO molecules from **12** shows promise as a way to prepare isolable quantities of cyclo[18]carbon.[134] Irradiation ($\lambda > 338$ nm) of **12** ($\tilde{\nu}$[C=O] = 1791 cm^{-1}) in a 1,2-dichloroethane glass at 30 K generates quantitatively within six minutes the hexaketene ($\tilde{\nu}$[C=C=O] = 2115 cm^{-1}). Subsequent irradiation at a shorter wavelength ($\lambda > 280$ nm) for three hours leads to complete disappearance of the ketene band and to the build up of the C≡O absorption band at 2137 cm^{-1}. Further experiments on this very promising route are now under way. The significance of the cyclocarbons in the gas-phase formation of fullerenes is described in detail in Section 6.

3.2.3. The Retro-Diels–Alder Route to Cyclo[18]carbon

The hexadehydro[18]annulene **13** (Scheme 9) was chosen as the precursor in our initial approach to cyclo[18]carbon since it should readily lose three anthracene molecules under thermolytic conditions with formation of C_{18}.[47] The macrocyle was assembled starting from anthracene via the bromochloro derivative **41**, a compound previously described by Hart et al. (Scheme 20).[135] Whereas enediynes



Scheme 20. Preparation of the C_{18} precursor **13**.

fused to cyclobutene rings (e.g. **28**, Scheme 15), are stable at room temperature, crystalline enediyne **42** is very unstable and, in one case, a crystalline sample exploded spontaneously. Oxidative coupling of **42** under Eglinton–Glaser conditions[136] yielded the red cyclic trimer **13** as the only product in 33% yield.

In contrast to **42** and the parent macrocycle **10**, the annelated hexadehydro[18]annulene **13** is an extraordinarily stable compound. It can be recrystallized from boiling pyridine, is stable to air, and can be heated in the solid state under N_2 to 250 °C without appreciable decomposition. It must be assumed that, in addition to the rigidification im-

posed by the annelation (Section 3.2.2.1), the steric shielding of the annulene perimeter by the six benzene rings contributes to the unusual stability of **13** with respect to bimolecular reactions and polymerization. The X-ray crystal structure of **13** (Fig. 2) shows a nearly perfectly planar 18-membered macrocycle. With an average value of 123.3°, the C=C–C angle α in **13** is small and close to the comparable angle in **42** (calculated by MM2: $\alpha = 125°$, AM1: $\alpha = 127°$).[137] As discussed in Section 3.2.2.1, this steric matching between monomer and macrocyclic oligomer explains the preferential formation a cyclic trimer. If ^{1}H NMR chemical shifts are used as a criterion for aromaticity, then **13** is aromatic: the diatropicity of **13** is reflected in the deshielding ($\Delta\delta = 0.75$) of the bridgehead methine protons ($\delta = 5.89$) compared to the methine protons in **42** ($\delta = 5.14$).

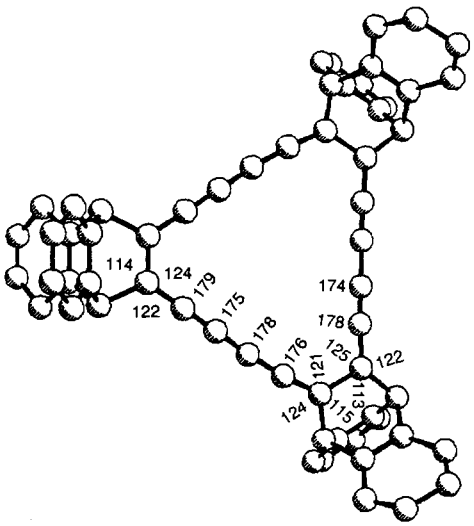


Fig. 2. X-ray crystal structure of the hexadehydro[18]annulene **13**. Important bond angles are noted.

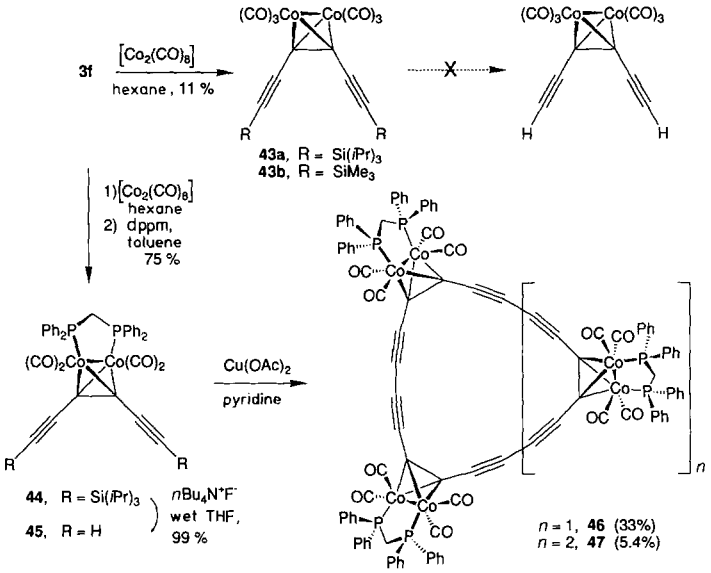
Laser flash heating experiments clearly demonstrated that cyclo[18]carbon can be prepared by the threefold retro-Diels–Alder reaction of **13** (Scheme 9). In these experiments, a thin film of **13** was coated onto a tantalum rod, which in turn was mounted in vacuum within a pulsed He jet nozzle source and molecular beam chamber.[138] Under flash heating with a XeCl laser ($\Delta T \geq 1000$ K), the macrocycle was desorbed and underwent retro-Diels–Alder reactions leading to the successive loss of one, two, and three anthracene units and formation of cyclo[18]carbon. After all of the charged species present in the He-cooled desorption cloud were deviated by an electrical field, the neutral products were detected by resonant two-photon ionization mass spectrometry. Anthracene and cyclo[18]carbon together with cleavage products of **13** with one or two anthracene units still attached were found to be by far the most abundant neutral species in the molecular beam. This clearly shows that, under thermolysis conditions, the retro-Diels–Alder reaction to cyclo[18]carbon is the predominant fragmentation channel of **13**. We have not yet been successful in generating cyclo[18]carbon by this route on a preparative scale: flash vacuum pyrolysis as well as solution-spray flash vacuum pyrolysis of **13** (see Section 2 and Table 2) have so far only afforded anthracene besides polymeric material.

3.2.4. Stable Cobalt Complexes of Cyclo[18]- and Cyclo[24]carbon

The last proposed route to the cyclocarbons involved the preparation of metal complexes of C_{18} and the larger cyclocarbons as direct precursors to the all-carbon molecules.[139] A variety of transition metals form stable complexes with alkynes.[140, 141] The chemistry of metal complexes with strained cycloalkynes and arynes has recently been reviewed.[142] Of particular interest to us was the chemistry of alkyne–dicobalt complexes,[143] since when an alkyne is complexed with $[Co_2(CO)_8]$ the two C≡C–C angles are reduced to a value of $\approx 140°$,[144] and the alkyne can be easily liberated from its complex through oxidation of cobalt,[145, 146] alkyne–ligand exchange,[147] or flash vacuum pyrolysis.[148] Hexacarbonyldicobalt fragments have been used as protecting groups to allow disfavored cyclization reactions to proceed by bending the alkyne moiety, or to stabilize strained alkynes.[146, 149, 150] Thus, the synthesis of cyclo[18]carbon seemed promising along the pathway outlined in Scheme 21.



Scheme 21. Synthesis of the cobalt complexes of C_{18} (**46**) and C_{24} (**47**). dppm = Bis(diphenylphosphino)methane.

Reaction of triyne **3f** with $[Co_2(CO)_8]$ afforded as expected the sterically least crowded dicobalt complex **43a** which, however, was found to be rather unstable. Attempts to remove the silyl protecting groups in **43a** with fluoride anion led to complete decomposition of the compound. A similar negative result was obtained with the TMS-derivative **43b** under milder conditions (K_2CO_3, MeOH). Complex **43a** could be stabilized by the bridging ligand dppm,[151] which could be introduced easily[152] to afford the heat and air stable complex **44** (Scheme 21). Complex **44** was then smoothly converted to the 1,3,5-hexatriyne complex **45** which was characterized by X-ray crystallography. Oxidative coupling under high-dilution conditions finally afforded the very stable cobalt complexes of cyclo[18]carbon (**46** = **14**) and cyclo[24]carbon (**47**), both as shiny black needles. The X-ray crystal structure of **46** (Fig. 3) shows

considerable bending of the three butadiyne units within the nearly planar C_{18} ring. With a value of 161°, some of the C≡C–C angles in **46** approach the degree of bending expect-

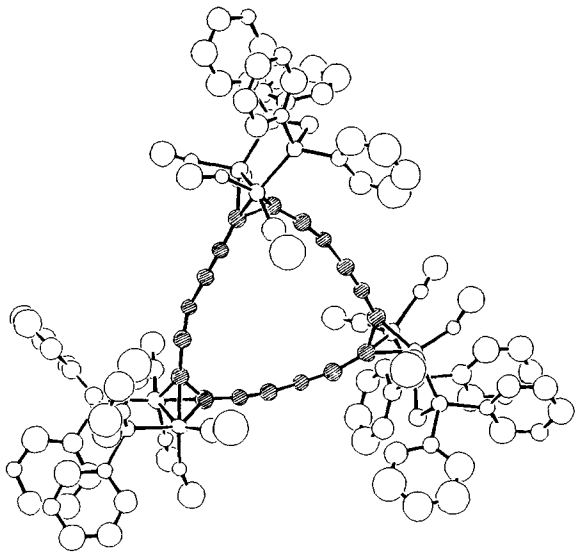


Fig. 3. X-ray crystal structure of the hexacobalt complex **46** of cyclo[18]-carbon. C atoms in the C_{18} ring are represented by shaded spheres.

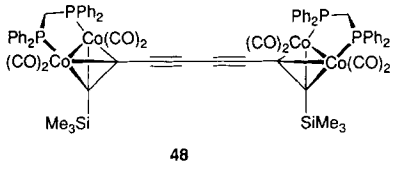
ed for **6** (Section 3.1). Comparisons between the electronic absorption spectra of monomer **45**, complex **48** with two dicobalt units in direct conjugation (Scheme 22),[139] and the two macrocycles **46** and **47** strongly suggest the presence of cyclic conjugation in the two cyclocarbon complexes.[153]



48

Scheme 22. Tetracobalt complex **48**.

Unfortunately, all attempts to free cyclo[18]carbon and cyclo[24]carbon from the coordinating metal atoms in **46** and **47** failed so far, partially because of the stabilization of the complexes by the basic dppm ligands and the extreme shielding of the cobalt atoms by the bulky dppm ligands.

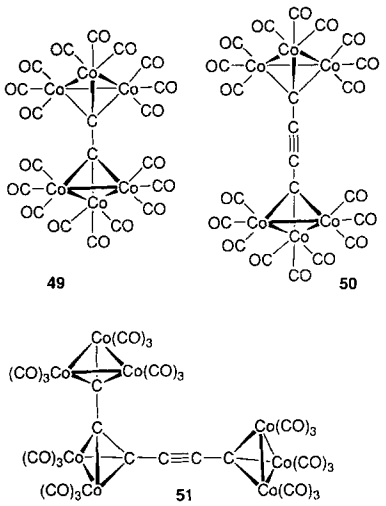
4. Transition Metal Complexes with All-Carbon Ligands

The arrival of fullerenes and the synthesis of other molecular and polymeric carbon allotropes have led to developments in the exciting area of transition metal complexes with all-carbon ligands. Prior to the preparation of cyclocarbon (Section 3.2.4) and fullerene complexes (Section 4.2), a number of stable complexes of small linear carbon units C_x ($x = 2-6$) had already been reported.

4.1. Small All-Carbon Ligands in Organometallic Complexes

We do not consider metal carbides MC_2 (M = Ca, Th, U, Lu, Tb, La), La_2C_3, or $Gd_2Cl_2C_2$ and the covalently bound Be_2C, SiC, and B_4C as carbon–metal complexes.[154, 155] The same holds for the graphite–metal intercalation compounds like C_8K.[154] However, there are a few classes of true organometallic complexes in which all-carbon units act as ligands. Organometallic complexes in which single C atoms are stabilized within a metal carbonyl cluster have become quite common and are called carbidocarbonyl cluster compounds.[156] First reported as a curiosity, they can now be prepared routinely. Besides the complexation of single carbon atoms, the preparation of C_2, C_4, and even C_6 carbidocarbonyl cluster complexes has been reported, and this chemistry has recently been reviewed.[155a, 156–159]

Another type of stable molecular complex with carbon ligands is based on the chemistry of the complex fragments carbyne(nonacarbonyl)tricobalt and alkyne(hexacarbonyl)-dicobalt.[160, 161] The C_2 complex **49** (Scheme 23) was prepared in the reaction of $[Co_2(CO)_8]$ with hexachloroethane or with diiodoethyne.[162] In the C_4 complex **50**, a C≡C unit



49 **50**

51

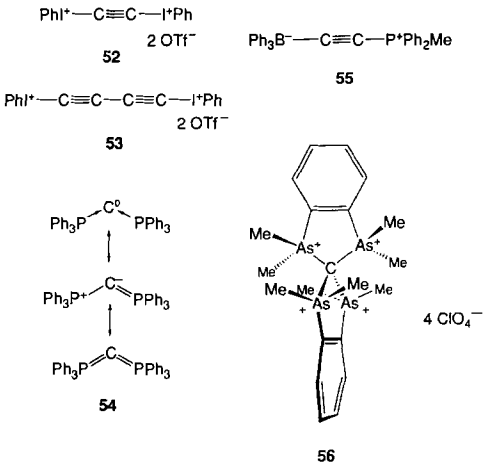
Scheme 23. Structures of cobalt complexes with C_2, C_4, and C_6 ligands.

separates the two carbyne(nonacarbonyl)tricobalt moieties.[163a] In the C_6 complex **51**,[163b, c] a butadiyne unit separates the carbyne(nonacarbonyl)tricobalt moieties and, in addition, a hexacarbonyldicobalt unit is capping one of the two C≡C bonds. The C_4 complex **50** and the C_6 complex **51** were not prepared by rational synthesis but rather obtained from the reaction of chloro- or bromomethinyl-(nonacarbonyl)tricobalt with xylene or mesitylene. Alternatively, the C_6 complex **51** was also prepared from hexachlorocyclopropane and $[Co_2(CO)_8]$.[163b]

In another class of complexes of all-carbon ligands, two transition metal atoms are bridged by μ-ethynediyl bridges. Although structures consistent with all three valence bond descriptions (M–C≡C–M, M=C=C=M, and M≡C–C≡M) have been prepared,[164a] most of the complexes contain an μ-C≡C bridge. Examples are [{(CO)$_5$-

$Re\}_2C_2]$,[164b] $[(Cp_2^*Sc)_2C_2]$ ($Cp^* = \eta^5$-C_5Me_5),[164c] $[\{Cp(CO)_2Ru\}_2C_2]$,[164d] and $[\{Cl(PBu_3)_2Pd\}_2C_2]$.[164e] A cumulenic bridge was found by X-ray crystallography in the tantalum complex $[\{(Me_3SiO)_3Ta\}_2C_2]$.[164f] The μ-C_2-bridged dinuclear complexes have been proposed as reactive intermediates in acetylene conversions on heterogenous surfaces and in the Fischer–Tropsch synthesis.[164d,f]

Finally, compounds with metalloids (Ge, Sn, Pb, Sb, As, etc.) flanking small molecular carbon units, for example alkynes, are common. More interesting in this respect are the bis(iodonium) salts **52** and **53**, which can be utilized in preparative conversions as "stabilized" forms of C_2 and C_4 (Scheme 24).[165] Similarly, compound **54** can be viewed as a



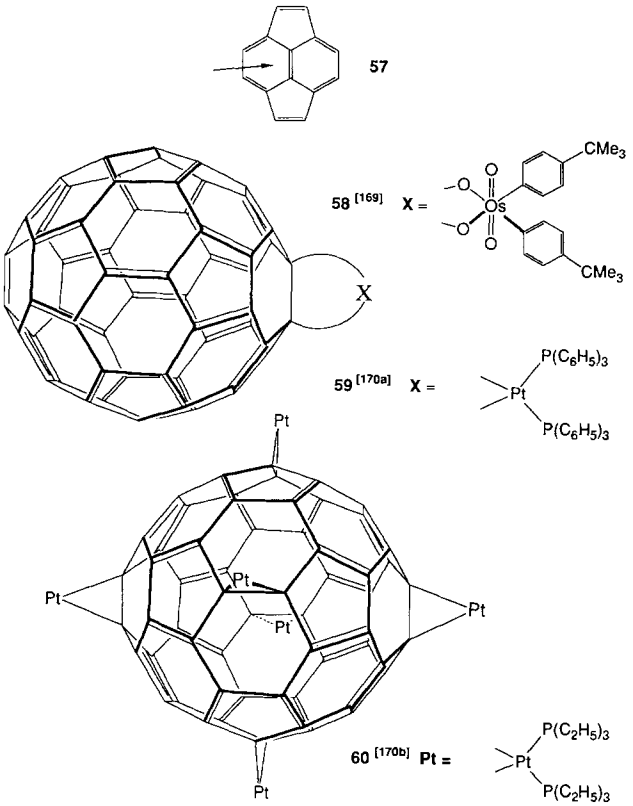
Scheme 24. Carbon complexes of metalloids.

C_1 complex consisting of two donor phosphane units and an electron-accepting carbon atom.[166,167] The stabilization of C_2 in **55** by a donor and an acceptor "ligand" was achieved by Bestmann et al.[166] The tetraarsonium salt **56** incorporating a C_1 unit within a tetrahedral array of positively charged arsenic atoms was prepared by the reaction of CBr_4 with the corresponding ditertiary diarsane ligand.[168]

4.2. Fullerene Transition Metal Complexes

4.2.1. Exohedral Fullerene Complexes

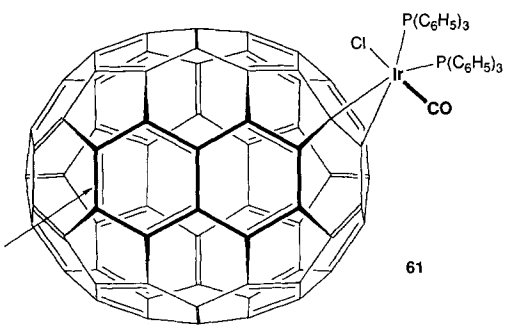
From the moment macroscopic quantities of fullerenes C_{60} and C_{70} became available, the formation of exohedral ("outside the cage") transition metal complexes was pursued. By osmylation, Hawkins et al. prepared the C_{60}–osmium tetraoxide adduct **58** (Scheme 25) and provided unambiguous confirmation of the soccerball structure of C_{60} by X-ray crystallography.[18h,169] Soon after, the preparation and X-ray crystal structure of the platinum derivative **59** was reported.[170a] These structures showed that the free space inside C_{60}, which is available for guest incorporation (Section 4.2.2), has a diameter of approximately 3.5 Å. Both **58** and **59** are formed by attack at one of the reactive C=C bonds in C_{60} found in the center of the pyracylene (**57**) subunits. Six of these reactive double bonds are located in a pseudo-octahedral arrangement on the fullerene surface.



Scheme 25. Transition metal complexes of C_{60} by addition to central pyracylene-type C=C bonds (marked in pyracylene (**57**) with an arrow).

Upon reaction of C_{60} with an excess of $[\{(C_2H_5)_3P\}_4Pt]$ in benzene, the sixfold metallated derivative **60** was obtained and subsequently characterized by X-ray crystallography.[18f,170b,171]

Iridium complexes of both C_{60} and C_{70} have been described[172,173] and the X-ray crystallographic analysis of **61** provided unambiguous confirmation of the ellipsoidal D_{5h}-symmetrical cage structure[173a] shaped like a rugby ball which had previously been assigned to C_{70} based on its ^{13}C NMR spectrum (Scheme 26).[17d,g,18k,174] Similar to **58**–**60**, the metallacycle **61** forms at the reactive pyracylene-type double bond. Two different bonds of this type are present in C_{70}: one on the more curved area of the fullerene cap and one on the flatter central region of the molecule. However, the metallacycle is formed only at the double bond in the more curved region. The binding of the metal is accompa-



Scheme 26. An iridium derivative of C_{70}[173a]. The less reactive pyracylene-type C=C bond is marked with an arrow.

nied by local distortion; the two carbon atoms involved in the coordination are pulled out from the C_{70} surface. This distortion is energetically more favorable on the more curved cap surface where the sp^2 carbon atoms are significantly rehybridized and more strongly pyramidalized than on the flatter central surface.

In gas-phase studies with an FT mass spectrometer, the formation of the exohedral complex cations $[Ni(C_{60})_2]^+$, presumed to have a metallocene-type structure, and $[MC_{60}]^+$ (M = Fe, Co, Ni, Cu) was observed.[175] In contrast to the endohedral ("inside the cage") complexes discussed in the next section, these ions require relatively little activation energy for loss of the metal from the complex leaving an intact C_{60} species.

In a metalloporphyrin derivative, the fullerene radical anion $C_{60}^{\bullet-}$ was found to act as a very weakly coordinating anion.[176] The reaction of $[Cr^{II}(tpp)]$ (tpp = tetraphenylporphyrin) in THF with a solution of C_{60} in toluene gave purple-black crystals of $[Cr^{III}(tpp)(thf)_2]^+[C_{60}^{\bullet}]^- \cdot thf$. EPR studies in solution demonstrated that the $C_{60}^{\bullet-}$ counterion in the salt is unable to compete with THF for axial ligation to the porphyrinatochromium(III).

4.2.2. Endohedral Fullerene Complexes

It is not difficult to predict that the development of endohedral[177] complexes will become one of the most active areas of fullerene chemistry. Some of the most spectacular discoveries both in terms of basic structural understanding as well as in materials applications may be expected. As early as 1985, Smalley et al. obtained the first mass spectrometric evidence for the gas-phase formation of endohedral metal–fullerene complexes MC_{60} (M = La, K, Cs) by laser vaporization of graphite impregnated with various metal salts.[18a, 178] In contrast to exohedral complexes, the endohedral complexes are quite stable, and substantial amounts of laser energy were required to induce their fragmentation by sequential C_2 losses which eventually led to species such as $C_{36}La^+$, $C_{44}K^+$, or $C_{48}Cs^+$.[178b] The metal ions remain encapsulated in the fragmented carbon shells as long as the latter retain a cage structure that fits the ion size.

Similarly to the first reports on the formation of stable C_{60} with I_h symmetry,[16, 17a, b] the early publications in which postulates for the formation of endohedral complexes were presented triggered some controversy.[179] With the recent isolation[180] of small amounts of soluble endohedral lanthanum and yttrium complexes from soot produced by resistive or arc-heating of graphite doped with La_2O_3 and Y_2O_3, all scepticism has vanished.[180–183] Among the most abundant lanthanum complexes is LaC_{82}, an air- and moisture-stable compound which can be extracted from the soot, together with C_{60} and other uncomplexed higher fullerenes, with solvents like toluene, CS_2, or pyridine. The endohedral complexes LaC_{60}, LaC_{70}, and LaC_{74}, which are also formed, are not extractable with toluene but can be detected in air-stable films obtained by sublimation.[180] Electron paramagnetic resonance[182] as well as X-ray photoemission spectroscopy[181] showed that the central La atom in LaC_{82} has a formal charge of 3 + . The most abundant yttrium derivatives have a similar stoichiometry to those of the lanthanum compounds. Dimetallofullerenes have also been reported: both Y_2C_{82} and La_2C_{80} were extracted as air-stable endohedral complexes from the soot.[181, 183a, b]

The endohedral metal fullerene complexes form in small yield (1–3%)[182] and have not yet been isolated in pure form. Characterization so far has been possible only for mixtures of metallated and free fullerenes. Although the endohedral nature of the complexes is strongly supported by a variety of experimental evidence data such as stability, EPR spectra, and typical fragmentation pattern in the mass spectrum,[180–183] the molecular structures of the encapsulating fullerenes as well the nature of the fullerene–metal ion interactions are not known. Since all endohedral complexes have been isolated in mixtures together with free fullerenes, the formation of saltlike structures like $[LaC_{82}]^+C_{60}^-$ cannot be excluded. Structural assignments[184a–c] currently rely mainly on theoretical predictions made by Manolopoulos and Fowler who combined their very successful search for fullerene geometries based on a spiral algorithm with restricted Hartree–Fock (RHF) ab initio calculations to generate favorable geometries for endohedral fullerene complexes.[184] In addition to a detailed experimental structural analysis, future studies should also provide a more quantitative evaluation of the stability[183b] and chemical reactivity of these fascinating and unprecedented materials.[185]

5. Carbon Networks

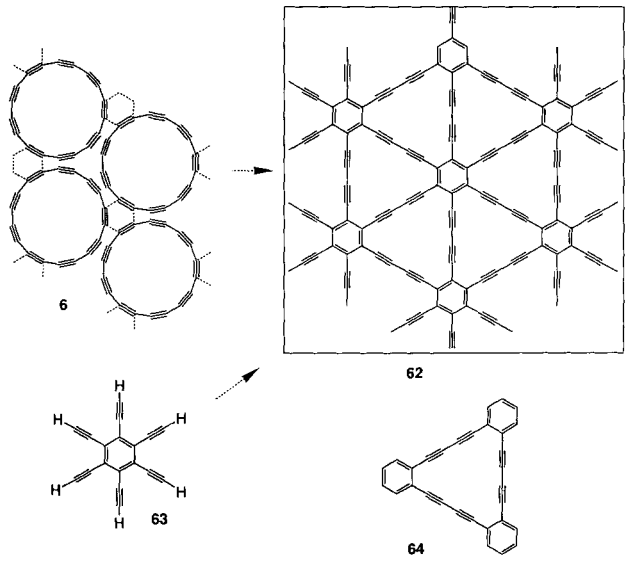
As already mentioned in the introduction, a great variety of carbon networks differing from the familiar, naturally occurring diamond and graphite can be written down on paper, and several of them have actually been proposed in published work.[6, 7, 12, 42, 43] However, the preparation of synthetic polymeric modifications of carbon has not received much attention from polymer and organic chemists in the past, which may be explained by the fact that the postulated synthetic networks are thermodynamically less stable than graphite and diamond, leading to the expectation that the unnatural allotropes should undergo facile conversion into the natural allotropes. The ongoing fullerene research clearly shows that, in view of the very high activation barriers required to break stable C–C bonds, such expectations are not justified. The standard heat of formation for crystalline C_{60} was determined as $\Delta H_f^\circ(c) = 544.99\ kcal\,mol^{-1}$.[186] This corresponds to 9.08 kcal mol^{-1} per C atom which compares with the values of 0.0 kcal mol^{-1} for graphite and 0.4 kcal mol^{-1} per C atom for diamond. Despite this large thermodynamic instability, crystalline C_{60} is kinetically a perfectly stable molecule under ambient conditions. By extrapolation, synthetic all-carbon networks for which no facile mechanisms for interconversion into graphite or diamond exist, should also exhibit high kinetic stability.

In our ongoing program[93] to prepare polymeric network allotropes of carbon, we have chosen target compounds according to the following criteria: 1) The network structures should neither be highly strained nor easily interconverted into graphite or diamond, 2) the new compounds should have the potential to exhibit interesting material properties such as electrical conductivity, and 3) promising synthetic routes should be available. The latter criterion includes the

"finite molecular approximation approach to infinite structures",[187] that is, the synthesis and study of monomers, dimers, and higher oligomers from which the properties of extended networks can eventually be extrapolated.

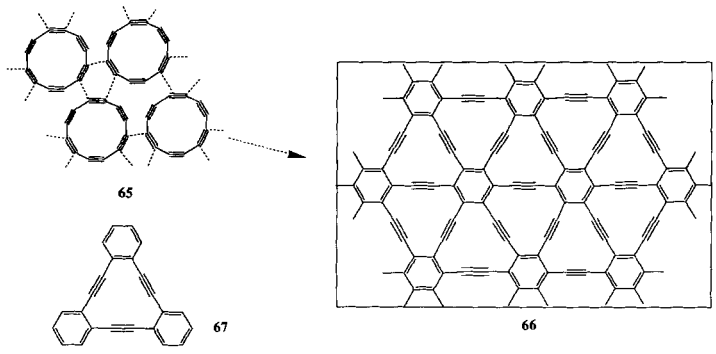
5.1. The Cyclo[*n*]carbons as Precursors to Carbon Networks

The unprecedented electronic structures of the cyclo[*n*]carbons (Section 3.1) make them fascinating target molecules. In addition, some of these C_n rings are precursors to interesting two-dimensional carbon networks. Thus, the controlled oligotrimerization[149b] of cyclo[18]carbon (**6**) should lead to the macromolecular network **62** (Scheme 27).



Scheme 27. Synthetic approaches to the planar carbon network **62**. Macrocycle **64** is a model compound for the substructure of **62** and has not yet been synthesized.

Another potential monomeric precursor to **62** is hexaethynylbenzene (**63**), which has been synthesized by Vollhardt et al.[188] The model compound **64** for another substructure in the network remains elusive since Eglinton–Glaser coupling of *o*-diethynylbenzene only leads to a dimer, not a trimer.[136, 189]

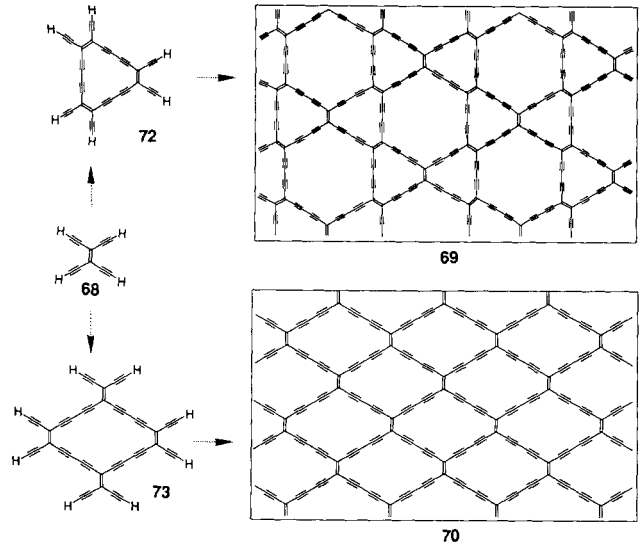


Scheme 28. From cyclo[12]carbon (**65**) to graphyne (**66**). Macrocycle **67** is a known model compound for the substructure of **66**.

The highly strained and presumably highly reactive cyclo[12]carbon (**65**) is a potential monomeric precursor which could undergo a controlled trimerization to yield the 2-D network **66** known as "graphyne" in the literature.[6] The formation energy calculated for **66** in the solid state, 12.4 kcal mol^{-1} per C atom, is quite low. Graphyne has been predicted to be a semiconductor with a large bandgap and to show interesting nonlinear optical properties including large third-order susceptibility.[6] A known stable model for a substructure of **66** is the stable tribenzohexadehydro[12]annulene **67**.[190]

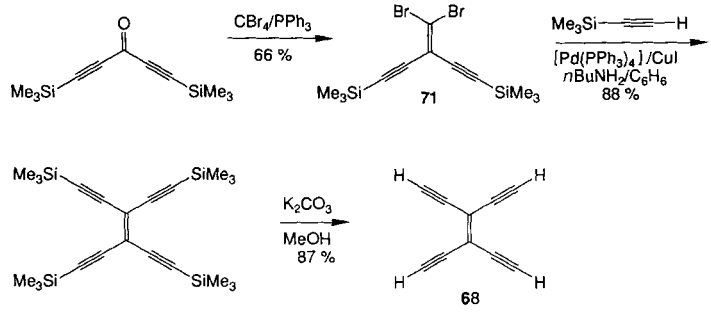
5.2. Two- and Three-Dimensional Carbon Networks Derived from Acyclic Acetylenic Precursors

Two fascinating planar carbon networks, **69** and **70**, characterized by the absence of significant strain in individual angles and bonds may be derived potentially from the monomer "tetraethynylethene" (3,4-diethynyl-3-hexene-1,5-diyne) **68** (Scheme 29). This cross-conjugated molecule was



Scheme 29. Planar networks derived from tetraethynylethene **68**.

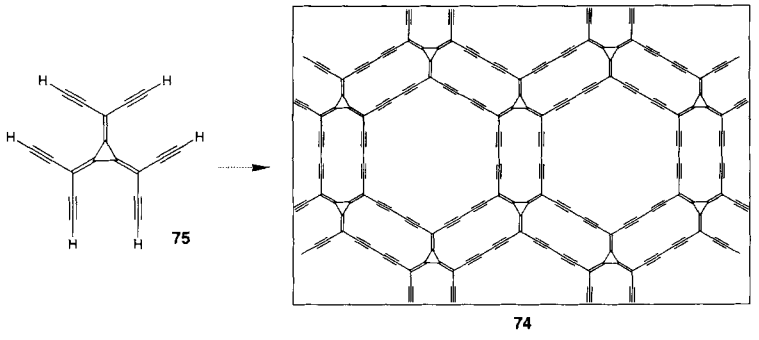
elusive for many years[191] until its synthesis was accomplished in 1991 (Scheme 30).[192] Its simple IR spectrum is characterized by four major bands which were assigned to the C–H stretch (3307 cm^{-1}), the C≡C stretch (2102 cm^{-1}) and the two coupled C–H deformations (symmetric and antisymmetric, 653 and 632 cm^{-1}, respectively). Recent ab ini-



Scheme 30. Synthesis of tetraethynylethene **68**.

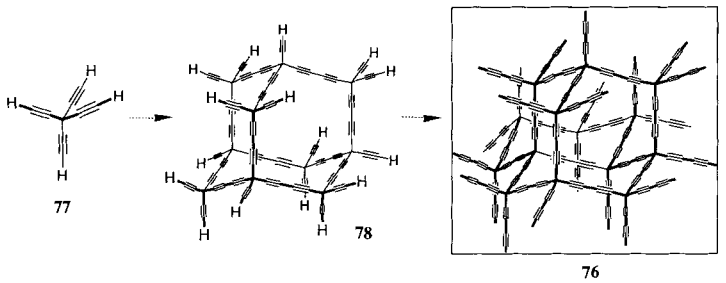
tio calculations support this assignment.[193] Rather than attempting to produce solid material with high crystallinity by oxidative coupling of tetraethynylethene, we are currently pursuing synthetic routes via the cyclic hexaethynyl and octaethynyl monomers **72** and **73**, both worthwhile target molecules in their own right.

Another interesting network structure, **74**, is derived from the [3]radialene **75** (Scheme 31), which in turn would be prepared from dibromide **71** following the radialene synthesis starting from 1,1-dibromoolefins described by Iyoda et al.[194]



Scheme 31. Planar networks derived from radialene **75**.

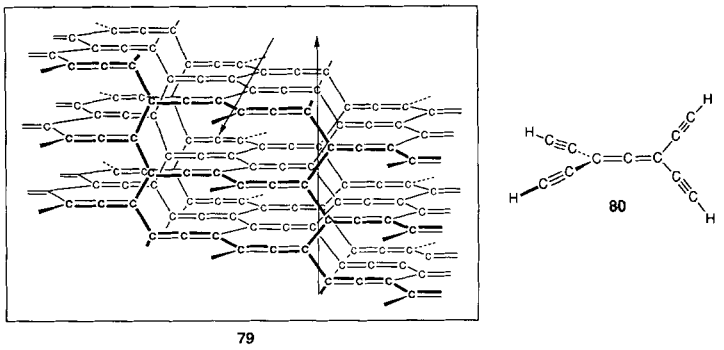
The networks **69**, **70**, and **74** represent structures that are under investigation in our laboratory. Undoubtedly, the readers of this article can imagine many more polymeric all-carbon structures that would present true synthetic challenges and may give rise to materials with unusual properties. Among the possible three-dimensional lattices,[6, 7, 12, 42, 43] the "superdiamond" structure **76** is of particular interest since, with its lack of extended acetylenic π conjugation, it can be expected to be quite stable. Several attempts to prepare the monomeric precursor "tetraethynylmethane" **77** (Scheme 32) have not been successful.[44, 195] A



Scheme 32. From tetraethynylmethane **77** to a "superdiamond" network **76**.

number of polyethynyl building blocks are currently being developed as monomers for all-carbon networks or for rigid polymers with a high C:H ratio.[196, 197] The expanded hexadecaethynyladamantane **78** en route to **76** is another interesting target molecule.

Finally, the carbon frame of allene is the monomeric subunit in yet another three-dimensional lattice (Scheme 33). The network **79** was recently proposed by Elguero et al.[198] and is closely related to the structure introduced earlier by

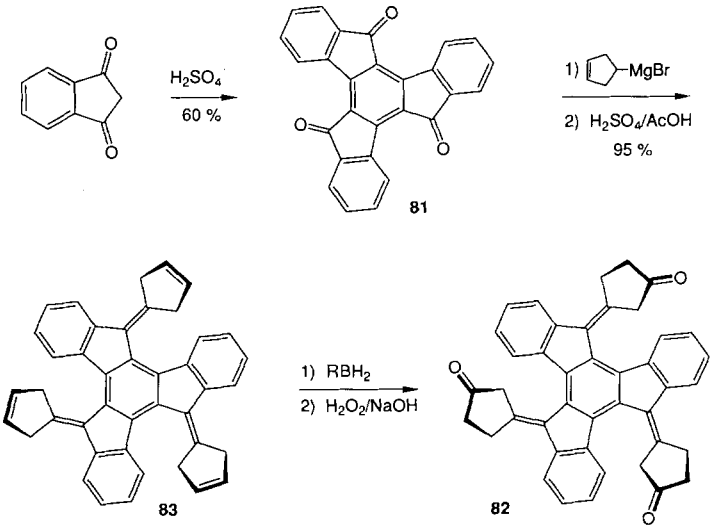


Scheme 33. A three-dimensional allenic carbon network **79**. Arrows indicate the directions of the orthogonal chains of sp^2-hybridized carbon atoms in the lattice [198]. A network similar to **79** can be constructed from tetraethynylallene **80**, yet unknown.

Hoffmann (Scheme 3c). In both systems, orthogonal chains of sp^2 carbon atoms extend across the network; in the earlier structure, these chains are directly interconnected, whereas in **79** they are separated by allenic sp-hybridized carbon atoms. A network related to **79** but derived from the elusive tetraethynylallene **80**[44a] has become of interest to us. The oxidative coupling of monomer **80** could lead to a structure similar to **79** but with butadiyne segments ($-C\equiv C-C\equiv C-$) instead of single bonds between the sp^2 carbon atoms in the orthogonal chains.

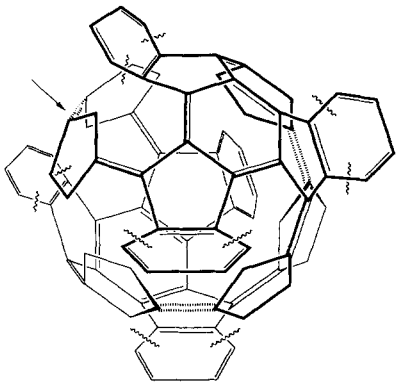
6. Toward a Total Synthesis of C_{60}

The greatest preparative challenge in organic chemistry today is the "classical" total synthesis of C_{60}! Since 1981, Chapman and his group at UCLA have explored a variety of synthetic routes to buckminsterfullerene.[46] Among them was the attempted preparation of the soccerball from two halves, each containing 30 of the 60 carbon atoms required (Schemes 34 and 35).[46c] In this approach, the triketone **82** could yield a spherical structure with 60 carbon atoms cor-



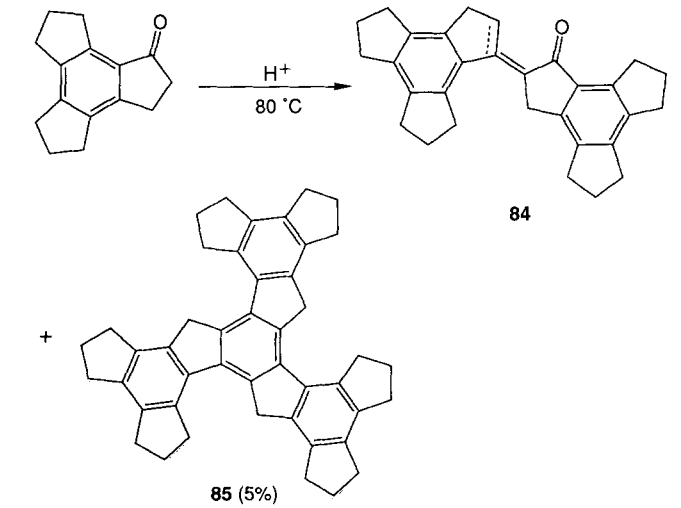
Scheme 34. Synthesis of the triketone **82**, a possible precursor in the [30C + 30C] route to C_{60} [46c, 199]. R = 1,1,2-trimethylpropyl (thexyl). The conversion of **83** to **82** proceeds in low yield.

rectly positioned for closure to C_{60} through a threefold McMurry coupling reaction (Scheme 34). Compound **82**[199] containing six of the twelve five-membered rings in C_{60} was synthesized from 1,3-indanedione in only a few steps via the novel hydrocarbon **83**, a severely distorted nonplanar[200] molecule according to X-ray crystallographic results.[46c]



Scheme 35. Assembly of a spherical precursor of C_{60} by threefold McMurry coupling of two molecules of triketone **82**[46c,199]. The arrow indicates the site of the McMurry coupling.

The synthetic route to C_{60} depicted in Schemes 34 and 35 is based on a geometrical [30C + 30C] partition of the carbon sphere. Buckminsterfullerene could also be constructed according to a geometrical [15C + 45C] partition. For such a synthetic approach, compound **84** was prepared as precursor to the C_{45} fragment **85**, which was also obtained in small yield in the condensation reaction (Scheme 36).[201]

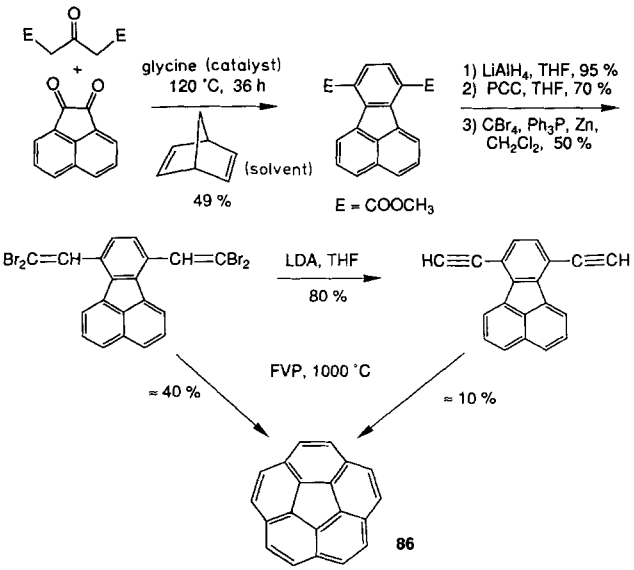


Scheme 36. Synthesis of ketone **84**, a precursor of the C_{45} fragment **85** in a [45C + 15C] approach to C_{60}[201]. The isomer of **84** with an exocyclic double bond is formed in 15% yield, that with an endocyclic double bond (double bond shown as a broken line) in 24% yield.

Are there more facile synthetic approaches to the fullerene framework? The chemistry of the cage hydrocarbons[202] reveals that the hypersurface for rearrangements of $C_{10}H_{10}$ has a minimum for adamantane and the hypersurface for rearrangements of $C_{20}H_{20}$ for dodecahedrane.[203, 204] Could the hypersurface for similar rearrangements of C_{60}, starting from functionalized or hydrogenated spherical or curved molecules with 60 carbon atoms, have a minimum for the soccerball structure of buckminsterfullerene? The removal of functional groups or hydrogen atoms at the end of such a synthesis should not be problematic. Many of the C_{60} derivatives prepared so far lose their functional groups under mild thermolysis conditions to regenerate the intact fullerene.[18i, 131, 205, 206] Therefore, the main question open is to what extent a molecule with 60 carbon atoms must resemble a soccerball to be able to undergo rearrangement into buckminsterfullerene. This question seems intimately connected to the mechanism for the exclusive formation of C_{60} by the Krätschmer–Huffman method in which the C atoms are arranged in the shape of a truncated icosahedron.[36c]

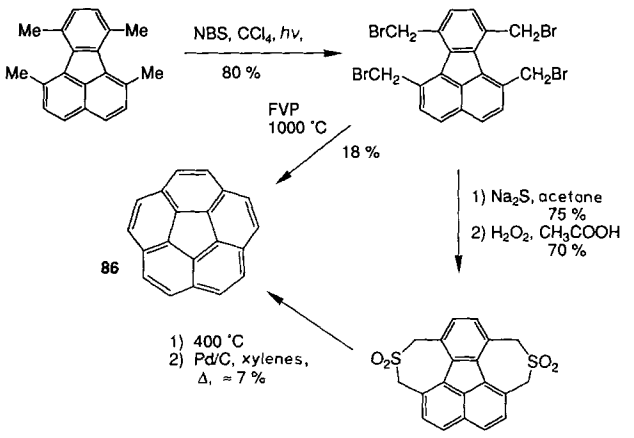
In FT mass spectrometric studies of the cyclocarbons C_{18}, C_{24}, and C_{30}, unexpected and fascinating ion–molecule reactions were observed leading from the all-carbon rings to fullerene ions.[69, 207] Cyclo[30]carbon, generated from the carbon oxide **33**, forms almost exclusively C_{60}: the observed typical fragmentation pattern showing successive losses of C_2 identifies the new ion as a fullerene. The smaller ring C_{24}, obtained from the oxide **32**, undergoes dimerization to C_{48}, followed by trimerization to C_{72} which, upon loss of one C_2 unit, generates almost exclusively fullerene C_{70} and no C_{60}.[207] Although caution is advised in deriving conclusions for syntheses on a preparative scale, the results of these ongoing gas-phase studies suggest that buckminsterfullerene could eventually be prepared by trimerization of suitable molecules with 20 carbon atoms followed by rearrangement and, if necessary, loss of residual functional groups.

Perhaps the best molecule for testing this hypothesis is corannulene (**86**, $C_{20}H_{10}$),[208, 46a] another key substructure of C_{60} in addition to pyracylene (**57**).[209] The connection of three corannulenes to a [0.0.0]corannulenophane would generate a spherical $C_{60}H_{24}$ molecule which could be rearranged and dehydrogenated to produce buckminsterfullerene. Until



Scheme 37. Corannulene synthesis by Scott et al. [46a, 208b]. PCC = pyridinium chlorochromate, LDA = lithium diisopropylamide. FVP = flash vacuum pyrolysis.

recently, the bowl-shaped corannulene was only available through the remarkable 17-step synthesis (0.40% overall yield) developed in 1966 by Barth and Lawton.[208a] The short and high-yielding new syntheses of corannulene (Schemes 37 and 38), recently developed by Scott et al.[208b] and Siegel et al.,[208c] now open the possibility of testing its potential as a precursor to C_{60}.



Scheme 38. Corannulene synthesis by Siegel et al. [208c]. NBS = *N*-bromosuccinimide.

7. Preparation of Fullerenes: Resistive versus Arc-Heating of Graphite

Since the discovery made by Krätschmer and Huffman,[13] the methods to prepare and purify fullerenes have been further developed and improved in many research groups. The most popular preparations of C_{60} and the higher fullerenes today are the original resistive heating[13, 210] and the arc-heating of graphite under inert atmosphere.[17a, 205a] A convenient benchtop reactor has been developed for the resistive heating process.[211] In other experiments, macroscopic quantities of the fullerenes have been prepared in oxidizing benzene flames,[212] and recently, by evaporation of graphite or amorphous carbon in a high-frequency oven.[213]

A great variety of chromatographic techniques have been applied to the separation of fullerenes. Good separations of C_{60} and C_{70} are obtained by gravity chromatography on neutral alumina with toluene/hexane solvent mixtures.[214] When this chromatography is done in a Soxhlet apparatus, the solvent quantities needed are reduced and the solvent can be efficiently recycled.[215] Separations of the higher fullerenes have been particularly successful by high-performance liquid chromatography (HPLC) on C18 reversed-phase columns with a diversity of eluents, for example toluene/acetonitrile, toluene/methanol or pure CS_2.[23, 24, 25b, 26] The two most abundant fullerenes, C_{60} and C_{70}, have also been separated on Pirkle columns with hexane as the mobile phase.[216a, b] Successful separations of these two fullerenes have also reported with graphite as the chromatographic support.[216c]

The application of most of the above methods to large-scale separations (> 500 mg) is limited by the low solubility of the fullerenes in the solvent mixtures chosen as eluents. For the separation of larger fullerene quantities, gel permeation chromatography with pure toluene as the mobile phase seems particularly effective.[217] Nonchromatographic methods[218] could provide valuable alternatives for fullerene separations. The preparation and X-ray crystallographic characterization of a 3:1 clathrate between hydroquinone and C_{60} by Ermer suggests the exploration of size-selective clathrate formation as an economic method for bulk separations of fullerenes.[219]

It was quite unexpected to find that the two most common methods for fullerene production, the resistive and arc-heating of graphite, lead to distinctively different product distributions. The soot produced at UCLA by the resistive heating of graphite contains C_{60} ($\approx$65%) and C_{70} ($\approx$30%) as the most prominent components together with approximately 5% of higher fullerenes.[18d] Among the higher fullerenes, chiral D_2-C_{76} is the most abundant[23] followed by the C_{78} and the C_{84} fractions. The C_{78} fraction contains the two isomers C_{2v}-C_{78} and D_3-C_{78} which were separated and isolated in pure form.[24] Very minor fractions that could be isolated comprise the higher fullerenes C_{90} and C_{94}.[25a] A more recent analysis of the fractions of the larger fullerene also indicates formation of C_{96} in quantities similar to those of C_{90} and C_{94}.[220] Fractions of C_{82}, which prefers forming endohedral complexes (Section 4.2.2), and C_{74} are so small that these fullerenes could not be isolated; the formation of minuscule amounts of these carbon spheres is only evident from mass spectrometric studies.[220]

Very different results were obtained by the group of Achiba et al. who produced soot by arc-heating of graphite.[26] These researchers isolated a significant amount of C_{82} and showed by ^{13}C NMR spectroscopy that among several isomers a C_2-C_{82} isomer with 41 independent resonances is the most abundant.[221, 222a] Besides the two isomers of C_{78} found by the UCLA group, Achiba et al. isolated an additional third. This isomer also has C_{2v} symmetry and is the most abundant one in the product mixture.[222b] Interestingly, although the UCLA group did not find this isomer, they predicted it by MM3 calculations to be the most stable one.[24] As an additional difference in the product distribution, arc-heating of graphite seems to produce significantly larger quantities of C_{90} and C_{96}. Also, fullerenes C_{76}, C_{78}, and C_{84} are obtained in similar yield.[26b] Both methods lead to the same C_{84} fraction containing as isolable isomers a D_2- (21 resonances in its ^{13}C NMR spectrum) and a D_{2d}-symmetrical isomer (11 resonances in its ^{13}C NMR spectrum).[222, 223]

All higher fullerenes isolated and characterized by Diederich et al. and Achiba et al. obey the "isolated pentagon" rule,[22, 184, 224] that is, all twelve pentagons are fully annelated by hexagons, yielding corannulene substructures. Therefore, this rule provides a rigorous guidance for identifying stable fullerene structures. The major difference in the product distribution obtained by the resistive and arc-heating methods awaits explanation. It clearly suggests that other processes for fullerene preparation could well lead to other product distributions with higher yields of the very large fullerenes with more than 100 carbon atoms, which so far have been isolated only as mixtures.[25a, c] The origin of the observed product distributions is obviously closely related to

the mechanisms of fullerene formation by resistive or arc-heating of graphite. The elucidation of these mechanisms[11, 17a, 18a, 24, 25a, 184g–i, 225] is one of the most ambitious as well as rewarding intellectual and experimental challenges in fullerene chemistry as well as in carbon chemistry in general.

8. Conclusions

With the spectacular discovery of a method for the bulk preparation of fullerenes by Krätschmer and Huffman, the chemistry and physics of carbon allotropes, which had been pursued in laboratories worldwide since the 1940s, has moved into the center of scientific interest. Efforts to prepare molecular and polymeric carbon allotropes such as the cyclocarbons and the networks discussed in this review are now rapidly expanding in many organic laboratories. As a result, macroscopic quantities of other fascinating synthetic all-carbon structures should soon become available. From this research, major fundamental and technological advances can be expected in the coming years. This optimism is based on the explosive growth of exciting discoveries since the end of 1990 when bulk quantities of the fullerenes became available. Since then, unprecedented structures of carbon-based matter have been explored, extending from the highly symmetrical C_{60} with the shape of a truncated icosahedron[13] to the chiral, doubly helical fullerene C_{76},[23] tubular carbon fibers,[226, 227] and three-dimensional carbon networks displaying the negative curvature of a saddle, instead of the positive curvature of the fullerenes.[228] The synthesis and study of alkali metal doped fullerene superconductors,[18e, 229–231] the preparation of a fulleride-based organic ferromagnet,[232] and the conversion of fullerenes into diamond[233] are only the tip of the iceberg in discoveries with high technological potential.

Several conclusions can be drawn from the ongoing research on fullerenes and other all-carbon molecules and networks. The successful exploration of the chemistry, physics, and materials properties of these compounds requires a highly interdisciplinary approach. Therefore, research in this area contributes to breaking down the artificial barriers of communication between faculty and students in departments and between departments. This way, synthetic chemists may discover techniques familiar to their colleagues in physics, physical chemistry, or material sciences, and test them as new methods to prepare new molecules. Examples for such cross-fertilization are the laser flash heating used for the generation of cyclo[18]carbon by means of the retro-Diels–Alder reaction, and the Krätschmer–Huffman process for fullerene production. The discovery of the latter suggests that other unconventional preparative techniques may be found in interdisciplinary collaborations, and entire classes of new compounds might become accessible by crossing the boundaries of classical synthesis. The ongoing work on synthetic carbon allotropes also sends a strong message to chemists interested in organic synthesis. Organic synthesis and the development of synthetic methodology are alive and well in organic materials sciences. Challenges in this future-oriented field easily rival those in the more established direction of natural product synthesis. Therefore, it is hoped that, in view of the great technological potential of new carbon allotropes, more synthetically oriented chemists will decide to pursue careers in this worthwhile direction.

This work would not have been possible without the generous support of the National Science Foundation and the Office of Naval Research. Additional funding was provided by the Petroleum Research Fund administered by the American Chemical Society, and by NATO and the Grand-Duchy of Luxemburg. Another important factor for the development of this research was the stimulating environment provided by the students and faculty in the Department of Chemistry and Biochemistry at UCLA. We are particularly grateful to Professors Orville Chapman, Ken Houk, and Robert L. Whetten for their continuing interest in this work. We warmly thank Drs. Roland Ettl and Carlo Thilgen, and John Anthony, Armen Boldi, Nancy Goroff, and Sophia Lin for their contributions to the science described in this article. Special thanks go to Dr. Carolyn B. Knobler for providing us with important structural information by solving the X-ray crystal structures of key molecules.

Flexible Molecules with Defined Shape—Conformational Design

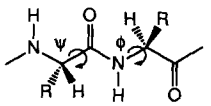
By Reinhard W. Hoffmann*

Chemists have for a long time considered molecules simply in terms of their constitution. The importance of molecular shape was recognized perhaps for the first time by the semiochemists, who were interested in the interactions of fragrant substances with a receptor. Apart from the case of rigid molecules, our ideas and concepts of molecular shape simply reflect an instantaneous situation, because flexible molecules take advantage of the whole range of conformation that is available to them. Nature frequently utilizes flexible molecules whose conformational space is restricted, in other words, molecules that can adopt only a few preferred conformations. This review discusses some of the principles that nature employs in order to impart a defined shape to flexible molecules. The purposeful application of these principles then allows the conformational design of molecular skeletons.

1. Introduction

The biological activity of many natural and synthetic substances is based on the fact that they bind to a receptor by the interaction of specific functional groups. The receptors have binding sites situated either in a pocket, in a cleft, or on the surface. For optimal binding the functional groups of the active substances complementary to those in the binding site must have or adopt a specific spatial arrangement. In only a few areas of biochemistry does nature use active substances that are predominantly rigid, such as steroids. Often conformationally flexible substances are involved, which nonetheless adopt a specific preferred conformation,[1] in other words, they take on a defined shape. If the preferred conformation of the active substance is also that required by the receptor, then the free energy of binding becomes more favorable in terms of both entropy and enthalpy. On the other hand, the conformational mobility allows the particular substances to diffuse rapidly into and out of the receptor.[1]

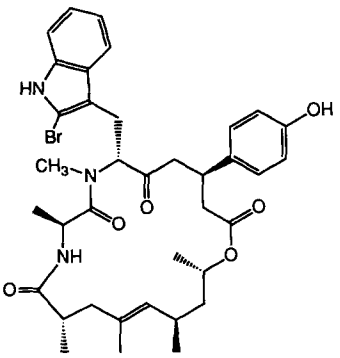
The principles according to which nature imparts a defined shape to such molecules while largely preserving their conformational mobility are of interest. In the case of proteins and oligopeptides these principles are generally known: the amide bond in these substances exists in the preferred conformation **1** and has, thanks to the partial double-bond character, a rotation barrier of approximately 20 kcal mol^{-1}.[2]



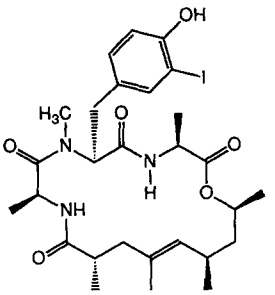
1

Although rotation about the amide bond is certainly still possible, at any given moment the preferred conformation is adopted almost exclusively. Preferred conformations exist also along the other N–C_α (dihedral angle ϕ) and C_α–C=O (dihedral angle ψ) skeletal bonds. Which preferred conformation is adopted in any particular case depends among other things on the nature of the side-chain groups R. It is known, for example, which amino acid sequences result as a rule in the formation of an α helix or a β turn or, again, which are typical of β-sheet structures.[3] In the area of the polypeptides one has therefore a general understanding of how structural elements affect the secondary structure, an understanding that can be utilized in designing peptide-like active substances.[4]

In the case of a biologically active substance that binds to the receptor by a short peptide sequence, it should be irrelevant whether the remainder of the molecular skeleton is a continuation of the peptide chain[1] or has another structure,[5, 6] as long as this produces a specific shape of the overall molecule. Substances such as jaspamide (**2**)[7] or geodiamolide A (**3**)[8] illustrate this clearly.



2



3

It may be concluded that the (propionogenic) partial structures in **2** and **3** derived from the fatty acid metabolism adopt quite specific preferred conformations as a consequence of the existing stereocenters, despite their obviously unrestricted conformational mobility. Chemists dealing with polyketide natural products are of course fully aware of this.[9] The principles illustrated in nature could thus be utilized, and indeed should also be developed further, in order to impart a specific shape to arbitrary molecular skeletons while retaining conformational mobility. These principles are a) the avoidance of g^+g^- interactions[10] and b) the avoidance of allylic 1,3 strain.

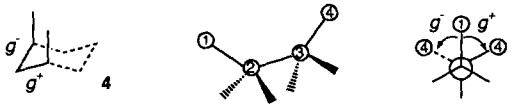
2. g^+g^- Interactions as a Conformation-Determining Factor

The g^+g^- interaction (also termed *syn*-pentane interaction) brings two methyl (alkyl) groups, for example the methyl groups of *n*-pentane (see **4** in Scheme 1) into such spatial proximity as to produce a destabilizing steric interaction. The nature of the interaction is well known in the form

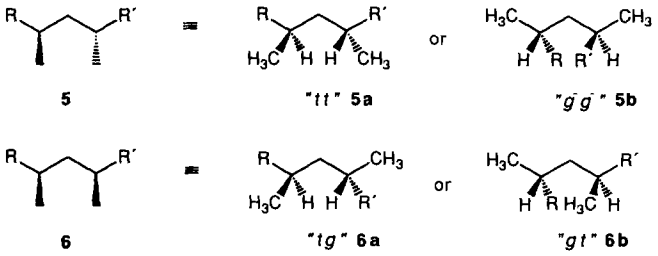


Scheme 1. Left: Conformation of *n*-pentane (**4**) leading to g^+g^- interactions. The cyclohexane ring drawn in dashed lines points out the analogy to 1,3-diaxial interactions. The g^+ and g^- interactions are defined with the help of sawhorse (middle) and Newman projections (right).

of the 1,3-diaxial interaction in cyclohexane derivatives. The term g^+g^- interaction derives from the fact that the conformation of a molecule can be given as a sequence of the dihedral angles of the principal chain. With a dihedral angle of about 60° one has a *gauche* arrangement; with a dihedral angle of +60° one speaks of g^+, with one of −60°, of g^-. A dihedral angle of 180° corresponds to a *trans* arrangement (*t*) of the chain. The sign of the dihedral angle is independent of whether the chain is analyzed from C1 to C4, or vice versa. The arrangement in structure **4** is characterized, when one looks at the principal chain of the molecule, by a g^+ dihedral angle followed by a g^- dihedral angle.

Calculations[11] and experiments[12] show that a 1,3-diaxial interaction of two substitutents on a cyclohexane ring produces a destabilization of approximately 2.6–6.2 kcal mol^{-1}. This would also apply to the *syn*-pentane conformation **4** compared to the all-*trans* chain,[13, 14] if the molecule did not decrease this strain by opening the dihedral angle to 80–95°.[14–17] Nevertheless, the relaxed g^+g^- interaction still produces a destabilization on the order of 1.4–3.0 kcal mol^{-1}.[10, 15, 18] The consequence of this is evident in the partial structures **5** and **6**, which in each case can adopt only two conformations that are free of g^+g^- interactions[9b] (Scheme 2, see also ref.[19, 20]).

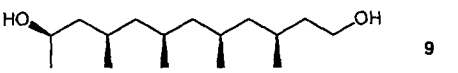
The structural elements **5** and **6** are typical of propionogenic natural substances. An evaluation of the X-ray structure analyses of 30 arbitrarily chosen compounds containing the partial structure **5** or **6** showed that in 46 out of 51 of these structural elements the specific conformation adopted



Scheme 2. **5a, b** and **6a, b** are the only conformations of **5** and **6** without g^+g^- interactions.

is one in which the g^+g^- interaction is avoided. This is demonstrated very clearly in the structure of a derivative of bougeanic acid **7**[21] and in the partial structures of ionomycin (**8**)[22] (Fig. 1).

Compounds with the unit **5** thus have a straight main chain (*tt* conformation **5a**, eight of thirteen cases, dihedral angles 170 ± 9°) or more rarely (five of thirteen cases, dihedral angles 68 ± 11°) a doubly bent chain (g^+g^+ or g^-g^- conformation). The unit **6** necessarily leads to a simple bending of the main chain (*tg* conformation, 33 cases, dihedral angles 171 ± 6°; 62 ± 8°). The structural formulas of a number of pheromones suggest that these molecules may have a specific folding pattern despite complete conformational mobility. For example, the shape of lardolure (**9**)[23] may well be essential for its biological signaling action. Epimers of **9**[24] having other preferred conformations of the chain are ineffective.



The different preferred conformations of the partial structures **5** and **6** have been known already for a long time from polymer chemistry. **5** corresponds to the repeating unit in syndiotactic polypropylene, which exists either as an all-*trans* chain[25] or as a ttg^+g^+ helix **10**.[26] **6** corresponds to isotactic polypropylene, in which the direction of the chain changes at every other double bond in order to avoid g^+g^- interactions. The resulting $tg^+tg^+tg^+$ conformation likewise leads to a helical structure **11**[27] (Scheme 3).

The stereotriads **A**–**D** frequently occur as structural elements in propionogenic natural substances.[28] Whitesell and Hildebrandt[29] pointed out that these partial structures have quite specific preferred conformations. An inspection

Reinhard W. Hoffmann was born in Würzburg, Germany in 1933. He studied chemistry at the University of Bonn and gained his doctorate in 1958 for research conducted with B. Helferich. After two years as a postdoctorate with G. W. Brindley at the Pennsylvania State University, he became an assistent to G. Wittig at the University of Heidelberg, where he habilitated in 1964. Three years later he was appointed as Dozent at the Technische Hochschule in Darmstadt. He has been professor at the University in Marburg since 1970. At various times he has been a guest professor at the University of Wisconsin, the University of Bern, and the University of California at Berkeley. He is currently interested in developing methods for stereoselective C–C bond formation and exploring their applications in natural products synthesis, as well as generally studying the stereochemistry of reactive organometallic compounds.

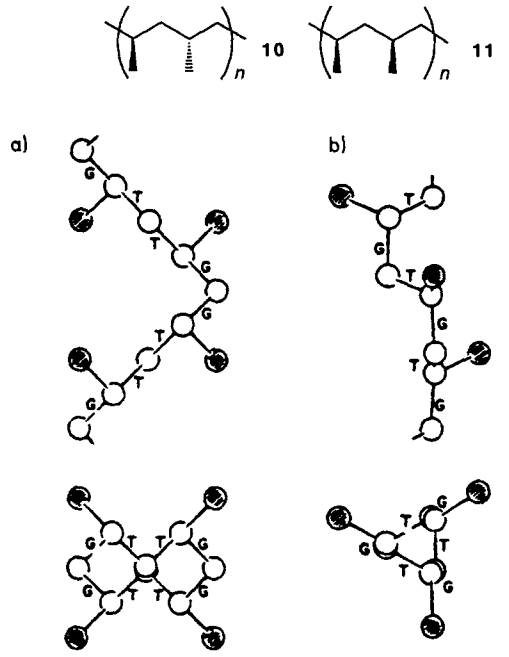
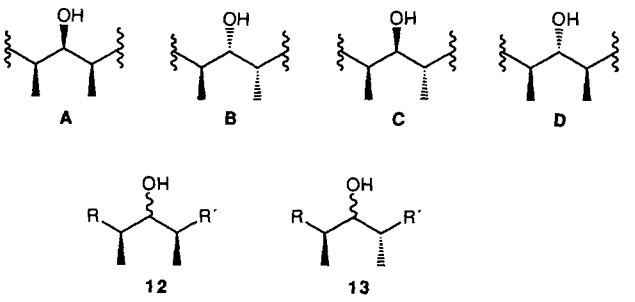
of the crystal structures of a random selection of 26 compounds with these structural elements show that the conformation of the main chain is again mainly determined by the methyl branchings, as in the case of **5** and **6**. In this respect only the structural types **12** and **13** are significant with regards to conformation. The hydroxyl groups are oriented outward into the free space independent of their relative configuration, even in the case of folded chains, and may interact either intramolecularly or intermolecularly.



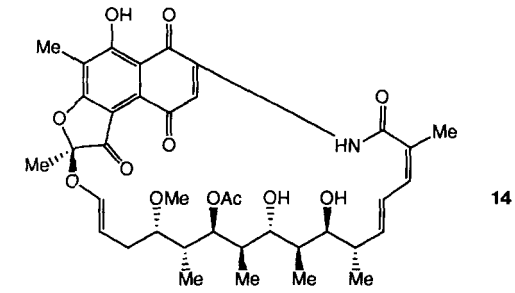
Scheme 3. a) Helical conformation of syndiotactic polypropylene **10** and b) of isotactic polypropylene **11**. T = *trans*, G = *gauche*.

If several hydroxyl groups on the main chain are at the relative positions 1 and 3, the conformation of the main chain can be stabilized additionally by hydrogen bonds if the hydroxyl groups have an appropriate spatial arrangement;[30] see for example the partial structures of rifamycin (**14**)[31] or zincophorin (**15**)[32] (Fig. 2).

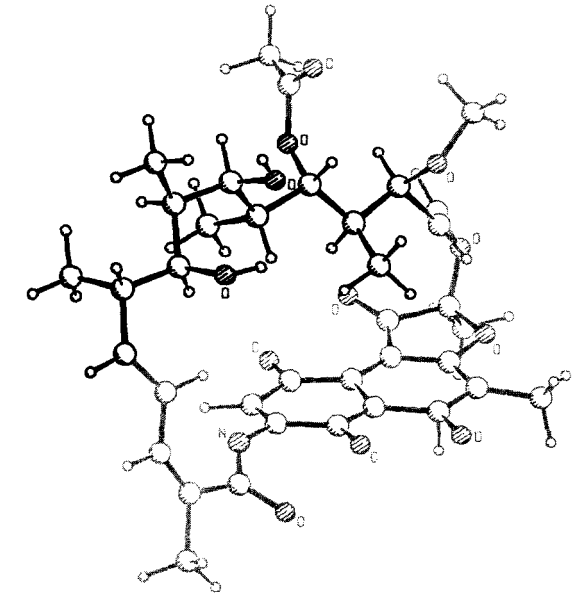


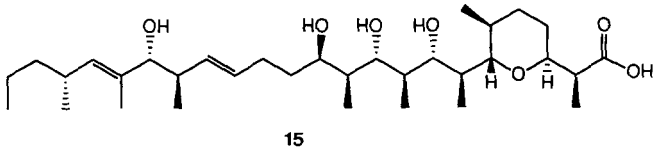
In the area of propionogenic natural substances, compounds are also found in which the conformational mobility of the main chain is restricted, but not suppressed, by a fused six-membered ring, as for example in the partial structures **16** and **17**.

Firl and Kresse et al.[33] showed by NMR investigations on terpenes that for these partial structures the illustrated conformations are largely populated, in other words, exactly those conformations in which a g^+g^- interaction is avoided. Thus, the equatorial (in **16**) or axial (in **17**) position of the substituent R determines the preferred conformation along the C2–C7 bond. This was subsequently discussed in detail also by Kishi et al.[34] and Sih et al.[35] Similar effects were also observed in five-membered ring lactones.[36] Finally, 14 randomly chosen X-ray structure analyses of propionogenic natural substances show that corresponding partial struc-



14





15

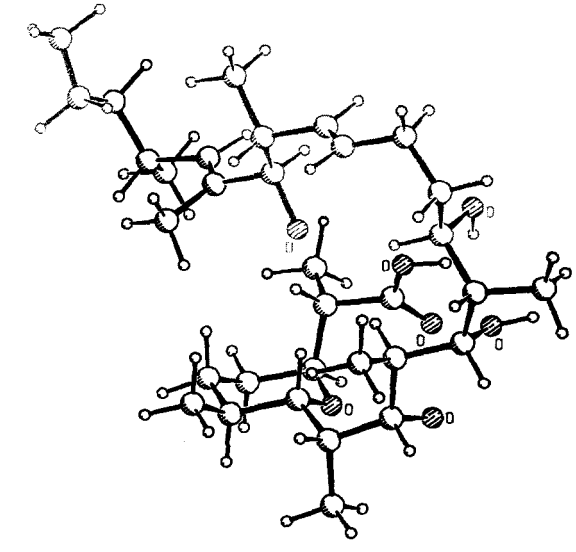


Fig. 2. Because of the appropriate spatial arrangement of OH groups, the conformations of rifamycin S (**14**, top) and zincophorin (**15**, bottom) are additionally stabilized by hydrogen bonds.

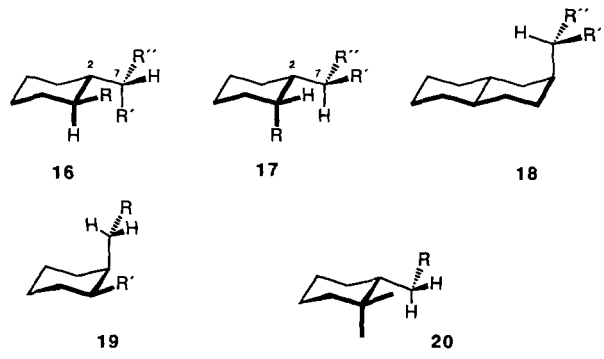
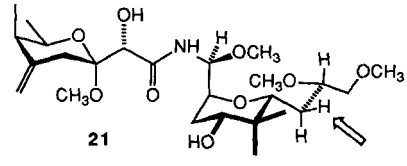
tures exist in exactly these conformations. One should keep in mind that, notwithstanding the preference for these conformations, both inversion of six-membered rings and rotation about the exocyclic bonds are fully possible at ambient temperature.

Allinger et al.[37] referred early on to the fact that a branched side chain in an axial position on a six-membered ring, as in **18**, adopts only a single preferred conformation in order to avoid g^+g^- interactions.[38] This arrangement[39] is found for example in the structure of zincophorin,[32] (see Fig. 2 bottom). However, even an unbranched axial side chain can be fixed in space if an equatorial group is present in the adjacent position, as in **19**.[9b] Essentially, this is a

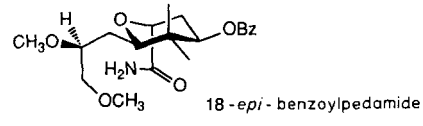


special case of the *gem*-dimethyl effect.[40,41] Likewise, a defined orientation of an unbranched, equatorially situated side chain can be achieved if it is located adjacent to a disubstituted ring position, as in **20**. This relates to structural elements that occur, for example in pederin (**21**),[44] onnamide,[45] mycalamide,[46] and bryostatin.[47] A section of



21

the crystal structure of 18-*epi*-benzoylpedamide[48] illustrates this effect clearly (Fig. 3).



18-*epi*-benzoylpedamide

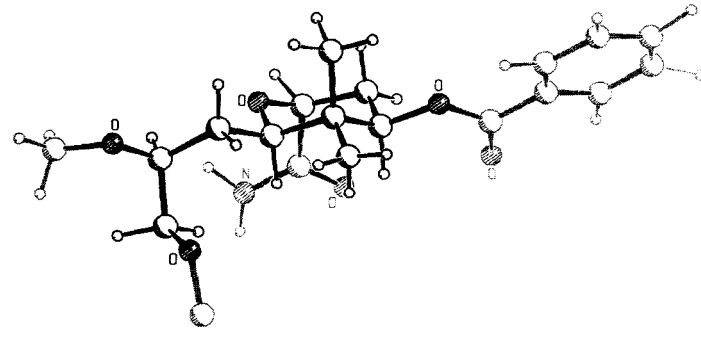


Fig. 3. Chemical formula and crystal structure of 18-*epi*-benzoylpedamide. The orientation of the side chain is dictated by the two neighboring *gem* methyl groups.

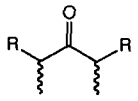
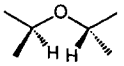
In the structures examined hitherto the central atom of the partial structures **5** and **6** was sp^3-hybridized. If it is sp^2-hybridized as in **22**, the central bond angle is larger, so that the methyl groups are better able to avoid one another. An analysis of a small number of randomly selected structures of compounds of type **22** show a broad multiplicity of possible conformations. The number of conformations that can be adopted at room temperature is thus not noticeably restricted by g^+g^- interactions in this type of structure.



22

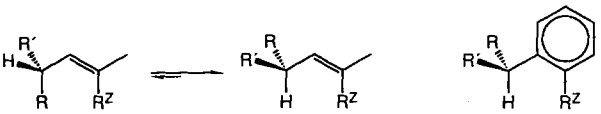


23

If the central atom of the structural units **5** and **6** is an oxygen atom, however, as in **23**, then the shorter C-O-C distances and the smaller C-O-C bond angles mean that g^+g^- interactions become more pronounced. This is reflected, for example, in the preferred conformation of diisopropyl ether **23**.[49]

3. Allylic 1,3 Strain as a Conformation-Determining Factor

Allylic 1,3 strain was defined by Johnson,[50] who stated that in partial structures of the type **24** ($R^Z \neq H$) those conformations in which the groups R and R^Z are coplanar, as in **24a**, are energetically unfavorable. The preferred conformation is **24b**, in which the H-C-C=C-R^Z unit lies in one plane.

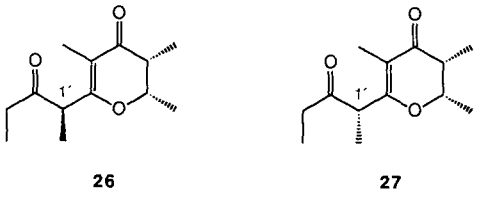


24a **24b** **25**

Recent calculations show[51] that conformation **24b** is almost exclusively populated, and that conformation **24a** is approximately 3.5 kcal mol^{-1} higher in energy. Rotation about the vinylic C–C bond is, however, fully possible at ambient temperatures. Calculations show furthermore that the potential curve for libration of the C=C-C-H dihedral angle ϕ is initially flat and increases more steeply only at $\phi > 35°$. An evaluation of about 50 crystal structures of natural substances and synthetic products with the structural element **24** shows, in agreement with this, that the dihedral angles are uniformly distributed in the range 0–30°. In individual cases values of 40° were obtained, but dihedral angles greater than 44° were not found. If the π bond in **24** is part of an aromatic system, as in **25**, then somewhat larger dihedral angles may be tolerated on account of the longer C=C bond. Values up to 48° have been found.[38, 52]

The partial structure **24** is thus a conformationally flexible element, which exists in a preferred conformation that always produces a bend in the main chain. The resulting change in the direction of the main chain is not identical to that which occurs in compounds with the partial structure **6** as discussed in Section 2.

The conformation-determining action of the allylic 1,3 strain is illustrated, for example, in the compounds stegobinone (**26**) and 1′-*epi*-stegobinone (**27**),[53] of which the former is the sex pheromone of the drugstore beetle, *stegobium paniceum*, whereas the 1′ epimer inhibits the pheromone action (Fig. 4).[54]



26 **27**

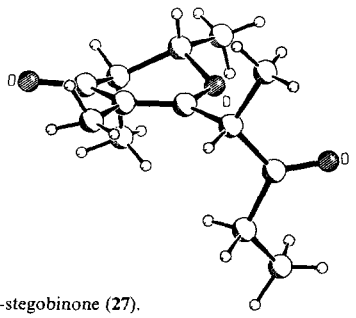


Fig. 4. Crystal structure of 1′-*epi*-stegobinone (**27**).

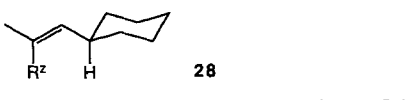
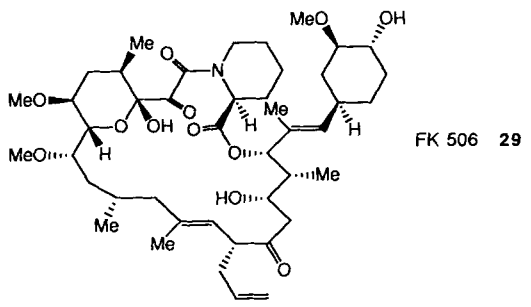
The configurational change in the transition from **26** to **27** appears at first glance to be only minor. Yet because of the allyl system, the spatial arrangement of the side chain[55] is completely different in the two epimers.[56] 2-Substituted vinyl units located in equatorial positions of six-membered rings, as in **28**, often serve to fix large structural units in natural products in an energetically preferred, spatial arrangement. Such a structural unit is found for example in



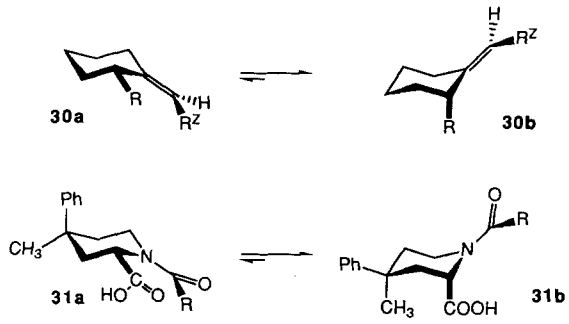
28



FK 506 **29**

FK 506 (**29**).[57] In **28** the orientations of the substituents on the vinyl group as well as those of all the bonds about the six-membered ring are set by the single preferred conformation of this structural unit.

The phenomenon of allylic 1,3 strain was originally recognized in compounds of type **30**.[50] Here, the ring substituent R prefers to adopt the axial position because of the *Z* orientation of the substituent R^Z. This also applies to amides of the type **31**, due to the double-bond character of the N–CO bond.[58] It has been known and understood for a long time that a ring substituent in the 2 position of *N*-acylpiperidines **31** preferentially adopts an axial arrangement, even if this is offset by a 1,3-diaxial interaction.



Nature utilizes this effect, as can be seen by a glance at the crystal structure of FK 506 (**29**) (Fig. 5). The COOR substituent on the piperidine ring of **29** is axial, and oriented analogously to that in conformation **31b**. A combination of

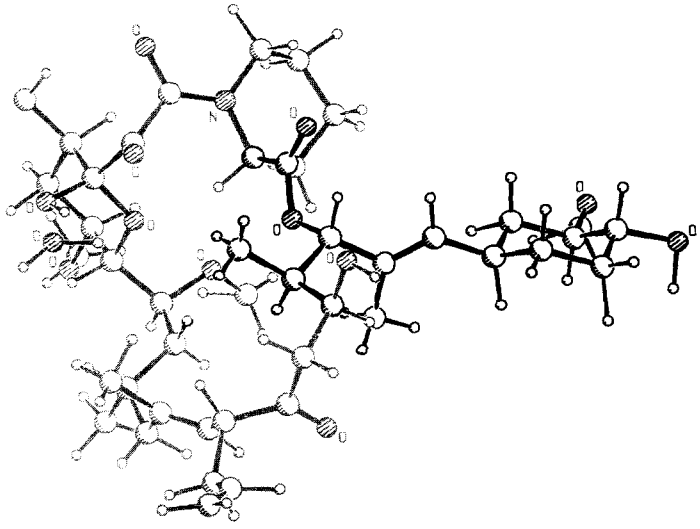


Fig. 5. Crystal structure of FK 506 (**29**). The COOR substituent on the piperidine ring is in the otherwise energetically unfavorable axial position, in order to minimize interactions with the *N*-acyl substituent.

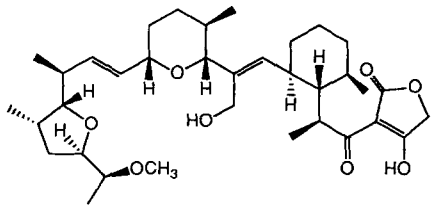
conformational control by allylic 1,3 strain with that produced by methyl substituents (avoidance of g^+g^- interactions) is found for example in the antibiotic M139603 (**32**)



M 139603 **32**

(Fig. 6).[59] One can follow through segment by segment in this structure how the substituents arranged in this particular way favor just the one conformation found in the X-ray crystal structure. Despite total conformational mobility, this conformation causes a 180° bend in the molecular backbone.

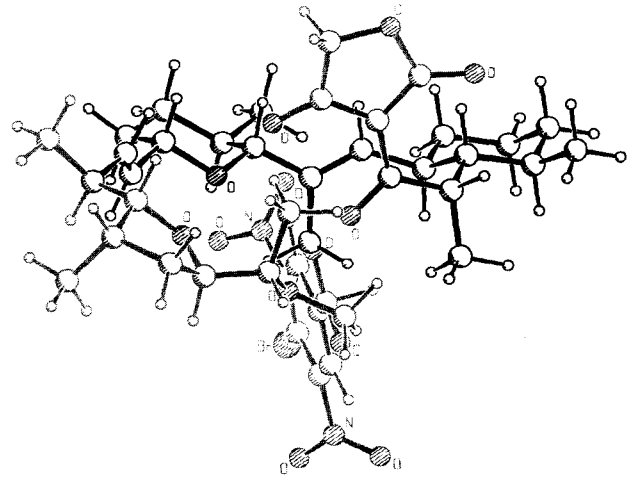


Fig. 6. Crystal structure of the antibiotic M139603 (**32**) as a 4-bromo-3,5-dinitrobenzoate. The conformation is determined by allylic 1,3 strain and the avoidance of g^+g^- interactions (CH_3 groups).

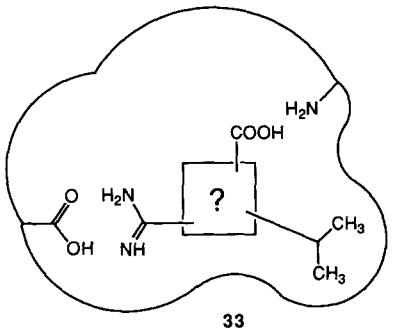
4. Conformational Design of Molecular Skeletons

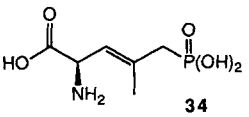
The goal of molecular design nowadays is frequently the synthesis of a complementary molecule for a receptor, so that this molecule exhibits specific functionalities in a spatial arrangement suitable for binding to the receptor. One of the problems in this connection is finding an appropriate molecular skeleton on which the bonds to the functional groups, for example to a C-NH_2 or C-COOH group (see **33**), not only have the correct spacing but are also vectorially in the correct spatial orientation. The program CAVEAT, developed by P. A. Bartlett et al.[60] (Berkeley) for this purpose, searches all structures stored in the Cambridge Structural Data File for a matching molecular skeleton. In this search it is irrelevant whether the molecular skeleton is rigid or flexible. A recent survey of peptide conformation mimetics[61] shows that up to now mainly rigid molecular skeletons have been tested in order to simulate, for example, a bend in a peptide chain corresponding to a β turn (β-turn mimetics).

An attempt could also be made in this context to connect the necessary functionalities with one another by means of a section from a diamond lattice. Assuming that this would be possible with sufficient spatial agreement, one could design a rigid, polycyclic molecule that would inevitably produce the necessary arrangement of the functional groups in space. By omitting individual skeleton bonds one by one, one would eventually reach the other extreme, namely a completely flexible chain-type molecule, which could of course adopt the desired conformation, but only as one of an almost infinite number of possibilities. The intellectual challenge now is to design, with the aid of principles illustrated in nature or developed by insight and intuition, a completely or overwhelmingly flexible molecular skeleton, which neverthe-

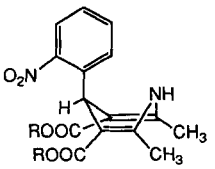
less has the desired conformation as its preferred conformation. For example, the recently described[62] antagonist **34** of *N*-methyl-D-aspartate exhibits (accidentally or intentionally) just such properties, since in **34** the allylic 1,3 strain ensures a specific preferred conformation of the molecular skeleton.



33



34



35

Likewise, the nitro group in the *ortho* position of the phenyl substituent in nifedipin (**35**) ensures, due to allylic 1,3 strain, that the phenyl ring is orthogonal to the dihydropyridine ring, an arrangement which is decisive for the pharmacological effect.[63]

4.1. Design of Preferred Conformations of a C_7 Chain; Flexible Building Blocks for Conformational Design

The chemist will be inclined to tackle a complex problem in conformational design stepwise, that is, by considering skeletal segments with specific preferred conformations. These segments could then be assembled like building blocks to form larger, realistic molecular skeletons. One could, for example, consider the C_7 chain of *n*-heptane as a skeletal segment which is long enough to illustrate repeatable units. The conformation of *n*-heptane can be described by a sequence of four dihedral angles. The 13 conformations that are free of g^+g^- interactions (see ref.[17]), as well as those with a partially relaxed g^+g^- interaction are all populated at room temperature.

The conformations of *n*-heptane without g^+g^- interactions can now be depicted on a diamond lattice.[64, 65] Scheme 4 illustrates this on the basis of the molecular skeleton of spirodiadamantane. Those conformations composed of a central *tt*, tg^+, or g^+g^+ unit are shown in separate groups. It becomes apparent that derivatives of spirodiadamantane may serve as rigid models for the conformers of *n*-heptane when a correct spatial arrangement of functional groups along a heptane chain is required.

In addition to the two extreme cases, namely the conformationally fully flexible *n*-heptane of unspecified shape on the one hand, and the completely rigid spirodiadamantane derivative with a fixed, defined shape on the other hand, flexible *n*-heptane skeletons with a defined shape should be able to be constructed according to the principles illustrated by nature (avoidance of g^+g^- interactions). In a first stage the problem can be simplified by fusing a six-membered ring to the C_7 chain. One or two dihedral angles can thus be set in a preferred conformation. Conformational mobility is retained, although restricted, about these intraring bonds as a consequence of the inversion of the six-membered ring, which is in full operation at ambient temperatures. With the fusion of a six-membered ring to the two internal bonds of *n*-heptane, a 1,3 diequatorial arrangement of substituents on the cyclohexane ring corresponds to a central *tt* conformation, and a 1,3 equatorial–axial arrangement to a central *tg* conformation. If further auxiliary substituents are attached to the ring or to positions 2 and 5 on the chain, any of the four arrangements of a C_7 chain with a central *tt* unit, or any of the six arrangements with a central *tg* unit can be rendered to be the preferred conformation (Scheme 5). Calculations with MACROMODEL[66] show that the conformation sought in each case should be populated predominantly.

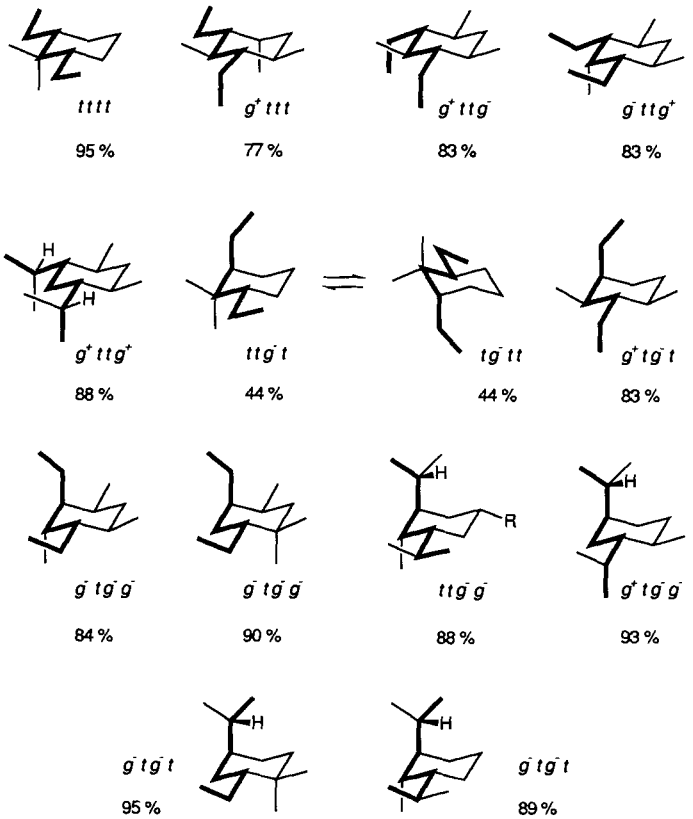
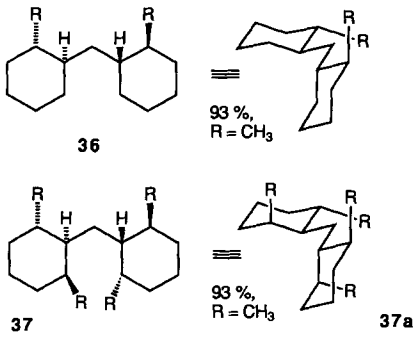
Scheme 4. Conformations of *n*-heptane without g^+g^- interactions superimposed on a diamond lattice.



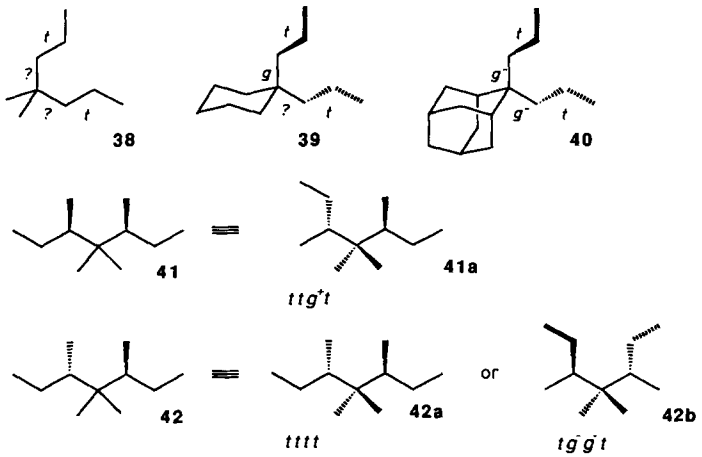
Scheme 5. Fusion of a six-membered ring to *n*-heptane. The 1,3 diequatorial orientation of the substituents on the cyclohexane ring corresponds to a *tt* conformation on the internal bonds of *n*-heptane, the 1,3 equatorial–axial orientation to a *tg* conformation.

Of course, one or both of the outer dihedral angles of the heptane chain can also be fixed in specific preferred conformations by ring fusion. For example, **36** corresponds to a chain with g^+ttg^+ conformation.

Without altering the conformational preference, two further methyl (alkyl) groups may be placed in a strategically correct manner on **36**. In the resultant compound **37**, 13 of the regular conformations of *n*-heptane can be superimposed onto the preferred conformation **37a**. The skeleton **37** thus offers numerous possibilities for spatially stabilizing specific heptane conformations, and this with unrestricted conformational mobility.



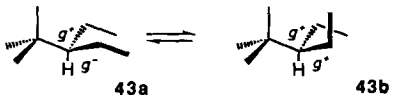
A *gem*-dialkyl substitution offers a further starting point for the conformational fixing of a heptane chain, for example at C4 in **38**. As Alder et al.[67] have pointed out, this means in the first place that the two outer dihedral angles of the C_7 chain prefer a *t* conformation (MACROMODEL calculations show a ca. 86% preference for a *t* conformation). Further methyl substituents, for example in **41**, favor the *ttgt* arrangement **41a** (74%). The isomer **42** on the other hand has, according to MACROMODEL calculations, two sets of similar, roughly equally populated conformations, namely the *tttt* arrangement **42a** and the tg^-g^-t arrangement **42b**.



If it is desired to model a heptane chain with a central g^+g^+ (or g^-g^-) conformation, the two geminal methyl groups can be replaced by a six-membered ring, as in **39**. A *g* conformation is thereby imposed on one of the internal bonds of the heptane chain. On account of the rapid inversion of the six-membered ring, a *g* conformation is then effectively preferred for both internal heptane bonds, that is, molecule **39** should exist mainly in the tg^+g^+t conformation (or the enantiomeric tg^-g^-t conformation). This can then be achieved completely by turning to the adamantane derivative **40**. This is a remarkable molecule: on the one hand rotation about all the bonds of the heptane chain is unrestricted, while on the other hand **40** has only one pair of enantiomeric preferred conformations!

The structures shown here model 11 of the 13 regular conformations of an *n*-heptane chain without g^+g^- interactions, such that the desired conformation is the preferred conformation with total or substantial preservation of the conformational mobility.

While as a rule g^+g^- conformations are energetically unfavorable if population of such a conformation chain is desired, this can be achieved by the introduction of a *tert*-butyl substituent on the chain. The molecule **43** might well exist to a large extent in the conformations **43a** and **43b**, which both exhibit a *syn*-pentane interaction.



According to DeClercq et al.[68] this "*tert*-butyl anchoring" is one way of populating the otherwise unfavorable g^+g^- conformation of a chain, so that ring-closing reactions of the chain ends are favored.

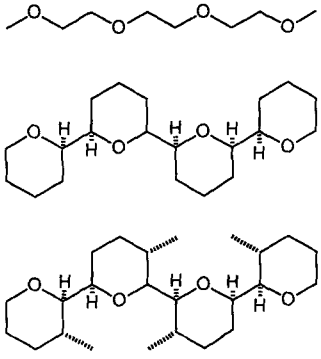
4.2. Applications of Conformational Design

The shape of a molecule and the associated spatial arrangement of functional groups are particularly important when the molecule is to be bound to another molecule or to ions. For this reason conformational design is currently used primarily in the development of host molecules for ions or amino acids.

Ligand conformation is particularly important in the development of optimum polydentate ligands. The coordination of the ligand is most favorable when its ground-state conformation resembles that in the complex. This can be achieved, for example, by suitably located methyl substituents.

Such conformational design was demonstrated by Still et al.[69] par excellence in the case of a polyether chain. Polyethers have many acceptor positions for hydrogen bonds; they thus have a marked tendency to complex ammonium ions. The polyether **44** may well prefer the $tg^+ttg^+ttg^+$ helical arrangement, which predominates in polyethyleneglycol derivatives,[70] though of course only as one of many other possible conformations. The fusion of six-membered rings as in form **45** specifies in each case two successive *t* arrangements of the main polyether chain. The resulting *t*?*tt*?*tt*? sequence still permits 25 conformations which are up to 3 kcal mol^{-1} higher in energy than the most stable conformation. Only when further methyl substituents are intro-

duced, as in **46**, is a molecule attained with only a single low-energy conformation, since all other conformations have destabilizing g^+g^- interactions. We are thus dealing with a conformationally fully flexible molecule, which nevertheless has only a single helical designer conformation ($g^+ttg^-ttg^+$). As a consequence, **46** exhibits a substantially higher enantioselective recognition of protected amino acids than **45**.[69, 71]

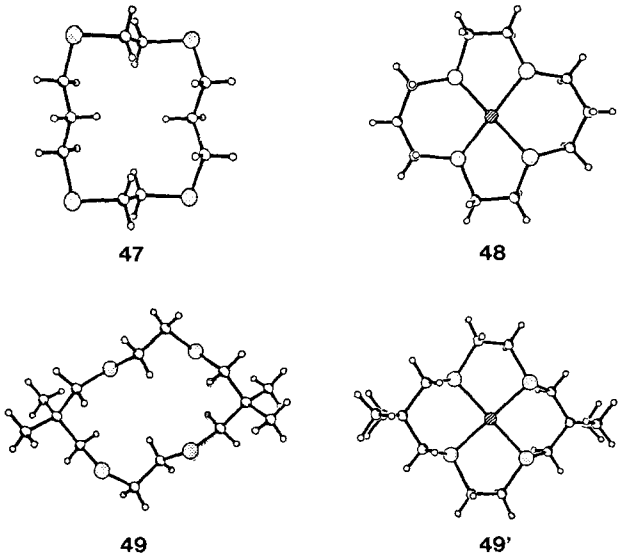


44

45

46

A further example of such a ligand design is provided by a [14]thiacrown-4 for complexing Ni^{2+} (Fig. 7).[72] By means of a geminal dimethyl substitution on the macrocycle **47**, a *trans* conformation of the CC–SC bond in **49** is induced which is also found in complex **48**. The binding constant for Ni^{2+} increases correspondingly by a factor of 50 in the transition from the ligand **47** to **49**.[72]

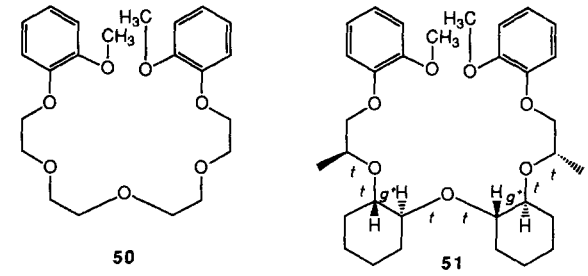


47 **48**

49 **49'**

Fig. 7. Crystal structures of the [14]thiacrown-4 macrocycles **47** and **49** as well as their respective complexes which form upon addition of Ni^{2+}, **48** and **49'**. Hatched spheres are Ni atoms, dotted spheres S atoms.

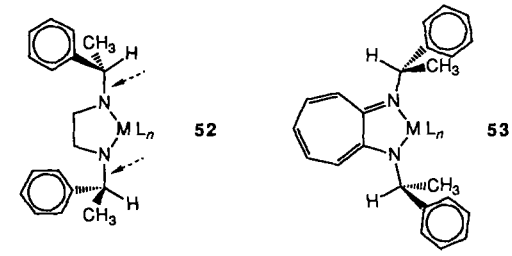
Molecules with a boomerang shape could also be tailor-made. For example, compound **51** should—by analogy to the investigations carried out by Vögtle et al.[73] on **50**—be even better able to bind thiourea than **50** since the host molecule **51** should spontaneously adopt the optimum conformation for bonding.[74]



50 **51**

The control of conformer populations by means of avoidance of g^+g^- interactions is just one of the principles that can be applied in conformational design. Flexible structural elements whose shape is determined by allylic 1,3 strain or by the conformational preferences of an amide or urea group,[75] may also be used.

A timely problem is the design and synthesis of chiral ligands for metal-catalyzed reactions. For example, the easily accessible complex **52** would have the disadvantage that the phenyl and methyl groups on the ligand, which should be responsible for asymmetric induction, are not spatially fixed. In other words, many conformations are possible regarding rotation about the indicated bonds. This disadvantage is

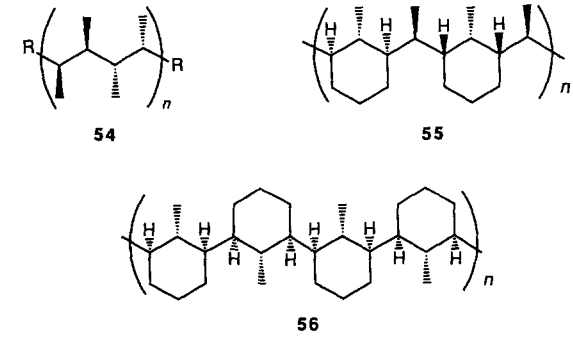


52 **53**

avoided in the complex **53**,[76] since allylic 1,3 strain specifically fixes the phenyl and methyl groups in the ligand to produce a defined chiral environment at the metal center.

5. Summary and Future Prospects

The spatial structure of many polyketide natural substances illustrates the principles that nature employs to impart a defined shape to these molecules while largely retaining conformational flexibility. These principles can be utilized as such or developed further in order to confer by structural modifi-



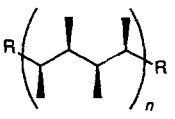
54 **55**

56

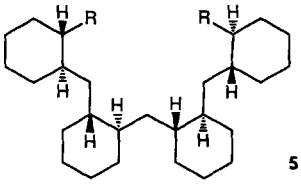
cation a definite preferred conformation on a molecular chain (conformational design). If, for example, it is desired to produce a rod-shaped flexible molecule, structures **54** to **56** could be sought.

In the syntheses of such compounds with fairly short chains the problem would be primarily that of stereoselectivity, while in the syntheses of those with longer chains it would that of stereoregular polymerization.[77]

If on the other hand it is desired to construct helical molecular chains, one could seek a steep helix through a $tg^+(tg^+)_n tg^+$ sequence, as in **57**. This would be an isotactic polypropylene reinforced in its conformational preference. A flatter helix would result from a $ttg^+(ttg^+)_n ttg^+$ conformation (cf. ref.[70]). This could be achieved for example with a structure such as **58**.



57



58

The examples given above are obvious solutions, though certainly not the only and perhaps also not the best solutions for the design problems presented. It is clear, however, that high demands will be placed on the art of stereoselective synthesis when such molecules are synthesized. In view of the breathtaking developments in methods and procedures of stereoselective synthesis over the last 15 years, it may be hoped that molecules such as **56** or **57** will soon no longer present insuperable synthetic problems. With further progress in synthesis, efficient conformational design will be able to be performed not only on the computer screen but also in the laboratory as a matter of routine. One will then also be able to answer the question of whether conformationally flexible, biologically active substances hitherto employed by nature have advantages over conformationally rigid, biologically active substances.

The review does not aim to, and certainly is not able to, deal exhaustively with all the possibilities in the conformational design of molecular skeletons. It should, however, indicate above all the relevant principles and provide a stimulus for further thought.

I wish to thank M. Brumm and Dr. T. Sander, Marburg, (FRG), for the results of MACROMODEL calculations reproduced herein. I also wish to thank Prof. G. Frenking, Marburg, for advice regarding technical details.

What subscribers and authors have to say about Angewandte Chemie:

Jean-Marie Lehn, Université Louis Pasteur, Strasbourg:

"I consider Angewandte Chemie as one of the top not only chemical but scientific journals... It presents the highly effective combination of well chosen, exciting and thorough review articles, reflecting timely topics that cover a very broad range in science, with short but informative communications reporting specific advances of particular interest for chemistry. It is also carefully produced and nicely presented, which adds to the reading pleasure."

The Organosulfur Chemistry of the Genus *Allium* – Implications for the Organic Chemistry of Sulfur

By Eric Block*

A Cook's tour is presented of the organosulfur chemistry of the genus *Allium*, as represented, inter alia, by garlic (*Allium sativum* L.) and onion (*Allium cepa* L.). We report on the biosynthesis of the *S*-alk(en)yl-L-cysteine *S*-oxides (aroma and flavor precursors) in intact plants and on how upon cutting or crushing the plants these precursors are cleaved by allinase enzymes, giving sulfenic acids—highly reactive organosulfur intermediates. In garlic, 2-propenesulfenic acid gives allicin, a thiosulfinate with antibiotic properties, while in onion 1-propenesulfenic acid rearranges to the sulfine (*Z*)-propanethial *S*-oxide, the lachrymatory factor (LF) of onion. Highlights of onion chemistry include the assignment of stereochemistry to the LF and determination of the mechanism of its dimerization; the isolation, characterization, and synthesis of thiosulfinates which most closely duplicate the taste and aroma of the freshly cut bulb, and additional unusual compounds such as zwiebelanes (dithiabicyclo[2.1.1]hexanes), a bissulfine (a 1,4-butanedithial *S,S'*-dioxide), antithrombotic and antiasthmatic cepaenes (α-sulfinyl disulfides), and *vic*-disulfoxides. Especially noteworthy in the chemistry of garlic are the discovery of ajoene, a potent antithrombotic agent from garlic, and the elucidation of the unique sequence of reactions that occur when diallyl disulfide, which is present in steam-distilled garlic oil, is heated. Reaction mechanisms under discussion include [3,3]- and [2,3]-sigmatropic rearrangements involving sulfur (e.g. sulfoxide-accelerated thio- and dithio-Claisen rearrangements) and cycloadditions involving thiocarbonyl systems. In view of the culinary importance of alliaceous plants as well as the unique history of their use in folk medicine, this survey concludes with a discussion of the physiological activity of the components of these plants: cancer prevention, antimicrobial activity, insect and animal attractive/repulsive activity, olfactory–gustatory–lachrymatory properties, effect on lipid metabolism, platelet aggregation inhibitory activity and properties associated with ajoene. And naturally, comments about onion and garlic induced bad breath and heartburn may not be overlooked.

1. Introduction

We remember the fish which we did eat in Egypt, the cucumbers, melons, leeks, onions and garlic!
Num. 11:4–6

What is more familiar and pleasant to the senses than freshly chopped or sauted garlic, sliced or boiled onions, steaming leeks, finely diced chives, crisp raw scallions, or the delicate shallot? The scents of these commonplace plants brings back memories of mother's kitchen, a favorite restaurant or even a walk through a meadow rich with the aroma of wild onions. The adjectives applied to these plants, zesty, lusty, assertive, piquant, and distinctive, and even the botanical name *Allium*, derived from the Celtic word "all", which means pungent, betray the presence of a host of remarkable flavorants and odorants all having in common one element, sulfur. Many of these flavorful sulfur compounds contain the allyl group, which in turn gets its name from *Allium*. It is the presence of these organosulfur compounds, more than any other attribute, that defines the character of this extraordinary genus. The great American poet Carl Sanburg said: *"Life itself is like an onion; it has a bewildering number of layers. You peel them off, one by one, and sometimes you cry."* The "bewildering number of layers" of the onion has its counterpart in the complex chemistry of this and other alliaceous plants, representing a microcosm of the field of organosulfur chemistry. More specifically, *Allium* chemistry presents us with examples of sulfur compounds with striking physiological activity as well as culinary appeal, reactive organosulfur intermediates with unusual bonding, challenging analytical problems, compounds with chirality at sulfur and other stereochemical features related to the presence of sulfur, novel organosulfur heterocycles with notable spectroscopic properties, redox reactions involving sulfur, as well as processes involving sulfur radicals, sulfur stabilized carbocations, pericyclic reactions, noteworthy rearrangements, and reactions of utility in synthetic organic chemistry.[1]

For twenty-five years I have been exploring the organosulfur chemistry of the genus *Allium*, as represented by garlic (*Allium sativum* L.), onion (*Allium cepa* L.), leek (*Allium ampeloprasum* L. var. porrum), scallion (*Allium fistulosum*), shallot (*Allium ascalonicum* auct.), great-headed ("elephant") garlic (*Allium ampeloprasum* L. var. holmense), wild garlic (*Allium ursinum*), chive (*Allium schoenoprasum* L.), and Chinese chive (*Allium tuberosum* L.) (Fig. 1). When I began this study, much outstanding research had already been done in this area, e.g. as summarized in a review article by Nobel Laureate Arturi Virtanen.[2] As my research proceeded it became clear that there were still significant puzzles remaining to be solved, that these most common plants could teach us much about sulfur chemistry, and that the compounds and mixtures produced when these plants are cut display an even broader range of biological activities than

earlier suspected. While extracts and potions of garlic and onion have been used for millennia in folk medicine, commercial products derived from these plants are now enjoying growing popular use in many countries. Furthermore, responding to epidemiological evidence that lower cancer risks are associated with increased consumption of alliaceous plants, health organizations have recently targeted garlic and onion as prime candidates for "designer foods" programs, programs to develop new foods that will help prevent cells from becoming cancerous. For all of these reasons a detailed exploration of the organosulfur chemistry of the genus *Allium* seemed justified as well as timely. This review summarizes progress in this field both in my own and other laboratories.[3]

2. Organosulfur Compounds of Intact Plants

Well loved he garleek, oynons, and eek lekes,
and for to drynken strong wyn, reed as blood.

"Canterbury Tales"
Geoffrey Chaucer (1342–1400)

The earliest reports concerning the isolation of organic compounds from garlic (1844, 1892) and onion by Wertheim (1844) and Semmler (1892) in Germany identified diallyl sulfide[4] (corrected in 1892 to the disulfide[5]) and a propenyl propyl disulfide[5] as the principal components of the distilled oils ("ätherische Öle") of garlic and onion, respectively. In the 1940s it became apparent that these and other volatile sulfur compounds were secondary compounds formed by enzymatic action on precursors in the intact bulb. Thus, in 1945, Cavallito et al. in Rennselaer, New York, reported that when garlic cloves were frozen in dry ice, pulverized, and extracted with acetone, "the acetone extracts upon evaporation yielded only minute quantities of residue and no sulfides, indicating the absence of free sulfides in the plant. The [white] garlic powder had practically no odor, but upon addition of small quantities of water, the typical odor was detected and the antibacterial principle (**1**) could be extracted and isolated. This demonstrates that neither **1** nor the allyl sulfides found in "Essential Oil of Garlic" are present as such in whole garlic. When the powder was heated to reflux for thirty minutes with a small volume of 95% ethanol, no activity could be demonstrated by addition of water to the insoluble residue. When, however, a small quantity (1 $mg\,mL^{-1}$) of fresh garlic powder was added to the alcohol insoluble fraction in water (20 $mg\,mL^{-1}$), the activity of the treated sample was shown to be equal to that of the original untreated powder. The 95% ethanol treatment has inactivated the enzyme required for cleavage of the precursor and addition of a small quantity of fresh enzyme brought about the usual cleavage.[6]

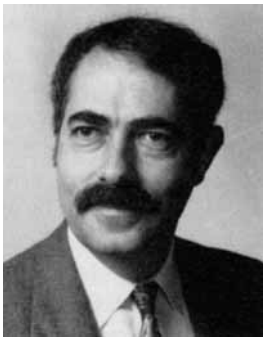
Since a strict definition of "essential oil" is "a volatile substance contained in certain aromatic plants that imparts distinctive odor to the plant" and since the volatile substances of the *Allium* spp. are not found in the plant but result from disrupting the plant cells, it is preferable to describe the process leading to a particular *Allium*-derived product, e.g. "steam volatile components" or "head space volatiles".[7]

2.1. Sulfur Amino Acids Secondary Metabolites in *Allium* spp.

Let onion atoms lurk within the bowl
and, scarce suspected, animate the whole.

"Recipe for Salad",
Sydney Smith (1771–1845)

Garlic, onion and other members of the *Allium* spp. contain 1–5% dry weight of nonprotein sulfur amino acid secondary metabolites. Pioneering studies in the 1940s by Stoll and Seebeck in Basel demonstrated that the stable precursor of Cavallito's antibacterial principle of garlic **1** is (+)-*S*-2-propenyl-L-cysteine *S*-oxide (**2**, "alliin").[8] In the intact cell, **2** and related *S*-alk(en)yl-L-cysteine *S*-oxides (aroma and flavor precursors) are located in the cytoplasm and the C–S lyase enzyme allinase in the vacuole.[9] Disruption of the cell results in release of allinase and subsequent α,β-elimination of the *S*-oxides, ultimately affording volatile and odorous low molecular weight organosulfur compounds such as **1** (Scheme 1). Four sulfoxides occur in *Allium* spp.: *S*-2-propenyl-, *S*-(*E*)-1-propenyl-, *S*-methyl- and *S*-propyl-L-cysteine *S*-oxides (**2**, **5**–**7** respectively). Onions contain **5**–**7** while garlic contains **2**, **5**, and **6**.[10–13] The distinctive flavors of the various *Allium* spp. reflect the varying amounts of compounds **2**, **5**–**7**, particularly of **5** ("isoalliin"), which is



Eric Block, born in 1942 in New York City, studied chemistry at Queens College of the City University of New York. He received his Ph.D. degree from Harvard University, where in the laboratory of Professor E. J. Corey he first developed an interest in organosulfur chemistry, the chemistry of natural products, synthetic methods, and organic reaction mechanisms. In 1967 he joined the faculty at the University of Missouri-St. Louis where he was promoted to Professor. In 1981 he moved to the State University of New York at Albany, serving as Chairman of the Chemistry Department from 1985 to 1991. He has been the recipient of a number of awards and honors including a Guggenheim Fellowship and the ACS Award for Advancement and Application of Agricultural and Food Chemistry; he serves on several journal editorial boards, and has been a visiting professor at Harvard, and the Universities of Illinois-Urbana, Frankfurt, and Bologna. He is an avid photographer and traveler. In his overseas travels he enjoys visiting produce markets to see displays of local Allium species.

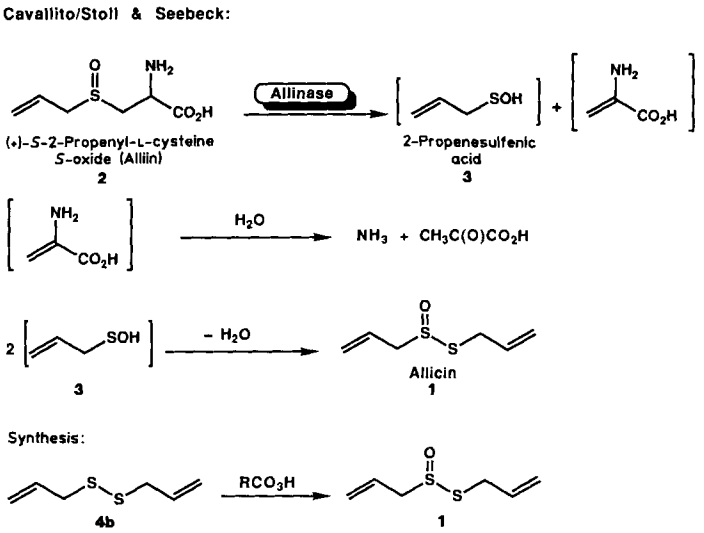
the precursor to the onion lachrymator, and of **2**, which is the precursor to the characteristic allylic compounds of garlic. Also present in *Allium* spp. are 24 γ-glutamyl peptides of sulfur amino acids. These are considered to function as storage compounds of nitrogen and sulfur (precursors to plant chemical defense agents?) and may have a role in the transport of amino acids across cell membranes.[14]



Scheme 1. Cavallito's pioneering discovery and synthesis of allicin **1**, the antibacterial principle of garlic (anticipating subsequent studies by Stoll and Seebeck on the precursor alliin **2**).

Scheme 2 summarizes the proposed biosynthesis of the various *Allium* spp. peptides and aroma precursors based on the results of labeling experiments, in which $^{35}SO_4^{2-}$ was fed to onion plants[15]. By briefly boiling the bulb or homogenizing the plants with alcohol containing limited quantities of water the allinase enzymes can be deactivated, thus permitting analysis of the peptides by HPLC.[12, 16] The sulfate is reduced and assimilated into cysteine in the chloroplasts[17] and then enters the glutathione cycle.[18] Michael addition of γ-glutamylcysteine to methacrylic acid (from valine) can afford γ-glutamyl-*S*-2-carboxypropylcysteine (**8**) which in onion undergoes sequential decarboxylation to give γ-glutamyl-*S*-1-propenylcysteine **e**, oxidation to γ-glutamyl-*S*-1-propenylcysteine *S*-oxide **i**, and cleavage by γ-glutamyl transpeptidase [EC 2.3.2.1] to **5**.[19a] Labeling experiments have established that the precursor **8** is converted into **5** with loss of the 3-*pro-R* hydrogen atom and that the oxidative decarboxylation reaction proceeds with *anti* geometry, analogous to terminal alkene biosynthesis (Scheme 2).[19b] Parallel processes involve Michael addition of glutathione to methacrylic acid giving *S*-2-carboxypropylglutathione **a** followed by conversion of the latter into **8** and methylation of glutathione giving *S*-methylglutathione **b** followed by conversion of the latter into γ-glutamyl-*S*-methylcysteine **f**. The situation with garlic is less clear. γ-Glutamyl-*S*-2-propenylcysteine **c**, formed from **8**, or more likely, from serine and 2-propenethiol by a process not well understood,[20] is converted into γ-glutamyl-*S*-2-propenylcysteine *S*-oxide **g** by an oxidase and is then cleaved by γ-glutamyl transpeptidase to **2**.

It has recently been reported[11] that the concentration of γ-glutamyl-*S*-(*E*)-1-propenylcysteine **e** and γ-glutamyl-*S*-2-propenylcysteine **c**, the dominant γ-glutamyl peptides in homogenates of fresh garlic, decreases markedly when freshly

picked garlic is stored, especially at 4 °C. The consequence of cold storage of garlic is increased production of **5** and therefore low molecular weight organosulfur compounds containing the 1-propenyl group (see Section 5.2.3). A second discovery, recently made in our laboratories is that garlic *grown* in colder climates contains far less **6** than garlic grown in more temperate climates, although levels of precursor compounds, such as γ-glutamyl-*S*-methylcysteine **f**, are normal.[21]

2.2. Allinase Enzymes

Allinases [EC 4.4.1.4] are pyridoxal 5′-phosphate dependent α,β-eliminating lyases which catalyze the decomposition of (+)-*S*-2-propenyl-L-cysteine *S*-oxide (**2**) and other (+)-*S*-alk(en)yl-L-cysteine *S*-oxides to ammonium pyruvate and allicin (**1**) and its homologs (Section 3). Synthetic **2** is racemic at the sulfur atom. The natural (+)-diastereomer (the first acyclic natural product with both an asymmetric carbon and an asymmetric heteroatom) is quantitatively and rapidly converted into **1** by garlic allinase, whereas the (−)-isomer of **2** decomposes much more slowly; derivatives of D-cysteine are completely inactive.[2] Conflicting results have been published in the case of garlic allinase. One group suggests that it is a dimer of molecular mass between 108000 and 111000 and subunit mass 53500 and requires a flavin-coenzyme in addition to pyridoxal 5′-phosphate,[22a] while a second group claims that it is a tetramer with a molecular mass of 180 kDa with subunits of mass 45 kDa.[23] Welsh onion (*Allium fistulosum* L.) allinase is a tetramer with a molecular mass of 220 kDa and subunit mass of 52 kDa and an optimum pH of 7.0.[24] Virtanen reported the purification of an onion allinase which showed maximal activity at pH 7.4.[3h, 8e, 25–27] Recent work suggests that there are *two* different allinase activities in garlic: one is specific for substrates **2** and **5**, has an optimum pH of 4.5, and cleaves 97% of **2**/**5** within 0.5 min at 23 °C; the second is specific for substrate **6**, has an optimum pH of 6.5, and cleaves 97% of **6** within 5 min at 23 °C. Both allinases are irreversibly deactivated at pH 1.5–3 (the pH of the stomach) and >9.[28]

2.3. A Question of Semantics

"What is a natural product?" This question can be raised with regard to all of the organic sulfur compounds that follow allinase-catalyzed release of the sulfenic acids, since none of the subsequently formed compounds occur in the bulb itself nor does their formation require enzyme involvement. On the other hand, volatile thiosulfinates are emitted in the field by *Allium* spp. such as the leek and are the most attractive compounds for predatory insects, e.g. the leek moth, *Acrolepiopsis assectella*.[29] Thus, in a broad sense, thiosulfinates and related secondary products such as disulfides and thiosulfonates can be classified as "natural products".

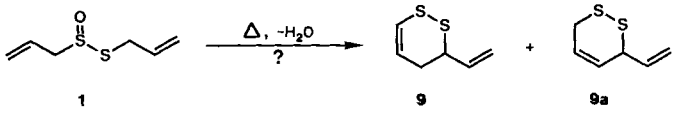
3. Organosulfur Compounds from Cut *Allium* spp.: Pre-1972 Results

If your Majesties is remembered of it, the Welshmen did good service in a garden where leeks did grow, wearing leeks in their Monmouth caps, which your Majesty know to this hour is an honourable badge of the service. And I do believe your Majesty takes no scorn to wear the leek upon Saint Davy's day.

"Henry V", IV. vii. 100
William Shakespeare (1564–1616)

For the purposes of this review I have chosen to first summarize research on the organosulfur compounds of cut *Allium* spp. prior to 1972, when my contributions first appeared, allowing me to subsequently describe my own work, and recent work of others, in the proper historical perspective. In 1944 a series of notable reports by Cavallito et al.[30] appeared describing the isolation and characterization of allicin (2-propenyl-2-propenethiosulfinate) (**1**),[31] an odoriferous, unstable antibacterial substance ("considerably more bacteriostatic than bactericidal"; "exceptionally sensitive and polymerizes easily ...must be stored at a low temperature"[30]) isolated from cut garlic cloves by extraction with ethanol at room temperature. Decomposition of allicin was said to afford diallyl disulfide as a major breakdown product. Cavallito found that reversal of this decomposition process, e.g. oxidation of diallyl disulfide (**4b**)[32] with peracetic acid, represents the most direct method of synthesizing allicin (Scheme 1).[33, 34] Attempts by Brodnitz et al. in 1971 to determine allicin **1** by GC-MS provided evidence for another more unusual mode of decomposition. A 2.4:1 mixture of two compounds claimed (incorrectly as we shall see below) to be 3-vinyl-3,4-dihydro-1,2-dithiin (**9**) and 3-vinyl-3,6-dihydro-1,2-dithiin (**9a**) were found by GC (Scheme 3).

Brodnitz:



1 **9** **9a**

Scheme 3. Decomposition of allicin **1** in a gas chromatograph according to Brodnitz.

It was suggested that "upon gas chromatography diallyl thiosulfinate undergoes dehydration" affording **9** and **9a**.[35a] At room temperature neat **1** is said to rearrange, affording sulfur dioxide and diallyl mono-, di-, and trisulfide (**4a–c**)[35]. Analytical methods for quantitative allicin determination which rely on GC detection of "**9**" and "**9a**" are still employed[36] even though serious problems exist with this method and more accurate HPLC methods have been developed.

All-S-All **4a** All-S-S-All **4b** All-S-S-S-All **4c**

After the discovery of alliin in garlic, other *S*-alk(en)yl-L-cysteine *S*-oxides such as **5–7** were discovered in other *Allium* spp.[37] Upon cutting the plants, such *S*-oxides (type **a** and **b**) are cleaved by allinase to sulfenic acids, whose condensation could lead to four types of thiosulfinates. These thiosulfinates, and polysulfides derived therefrom, were assumed to be the principle sources of flavor and aroma in *Allium* spp., and were viewed as important taxonomic markers. Indirect methods were used to identify and quantify the various thiosulfinates.

$RS(O)CH_2CH(NH_2)COOH$ **a** $R'S(O)CH_2CH(NH_2)COOH$ **b**

RS(O)SR **c** RS(O)SR′ **d** R′S(O)SR **e** R′S(O)SR′ **f**

One method involved separation of the thiosulfinates by paper chromatography followed by treatment with cysteine to form *S*-alk(en)ylthiocysteines, which in turn were chro-

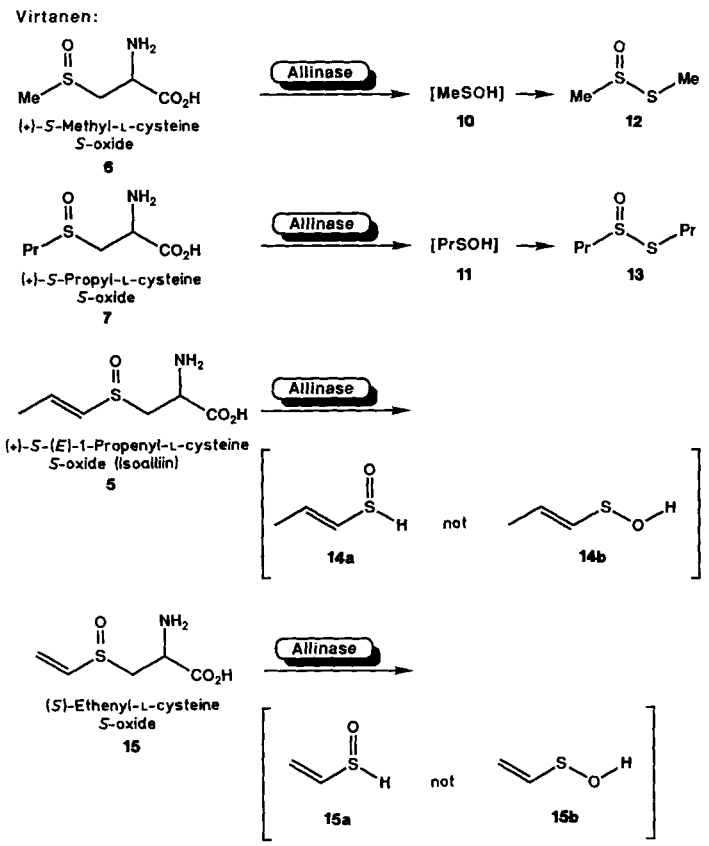
$RSSCH_2CH(NH_2)COOH/R'SSCH_2CH(NH_2)COOH$

matographed.[38] In this manner the following thiosulfinate profiles were determined (increasing amounts indicated as +, ++, +++): in garlic, MeS(O)SMe **12** (+), MeS(O)SAll **101** (++), MeS(O)SPr **29** (+), AllS(O)SAll **1** (+++), AllS(O)SPr (++), PrS(O)SPr **13** (+); in onion, **13** (++), **29** (+), **12** (+); in Chinese chive, **12** (+++), **101** and **1**.[38] This working group also allowed allinase to react with a mixture of **2** and **6**, and obtained **1**, **12**, and "MeS(O)SAll".[38]

A second method involved "headspace" GC analysis, where it was assumed that the proportion of different alk(en)yl groups in the stable, volatile polysulfide fraction paralleled the relative abundance of the same alk(en)yl groups in the thiosulfinates.[39] It was felt that even if the polysulfides revealed by GC are artifacts of analysis, they are [still] clearly related to *Allium* odors.[39] Although both methods of analysis give data which are generally in agreement with more recent composition profiles, significant errors are apparent (see Section 5.2).

With the development of mass spectrometry, gas chromatography (GC), and IR spectroscopy it was possible in 1956 to identify the following compounds as constituents of raw onion vapor:[40] 1-propanethiol, propanal, dipropyl disulfide, SO_2, H_2S, and a substance of *m/z* 90 (C_3H_6SO), showing loss of OH (*m/z* 73) as well as *m/z* 45. It was assumed, albeit on somewhat feeble grounds, that it could be 3-hydroxypropanethial. In 1961 Virtanen et al. showed[10a] that (+)-*S*-((*E*)-1-propenyl)-L-cysteine *S*-oxide (**5**), present to the extent of ca. 0.2% by weight in the onion, is the precursor of the lachrymatory factor (LF; the *E*-geometry of the 1-propenyl group was later established by NMR spectroscopy).[10a, 12, 41–43] Virtanen also demonstrated that onion allinase converts *S*-methyl- and *S*-propyl-L-cysteine *S*-oxides (**6** and **7**, respectively), present to the extent of ca. 0.005–0.02% by weight in the onion,[44, 45] and *S*-2-propenyl-L-cysteine *S*-oxide (**2**), found in garlic, into the corresponding thiosulfinates **12**, **13**, and **1** via sulfenic acids **10**, **11**, and **3**, respectively (Schemes 4 and 1).[2]

On the basis of the above results, Virtanen formulated the LF as the S–H tautomer (**14a**) of (*E*)-1-propenesulfenic acid rather than the S–OH tautomer **14b** (Scheme 4).[2] The assignment of structure **14a** to the LF was said to be consistent with deuteration studies involving crystallized precursor **5** and a purified onion enzyme preparation. Thus, when the

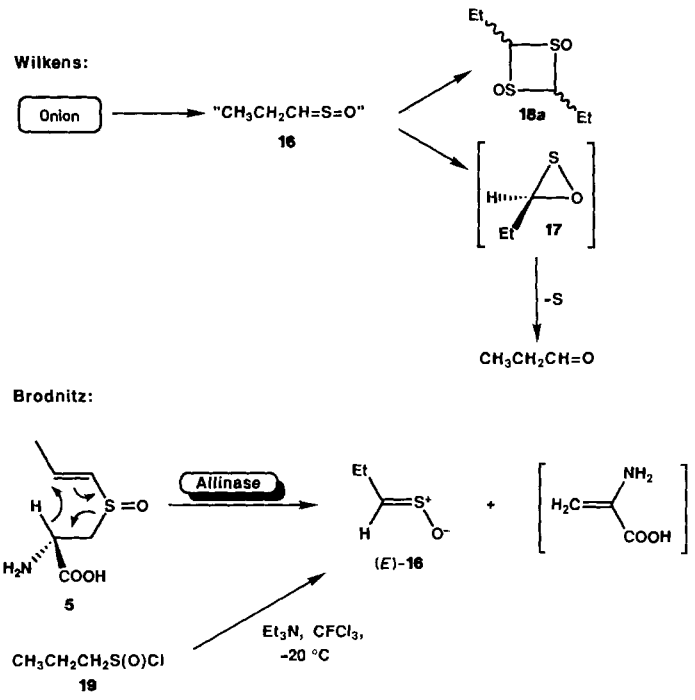


Scheme 4. Virtanen's view of the action of allinase on homologues of alliin **2**. In the case of **6**, **7**, **5**, and **15** they are L-cysteine derivative; **6**, **7**, and **5** are dextrorotatory.

LF is generated in D_2O, its mass spectrum shows a shift in the molecular peak from 90 to 91, indicating a single exchangeable proton. Fragmentation of the normal LF as well as the deuterated LF shows that in both cases an OH fragment is set free. The molecule therefore contains no OH group (the hydrogen of which would be replaced by deuterium in D_2O).[10b] Virtanen raises the perplexing question of why **14a** does not form 1-propenyl 1-propenethiosulfinate analogous to the ready formation of allicin from 2-propenesulfenic acid.[43] He hypothesizes that perhaps 2-propenesulfenic acid disproportionates immediately to 2-propenesulfinic acid and 2-propenethiol, which afford allicin by elimination of water, whereas in **14a** the position of the double bond is a possible stabilizing factor.[2] Virtanen suggests that (*E,Z*)-1-propenyl propyl (and methyl) disulfides, found in *Allium* volatiles and possessing "strong onion-like flavors", might arise from precursor **5** by splitting of a C–S bond, reduction, and coupling with some thiol present when the plants are crushed.[43] Virtanen and Däbritz synthesized the non-natural homolog of **5**, *S*-vinyl-L-cysteine *S*-oxide (**15**) and demonstrated that onion allinase converted it into a lachrymatory substance formulated as ethenesulfenic acid tautomer **15a**, paralleling the conversion of **5** into **14a**.[46]

In 1961, simultaneous with the work of Virtanen, Wilkens of Cornell University isolated by preparative GC the purified LF, which was depicted as propanethial *S*-oxide (**16**; Scheme 5; drawn by him with a linear ketene-like structure $CH_3CH_2CH{=}S{=}O$).[47] Evidence supporting structure **16** included: 1) the presence of strong IR absorption bands at 1113 and 1144 cm^{-1} (S=O region) together with the absence of bands attributable to S–H, O–H, or C=C; 2) ready decomposition of the LF to propanal (suggested to involve the intermediacy of 3-ethyloxathiirane (**17**)) and to a second compound possessing IR bands at 1140 and 1330 cm^{-1} formulated as condensation product 2,4-diethyl-1,3-dithietane 1,3-dioxide (**18a**).[47] Wilkens rationalized the inconsistency between the IR data for **18a**, which showed absorption bands typical of the sulfone stretching modes, and the postulated disulfoxide structure **18a** as due to the proximity of the antipodal sulfinyl groups in this strained-ring structure... postulated to induce a pseudosulfone infrared absorption, which would be of less intensity than that of a true sulfone.[47]

In 1963–1964 the first syntheses of *S*-oxides of thials and thiones (termed *sulfines*) were reported, involving dehydrochlorination of the corresponding sulfinyl chlorides (Scheme 5),[48,49] and evidence was presented for a bent C–S–O group[48,49] (e.g. the methyl groups in Me_2CSO are nonequivalent according to NMR).[48a] In 1971 Brodnitz



Scheme 5. Contributions by Wilkens and Brodnitz on proposed structure, "biosynthesis" and laboratory synthesis, and mechanisms for desulfurization and dimerization of onion lachrymatory factor (LF).

and Pascale[50] showed that propanethial *S*-oxide (arbitrarily depicted by them as (*E*)-**16**), from dehydrochlorination of propanesulfinyl chloride (**19**), was spectroscopically identical to the natural onion LF. These authors provided the

mechanism for the formation of the LF from its known precursor **5** shown in Scheme 5.[50]

4. Structures of Reactive Organosulfur Compounds Relevant to *Allium* Chemistry

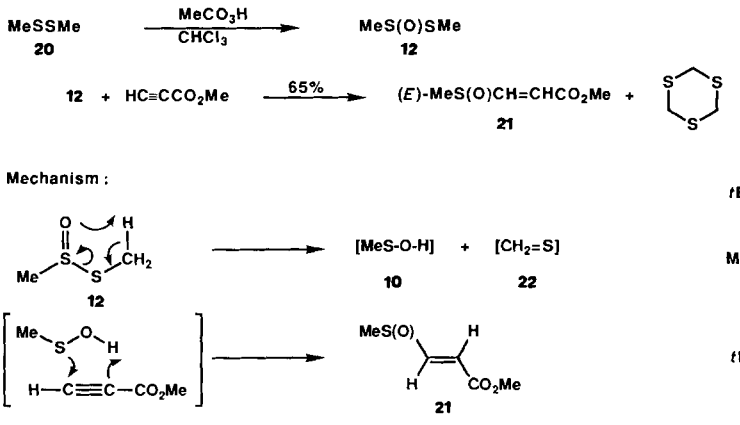
I counted two and seventy stenches,
All well defined, and several stinks.

"Cologne"
Samuel Taylor Coleridge (1772–1834)

4.1. Methyl Methanethiosulfinate, Higher Homologs and Derivatives

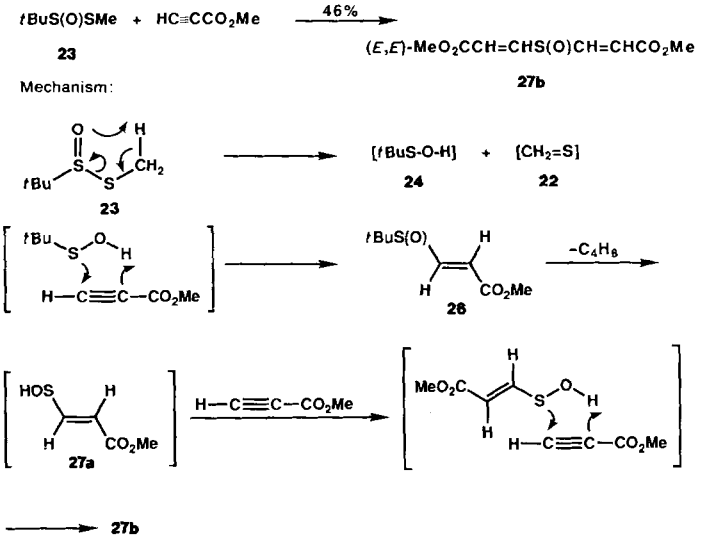
Despite the identification of the active agent of garlic as allyl 2-propenethiosulfinate (**1**, allicin), an alkyl alkanethiosulfinate, little systematic information existed in 1970 on the chemistry of this class of compounds, perhaps because of their reputation as malodorous, unstable substances.[51] Thus, in 1970 I undertook a study of the naturally occurring parent member of this family, methyl methanethiosulfinate (**12**).

True to its reputation, methyl methanethiosulfinate (**12**) prepared by careful oxidation of dimethyl disulfide (**20**) with peroxy acids or singlet oxygen,[52, 53] is an unpleasant smelling, reactive and unstable vesicant with the property of readily attaching itself to hair and clothing. Fortunately, **12** proved to have a rich chemistry.[54] Pyrolysis of **12** in the presence of methyl propiolate affords methyl (*E*)-β-(methylsulfinyl)acrylate (**21**) in good yield by a sequence involving cycloelimination to methanesulfenic acid (**10**) and thioformaldehyde (**22**), followed by regiospecific addition of the



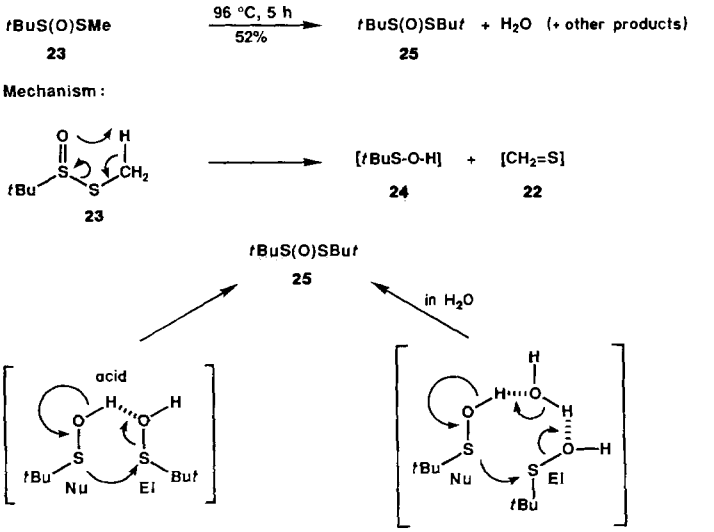
Scheme 6. Methyl methanethiosulfinate decomposes into thioformaldehyde **22** and methanesulfenic acid **10**. The latter can be trapped giving α,β-unsaturated sulfoxides such as **21** in a synthetically useful procedure.

former to the alkyne and trimerization of the latter (Scheme 6). This procedure represents a convenient synthesis of α,β-unsaturated sulfoxides.[54] Both **10** and **22** were subsequently identified by microwave spectroscopy; **10** was shown (see Section 4.3) to have the structure MeS–O–H rather than MeS(O)H.[55] When methyl 2-methyl-2-propanethiosulfinate (**23**) is heated with methyl propiolate, the major product is (*E,E*)-dimethyl-3,3′-sulfinyldiacrylate (**27b**; Scheme 7).[54] Compound **27b** is thought to be formed by a sequence involving generation of 2-methyl-2-propanesulfenic acid (**24**), addition of this to methyl propiolate giving methyl (*E*)-β-*tert*-butylsulfinylacrylate (**26**), elimination of isobutylene from **26** giving α,β-unsaturated sulfenic acid **27a**, and finally addition of **27a** to methyl propiolate. When



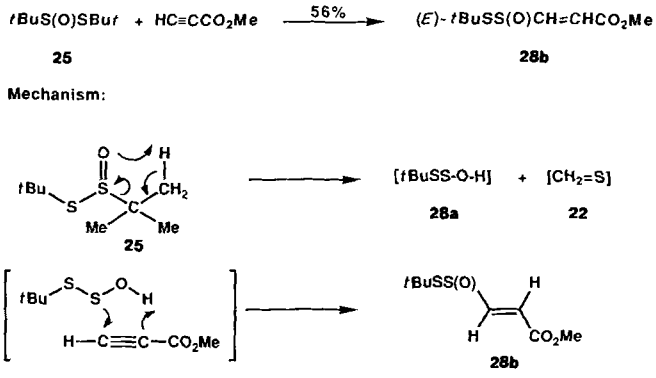
Scheme 7. Alkyl-2-methylpropanethiosulfinates like **23** react with alkynes to furnish adducts which lose isobutylene giving α,β-unsaturated sulfenic acids such as **27a**. These add to a second molecule of alkyne ultimately giving bis(1-alkenyl)sulfoxides such as **27b**.

23 is heated neat at 96 °C for 5 hours, the major product is *tert*-butyl 2-methyl-2-propanethiosulfinate (**25**). Sulfenic acid **24** is suggested to be an intermediate in this reaction, condensing with itself via an acid-catalyzed S_N2-like process or, orbital geometry-permitting, via a five-membered or seven-membered hydrogen bonded transition state (Scheme 8). In these condensation reactions the sulfenic acid functions as both a nucleophile and electrophile. Compound **25** was also



Scheme 8. Upon heating, unsymmetrical alkyl alkanethiosulfinates such as **23** give symmetrical thiosulfinates such as **25** by a mechanism involving sulfenic acids.

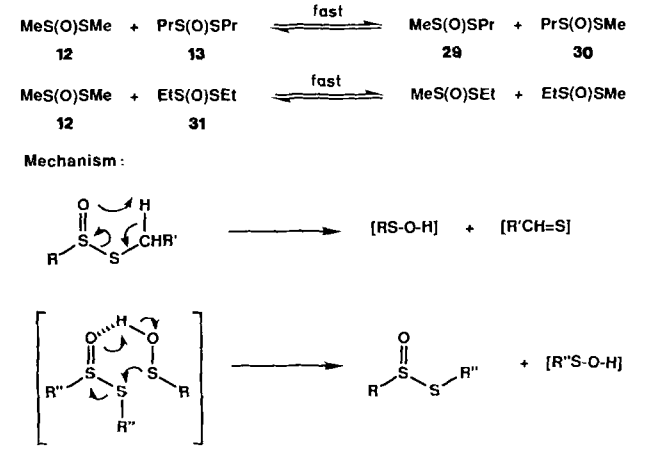
found to decompose thermally. When heated in the presence of methyl propiolate it gave the α,β-unsaturated adduct **28b** by way of 2-methyl-2-propanethiosulfoxylic acid (**28a**), a member of a previously unknown class of sulfur acids (Scheme 9).[54b]



Scheme 9. Formation and trapping of the thiosulfoxylic acid ester **28a**.

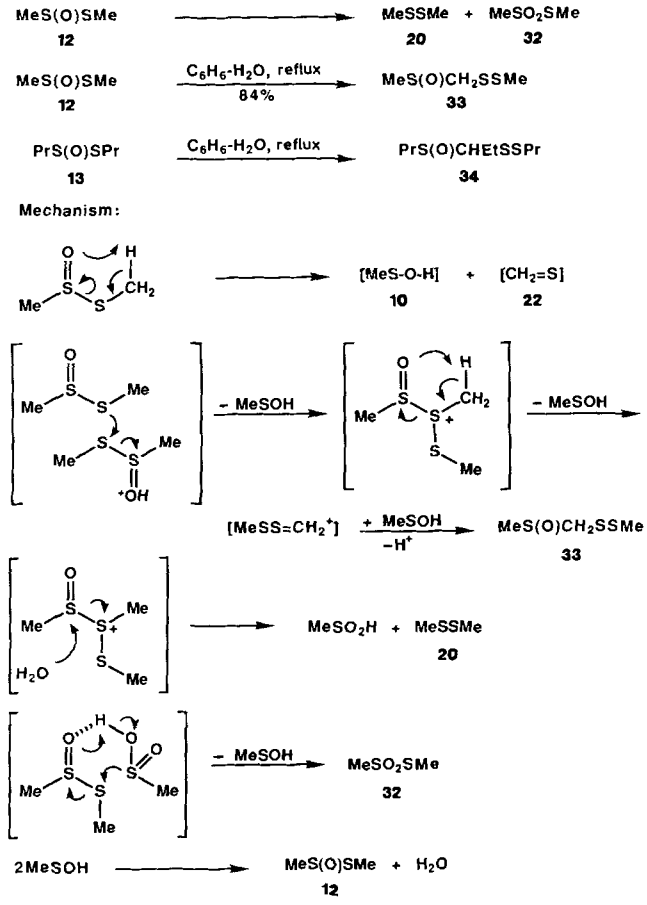
The unimolecular decomposition of **12** (cf. Scheme 6) is favored by the weak S–S bond, determined by appearance potential measurements to have a bond energy of 46 ± 4.6 kcal mol^{-1}, comparable to the S–S bond dissociation energy in dimethyl trisulfide, but considerably smaller than that in dimethyl disulfide (75 kcal mol^{-1}).[54f] For comparison the S–S bond energies in phenyl benzenethiosulfinate and diphenyl disulfide are ca. 35 and 65 kcal mol^{-1}, respectively.[56] The thiosulfinate oxygen actively participates in hydrogen bonding, although not quite as strongly as the oxygen in sulfoxides. Using the hydrogen bond strength method,[57] whereby the phenol OH stretching vibration band frequency shift is determined in the presence of oxygen donors, it was demonstrated that **12**, ethyl ethanethiosulfinate (**31**) and dimethyl sulfoxide caused frequency shifts of 278, 308 and 360 cm^{-1}, respectively.[54] Thiosulfinates can be distinguished from sulfoxides by a shift in the position of the S=O stretch in the infrared from 1075–1090 cm^{-1} for the former to 1030–1065 cm^{-1} for the latter.

When **12** and its higher homologs **13** or **31** were mixed, rapid equilibria were established at 25 °C affording in each case statistical mixtures of four thiosulfinates, even after substantial dilution (Scheme 10). The scrambling reaction is catalyzed by acid, inhibited by base or methyl acrylate, and the ESR spectrum shows no evidence of free radical formation. A rapid sulfenic acid–thiosulfinate exchange is postulated. In this reaction the sulfenic acid functions as a nucleophile and as a proton donor. Gas chromatography (GC) using short packed columns (2 m × 3 mm internal diameter) and injection port and column temperatures below 100 °C nicely separates the various thiosulfinates shown in Scheme 10; unique GC-MS data can be obtained for each regioisomer.[54e] As we shall see in Section 5.2.1, the processes of Scheme 10 and methods of isomer separation play an important role in *Allium* chemistry.



Scheme 10. The exchange reaction of the thiosulfinate pairs **12**/**13** and **12**/**31** involves attack of sulfenic acids on thiosulfinates.

While **12** undergoes ready disproportionation to dimethyl disulfide (**20**) and methyl methanethiosulfonate (**32**, Scheme 11), when **12** is refluxed in benzene with an equivalent of water, 2,3,5-trithiahexane 5-oxide (**33**) is formed in 84% yield. In a similar manner **13** affords 6-ethyl-4,5,7-



Scheme 11. Rearrangement of the Pummerer-type for the conversion of alkyl alkanethiosulfinates such as **12** and **13** into α-sulfinyl disulfides such as **33** and **34**, respectively. Reaction of sulfinic acids with thiosulfinates leading to alkyl alkanethiosulfonates, e.g. **32**.

trithiadecane 7-oxide (**34**). We had anticipated as long ago as 1973 that the unique combination of functional groups in α-sulfinyl and α-sulfonyl disulfides ought to lead to unusual physiological properties,[54d] a prediction recently borne out with the discovery of structurally analogous antithrombotic and lipoxygenase inhibitory cepaenes in onions (Sec-

tion 5.2.6). In order to account for the formation of **33** from **12**, we postulated the intermediacy of an α-alkyldithiocarbocation in a Pummerer-like reaction (Scheme 11). Solvolysis studies revealed that acyclic α-alkyldithiocarbocations are far less stable than α-alkylthiocarbocations (for example $MeSCH_2Cl$ hydrolyzes 6800 times faster than $MeSSCH_2Cl$.[58] We have suggested that the near 90° C–S–S–C dihedral angle adopted by acyclic disulfides is also favored by acyclic α-alkyldithiocarbocations and that this conformation precludes charge delocalization by the second (distant) sulfur, while at the same time diminishing by inductive effects the electron availability on the first (nearest) sulfur (see Fig. 2).[58] The above solvolysis study is relevant to

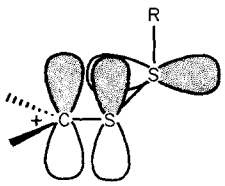


Fig. 2. Postulated conformation of acyclic carbocations containing the S–S–C$^+$ group.

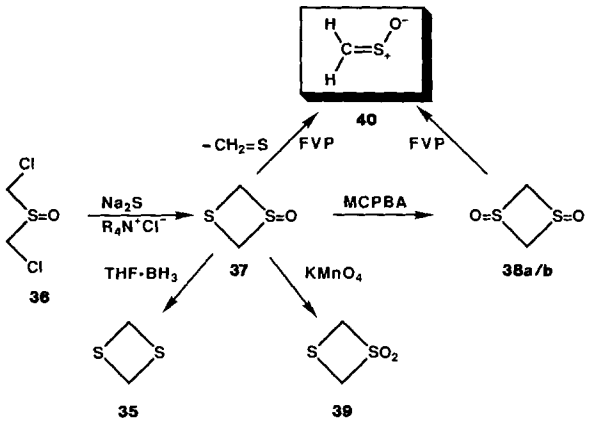
the observation that in the mass spectrum of $MeSCH_2SSMe$, fragmentation to $MeSCH_2^+$/MeSS$^\bullet$ is greatly favored over fragmentation to $MeSSCH_2^+$/MeS$^\bullet$. This observation also proves useful in establishing the structures of "deoxycepaenes" (see Section 5.2.6).

4.2. 1,3-Dithietane *S*-Oxides

The suggestion by Wilkens that the dimer of the onion LF is 2,4-diethyl-1,3-dithietane 1,3-dioxide **18a**[47] piqued our interest in this little studied class of heterocycles. Although derivatives of 1,3-dithietane have been known since 1872, the parent compound **35** was unknown prior to our work. We developed convenient syntheses of **35** and its *S*-oxides (Scheme 12).[59] Thus, treatment of bis(chloromethyl)

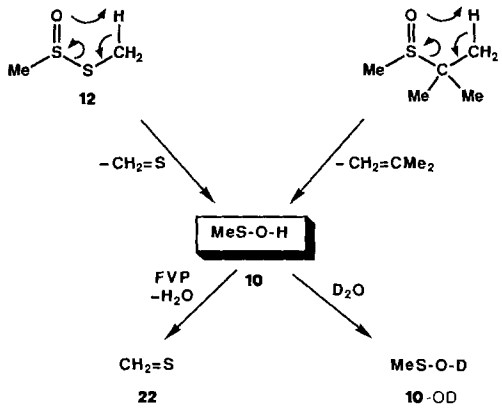


Scheme 12. Synthesis of 1,3-dithietane (**35**) ($\delta_C = 19$), 1,3-dithietane 1-oxide (**37**) ($\delta_C = 53$), 1,3-dithietane 1,3-dioxide (**38a/b**) ($\delta_C = 69$), and 1,3-dithietane 1,1-dioxide (**39**) ($\delta_C = 68$), and pyrolytic conversion of **37** and **38a/b** into sulfine (thioformaldehyde *S*-oxide) (**40**) ($\delta_C = 159$, $\delta_H = 7.73$, 7.84 ($J = 5.5$ Hz)). MCPBA = *m*-chloroperbenzoic acid.

sulfoxide (**36**) with sodium sulfide in the presence of a phase transfer catalyst gave 1,3-dithietane 1-oxide (**37**) in 36% yield as a colorless solid with a garlic like odor. Compound **37** could be reduced with THF · BH_3, giving the parent compound **35** in 70% yield, or oxidized with MCPBA or $KMnO_4$/acetone, giving *cis/trans*-1,3-dithietane 1,3-dioxide (**38a/b**) or 1,3-dithietane 1,1-dioxide (**39**), respectively, in excellent yields. While Wilkens[47] indicated that his LF dimer, formulated as **18a**, had sulfone type IR absorption at 1330 and 1140 cm^{-1}, we found compounds **37** and **38a/b** to have sulfoxide bands in the normal 1100–1035 cm^{-1} region,[1] with additional bands at 1132–1159 cm^{-1}, presumably associated with the four-membered ring. Sulfone **39** showed typical sulfonyl absorption bands[1] at 1393–1315 and 1200–1130 cm^{-1}. Compounds **38a/b** are stable solids melting above 200 °C, in contrast to **18a**, described by Wilkens[47] as an unstable liquid. Flash vacuum pyrolysis (FVP) of **37** and **38a/b** at 350–480 °C gave sulfine **40** (thioformaldehyde *S*-oxide).[59]

4.3. Sulfenic Acids

Sulfenic acids are key enzymatically formed intermediates in *Allium* chemistry. Prior to 1978 it was not known whether the structure of simple sulfenic acids was best represented by RS–O–H (**A**) or RS(O)H (**B**) or an equilibrium involving both forms.[51,60] Isolation proved difficult because of the high reactivity of sulfenic acids as *both* electrophiles and nucleophiles (cf. Scheme 8).[55] Using flash vacuum pyrolysis (FVP) we were able to demonstrate that above 250 °C at 0.1 torr both *tert*-butyl methyl sulfoxide and methyl methanethiosulfinate (**12**) decompose affording methanesulfenic acid (**10**) and isobutylene or thioformaldehyde (**22**), respectively (Scheme 13).



Scheme 13. Generation of methanesulfenic acid (**10**) by FVP methods.

Compound **10** showed a molecular ion at *m/z* 64 when examined using coupled FVP-mass spectrometric analysis. Through coupled FVP-microwave spectroscopic studies of a series of isotopically substituted forms of **10** (^{13}C, CD_3; ^{18}O, OD) its full structure was determined (Fig. 3). Compound **10** contains dicoordinate rather than tricoordinate sulfur (form

A rather than **B**) and a geometry similar to that of H_2S_2 (HSSH angle 90.6°).[61] The structural determination was aided by the finding that **10** readily exchanges with deuterium oxide in the waveguide giving **10**-OD. By means of a tandem pyrolysis experiment it was further demonstrated that **10** undergoes dehydration giving thioformaldehyde (Scheme 13). The half-life of **10** in the gas phase at 0.1 torr and 25 °C is ca. one minute. When condensed at −196 °C **10** could not be recovered on warming in vacuum. Analysis of calculated charge densities. The gas-phase lifetimes of **40** and **22** at room temperature and 30 μm are ca. 30 minutes and 20 seconds, respectively. Compound **40** could be generated at room temperature by fluorodesilylation of (trimethylsilyl)methanesulfinyl chloride (**41**; Scheme 14).[70] Cyclopentadiene was used as an *in situ* trap for **40**. The major cyclopentadiene Diels–Alder adduct of **40**, 2-thiabicyclo-[2.2.1]hept-5-ene *endo*-2-oxide (**42**; 10% of the *exo* isomer was also present) proved to be thermally unstable at room

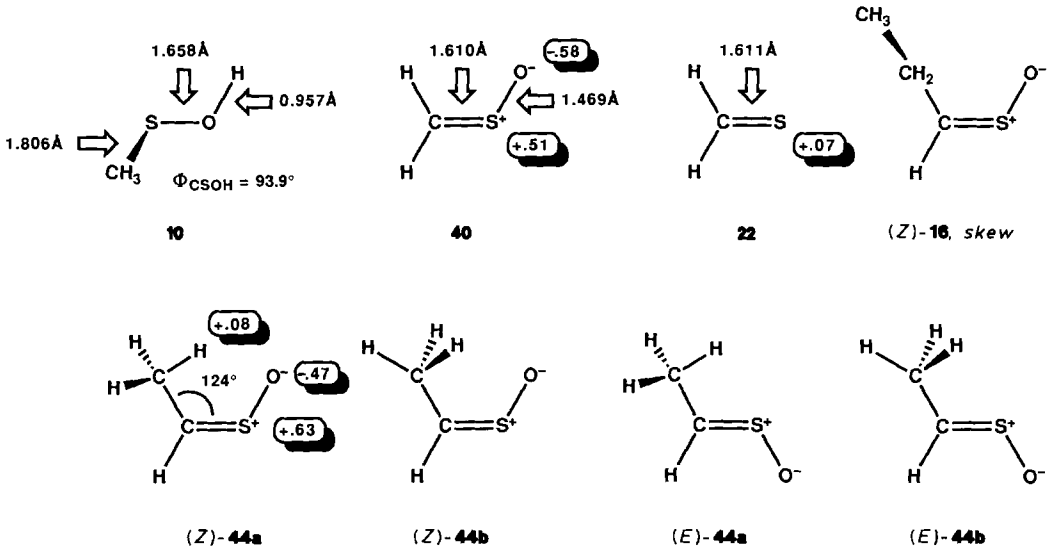


Fig. 3. Structures of methanesulfenic acid (**10**), thioformaldehyde *S*-oxide (**40**), thioformaldehyde (**22**), propanethial *S*-oxide (**16**), and the conformers of ethanethial *S*-oxide (**44**) determined by microwave spectroscopy.

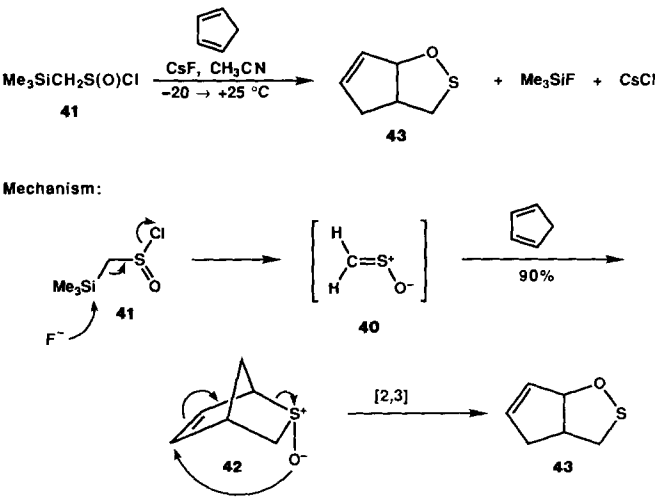
the low-temperature condensate warmed to room temperature revealed the presence of **12**. In the gas-phase experiments we were unable to detect even minor amounts of the tautomer of type **B**. In agreement with our experimental observations, theoretical calculations confirm that CH_3S–O–H and its inorganic homologue H–S–O–H are significantly more stable than their respective isomers $CH_3S(O)H$[62] and $H_2S(O)$.[63] The preference for form **A** rather than **B** has also been found with stable, sterically hindered sulfenic acids.[64] In other relevant work, 1-anthraquinonesulfenic acid, another stable sulfenic acid, has been found to have a pK_a value of 7.51.[65]

4.4. Sulfine (Thioformaldehyde *S*-Oxide)

Like sulfenic acids, sulfines (thiocarbonyl *S*-oxides) are key compounds in *Allium* chemistry. We generated the previously unknown parent sulfine, thioformaldehyde *S*-oxide (**40**), by pyrolysis of 1,3-dithietane 1-oxide (**37**), 1,3-dithietane 1,3-dioxide (**38a/b**; cf. Scheme 12), or methanesulfinyl chloride. Compound **40** was fully characterized by mass spectrometry, microwave, photoelectron, IR and NMR spectroscopy.[66–69] The structures of **40** and, for comparison, thioformaldehyde (**22**) are shown in Figure 3 along with temperature, undergoing a [2,3]-sigmatropic rearrangement to 2-oxa-3-thiabicyclo[3.3.0]oct-7-ene (**43**), a rare example of an isolable sultene (a heterocycle containing an S–O single bond).



Scheme 14. Generation and Diels–Alder trapping reaction of sulfine **40**, which was generated from **41** by fluorodesilylation. The rearrangement of the primary adduct **42** to led to the **43**.

5. Organosulfur Compounds from Cut *Allium* Spp.: Post-1972 Results

Come, follow me by the smell,
here are delicate onions to sell;
I promise to use you well.
They make the blood warmer,
You'll feed like a farmer;
For this is every cook's opinion,
no savoury dish without an onion;
But, lest your kissing should be spoiled,
Your onions must be thoroughly boiled:
Or else you may spare your mistress a share,
the secret will never be known:
She cannot discover the breath of her lover but think it as sweet as her own.

"Verses for Fruitwomen",
Jonathan Swift (1667–1745)

The work done prior to 1972 suggests that, when *Allium* spp. are cut, highly reactive sulfenic acids and/or sulfines are produced by enzymatic action on precursors in the intact bulb. The main fate of the short-lived sulfenic acids appears to be condensation to form thiosulfinates. The thiosulfinates can then participate in a variety of subsequent reactions which depend on conditions and which afford various types of organosulfur compounds. These compounds can be categorized as headspace volatiles (products formed above cut *Allium* or *Allium* homogenates at room temperature), products formed when the thiosulfinates stand in solution at room temperature, or compounds produced by more vigorous processes such as steam distillation (or decomposition in the injection port of a GC[71]!) (Scheme 15). The volatile, thermally stable compounds are best analyzed by GC or GC-MS while the thermally unstable compounds are preferably isolated/identified by milder chromatographic methods (e.g. HPLC, supercritical fluid chromatography (SFC), or GC under modified injection conditions). In our discussion we will first treat the unique low-temperature volatile onion lachrymatory factor and its dimer, then those thermally unstable constituents of *Allium* homogenates formed in solution, and finally those constituents of headspace volatiles and steam distillates identified primarily by gas chromatography.

5.1. Onion Lachrymatory Factor (LF) and its Dimer

Indeed the tears live in an onion that should water this sorrow.

"Antony and Cleopatra", I. ii. 173
William Shakespeare (1564–1616)

A number of points from the published work on the onion LF required clarification. Assuming that the LF is propanethial *S*-oxide (**16**) as postulated by Wilkens[47] and Brodnitz,[50] how can the exchange of a single proton (from Virtanen's deuteration studies[2]) be rationalized? Is the stereochemistry of the LF indeed *E* (anti)? Is it reasonable to assume that the same enzyme allinase could catalyze *both* the sulfenic acid eliminations of Schemes 1 and 4 as well as Brodnitz's retro-ene mechanism of Scheme 5? These questions will be addressed below.

Extraction of chopped onions at low temperatures with $CFCl_3$ followed by low-temperature vacuum distillation gave the onion lachrymatory factor (LF). The LF was purified by trap-to-trap distillation (−35 to −196 °C) at 0.001 torr. Authentic propanethial *S*-oxide (**16**) and its lower homolog ethanethial *S*-oxide (**44**) were prepared from the reactions of propanesulfinyl chloride (**19**) and ethanesulfinyl chloride (**45**), respectively, with triethylamine.

$$\underset{\mathbf{19}}{CH_3CH_2CH_2S(O)Cl} \longrightarrow \underset{\mathbf{16}}{CH_3CH_2CH{=}S^+{-}O^-}$$

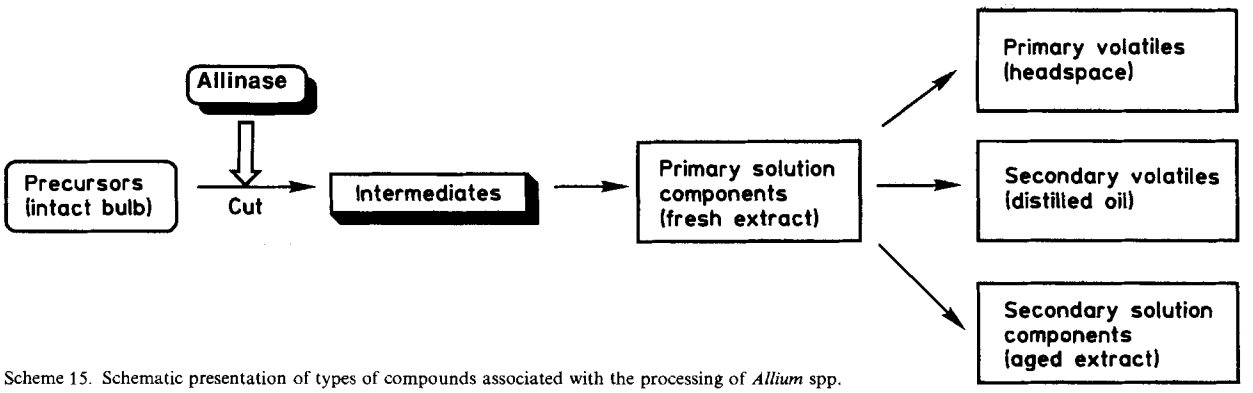
$$\underset{\mathbf{45}}{CH_3CH_2S(O)Cl} \longrightarrow \underset{\mathbf{44}}{CH_3CH{=}S^+{-}O^-}$$

5.1.1. Microwave and NMR Spectroscopic Analysis of Onion LF and Homologs

Mine eyes smell onions; I shall weep anon;
good Tom Drum, lend me a handkercher.

"All's Well That Ends Well", V. iii. 316
William Shakespeare (1564–1616)

Samples of the LF and **44**, prepared as described in Section 5.1, were evaporated at room temperature into a microwave guide. Only the normal isotopic species were used in the analysis of the microwave spectra of **16** and **44**. Structural conclusions for **44** are based upon the assumption that



Scheme 15. Schematic presentation of types of compounds associated with the processing of *Allium* spp.

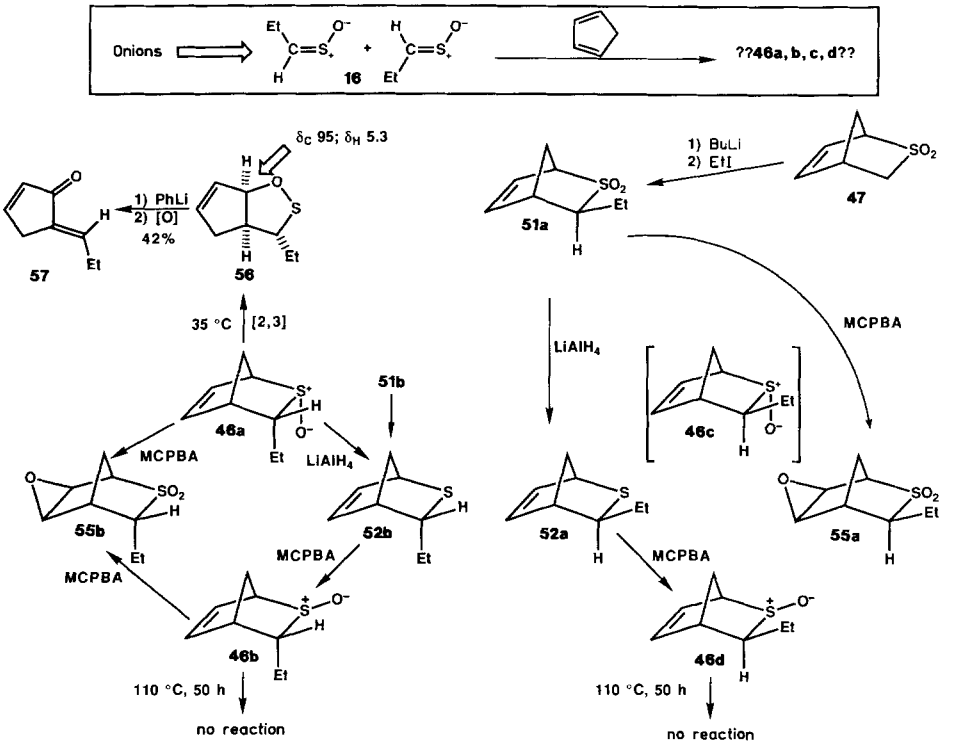
the CHSO framework is identical to that of thioformaldehyde *S*-oxide (**40**) and that the methyl groups are tetrahedral with C–H = 1.093 Å. The structures of (*Z*)-**44** and the onion LF, (*Z*)-**16**, determined by microwave spectroscopy, are given in Figure 3 (also see Section 5.1.4).[72] The *E* (*anti*) isomer of **44** could not be detected by microwave spectroscopy. The dipole moment of (*Z*)-**44** is 3.23(2) D, slightly larger than that determined for **40** (2.994 D). Microwave analysis of **16** is complicated by the fact that internal rotation about the $CH–CH_2$ bond gives this sulfine an additional conformational degree of freedom. Of the four possible conformations/structures for **16**—*Z* skew ((*Z*)-**16a**), *Z cis* ((*Z*)-**16b**), *E* skew ((*E*)-**16a**), and *E cis* ((*E*)-**16b**)—only (*Z*)-**16a** fits the calculated rotational constants and fulfills the heavy-atom nonplanarity implied by the observed constants. Unlike **40**, sulfines **16** and **44** are stable in the wave guide at 0.050 torr and 25 °C. Neither ethenesulfenic acid (**15a**/**15b**) nor (*E*)- or (*Z*)-1-propenesulfenic acid (**14**) could be detected in any of the samples examined by microwave spectroscopy (cf. Scheme 4). As will be detailed in Section 5.3.1, ^{1}H-NMR analysis of the onion LF indicated a *Z*:*E* ratio of 95:5 for **16**. Similar *Z*:*E* ratios were obtained for **44** and other thioaldehyde *S*-oxides.

5.1.2. Determination of the Configuration of Onion LF from the Structures of Cyclopentadiene Diels–Alder Adducts

Determination of the configuration of the onion LF by spectroscopic means requires concentration and, in the case of microwave spectroscopy, vaporization. An alternative approach involves directly trapping the LF with cyclopentadiene at low temperature followed by NMR measurement of the adduct *cis*:*trans* ratio [(**46a** + **46d**):(**46b** + **46c**), Scheme 16]. As we have already mentioned in Section 4.3, sulfine **40** is readily trapped by cyclopentadiene giving thermally labile *endo*-adduct **42** which undergoes a facile [2,3]-sigmatropic rearrangement to **43** even at 0 °C (see Scheme 14).

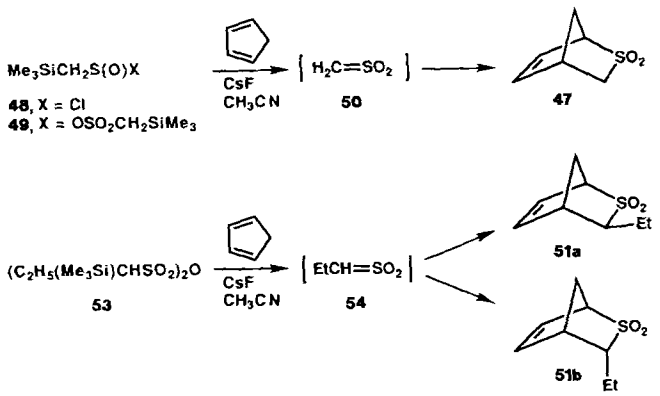
Adducts **46b** and **46d** were independently synthesized and characterized (Schemes 16 and 17); adduct **46c** could not be prepared.[73] A novel procedure was used to prepare 2-thiabicyclo[2.2.1]hept-5-ene 2,2-dioxide (**47**). Thus, treatment of (trimethylsilyl)methanesulfonyl chloride (**48**) or (trimethylsilyl)methanesulfonic anhydride (**49**) with cesium fluoride and excess cyclopentadiene gave **47** in 64% isolated yield from **48** or 75% isolated yield from **49** by a reaction which must involve thioformaldehyde *S*,*S*-dioxide (**50**, sulfene) as an intermediate.[74] This reaction represents the first instance of Diels–Alder trapping of sulfene.[48b] Compound **47** could also be prepared by oxidizing the unstable adduct **42** of cyclopentadiene and sulfine (**40**) or by oxidation of the known 2-thiabicyclo[2.2.1]hept-5-ene.[75] Sequential treatment of **47** with butyllithium followed by ethyl iodide gave *exo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene 2,2-dioxide (**51a**), which was reduced with lithium aluminum hydride to *exo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene (**52a**) and then oxidized with MCPBA to *exo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene *exo*-2-oxide (**46d**).

A 23:77 mixture of **51a** and its *endo*-isomer (**51b**) could be prepared in 76% yield by treatment of 1-(trimethylsilyl)propanesulfonic anhydride (**53**) with cesium fluoride and excess cyclopentadiene, a reaction which must involve propanethial *S*,*S*-dioxide (**54**) as an intermediate (Scheme 17). When the product from the Diels–Alder reaction of cyclopentadiene with the onion LF or **16**, prepared from propanesulfinyl chloride (**20**), was oxidized with one



Scheme 16. Cyclopentadiene-LF adducts of type **46**: their synthesis, interconversion, and rearrangement.

equivalent of MCPBA, **51b** could be isolated in 79% yield. Lithium aluminum hydride reduction of the above cyclopentadiene-LF or cyclopentadiene-**16** adduct gave *endo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene (**52b**)[76] which on reoxidation with one equivalent of MCPBA gave *endo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene *exo*-2-oxide (**46b**). Oxidation of **51a** and **51b** with excess MCPBA gave *exo*-5,6-epoxy-*exo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene 2,2-dioxide (**55a**) and *exo*-5,6-epoxy-*endo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene 2,2-dioxide (**55b**), respectively. The structure of **55b** was established by X-ray crystallography.[73, 77a]



Scheme 17. Synthesis of **47** (64–75% yield) and **51a,b** (76% yield) by trapping of thioformaldehyde *S,S*-dioxide (**50**) and propanethial *S,S*-dioxide (**54**) with cyclopentadiene. The sulfenes are generated by fluorodesilylation.

While compounds **46b** and **46d** were unchanged after refluxing in deuteriotoluene for 50 hours, the adducts of cyclopentadiene with LF or **16** rearranged upon refluxing in methylene chloride for 1.5 hours to give *exo*-4-ethyl-2-oxa-3-thiabicyclo[3.3.0]oct-7-ene (**56**), isolated in 50% yield. The same type of rearrangement was also observed for the adducts of cyclopentadiene with ethanethial *S*-oxide (**44**), and butanethial *S*-oxide.[77a] This novel rearrangement forms the basis for a useful synthesis of 5-alkylidene-2-cyclopentenones, e.g. **57** (Scheme 16).[77a]

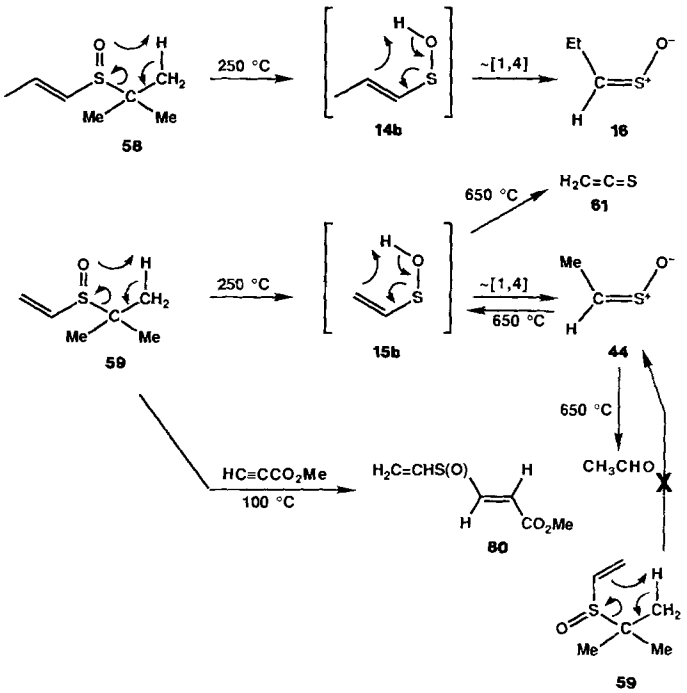
When an onion slurry, prepared from frozen chopped onions, was extracted with Freon-11 and the dried extract treated with cyclopentadiene at −78 °C followed by low-temperature concentration, a 15:1 mixture of *endo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene *endo*-2-oxide (**46a**) and *exo,exo*-adduct **46d** could be detected through coincidence of ^{13}C-NMR peaks in the olefinic region with corresponding peaks of authentic samples. We were unable to detect NMR peaks corresponding to *exo,endo*-adduct **46b**. The reason for the absence of **46b** is clear if we assume that formation of *exo*-3-ethyl-2-thiabicyclo[2.2.1]hept-5-ene *endo*-2-oxide (**46c**) is significantly favored by secondary orbital interactions over **46b** and that substantially less **46c** is formed than **46a**. While we could not prepare an authentic sample of **46c**, in the LF-cyclopentadiene adduct mixture we observed several minor unidentified olefinic ^{13}C-NMR signals which disappeared on warming, and could be due to **46c**. We estimate that the concentration of **46c** is less than 5%, reflecting a *Z*:*E* ratio for the LF of at least 95:5, in agreement with the NMR data (see Section 5.3.1).[77b]

5.1.3. *Mechanism for the Formation of Onion LF from (E)-1-Propenesulfenic Acid*

And if the boy have not a woman's gift to rain
a shower of commanded tears,
An onion will do for such a shift,
which in a napkin being close conveyed,
Shall in despite enforce a watery eye.

"The Taming of the Shrew", Introduction, 122.
William Shakespeare (1564–1616)

We examined the pyrolysis of (*E,Z*)-*tert*-butyl-1-propenyl sulfoxide (**58**) and *tert*-butyl-2-vinyl sulfoxide (**59**) with the hope of generating (*E,Z*)-1-propenesulfenic acid (**14b**) and ethenesulfenic acid (**15b**) (which, by analogy with the structure of methanesulfenic acid (**10**), should possess dicoordinate sulfur) and determining the relationship, if any, between these sulfenic acids and propanethial *S*-oxide (**16**) and ethanethial *S*-oxide (**44**), respectively. Both **58** and **59** are efficiently converted by FVP at 250 °C into the respective (*Z*)-sulfines (*Z*)-**16** and (*Z*)-**44**, as characterized by both microwave and NMR spectroscopy (Scheme 18). A 97:3 (*Z*)-

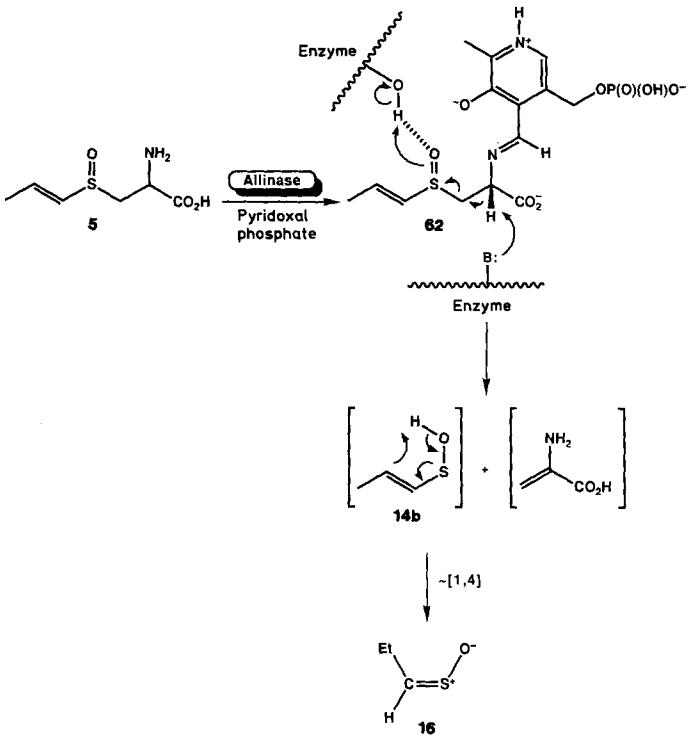


Scheme 18. Flash vacuum pyrolysis of 1-alkenyl *tert*-butyl sulfoxides such as **58** and **59** as a route to 1-alkenesulfenic acids such as **16** and **44**, respectively.

16:(*E*)-**16** ratio and a 95:5 (*Z*)-**44**:(*E*)-**44** ratio was established by ^{1}H-NMR analysis (discussed in Section 5.3.1). Heating a solution of **59** in excess methyl propiolate at 100 °C affords sulfenic acid adduct **60**. Neat **59** decomposes within 4 h at 100 °C to give, among other products, acetaldehyde, which we have separately found to be a major decomposition product of ethanethial *S*-oxide (**44**). Finally, microwave spectroscopic analysis indicates that sulfine **44** decomposes under high-temperature FVP conditions (650–750 °C) to both acetaldehyde and thioketene (**61**).[72]

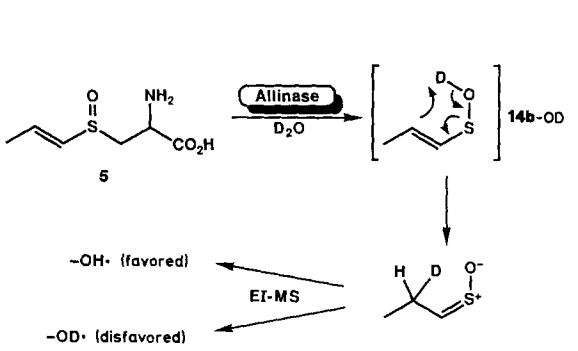
The above results are most simply explained in terms of a [1,4]-sigmatropic rearrangement of **14b** and **15b** (Scheme 18), a reaction leading to (*Z*)-sulfines. The conversion of **58** via **14b** into **16**, and of **59** via **15b** into **44** finds precedence in the known tautomerism of thioamide *S*-oxides[78] and the isomerization of other α,β-unsaturated sulfenic acids to sulfines.[79] At high temperatures **15b** undergoes unimolecular dehydration to thioketene (**61**), in analogy with the previously noted high-temperature dehydration of methanesulfenic acid (Scheme 13). McLafferty et al. have examined the formation of **15b** and **44** from **59** by tandem FVP and neutralization-reionization mass spectrometry and ab initio calculations.[80] Their studies exclude an alternative retro-ene route from **59** to **2** (Scheme 13) and indicate that **44** is 12 kJ mol^{-1} (2.9 kcal mol^{-1}) more stable than **15b** with a transition state interconversion barrier of 137 kJ mol^{-1} (33 kcal mol^{-1}) and that **15b** has a near-orthogonal geometry with a CSOH dihedral angle of 88°. When **15b**-OD is examined in the mass spectrometer under conditions allowing conversion into **44**, OH loss predominates >2:1 over OD loss.

A mechanism for the genesis of the onion LF from precursor **5** is proposed (Scheme 19). Our mechanism is consistent



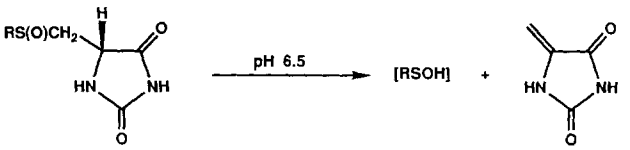
Scheme 19. Mechanism for allinase catalyzed conversion of **5** into the onion LF **16**.

with the deuteration studies of Virtanen if it is assumed that rearrangement of deuterated 1-propenesulfenic acid **14b**-OD precedes electron-impact-induced fragmentation (Scheme 20). Our mechanism also has the advantage of allowing a common mode of enzymatic decomposition for LF precursor **5** and cysteine sulfoxides **2**, **6**, and **7**. The intermediacy of Schiff base **62** is consistent with the requirement for pyridoxal phosphate as a cofactor for the enzymatic reac-



Scheme 20. Mechanisms of the allinase-catalyzed conversion of **5** into LF **16** in the presence of deuterium oxide.

tion[3h, i] and the demonstration that sulfenic acids can be eliminated from related structures (Scheme 21) in vitro at neutral pH and ambient temperatures.[81]



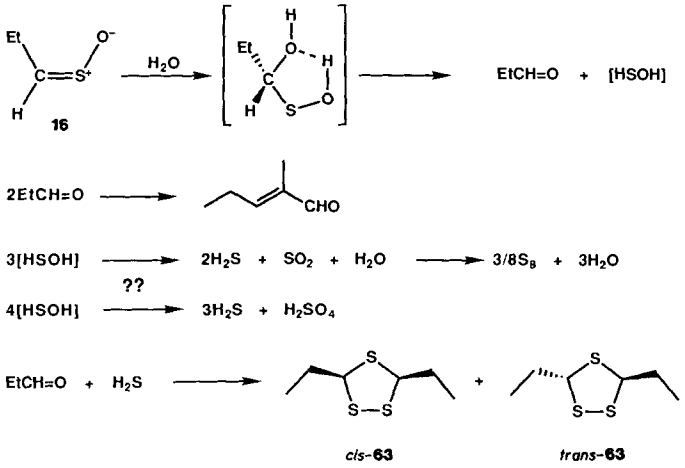
Scheme 21. Formation of sulfenic acids from hydantoins at room temperature in almost pH neutral solution.

5.1.4. The "Syn Effect" of Onion LF and Other Sulfines

While the [1,4]-sigmatropic rearrangements of **14b** to (*Z*)-**16** and **15b** to (*Z*)-**44** are aesthetically appealing and accommodate most observations (Scheme 18), it is curious that (*Z*)-**16** and (*Z*)-**44** are also the predominant products formed upon treatment of propanesulfinyl chloride (**19**) and ethanesulfinyl chloride (**45**), respectively, with triethylamine, reactions that should not involve the intermediacy of **14b** and **15b**! Theoretical calculations were therefore performed to examine the relative energies of the conformers of **44**.[82] Restricted Hartree-Fock calculations on **44** indicate that conformer (*Z*)-**44a** is more stable than conformers (*Z*)-**44b**, (*E*)-**44a**, and (*E*)-**44b** by 0.8, 1.7, and 3.1 kcal mol^{-1}, respectively (Fig. 3). These calculations are in good agreement with microwave spectroscopic studies of **44**-CH_2D ($CH_2DCH{=}S^+{-}O^-$), in which **44a** was the only conformation to be observed. The conformational preference for *Z*-**44a** can be explained in terms of orbital and electrostatic interactions between the terminal oxygen and methyl hydrogens, which are negligible in the (*E*)-form. Calculations indicate substantial negative charge on the sulfine oxygen (Fig. 3). It is suggested that there is an attractive electrostatic interaction between the methyl hydrogens (which according to the calculations bear a positive charge) and the negatively charged oxygen. A σ-type interaction, characterized by the formation of six σ-MOs, of which the HOMO is 1,5-bonding, also favors conformer (*Z*)-**44a**.[82] Both of these types of interactions are missing in the (*E*)-conformers. The general phenomenon of enhanced stability of (*Z*)- or *syn* isomers, the "*syn*-effect", is in fact well known.[82, 83] An important consequence of the above theoretical findings is that alternative routes from **14b** to (*Z*)-**16**, e.g. by protonation of the enolate of the (*E*)-1-propenesulfenate anion, cannot be excluded.

5.1.5. The Hydrolysis of Onion LF

When **16** is allowed to remain in contact with water, sulfur is split off, perhaps initially as HSOH, leaving behind propanal, which readily undergoes aldol condensation. In the medium following hydrolysis of **16**, sulfur is found as the free element as well as (in minor quantities) sulfate and sulfite. Hydrogen sulfide, detected in onion volatiles and presumably a decomposition product of **16**, may be trapped by propanal, forming *cis*- and *trans*-3,5-diethyl-1,2,4-trithiolane (**63**). **63** has likewise been isolated from volatiles of onion and other *Allium* spp. (Scheme 22).[84]

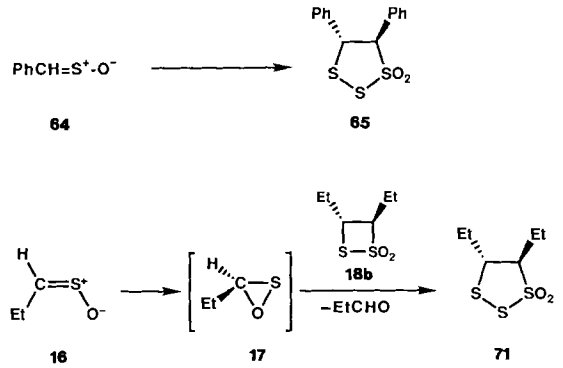


Scheme 22. Hydrolysis of LF **16** and formation of 1,2,4-trithiolanes *cis*- and *trans*-**63**.

5.1.6. The Dimer of Onion LF

As already noted, in 1961 Wilkens reported that the onion LF dimerized, affording a compound claimed to be 2,4-diethyl-1,3-dithietane 1,3-dioxide (**18a**) (cf. Scheme 5).[47] The proposed structure seemed to us to be at odds with the IR spectrum of the dimer, which indicated the presence of a sulfonyl group, and our examination of the IR spectra of authentic *cis*- and *trans*-1,3-dithietane 1,3-dioxide (**38a/b**) (cf. Scheme 12),[59] which failed to show the type of unusual "pseudo-sulfone infrared absorption" proposed by Wilkens to explain the spectrum of **18a**. Furthermore, the stability of the **38a/b** contrasts with the instability of **18a**. Finally, it is mechanistically difficult to reconcile the formation of **18a** from **16** with the reported formation of *trans*-4,5-diphenyl-1,2,3-trithiolane 1,1-dioxide (**65**) from thiobenzaldehyde *S*-oxide (**64**, Scheme 23).[85] In view of the uncertainty about the structure of the LF-dimer we re-examined the self-condensation of **16**.

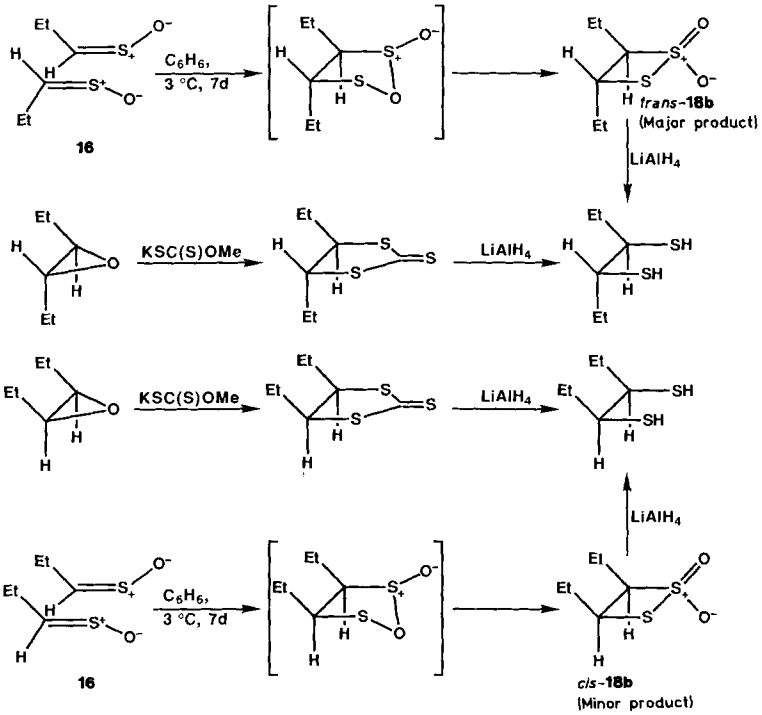
A sample of **16** from natural or synthetic sources was purified by trap-to-trap distillation at −30 °C, dissolved in about twice its volume of freshly dried benzene and kept in the dark at 3 °C for 7 days. The slightly yellow solution, now devoid of lachrymatory properties, was concentrated in vacuo and the residue subjected to molecular distillation, affording a clear, practically colorless liquid with a strong onion-like odor. Analysis by GC indicated a single major



Scheme 23. Formation of 1,2,3-trithiolane 1,1-dioxides **65** and **71** from sulfines **64** and **16**, respectively.

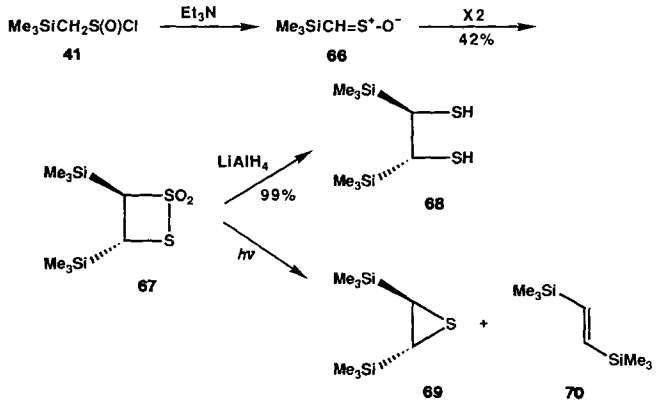
product with retention time slightly longer than that of propyl propanethiosulfonate. High resolution mass spectrometry confirmed the formula $C_6H_{12}S_2O_2$ for the LF dimer. The IR spectrum, showing sulfonyl bands, was very similar to that published by Wilkens.[47] The LF dimer gave a positive thiosulfonate test[86] and absorbed in the UV (EtOH or hexane) at $\lambda_{max} = 280$ (ε 100, sh).[87] Reduction of the compound with $LiAlH_4$ in ether gave 90% (±)-hexane-3,4-dithiol and 10% *meso*-hexane-3,4-dithiol. The above data and the ^1H- and ^{13}C-NMR spectra, discussed in Section 5.3.2, are most consistent with *trans*-3,4-diethyl-1,2-dithietane 1,1-dioxide (**18b**) as the structure of the LF dimer.[88a] Compound **18b** is formed by a process that begins with 1,3-dipolar addition of **16** to itself followed by rearrangement (Scheme 24).[88b] Minor amounts of *cis*-**18b** are also formed.

(*Z,E*)-(Trimethylsilyl)methanethial *S*-oxide (**66**), prepared by treatment of (trimethylsilyl)methanesulfinyl chloride (**41**)



Scheme 24. Mechanism for the dimerization of propanethial *S*-oxide **16** to **18b**.

with one equivalent of triethylamine. also dimerizes on storage at room temperature for several days to afford *trans*-3,4-bis(trimethylsilyl)-1,2-dithietane 1,1-dioxide (**67**) in 42% yield as a colorless, crystalline solid of m.p. 100–101 °C (Scheme 25).[77b, 89] Compound **67** affords (±-1,2-bis-

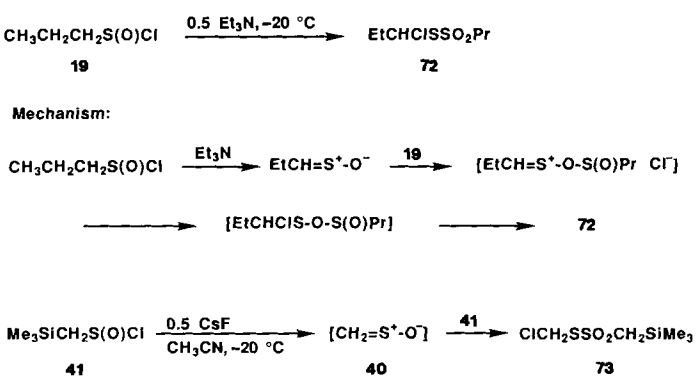


Scheme 25. Synthesis of silylated 1,2-dithietane 1,1-dioxide **67** from (trimethylsilyl)methanethial *S*-oxide (**66**); conversion of **67** into 2,3-bis(trimethylsilyl)thiirane (**69**) and the compounds (±)-**68** and **70** (only the *S,S* forms are shown).

(trimethylsilyl)-1,2-ethanedithiol (**68**) on reduction and *trans*-2,3-bis(trimethylsilyl)thiirane (**69**) and *trans*-1,2-bis(trimethylsilyl)ethene (**70**) on photolysis.[89] In benzene solution, the LF **16** may also undergo unimolecular rearrangement giving oxathiirane **17**, which in turn could donate sulfur to LF dimer **18b** giving *trans*-4,5-diethyl-1,2,3-trithiolane 1,1-dioxide (**71**, Scheme 23).

5.1.7. α-Chloroalkyl Alkanethiosulfonates: By-products in the Synthesis of Onion LF and Other Alkanethial S-Oxides from Alkanesulfinyl Chlorides

In the course of preparing onion LF **16** by treatment of propanesulfinyl chloride (**19**) with triethylamine we noticed the formation of small quantities of 1-chloropropyl propanethiosulfonate (**72**). We found that the formation of α-chloroalkyl alkanethiosulfonates was a general reaction with optimum yields when an alkanesulfinyl chloride was



Scheme 26. Synthesis of α-chloroalkyl alkanethiosulfinates such as **72** and **73** from sulfines such as **19** and **41**, respectively.

treated at low temperature with *one-half an equivalent* of triethylamine.[90] Thiosulfonates such as **72** result from reaction of the sulfine, functioning as a nucleophile, with the sulfinyl chloride, functioning as an electrophile (Scheme 26). In support of this mechanism we found that separately generated sulfines react with sulfinyl chlorides forming the expected chlorinated thiosulfonates. If thionyl chloride is substituted for the sulfinyl chloride, the product is a bis(α-chloroalkyl) disulfide. In another variant, we found that slow addition of 0.5 equivalent of cesium fluoride to (trimethylsilyl)methanesulfinyl chloride (**41**) in acetonitrile at −20 °C gave *S*-chloromethyl (trimethylsilyl)methanethiosulfonate (**73**) in nearly quantitative yield. Here the sulfine being trapped is the parent compound **40**.[70] We have recently utilized this reaction to establish the formation of cyclopropanethione *S*-oxide from cyclopropanesulfinyl chloride.[91]

5.2. Organosulfur Constituents of *Allium* Homogenates Separated by HPLC and GC-MS

If Leekes you like but do their smell dis-leeke
Eat Onyuns and you shall not smell the Leeke.
If you of Onyuns would the scent expelle
Eat Garlicke and that shall drowne the Onyun's smelle.
Anonymous

A variety of procedures have been examined for the separation of compounds formed in solution from cut *Allium* spp. The plant can be finely cut using a Waring Blender, a food processor or a tissue homogenizer. While the Waring Blender gives satisfactory results with "softer" plants, garlic and shallot bulbs are best cut first with a food processor followed by a tissue homogenizer. The plant is chopped using a 2:1 water:plant ratio. For the preparation of an *extract*, the homogenate is squeezed through cheese cloth or nylon mesh, saturated with sodium chloride, and shaken twice with dichloromethane, filtering/centrifuging each time. The separated dichloromethane layers are combined, dried and concentrated in vacuo at room temperature and then analyzed by FT-NMR and HPLC and/or GC (with a modified injector; see Section 5.2.1). Supercritical carbon dioxide can also be used as the extraction solvent.[92] For preparation of *a room temperature "steam distillate"*, the above homogenate is subjected to distillation at high vacuum using an oil bath to keep the pot at room temperature. The distillate is collected at −196 °C,[93, 94] saturated with sodium chloride and extracted and analyzed as above. For a particular plant the extract and room-temperature distillate were analytically quite similar (cf. Fig. 4). Although the distillates were generally cleaner with less component isomerization, in some cases more material was lost by distillation than by extraction, or other differences were observed.

5.2.1. Thiosulfinates: Primary Products in Cut Allium spp.

In addition to LF **16**, detected exclusively in the case of the onion but probably formed in other *Allium* spp., the primary

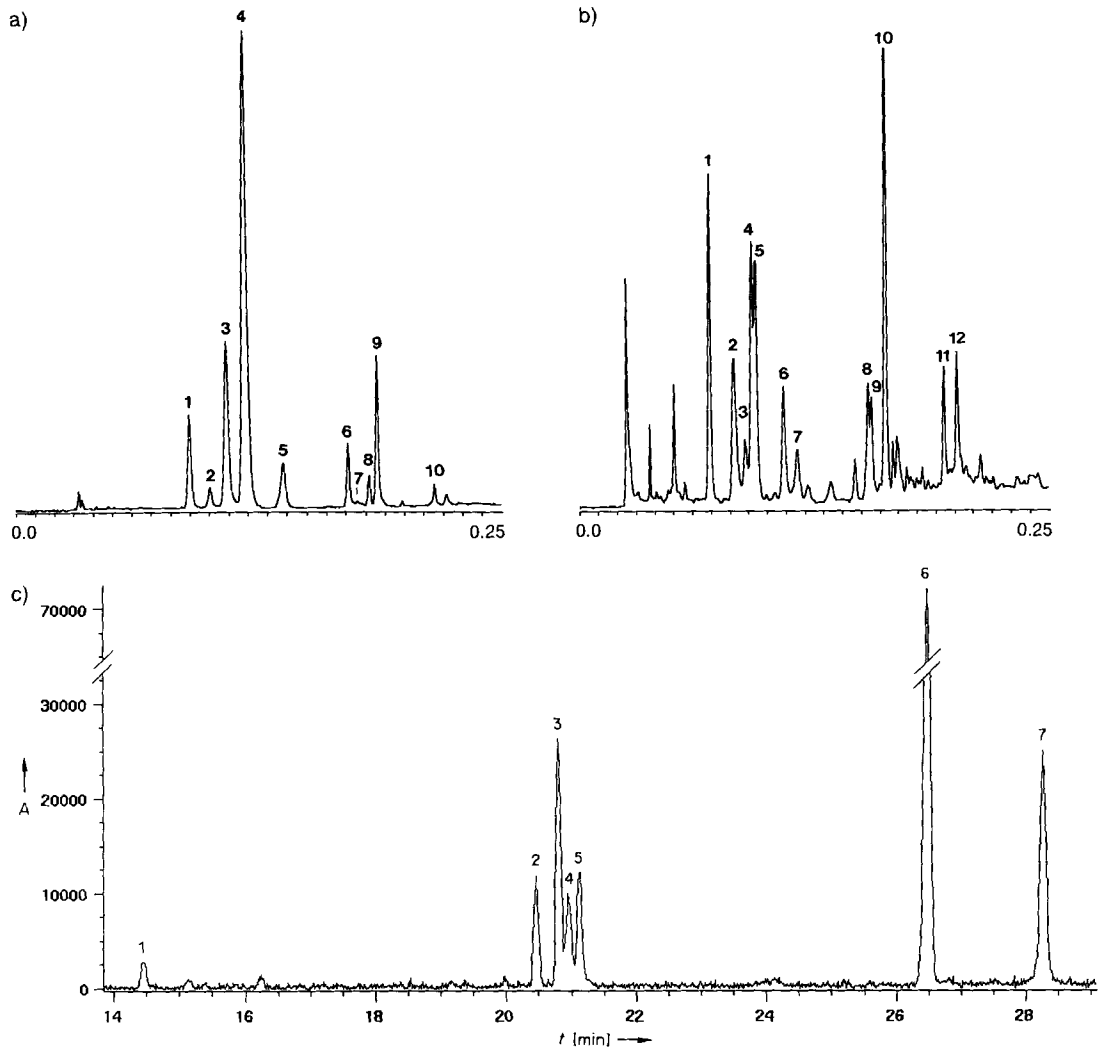


Fig. 4. a) HPLC separation of an extract of store-purchased garlic containing benzyl alcohol as internal standard. Conditions: 250 × 4.6 mm, 5 μm Rainin Microsorb silica gel column, UV detection at 254 nm; 1.6 mL min^{-1}, gradient from 2:98 2-propanol:hexane (10 min hold), to 20:80 during 10 min (5 min hold). Peak identification: 1, (*E*)-**105**, R = All); 2, (*Z*)-**106**, R = All); 3, (*E*)-**106**, R = All); 4, allicin **1**; 5, benzyl alcohol, internal standard; 6, **102**; 7, (*Z*)-**106**, R = Me; 8, (*E*)-**106**, R = Me; 9, **101**, 10, **12** (cf. Schemes 1, 4, 34, and 37). b) HPLC separation of a distillate of white onion (conditions as above). Peak identification: 1, (*E*)-**105**, R = Pr; 2, (*Z*)-**106**, R = Pr; 3, **16**; 4, (*E*)-**106**, R = Pr; 5 (shoulder), **13**; 6, (*E*)-**105**, R = Me; 7, benzyl alcohol, internal standard; 8, **30**; 9, (*Z*)-**106**, R = Me; 10, (*E*)-**106**, R = Me and **29** (overlapping peaks); 11, **123**; 12, **12** (cf. Schemes 4, 5, 10, 37, and 46). c) GC-EI-MS total ion chromatogram of the same sample of white onion as in Figure 4b. A = abundance. Conditions: 30 m × 0.53 mm methyl silicone gum capillary column, cryogenic on-column injection at 0 °C, column programmed from 0–200 °C at 5 °C min^{-1}; column head pressure 34.5 × 10^3 Pa (5 psi), GC-MS transfer line temperature, 100 °C. Peak identification: 1, **12**; 2, **29**; 3, (*E,Z*)-**106**, R = Me; 4, **30**; 5, (*E*)-**105**, R = Me; 6, (*E*)-**106**, R = Pr and *trans*-zwiebelane (**118**); 7, *cis*-zwiebelane (**117**) (cf. Schemes 4, 10 and 37, and Fig. 7).

products detected by HPLC, NMR, and GC-MS from the above procedures are thiosulfinates (Table 1) with negligible di- and polysulfides or thiosulfonates. Together with LF **16**, these thiosulfinates closely duplicate the taste and aroma of the freshly cut *Allium* spp. and serve as progenitors of virtually all of the organosulfur compounds formed in the cut plants. In view of the thermal instability of allicin **1** and other thiosulfinates it is surprising that vacuum "steam distillation" succeeds so well. Room-temperature steam distillation is successful because of the stabilizing effect of water, through hydrogen bonding, on the thiosulfinates; mildly acidic conditions (e.g. pH 2–4) also seem to stabilize thiosulfinates.[28] Since the thiosulfinates are water soluble, the physical laws applied to steam distillation of water-insoluble compounds are not applicable. It is likely that thiosulfinates form azeotropes under our vacuum "steam distillation" conditions.[21b]

Some comments are necessary regarding the "best" chromatographic methods for characterizing and quantifying unstable aroma and taste substances such as thiosulfinates produced on cutting *Allium* spp. Because of their excellent resolving powers, GC and GC-MS have dominated studies on *Allium* headspace volatiles and room-temperature extracts, despite early cautionary notes that many of the compounds seen by GC may be "artifacts of analysis"[39] and that more recent work suggests that equivalent or superior resolution of *Allium* components may be achieved at room temperature using HPLC![95, 96, 121] We have already noted in Section 4.1 that some, but not all, aliphatic thiosulfinates possessing up to eight carbons survive GC analysis using short columns and low injection port and column temperatures.[29, 54e] Unfortunately most studies on *Allium* volatiles employ long, narrow bore capillary columns (e.g. 0.20 mm × 50 m) and/or injection port temperatures as high

as 280 °C,[71, 92b, 97, 98] conditions which are especially conducive to thiosulfinate decomposition.

Our comparison of the results of both GC and HPLC analyses of fresh extracts and room-temperature distillates of *Allium* spp., using authentic samples of the thiosulfinates thought to be present to evaluate analysis conditions, reveal that *gas chromatography, as typically performed with high injector and column temperatures, presents a highly inaccurate picture of the composition, both of the headspace volatiles as well as of the room-temperature extracts from Allium species.*[21b] Thus, analysis of *Allium* extracts or vacuum distillates by both normal (Si) and reverse phase (C-18) HPLC, using diode-array UV detection, indicate that the predominant constituents are thiosulfinates. *We find no evidence from HPLC for the presence in these samples of the polysulfides claimed by prior GC-MS studies*! Using Si-HPLC, almost all of the thiosulfinates from *Allium* spp. can be separated and quantified using an internal standard.

While some thiosulfinates survive gas chromatography using short columns and low temperatures, these earlier GC analyses frequently suffered from peak broadening and tailing, indicative of partial sample decomposition. We find that

by using a standard polymethylsilicone column (30 m, 0.53 mm internal diameter, "Megabore") with *on-column injection ramped from 0 °C (liquified CO_2 cooling) with a 5 °C min^{-1} temperature injector and column program and a GC-MS transfer line temperature of 100 °C*, nicely resolved, clean GC-MS total ion chromatograms could be obtained for pairs of thermally unstable C_4 regioisomers such as **105**/**106**, R = Me, and **29**/**30**.[21c] While some C_6 compounds

RSS'(O)CH=CHMe	RS(O)SCH=CHMe	MeS(O)SPr	MeSS(O)Pr
105, R = Me	**106**, R = Me	**29**	**30**

could also be resolved under the above conditions, compounds such as PrS(O)SPr **13** required a slower temperature program (2 °C min^{-1}) and higher flow rates or a shorter (15 m) column for analysis. The various allylic thiosulfinates from garlic, such as allicin, could not be satisfactorily analyzed even under the mildest GC conditions.[21c]

The Si-HPLC and cryogenic-injector silicone capillary column GC-MS *Allium* analyses are complementary since the former separates on the basis of polarity and uses UV detection, while the latter separates on the basis of boiling point and uses EI/CI-MS detection. Peaks that are not resolved using one technique can often be separated using the other technique. Furthermore, ion extraction and selective ion MS methods (SIMS) can be employed to resolve overlapping GC peaks, especially when authentic samples are available for calibration purposes. Because of the great thermal instability of allylic thiosulfinates, HPLC represents the preferred method of analysis for garlic, elephant garlic, wild garlic, and Chinese chive extracts. HPLC peaks can also be identified by LC-MS, although the volatility of the C_2 and C_4 components limit the utility of this technique at present.[21b] Representative analyses of *Allium* extracts under our HPLC and GC-MS conditions are shown in Figure 4a–c and Table 1. An important conclusion from these analyses is that *thiosulfonates and di- and polysulfides are not detected in the fresh Allium extracts examined by us*. Thiosulfonates are seen in some samples that have been allowed to stand for some time. These compounds therefore may contribute to the flavor (or off-flavor!) of processed or cooked *Allium* spp.

The *Allium*-derived thiosulfinates are of four types: 1) fully saturated, RS(O)SR' (R,R' = Me or Pr) such as **12**, **13**, **29**, and **30**; 2) mono- or bis-β,γ-unsaturated thiosulfinates AllS(O)SMe **102**, AllSS(O)Me **101** or AllS(O)SAll **1**; 3) mono-α,β-unsaturated thiosulfinates, (*E*)-**105** or (*E,Z*)-**106** (R = Me or Pr); 4) mixed α,β- and β,γ-unsaturated thiosulfonates, (*E*)-**105** or (*E,Z*)-**106**, R = All. Notable in their omission from this listing are the isomeric bis-α,β-unsaturated thiosulfinates, MeCH=CHS(O)SCH=CHMe. These are thought to be formed and to rapidly rearrange; they will be considered separately (see Section 5.2.5). The chemistry of the fully saturated thiosulfinates has already been discussed above (Section 4.1). The chemistry of the other classes of *Allium* thiosulfinates will be considered in Sections 5.2.3 and 5.2.4 following some general observations on thiosulfinates from garlic, wild garlic, elephant garlic, onion, shallot, scallion, chive, leek, and Chinese chive (see Table 1).

5.2.2. *General Observations on Thiosulfinates from Each Allium spp.*

One way to categorize the different *Allium* spp. is by the types of alkyl groups present in the thiosulfinates, or less reliably (using gas chromatography), in derived compounds such as polysulfides. This type of chemotaxonomic information has been used to establish relationships between different members of the *Allium* genus.[39, 99, 100] Only the Chinese chive showed a predominance of *methyl* groups, although all of the *Allium* species examined contain methyl groups.[101] In three of the plants, garlic, elephant garlic, and wild garlic, the *allyl* group is the major alkyl group (Fig. 5). The only

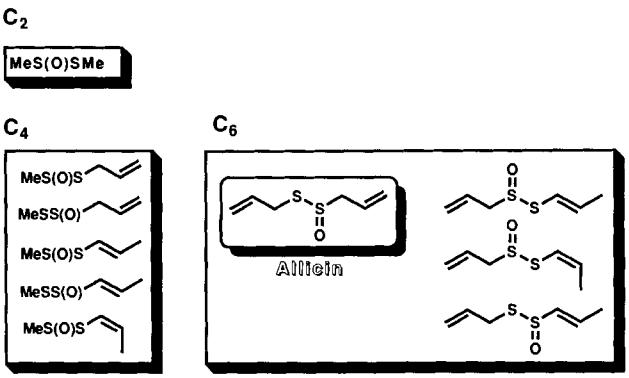

Fig. 5. C_2, C_4, and C_6 thiosulfinates in garlic extracts.

other plant containing detectable quantities of allyl groups is Chinese chive. The *propyl* group is the major alkyl group in chive, scallion, shallot, and leek, and is present in onion. Contrary to earlier reports[3i, 38] but consistent with Lawson's observation[121] the *propyl* group is *absent* in garlic as well as in elephant garlic, wild garlic and Chinese chive, the *1-propenyl* group being present instead. While *all* of the plants contain *1-propenyl* groups, it is the dominant group only in onion (Fig. 6). The total percentage of the 1-propenyl

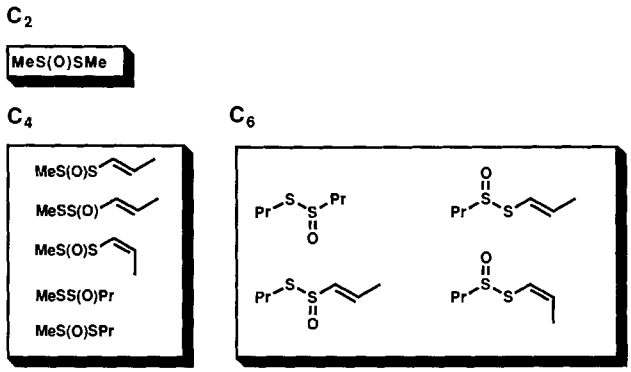

Fig. 6. C_2, C_4, and C_6 thiosulfinates in onion extracts.

group incorporated in onion thiosulfinates, zwiebelanes and bissulfine (e.g. 59% for white onions) is somewhat misleading since the majority of the 1-propenyl group generated as

1-propenesulfenic acid ends up as the LF, which is not included in the calculation because most is lost during analysis. However, in one experiment using ether as solvent to extract white onion, 0.5 $\mu mol\,g^{-1}$ of LF was isolated compared to ca. 0.2 $\mu mol\,g^{-1}$ total thiosulfinate! Small quantities of bissulfine were also found in some of the extracts. When the plant homogenates were allowed to stand in *methanol* for 24 hours before extraction and workup by chromatographic methods, a number of other organosulfur compounds were isolated as described below.

In view of the ephemeral nature of *Allium* thiosulfinates, the significance of the numbers in Table 1 can be questioned both with regard to variation in isolation techniques and in plant specimens. *Allium* homogenates prepared from the trimmed bulbs (garlic, elephant garlic, wild garlic, onion, shallot) or the trimmed plants (scallion, chive, leek, Chinese chive; roots and tips of stalks removed) were typically allowed to stand at room temperature for 30 min and then analyzed after rapid extraction and extract concentration. The analytical results were not altered upon increasing the interval between homogenization and extraction to 6 h. When the homogenate was allowed to stand overnight at room temperature, the only significant change was the disappearance of thiosulfinates of type MeCH=CHS(O)SR **105** (see Section 5.2.5). For quantitative analysis, some variation is seen between different methods of homogenization. Lower yields of thiosulfinates and, in some cases, minor qualitative differences were obtained using distillation rather than extraction methods. Organoleptic evaluation of the room temperature "steam distillate" of the onion indicated that the taste and smell closely duplicate that of the freshly cut plant. Thus, for a given plant sample, reasonable reproducibility is achieved and the analytical data so obtained is relevant to plant flavor.

The situation with regard to the plant specimens is more ambiguous. Thus, the relative percentages for different alkyl groups can vary with the part of the plant, e.g. in Chinese chives the methyl:allyl ratio varies from 71:29 to 36:64 with the leaves, roots, and rhizomes,[102] with the plant variety (e.g. yellow, white or red onion), with the developmental stage[45] and, as we shall discuss below, with the growing and storage conditions.[28c] In particular, we find considerable variation in methyl group percentages between plant samples.

Despite limitations in the reproducibility of the data in Table 1, a number of interesting features can still be noted. The following data, extracted from Table 1 and from more extensive studies, will be considered in more detail in Sections 5.2.3 to 5.2.5:

a) There is excellent qualitative agreement in the thiosulfinate composition of extracted and room temperature "steam-distilled" garlic (see Table 1) and elephant garlic (NY extract not shown).
b) For thiosulfinates of type **106** both *E* and *Z* isomers are found, with *E*:*Z* ratios varying from 9:1 to 1.1:1, with an average value of 2:1. Since pure *E* and *Z* isomers undergo rapid isomerization in solution (see Section 5.2.4) only the *E* + *Z* sum is reported. For thiosulfinates of type **105**, only the *E* isomer is found in plant extracts or distillates. In all but one case, significantly more (*E*,*Z*)-**106** is found than (*E*)-**105**.
c) Store-purchased garlic (origin: Mexico) shows a typical allyl:methyl:1-propenyl ratio of 80:16:4; the ratio of **101**:**102** is 2.2:1.
d) Refrigerated store-purchased garlic shows an allyl:methyl:1-propenyl ratio of 78:11:11; the ratio **101**:**102** is 1.4:1.
e) New York grown garlic (average growing temperature 19–22 °C) shows an allyl:methyl:1-propenyl ratio of 95:2:3; the ratio **101**:**102** is 1.8–2.1:1.
f) Refrigerated New York grown garlic shows an allyl:methyl:1-propenyl ratio of 89:3:8; the ratio **101**:**102** is 2.4:1.
g) Garlic grown in a plains region of India (average growing temperature 30–32 °C) shows an allyl:methyl:1-propenyl ratio of 74:24:2; the ratio **101**:**102** is 2.5:1.
h) Garlic grown in a mountainous region of India (average growing temperature 22–23 °C) shows an allyl:methyl:1-propenyl ratio of 80:18:2; the ratio **101**:**102** is 2.2:1.
i) "Deodorized" garlic[103] shows an allyl:methyl:1-propenyl ratio of 84:11:6 (not listed in Table 1).
j) Store-purchased elephant garlic shows an allyl:methyl:1-propenyl ratio of 61:34:5; the ratio **101**:**102** is 1.8:1.
k) New York grown elephant garlic shows an allyl:methyl:1-propenyl ratio of 67:31:2; the ratio **101**:**102** is 1.8:1.

5.2.3. *Mono- and Bis-β-γ-unsaturated Thiosulfinates and Their Derivatives*

The first thiosulfinate to be discovered was allicin (**1**), so it is appropriate to consider its chemistry first. As already noted, **1** is a colorless, odoriferous, unstable antibacterial substance with a characteristic garlic odor (cf. Section 3).[30] While **1** was first described as being optically inactive[30] recent work suggests that *natural* **1** *is in fact optically active* as determined qualitatively by HPLC with a chiral detector and quantitatively using a polarimeter.[104] Natural **1** shows a specific rotation of $-3.90°$; its optical purity is unknown. Thiosulfinates such as methyl 2-methyl-2-propanethiosulfinate (**23**) have been prepared in optically active form.[105] In the absence of *tert*-butyl or other bulky groups they tend to be optically unstable. If the optical activity of **1** is real, what is its origin? Based on mechanisms suggested above for thiosulfinate formation (Scheme 8), if natural **1** originates from free, achiral 2-propenesulfenic acid (**2**) or its anion, it must also be achiral. On the other hand, if the sulfenic acid remains bound to the allinase via hydrogen bonding (cf. Scheme 19) when it is attacked by a second, free sulfenic acid, asymmetric induction giving optically active **1** is possible.[105b] Further research is necessary to clarify these possibilities.

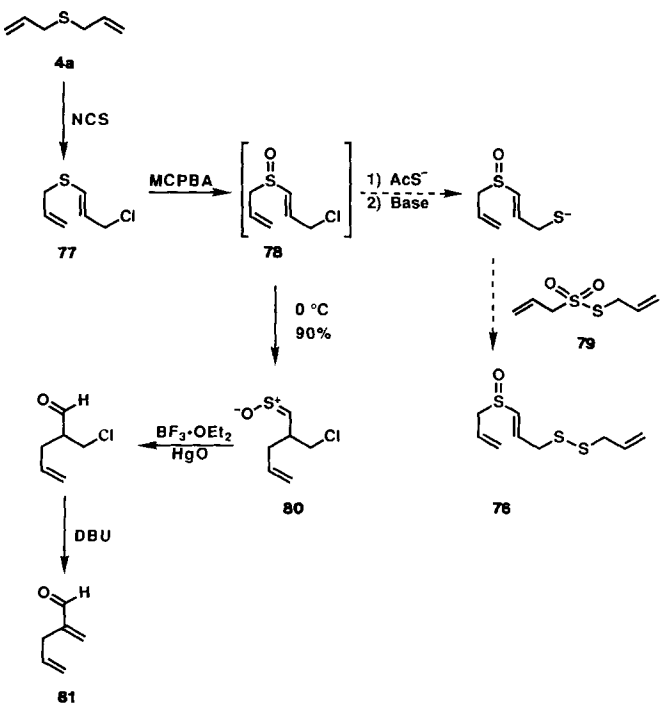
Decomposition of neat allicin is said to afford sulfur dioxide along with allyl alcohol, dimethyl trisulfide, diallyl mono-, di- and trisulfides (**4a–c**), and allyl methyl di- and trisulfides, while passage through a gas chromatograph is said to furnish a 2.4:1 mixture of 3-vinyl-3,4-dihydro-1,2-dithiin (**9**) and 3-vinyl-3,6-dihydro-1,2-dithiin (**9a**) (Scheme 3).[35a] Thiosulfonates (RSO_2SR'), typically produced along with disulfides upon disproportionation of most thiosulfinates (cf. Scheme 11), were not formed from **1**.

Compounds **9** and **9a** were thought to be dehydration products of **1** formed according to the following equation akin to

$$\underset{\mathbf{1}}{C_6H_{10}S_2O} \longrightarrow \underset{\mathbf{9/9a}}{C_6H_8S_2} + H_2O$$

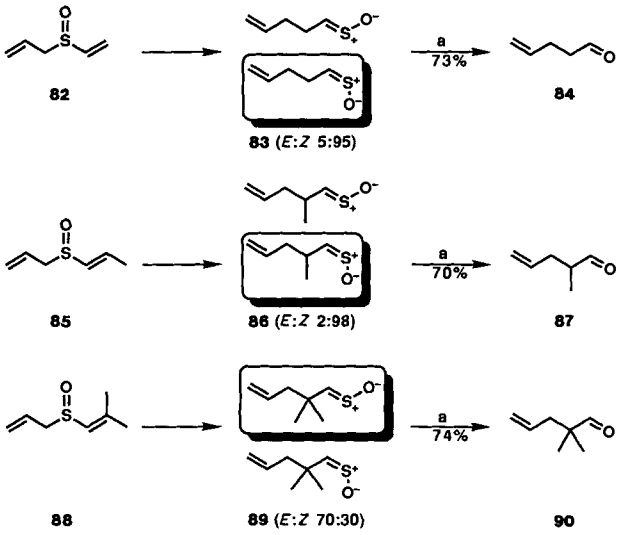
the formation of 1-propenyl propyl disulfide from propyl propanethiosulfinate (**13**).[35a] (cf. Ref. [35b]). Our investigation of the mechanism of decomposition of **1** was prompted by a collaborative study with M. K. Jain and R. Apitz-Castro on the identity of several antithrombotic substances they had isolated from garlic extracts[106] and it is this work that is presented first. The chromatographic separation of solutions prepared by soaking chopped garlic in methanol afforded allicin (**1**), diallyl di-, tri-, and tetrasulfides (**4b–d**), allyl methyl trisulfide, 2-vinyl-2,4-dihydro-1,3-dithiin (**74**), 3-vinyl-3,4-dihydro-1,2-dithiin (**9**) along with two isomeric polar compounds, showing the greatest antithrombotic activity. The substances were named (*E*)- and (*Z*)-ajoene (based on the Spanish word for garlic, ajo, pronounced "aho"), ultimately characterized as (*E*)- and (*Z*)-4,5,9-trithiadodeca-1,6,11-triene 9-oxide (**75**) (cf. Scheme 31) by spectroscopic and synthetic methods.[107]

The sulfoxide thio-Claisen rearrangement: Two pairs of structures, (*E,Z*)-**75** and (*E,Z*)-4,5,9-trithiadodeca-1,7,11-triene 9-oxide (**76**), seemed compatible with the spectroscopic data for (*E,Z*)-ajoene and we sought syntheses of both. A proposed synthesis of **76** involved oxidation of allyl 3-chloro-1-propenyl sulfide[108] (**77**) to allyl 3-chloro-1-propenyl sulfoxide **78**, displacement of chloride by thioacetate, and hydrolysis of thioacetate to thiolate followed by use of allyl 2-propenethiosulfonate (**79**) to construct the S–S bond (Scheme 27). To our surprise MCPBA oxidation of **77** at 0 °C did not lead to **78** but rather to (*Z*)-2-chloromethyl-4-pentenethial *S*-oxide (**80**) in 90% isolated yield. This sulfine could be converted into 2-methylene-4-pentenal (**81**) by sequential desulfurization with boron trifluoride etherate-mercuric oxide[109] and dehydrochlorination with DBU.[110]



Scheme 27. Discovery of the sulfoxide thio-Claisen rearrangement.

The conversion of **78** into **80** is an example of a sulfoxide-accelerated thio-Claisen rearrangement,[79] a stereospecific [3,3]-sigmatropic process occurring under unusually mild conditions. Additional examples of the sulfoxide thio-Claisen rearrangement include conversion of allyl vinyl sulfoxide (**82**) into lacrymatory (*E,Z*)-4-pentenethial *S*-oxide (**83**; *E,Z* = 5:95) and then aldehyde **84**, of allyl (*E*)-1-propenyl sulfoxide (**85**) into (*E,Z*)-2-methyl-4-pentenethial *S*-oxide (**86**; *E,Z* = 2:98) and then aldehyde **87**, and of allyl 2-methyl-1-propenyl sulfoxide (**88**) into (*E,Z*)-2,2-dimethyl-4-pentenethial *S*-oxide (**89**; *E,Z* = 70:30) and then aldehyde **90** (Scheme 28).[110]

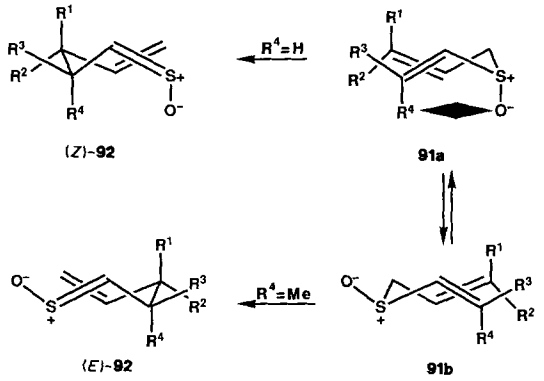


Scheme 28. Examples of the sulfoxide thio-Claisen rearrangement. a: $BF_3 \cdot OEt_2$, HgO.

While the activation enthalpy for the thio-Claisen reaction is typically greater than that for the Claisen rearrangement,[111] the activation energy for the sulfoxide thio-Claisen reaction of allyl vinyl sulfoxide **82** ($\Delta H^{\neq} = 19.32\ kcal\,mol^{-1}$, $\Delta S^{\neq} = -4.3\ cal\,mol^{-1}K^{-1}$) is *lower* than that for the Claisen rearrangement of allyl vinyl ether ($\Delta H^{\neq} = 25.40\ kcal\,mol^{-1}$, $\Delta S^{\neq} = -15.9\ cal\,mol^{-1}K^{-1}$[112]). The sulfoxide thio-Claisen rearrangement, an example of a zwitterion-accelerated Cope process,[113] proceeds with comparable substrates at 23 °C ca. 50 times faster than the thio-Claisen rearrangement under neutral conditions and 39 times faster under acidic conditions. The low $\Delta H^{\neq}$ for this reaction reflects, in part, the low C_{sp^3}–S(O) bond strength (ca. 46 $kcal\,mol^{-1}$ in **82**).

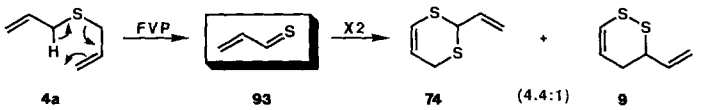
We have noted (Section 5.1.4) that the *Z*-stereochemistry is favored for sulfines. Thus, it is of interest to observe that **88** (and several other similarly substituted 1-alkenyl allyl sulfoxides) prefer the *thermodynamically less stable E-configuration* in the rearranged sulfine **89**. If it is assumed that the sulfoxide thia-Claisen rearrangement involves a pseudo chair transition state then pseudoaxial or pseudoequatorial

orientations are possible for sulfoxide oxygen. For thiane *S*-oxides an axial oxygen orientation is favored *except* when there are substituents at the 3- or 5-positions *cis* to sulfoxide oxygen, such as 3,3-dimethylthiane *S*-oxide where the equatorial/axial oxygen ratio is >95:5.[114] Similar effects should prevail in the sulfoxide thio-Claisen favoring **91a** → (*Z*)-**92** when $R^4 = H$ but favoring **91b** → (*E*)-**92** when $R^4 = Me$ (Scheme 29).[110, 115]



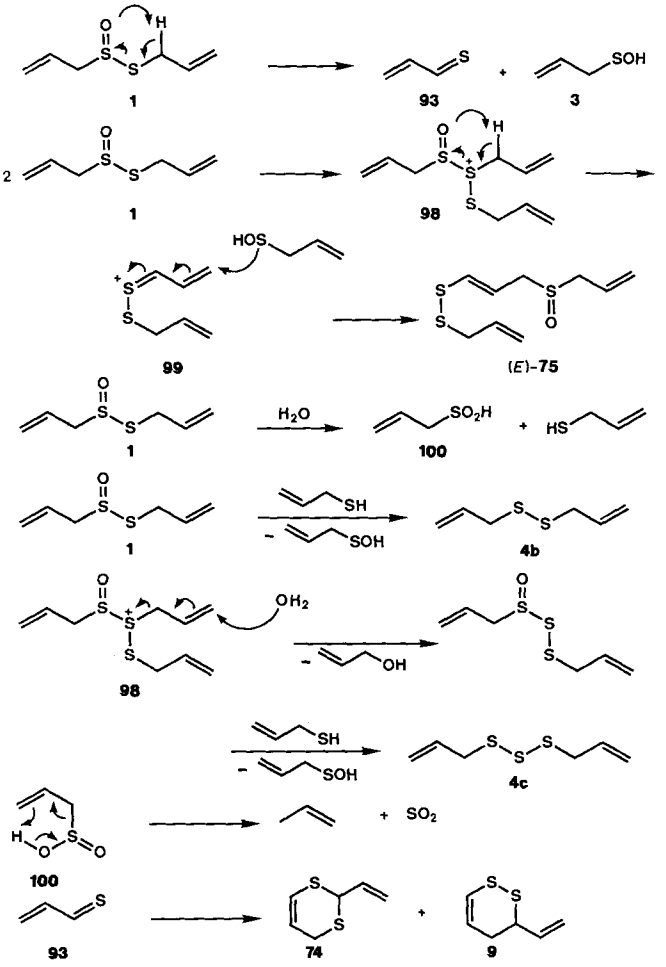
Scheme 29. Steric arrangement of the transition state **91a** ⇌ **91b** for the sulfoxide thio-Claisen rearrangement.

Synthesis of ajoenes, 2-vinyl-2,4-dihydro-1,3-dithiin and 3-vinyl-3,4-dihydro-1,2-dithiin and mechanistic considerations: Our discovery of the significant facilitating effect of the sulfinyl oxygen on the thio-Claisen rearrangement made it apparent that structure **75** (cf. Scheme 31) was to be preferred to **76** for (*E,Z*)-ajoene as there was no indication of rearrangement of this material to a sulfine upon heating. Since allicin (**1**) is the first isolable product formed when garlic is cut, we suspected that **1** might be the immediate precursor of **75**. Indeed, we found that when synthetic **1** was refluxed with 3:2 acetone:water for 4 hours, (*E,Z*)-**75** could be isolated in 34% yield.[107, 116] Other products included 2-vinyl-2,4-dihydro-1,3-dithiin (**74**) and 3-vinyl-3,4-dihydro-1,2-dithiin (**9**), in a 4.4:1 ratio, diallyl di- and trisulfides (**4b** and **4c**), and propene. The structures of **74** and **9** were established by comparison with the known products of the dimerization of thioacrolein (**93**) at −180 °C *which likewise affords* **74** *and* **9** *in a 4.4:1 ratio*. **93** is formed in the flash vacuum pyrolysis of diallyl sulfide (**4a**) (Scheme 30).[117]

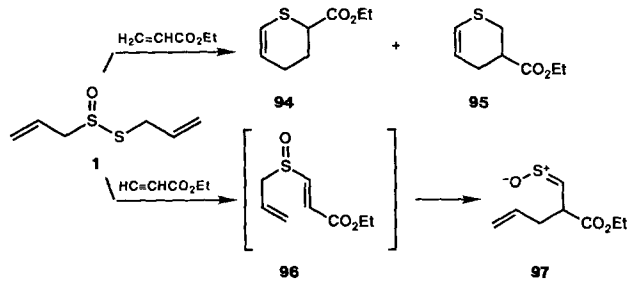


Scheme 30. Dimerization of thioacrolein (**93**) from flash vacuum pyrolysis of diallyl disulfide (**4a**).

The isolation of **74** and **9** as decomposition products of **1** and the identity of the **74**:**9** ratio to that observed upon dimerization of **93** suggests that the first step in the decomposition of **1** involves Cope-elimination to give 2-propenesulfenic acid (**3**) and **93** (Scheme 31). This postulate, which is consistent with our suggestion for the decomposition of methyl methanethiosulfinate (**12**) (Scheme 6), finds additional support in our observation of the characteristic sapphire blue color of **93** when **1** is distilled into a liquid nitrogen cooled trap, and our isolation of ethyl-3,4-dihydro-2*H*-thiopyran-2- (**94**) and -3-carboxylates (**95**) and (*Z*)-ethyl-2-thioformyl-4-pentenoate *S*-oxide (**97**) when solutions of **1** in ethyl acrylate and ethyl propiolate, respectively, are kept overnight at room temperature (Scheme 32).[118] Presumably **97** results from sulfoxide thio-Claisen rearrangement of the initial adduct **96** of ethyl propiolate and **3**. The earlier work of Brodnitz[35a] (Scheme 3) on the decomposition of **1** in a gas chromatograph must be corrected by replacing his incorrect structure **9a** with **74**.

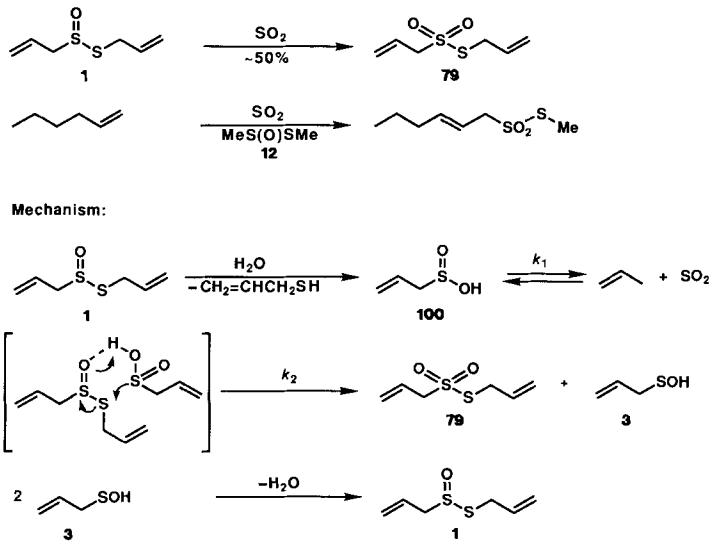


Scheme 31. Mechanism for the decomposition of allicin (**1**) and formation of ajoene (**75**).



Scheme 32. Trapping of thioacrolein (**93**) (H_2C=CH-CH=S) and 2-propenesulfenic acid (**3**) (H_2C=CH-CH_2SOH) from allicin (**1**) as **94** + **95** and **97**, respectively.

With the mechanism proposed by us for the decomposition of **12** (Scheme 11) as a model, a detailed scheme for the decomposition of allicin **1** can be suggested (Scheme 31). A key step involves *S*-allylthiolation of **1** to give the sulfonium ion **98**, which can: a) undergo β-elimination to give carbocation **99** followed by γ-addition of **3** to give (*E*,*Z*)-**75**; b) undergo S_N2' hydrolysis giving allyl alcohol and then **4c**; c) undergo hydrolysis to 2-propenesulfinic acid (**100**) and **4b**.[119a] Direct hydrolysis of **1** can give **100** and 2-propenethiol. β,γ-Unsaturated sulfinic acids such as **100** are known to readily lose sulfur dioxide by retro-ene type reactions.[119c] A search was made for the presence of allyl 2-propenethiosulfonate (**79**) among the decomposition products of **1**, but none was found. This observation can be rationalized by assuming that the rate of loss of sulfur dioxide from **100** (k_1) is more rapid than its rate of nucleophilic attack on **1** (k_2; Scheme 33).[119d] It is noteworthy that when **1** is dissolved in liquid sulfur dioxide and the solution is allowed to stand at room temperature in a sealed vial, **79** can be isolated in good yield (Scheme 33).[135d] Compound **79**, sometimes referred to as pseudoallicin, has only 50% of the antibacterial activity of alliicin.[120]

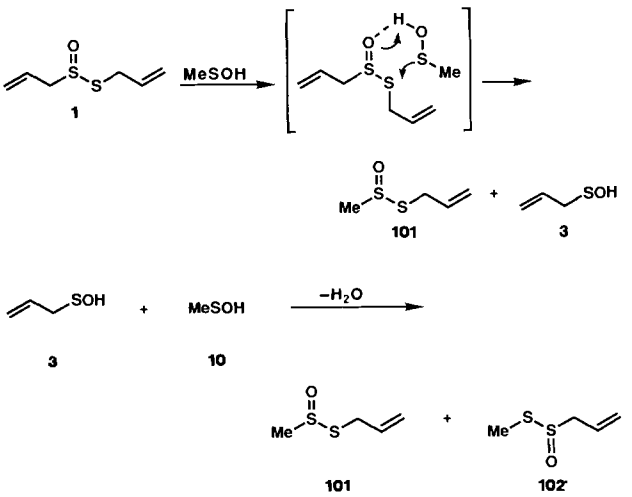


Scheme 33. Formation of allyl 2-propenethiosulfonate (**79**) from allicin (**1**) and sulfur dioxide.

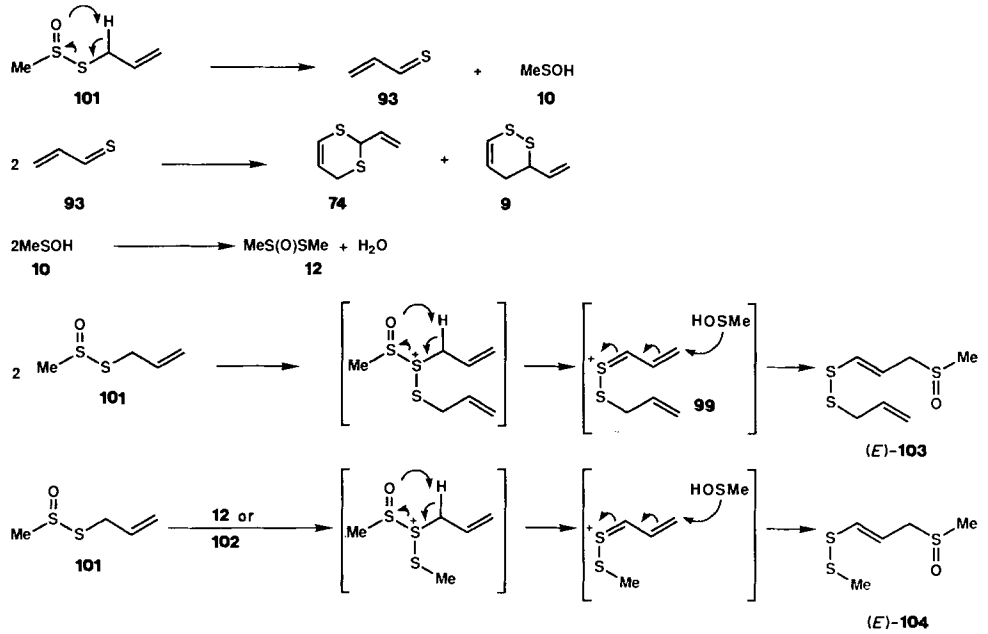
Other allyl thiosulfinates in garlic, elephant garlic, and wild garlic: We have previously noted (Section 2.1) that garlic *grown* in colder climates contains far less (+)-*S*-methylcysteine *S*-oxide (**6**) than garlic grown in more temperature climates.[21] This lower concentration of **6** translates into diminished levels of methyl group-containing thiosulfinates. Thus, some garlic grown in New York State (cooler climate: 19–22 °C average growing temperatures) shows an allyl:methyl:1-propenyl ratio of 94:2:3, which differs dramatically from the more typical ratio of 80:16:4 seen in store-purchased garlic of Mexican origin. A similar but smaller decrease in methyl group levels is seen when the composition of New York State grown elephant garlic (allyl:methyl:1-propenyl ratio of 67:31:2) is compared to that of store-purchased elephant garlic (allyl:methyl:1-propenyl ratio of 62:35:3), grown in a warmer climate. A comparison of samples of Indian garlic obtained from a mountainous area (22–23 °C average) and from an area with a climate averaging 10 °C warmer show a similiar trend: the allyl:methyl ratio is larger for the garlic grown in a cooler climate. Finally, garlic treated to allegedly make it "odorless"[103] also shows a lower relative methyl content (allyl:methyl:1-propenyl ratio of 84:11:6). It can therefore be concluded that when garlic (and elephant garlic) is grown under harsher conditions or treated with certain chemicals the specific enzymes associated with formation or hydrolysis of *S*-methylcysteine *S*-oxide (**6**) are attenuated or destroyed.[21, 28b]

Lawson has observed that γ-glutamyl-*S*-(*E*)-1-propenylcysteine and γ-glutamyl-*S*-2-propenylcysteine (see **e** and **c**, respectively, in Scheme 2), the dominant γ-glutamyl peptides in homogenates of fresh garlic, decrease markedly when freshly picked garlic is refrigerated.[11, 121] This decrease is coupled with a corresponding increase in (+)-*S*-(*E*)-1-propenylcysteine *S*-oxide (**5**) and (+)-*S*-2-propenylcysteine *S*-oxide (**2**), respectively, which in turn afford 1- and 2-propenesulfenic acids. Thus, for store-purchased garlic of Mexican origin the allyl:methyl:1-propenyl ratio of 80:16:4 changes to 78:11:11 after refrigeration for two months; for New York grown garlic the allyl:methyl:1-propenyl ratio of 94:2:3 changes to 90:3:8 after refrigeration for this same period.

In addition to **1** and α,β-unsaturated thiosulfinates, two isomeric thiosulfinates, allyl methanethiosulfinate **101**, and methyl 2-propenethiosulfinate **102**, are important components of some *Allium* homogenates. Interpretation of the data in Table 1 is facilitated if it is recognized that in garlic, thiosulfinates containing only the 1- and 2-propenyl groups are formed *ten times more rapidly* than thiosulfinates containing methyl groups.[122] There would therefore be little 1- or 2-propenesulfenic acid available to condense with the more slowly forming methanesulfenic acid (**10**). A mechanism involving reaction of **10** with allicin **1** (Scheme 34) accommodates the facts that: 1) after **1** is maximally formed in 0.5 min it decreases until the mixed allyl methyl thiosulfinates are maximally formed after 5 min;[122] 2) for each mole of **1** lost, 1.9 moles of mixed allyl methyl thiosulfinates are formed;[122] 3) the **101**:**102** ratio increases to ca. 2:1 after



Scheme 34. Formation of allyl methanethiosulfinate (**101**) and methyl 2-propenethiosulfinate (**102**) in garlic.

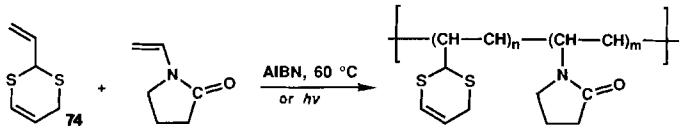


Scheme 35. Formation of methylajoene (**103**) and dimethylajoene (**104**) from allyl methanethiosulfinate **101**.

1–5 min and **101** dominates; 4) when powdered garlic (e.g. alliin/allinase) is added to excess aqueous methyl methanethiosulfinate (**12**), the major product is **102** (Scheme 34).[21a]

Decomposition of an authentic sample of **101** in acetone/water affords **9**, **74**, **12**, **4b**, **4c**, allyl methyl trisulfide and two new polar compounds identified as (*E*,*Z*)-2,6,7-trithiadeca-4,9-diene 2-oxide (**103**, "methyl ajoene") and (*E*,*Z*)-2,3,7-trithiaocta-4-ene 7-oxide (**104**, "dimethyl ajoene") (Scheme 35). Compounds **103** and **104**, thought to be present in low concentrations in garlic extracts, have recently been found in extracts of ramsons or wild garlic (*Allium ursinum*) and are derived from the isomers **101**/**102**, which predominate over allicin **1** in this plant (ratio of **1**:**101**/**102**:**12** is 1.26:0.14:0.01 in garlic and 0.53:0.70:0.27 in ramsons).[123]

After our identification of **74** as one of the antithrombotic components of garlic extracts, the novel use of **74** in a copolymer with *N*-vinylpyrrolidone was described (Scheme 36).[124] This copolymer is proposed as an anti-



Scheme 36. Copolymer of 2-vinyl-2,4-dihydro-1,3-dithiin (**74**) and *N*-vinyl pyrrolidone [124].

thrombogenic and antibiotic composition for use as a coating for artificial prostheses and implants which remain in contact with blood.

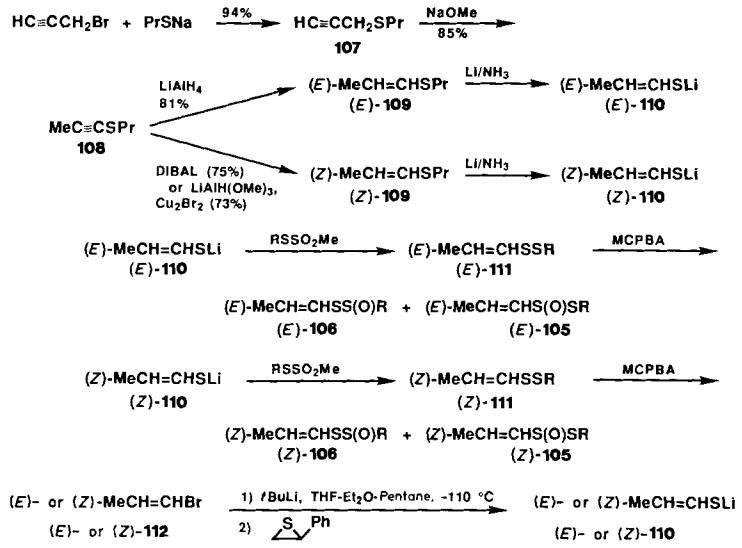
5.2.4. *Mono-α,β-unsaturated Thiosulfinates*

While saturated aliphatic and allylic thiosulfinates have been known for many years, little work has been carried out on α,β-unsaturated thiosulfinates, despite the fact that such compounds are present in onion and garlic extracts and display significant inhibitory activity toward lipoxygenase and cyclooxygenase enzymes.[28, 125] We therefore conducted a systematic study of the natural occurrence, synthesis and properties of these compounds.

Natural occurrence of mono-α,β-unsaturated thiosulfinates: Considerable quantities of α,β-unsaturated thiosulfinates of type (*E*)-**105** (alkyl (*E*)-1-propenethiosulfinate) and (*E*,*Z*)-**106** ((*E*,*Z*)-1-propenyl alkanethiosulfinates, R = Me, Pr, or All) are present in fresh extracts or room-temperature steam distillates of all of the *Allium* spp. examined as noted in Table 1. The thiosulfinates **106** (R = Me, Pr) have been identified in yellow onion extracts by Wagner et al.[150] and by Kawakishi et al.;[149d] Wagner also noted the rapid interconversion of geometric isomers. Lawson reports the presence of **105** and **106** (R = Me and Pr) in scallion, shallot, leek, yellow onion, boiling onion, white onion and red onion[121] and of **105** and **106** (R = Me, All) in garlic, and also comments on the ease of geometric isomerism in **106**.[121b]

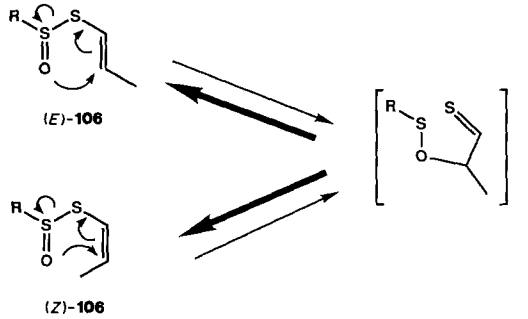
Synthesis of mono-α,β-unsaturated thiosulfinates: Synthetic routes to the stereoisomers **105** and **106** (R = Me, Pr, All) are summarized in Scheme 37. One approach involves propyl 1-propynyl sulfide (**108**), available from base-catalyzed isomerization[126] of propyl 2-propynyl sulfide (**107**), as the key intermediate. Lithium aluminum hydride converts **108** into (*E*)-1-propenyl propyl sulfide ((*E*)-**109**) while diisobutylaluminum hydride or trimethoxyaluminum hydride-cuprous bromide[127] converts **108** into (*Z*)-**109**. Lithium-liquid ammonia reduction of (*E*)- and (*Z*)-**109** gives lithium (*E*)- and (*Z*)-1-propenethiolate (**110**), which are treated with the appropriate thiosulfonate to afford alkyl (*E*)- and (*Z*)-1-propenyl disulfides (**111**). Oxidation of (*E*)- and (*Z*)-**111** affords (*E*)-**105**/(*E*)-**106** and (*Z*)-**105**/(*Z*)-**106**, respectively. A second approach to (*E*)- and (*Z*)-1-propenethiolate (**110**) involves lithiation at −110 °C of readily available pure (*E*)- and (*Z*)-1-bromo-1-propene[128, 129] (**112**) followed by treat-

ment of each lithio compound with styrene sulfide. The unique ^{1}H- and ^{13}C-NMR chemical shifts for **105**/**106** are useful[130] in determining the composition of *Allium* extracts.[21, 135a]



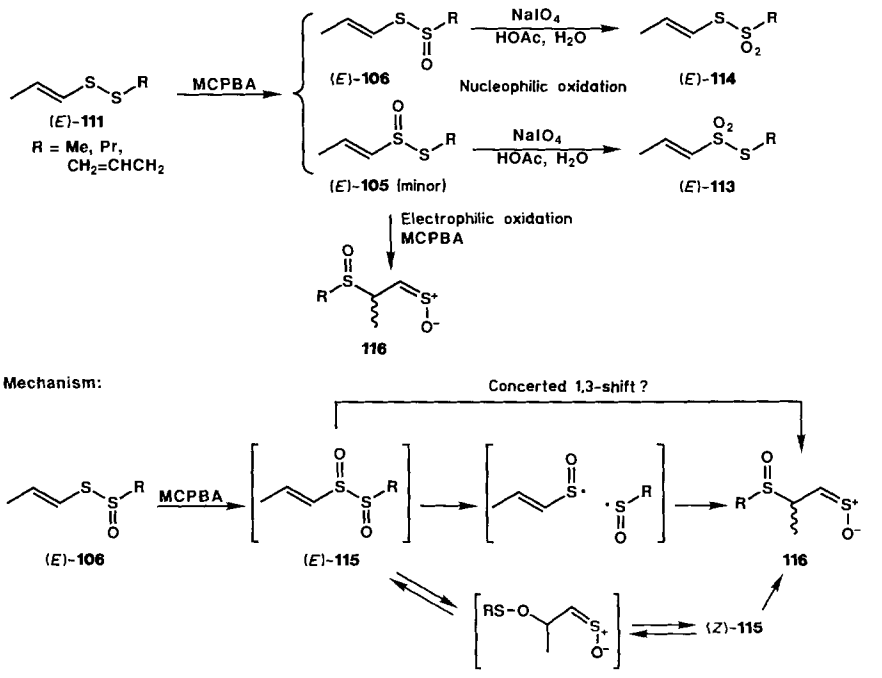
Scheme 37. Synthesis of the α,β-unsaturated thiosulfinates **105** and **106**.

E,Z-Isomerization of mono-α,β-unsaturated thiosulfinates: All attempts to isolate pure samples of (*E*)- or (*Z*)-**106** from mixtures with **105** always led to mixtures of (*E,Z*)-**106**. Furthermore stereochemically pure samples of (*E*)-**105**/(*E*)-**106** or (*Z*)-**105**/(*Z*)-**106** were converted during the course of one hour at 25 °C into (*E*)-**105**/(*E,Z*)-**106** or (*Z*)-**105**/(*E,Z*)-**106**, respectively. This facile isomerization of isomers of **106**, but not **105** or precursor disulfides **111**, can be explained by a [2,3]-sigmatropic rearrangement (Scheme 38) analogous to reactions of allylic sulfoxides or methallyl 2-methyl-2-propenethiosulfinate.[131] This isomerization explains the puzzling observation that although only (+)-*S*-(*E*)-1-propenyl-L-cysteine *S*-oxide (**5**) occurs naturally, affording, it is assumed, only (*E*)-1-propenesulfenic acid ((*E*)-**14b**), both (*E*)- and (*Z*)-**106**, but only (*E*)-**105**, are found in *Allium* extracts and distillates. Compound **105**, of course, is incapable of isomerization by the mechanism of Scheme 38.



Scheme 38. Interconversion of (*E*)- and (*Z*)-1-propenyl alkanethiosulfinate geometric isomers **106**. The half-life at 25 °C is ca. 1 h.

Oxidation of mono-α,β-unsaturated thiosulfinates: We have examined the oxidation of **105**/**106** as a route to the corresponding thiosulfonates **113**/**114**, of interest as natural products themselves (e.g. methyl (*E*)-propenethiosulfonate, (*E*)-**113**, R = Me, has been isolated from *Allium grayi*)[132] as well as synthetic reagents for preparation of α,β-unsaturated disulfides. "Nucleophilic" oxidation[133] of (*E*)-**105**/(*E*)-**106** or (*Z*)-**105**/(*Z*)-**106** using sodium metaperiodate/acetic acid gave (*E*)-**113**/(*E*)-**114** or (*Z*)-**113**/(*Z*)-**114** (R = Me, Pr, All) with no stereoisomerization (Scheme 39). Unlike (*E*)- and (*Z*)-**106**, stereoisomers of **114** were configurationally stable, showing no tendency to undergo *E,Z*-isomerization. "Electrophilic" oxidation[133] of either (*E*)-**105**/(*E*)-**106** or (*Z*)-**105**/(*Z*)-**106** with MCPBA gave identical 1:1 mixtures of



Scheme 39. Nucleophilic and electrophilic oxidation of 1-propenyl alkanethiosulfinates (**106**) and alkyl 1-propenethiosulfinates (**105**) furnishing thiosulfonates **113**/**114** and α-sulfinylsulfines **116**.

compounds characterized as (*Z*)-2-(alkanesulfinyl)propanethial *S*-oxide (*Z*)-**116** (see below for NMR assignment of sulfine stereochemistry as *Z*). We presume that initial oxidation of **105**/**106** gives α-disulfoxide **115**. While **115** could undergo pseudopericyclic[134] rearrangement to **116**, stereochemistry would be expected to be conserved, which is not the case. Therefore either: 1) stereochemistry in **115** is lost through [2,3]-sigmatropic rearrangement (Scheme 39) which is more rapid than pseudopericyclic processes; 2) *two* diastereomers of **115** are formed initially; or 3) a free radical mechanism (Scheme 39) is involved in conversion of **115** into **116**.[135a]

5.2.5. *Bis-α,β-unsaturated Thiosulfinates*

"Is there any point to which you would wish to draw my attention?"
"To the curious incident of the dog in the nighttime."
"The dog did nothing in the nighttime."
"That was the curious incident," remarked Sherlock Holmes.

"Silver Blaze"
Sir Arthur Conan Doyle (1859–1930)

What is unusual about the thiosulfinates isolated from cut *Allium* spp. is the *complete absence* of bis-α,β-unsaturated derivatives, despite the preeminence of the bis-β,γ-unsaturated thiosulfinate allicin (**1**) from garlic and the abundance of mono-α,β-unsaturated thiosulfinates from onion. Our curiousity piqued, we examined synthetic approaches to 1-propenyl 1-propenethiosulfinates. Serendipitously, while these efforts were underway, Professor Hildebert Wagner invited our participation in a study of some unusual organosulfur compounds isolated by his doctoral student, Thomas Bayer.[136] This collaborative study led to some fascinating chemistry, detailed below.

2,3-Dimethyl-5,6-dithiabicyclo[2.1.1]hexane 5-oxides ("zwiebelanes"): Two isomers **117** and **118** (smaller amounts of latter) were isolated as colorless oils of formula $C_6H_{10}OS_2$ following chromatography of onion extracts. Compound **117** showed intense IR bands at 1065 and 1085 cm^{-1} (S=O) and UV $\lambda_{max} = 250$ nm. NMR data for **117** and **118** are discussed in Section 5.3.3. The above spectroscopic data, the chemical shifts in presence of $Eu(fod)_3$ shift reagent and aromatic solvents, as well as the synthetic results described below point to **117** and **118** having the structures (1α,2α,3α,4α,5β)- and (±)-(1α,2α,3β,4α,5β)-2,3-dimethyl-5,6-dithiabicyclo[2.1.1]hexane 5-oxide, respectively (Fig. 7). These two compounds were given the trivial names *cis*- and *trans*-zwiebelane ("zwiebel" is German for onion), respectively.[137] Compounds **117** and **118** have been isolated by us from extracts of shallot, scallion and chive as well. The mixture of **117** and **118** showed a 65–90% inhibition of thrombin-induced TXB_2 biosynthesis in human platelet rich plasma at a concentration of 0.1–1.0 $mg\,mL^{-1}$. Recently, other examples of substituted 5,6-dithiabicyclo[2.1.1]hexanes have been reported.[138]

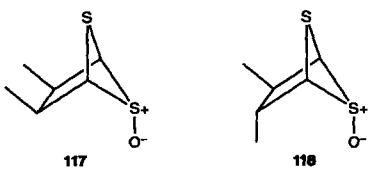


Fig. 7. Isomeric "zwiebelanes" **117** and **118** isolated from onion extracts.

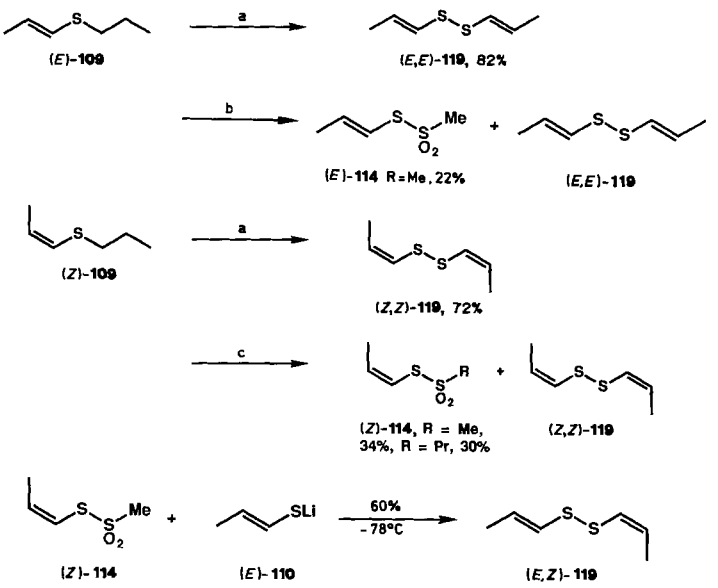
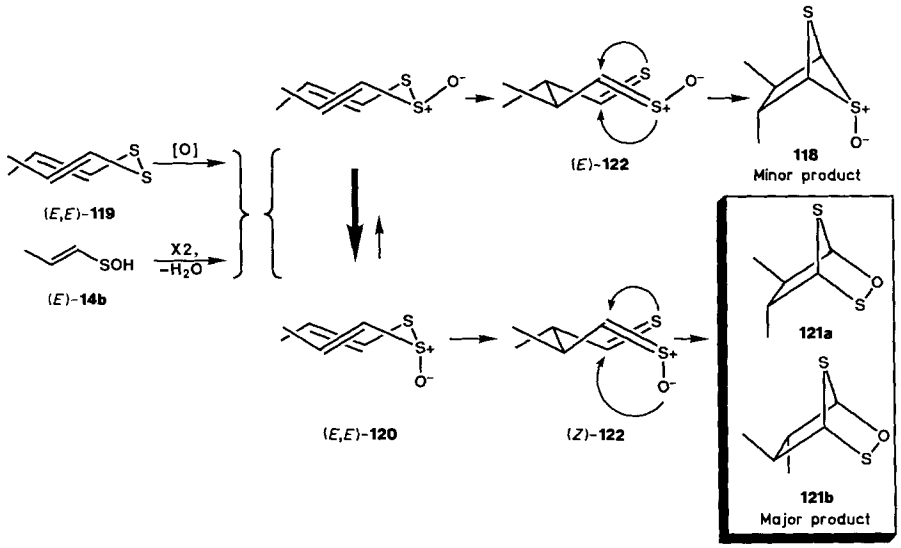
Monooxidation of the isomeric bis(1-propenyl) disulfides: The isomeric bis(1-propenyl) disulfides (*E,E*)-**119** and (*Z,Z*)-**119** were prepared by oxidation of lithium (*E*)- and (*Z*)-1-propenethiolate ((*E*)-**110** and (*Z*)-**110**) while (*E,Z*)-bis(1-propenyl) disulfide ((*E,Z*)-**119**) was prepared by reaction of (*E*)-**110** with (*Z*)-1-propenyl methanethiosulfonate ((*Z*)-**114**) at −78 °C (Schemes 37 and 40).[135d] Compound (*Z*)-**114** can be conveniently synthesized through reaction of (*Z*)-**110** with methanesulfonyl chloride; the latter reagent can also be used for the conversion of (*E*)-**110** and (*Z*)-**110** into (*E,E*)-**119** and (*Z,Z*)-**119**, respectively (Scheme 40).[135c] Isomers of **119** can be separated by preparative HPLC on a C-18 reverse phase column. While (*E,E*)-**119** and (*Z,Z*)-**119** are relatively stable at room temperature, (*E,Z*)-**119** disproportionates on standing to a mixture of all three isomers of **119**.



Scheme 40. Synthesis of (*E,E*)-, (*Z,Z*)-, and (*E,Z*)-bis(1-propenyl) disulfide **119**. For the reaction **109** → **110** cf. Scheme 37. a: 1) Li/NH_3; 2) $2\,MeSO_2Cl$, −78 °C; 3) H_2O. b) 1) Li/NH_3; 2) $20\,MeSO_2Cl$, −78 °C; 3) H_2O. c) 1) Li/NH_3; 2) $20\,RSO_2Cl$, −78 °C; 3) H_2O.

Solutions of pure isomers of **119** in $CDCl_3$ at −60 °C were treated with chilled solutions of MCPBA in the presence of one equivalent of anhydrous sodium carbonate. After 5 min the reaction mixture was transferred to an NMR tube cooled to −60 °C and placed in a −60 °C NMR probe. Thus, (*E,E*)-**119** gave (*E*)-1-propenyl (*E*)-1-propenethiosulfinate ((*E,E*)-**120**) (Scheme 41), (*Z,Z*)-**119** gave the (*Z,Z*)-isomer, ((*Z,Z*)-**120**) (Scheme 42), and (*E,Z*)-**119** gave a ca. 2:1 mixture of (*Z*)-1-propenyl (*E*)-1-propenethiosulfinate ((*E,Z*)-**120a**) and (*E*)-1-propenyl (*Z*)-1-propenethiosulfinate ((*E,Z*)-**120b**) (Scheme 43). Qualitative studies indicate that the relative rates of oxidation are (*E,E*)-**119** > (*E,Z*)-**119** > (*Z,Z*)-**119**. Assignment of structures to isomers

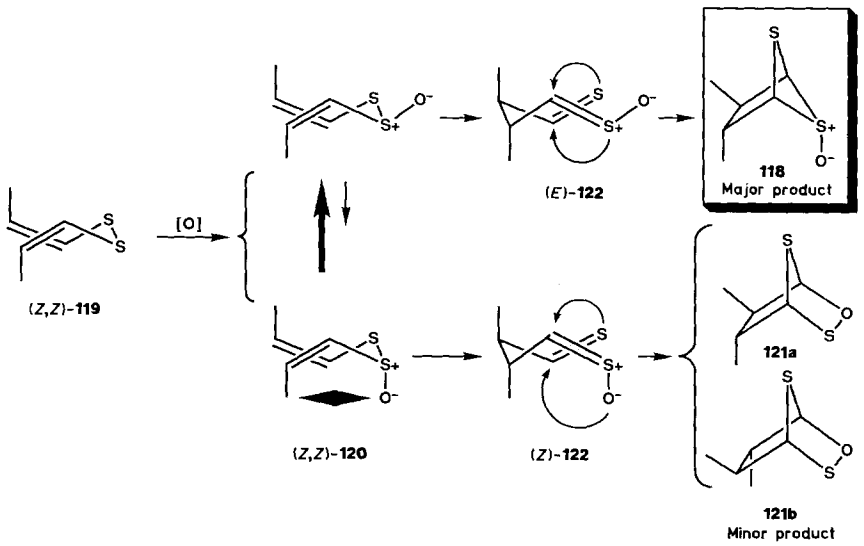


Scheme 41. Oxidation of (*E,E*)-bis(1-propenyl) disulfide (*E,E*)-**119** giving **121a** (via (*E,E*)-**120**). **122** always shown as the (2*S*,3*R*) form.

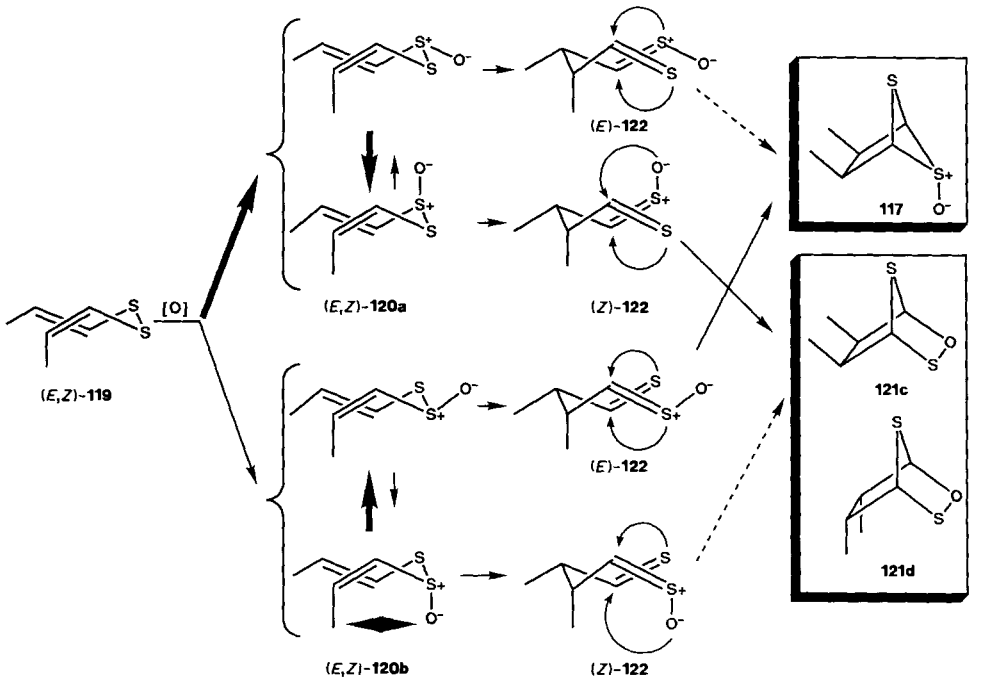
(*E,Z*)-**120a,b** is based both on kinetic considerations that the disulfide sulfur adjacent to a *cis* double bond is oxidized at a slower rate than the disulfide sulfur adjacent to a *trans* double bond, as well as on careful comparison of the ^{1}H and ^{13}C chemical shift data for thiosulfinates (*E,E*)-**120**, (*Z,Z*)-**120**, (*E,Z*)-**120a,b**, and the methyl 1-propenethiosulfinates (*E*)-**106** and (*Z*)-**106**, R = Me.

Solutions of thiosulfinates (*E,E*)-**120**, (*Z,Z*)-**120**, and (*E,Z*)-**120a,b** in NMR tubes with dioxane as internal standard were warmed to −15 °C. The disappearance of peaks associated with the thiosulfinates was followed with time. The so-determined first order rate constants for disappearance of thiosulfinates at −15 °C are $8.22\times10^{-4}\,s^{-1}$ for (*E,E*)-**120**, $4.13\times10^{-4}\,s^{-1}$ for (*E,Z*)-**120a,b**, and $3.02\times10^{-4}\,s^{-1}$ for (*Z,Z*)-**120**. From the rate data for disappearance (rearrangement) of (*Z,Z*)-**120** we calculate: $E_a = 16\,kcal\,mol^{-1}$, $\Delta H^{\neq} = 15.5\,kcal\,mol^{-1}$, $\Delta S^{\neq} = -15.3\,cal\,mol^{-1}K^{-1}$, and $\Delta G^{\neq} = 19.5\,kcal\,mol^{-1}$, all at 273 K. These values may be compared to those described in Section 5.2.3 for the Claisen and sulfoxide thio-Claisen rearrangements. If the ratio of these rate constants, 2.7:1.4:1, is compared to the analogous ratio for Claisen rearrangement of isomeric 1-propenyl 2-butenyl ethers,[139] it is apparent that the rate ratio for the rearrangement of thiosulfinates is contracted suggesting a more *advanced* transition state than for the Claisen rearrangement. The initial products of rearrangement are a 4.5:1 mixture of *endo*-5-methyl-*exo*-6-methyl-2-oxa-3,7-dithiabicyclo[2.2.1]heptane (**121a**) and its *exo,endo*-isomer **121b** from (*E,E*)-**120** after 3 h at −40 °C, a 27:3:1 mixture of (±)-**118**, **121a** and **121b** from (*Z,Z*)-**120** after 3 h at −40 °C, and a 10:10:1 mixture of **117**, *exo*-5-methyl-*exo*-6-methyl-2-oxa-3,7-dithiabicyclo[2.2.1]heptane (**121c**) and its *endo,endo*-isomer **121d** from (*E,Z*)-**120a,b** after 3 h at −40 °C (Schemes 41–43). Isomers **121** are bicyclic sultenes similar to compounds **43** and **56** (see Sections 4.4 and 5.1.2 and Schemes 14 and 16). Isomers **121** react rapidly with thiophenol giving ring-opened thiolane derivatives.

Mechanistic considerations: We propose that—following the oxidation of (*E,E*)-**119** with *one* equivalent of peroxy acid—the thiosulfinate ((*E,E*)-**120**) oxygen assumes a pseudoaxial orientation for the [3,3]-sigmatropic rearrangement since this orientation is also favored in 1,2-dithiane 1-oxides



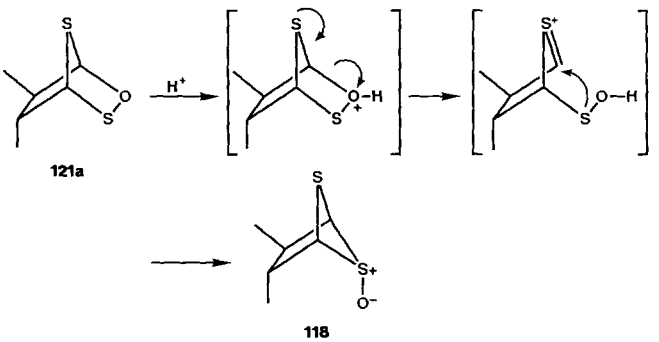
Scheme 42. Oxidation of (*Z,Z*)-bis(1-propenyl) disulfide (*Z,Z*)-**119** giving **118** (via (*Z,Z*)-**120**). **122** always shown as the (2*R*, 3*S*) form.



Scheme 43. Oxidation of (*E*,*Z*)-bis(1-propenyl) disulfide (*E*,*Z*)-**119** giving **117** and **121c** (via (*E*,*Z*)-**120a**,**b**). **122** always shown as (*R*,*R*) form.

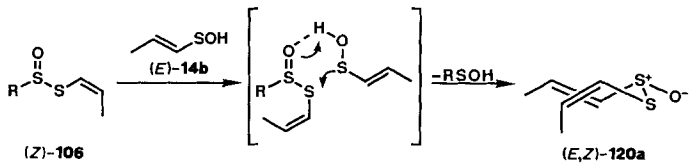
and in sulfoxide thio-Claisen rearrangements.[115,135b] Rearrangement from this transition state gives (*Z*)-(2*R*,3*S*/2*S*,3*R*)-2,3-dimethyl-1,4-butanedithial *S*-oxide ((*Z*)-**122**), which can assume an appropriate conformation to undergo a very facile intramolecular 1,3-dipolar cycloaddition of the $C{=}S^{+}{-}O^{-}$ group to the C=S function[88b] with formation of **121a,b** (Scheme 41), a structure similar to the well-known 2,5-dimethylthiophene–singlet oxygen adduct[140] and to 5,6-dimethyl-2,3,7-trithiabicyclo[2.2.1]heptane, recently isolated from scallion distillates.[141] Rearrangement of (*E*,*E*)-**120** should be facilitated by the weak S–S bond (the bond dissociation energy would be expected to be quite similar to that of phenyl benzenethiosulfinate, e.g. 35 kcal mol^{-1}). Subsequent cyclization should be aided by the very high reactivity of the thial group of (*Z*)-**122** as a 1,3-dipolarophile.[142] Precedence exists for formation of heterobicyclo[2.2.1]heptanes via intramolecular 1,3-dipolar cycloaddition reactions.[143] On the other hand, on analogous oxidation of (*Z*,*Z*)-**119**, steric effects associated with the *cis* double bonds lead the intermediate to adopt a transition state geometry in which thiosulfinate ((*Z*,*Z*)-**120**) oxygen is pseudoequatorial, resulting in the formation of (*E*)-(2*R*,3*S*/2*S*,3*R*)-2,3-dimethyl-1,4-butanedithial *S*-oxide ((*E*)-**122**), where the (*E*)-geometry of the $C{=}S^{+}{-}O^{-}$ group favors the [2+2] process yielding **118** over the sterically now more difficult 1,3-dipolar cycloaddition (Scheme 42). In the case of (*E*,*Z*)-**119** either pseudoaxial or pseudoequatorial thiosulfinate ((*E*,*Z*)-**120a**, (*E*,*Z*)-**120b**) oxygen transition state geometry is possible with the consequence that the heterobicyclo[2.1.1]hexane and heterobicyclo[2.2.1]heptane systems (**117** and **121c** respectively) are formed in comparable amounts (Scheme 43). While there is variation in the type of ring system formed on monooxidation of (*E*,*E*)-, (*Z*,*Z*)- and (*E*,*Z*)-**119**, there is complete stereoselectivity in carbon–carbon bond formation.[135b]

Problems are encountered in extending the above concepts of the mechanism of the monooxidation of stereoisomers of **119** to reactions that occur when onions are cut. We have shown that zwiebelane **118** originates from (*Z*,*Z*)-**120**. Formation of this latter compound in onion homogenates would require condensation of two molecules of (*Z*)-1-propenesulfenic acid ((*Z*)-**14b**). However, since (*Z*)-(+)-*S*-1-propenyl-L-cysteine *S*-oxide ((*Z*)-**5**) is not found in onions, and the barrier to interconversion of (*E*)- to (*Z*)-1-propenesulfenic acid is anticipated to be substantial (a 33 kcal mol^{-1} activation energy barrier separates ethenesulfenic acid and ethanethial *S*-oxide;[80] a similar barrier should exist for interconversion of (*E*)- and (*Z*)-**14b** by way of LF **16**), it is unlikely that the concentration of (*Z*)-**14b** would suffice for *self condensation* to take place. Furthermore, the detection of substantial amounts of alkyl (*E*)-1-propenethiosulfinates ((*E*)-**105**), *but not a trace of the Z-isomers* in *Allium* spp. extracts, also argues against the formation of significant amounts of (*Z*)-**14b** and thus of (*Z*,*Z*)-**120**. It is possible, under the conditions existing when onions are cut, that **121a** can isomerize to **118** (Scheme 44), and that **117** is similarly formed by isomerization of **121c**. Alternatively, a molecule of (*E*)-**14b** could react with a second molecule of (*E*)-**14b** that is hydrogen bonded to allinase (see Scheme 19; the



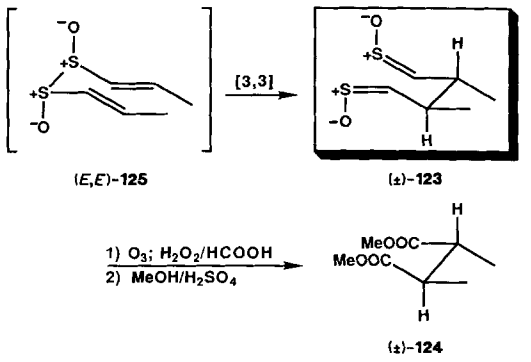
Scheme 44. Possible isomerization of **121a** to **118**.

dimeric/tetrameric structure proposed for allinase is consistent with the presence of more than one sulfenic acid molecule within the enzyme at any given time). The resultant (*E,E*)-**120**, if still associated with the allinase, may undergo a [3,3]-sigmatropic process from a more compact transition state, with the sulfoxide oxygen pseudoequatorial, to give **118**. (*E,Z*)-**120a**, the postulated precursor to **121c**, could be formed in onion homogenates through reaction of (*E*)-**14b** with (*Z*)-**106** (Scheme 45).



Scheme 45. Reaction of (*E*)-**14b** with (*Z*)-**106** giving (*E,Z*)-**120a**.

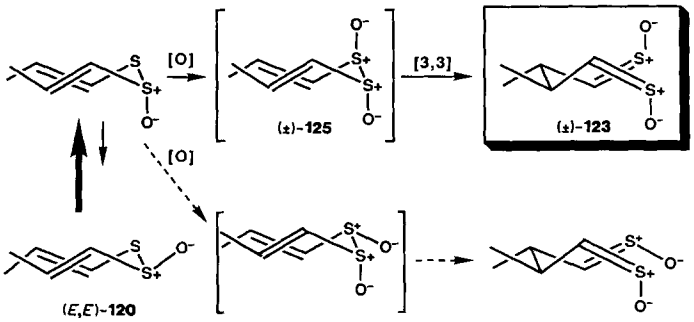
(Z,Z)-(±)-2,3-Dimethylbutanedithial S,S'-dioxide: Examination of the ^{1}H-NMR spectrum of onion extracts revealed the presence of a doublet at $\delta = 8.09$ just upfield from the position of the triplet for the methine proton in LF **16** ($\delta = 8.21$), suggesting the natural occurrence of a second sulfine.[77b, 144] Ultimately, compound **123** was isolated as a colorless solid of formula $C_6H_{10}S_2O_2$ which showed absorption bands at 1103 and 1120 cm^{-1} (C=S=O) in the IR spectrum. Sequential treatment of synthetic **123** (see below) with ozone (at −50 °C), H_2O_2/HCOOH and MeOH/H_2SO_4 gave in 88% yield a compound which according to GC-MS and ^{13}C-NMR was identical with an authentic sample of (±)-dimethyl 2,3-dimethylsuccinate ((±)-**124**), but different from an authentic sample of *meso*-**124**, thereby establishing **123** as (*Z,Z*)-(±)-2,3-dimethylbutanedithial *S,S'*-dioxide ((±)-**123**) (Scheme 46). The *Z,Z* arrangement of the CSO



Scheme 46. Proof of structure of bis-sulfine **123** by ozonolysis. **123** and **125** always shown as (*R,R*) form.

group was established by NMR methods similar to those used with **16** (see Section 5.3.1). Compound **123** is unique as the first example of a bis(thial *S*-oxide); so far, also only a single example of a bis(thione *S*-oxide) is known.[145]

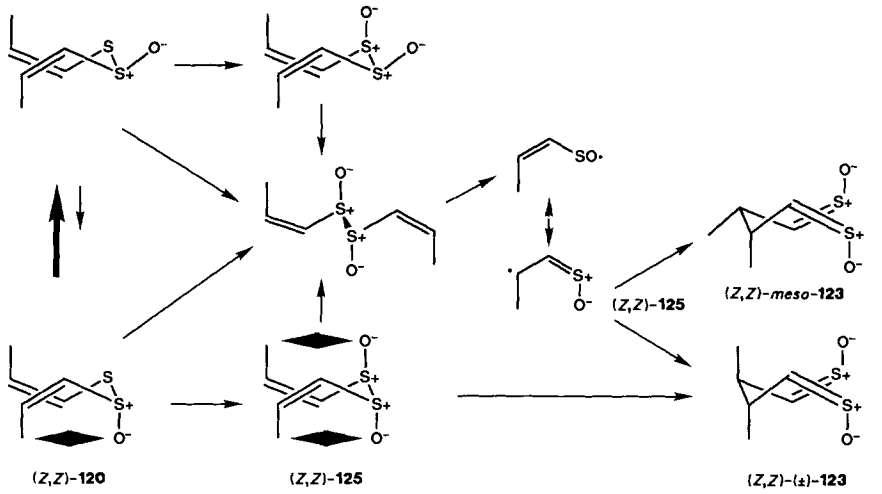
Bis-oxidation of bis(1-propenyl) disulfides; mechanistic considerations: The close relationship that **123** bears to intermediate (*Z*)-**122** in Scheme 41 suggests that **123** originates via a novel double sulfoxide-accelerated dithio-Claisen rearrangement of (*E,E*)-bis(1-propenyl) *vic*-disulfoxide ((*E,E*)-**125**) (Scheme 46). Indeed, oxidation of (*E,E*)-**119** with 2.2 equivalents of MCPBA at −60 °C or of (*E,E*)-**120** with one equivalent of MCPBA (Scheme 47) leads to a product identical to **123** isolated from onion extracts.[144] Oxidation of (*E,E*)-**120** should give (*E,E*)-**125** with an *anti* (diaxial) arrangement of the oxygens, which represents an energy minimum according to theoretical calculations on model systems.[146] This geometry of (*E,E*)-**125** correlates with (*Z*)-CSO geometry in **123** (Scheme 47). Compound (*E,E*)-



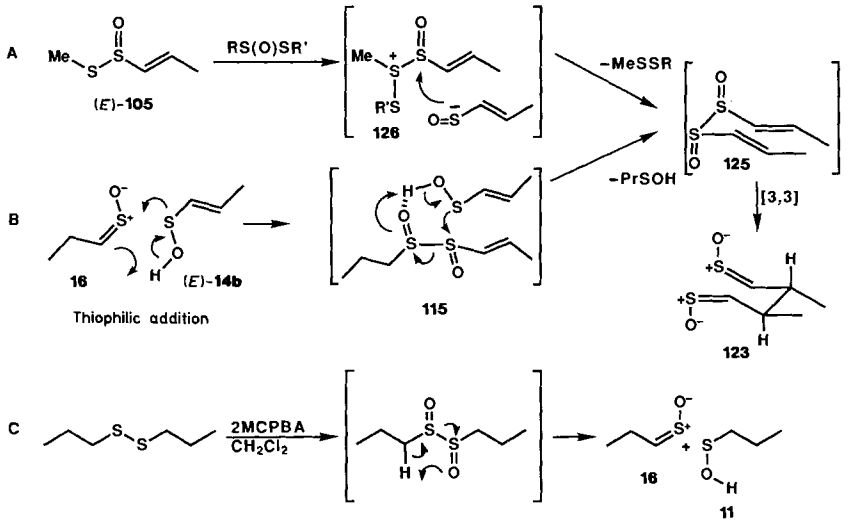
Scheme 47. Oxidation of (*E,E*)-**120** to (±)-**123** (shown as (*S,S*) form).

125 should undergo particularly facile [3,3]-sigmatropic rearrangement due to the weakness of the S–S bond (comparable with the S–S bond in diphenyl *vic*-disulfoxide, i.e. ca. 26 kcal mol^{-1}) as well as the rate-enhancing effect of the two zwitterionic sulfinyl functions.[113] This assumption is in agreement with the observation that (*E,E*)-**125** could not be detected in low-temperature NMR studies[147] of the oxidation of (*E,E*)-**120**. In contrast, to the stereospecificity seen in the oxidation of (*E,E*)-**120** or its precursor (*E,E*)-**119**, oxidation of (*Z,Z*)-**119** with two equivalents of MCPBA gives a 2:1 mixture of (±)-**123** and *meso*-**123** (Scheme 48).[135b] In this case, for the second oxygen to be antiperiplanar to the first, the bis(1-propenyl) *vic*-disulfoxide (*Z,Z*)-**125** would have to assume an open conformation unsuitable for [3,3]-sigmatropic rearrangement, and favoring a homolytic process.[135b]

How is **123** formed in onion extracts? One possibility would involve thioalkylation of (*E*)-**105** (R = Me) giving thiosulfonium ion **126**, which could undergo nucleophilic displacement at the sulfinyl sulfur by (*E*)-1-propenesulfenate (Scheme 49 A). A second possibility would involve "thiophilic" addition of (*E*)-**14b** to **16** (Scheme 49 B; the reverse of *vic*-disulfoxide decomposition,[148] shown in Scheme 49 C) followed by nucleophilic attack of a second molecule of (*E*)-**14b** on *vic*-disulfoxide intermediate **115**. A weakness of both mechanisms is the need for one reactive intermediate ((*E*)-**14b** or its anion) to attack another one (**126** or **115**). An additional problem with the second mechanism is that attack of (*E*)-**14b** on **115** would have to occur more readily than the rate of rearrangement **115** to **116** (see Scheme 39), since the latter is not found in onion extracts.



Scheme 48. Oxidation of (*Z*,*Z*)-**120** to (±)-**123** (shown as (*R*,*R*) form) and *meso*-**123**.

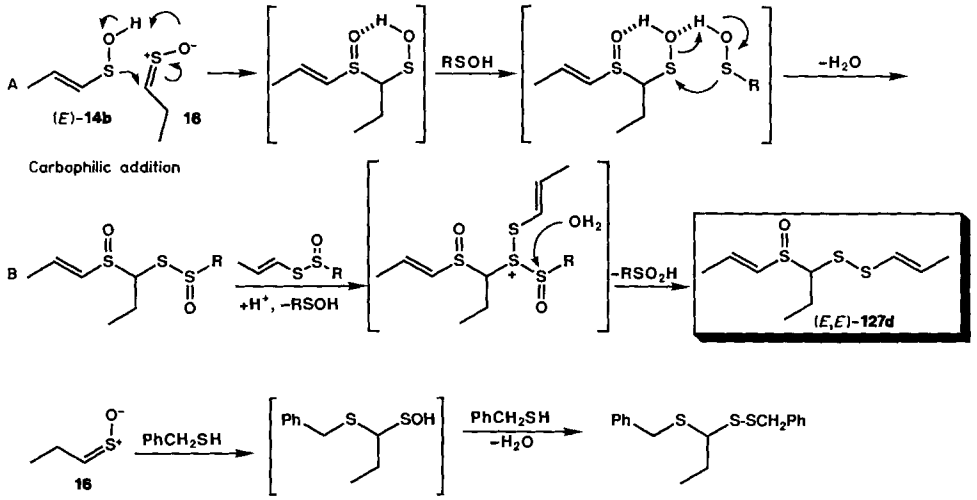


Scheme 49. Proposed mechanisms for formation of bissulfine **123** in onion homogenates. A–C, see text.

5.2.6. Cepaenes

Isolation of cepaenes and mechanisms of formation: In 1988 Kawakishi and Morimitsu identified methyl 1-(methylsulfinyl)propyl disulfide (**127a**, R = R′ = Me) as a new platelet aggregation inhibitor from onion extracts.[149a] Simultaneously, Wagner et al. reported the isolation of diastereomeric pairs 1-((*E*)-1-propenylsulfinyl)propyl propyl disulfide (**127c**) (R = (*E*)-MeCH=CH, R′ = Pr) and 1-((*E*)-1-propenylsulfinyl)propyl (*E*,*Z*)-1-propenyl disulfide (**127d**) (R = (*E*)-MeCH=CH, R′ = (*E*,*Z*)-MeCH=CH) as cyclooxygenase and 5-lipoxygenase inhibitors from onion extracts.[125c, 136] Wagner proposed that the onion α-sulfinyl disulfides be called "cepaenes". Later it was reported that: 1) other cepaenes could be isolated including 1-(methylsulfinyl)propyl (*E*,*Z*)-1-propenyl disulfide (**127b**, R = Me, R′ = (*E*,*Z*)-MeCH=CH);[149b] 2) individual enantiomers of diastereomeric pairs showed only a twofold to fourfold difference in biological activity, contrary to expectations of substantial differences associated with stereospecific enzymatic recognition;[149c] 3) cepaenes display a variety of types of interesting biological activity (see Section 7.3);[125a, b, 149d, 150] 4) by combining fresh onion and garlic juice, various mixed cepaenes, including some with allylic groups, can be prepared.[149d] A mechanism for formation of cepaenes in onion juice is proposed (Scheme 50A).[135c, 144, 149c, d] Precedence for "carbophilic" addition of (*E*)-**14b** to **16** includes addition of thiols to **16** (Scheme 50B)[151] and sulfenic acids to thiones.[152] α-Alkylthiodisulfides ("deoxycepaenes") are found in distilled oils of shallot and scallion, e.g. ethyl-1-(methylthio)propyl disulfide,[95] methyl 1-(methylthio)propyl disulfide, 1-(methylthio)propyl propyl disulfide,[153] 1-(methylthio)-propyl 1-propenyl disulfide, 1-propenyl-1-(propylthio)-propyl disulfide, and 1-propenyl-1-(1-propenylthio)propyl disulfide.[141, 153, 154] It is not known whether these compounds originate via deoxygenation of cepaenes, either in solution or in the inlet of a gas chromatograph, or through entirely different mechanisms.

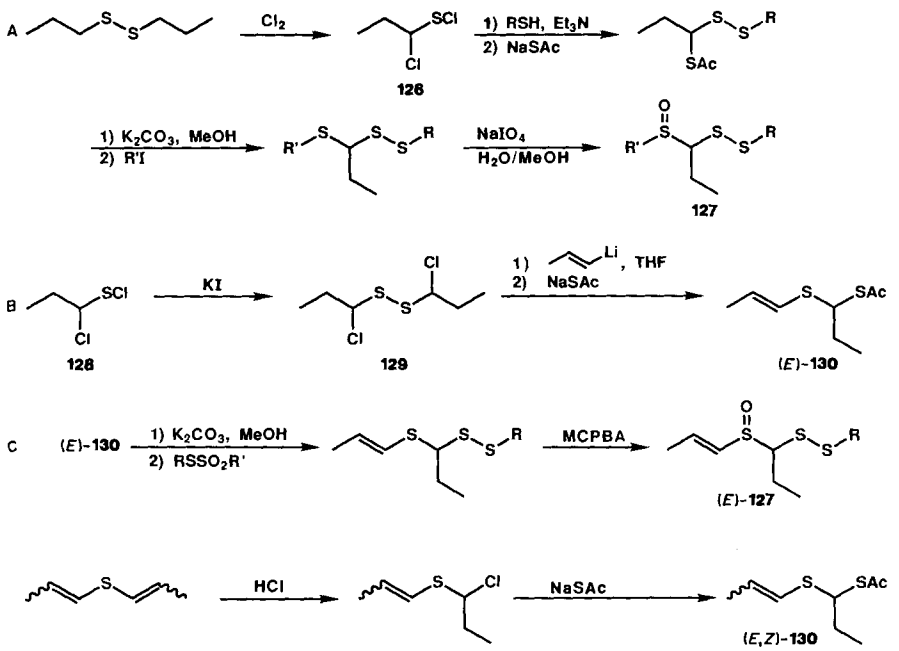
Synthesis of fully saturated cepaenes: In 1973 we reported that refluxing alkyl alkanethiosulfinates in benzene/water affords α-sulfinyl disulfides, e.g. **33** or **34** (Scheme 11).[54d] The isolated yield of **33** was high, whereas the yield of **34** was quite low. A more efficient synthesis of the saturated cepaenes such as **127a** was developed starting from 1-chloropropanesulfenyl chloride (**128**) via: 1) nucleophilic attack on



Scheme 50. Proposed mechanism for formation of cepaenes **127** in onion homogenates. A, B see text.

the sulfenyl chloride group by an alkanethiol with formation of an alkyl 1-chloropropyl disulfide; 2) replacement of the α-chloride by thioacetate; 3) hydrolysis and alkylation of the latter giving an alkyl 1-(alkylthio)propyl disulfide; 4) oxidation of the latter to the alkyl 1-(alkylsulfinyl)propyl disulfide **127**, formed as diastereomeric pairs (Scheme 51 A). When methanethiol was used, **128** could be directly converted into methyl 1-(methylthio)propyl disulfide.[155a]

chloride by thioacetate to give **130**; 3) hydrolysis of **130** followed by thioalkylation with an alkyl alkanethiosulfonate to give an alkyl 1-((*E*)- or (*Z*)-1-propenylthio)propyl disulfide; 4) oxidation of the latter to the alkyl 1-((*E*)- or (*Z*)-1-propenylsulfinyl) propyl disulfide diastereomers (Scheme 51 B). An alternative non-stereospecific synthesis of **130** involves addition of one equivalent of HCl to bis(1-propenyl) sulfide followed by displacement of the α-chlo-

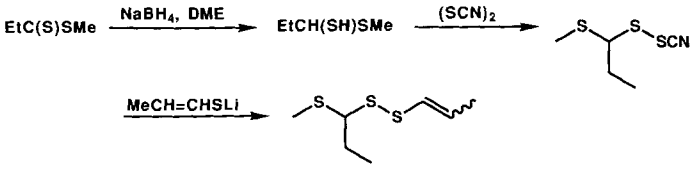


Scheme 51. Synthesis of fully saturated and singly unsaturated cepaenes. A–C see text.

Synthesis of singly unsaturated cepaenes: In the above syntheses, the sulfenyl chloride group becomes the disulfide function of **127** while the α-chloride of **128** becomes the alkylsulfinyl group. The fate of these groups is reversed in a synthesis of singly unsaturated cepaenes, which involves: 1) oxidation of **128** to bis(1-chloropropyl) disulfide (**129**); 2) treatment of **129** with (*E*)- or (*Z*)-1-propenyllithium at low temperature followed by immediate displacement of the α-

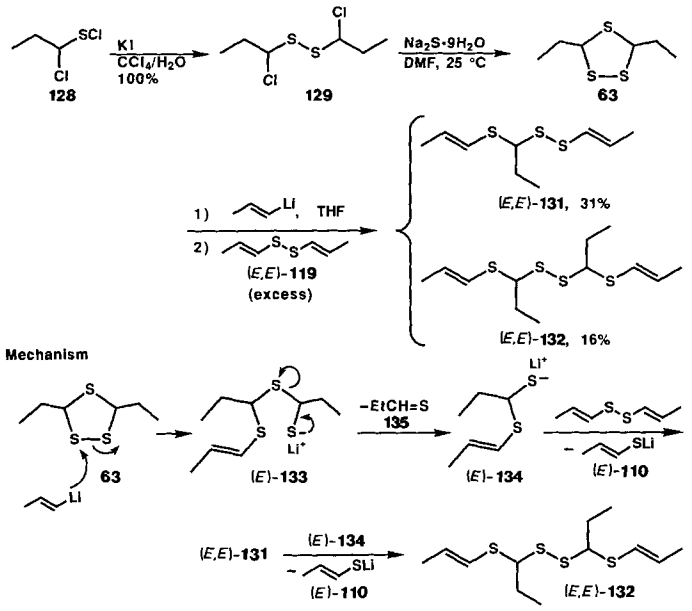
rides by thioacetate (Scheme 51 C). 1-(Methylthio)propyl (*E,Z*)-1-propenyl disulfide (a deoxycepaene) has been synthesized from methyl dithiopropionate (Scheme 52).[156]

Synthesis of doubly unsaturated cepaenes: Two novel syntheses of doubly unsaturated cepaenes have been developed. The first involves 3,5-diethyl-1,2,4-trithiolane (**63**), a component of onion oil. Treatment of **63** with (*E*)-1-propenyllithium followed by bis((*E*)-1-propenyl) disulfide ((*E*)-**119**) gives



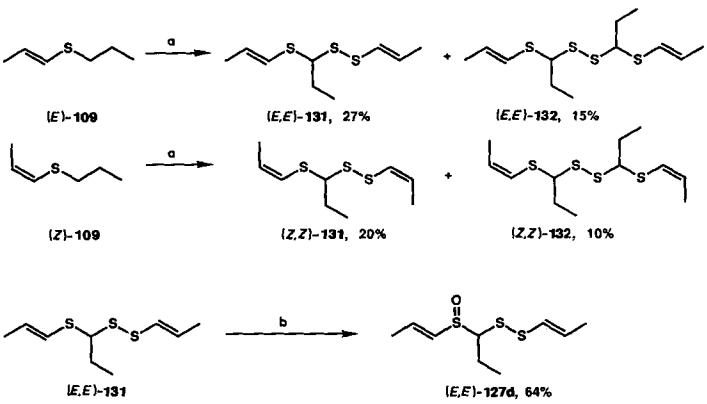
Scheme 52. Synthesis of the deoxycepaene 1-(methylthio)propyl (*E,Z*)-1-propenyl disulfide; total yield 36%.

the deoxycepaenes (*E,E*)-6-ethyl-4,5,7-trithiadeca-2,8-diene (**131**; 31%) and (*E,E*)-6,8-diethyl-4,6,7,9-tetrathiadodeca-2,10-diene (**132**; 16%) (Scheme 53).[135d, 155b] We suggest that the initial product (**133**) from ring-opening of **63** fragments to **134** and propanethial (**135**) at a rate competitive with nucleophilic attack on (*E,E*)-**119** to form **132**. The reverse of the fragmentation reactions, carbophilic addition to **135**, may also take place.

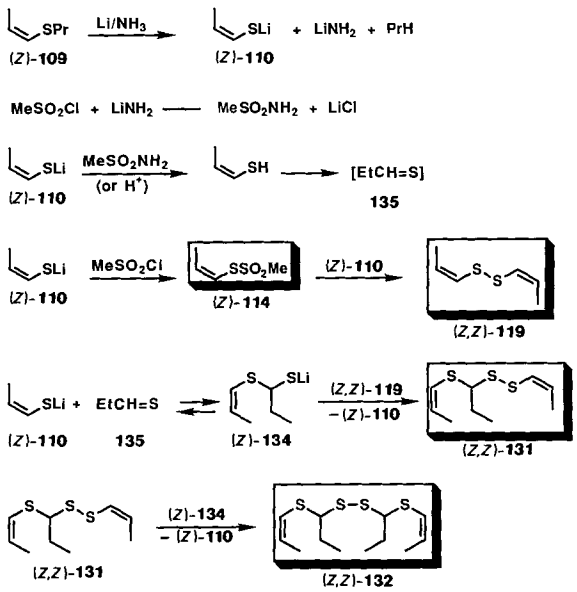


Scheme 53. Synthesis of doubly unsaturated deoxycepaenes **131** and **132** via 3,5-diethyl-1,2,4-trithiolane **63**.

A second synthesis of **131** and **132** also involves fragmentation of α-(alkenylthio)alkanethiolates such as **134** to thials such as **135**. This synthetic route was developed in connection with a study concerning the use of mesyl chloride as an alternative to iodine for stereospecific conversion of (*E*)- or (*Z*)-1-propenethiolate (**110**) into (*E,E*)- or (*Z,Z*)-**119**, respectively (Schemes 37 and 40).[135d] While treatment of (*E*)-**110** (from lithium-ammonia cleavage of (*E*)-**109**) with two equivalents of mesyl chloride gave (*E,E*)-**119** in 82% yield, use of 0.7 equivalents of mesyl chloride led instead to a mixture of (*E,E*)-**131** (27%) and (*E,E*)-**132** (15%). Similarly, while treatment of (*Z*)-**110** (from (*Z*)-**109**) with 2 equivalents of mesyl chloride gave (*Z,Z*)-**119** in 72% yield, use of 0.7 equivalents of mesyl chloride led to a mixture of (*Z,Z*)-**131** (20%) and (*Z,Z*)-**132** (10%). Oxidation of (*E,E*)-**131** with MCPBA led to a 2:1 diastereomeric mixture of the cepaene (*E,E*)-6-ethyl-4,5,7-trithiadeca-2,8-diene 7-oxide **127d** (64%) which could be separated by chromatography. The results in Scheme 54 can be explained by the mechanism shown in Scheme 55.[135d]



Scheme 54. Synthesis of **131**, **132**, and **127d**. (*E,E*)-**127d** formed as a chromatographically separable 2:1 mixture of diastereomers. a: 1) Li/NH_3; 2) 0.7 $MeSO_2Cl$, −60 °C; 3) −5 °C 1.5 h; H_2O. b) 100% MCPBA, −78 °C, CH_2Cl_2.



Scheme 55. Mechanism for formation of (*Z,Z*)-**131** and (*Z,Z*)-**132** by reaction of (*Z*)-**110**, obtained by liquid ammonia reduction of (*Z*)-**109**, with mesyl chloride.

5.3. Characterization of Organosulfur Constituents of *Allium* Preparations by Nuclear Magnetic Resonance Spectroscopy

My dear Watson, you see but you do not observe!

Sir Arthur Conan Doyle (1859–1930)

Of the analytical techniques available for the study of such sensitive organosulfur compounds as are associated with *Allium* spp., none is more powerful than NMR spectroscopy. It permits the direct observation of all of the relevant nuclei (H, C, O) at low as well as ambient temperatures. A broad range of chemical shifts are observed, allowing identification of the components of complex mixtures. The configuration

can be determined by analysis of coupling constants, facilitated by two-dimensional NMR methods, and by studying solvent- or reagent-induced chemical shift effects in compounds containing the sulfinyl group. With the more unusual organosulfur components, novel NMR effects abound.

5.3.1. NMR Study of the Onion Lachrymatory Factor (LF) and Related Sulfines

Sulfines (thiocarbonyl *S*-oxides) play an important role in *Allium* chemistry. We have studied the *S*-oxides of ethanethial (**44**), propanethial (**16**), (trimethylsilyl)methanethial (**66**), and 2-(alkanesulfinyl)propanethial (**116**), as well as the bissulfine (±)-2,3-dimethyl-1,4-butanedithial *S,S'-dioxide* (**123**). The stereochemistry about the C=S bonds was established by NMR methods.

The NMR spectrum of onion lachrymatory factor (LF) **16** in $CDCl_3$ shows a downfield methine triplet at $\delta = 8.21$ ($J = 7.81$ Hz), in agreement with the spectrum of **16**, which was prepared from propanesulfinyl chloride (**19**) or by pyrolysis of (*E,Z*)-*tert*-butyl 1'-propenyl sulfoxide (**58**). Examination of the NMR spectrum of the natural **16** in $CDCl_3$ reveals the presence of a second downfield triplet at $\delta = 8.88$ ($J = 8.79$ Hz), with ca. 5% of the area of the triplet at $\delta = 8.21$. This minor triplet, not reported in earlier NMR studies of LF **16**, was found to be present at somewhat lower intensity in the NMR spectrum of synthetic **16**. In C_6D_6, **16** shows downfield triplets at $\delta = 7.61$ (major triplet; $J = 7.82$ Hz) and 8.37 ppm (minor triplet; $J = 8.89$ Hz).[77b, 157]

Thus, the NMR spectrum of **16** reveals a minor triplet $\Delta\delta = 0.67-0.68$ downfield from the major triplet in $CDCl_3$ and $\Delta\delta = 0.77$ downfield from the major triplet in C_6D_6. On using C_6D_6 instead of $CDCl_3$ as solvent, the major triplet was shifted $\Delta\delta = 0.59$, the minor triplet $\Delta\delta = 0.50$ to higher field. From a comparison of this NMR data with NMR data of related structures of the type RCH=N–X (X = OR, NR'R")[158] we concluded that **16** exists as a mixture of *E*- and *Z*-isomers, with the latter dominating. This assignment is consistent with the observation in the nitrogen systems that: 1) protons resonate at lower fields when *syn* than when *anti* to X in RCH=N–X; 2) *anti* protons are shifted further upfield than *syn* protons on changing the solvent from CCl_4 to C_6D_6; and 3) the coupling constant $J_{H_1H_\alpha}$ (e.g. $J_{H_1H_2}$ in **16**) is slightly larger in the *anti* compound than in the *syn* compound.[158] In analogy with the mechanism proposed for the aromatic solvent induced shifts in nitrogen systems[158] and sulfoxides,[73, 159] dipole forces should favor the orientation relative to benzene shown in Figure 8 in which the *anti*-proton in the (*Z*)-isomer (Et) should experience greater shielding than the *syn*-protons (R_2 = H) in the (*E*)-isomer.

Similar conclusions are drawn from consideration of solvent effects on the ^{1}H-NMR spectra of **44**, **66**, **116**, and **123**. In the case of the bissulfine **123** isolated from onion a *Z,Z*-configuration is assumed, since the HC=SO proton is shifted to even lower field ($\delta = 8.09$ in $CDCl_3$, $\delta = 7.06$ in C_6D_6), and this change of solvent influences the chemical shift even more strongly ($\Delta\delta = 1.03$) than in the case of the corresponding proton in (*Z*)-**16**. In the case of the sulfine **116** (R = Me and Pr) a *Z*-configuration is assumed, because of similarity of the chemical shifts of **116** and of (*Z*)-**16** (**116**, R = Me, diastereomer **A**: HC=SO appears as a doublet at $\delta = 8.27$ in $CDCl_3$ and $\delta = 7.19$ in C_6D_6; diastereomer **B**: HC=SO appears at $\delta = 8.44$ in $CDCl_3$ and $\delta = 7.62$ in C_6D_6; very similar effects are seen for the two diastereomers of **116**, R = Pr). Interestingly, in methanethial *S*-oxide (**40**) the chemical shifts of the two protons ($\delta = 7.84$ and 7.73 in $CFCl_3$[68]) are much closer together in value than in the higher homologs, perhaps due to the slight change in HCS angles. It is also of interest to contrast the chemical shift of the *HC*=S proton in 2,2-dimethylpropanethial (*t*BuCH=S)[160] at $\delta = 11.67$ with the chemical shift of this proton in 2,2-dimethylpropanethial *S*-oxide (*t*BuCH=SO) at $\delta = 7.62$ (*Z*)/9.00 (*E*) (all data recorded in $CDCl_3$ as solvent). While the C=S group deshields an attached proton relative to C=O, the C=SO group has the opposite effect!

The ^{13}C-NMR spectra of (*Z*)- and (*E*)-**16** show the resonances for *C*=SO at $\delta = 180.5$ and 184.5, respectively. The minor *E*-isomer shows deshielding at the sp^2-carbon center compared to the major *Z*-isomer. In the case of the sulfine **116** (R = Me or Pr) and the bissulfine **123** in $CDCl_3$, *C*=SO appears at $\delta = 175.92$ (**116**, R = Me), 176.24 (**116**, R = Pr), and 179.6 (**123**), values more consistent with a *Z*- rather than an *E*-configuration. These ^{13}C-NMR values for *C*=SO differ markedly from the value for *HC*=S in 2,2-dimethylpropanethial[160] ($\delta_C = 255.6$).

In the ^{17}O-NMR spectrum the signal for the sulfine oxygen atom of (*Z*)-**16** and (*Z*)-**44** appears at $\delta_O = 196$ and 199, respectively. These values may be compared to the ^{17}O chemical shifts of $SOCl_2$, $(MeO)_2S{=}O^*$, $Me_2S{=}O$, thiane *S*-oxide and thiolane *S*-oxide which have been determined as $\delta_O = 292$, 176, 13, −3, and 15, respectively.[49, 161] The strong deshielding of the oxygen in sulfines compared to that in simple sulfoxides may be a consequence of the enhanced electronegativity of carbon sp^2 orbitals attached to the sulfine sulfur compared to carbon sp^3 orbitals utilized in the sulfoxides, since other sulfinyl compounds containing electronegative substituents on sulfur are also deshielded relative to simple sulfoxides.

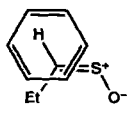


Fig. 8. Aromatic solvent induced shift (ASIS) effects on onion LF (*Z*)-**16**.

5.3.2. NMR Spectroscopy of the Dimer of LF: the Four-Membered Ring Sulfone Effect

The ^{1}H- and ^{13}C-NMR data of the LF dimer **18b** (see Scheme 24) and of the homolog *trans*-3,4-bis(trimethylsilyl)-1,2-dithietane 1,1-dioxide (**67**) (see Scheme 25) clearly indicate the presence of two substantially different, coupled, "CHR" groups, i.e. $-SO_2CHR$ and $-SCHR$. The difference in the δ_c values of the two pairs of methine carbon atoms (e.g. 97.9 and 39.2 in **18b** and 88.4 and 14.8 in **67**) is quite striking. While part of the difference is due to deshielding of the α-sulfonyl carbon atoms of thiosulfonates compared with sulfones,[162] and a vicinal deshielding effect due to the *trans*-ethyl or *trans*-trimethylsilyl groups (e.g. 2-methyloxetane and *cis*- and *trans*-2,3-dimethyloxetane show ^{13}C shifts

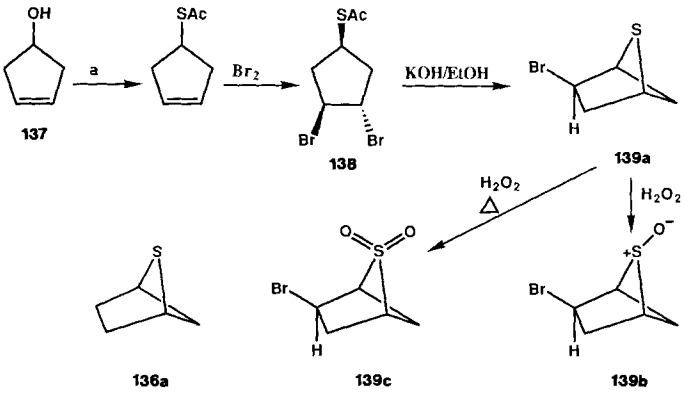
for C-2/C-3 at δ_c = 78.3/29.2, 79.6/31.8 and 85.0/37.4, respectively),[163] it is necessary to invoke an unusual deshielding effect characteristic of four-membered ring sulfones[164] to fully explain the magnitude of the difference.

Consider the ^{13}C-NMR shifts of the α-carbon atoms in the three- to six-membered ring sulfur heterocycles thiirane, thietane, thiolane and thiane (with –S– group), which are 18.1, 26.1, 31.7, 29.1. In the analogous sulfoxides (–S(O)–) and sulfones (–S(O_2)–) the values are 33.8, 52.7, 54.3, 49.0 and 31.6, *65.6*, 51.1, 52.6, respectively.[164] Note the downfield shift of the C_α-signal of $\Delta\delta$ = 40 on oxidation of thietane to thietane 1,1-dioxide and the downfield shift of $\Delta\delta$ = 13 in the oxidation of thietane 1-oxide to the 1,1-dioxide. With most sulfide-sulfoxide-sulfone systems, oxidation of a sulfide to a sulfone results in such a downfield shift of only $\Delta\delta$ = 20–25; very little difference is seen in the chemical shifts of the α-carbon atoms in the sulfoxides and sulfones, the latter sometimes even appearing slightly upfield of the former (cf., e.g., the above data for thiolane 1-oxide and 1,1-dioxide). The so-called "four-membered ring sulfone effect" contributes to the above noted differences in the chemical shifts of the methine carbon atoms in the sulfine dimers **18b** and **67**.

The unusual ^{13}C chemical shift effects for thietane 1,1-dioxides and related four-membered rings such as **18b** and **67** are reflected in similar but smaller effects in the ^{1}H and ^{17}O chemical shifts. Thus, unusually deshielded *H*CSO_2 protons are observed in **18b** (δ = 4.35) and **67** (δ = 5.06). The ^{17}O chemical shifts for thiirane, thietane, thiolane and thiane 1,1-dioxide appear at δ_O = 111, *182*, 165, and 142, respectively, once again showing maximum deshielding for the four-membered ring. Compound **18b** shows bands at δ_O = 210 and 243 which is notable for the substantial deshielding seen as well as the fact that *for the first time discrete ^{17}O chemical shifts are observed for nonequivalent sulfone oxygens.*[164] Additional examples of ^{17}O-NMR investigations on sulfones with diastereotopic protons have subsequently appeared in the literature.[165]

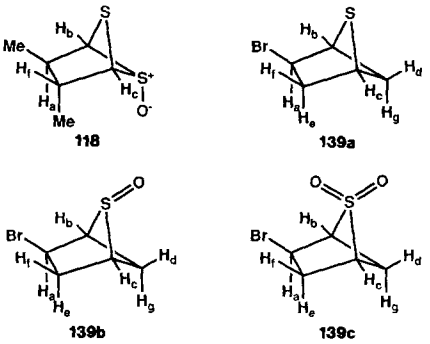
5.3.3. *Comparative NMR Spectroscopy of Derivatives of Bicyclo[2.1.1]hexane, 5-Thiabicyclo[2.1.1]hexane, and 5,6-Dithiabicyclo[2.1.1]hexane*

In connection with the identification of the zwiebelanes by ^{1}H- and ^{13}C-NMR spectroscopy, heterobicyclo[2.1.1]-hexanes were sought as model compounds for comparison of coupling constants. While 5-thiabicyclo[2.1.1]hexane (**136a**), its *S*-oxide **136b**, and its *S,S*-dioxide **136c** are known, the symmetry of **136** limits the number of H–H couplings seen. The synthesis of a less symmetrical derivative of **136a**, namely **139a**, was therefore developed (Scheme 56).[166] Exposure of 3-cyclopentenol (**137**) to Mitsunobu thioacetylation conditions affords *S*-3-cyclopentenylthioacetate, which was treated directly with bromine in CCl_4 to give the *trans*-1,2-dibromo derivative **138** in 54% overall yield. Treatment of **138** with KOH in aqueous ethanol at reflux for 90 hours afforded *exo*-2-bromo-5-thiabicyclo[2.1.1]hexane (**139a**) in 40% yield. Compound **139a** was oxidized to the corresponding sulfoxide **139b** and sulfone **139c** with H_2O_2/HOAc/CH_2Cl_2 at 0 °C and at reflux, respectively. Table 2 enables a comparison to be made of the NMR data for zwiebelane **118** with those for model compounds **139a–c**. It is noteworthy that



Scheme 56. Synthesis of 2-bromo-5-thiabicyclo[2.1.1]hexane **139a** and its *S*-oxides **139b** and **139c**. a: HSAc, Ph_3P, $EtO_2CN{=}NCO_2Et$.

Tabelle 2. ^{1}H- and ^{13}C-NMR data for compounds **118** and **139a–c**.



Cpd.		Position a	b	c	d	e	f	g
118	^{13}C	48.0	79.4	77.7			39.4

the $^4J_{HH}$ bridgehead-bridgehead coupling in **118** (6.7 Hz) is quite similar to that in **139a–c** (6.1 Hz) and that reported for bicyclo[2.1.1]hexane (6.23 Hz).[167] Apparently this large "W" long-range coupling is little affected by the nature of the "spacer atoms" between the CH groups.

5.3.4. *Diastereotopic Effects in Polysulfides*

The diastereotopic character of CH_2 protons in sulfinyl compounds is well known, and leads to complex NMR spectra for compounds such as allicin, alliin, and ajoene. It is less well recognized that the helical geometry of polysulfides can also lead to magnetic nonequivalence of methylene protons or enhancement of this effect in molecules containing other chiral centers. In the case of the ^{1}H-NMR spectra of compounds **140a–c** (Fig. 9) found in the distilled oil of garlic, we find that the $SCH_cCH_aH_bS$ group shows the *largest difference* between H_a and H_b in the case of **140c** ($\delta_a = 3.09$, $\delta_b = 3.17$, $J_{ab} = 14.1$ Hz, $J_{ac} = 8.7$ Hz, $J_{bc} = 6.5$ Hz). The

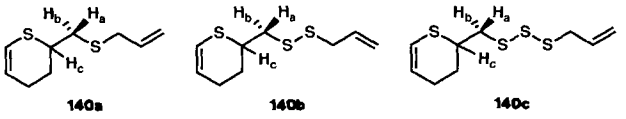

Fig. 9. 3,4-Dihydro-2*H*-thiopyran derivatives **140a–c**.

^{1}H-NMR spectrum of **140a** shows no separation of H_a and H_b while that of **140b** shows a separation of only $\Delta\delta = 0.01$ for these protons.[118]

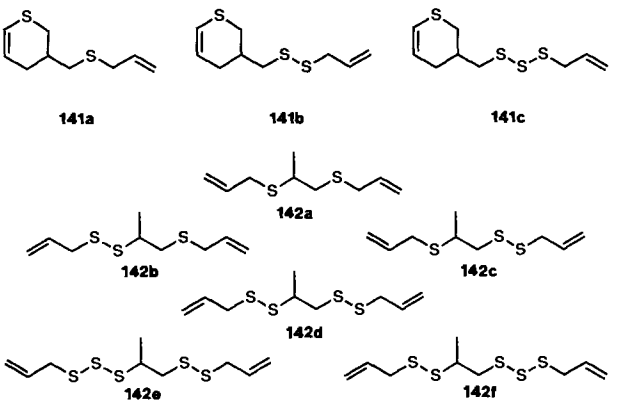
6. Steam-Distilled Oils

The earliest chemical studies on garlic and onion involved distillation procedures. While the first detailed chemical report of the preparation and analysis of the distilled oil of garlic appeared in 1844,[4] it is likely that many centuries earlier alchemists and pharmacists distilled garlic bulbs to produce potions for a plethora of ailments. Wertheim's 1844 paper attributes garlic's appeal to "the presence of a sulfur-containing, liquid body, the so-called garlic oil. All that is known about the material is limited to some meager facts about the pure product which is obtained by steam distillation of bulbs of *Allium sativum*. Since sulfur bonding has been little investigated so far, a study of this material promises to supply useful results for science." The components of garlic oil, separated by Wertheim by fractional distillation, were described as forms of "allylschwefel", establishing the garlic connection to the common name "allyl". Semmler[5] indicated that the principal constituents of the distilled oils of garlic and onion are, respectively, diallyl disulfide (**4b**) and a compound of formula $C_6H_{12}S_2$, structurally unspecified by him but suggested by others to be allyl propyl disulfide.[168] For the onion oil analysis, 5000 kg of onions were steam distilled, affording only 233 g (0.005%) of oil! Today the steam-distilled oils of garlic and onion are items of commercial importance for use both in food and health products.

6.1. Oil of Garlic

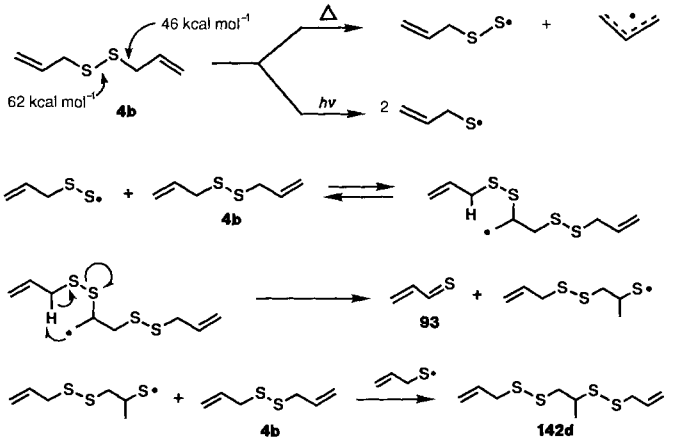
Although distilled garlic oil lacks the antibacterial and antithrombotic activity of the room temperature extract, it possesses equally interesting antitumor and antioxidant properties. Garlic oil and some of its components inhibit lipoxygenase (LO), one of the enzymes involved in arachidonic acid metabolism, which may be related to its antitumor activity and other biological properties. Two observations in particular prompted us to study the effect of heat on garlic oil: 1) Belman and Barany noted that ageing or heating of the garlic oil component allyl methyl trisulfide effected an increased inhibitory activity toward the soybean 15-lipoxygenase (LO) enzyme compared to a freshly synthesized sample;[169] 2) Granroth observed that "diallyl disulfide **4b** is slowly decomposed even at room temperature, and at 100 °C at least 25 reaction products were revealed by gas chromatography, the true number being still greater" and that "allylic compounds may undergo changes upon heating garlic-spiced foods, but the chemistry and possible physiological importance of these changes do not so far appear to have been investigated."[20] Analysis of the thermally more robust heavier compounds in garlic oil by GC and GC-MS suggested the presence of an unusual family of thiaheterocycles and acyclic compounds. The composition and origin of this group of compounds was clarified by examining the behavior of diallyl disulfide upon heating.

We have analyzed distilled garlic oil preparations using the inhibition of soybean lipoxygenase (LO) to determine the compounds responsible for its biological activities. We found that: 1) the LO-inhibitory activity of garlic oil increases upon heating and concentration; 2) GC-MS analysis of garlic oil revealed a group of previously unknown higher boiling cyclic and acyclic organosulfur compounds with two to five sulfur atoms (e.g. **140a–c**, **141a–c**, **142a–f**, Scheme 57); 3) most



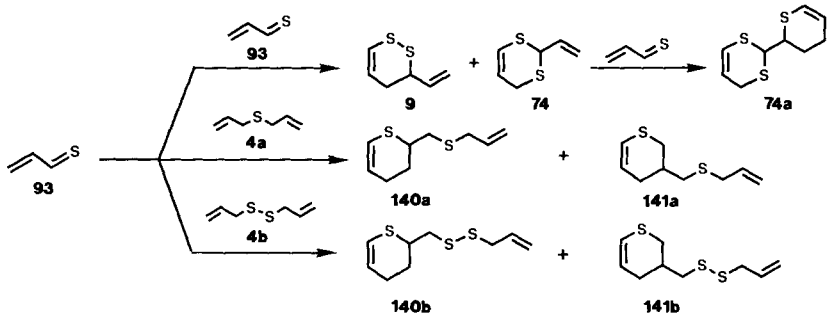
Scheme 57. Higher molecular weight compounds of type **140–142** from the pyrolysis of diallyl disulfide.

of these same compounds are generated upon heating pure samples of diallyl disulfide (**4b**); 4) the formation of these new compounds is best explained by a remarkable sequence involving thermal C–S homolysis of **4b** (rather than S–S homolysis, which only occurs upon photolysis), addition of the allyldithio radical in Markownikoff fashion to **4b**, intramolecular hydrogen atom abstraction-fragmentation of the radical adduct to produce thioacrolein (**93**, Scheme 58), and finally Diels–Alder addition of **93** as a heterodiene to diallyl sulfide (**4a**) and **4b** and dimerization to form **9** and **74** (Scheme 59).[118] The viability of such processes could be independently established using known thermal sources of **93** including allicin (Scheme 32) and diallyl sulfide (in a



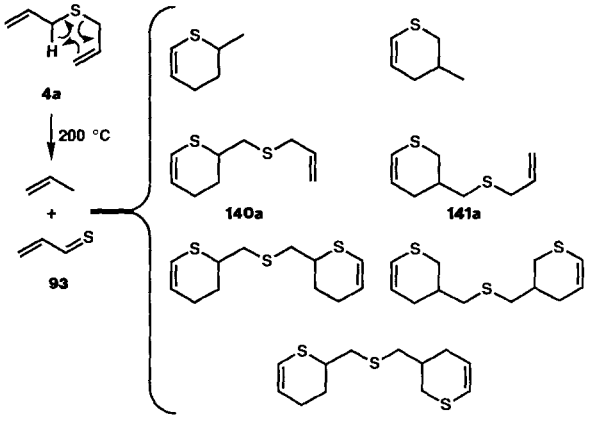
Scheme 58. Mechanism for decomposition of diallyl disulfide (**4b**).

An unexpected dividend to our examination of different thermal sources of **93** was our discovery that one of the most efficient low-temperature sources of **93** is diallyl sulfoxide (**143**)! Thus, when excess **143** is heated at 110 °C with dienophiles such as *N*-phenylmaleimide, dimethyl fumarate or ethyl acrylate, the corresponding thioacrolein Diels–Alder adducts such as **144** can be isolated in good to excellent yields (Scheme 61).[171] We suggest that the sulfur atom of reversibly formed allyl-2-propenesulfenate (**145**) acts as a nucleophile toward a second molecule of **145**, forming thiosulfonium ion **146**, a process similar to that observed with thiosulfinates (Schemes 11 and 31). Hydrolysis of **146** gives allicin **1**, known to be a low-temperature source of **93** (Scheme 32). When garlic oil is examined by HPLC, polysulfides with up to six sulfur atoms (e.g. All_2S_6, **4f**) are



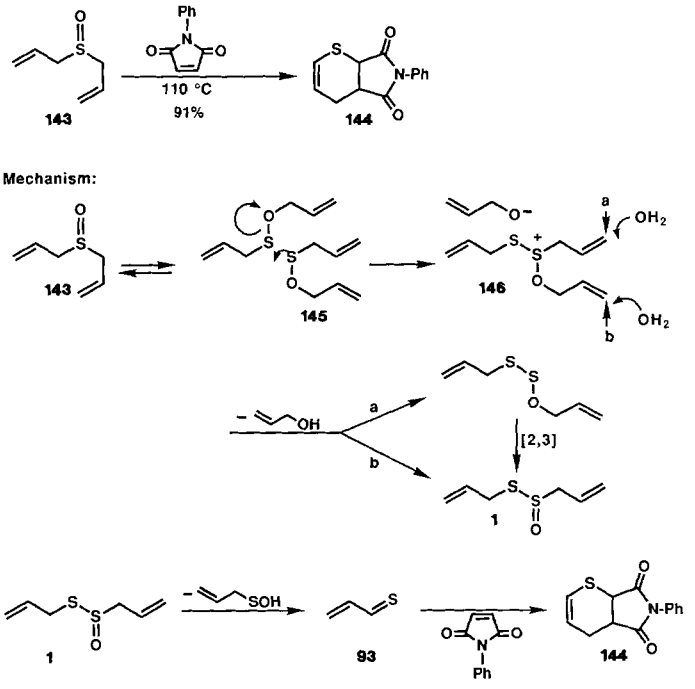
Scheme 59. Diels–Alder reaction of thioacrolein (**93**).

sealed tube; Scheme 60) and by demonstrating by mass spectrometric methods that the C–S and S–S bond dissociation energies in **4b** are 46 and 62 kcal mol^{-1}, respectively.[118] We conclude that the formation of the complex mixture of acyclic and heterocyclic polysulfides in the distilled oil of garlic is a consequence of the action of heat during the distillation process on the allicin and **4b** forming **93** and allyldithio radicals. Obviously any culinary procedure which exposes garlic or garlic-spiced food to heat could also generate the types of compounds described herein with possible health benefits associated with the antioxidant or lipoxygenase-inhibitory activity.[170a]



Scheme 60. Sealed tube pyrolysis of diallyl sulfide (**4a**).

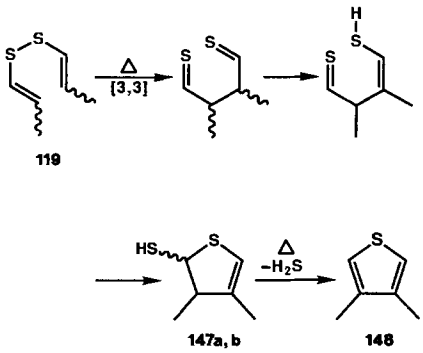
found.[170b] These are difficult to detect by GC because of their thermal instability. They may be formed by known sulfur transfer processes from allylic disulfides.[118, 172]



Scheme 61. Pyrolysis of diallyl sulfoxide (**143**) to give thioacrolein **93**; trapped as 3,4-dihydro-2*H*-thiopyran derivative **144**.

6.2. Pyrolysis of Bis(1-propenyl) Disulfide

When a 1% solution of the isomers of bis(1-propenyl) disulfide **119** in benzene is kept at 85 °C for 3 hours two new compounds, identified as *cis*- and *trans*-3,4-dimethyl-2,3-dihydrothiophene-2-thiol (**147a,b**), are formed in a 1:1 ratio in over 85% yield together with minor quantities of 3,4-dimethylthiophene (**148**).[173] Compound **148** was previously observed as the predominant product formed when **119** is heated to 150–200 °C in the presence of $KHSO_4$.[174] Prolonged heating at higher temperatures results in the conversion of **147a,b** into **148** (Scheme 62). All three isomers of **119** lead to the same mixture of **147a,b**; no isomerization from one isomer of **119** to another occurs under pyrolysis conditions. The relative rates of reaction of the three isomers of **119** were found to be *E,Z* > *E,E* > *Z,Z*.



Scheme 62. Dithio-Claisen reaction of bis(1-propenyl) disulfide (**119**) and formation of *cis*- and *trans*-3,4-dimethyl-2,3-dihydrothiophenethiol (**147a,b**) and 3,4-dimethylthiophene (**148**).

Compounds **147a,b** are thought to be formed from **119** via a [3,3]-sigmatropic dithio-Claisen rearrangement[175] followed by thioenolization and intramolecular addition of SH to CH=S (Scheme 62), similarly to cyclizations involving 1,4-diketones. The similarity of the activation parameters for rearrangement of (*Z,Z*)-**119** (E_a = 19 kcal mol^{-1}, $\Delta H^{\neq}$ = 18.3 kcal mol^{-1}, $\Delta S^{\neq}$ = −24.8 cal mol^{-1}K^{-1}, and $\Delta G^{\neq}$ = 27.5 kcal mol^{-1}, all at 373 K)[135a] to the corresponding values for (*Z,Z*)-**120** (Section 5.2.5, cf. Schemes 41–43) suggests a similar mechanism. The absence of interconversion of isomers of **119** under the reaction conditions precludes a homolytic route to **147a,b**. Compounds **147a,b** as well as 2-alkyldithio-3,4-dimethylthiophenes (alkyl = Me or Pr) have been detected in steam-distilled volatiles from scallion and Welsh onion.[141] It is likely that the thiophene **148**, one of the significant contributors to the aroma of garlic, leek, and cooked or fried onion,[176] is formed in these plants from **147a,b** by loss of H_2S, although additional routes to **148** and other dimethylthiophenes are conceivable.

7. Physiological Activity

Belief in the preventive or curative effect of vegetables towards disease has persisted for thousands of years. Garlic, onion, cress, and cabbage are examples. In Eastern Europe and Asia Minor, large amounts of raw onion or garlic are a normal feature of the diet. The science of nutrition has paid little serious attention to these beliefs, since, to some extent, they can be explained on the basis of the vitamins and minerals contained in these vegetables, and because other alleged effects, if they exist, seem to be connected with substances better regarded as drugs than foods.

A. Virtanen (1895–1973)[2]

7.1. Antimicrobial Activity

Since things that here in order shall ensue,
Against all poysons have a secret power.
Peare, garlicke, reddish root, nuts, rape and rue—
But garlicke chiefe; for they that it devoure
May drinke, and care not who their drinke do brewe.
May walk in aires infected, every houre
Sith garlicke them have power to save from death,
Bear with it though it maketh unsavory breath,
And scorne not garlicke, like some that thinke
It only maketh men winke, and drinke—and stinke.

"The Englishman's Doctor"
Sir John Harington (1561–1612) [177a]

Before the availability of modern antibiotics, garlic preparations were widely used in epidemics of typhus, cholera, dysentery, amoebic dysentery, diphtheria, and tuberculosis.[3i] Albert Schweitzer first treated amoebic dysentery in Africa with garlic only.[177b] The antimicrobial effect of allicin is considerable.[122b] It has a growth inhibiting effect on both gram-negative and gram-positive bacteria (e.g. *Streptococci, Staphylococci, Eberthella typhosa, B. dysenteriae, B. enteritidis* and *Vibrio chlorae*) even at a 1:100000 dilution.[33] The antimicrobial effect of methyl methanethiosulfinate (**12**), propyl propanethiosulfinate (**13**), and thiosulfinates found in onion extracts (first noted to be antibacterial by Louis Pasteur![178]) are weaker than allicin **1**.[2, 179, 180] Allicin and garlic extracts show anticandidal and antifungal (e.g. anti-*Cryptococcus neoformans*) activity.[181–183] Garlic bulb volatiles have fungicidal properties[184, 185] which may protect the bulb against invading microorganisms. Diallyl trisulfide, **4c**, a constituent of garlic oil, has been used in China to treat viral infections and cryptococcal meningitis.[186]

7.2. Cancer Preventive Properties

Since the 1957 discovery that ethyl ethanethiosulfinate **31** showed anti-tumor activity, considerable attention has focussed on the cancer preventive properties of *Allium* spp.[186, 187] A fascinating epidemiological study conducted in the People's Republic of China reveals that in a region of China where gastric cancer rates are high, a significant reduction in gastric cancer risk parallels increasing consumption of garlic, scallion, and Chinese chive. Persons in the highest quartile of intake of these plants experienced only 40% of the risk of those in the lowest.[188] Since nitrites have been implicated in gastric cancer, it is relevant that gastric juice nitrite concentrations were lower in individuals consuming garlic compared to those who rarely take garlic; the

reduction of nitrite concentration in gastric juice after introduction of fresh garlic homogenate was significantly larger than that of controls.[189a] It is also known that diallyl disulfide **4b** inhibits in vivo activation of nitrosamines.[189b] Unsaturated polysulfides found in *Allium* spp. inhibit tumor promotion,[187, 190-193] perhaps by enhancing glutathione-dependent detoxification enzymes,[194a, b] and also modulate mutagenesis of aflatoxin B1.[194c] Steam-distilled onion oil, but not garlic oil, can also function as a weak tumor *promoter* as well as antipromoter in 7,12-dimethylbenz[*a*]-anthracene-initiated mouse skin.[195]

7.3. Cardiovascular Effects on Lipid and Arachidonic Acid Metabolism, and Platelet Aggregation Inhibitory Activity

Dietary garlic has a lipid- and cholesterol-lowering effect.[3i, 196] γ-Glutamyl-*S*-alkylcysteines inhibit the blood-pressure regulation hormone.[201a] A detailed mortality study[196b] on patients who had prior heart attacks showed that of those given gelatin capsules containing garlic oil (ca. 6 mg/person/day) high in ajoene (**75**) and dithiins (**9**, **74**)[119b] for three years, there was significant reduction in serum lipids, a 35% reduction in new heart attacks, and a 45% reduction in total deaths compared to those consuming placebo capsules. Allicin (**1**) is a specific inhibitor of acetyl-CoA synthetases from plants[197a] while diallyl disulfide (**4b**) inhibits 3-hydroxy-3-methylglutaryl CoA;[197b] in this manner lipid, cholesterol and fatty acid biosynthesis may be inhibited. The inhibitory effect of garlic and onions on human platelet aggregation has been known for two decades and has been variously attributed to adenosine, allicin **1**, alliin **2**, ajoene **75**, polysulfides (such as **4f**), and vinyl dithiins (e.g. **9** and **74**).[28, 198] The identity of the organosulfur compounds found in the blood or tissues after consumption of the plants remains unknown (apart from the compounds found in breath or sweat after ingestion of garlic). In view of the in vivo findings of Lawson[28] and the observations of Cavallito[30] and Wills[199a] that allicin reacts immediately with the SH-group of free or enzyme-bound cysteine forming *S*-(allylthio)cysteine, it is unlikely that allicin itself is found in blood after consumption of garlic. Indeed *S*-(allylthio)-cysteine may well be responsible for much of the biological effects of garlic within the body.[28a] Several studies indicate that the components of freshly cut garlic[199b] and onion[149] inhibit platelet aggregation and smooth muscle contraction through inhibition of cyclooxygenase and related enzymes. The antiasthmatic effects of onion extracts has been demonstrated; some of the most active components are thiosulfinates and cepaenes. These compounds exert a wide range of pharmacological effects such as inhibition of the cyclooxygenase and lipoxygenase pathways of arachidonic acid metabolism, inhibition of histamine release and leukotriene biosynthesis, prevention of bronchial asthma in guinea pigs after inhalation of allergens and platelet-activating factor, and inhibition of inflammatory cell influx.[125] Allicin is reported to inhibit human platelet aggregation in vitro without affecting cyclooxygenase or thromboxane synthase activity or cyclic AMP levels, possibly by influencing calcium movement.[198a]

7.4. Physiological Activity of Ajoene

Ajoene **75** is cytotoxic toward a tumorgenic lymphoid cell line with an EC_{50} of 12 μM;[200] it shows an IC_{50} of 1.6 μM and 5.1 μM towards the 5-lipoxygenase and cyclooxygenase enzymes, respectively;[201] it synergistically potentiates the antiaggregatory action of prostacyclin, forskolin, indomethacin and dypiridamole on human blood platelets.[106] Administration of **75** to dogs under conditions used in open heart surgery prevents the thrombocytopenia induced by contact of blood with artificial surfaces; it shows excellent activity in preventing the loss of platelets and in increasing the rate of restoration of platelet clotting activity.[202a] Other anticlotting agents (aspirin, heparin) had longer lasting effects and did not protect platelets. Ajoene is thought to inhibit platelet activation by impairing the interaction of fibrinogen receptors on the platelet surface with the rest of the membrane signal transduction system and by affecting the plasma-membrane internal microviscosity.[202b-d] Alternatively, it is suggested that ajoene alters the conformation of a hemoprotein implicated in platelet activation.[203a] Ajoene can also inhibit adhesive interactions of human neutrophiles and consequently effect in vivo superoxide anion formation.[203b] Ajoene possesses significant antifungal activity, inhibiting the growth of *Aspergillus niger, Candida albicans, Paracoccidioides-Brasiliensis*, and *Fusarium* species at concentrations of $< 20\ \mu g\,mL^{-1}$,[204] possibly by damaging the fungal cell walls.[204b] Ajoene inactivates human gastric lipase (HGL), a sulfhydryl enzyme involved in the digestion and adsorption of dietary fats. This observation corroborates previous reports on the ability of garlic to lower triacylglycerol blood levels ("blood thinning" effect of folk medicine).[205] A garlic preparation prepared by dissolving fresh garlic extract in coconut oil (forming ajoene and dithiins[28]) significantly decreases ADP-induced platelet aggregation in volunteers consuming $0.25\ mg\,kg^{-1}$ daily for 4 weeks.[206]

7.5. Acid Reflux Effect

Eat no onions nor garlic, for we are to utter sweet breath.

"A Midsummer Night's Dream"
William Shakespeare (1564-1616)

Anyone who has overindulged in onions is aware of the consequences. Gastroenterologists refer to the effect as "acid reflux and reflux symptoms", e.g. regurgitation of the stomach contents into the esophagus with resultant "heartburn". A more precise physiological description is inappropriate transient lower esophageal sphincter (LES) relaxation, e.g. erratic opening of the valve separating the esophagus from the stomach.[207] Since, as we have already mentioned in Section 7.3, several of the organosulfur compounds formed when onions are cut are potent inhibitors of the cyclooxygenase and lipoxygenase pathways of arachidonic acid metabolism, raw onions may cause heartburn by blocking these pathways.[208] This inhibition might then result, either singly or in combination, in the transient relaxation of the LES as well as injury to the esophageal mucosa.

7.6. Lachrymatory, Olfactory, and Gustatory Characteristics of *Allium* spp.

Provence with her garlic-scented smile.
Rudyard Kipling (1865–1936)

While it is not known precisely how crying is triggered by an onion, it has been suggested that the onion LF, along with other lachrymators such as tear gases, undergo particularly facile reduction by NADPH following reception in a nerve cell membrane.[209] The organoleptic properties of some fresh onion extract and distilled onion oil components have been evaluated by "expert flavorists" who described odor and taste. The "room-temperature steam distillate" of onion, consisting primarily of α,β-unsaturated thiosulfinates, had an odor and taste quite similar to that of fresh onions. Of the isomeric pair (*E*)-**106**, R = Me/(*E*)-**105**, R = Me, the former had a pronounced fresh raw onion or shallot flavor while the latter had more of a cabbage or radish note. The flavor of (*E,Z*)-**106**, R = Pr, is that of green, raw fresh onions. On the other hand, (*E,Z*)-**114**, R = Pr, lacked the fresh raw onion flavor of the thiosulfinates, having more of an oniony, solvent-like flavor. The cepaene (*E,E*)-**127d** had a fruity melon-like flavor combined with a slight fresh onion flavor.[21] Propyl, propenyl di- and trisulfides possess the odor of cooked onions.[176] The threshold (minimal levels for detection in aqueous solutions by taste) range from 5–10 ppb for the thiosulfinates, the deoxycepaenes (*E,E*)- and (*Z,Z*)-**131** and the cepaene **127d** to 0.01–6 ppb for (*Z,Z*)-**119**, Pr_2S_2, MeSSCH=CHMe, and PrSSCH=CHMe, to an amazing level (for one experienced flavorist) of 0.001 ppb for (*E,Z*)-**114**, R = Pr.[21,176]

7.7. Bad Breath and Further Negative Effects of Garlic and Other *Allium* spp.

...edit cicutis alium nocentius.[*]
"Episode 3"
Horace (65 B.C.–8 B.C.)

Eating alliaceous plants causes bad breath and perspiration odors. Components of garlic breath and prespiration include: allyl methyl sulfide and disulfide, diallyl sulfide and disulfide, 2-propenethiol, and *p*-cymene and (+)-limonene (present in garlic distilled oils).[210,211] Garlic breath odor comes from the lungs presumably by way of the blood and not solely from particles of garlic retained in the structures about the mouth.[212] After ingestion of 2 g of raw garlic, garlic odor in human urine was said to persist up to 96 hours while exhaled air no longer had an odor after 24 hours.[213a] When garlic is rubbed on the foot, a garlic taste is soon detected.[213b] Presumably fat-soluble allicin is absorbed through the skin (as in the case of dimethyl sulfoxide) into the lymphatic system which carries it intact to the upper part of the body in a medium where no protein or cysteine is present.[213b] In areas where *Allium* spp. grow wild, cows often eat them, causing a bad flavor in milk. A vacuum treatment can remove these sulfur compounds and the bad taste.[20] Studies on nursing mothers have shown that their milk has a more intense odor 2 hours after having ingested garlic. Furthermore it was found that the nursing babies sucked more and ingested more milk when the milk smelled like garlic.[214]

A few individuals have an allergic response, e.g. dermatitis or asthma, to fresh garlic or onions,[215a] diallyl disulfide, allicin or garlic dust.[3i,215] Freshly ground garlic can cause severe dermatitis on prolonged contact with the skin.[216] In a case associated with excessive garlic ingestion, spontaneous spinal epidural hematoma causing paraplegia following a qualitative platelet disorder has been reported.[217] When given orally to laboratory animals, garlic has been noted to cause anemia,[3i] abdominal hemorrhage and death.[187] In mice, allicin (**1**) has an LD_{50} of 60 mg kg^{-1} i.v. and 120 mg kg^{-1} s.c.[30] An occupational hazard associated with sulfur compounds in the perspiration of a garlic lover has been reported.[211]

[*] That wicked garlic, more poisonous than the hemlock.

7.8. Insect and Animal Attractive/Repulsive Effects

Propyl propanethiosulfinate (**13**) has been identified as the most attractive substance from crushed leek for the leek moth, *Acrolepiopsis assectella*; **13** is repellent to *Ephestia kuehniella* (based on our recent analyses of thiosulfinates from leek, this work may require revision!)[29] Allicin, its homologs, and related sulfur compounds are thought to protect *Allium* spp. against pathogens and predators.[10b,14b] Garlic oil components/metabolites diallyl disulfide and trisulfide are toxic to mosquito and other insect larvae at levels of 2 ppm[218] and are repellant to *Ixodes ricinus*, the tick which carries the encephalitis virus.[219] Diallyl disulfide has been employed to drive away crop-damaging birds.[3i]

8. Summary and Outlook

In the fifty years since the discovery of allicin (**1**)[30] much progress has been made in identifying the various unusual organosulfur compounds formed when garlic and onion are cut (Figs. 10 and 11) and in understanding their origin. Despite this progress, many other compounds remain to be identified in *Allium* extracts. For example, application of field desorption mass spectroscopy to the analysis of onion extracts indicates that the heaviest compounds present have masses of m/z = 325–326 and 298–301, corresponding respectively to molecular formulas $C_{12}H_{20}S_4O_2/C_{12}H_{22}S_4O_2$ and $C_{10}H_{18}S_4O_2/C_{10}H_{20}S_4O_2$. Analysis of these extracts by LC-MS indicate the presence of a series of compounds (perhaps a family of homologous isomers?) with masses 324/326 and 298. Possible structures include *S,S'*-dioxides of **132** (Scheme 53) or isomers **149** (Scheme 63), together with ho-

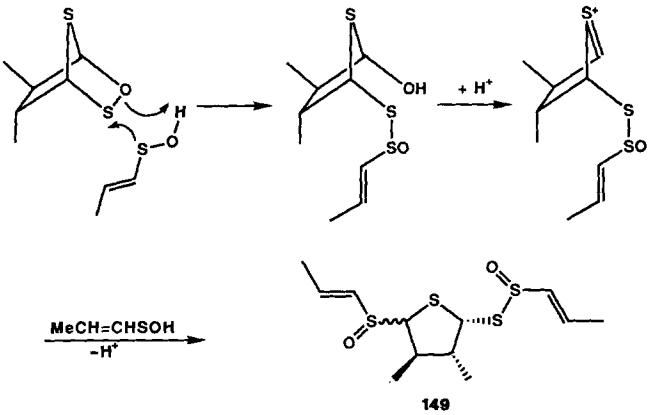

Scheme 63. Possible structure for *m/e* 324 compound (**149**) from onion extracts.

mologs with methyl replacing a 1-propenyl group. Efforts to identify these compounds are underway.

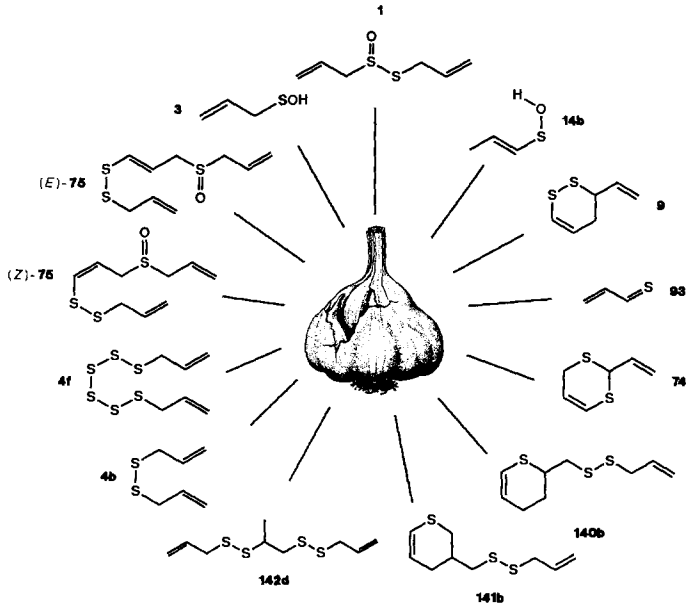

Fig. 11. Collection of some of the principal organosulfur compounds and intermediates associated with garlic.

How might dietary *Allium* spp. benefit us? Consider the following: 1) The *Allium* spp. tissue is not completely crushed when it is eaten, thus allowing a significant portion of the *S*-alk(en)ylcysteine *S*-oxides such as **2**, **5**, **6**, and **7** to pass unchanged into the intestinal tract. While allinases are irreversibly deactivated at the pH of gastric juice, intestinal bacteria have been shown to cleave the sulfoxides, ultimately giving the corresponding disulfides.[10b] 2) Thiosulfinates which have made their way into the stomach may survive the low pH long enough to act on pathogenic microorganisms present. 3) Alk(en)ylthiolation of certain biological SH groups by thiosulfinates, di- or polysulfides or ajoene might be beneficial. For example, "allylthiolation" of thiamine readily occurs affording allithiamine, which is more easily absorbed from the intestine than thiamine.[3i, 38] 4) Disulfides and other sulfur compounds formed from *Allium* spp. are thought to play an important role in the intestinal tract in deactivating nitrites or other environmental toxins. One thing is clear: tracking the metabolic fate of *Allium* spp. organosulfur compounds is both an important and a fertile area for future research.

I am profoundly grateful to my many excellent co-workers and collaborators, whose names appear in the references, for their valuable contributions to the research described herein. I particularly thank S. Naganathan, D. Putman, and S. H. Zhao for their expert assistance in the preparation of this manuscript. I am deeply appreciative for financial support of this work by the National Science Foundation, the American Heart Assocation, the John Simon Guggenheim Foundation, the Petroleum Research Fund, administered by the American Chemical Society, the Herman Frasch Foundation, NATO, Société Nationale Elf Aquitaine, McCormick and Company, Wakunaga Pharmaceutical Company, and the State University of New York at Albany. I thank Dr. Larry Lawson for critically reviewing the entire manuscript and C. T. Ho, W. le Noble, O. Sticher, and L. Lawson for unpublished material.

[31] Chemical Abstracts names allicin **1** as 2-propene-1-sulfinothioic acid *S*-2-propenyl ester, **12** as methanesulfinothioic acid *S*-methyl ester, and alliin **2** as L-alanine, 3-(2-propenylsulfinyl)-, (*S*)-. As these names are quite cumbersome to use, we employ here the IUPAC nomenclature. Compounds of the type RS(O)SR′ are named according to Rule C-641 as esters of the thiosulfinic acid RS(O)SH. Accordingly, allicin **1** is named *S*-2-propenyl(or *S*-allyl) 2-propenethiosulfinate. (Since only *S*-esters occur here the *S* will be omitted.) This system of nomenclature is preferable to an alternative system where compounds RS(O)SR are named alk(en)yl alk(en)yl′ thiosulfinate with the first group (R) attached to the sulfinyl sulfur and the second ("primed") group (R′) to the sulfenyl sulfur [121].

[37] a) Alkylcysteine *S*-oxides have been found in other plants [37b] including cabbage [37c], turnip [37d], and *Phaseolus* [37e]; allinase is not always present [42]. Allicin is produced on cutting the Amazonian garlic bush (*Adenocalymma alliaceum*) [37f]. In nature the –SS(O)– and –SSCH=CH– linkages are uncommon. Examples of the former are all cyclic [37g]; examples of the latter include the powerfull antitumor agents esperamycin [37h] and calicheamicin [37i], and compounds from the plants *Agathosma apiculata* [37j], *Azadirachta indica* [37k], and *Ferula assa-foetida* [37l]; b) R. [119] a) Lawson finds that **1** from garlic homogenized in water decomposes to the extent of 9% after 24 h at room temperature affording **4c** and **4b** in a 2:1 molar ratio [119b]. He also finds that the half-life of **1** at room temperature is 10 days in 1 mM citric acid (pH 3), 4 days in water, 48 h in MeOH or $CHCl_3$, 3 h in ether, 2 h in hexane and 16 h in the absence of solvent [119b]. On the other hand, Brodnitz reports that *neat* **1** decomposes nearly completely in 20 h at 20 °C giving **4c** and **4b** in a 0.14:1 molar ratio [35a]; b) L. D. Lawson in *Human Medicinal Agents from Plants* (Eds: A. D. Kinghorn and M. Balandarin), American Chemical Society, Washington, D. C., in press; c) E. J. Corey, T. A. Engler, *Tetrahedron Lett.* **1984**, *25*, 149–152; d) recent work indicates that as much as 10% of **79** may in fact be formed from decomposition of **1** (L. D. Lawson, personal communication).

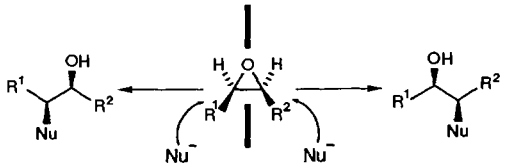
meso Epoxides in Asymmetric Synthesis: Enantioselective Opening by Nucleophiles in the Presence of Chiral Lewis Acids

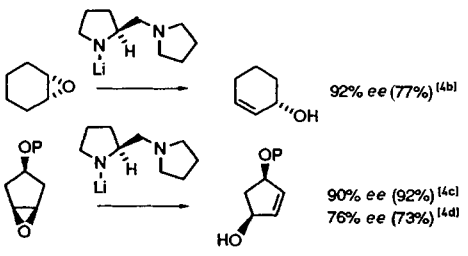
By *Ian Paterson** and *David J. Berrisford*

It is over a decade since the seminal discovery[1] of the asymmetric epoxidation of allylic alcohols catalyzed by titanium(IV) isopropoxide and tartrate esters. The utility of this transformation is a result of many factors, not least of which is the regio- and stereocontrol possible in the subsequent nucleophilic substitution (opening) reactions of the derived epoxy alcohols. Thus a reaction sequence of asymmetric epoxidation, epoxide opening, and further functionalization allows access to an impressive array of target molecules in enantiomerically pure form. In contrast to the asymmetric epoxidation, the enantioselective epoxidation of nonfunctionalized alkenes[2] is only just emerging as a viable synthetic method. At present, the substrates are limited to certain *cis* alkenes. A less common strategy, but one with considerable merit, is the enantioselective opening[3] of *meso* epoxides by achiral nucleophiles in the presence of chiral Lewis acids (Scheme 1 for $R^1 = R^2$). The metal center of the Lewis acid



Scheme 1. Enantioselective opening of *meso* epoxides ($R^1 = R^2$).

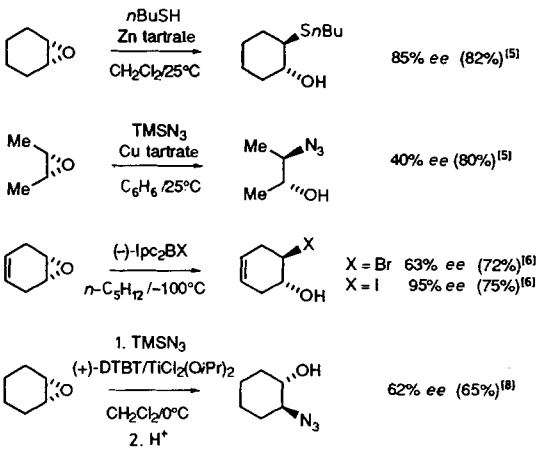
catalyst or reagent should be able to complex the epoxide oxygen atom, and the ligand environment should allow the discrimination of the formally enantiotopic carbon–oxygen bonds of the epoxide by an appropriate achiral nucleophile. Such a process leads to an enantioselective epoxide-opening reaction. The discrimination of enantiotopic groups[3] remains relatively rare in nonenzymic asymmetric reactions. Scheme 2 shows some examples[4] of the discrimination attainable *without* a nucleophile—using chiral lithium amide bases in the rearrangements of *meso* epoxides to allylic alcohols.



Scheme 2. P = Si*t*BuMe$_2$.

[*] Dr. I. Paterson, Dr. D. J. Berrisford
University Chemical Laboratory
Lensfield Road, GB-Cambridge CB2 1EW (UK)

Enantioselective opening of *meso* epoxides by heteroatom nucleophiles has been investigated previously. Some examples are shown in Scheme 3. Zinc tartrate (10 mol%) promotes the opening of simple epoxides with *n*-butyl thiol and aniline with good enantioselectivity.[5] Copper tartrate is more efficient than zinc tartrate in promoting the reaction of trimethylsilyl azide with epoxides.[5] Diisopinocampheylboron halides also display[6] promising asymmetric induction in their reactions with epoxides to give β-halohydrins. The reagents, derived from either (+) or (−)-α-pinene, are used in stoichiometric quantities at very low temperatures. In certain cases, recrystallization leads to enantiomerially pure product. The combination of various ligands with titanium alkoxides has been explored[7, 8] with trimethylsilyl azide for epoxide opening. A recent refinement[8] is the combination of $TiCl_2(OiPr)_2$ with the sterically demanding di-*tert*-butyl tartrate. In the presence of trimethylsilyl azide and 10 mol% of the titanium catalyst, cyclohexene oxide gives the corresponding β-azido cyclohexanol with 62% *ee*.

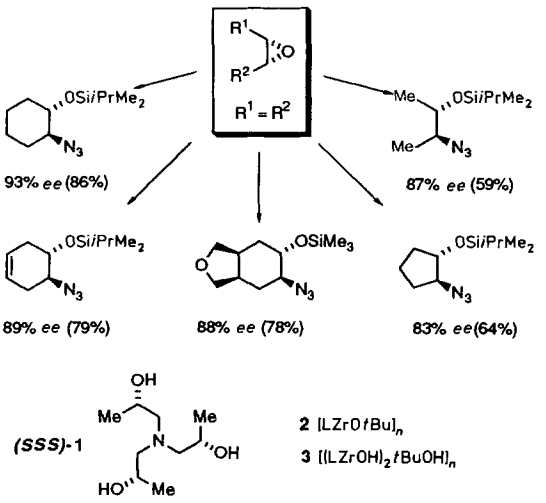


Scheme 3. TMS = trimethylsilyl; Ipc = isopinocamphenyl; DTBT = di-*tert*-butyltartrate.

The methodology described[9] recently by W. A. Nugent at DuPont is a major advance in this area (Scheme 4). A novel chiral zirconium Lewis acid promotes the reaction of trialkylsilyl azide with a range of *meso* epoxides to give the corresponding β-azido alcohols in excellent enantiomeric excess. The catalyst is derived from zirconium *tert*-butoxide and the tetradentate C_3-symmetric ligand **1**. This ligand is readily available from commercial (albeit expensive) starting materials—(*S*)-propene oxide and (*S*)-1-aminopropan-2-ol—with a high diastereomeric excess. Other epoxide/aminoalcohol combinations may also be useful for the preparation of other ligands with C_3 symmetry. In this way the reaction can be optimized for each substrate. Furthermore, **1** is one of the few C_3-symmetric ligands[10, 11] that

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0909-1179 $ 3.50+.25/0

have been designed, synthesized, and successfully employed in asymmetric catalysis. Other reactions[9] may be amenable to catalysis by metal complexes with these or related chiral ligands. The reaction of **1** with $Zr(OtBu)_4$ at room temperature affords complex **2** with the loss of three equivalents of *tert*-butanol. Controlled addition of water to **2** in THF affords complex **3** which may be isolated. The analyses show that this complex contains 0.5 equivalents of *tert*-butanol per equivalent of zirconium. The spectroscopic properties of **3** are complex, and the precise mechanistic details of the catalysis will therefore be difficult to determine. The relative rates of the reactions mediated by the precursor zirconium alkoxide and the new chiral complexes such as **3** have not been reported. It will be interesting to note the rate differences between the titanium and zirconium complexes with identical ligands and to investigate the effect of the ligand structure on the rate as well as the enantioselectivity.



Scheme 4. Synthetic applications of zirconium complex **3**. All reactions were performed in CH_2Cl_2 at 0 °C or room temperature (48 h) with 1.04 equivalents of trialkylsilyl azide/2 mol% $CF_3CO_2SiMe_3$/8 mol% **3**.

The reaction is carried out by combining **3** (8 mol%), trimethylsilyl trifluoroacetate (2 mol%), and a trialkylsilyl azide with the epoxide substrate. The *ee* values of the β-azido alcohols produced are dependent on the bulk of the nucleophilic azide with isopropyldimethylsilyl azide being superior to trimethylsilyl azide. The trimethylsilyl trifluoroacetate is essential for the enantioselectivity. The reaction is simple to carry out, proceeds at either room temperature or 0 °C, and affords excellent yields. Thus the method offers an expeditious route to *threo* amino alcohols. One limitation is the lack of reactivity with highly hindered epoxides such as cyclooctene oxide. New developments are anticipated with the use of other nucleophiles, for example, trimethylsilyl cyanide.

The work of W. A. Nugent addresses one of the major classes of epoxides—symmetrically substituted *cis* epoxides. However, kinetic resolution[12] of racemic *trans* epoxides may also be possible. One of the challenges stemming from the discovery of the asymmetric catalytic epoxidation of nonfunctionalized alkenes is the problem of regiocontrol in the opening of unsymmetrically substituted epoxides. Here too, the opening of epoxides mediated by chiral Lewis acids may be useful in discriminating between the "pseudoenantiotopic" (actually diastereotopic) carbon–oxygen bonds (Scheme 1 for $R^1 \neq R^2$) when there is little, if any, substrate control during epoxide opening.

The Nugent reaction, just as the Sharpless asymmetric epoxidation,[1] utilizes an early transition metal alkoxide as the catalyst precursor. This is further proof, if any is required, of the rewards of searching for new reactivity in this area of the periodic table.

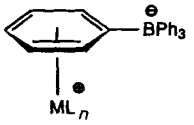
"Non-Coordinating" Anions: Underestimated Ligands

By *Manfred Bochmann**

The mention of "non-coordinating anions" usually brings to mind complex anions such as BF_4^-, PF_6^- or ClO_4^-, and it is certainly true that in the presence of only relatively weak donor ligands these anions show no noticeable interactions with metal centers. On the other hand, Fischer et al. and Beck et al. pointed out several years ago[1, 2] that coordinatively unsaturated complexes, for example $[CpMo(CO)_3]^+$, coordinate anions such as BF_4^- through fluoride bridges, and it is therefore not surprising that with strongly electrophilic cationic complexes such as $[Cp_2M(CH_3)]^+$ (M = Ti, Zr) fluoride abstraction is a facile process.[3] Even the recently reported very weakly basic anion $[B(OTeF_5)_4]^-$ is still capable of coordinating to metals through O and F bridges and of transferring F_5TeO groups as has been demonstrated, for example, in the synthesis of $Ag[B(OTeF_5)_4]$.[4]

In cases where BF_4^- or PF_6^- prove too reactive, BPh_4^- is often used to advantage because of its well-known stability and low basicity. It is sometimes overlooked, however, that BPh_4^- as a π ligand has been known for a long time, and that it is able to form η^6-arene complexes such as **1** with electron-rich metal centers (Scheme 1). The first complex of this kind

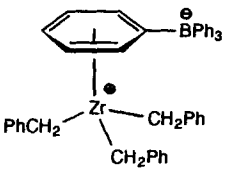


1

Scheme 1. ML_n = CrCp* [5], $Mo(C_7H_7)$ [6], $Mo(CO)_3^-$ [6], CoL_2 (L = pyridine, PMe_3) [7], $Rh[P(OMe)_3]_2$ [8], MCp (M = Fe, Ru) [9a].

$[\{(MeO)_3P\}_2Rh(\eta^6\text{-}C_6H_5BPh_3)]$, was crystallographically characterized as long ago as 1969,[8] and analogous compounds have been described for a number of different transition metals. The complexes are fairly unreactive, and the coordinated phenyl ring is relatively inert towards substitution by other ligands. It appears that in these compounds the coordination of BPh_4^- is stabilized not only by π back-donation but also by electrostatic cation–anion interactions. BPh_4^- is also capable of coordination to two and three metal centers, as was recently shown[9b] for $[\{(C_2H_4)_2Rh\}_2(\eta^6\text{-}Ph_2BPh_2)]^+CF_3SO_3^-$ and $[\{(C_2H_4)_2Rh\}_3(\eta^6\text{-}Ph_3BPh)]^{2+}\text{-}(CF_3SO_3^-)_2$.

Cation–anion interactions have attracted special attention recently, particularly in the case of electron-deficient early transition metal compounds with d^0 electron configurations, since it is now accepted that cationic alkyl complexes of group IV metals represent the catalytically active species in olefin polymerizations with homogeneous Ziegler–Natta catalysts. The coordination of a phenyl ring of BPh_4^- to a d^0 metal center, i.e. without stabilization by back-bonding, was first demonstrated for the zirconium complex **2** using variable-temperature NMR spectroscopy.[10]

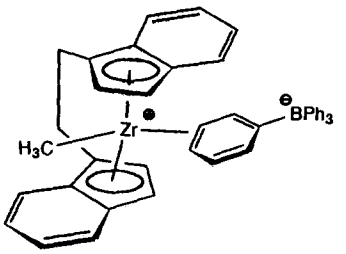


2

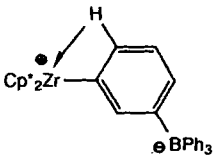
In contrast to complexes of type **1** the coordination of the phenyl ring is temperature dependent, and the molecule is fluxional. In spite of this, the BPh_4^- ligand cannot be displaced by electron-rich neutral arenes, an indication for the importance of electrostatic interactions with complexes of this kind.

Horton et al. were able to show that in cationic zirconocene derivatives **3** one of the phenyl groups of BPh_4^- may be coordinated in η^2- or η^3-fashion.[11] Here, too, the anion is fluxional on the NMR time scale, and it is not clear whether the anion interacts with the metal through the π electron system or through some of the hydrogen atoms of the phenyl ring.

For catalytic applications such interactions are highly undesirable. Phenyl coordination as in **2** or **3** may be regarded as the first step towards catalyst deactivation by phenyl group transfer, but metalation of the phenyl ring can also subsequently occur, as in **4**.[12] More stable catalysts with



3



4

significantly higher catalytic activities are obtained if the tendency of the anion towards coordination is reduced, for example by introducing fluoro substituents on the ring. Thus, in the zwitterionic complex **5** recently prepared by Marks et al. metal–aryl interactions are absent, and the anion is bonded through a methyl bridge.[13] On the other Hand, Horton et al. has shown in the case of complex **6** that even the basicity of a C–F bond may be sufficient in certain circumstances to give isolable adducts.[14] As far as is known, only the extremely weakly basic perfluorinated anion $B(C_6F_5)_4^-$ is inert enough for cation–anion interactions

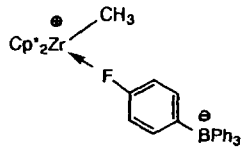
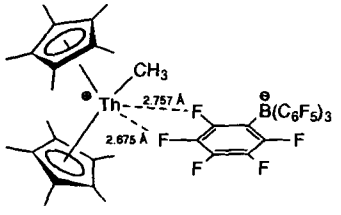
5



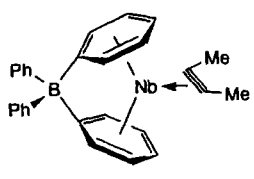
6

to be essentially absent. For example, the crystal structure of 7 shows thorium–fluorine distances which are significantly longer than the sum of the ionic radii.[15] In agreement with this assumption such cationic alkyl complexes with $B(C_6F_5)_4^-$ as the counter ion are highly active polymerization catalysts.

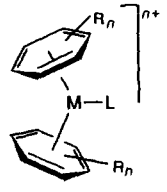


7

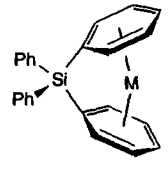
Pampaloni et al. have now been able to extend the spectrum of coordination modes of tetraarylborates further by synthesizing $[\{Ph_2B(\eta^6\text{-}C_6H_5)_2\}Nb(C_2Me_2)]$ **8**, the first example of a complex which contains BPh_4^- as a chelating ligand, with two of the phenyl groups η^6-bonded to the metal (Scheme 2).[16] The compound is prepared by thermolysis of $[Nb(C_6H_3Me_3)_2(C_2Me_2)]BPh_4$ in toluene. Judging from the



8



9



10

Scheme 2. **9**: $n = 0$, M = Zr, Hf, L = PMe_3 [17]; $n = 1$, M = Nb, L = Co [18], M = Nb, L = PEt_3 [19], M = W, L = H [17].

length of the C≡C bond the coordinated butyne acts as an η^2-ligand, and the metal has to be regarded as Nb(I) (d^4). As is the case with complexes of type **1** the phenyl ring coordination in **8** is stabilized by back-bonding; the complex is nonfluxional, and the BPh_4^--ligand cannot be replaced by neutral arenes. Structurally, **8** is related to a series of well-known non-bridged bis(arene) complexes **9**. *Ansa*-arene complexes such as **8** or the silyl-bridged complexes **10** (M = V, Cr) synthesized by Elschenbroich et al.[20] are comparatively rare. The surprising synthesis of **8** demonstrates a coordination mode for tetraarylborates which has apparently not been considered until now and should serve as a precedent for the synthesis of further complexes of this type.

Enantioselective Rhodium(II) Catalysts

By *Henri Brunner**

In the complexes $[M_2(OAc)_4]$ (OAc = CH_3COO) two metal(II) cations are bridged by four acetate anions (Fig. 1). In this highly symmetrical framework four oxygen atoms occupy the corners of two ecliptically arranged squares.[1] The valencies of the two octahedrally coordinated metal atoms perpendicular to these squares are oriented to the inside and to the outside of the $M_2(OAc)_4$ unit. The metal–metal interaction within the $M_2(OAc)_4$ unit depends critically on the electron configuration of the metal atoms.[1] It ranges from a quadruple bond in $[Cr_2(OAc)_4]$ (Cr^{2+} is a d^4 system) to a weak interaction in $[Cu_2(OAc)_4]$ (Cu^{2+} is a d^9 system). Further ligands can be bound, but also catalyses can be carried out at the valencies of the $M_2(OAc)_4$ unit which point outwards.

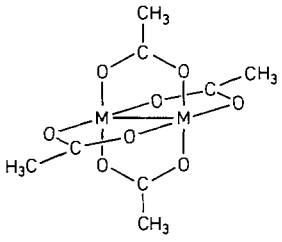

Fig. 1. The structural unit $M_2(OAc)_4$.

$[Rh_2(OAc)_4]$ is a green, air-stable compound, which is soluble in organic solvents with the retention of its dinuclear structure. It is prepared from $RhCl_3$ and HOAc/NaOAc in boiling ethanol.[2] Other carboxylate ions can also be incorporated in place of acetate ions. Anions of fluorinated carboxylic acids afford particularly stable compounds such as $[Rh_2(OOCCF_3)_4]$. $[Rh_2(OAc)_4]$ and its derivatives have for a long time proven valuable as catalysts for carben(oid) reactions, for example, the formation of cyclopropanes from olefins and diazo compounds or the formation of five-membered rings in intramolecular C–H insertions.[3–6] They are also considered to show anti-tumor activity.[1] Recently these dimeric rhodium(II) compounds have created a furore in enantioselective catalysis.

The dimeric rhodium(II) compounds become enantioselective catalysts if they contain optically active ligands. For this the anions of optically active carboxylic acids seemed to be the most appropriate. The complex in which the Rh_2 unit is clamped by four mandelate anions was synthesized and structurally characterized some time ago.[7] As a catalyst, however, this complex results in only small enantiomeric excesses.[8] The reason for this is probably that the asymmetrical centers lie in a plane between the two Rh atoms and are thus too far away from the coordination sites directed to the outside, at which the catalysis occurs. Chiral substituents at the nitrogen atoms of carboxamide anions would be considerably closer to these reaction centers, and indeed on this basis a breakthrough has been achieved recently, which in particular, is linked to the $[Rh_2(5S\text{-mepy})_4]$ complex (Fig. 2). The name of the optically active ligand has, as usual, been abbreviated, and in this case mepy[*] stands for the methyl ester of the pyrrolidone-5-carboxylic acid, which is deprotonated at the nitrogen atom. In the following the complex $[Rh_2(5S\text{-mepy})_4]$ and its "capacity" for enantioselective catalysis are introduced before finally discussing why complexes of the type $[Rh_2(5S\text{-mepy})_4]$ are so successful.

The introduction of carboxamides instead of carboxylates as bridging ligands is achieved by an exchange reaction between $[Rh_2(OAc)_4]$ and the appropriate amides. In this way $[Rh_2(5S\text{-mepy})_4]$ is prepared from methyl (−)-(*S*)-pyrrolidone-5-carboxylate. Similarly, $[Rh_2(5R\text{-mepy})_4]$ is accessible from methyl (+)-(*R*)-pyrrolidone-5-carboxylate so that the catalysts are available in both configurations (5*S* and 5*R*). In $[Rh_2(5S\text{-mepy})_4]$ each rhodium atom is in a square-planar environment in which two O atoms and two N atoms are arranged *cis* to each other (Fig. 2).

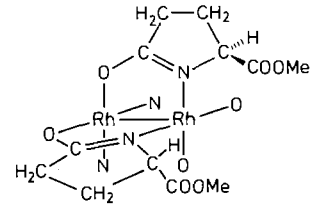

Fig. 2. $[Rh_2(5S\text{-mepy})_4]$. The two amide ligands which are directed downwards and to the rear are incompletely drawn to provide a better overview.

$[Rh_2(5S\text{-mepy})_4]$ was first used for cyclopropanation. Enantioselective cyclopropanation is industrially important since synthetic pyrethroids, which are used as insecticides, contain substituted three-membered rings, whose configuration is crucial for their biological effect.[9] Enantioselective cyclopropanation has tradition. It was this reaction type which in 1966 opened up the field of enantioselective homogeneous catalysis with transition metal complexes. The copper(II) complex of the Schiff base from salicylaldehyde and optically active 1-phenylethylamine at that time reached 6% *ee*.[10] With optimized optically active amines in the salicylaldimine ligands the industrial group headed by Aratani set early records in the 1970s.[11] New aspects were forthcoming with the introduction of the cobalt(II) semicorrin complexes by Pfaltz et al. 1986,[12, 14] and more recently with the bisoxazoline ligands from Masamune et al.[13a, 14] and Evans et al.[13b, 14]

The reaction of styrene with (1*S*,3*S*,4*R*)-menthyl diazoacetate [Eq.(a)] leads to the incorporation of two new stereocenters into the cyclopropane ring. The *cis* and *trans* isomers are formed each consisting of an enantiomeric pair. With the

[*] Prof. Dr. H. Brunner

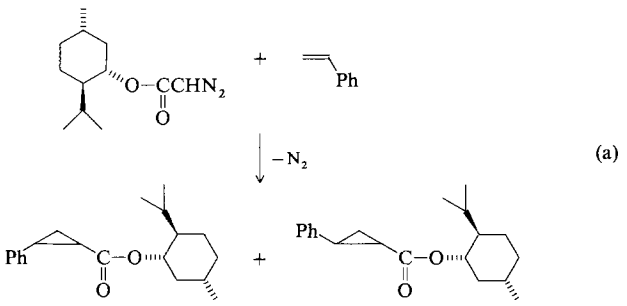
Universitätsstrasse 31, D-W-8400 Regensburg (FRG)

[*] The acronym mepy has usually been written in capital letters. However, according to the IUPAC rules for nomenclature abbreviations for ligands should be written with small letters.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0909-1183 $ 3.50+.25/0

$[Rh_2(5S\text{-mepy})_4]$ catalyst 86 % *ee* is achieved in the *cis* series and 48 % *ee* in the *trans* series.[15]

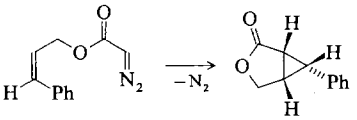


(a)

In the catalysis shown in Equation (a) a double stereoselection is involved. The formation of the new asymmetrical centers in the cyclopropane ring is influenced by the menthyl group contained in the substrate (1*S*,3*S*,4*R*)-menthyl diazoacetate and by the mepy ligand contained in the catalyst. The two influences are referred to as substrate and catalyst control, respectively. With regard to the efficiency it has to be noted that whereas substrate control requires a stoichiometric amount of the reagent, catalyst control requires a substoichiometric amount of the catalyst. For example, in the case of $[Rh_2(5S\text{-mepy})_4]$ a catalyst concentration of 1 mol% is sufficient with respect to the substrates.

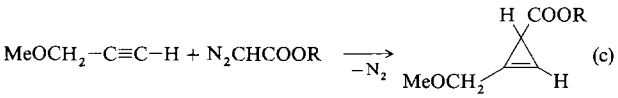
The reaction in Equation (a) is controlled mainly by the catalyst; substrate control by the menthyl group plays only a minor role. This is evident from the fact that with the achiral $[Rh_2(OAc)_4]$ catalyst only 9 % *ee* can be achieved for the *cis* product and 13 % *ee* for the *trans* product. Catalysis with $[Rh_2(5S\text{-mepy})_4]$ was extended from styrene to other prochiral olefins for which similar results were obtained.[15]

$[Rh_2(5S\text{-mepy})_4]$ is particularly useful for intramolecular cyclopropanation; in several examples up to 94% *ee* was obtained.[16] Highly substituted cyclopropanes are accessible by this reaction; an example is given Equation (b). With the two enantiomeric catalysts both enantiomeric products can be obtained from the same allyl diazoacetate. For this intramolecular variant the (*Z*) configuration of the olefin proves superior to the (*E*) configuration.



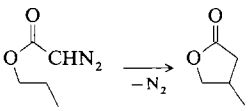
(b)

As mentioned previously, enantioselective cyclopropanation has been known for a long time and there are other efficient catalysts for this reaction apart from dimeric rhodium(II) complexes. This is different to the cyclopropenation of alkynes with diazo compounds. Copper catalysts do not only result in lower enantiomeric excesses but also poor yields, since the high temperatures required for the reaction favor side and consecutive reactions such as the ring opening of the primary products. The improvements brought about by the use of $[Rh_2(5S\text{-mepy})_4]$ (with regard to yield and enantioselectivity) are shown for the cyclopropenation of propargyl methyl ether with a series of diazo esters in Equation (c). For the ethyl ester (R = Et) the enantiomeric excess is 69%, for the *tert*-butyl ester (R = *t*Bu) 78%, and for the (+)-menthyl ester (R = 1*S*,3*S*,4*R*-menthyl) 98%. The yields of the reactions range between 43 and 73%.[17]



(c)

Metal-catalyzed enantioselective C–H insertions of carbenes have so far not been studied in great detail. Copper catalysts are of no use for this type of reaction, rhodium(II) catalysts, however, allow intramolecular C–H insertions, for example, in the alkyl group of diazoacetates with longer chains. The formation of five-membered rings such as γ-lactones is favored. $[Rh_2(5S\text{-mepy})_4]$ affords 3-methyl-γ-butyrolactone (see [Eq. (d)]) in 91 % *ee* and is thus unprecedented for such reactions.[18]



(d)

In order to explain the success of $[Rh_2(5S\text{-mepy})_4]$ a general and a specific argument shall be put forward. Generally for enantioselective catalysts, a reduction of the conformative variety has a favorable effect on the enantioselectivity. In $[Rh_2(5S\text{-mepy})_4]$ at each of the two planes of the Rh_2 unit which point outwards, a chiral framework is built whose rigidity is mainly the result of the incorporation of the amide part into the five-membered ring. In the case of $[Rh_2(5S\text{-mepy})_4]$ special electronic and steric effects are also involved. Model considerations as well as reactivity and selectivity studies show that during the cleavage of nitrogen from the diazo compound a carbene-rhodium complex is formed, whose empty p orbital at the carbene carbon atom can be stabilized by interaction with a polar substituent.[6] Therefore, as shown in Figure 3, the two *cis* ester groups in

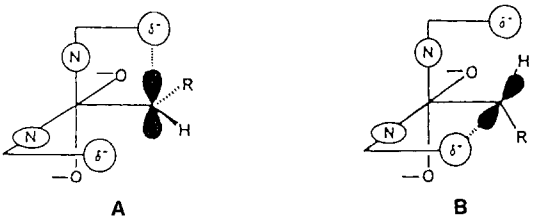


Fig. 3 Carbene ligand at $[Rh_2(5S\text{-mepy})_4]$ stabilized by the polar COOMe substituents.

$[Rh_2(5S\text{-mepy})_4]$ fix the carbene ligand in the positions **A** and **B**, in which the large substituent R of the carbene adopts the less hindered position. The attack of the nucleophile at the conformations **A** and **B** occurs from the rear. The observed stereochemistry of the products can be understood

when the preferred orientation of the reaction partners with their C=C, C≡C, and C–H bonds in the inter- or intramolecular reactions are taken into consideration.

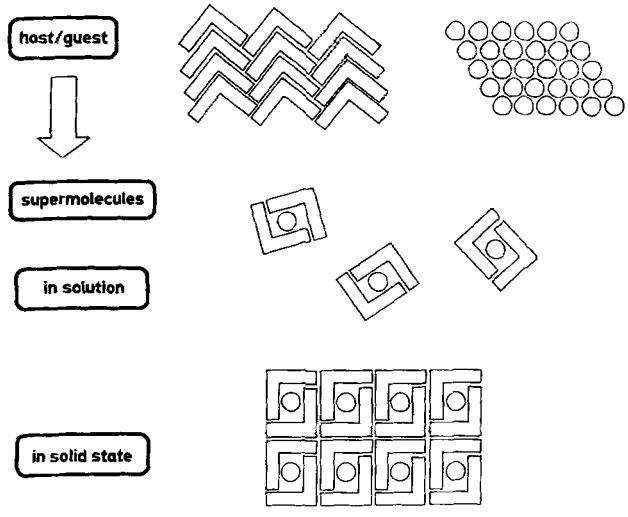
New Impetus for Inorganic Host-Guest Chemistry

By *Hans Reuter**

Exactly 25 years ago the probably coincidental dislodging of a small stone—the synthesis of the first crown ether and the discovery of its coordinating properties[1]—started an avalanche—supramolecular organic chemistry. The rapid development of this field, which reached an all-time high in 1987 with the award of the Nobel Prize in Chemistry to C. J. Pedersen, J.-M. Lehn, and J. Cram, rests on the fact that through it abiotic counterparts to biological processes, for example enzyme catalysis, can be studied. It is therefore not surprising that here a very close interaction between organic chemistry and biochemistry exists and that receptor–substrate interactions are fundamental in supramolecular chemistry.[2]

Under the term supramolecular compounds, as portrayed graphically in Scheme 1, is meant aggregates of two or more different building blocks, stable in solution as well as in the solid state, in which the parts themselves are already compounds with defined physical and chemical properties. Characteristic of this type of host–guest relationship is, first, that the bonding interactions (hydrogen bonds, van der Waals forces) between the partners are so weak that the supermolecule can also dissociate reversibly into its starting compounds again under specific conditions, and second, that the host has a structure that enables it to enclose the guest selectively and securely.

On this point inorganic chemistry need not be modest, since after all, it has dealt with host–guest compounds for more than 150 years. Already in 1826 J. Berzelius[3] described the transformation of ammonium molybdate (**1**) with phosphoric acid (**2**), formulated in Equation (a), in which he obtained a yellow precipitate. Today we know that it must have been the compound **3**, the ammonium salt of 12-molybdatophosphoric acid. The anion of **3** consists of a



Scheme 1.

shell of twelve $\{MoO_6\}$ octahedrons linked together according to the principle of the α-Keggin structural type, leaving a hole in the middle that accommodates a single phosphorus atom.

$$\underset{\mathbf{1}}{12(NH_4)_2MoO_4} + \underset{\mathbf{2}}{H_3PO_4} \longrightarrow \underset{\mathbf{3}}{(NH_4)_3[(PO_4)Mo_{12}O_{36}]} + 21\,NH_3 + 12\,H_2O \quad \text{(a)}$$

A significant difference between such a compound and the typical supramolecular compounds of organic chemistry, however, lies in the special position of the oxygen atoms of the phosphate group of this heteropolyanion, which are simultaneously components of the host compound. Thus according to the narrow definition of organic chemistry, **3** is strictly speaking not a supramolecular compound. In this case one prefers to call it a molecular material.[4]

[*] Dr. Hans Reuter
Institut für Anorganische Chemie der Universität
Gerhard-Domagk-Strasse 1, D-W-5300 Bonn (FRG)

This rigid distinction is, however, only of secondary importance for the compound class of the heteropolyacids described here,[5] especially since depending on the pH of the solution, the compounds also dissociate again into the starting compounds. The dissociation shows very clearly the influence of the solvent on the formation of such compounds, since—in the sense of the above-mentioned definition—the solvent itself enters more or less strongly into a supramolecular interaction with the two starting materials and thereby influences their reactivity and availability decisively.

Furthermore, this example depicts very clearly another aspect of inorganic host–guest chemistry. The structure of the heteropolyanion can only be explained if the host is built up around the guest in the condensation reaction in solution, a phenomenon known as the *template effect*.

If in a limiting case the interactions between the units in a host–guest complex are extremely weak, the supercomplex may be stable in the crystalline state but dissociate to its individual components in solution, because these enter into significantly stronger interactions with the solvent. Such host–guest complexes existing only in the solid state are termed inclusion compounds or clathrates. A known example from inorganic chemistry is the chlorohydrate $Cl_2 \cdot 7.27\,H_2O$, described in many textbooks.[6]

Although the field of inclusion compounds today is mainly the domain of organic chemistry, there have recently been interesting developments in inorganic chemistry. By far the most remarkable discovery was certainly the compound $CsF \cdot Br_2$,[7] in which the Br_2 dumbbells are only marginally extended and embedded in a tetragonally distorted CsF arrangement of the NaCl structural type.

Another example of recent developments in inorganic clathrates is the compound $Cd(CN)_2 \cdot$ neopentane (**4**).[8] In contrast to the layered structure of $Ni(CN)_2NH_3 \cdot$ benzene,[9] the very first structurally elucidated inclusion compound, the host lattice of $[Cd(CN)_2]$ in **4** is based on a spatial network structure (Fig. 1) in which structural elements such as those in SiO_2 and H_2O modifications are present. Cadmium

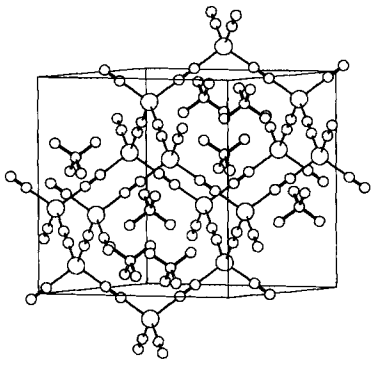


Fig. 1. Section of the crystal structure of $Cd(CN)_2 \cdot$ neopentane (from [8]).

is tetrahedrally surrounded by four cyanide groups, which in turn bridge two metal atoms, building cavities in which stoichiometric amounts of neopentane molecules are enclosed in an ordered fashion. In this compound the relationship between host and guest is thus inverted: the organic molecule no longer constitutes the host; instead the inorganic compound does.

The structural analogy of the two clathrate types introduced here to other AB and AB_2 compounds allows the imagination free rein and now, since this conceptual hurdle has been crossed, the discovery of many original examples of such inorganic host–guest compounds can be predicted.

In contrast to these clathrates, "true" supramolecular inorganic compounds remained unknown for a long time. However, many years ago evidence was found that the large isopolyvanadates can possibly enclose water molecules in the interior of the vanadium–oxygen cage. Nevertheless, it came as a great surprise when Day et al. first showed that these compounds also incorporate organic solvent molecules. In the compound $(Ph_4P)_4[(CH_3CN) \subset V_{12}O_{32}] \cdot 3\,CH_3CN \cdot 4\,H_2O$ (**5**) prepared and studied by X-ray diffraction, the water molecules and three of the four acetonitrile molecules are built into the spaces in the crystal lattice, while the other, as shown in Figure 2, is almost completely immersed (its methyl group projects) in the interior of the $[V_{12}O_{32}]^{4-}$ ion, which is shaped like a basket. Although the distances between the atoms of the guest and the host are very large, and the interactions between them therefore only relatively weak, this "open" aggregate is retained in solution, as proven by NMR spectroscopy.[11]

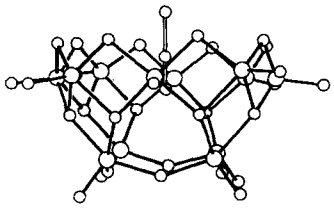

Fig. 2. Crystal structure of the $[V_{12}O_{32}]^{4-}$ ion, showing the incorporated acetonitrile molecule (from [11]).

The astonishment was even greater when a short time later A. Müller et al. proved for the first time with complexes of the type $(NMe_4)_6[(X) \subset V_{15}O_{36}]$ (**6**) that simple ($X = Cl^-$, Br^-) and complex anions ($X = CO_3^{2-}$) can also be incorporated into such polyvanadates.[12] But not only the inclusion of an *anion in an anion* is surprising; the *widely divergent sizes* of the included anions is exceptional. As can be seen from Figure 3, all vanadium atoms of the $[V_{15}O_{36}]^{5-}$ ion of **6** are pentacoordinate; the oxygen atoms are arranged in a square

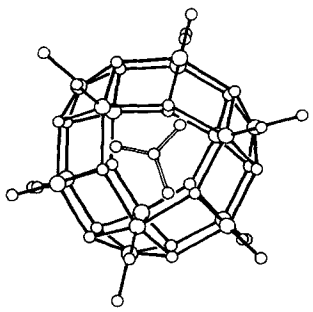

Fig. 3. Crystal structure of the $[V_{15}O_{36}]^{5-}$ ion, showing the included carbonate ion (from [12]).

pyramid around them with the apexes directed outwards. For the first time this basal linkage of the 15 individual polyhedrons leads to a closed structure with a cavity of such dimensions that different sized components can be accommodated.

That in all the previous cases the structure and charge of the guest determined the geometry of the cavity and thereby the constitution of the isopolyvanadate was demonstrated by the same research group only a little later with the complexes $(NEt_4)_6[(ClO_4) \subset V_{22}O_{53}(OH)]$ (**7**) and $(NEt_4)_5[(N_3) \subset V_{18}O_{42}(OH)_2]$ (**8**). In **7** a tetrahedral perchlorate ion guest is present in a $[V_{22}O_{53}(OH)]^{5-}$ host and in **8** a linear azide ion guest in a $[V_{18}O_{42}(OH)_2]^{4-}$ host, which indicates that the formation of the isopolyvanadate shells is controlled by the molecular recognition of the template. Also remarkable is that the two hosts are structurally directly related and that as in the previous cases mixed-valent V^{IV}–V^{V} complexes are involved.[13]

That is not yet the end. In this issue A. Müller et al. describe the compound $(Me_2NH_2)_5(NH_4)[(NH_4Cl)_2 \subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8] \cdot 5H_2O \cdot 4DMF$ (**9**) in which for the first time two anions are simultaneously incorporated in a large cavity divided into two by two coordinatively bound water molecules. The shell of this cage, as depicted in Figure 4, is formed from two half shells in which isopolyvanadate building blocks are linked internally and to one another by phenylphosphonate groups. Furthermore, the

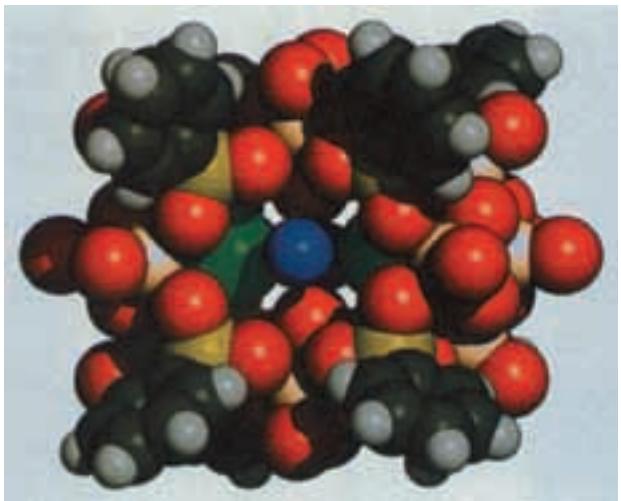

Fig. 4. Crystal structure of the $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ ion, showing the incorporated chloride and ammonium ions (from [14]). Color code: V light brown; O red; P yellow; C black; H white; Cl green; NH_4 blue.

cage is formed and polarized by the combination of apolar organic residues (phenyl groups) and polar inorganic ligands (terminal oxygen atoms) in such a way that two niches are created, in which two ammonium ions can be incorporated as in a coronand. The anions (Cl^-) and cations (NH_4^+) are not only approximately as far apart as in the ionic crystal, but also in a square planar environment as there.[14]

It seems to be only a question of time and the dexterity of the preparative chemists until not only single ions, ion pairs, or as in the case of **9**, two-dimensional fragments of ionic crystals will be built into supramolecular inorganic compounds, but also three-dimensional fragments. The inclusion and thus the directed synthesis of nanocrystals would be a good deal closer.

Naturally the hetero- and isopolyacids are in the forefront of the research activities in the search for such supramolecular inorganic compounds, because decades of practical experience is available. But one must not forget that supramolecular effects can also occur in other sectors of inorganic chemistry. Recently we found the first example for the inclusion of ions in organometallic compounds by use of the template effect.[15] In the compound $[(Na) \subset (i\mathrm{PrSn})_{12}O_4(OH)_{24}][Ag_7I_{11}]Cl \cdot 10\,DMSO \cdot H_2O$ (**10**), each atom of the tin–organic cation is surrounded by a distorted octahedron of five oxygen atoms and one isopropyl group. The individual octahedrons are linked to each other as in the γ-Keggin structural type. This produces a cavity in the center that is the right size to take up a sodium ion, which is then coordinated tetrahedrally to four μ_3-O atoms.

The construction and type of octahedron linkage in the cation of **10** might still strongly resemble a heteropolycation surrounded by organic residues, but the supramolecular unit of the compound $(NH_4)_3[(Na) \subset Au_{12}Se_8]$ (**11**), described only recently by S.-P. Huang and M. G. Kanatzidis, bears no trace of similarity to such a structure.[16] In the crystal lattice, besides the ammonium ions, the centrosymmetric $[Au_{12}Se_8]^{4-}$ ions exist in the form of an almost regular cube. The selenium atoms occupy the eight corners, and the gold atoms the centers of the twelve edges. Exactly in the middle of this gold selenide, a sodium atom is situated, forming twelve short distances to gold atoms and eight long distances to selenium atoms (Fig. 5).

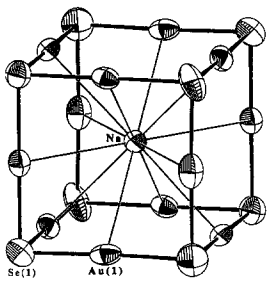

Fig. 5. Crystal structure of the cubic $[Au_{12}Se_8]^{4-}$ ion, showing the included sodium ion (from [16]).

Similarly unusual host–guest relationships are also found in the compound $Ph_4P[\{(\eta^5\text{-}C_5Me_5TiF_3)_4F_2\}Na]$ (**12**), which was recently described by Roesky et al.[17] In **12** two $[(\eta^5\text{-}C_5Me_5TiF_3)_4F_2]^-$ fragments form the nucleophilic host, and its fluoride surface binds the Na^+ ion in a similar way as the oxygen-containing analogues, the crown ethers. The sodium ion is thereby surrounded by eight fluorine atoms.

All these examples show that the inorganic host–guest chemistry is experiencing an upswing. Already the range of isolated observations demonstrates the scope of this field.

[5] On account of the relatively long bonds between the transition metal atoms and the oxygen atoms on the phosphorus atom, an alternative description has also been suggested for this heteropolyanion (C. J. Clark, D. Hall, *Acta Crystallogr. Sect. B* **1976**, *32*, 1545), in which the shell comprises twelve square-pyramidal $\{MoO_5\}$ units linked to each other through their basal oxygen atoms. In this case a further largely isolated phosphate ion is situated in the center of the anion, and a true supramolecular compound is indeed present; for a comprehensive discussion of the bonding, see G. ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. The 30 year review index was compiled to provide easy access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes and costs DM 98.00 or sFr 96.00 (plus shipping costs). This is your last chance to order a copy of the **printed version.** In order to clear out our warehouse we are selling the remaining lot for the reduced price of DM 48.00, £ 19.00, or sFr 41.00 (plus shipping costs). Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28. U.S. customers please contact VCH Publishers, Inc., 303 N.W. 12th Avenue, Deerfield Beach, FL 33442-1788; Telephone 1-(8 00) 422-8824; Telefax (305) 428-8201.**

Communications may be submitted in English *or* in German. Further details regarding the submission of communications can be found in the "Notice to Authors" reproduced in the January issue of the journal. Copies thereof may be obtained from the editorial office upon request.

Selective Oxidation of Methane to CO and H_2 over Ni/MgO at Low Temperatures

By *Vasant R. Choudhary**, *Ajit S. Mamman*, and *Subhash D. Sansare*

The energy-efficient conversion of methane (or natural gas) to CO and H_2 (i.e. to syngas, a versatile feedstock for ammonia, methanol, and Fischer–Tropsch synthesis as well as hydrogenation and carbonylation processes) is of great practical importance in the present energy crisis. Selective oxidation of methane to syngas [Eq. (a)] is only mildly exothermic ($\Delta H = -5.4\,\mathrm{kcal\,mol^{-1}}$) and is hence quite

$$CH_4 + 0.5\,O_2 \longrightarrow CO + 2H_2 \qquad (a)$$

promising. However, in this process the formation of CO and H_2 over that CO_2 and H_2O is favored only at high temperatures.[1, 2] The noncatalytic oxidation of methane to syngas[3, 4] at thermodynamic equilibrium is possible only at very high temperatures (>1300 °C) and is thus not employed. Recently, a few studies on the selective, catalytic oxidation of methane to CO and H_2 over $Ln_2Ru_2O_7$ (Ln = lanthanide),[1] $Eu_2Ir_2O_7$, supported transition metal oxides,[5] and Ni/Al_2O_3[2] at >750 °C with the establishment of thermodynamic equilibrium have been described. However, although these catalytic processes display high conversion and selectivity, they are technically difficult to regulate and more hazardous because of the high temperatures required. Since at low temperatures and equilibrium conditions the CO selectivity in the oxidation process is very low,[2] it is essential to operate the process far from the equilibrium with a catalyst showing high activity/selectivity at lower temperatures (<700 °C) and extremely high space velocities (i.e. very low contact times). We report here our preliminary, highly promising results on the oxidative conversion of methane to syngas at atmospheric pressure with a Ni/MgO catalyst and at much lower temperatures. Our system shows high activity/selectivity and efficiency at extremely high flow velocities.

Our results are summarized in Figure 1. The high catalytic activity of both NiO/MgO (Fig. 1a) and the reduced catalyst, Ni/MgO, (Fig. 1b) in the oxidation of methane to syngas (mol ratio H_2/CO 2:1) is evident at lower temperatures (300–700 °C) with high conversion and much higher CO selectivity than that achieved at equilibrium conditions.[2]

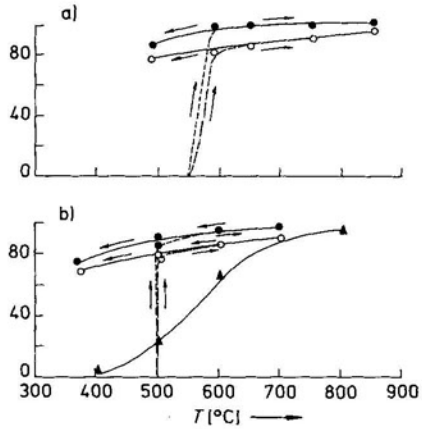

Fig. 1. Effect of temperature on the catalytic activity/selectivity of the catalysts a) NiO/MgO (unreduced) and b) Ni/MgO (reduced). Ni/Mg mol ratio = 3:1, (feedstock: 67 mol% CH_4, 33 mol% O_2, GHSV = $5.2\times10^5\,cm^3g^{-1}h^{-1}$). The ordinates correspond to the conversion of CH_4 (○), the CO selectivity (●), and the CO selectivity under equilibrium conditions (▲) in % [2].

The reaction over NiO/MgO, however, starts at higher temperatures than that over Ni/MgO. The NiO/MgO catalyst was expected to be reduced by the H_2 formed in the reaction at temperatures ≥550 °C. It is interesting to note that not only the unreduced catalyst but also the reduced one showed catalytic activity at temperatures below 500 °C only after they had been used in the reaction at ≥500 °C. This suggests that the active sites responsible for the low-temperature catalytic activity/selectivity may arise from further reduction of the catalyst and/or formation of surface carbon species. The latter was confirmed by O_2 pulse experiments over the used catalysts. Such surface species are probably formed according to Equations (b) and (c). Figure 2 reveals that the cata-

$$2CO \longrightarrow CO_2 + C_{adsorbed} \qquad (b)$$

$$CO + H_2 \longrightarrow H_2O + C_{adsorbed} \qquad (c)$$

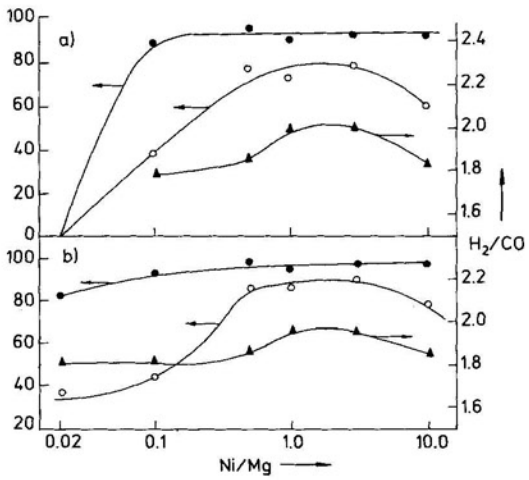

Fig. 2. Effect of the mol ratio Ni/Mg on the catalytic activity/selectivity of Ni/MgO at a) 500 °C and b) 700 °C; (feedstock: 67 mol% CH_4 and 33 mol% O_2, GHSV = $5.2\times10^5\,cm^3g^{-1}h^{-1}$). The ordinates on the left correspond to the conversion of CH_4 (○) and the CO selectivity (●) in %. The ordinates on the right correspond to the mol ratio H_2/CO in the product mixture (▲).

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0909-1189 $ 3.50+.25/0

lyst with an Ni/Mg ratio between 1:1 and 3:1 shows the best performance in this process. This catalyst showed no loss of activity over a period of 20 h.

The influence of gas hourly space velocity (GHSV) of the methane feedstock on the process performance (Fig. 3) can be summarized as following: The conversion passes through a maximum, the CO selectivity increases with increasing GHSV, and H_2/CO ratio decreases with increasing GHSV. The increase in the selectivity of the reaction indicates that it is controlled by kinetics rather than the thermodynamic equilibrium. The production of CO is also much higher (one to three orders of magnitude) than that observed previously.[1, 2, 5]

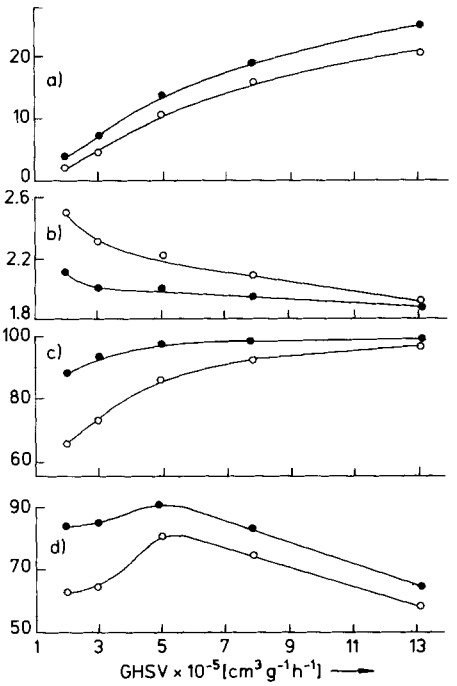

Fig. 3. Influence of the GHSV on catalytic activity/selectivity of Ni/MgO (Ni/Mg ratio ≈ 3:1) at 500 °C (○) and 700 °C (●). The ordinates correspond to the amount of CO formed [mol $g^{-1}h^{-1}$] (a), the mol ratio H_2/CO (b), the CO selectivity [%] (c), and the conversion of CH_4 [%] (d).

Upon addition of steam to the methane feedstock, the H_2/CO and CO_2/CO ratios increased. This indicates the existence of a CO conversion according to Equation (d) which

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \qquad (d)$$

operates parallel to the oxidative methane conversion. Further, the formation of CO and CH_4 in the hydrogenation of CO_2[7] indicates that the back reaction of the CO conversion may operate simultaneously when the methane conversion is conducted at low temperatures.

The negligibly small conversion of methane in its reaction with CO_2 or steam[8] reveals that CO_2 and water are not the reaction intermediates in the process described here, in contrast to high-temperature noncatalytic or catalytic processes.[1-3] In the present case, the direct formation of CO and H_2 from methane may involve its heterolytic dissociation into CH_3^- and H^+, followed by the oxidation of CH_3^- to OCH_3^-, providing H_2, CO, H_2O, and CO_2, similar to the process observed in the oxidation of preadsorbed methane on MgO at low temperatures.[9]

Experimental Procedure

The NiO/MgO catalysts were prepared from a thick paste of thoroughly mixed, finely ground nickel nitrate (GR LOBA), magnesium carbonate (GR LOBA), and deionized water, which was dried and heated in air at 600 °C for 4 h. The treated solid was powdered, pressed without a binding agent, crushed to particles of 22–30 mesh, and calcined in air at 900 °C for 6 h. The catalytic reactions were carried out in a continuous microreactor constructed of quartz (i.d.: 4 mm) containing about 20 mg catalyst which was pretreated in situ at 900 °C in a flow of moisture-free N_2. The reaction temperature was measured with a Chromel-Alumel thermocouple located in the catalyst bed. The reaction was carried out over the catalyst with or without its prereduction by H_2 at 500 °C with a flow (80 cm^3min^{-1}) of 20% H_2 (80% N_2) for 1 h (i.e. over Ni/MgO and NiO/MgO). The water formed in the reaction was condensed from the product gases at 0 °C and measured. The feedstock and products were analyzed by on-line gas chromatography. The C,H, and O balances were within 5%.

trans-2-*tert*-Butylcyclohexanol, a Simple Selectively Optimized Cyclohexanol Auxiliary**

By *Peter Esser, Helmut Buschmann, Markus Meyer-Stork*, and *Hans-Dieter Scharf**

Systematic investigation of the asymmetric Paternó–Büchi reaction gave rise to the isoinversion principle,[1] a general chemical selection model. The isoinversion principle, applied to the same reaction, was utilized to develop a model concerning the relation between structure and selectivity in cyclohexanol auxiliaries.[2] As a result of these studies, *trans*-2-*tert*-butylcyclohexanol **1** was derived as a "structurally minimized" cyclohexanol auxiliary with an optimized induction potential. Besides, its two enantiomers can be prepared on a large scale by an economical and simple route.

[*] Prof. Dr. H.-D. Scharf, Dipl.-Chem. P. Esser, Dr. H. Buschmann, M. Meyer-Stork
Institut für Organische Chemie der Technischen Hochschule
Prof.-Pirlet-Strasse 1, D-W-5100 Aachen (FRG)

[**] This work was supported by the Deutsche Forschungsanstalt für Luft und Raumfahrt e.V., Hauptabteilung Energietechnik, Köln, der Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. We are grateful to Hüls AG (Marl) for supplying technical 2-*tert*-butylcyclohexanol. We also thank D. Gillmann for the synthetic work and S. Diebel for performing the GC analyses.

The induction potential of *trans*-2-*tert*-butylcyclohexanol **1** is similar to that of 8-phenylmenthol **5**. In this respect, the auxiliary **1** differs considerably from menthol **6** and from *trans*-2-phenylcyclohexanol **7**,[3] as exemplified by the four test reactions shown in Table 1. The *de* values listed in Table 1 were obtained for reactions at the listed temperatures. Temperature optimization according to the inversion principle thus makes it possible to increase the *de* value of the Paternó-Büchi reaction of *trans*-2-*tert*-butylcyclohexanol **1** at 231 K to 96%.

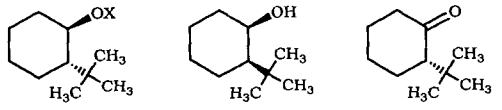
Table 1. Comparison of the diastereoselectivity (*de* values in %) achieved with the auxiliaries R*OH in four test reactions.

	7	**8**	**1**	**5**
R* =				
	56	58	92	> 96
	47	26	72	76
	> 96	66	> 96	> 96
	35[a]	15	38	46

[a] While almost complete conversion was attained with the three other auxiliaries, in this case only 50% conversion was reached after the same reaction time (3 h).

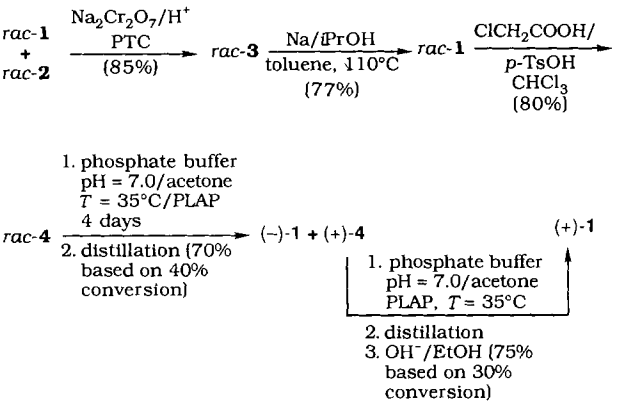
Both isomers, (−)-(1*R*,2*S*)- and (+)-(1*S*,2*R*)-2-*tert*-butylcyclohexanol, can be synthesized on a preparative scale from economical starting materials by a simple enzymatic process. The starting material, racemic 2-*tert*-butylcyclohexanol as a mixture of diastereomers in a *cis*/*trans* ratio of 8:2, is a technical product resulting from catalytic hydration of *ortho*-*tert*-butylphenol.[4]

The technically accessible mixture of isomers was oxidized by treatment with sodium dichromate in sulfuric acid solution and then reduced selectively to afford *trans*-2-*tert*-butylhexanol **1**. Recrystallization from *n*-hexane yielded a diastereomerically pure product. **1** may be esterified to form the corresponding acetate **4a**[7] or the chloroacetate **4b**.[8]



X = H : (−)-**1** (−)-**2** (−)-**3**
X = Ac : (−)-**4a**
X = $ClCH_2CO$: (−)-**4b**

Enzyme-catalyzed esterifications and saponifications of racemic cyclohexanol derivatives have been described a number of times.[9, 10] However, the good enantioselectivity obtained was compromised by low substrate concentration and extended reaction times. The esters were enantioselectively saponified with PLAP (pig liver acetone powder).[11] Because of its ready availability, fresh pig liver was ground, extracted with acetone, and dried for better stability. PLAP-



Scheme 1. Synthesis of enantiomerically pure (−)-**1**, starting from a technical racemic mixture of **1** and **2**. PTC = Phase-transfer catalysis.

catalyzed saponification was performed in water/acetone[12] at 35 °C and a pH of 7. A high-capacity buffer eliminated the need for an autoburet. At a pH below 6.5, the reaction rate dropped noticeably, while the enantioselectivity was considerably reduced at a pH above 7.5. The heterogeneous substrate/water/acetone/enzyme system, containing 40 g of PLAP per 900 mL aqueous phase, was saturated with enzyme. It is important to stir this mixture well in order to optimize the reaction rate. The chloroacetate **4b**[9] showed a reaction rate which is ten times greater than that of acetate **4a** and an equal enantioselectivity. The resulting space-time yield is considerable for an enzymatic reaction. For kinetic reasons,[13] the saponification reaction was interrupted at 40% conversion. After the mixture of ester and (−)-(1*R*,2*S*)-2-*tert*-butylcyclohexanol (−)-**1** was extracted from the aqueous phase, enantiomerically pure (−)-**1** was isolated by distillation (chloroacetate) or column chromatography (acetate) and subsequent crystallization from *n*-hexane. The enantioselectivity values are consistent with the active site model by Toone et al.[11c, 14] In addition, the assignment of the enantiomers is consistent with the structure–selectivity model for cyclohexanol auxiliaries[2] and with the stereochemical assignment according to Djerassi et al.[15] The remaining ester, now enriched with (+)-**4**, was saponified again in the same enzymatic system with up to 30% conversion. The resulting enantiomerically pure ester (+)-**4** was saponified and recrystallized from *n*-hexane to yield (+)-(1*S*,2*R*)-2-*tert*-butylcyclohexanol (+)-**1**.

Experimental Procedure

GC: HP 5890 series II, FID detector with HP 3396 A integrator; for chiral GC, Analytik Siemens Sichromat, FID detector with Shimadzu CR3A integrator. NMR, IR, MS, and CH analyses agree with the structure [16].

tert-Butylcyclohexanone **3**: A 3 M solution of *cis*/*trans*-2-*tert*-butylcyclohexanol was oxidized with sodium dichromate in a sulfuric acid solution, according to the procedure outlined in Organikum [5]. Distillation afforded the ketone in 85% yield. B.p. 76 °C/10 Torr.

trans-2-*tert*-Butylcyclohexanol **1**: 154 g (1 mol) of ketone **3** in 440 g of 2-propanol were quickly added to a well agitated, refluxing suspension of sodium sand (128 g) and toluene (4 L) (the quality of the toluene suspension has a decisive influence on the quality of the *trans* selectivity). (Temperature of the oil bath approx. 160 °C.) Initially, the oil bath was removed. After 3 h of stirring at an oil bath temperature of 140 °C, the mixture is allowed to cool. Then 110 g of sodium dihydrogenphosphate in 550 mL water followed by 660 mL of concentrated hydrochloric acid in 2.2 L of water were added. The aqueous phase was extracted with ether. After drying, the solution was concentrated to afford *trans*-2-*tert*-butylcyclohexanol **1** with a *trans* selectivity of more than 90% (GC = HP FFAP 25 m × 0.32 mm, T = 100 °C, 10 min, N_2 = 2 atm). Recrystallization from *n*-hexane gives 120 g (77%) of *trans*-2-*tert*-butylcyclohexanol **1** with more than 99.9% purity.

trans-2-*tert*-Butylcyclohexylchloroacetate **4b**: 468 g (3 mol) of *trans*-2-*tert*-butylcyclohexanol **1** and 283.5 g (3 mol) of chloroacetic acid were esterified azeotropically by adding 0.5 g (2.6 mmol) of *para*-toluenesulfonic acid in chloroform. When no more water was removed, the catalytic acid was washed out with water, aqueous hydrogen carbonate, and again with an aqueous solution.

Distillation of the crude product afforded the ester **4b** in 80% yield. B.p. 60 °C, 0.19 Torr. (*trans*-2-*tert*-Butylcyclohexanol was acylated in 1 M solution with acetic anhydride, a proton-catalyzed reaction which proceeds analogously to the reaction outlined in Organikum [8].) Distillation afforded the ester **4a** in 82% yield. B.p. 78 °C/3 Torr.

(−)-(1*R*,2*S*)-2-*tert*-Butylcyclohexanol (−)-**1**: A 1 L four-necked flask equipped with a glass precision stirrer shaft, an Ultraturraux stirrer, and a pH meter was filled with a solution of 800 mL of water, 110 mL of acetone, 41.4 g of potassium hydrogen phosphate, 22.4 g of potassium dihydrogen phosphate, 0.5 g of albumin, 40 g of PLAP, and 0.5 mol of *trans*-2-*tert*-butylcyclohexylester **4** (99 g acetate **4a** or 116 g chloroacetate **4b**). The reaction solution was thermostatted at 35 °C and a pH of 7.0 ± 0.5 was maintained by occasionally adding NaOH solution. The reaction was halted at 40% conversion (in the case of acetate **4a**, after about 30 days (conversion rate approx. 0.006 mol per day), in the case of chloroacetate **4b**, after about 4 days (conversion rate approx. 0.05 mol per day). The activity of PLAP depends on the charge and on the freshness of the liver used. The reaction solution was extracted with ether, and the extracts were concentrated and distilled (chloroacetate; *trans*-2-*tert*-butylcyclohexanol (−)-**1**, b.p. 88 °C/8 Torr, chloroacetate (+)-**4b**, b.p. 84 °C/0.2 Torr) or separated by chromatography (acetate **4a**) (cyclohexane/ethyl acetate = 9/1). *trans*-2-*tert*-Butylcyclohexanol **1** is highly volatile; it is thus important to distill the solvents at moderate conditions. Crystallization from *n*-hexane afforded (−)-(1*R*,2*S*)-2-*tert*-butylcyclohexanol (−)-**1** in 70% yield, relative to the conversion, and > 99% *ee* (GC: 25 m × 0.25 mm dimethylacetyl-β-cyclodextrin/polysiloxane. T: 60–190 °C (0.5 K min^{-1}, H_2 = 0.8 bar), $[\alpha]_D^{23}$ −41.1 (*c* = 1.1, $CHCl_3$).

(+)-(1*S*,2*R*)-2-*tert*-butylcyclohexanol (+)-**1**: "Oversaponification" was carried out analogously. At another 30% conversion, the reaction is interrupted and the reaction solution was extracted with ether, and the extracts were concentrated and separated by distillation (chloroacetate) or chromatography (acetate). The ester was saponified in ethanol/KOH. After the solution was concentrated, ether/water was added, the aqueous phase extracted, and the combined organic phases dried over magnesium sulfate and evaporated to dryness. The remaining alcohol was recrystallized from *n*-hexane to afford (+)-(1*S*,2*R*)-2-*tert*-butylcyclohexanol (+)-**1** in 75% yield, relative to the conversion.

A Novel Host/Guest System with a Nanometer Large Cavity for Anions and Cations: $[2\,NH_4^+, 2\,Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(C_6H_5PO_3)_8]^{6-}$**

By *Achim Müller*,* *Kai Hovemeier*, and *Ralf Rohlfing*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Host/guest chemistry, molecular recognition, and nanotechnology are buzzwords that characterize highly topical fields in chemistry.[1] Whereas the relationship between electrophilic "guest ions", such as alkali metal ions, and nucleophilic "host molecules", such as crown ethers, have been studied intensively for many years, only recently has anionic complex chemistry with electrophilic "hosts" been reported.[1] Polytopic hosts for several cations *and* anions or cation/anion aggregates were hitherto unknown.[2] Such host/guest systems should open new fields of application; with them the cooperative, allosteric, and regulatory effects can be studied as well as the condensation of substrates that are brought into proximity by the host.[1] We have now been able to detect the organization of a large "host"[3] (nanometer dimensions), which is probably the result of a novel synergetic template effect by a cation/anion aggregate. Another unusual feature is the nature of the coupling of the guest(s) to the host.

On reaction of ammonium metavanadate with phenylphosphonic acid and hydrazine hydrate in the presence of dimethylammonium chloride in a 3:1 mixture of water and *N*,*N*-dimethylformamide, the host/guest compound **1** is formed, which has been characterized by elemental analysis, manganometric titration of V^{IV}, IR, Raman and UV/VIS/near IR spectroscopy, magnetochemical measurements, calculations of bond-valence sums,[4] and single crystal X-ray analysis.[5]

$$[(CH_3)_2NH_2]_5[NH_4][2\,NH_4^+, 2\,Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(C_6H_5PO_3)_8] \cdot 5\,H_2O \cdot 4\,(CH_3)_2NCHO \quad \mathbf{1}$$

[**] We thank Dr. H. Bögge for discussions in connection with the X-ray structure analysis.

The anion of **1** (cf. Fig. 1 and the structures of fragments in Fig. 2) lies on a crystallographic center of inversion and (without the phenyl groups) has approximate D_{2h} symmetry. It consists formally of two $\{V_5O_9\}^{3+}$ units (**2**, each with a localized V^V center) and two hypothetical binuclear complexes $[V_2^{IV}O_2(OH)_2(H_2O)(C_6H_5PO_3)_4]^{6-}$ (**3**). Two each of

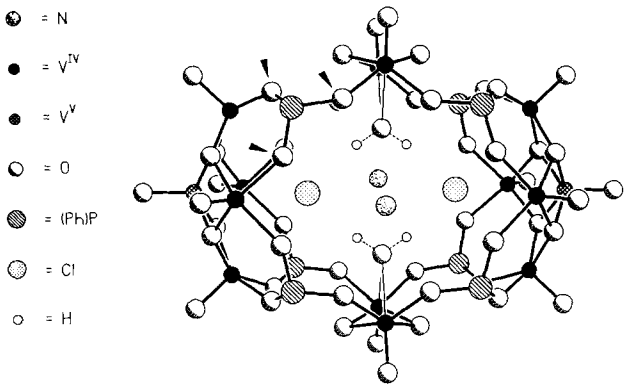

Fig. 1. Structure of the anion in crystals of **1** with illustration of the hydrogen bonds important for the binding of the guest system to the host system, viewed approximately along one of the idealized C_2 axes (characteristic distances [pm]: V-O_{term} 157.8(3)–160.0(2), V^V-O_{br} 185.7(2)–188.8(2), V^{IV}–O_{br} 195.1(2)–198.0(2), V-O(H) 199.9(2)–200.6(3), V-O$(H)_2$ 247.7(3); 252.0(3), P-O 151.6(3)–152.7(2), P-C 179.1(4)–179.9(3); the O atoms of a phosphonate ligand (**6**) are marked by arrows).

components **2** and **3** together form a cavity in which an $(NH_4)_2Cl_2$ ring system (**4**) is enclosed. Unit **2** occurs, for instance, as fragment in the cage system of $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I),[6] but also in the complex $[V_5O_9Cl(tca)_4]^{2-}$ (tca^- = thiophene-2-carboxylate).[7] The binuclear fragment **3** consists of the central $\{V_2^{IV}O_2(OH)_2(H_2O)\}^{2+}$ group (**5**) and four monodentate phenylphosphonate ligands $[C_6H_5PO_3]^{2-}$ (**6**, Fig. 2a). The V–O distances and results of computations of the bond-valence sums suggest that the three bridging O atoms of **5** are singly and doubly (oxygen atom *trans* to $V{=}O_t$) protonated, which is in accord with the overall charge on the anion of **1**. Because of its open structure, **3** would not be stable as an isolated entity. Stability is, however, expected for the same central unit **5**, but with two bidentate ligands **6**.[8]

The (formal) condensation of the two $\{V_5O_9\}^{3+}$ units (**2**) with two phosphonato complexes **3** to form V_2PO_3 hexagons, which correspond to the M_3O_3 rings of $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I), produces a cavity with nanometer dimensions (about 1.2 nm between two V^V centers), which is partitioned by two H_2O ligands (Fig. 1).

The novel and almost planar coronand formed from four PO_2 units and four V atoms (formally comparable with a hitherto unknown "[16]crown-8-crown ether"; Fig. 2b,c) occurs twice in **1**. In each of these coronands an ammonium ion is localized at distances from 299 to 366 pm to the eight O atoms. The deviation of the eight O atoms, four P atoms, and also two of the four V atoms and the central N atom from the best plane through the O atoms is maximally 27 pm.

Alternatively, the cavity of the anion of **1** can be visualized as derived from the intact inner spherical shell of $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I), which has D_{4d} symmetry and the composition $(V_{18}O_{24})$ (Fig. 2d). (This is important for the explanation of the template effect of the chloride ion; see below.) The $V_{18}O_{24}$ shell in which 24 oxygen atoms form a pseudo-rhombicuboctahedron, is divided into two halves

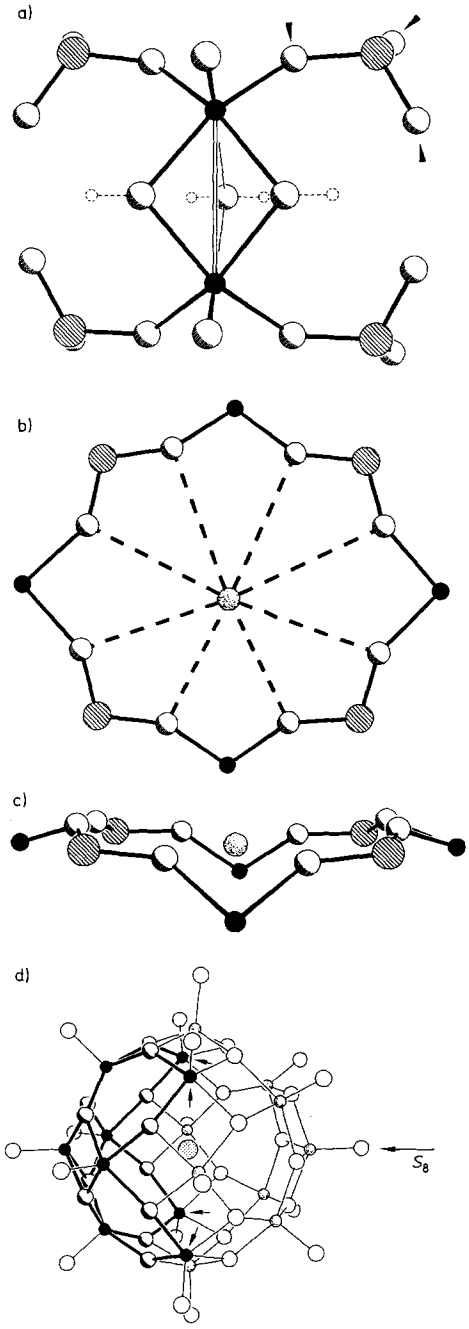

Fig. 2 Important fragments of **1**: a) a hypothetical complex **3** shown perpendicular to the position in Figure 1 (V^{IV}-V^{IV} distance 305 pm; O atoms of one ligand **6** marked by arrows); b) nucleophilic coronand viewed as in Figure 1 and c) perpendicular to that position to illustrate the site of the NH_4^+ ion; d) V_9O_{12} and $V_5P_4O_{12}$ fragment (boldface lines) described as part or half, respectively, of the (inner) $V_{18}O_{24}$ half-shell of $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I) [6a] (the V atoms of the equator marked by arrows must be replaced by P atoms for the topological generation of the anion of **1**.

as if zipped open along the equator perpendicular to the S_8 axis; four V_3O_3 hexagons are thus retained in each half shell. Then all eight atoms of the equator (marked in Fig. 2d for one half of the shell) that belong to the V_3O_3 hexagons are replaced by the P atoms of **6**. The two substituted half shells visualized in this way are twisted through 45° relative to each other and linked with two units of **5** through eight additional O atoms as shown in Figure 1. The half shells lie symmetrically about the horizontal mirror plane of **1**. The analogy to $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I) is also obvious in the similar V···Cl distances (from 359 to 376 pm[6a]).

For the twelve localized V^{IV} centers, at least for the $\{V_5O_9\}^{3+}$ fragments at room temperature, magnetic coupling is negligible,[4] as the V^{IV}–V^{IV} distances of 367–369 pm in those fragments are too large. In accord with this the compound is green. Since the two V^{V} centers at the poles are closer to the V^{IV} centers (288–293 pm), a strong antiferromagnetic interaction has to be anticipated for the fully reduced V^{IV}_{14} cluster. The organization of the spins in **1** and the corresponding reduced species is a step towards *supramolecular magneto chemistry*.

The organization of the cluster shell—a novel host—might be directed by two Cl^- ions inducing the generation of two polar $\{V_5O_9\}^{3+}$ fragments,[9] and the two NH_4^+ ions inducing the formation of the two nucleophilic coronands (Fig. 2b,c). Thus the formation of **1** formally corresponds to the linking of nucleophiles and electrophiles, that is, of electronically inverse hosts;[10] four V atoms are thus shared by these different kinds of hosts.

The organization of the central guest system **4** is determined predominantly by electrostatic interactions, since the distances in the planar four-membered rings are comparable to those of the ion lattice of NH_4Cl (Fig. 3). The two encapsulated chloride ions are 475 pm apart (other distances: to the V^{IV} centers 332–363 pm, to the V^{V} center of the $\{V_5O_9\}^{3+}$ fragments 361 pm). In the docking of **4** to the host, besides the already mentioned interactions between the V/O shell fragments and Cl^- ions[10] and between the nucleophilic O functions of the two coronands and the NH_4^+ ions, hydrogen bonds also play a role, because the relevant O–H–Cl arrangement (see Fig. 1) is approximately linear (O···Cl, 311 and 316 pm). In contrast, hydrogen bonds with NH_4^+ are not crucial, because derivatives of **1** can also be synthesized with alkali metal ions. Exchange of the NH_4^+ ion after the assembly of the host system has not yet been achieved. However, analogous systems with alkali metal ions, for example, the host–guest system with the isostructural anion $[2Rb^+, 2Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(C_6H_5PO_3)_8]^{6-}$, can be synthesized. (We will not discuss the crystal structure here because of an unresolved disorder in the cationic lattice.)

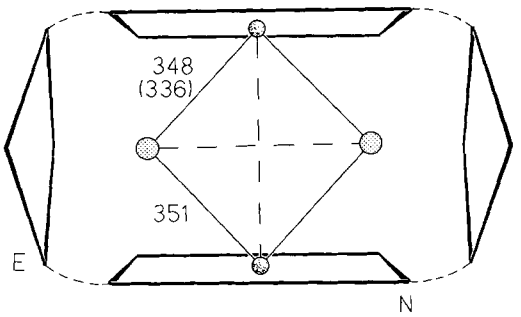

Fig. 3. Host/guest relationships in **1** drawn to scale for the host systems E and N which are perpendicular and electronically inverse to one another: E corresponds to the electrophilic half-shell (see text; the illustrated plane is spanned by four V^{IV} centers), and N corresponds to the nucleophilic coronand plane (the illustrated plane is spanned by four P atoms). Distances in **1** and in the NH_4Cl ionic lattice (in parentheses) in pm.

These results are significant for the following fields: anion–cation separations under physiological conditions,[11] control of oligomer formation from cations and anions and their template function, for example as tips or holes on crystal surfaces with potential relevance for directed prebiotic reactions, and the interaction in confined spaces of simple ion lattices on variation of the interionic distances. With unsymmetric poly/heterotopic hosts that are comparable with **1**, information on the charge separation processes could become available. In order to draw further conclusions, the study of systems[12] with larger ion aggregates as guests would be necessary.[13]

Experimental Procedure

Dimethylammonium chloride (2.04 g, 25.0 mmol) and *N*,*N*-dimethylformamide (30 mL) were added to a solution of NH_4VO_3 (2.92 g, 25.0 mmol) in water (100 mL) at 100 °C in a 300 mL narrow-necked Erlenmeyer flask. Phenylphosphonic acid (1.00 g, 6.3 mmol) was added at 90 °C (color change to orange-red). After reduction with N_2H_5OH (99%, 0.36 mL, 7.5 mmol) the almost black solution was cooled to 65 °C and kept at this temperature for approximately one day. The precipitated green crystals, which weather slowly outside the mother liquor but are soluble in DMF without decomposition, were filtered off. Yield: about 1.2 g (21.3% referred to V).

Chem.* **1991**, *103*, 1515; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1472; for inorganic Lewis acidic host compounds, cf. also X. Yang, C. B. Knobler, M. F. Hawthorne, *ibid.* **1991**, *103*, 1519 and **1991**, *30*, 1507.

[3] The term host/guest system is intended to reflect the structure of the anion of **1**.

[4] Characterization of **1**: IR (KBr, some characteristic bands): $\tilde{\nu}$ [cm^{-1}] = 1652 (s, δ, H_2O and ν, CO), 1466 (m, δ_{as}, CH_3), 1418 (vw, δ_{as}, NH_4^+), 1387 (m, δ_s, CH_3), 1095 (vs, ν_{as}, PO_3), 1017 (s, ν, V^V = O, 996 (vs, ν, V^{IV} = O). Characteristic bands in the Raman spectrum (solid, rotating pellet/ λ_e = 488.0 nm): $\tilde{\nu}$ [cm^{-1}]: 1026(vw, ν_s, PO_3), 996(m, ν, V^{IV} = O); (λ_e = 514.5 nm): $\tilde{\nu}$ [cm^{-1}] = 1025(w,ν_s, PO_3), 993(m, ν, V^{IV}=O). UV/VIS/near IR (in DMF): $\tilde{\nu}$ = 38000 (π(C···C) → π^*(C···C)), 31800, 25100 (π(O) → d(V)-CT, 16300(d(V)) 14400 (intervalence charge transfer). Magnetism (room temperature): μ_{eff}/anion = 6.12 $\mu_B \triangleq \mu_{eff}/V^{IV}$ = 1.77 μ_B. The bond valence sum $\sum\exp(-(R-R_0)/B)$ (R = V–O distance [pm], R_0 = 179 pm, B = 31.9 pm) is 4.94 for the two V^V centers and between 4.04 and 4.18 for the twelve V^{IV} centers (cf. I. D. Brown in *Structure and Bonding in Crystals Vol. II* (Eds.: M. O'Keeffe, A. Nawrotsky), Academic Press, New York, **1981**, p. 1).

[5] **1**: Correct elemental analysis. Crystal structure analysis: $P\bar{1}$, a = 1405.9(4), b = 1473.0(5), c = 1713.1(5) pm, α = 69.32(2), β = 67.37(2), γ = 83.17(3)°, V = 3062.9(16) × 10^6 pm^3, Z = 1, ρ_{calcd} = 1.711 $g cm^{-1}$; solution with direct methods, R = 0.050 for 11203 independent reflections, ($F_0 > 4\sigma(F_0)$). The measured powder diffractogram agrees with the results calculated from the single crystal data. On account of their sensitivity to weathering, the crystals from the mother liquor were embedded in silicon oil and sealed in capillary tube for the measurement, which was performed at −78 °C. Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56243, the names of the authors, and the journal citation.

[10] One could expect the generation of a nucleophilic coronand through condensation of RPO_3 groups. The reason for the electronically inverse host behavior of the V/O shell system lies in the (extremely) weak attraction of the central anions by the Lewis acidic $V^{IV/V}$ centers (but simultaneously very weak repulsion by the O atoms of the shell seems to be important, too). EH-SCCC (Extended Hückel–Self Consistent Charge and Configuration) calculations for the anions of the compounds $(PhCH_2NEt_3)_2[V_5O_9Cl(tca)_4]\cdot MeCN$ [7], $(Me_4N)_6[V_{15}O_{36}Cl]\cdot 4H_2O$ (A. Müller, E. Krickemeyer, M. Penk, H.-J. Walberg, H. Bögge, *Angew. Chem.* **1987**, *99*, 1060; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1045), and $K_9[H_4V_{18}O_{42}Cl]\cdot 16H_2O$ [6a] confirm the picture of attractive interactions between electrophilic V centers and Cl^- ions, for example by the significantly reduced negative charge density on the Cl^- ions; for larger systems the interaction per V–Cl vector is extremely weak (corresponding to the larger distance; A. Müller, D. Sölter, unpublished).

[11] A model for the anion paradox in sodium taste reception has been published recently: Q. Ye, G. L. Heck, J. A. DeSimone, *Science* **1991**, *254*, 724.

[12] The term system here refers to a set of elements interacting with one another; the term organization here also represents the construction of a structure or ordered system of elements (atoms) or subsystems (host/guest).

[13] *Addition in the proof*: A very recent publication makes clear that an ion (e.g. Na^+) that, according to the classical view, is predominantly involved in ionic lattice formation can generate environments even from very hard "particles" (e.g. F^-) by template control in discrete molecular systems, as occurs in topologically comparable preorganized hosts such as crown ethers (H. W. Roesky, M. Sotoodeh, M. Noltemeyer, *Angew. Chem.* **1992**, *104*, 869; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 864.

The Thermal Conversion of Poly[(silylene)-diacetylene] Metal Oxide Composites: A New Approach to β-SiC–MC Ceramics**

By *Robert Corriu,* Philippe Gerbier, Christian Guérin,* and *Bernard Henner*

Polymers **1** with a regular alternating arrangement of (di)silylene and diacetylene units[1] are interesting because of their charge-transport properties, which are consistent with a delocalization of the π electron density along the main chain, and because of their thermal properties.[1, 2] As summarized in Table 1, their pyrolysis in an argon atmosphere

$$\{(SiR^1R^2)_m(C{\equiv}C{-}C{\equiv}C)\}_n$$

1a, $R^1 = R^2 = CH_3$, $m = 1$
1b, $R^1 = R^2 = C_2H_5$, $m = 1$
1c, $R^1 = R^2 = CH_3$, $m = 2$
1d, $R^1 = CH_3$, $R^2 = C_6H_5$, $m = 1$
1e, $R^1 = R^2 = C_6H_5$, $m = 1$

at 1400 °C affords β-SiC-containing ceramics in high yields.[2, 3] All the silicon present in the organosilyl groups of the starting polymers is found in the ceramic as SiC. In addition, the ceramic chars contain a large excess of free carbon coming in part from the diacetylene units. The carbon content can range from 37.5 to 78.3%,[2–4] depending on the type of groups attached to silicon. Both these observations have been related to the crucial influence of the crosslinking of the polymers through the triple bonds. The polymers are thermally converted into an amorphous matrix of sp^2-hybridized carbon atoms in which the SiC network is formed without loss of volatile organosilicon compounds.[2, 3]

Table 1. Pyrolysis of poly[(silylene)diacetylene]s **1a–e** in an argon atmosphere.

Polymer	Ceramic yield [%]	Composition of the ceramic	C content [%]
1a	85	SiC-4C	54.5
1b	72	SiC-4C	54.5
1c	72	2(SiC)-4C	37.5
1d	87	SiC-9C	73
1e	83	SiC-12C	78.3

Taking advantage of such particular properties, we decided to investigate the use of poly[(silylene)diacetylene]s as reactive wrapping polymers for metal oxide particles. Thermal conversion of the preceramic polymer metal oxide composites should result in the "carboreduction" of the encapsulated oxide and the formation of SiC metal carbide ceramics[5, 6] as shown in Scheme 1 for **1a**. This approach would allow a great deal of flexibility in the preparation of these types of binary ceramics. We wish now to report our preliminary data in this area.

$$4MO_2 + \mathbf{1a} \xrightarrow{\text{Ar, } 210\,^\circ C} 4MO_2 + 3\,\mathbf{1a}' \quad \text{(a)}$$

$$4MO_2 + 3\,\mathbf{1a}' \xrightarrow{\text{Ar, } 450\text{–}700\,^\circ C} 4MO_2 + 3\,(\text{SiC-4C}) \quad \text{(b)}$$

$$4MO_2 + 3\,(\text{SiC-4C}) \xrightarrow{\text{Ar, } 1300\text{–}1400\,^\circ C} 3SiC + 4MC + 8CO \quad \text{(c)}$$

Scheme 1. Formation of SiC–MC ceramics from **1a** metal oxide composites. **1a**′ denotes the crosslinked polymer.

In a typical experiment, for example for SiC–TiC ceramics, a precursor material was formed by dispersing 0.266 g of a finely divided TiO_2 powder[7] in 25 mL of a solution of 0.265 g of the poly[(dimethylsilylene)diacetylene] in THF. The molar ratio TiO_2:polymer was based on the reaction $3\,\mathbf{1a} + 4TiO_2 \rightarrow 3SiC + 4TiC + 8CO$, that is, 4:3. The mixture was treated with ultrasound while the solvent was evaporated under vacuum.[8] A sample of the resulting solid

Fourcade (Lavoratoire des Agrégats Moléculaires et Matériaux Inorganiques, URA CNRS 79, Université Montpellier II) for X-ray diffraction studies.

was then heated in an aluminum boat in a cylindrical furnace under argon at 1400 °C for 2 h. The solid residue was obtained in 60% ceramic yield[9] (theoretical ceramic yield: 56.4%). The X-ray powder diffraction spectrum shows only lines caused by SiC and TiC[10] (Fig. 1) and provides no evidence of either unreacted TiO_2 or other crystalline complex oxides. As shown in Figure 2, the strong band in the IR spectrum of the solid residue (KBr pellet) centered near 830 cm^{-1}, characteristic of the Si–C stretch,[11] provides further evidence for the formation of β-SiC. Moreover, IR peaks that could be characteristic of the presence of amorphous O-, C-, Si-, and Ti-containing phases are absent in the region 900–1100 cm^{-1}.[12] Peaks that could be due to residual TiO_2 were not observed in the region 200–500 cm^{-1} (polyethylene pellet).

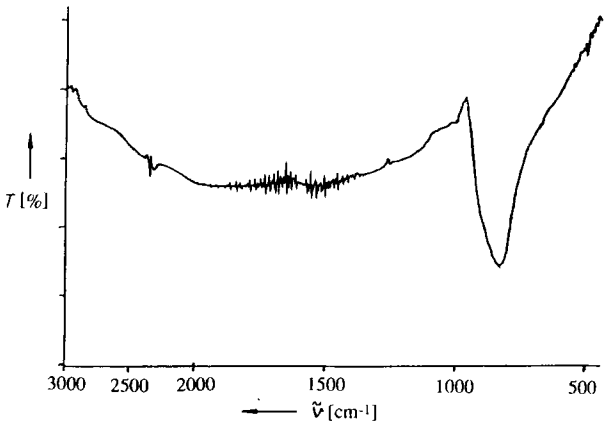

Fig. 2. IR spectrum of the ceramic obtained by pyrolysis of 3 **1a**–4 TiO_2. T = transmittance.

Thermogravimetric (TGA) and differential thermal analysis (DTA) were conducted with a thermogravimetric analyzer interfaced with a mass spectrometer.[13] Total weight loss is about 45–46%, very close to the expected theoretical value of 43.6%. Moreover, the thermograms (Fig. 3) clearly suggest that a three-step reaction takes place when the temperature of the sample is increased up to 1400 °C:

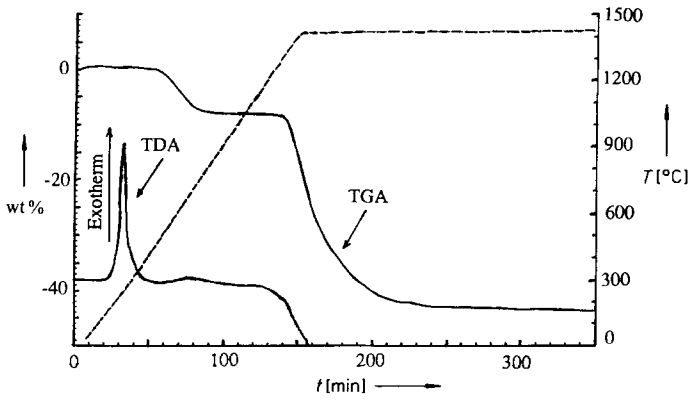

Fig. 3. Pyrolysis of 3 **1a**–4 TiO_2 under argon followed by TGA and TDA. (– – –: temperature in the furnace).

1) Initially, the DTA curve exhibits a strong maximum at about 210 °C, as observed previously for **1a**.[2] The exothermic transformation indicated is related to the thermally induced cross-polymerization through the diacetylene groups [Scheme 1, Eq. (a)]. The presence of TiO_2 has no significant effect on this step.

2) Second, the TGA trace shows an initial weight loss primarily between 500 and 700 °C (versus 400–750 °C for **1a**). The off-gases from the pyrolysis were identified by mass spectrometry as CH_4 and H_2 (Fig. 4). No gaseous silicon-

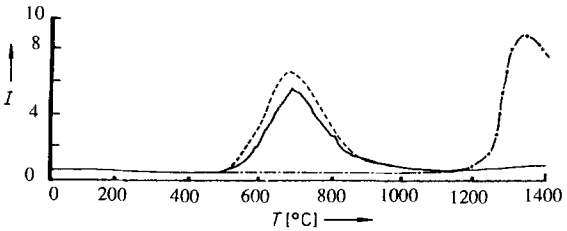

Fig. 4. Pyrolysis of 3 **1a**–4 TiO_2 under argon. Analysis of the volatiles by mass spectrometry. (– – –: CH_4; ——: H_2; –·–·–: CO). I = ion flow (arbitrary units).

containing species were detected. Furthermore, the measured weight loss (8–9%) is quite close to that expected for the thermal decomposition of the starting polymer alone leading to a 3(SiC-4C)–4 TiO_2 material (theoretical yield: 8.5%) [Scheme 1, Eq. (b), and Table 1].

3) Finally, this intermediate material reacts at higher temperatures (1300–1400 °C) with TiO_2 to produce the SiC–TiC ceramic. All the free carbon present is converted into CO and TiC. The weight loss (36%) is consistent with a complete carboreduction of the metal oxide [Scheme 1, Eq. (c)].

Interestingly, the carboreduction starts at a relatively low temperature, namely 1300 °C. As a comparison, TiO_2 is converted by carbon alone at temperatures higher than 1700 °C.[14] The crucial influence of the cross-polymerization of **1a** on the overall yield of the carboreduction of TiO_2 was demonstrated in the following reference reaction. Under similar experimental conditions (1400 °C, 5 h), thermal treatment of TiO_2 with a SiC–4C powder obtained by a separate pyrolysis of **1a** led to a complex residue containing a high percentage of TiO_2 and other oxides besides SiC. This clearly suggests that the ability of the poly[(dimethylsilylene)-diacetylene] **1a** to act as an efficient reagent in carboreduction reactions originates from its conversion into a silylated carbon matrix which coats the TiO_2 particles during the initial stages of the pyrolysis.

The above approach is quite general, and a wide range of binary SiC-MC ceramics can be easily obtained (Tables 2 and 3). Two observations may be summarized: 1) The method can be extended to a number of metal oxides including B_2O_3.

Table 2. Generation of β-SiC metal carbide ceramics from pyrolysis of **1a** metal oxide composites.

Polymer (equiv)	Metal oxide [a] (equiv)	Ceramic yield [%]	Composition of the ceramic [b] (MC [%])
1a (3)	TiO_2 (4)	56	3 SiC-4 TiC (72.7)
1a (3)	ZrO_2 (4)	62	3 SiC-4 ZrC (77.4)
1a (7)	B_2O_3 (8)	35	7 SiC-4 B_4C (44.4)
1a (7)	MoO_3 (8)	59	7 SiC-4 Mo_2C (60.7)
1a (13)	V_2O_5 (8)	52	13 SiC-4 V_4C_3 (64.8)
1a (3)	HfO_2 (4)	71	3 SiC-4 HfC (86.4)
1a (7)	Nb_2O_5 (4)	62	7 SiC-8 NbC (80.5)

[a] Temperatures for carboreduction[14]: TiO_2 (>1700 °C); ZrO_2 (1900–2100); B_2O_3 (2000–2500 °C); MoO_3 (>1600); V_2O_5 (1150–1300); HfO_2 (>1700); Nb_2O_5 (>1600). [b] SiC and metal carbides were characterized by X-ray powder diffraction.

Under similar experimental conditions (1400 °C, 5 h), the pyrolysis of the poly[(dimethylsilylene)diacetylene] metal oxide composites in an argon atmosphere gave high yields of crystalline solid phases that contained the respective metal carbide and SiC. In all cases, the reaction with the metal oxide takes place at lower temperatures than with only carbon. 2) Variation of the poly[(silylene)diacetylene]s allows the modulation of the composition of the final ceramics as summarized for TiO_2 (Table 3). When aryl groups are bonded to the silylene unit, ceramic residues containing higher amounts of TiC result (Table 3, run 3). In contrast, **1c**, a polymer with two dimethylsilylene units, produces a ceramic with a TiC content of 57.1 % (Table 3, run 2).

Table 3. Pyrolysis of poly[(silylene)diacetylene]–TiO_2 composites.

Run	Polymer (equiv)	TiO_2 (equiv)	Ceramic yield [%]	Composition (MC [%])
1	**1a**	(4)	56	3 SiC-4 TiC (72.7)
2	**1c**	(4)	60	6 SiC-4 TiC (57.1)
3	**1e**	(4)	51	SiC-4 TiC (88.9)

Thus, we may expect to prepare a wide range of multiphase ceramics of defined composition. Investigation of the potential of this method and the mechanistic implications are now under progress.

(Organoarsonato)polyoxovanadium Clusters: Properties and Structures of the V^V Cluster $[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{4-}$ and the V^{IV}/V^V Cluster $[H_2\{V_6O_{10}(O_3AsC_6H_5)_6\}]^{2-}$ **

By *M. Ishaque Khan, Yuanda Chang, Qin Chen, Hakon Hope, Sean Parking, D. P. Goshorn*, and *Jon Zubieta**

The chemistry of polyoxovanadium clusters incorporating Group 5 elements has witnessed significant growth in recent years. Arsenic–vanadium clusters exhibit a variety of structural types of considerable topological interest[1, 2] and possess a range of stable cluster oxidation states as well as unusual magnetic properties.[3–6] Furthermore, these heteropolyvanadates exhibit a pronounced tendency to form cage structures which may encapsulate neutral molecules or anions, a feature shared with a number of isopolyanions such as $[V_{18}O_{42}(H_2O)]^{12-}$,[7] $[V_{14}O_{42}(SO_4)]^{8-}$,[5] $[H_4V_{18}O_{42}(X)]^{9-}$ (X = Cl, Br, I),[8–10] and $[V_{12}O_{36}(CH_3CN)]^{4-}$[11] and recently described for $[V_{12}As_8O_{40}(HCO_2)]^{n-}$ (n = 3,5),[3] $[V_{15}As_6O_{42}(H_2O)]^{6-}$,[4] $[V_{14}As_8O_{42}(SO_4)]^{6-}$,[5] and $[V_{14}As_8O_{42}(0.5\,H_2O)]^{4-}$.[6] A related family of (organophosphonato)polyoxovanadium clusters constitutes a new class of layered compounds which can exhibit useful sorptive and catalytic properties,[12–14] while the molecular polyanions $[H_{12}V_{12}O_{24}(O_3PC_6H_5)_8]^{4-}$[15] and $[H_6V_{16}O_{32}(O_3PCH_3)_8]^{8-}$[16] provide examples of structures displaying cage and "tire" structural motifs, respectively. However, in contrast to this rapid development of the arsenic- and (organophosphonato)polyoxovanadium systems, the chemistry of oxovanadium clusters with organoarsonates $RAsO_3^{2-}$ remains relatively unexplored, although one example of a layered structure $[V_2O_4(C_6H_5AsO_3H)] \cdot H_2O$[17] has been described. In this communication, we report two novel polyoxovanadium structural types found in the "oxidized" cluster **1** and the mixed valence cluster **2**. The structures of these clusters illustrate the dramatic influences of small changes in ligand type upon the overall molecular geometry.

$(TBA)_2(NH_4)_2[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]$ **1**
$(TBA)_2[H_2\{V_6O_{10}(O_3AsC_6H_5)_6\}] \cdot 2H_2O$ **2**
TBA = $(n\text{-}C_4H_9)_4N$

Red, parallelepiped crystals of **1** were prepared in approximately 45% yield by heating a mixture of $(NH_4)_2Na_2K_2[V_{10}O_{28}]$, arsanilic acid $4\text{-}NH_2C_6H_4\text{–}AsO(OH)_2$, and (TBA)Br in methanol at reflux for 20 min. X-ray structure analysis of **1**[18] revealed the presence of discrete (TBA) and NH_4^+ ions and a $[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{4-}$ ion, whose structure is shown in Figure 1. The overall structure may be described as a $[V_9O_{21}(O_3AsC_6H_4NH_2)_3]^{3-}$ toroid encapsulating a VO_3^- moiety. The toroid consists of three trinuclear $\{V_3O_{13}\}$ units of edge-sharing octahedra with the conventional 60° angle formed by the V centers,[19] which are linked through bridging oxo groups and the arsonato

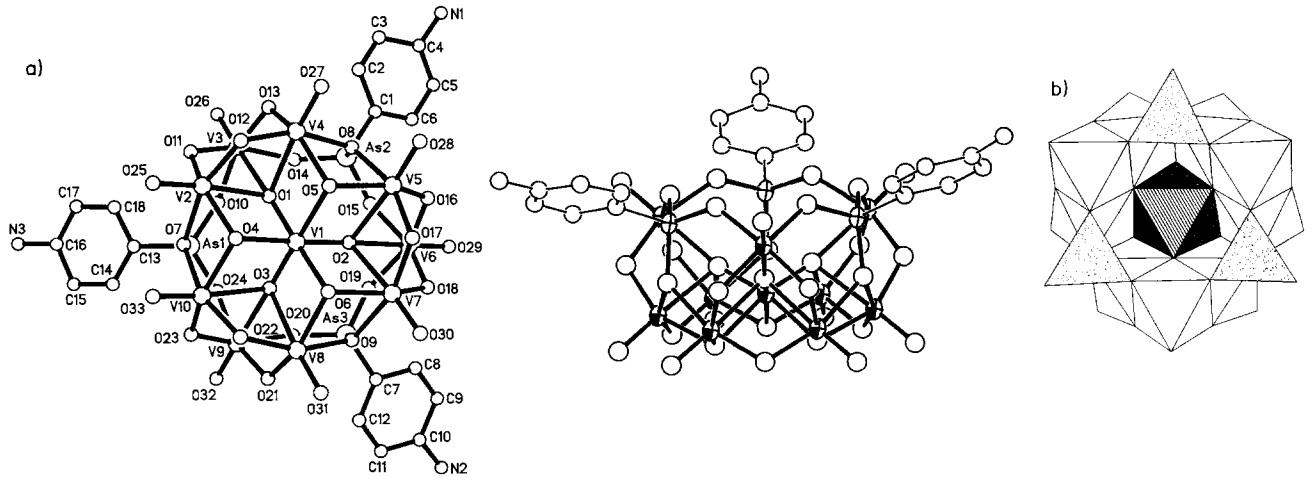

Fig. 1. a) Perspective views of the crystal structure of the anion in **1**. Left: View along the approximate threefold axis of the anion. Right: View perpendicular to this threefold axis. Selected bond lengths [Å] and angles [°]: V(ring)-O(terminal), 1.56(1)–1.61(1); V(ring)-O(μ^2), 1.79(1)–1.86(1); V(ring)-O(μ^3), 1.92(2)–1.99(1); V(ring)-O(μ^4), 2.28(1)-2.33(1); V1-O(μ^3), 2.10(1)–2.20(1); V1-O(μ^4), 1.69(1)–1.71(1); As-O(μ^2), 1.65(2)–1.69(2); As-O(μ^3), 1.72(2)–1.75(2); O1-V1-O6, 166.1(6); O2-V1-O4, 167.1(6); O3-V1-O5, 168.8(6). b) A polyhedral representation of the structure of the anion illustrating the stacking one ring of V octahedra and As tetrahedra, $[V_3(RAsO)_3]^{9+}$, on an Anderson core $[V_7O_{24}]^{13-}$.

ligands. The central vanadium atom V1 is in a highly distorted octahedral environment, in which the metal atom is displaced toward the O1-O2-O3 face; the average V–O(1,2,3) distance is 1.70(2) Å as compared to an average distance of 2.14(2) Å for V–O(4,5,6). This unusual oxometalate arrangement in **1** gives rise to four distinct types of oxo groups: terminal O atoms associated with the V centers of the nine-membered ring, μ^2 oxo groups that bridge V atoms of the $\{V_3O_{13}\}$ units, μ^3 types that link the $\{V_3O_{13}\}$ units to the central vanadium atom, and μ^4 oxo groups which provide both the common vertex for the V octahedra of the trinuclear units and the link to the encapsulated V atom. Each organoarsonate group shares two of its oxygen atoms with vanadium centers of adjacent trinuclear units, while the third is bound to two vanadium centers in neighboring trinuclear units. The anion in **1** exhibits structural features common to polyanions exhibiting a central MO_6 octahedron[20–22] and to ε-Keggin types.[23] The polyhedral representation of Figure 1b clearly shows the relationship of **1** to the Anderson $\{M_7O_{24}\}$ clusters.[23] The structure of the anion in **1** may be best described as a double layer of polyhedra, one layer composed of the $[V_7O_{24}]^{13-}$ Anderson core and the second consisting of a $[V_3(RAsO_3)_3]^{9+}$ ring which rests on one face of the Anderson core.

Complex **1** undergoes a reversible one-electron reduction at -0.54 V to give the green-brown $[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{5-}$ which displays a broad EPR signal centered at $g = 1.95$. In contrast, chemical oxidation of **1** with hydrazines results in multiple-electron transfer coupled to proton transfer to give purple solutions of $[V_{10}O_{21}(OH)_3(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{4-}$. Carefully controlled addition of the hydrazine reagents produces anions of intermediate reduction/protonation states. Such multiple electron–proton transfer processes appear to be characteristic of the chemistry of polyvanadates stabilized by organic ligands.[30]

The reaction of $(NH_4)_2Na_2K_2[V_{10}O_{28}]$ with $C_6H_5AsO(OH)_2$ in the presence of (TBA)Br quite unexpectedly resulted in partial reduction to give **2** as bright green crystals in 65% yield. The structure of **2**[24] consists of discrete (TBA) ions and molecular anions of $[H_2\{V_6O_{10}(O_3AsC_6H_5)_6\}]^{2-}$, shown in Figure 2a. Although the numerous examples of arsonatopolyoxovanadates studied to date invariably exhibit spherical or annular structures, similar to that of the anion in **1**, the structure of the anion in **2** consists of a twisted 24-membered ring $\{V_6As_6O_{12}\}$ (Fig. 2b), which is highly distorted by the presence of additional intraring V-O-V and As-O-V bridges; the As-phenyl substituents, the ter-

minal oxo groups of the vanadium atoms, and the hydroxyl groups of As1 and As1a project from this central ring. Alternatively, the structure may be described in terms of a layer structure of three $\{V_2As_2O_4\}$ rings connected in a stacking fashion by μ^2 oxo groups, as shown in Figure 2c.

The vanadium centers exhibit square-pyramidal geometry with the standard apical disposition of the terminal oxo groups. Each of the organoarsonate groups is bound to two oxygen atoms and contributes to the formation of the $\{V_2As_2O_4\}$ rings, and four of them employ a third oxygen atom to coordinate to an adjacent ring. The remaining two organoarsonate groups participate in the outermost $\{V_2As_2O_4\}$ rings, while the third oxygen atom of each is a terminal ligand. The latter oxygen atoms, O6 and O6a, are protonated. This assignment is based on the fact that the As3–O6 bond is long relative to the value anticipated for a terminal As=O bond, and the location of one peak in the difference electron density maps is consistent with a hydroxyl proton. The overall anionic charge of 2– requires the presence of four V^V and two V^{IV} centers, an assumption confirmed by potentiometric titration. On the basis of valence sum calculations,[25] the reduced sites are identified as V3 and V3a.

The presence of two reduced centers is confirmed by the magnetic properties of **2**. This compound exhibits behavior characteristic of isolated V_2 units. The temperature dependence of the magnetic susceptibility in the range 4.2 to 300 K follows the Bleany–Bowers equation[26] for isolated dimers containing two $S = 1/2$ cations with isotropic g tensors; the susceptibility displays a maximum at 20 K. The susceptibility data are consistent with extremely weak exchange coupling ($2J = -9.1\ cm^{-1}$) within vanadium dimers which are effectively isolated from each other. The magnetic data may be compared to that for $(VO^{2+})_2$ systems in which J ranges from -25 to $-250\ cm^{-1}$.[27] The weak exchange coupling in **2** is similar to that observed for $VO(HPO_4) \cdot 0.5\ H_2O$[28] and $VO(HPO_4) \cdot 2H_2O$,[29] salts which possess building blocks made up of two VO^{2+} units with similar exchange networks. Furthermore, in contrast to **1**, **2** undergoes two successive, facile, and reversible one-electron oxidations at +0.09 and +0.46 V, which is consistent with the presence of two readily oxidized V^{IV} centers. Thus, the cluster possesses magnetic and electron-transfer properties suggestive of a dimer $\{V_2O_4(O_3AsC_6H_5)_2\}$ encapsulated and stabilized by sandwiching between two $\{V_2O_5(O_3AsC_6H_5)_2\}$ fragments. While ligand-free polymetalates undergo almost exclusively cathodic processes, the introduction of organic ligands into the polymetalate framework allows the development of a more extensive electrochemistry by stabilizing a variety of "reduced" and mixed valence clusters with modified electron-storage and proton-transfer properties.[30]

The organoarsonate chemistry of vanadium appears to be remarkably diverse, such that relatively minor changes in substituents can produce dramatic structural differences as exemplified by **1** and **2**. Furthermore, their electrochemical and magnetic properties suggest extensive electron storage and coupled electron–proton transfer in the chemistry of clusters of this type.

Experimental Procedure

1: Under an atmosphere of argon, (TBA)Br (2.58 g, 8 mmol) and arsanilic acid (0.868 g, 4 mmol) were placed in a Schlenk tube fitted with a reflux condenser and were then dissolved in methanol (25 mL). $(NH_4)_2Na_2K_2[V_{10}O_{28}]$ (0.56 g, 0.5 mmol) was added, and the resulting suspension was heated at reflux with stirring for 20 min whereupon a clear red-brown solution was obtained. After the hot solution was filtered and cooled to room temperatue, it was stored at 4 °C for 20 h. Shiny red crystals of **1** were collected in 45% yield. Satisfactory C,H,N-analysis. IR (KBr): $\tilde{\nu}\ [cm^{-1}] = 3456(s), 3365(s), 1624(s), 1591(s), 1500(s), 1479(m), 1457(m), 1307(m), 1181(m), 1092(s), 985(s), 972(vs), 878(s), 790(sh), 733(s), 626(m), 530(m)$; UV/VIS ($CH_3CN$): λ_{max} [nm] ($\varepsilon\ [cm^{-1}M^{-1}]$) = 258 ($6.72 \times 10^4$), 294 (sh). ^{51}V NMR (CH_3CN, $VOCl_3$ standard): $\delta = -499, -507, -533$; electrochemical parameters (10^{-3} M **1**, 10^{-1} M (TBA)PF_6, CH_3CN, ferrocene/ferrocenium standard): -0.54 V (ΔE = 64 mV).

2: A mixture of phenylarsenic acid (0.802 g, 4 mmol), (TBA)Br (2.58 g, 8 mmol), and $(NH_4)_2Na_2K_2[V_{10}O_{28}]$ (0.56 g, 0.5 mmol) in methanol (40 mL) was heated at reflux for 40 min to give a bright green solution. A small amount of insoluble residue was removed by filtration, and the filtrate was evaporated to dryness. The resultant green solid was dissolved in a minimum amount of acetronitrile, carefully layered with 50 mL of pentane, isopropanol, and diethyl ether (1:1:1), and allowed to stand at room temperature for 4 d. Dark green crystals of **2** were isolated in 65% yield. Satisfactory C,H,N-analysis. IR (KBr): $\tilde{\nu}\ [cm^{-1}] = 3058(w), 2962(m), 2874(m), 1482(m), 1440(m), 1382(w), 1094(m), 982(s), 872(vs), 841(vs), 743(s), 691(m), 561(sh), 492(s)$. UV/VIS ($CH_3CN$): λ_{max} [nm] ($\varepsilon\ [cm^{-1}M^{-1}]$) = 240 ($2.25 \times 10^4$), 275 (sh), 368 ($3.30 \times 10^3$), 660 (352); magnetic properties: Bleany–Bowers fit: $\chi_o = -3.74 \times 10^{-4}\ cm^3mol^{-1}$, $C_i = 0.0139\ cm^3K\ mol^{-1}$, $C_d = 0.3036\ cm^3K\ mol^{-1}$, $2J = -9.1\ cm^{-1}$; μ_{eff} = 1.73 μ_B; electrochemical parameters (10^{-3} M **2**), 10^{-1} M (TBA)PF_6, CH_3CN, ferrocene/ferrocenium standard): +0.09 V (ΔE_p = 62 mV), +0.46 V (ΔE_p = 74 mV).

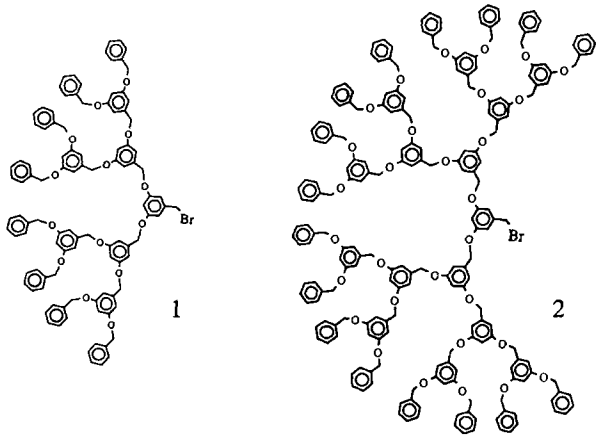
Novel Polyether Copolymers Consisting of Linear and Dendritic Blocks**

By *Ivan Gitsov, Karen L. Wooley,* and *Jean M. J. Fréchet**

Polyethylene glycols (PEGs), their derivatives and amphiphilic block copolymers have many applications as phase-transfer reagents,[1] as compounds that could potentially encapsulate other materials,[2] and as emulsifying agents.[3] Their properties arise from the existence of both hydrophilic and hydrophobic parts of the macromolecules. In spite of the promising results achieved up to now, the synthesis of novel polymers and copolymers of that type is still of importance due to the high demand for new materials with defined architecture and improved properties.

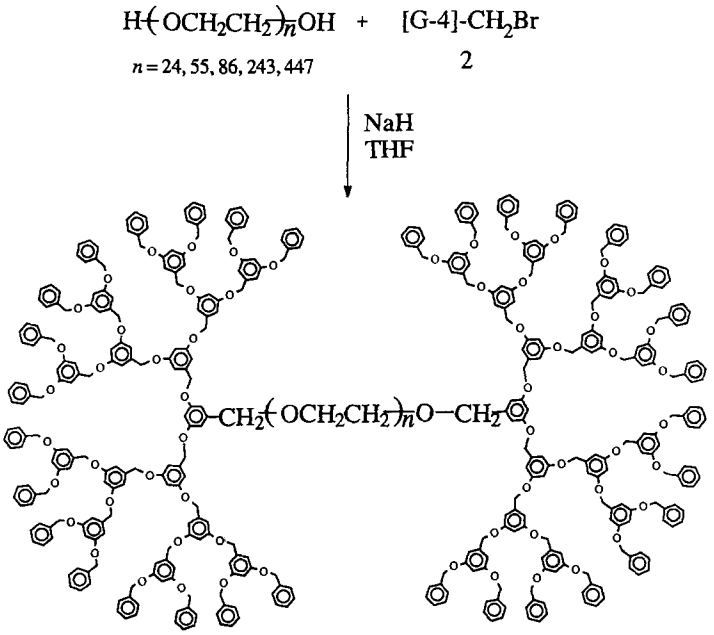
Recently, the synthesis of novel dendritic polyethers was reported.[4, 5] Because of their dense, but nonentangled structure these dendrimers are expected to impart unusual properties to other polymeric materials when incorporated in the polymer chain. This report explores the incorporation of these highly branched amorphous and hydrophobic dendrimers in a crystalline hydrophilic PEG as well as the properties of the resulting copolymers.



Scheme 1. The dendritic macromolecules employed in the reaction with the polyethylene glycols.

In a first approach PEG copolymers containing dendritic blocks were prepared by capping the ends of α, ω-bifunctional PEGs with dendrimers possessing a reactive functional group at their core. In order to estimate the influence of the size of the dendritic molecule on the reaction yields and the properties of the copolymers that are formed, dendrimers of the third ([G-3]-Br: **1**) and fourth ([G-4]-Br: **2**) generations were used (Scheme 1).

In order to avoid the association of acidic moieties with PEG[6] and the incomplete conversion[1] of some Williamson-type syntheses, the formation of the PEG dianion in situ by reaction with NaH was carried out in the presence of the dendritic bromide (Scheme 2) as described previously for the synthesis of PEG macromers.[7]



Scheme 2. Synthesis of the copolymers.

In all cases investigated, the end-capping reaction proceeded smoothly at room temperature and was complete within 24 h. The length of the initial PEG block and the size of the dendritic bromide have no influence on the rate of formation of the copolymers. In contrast to the previously reported end-capping reactions of PEGs,[1, 7] the low molar ratio of the dendritic bromides to terminal hydroxyl groups (1.2:1) does not affect the yields, which remain over 90%.

The molecular weights of the starting materials and the resulting block copolymers are listed in Table 1. The molecular weights at the peak apex M_p in the size-exclusion chromatography (SEC) traces are used as characteristic values for each product since they are less affected by low- and high-molecular weight impurities. The molecular weight distribution is calculated as the average of three measurements. It should be noted that most copolymers obtained have narrower molecular weight distributions than the inital PEGs, and all of them have apparent molecular weights lower than the values predicted for triblock copolymers of the type [G-m]-PEG-[G-m] (Table 1, Fig. 1). This difference between calculated and apparent molecular weights increases with the length of the initial PEG block.

[a] Reaction product of monofunctional lauryl PEG $C_{12}H_{25}(OCH_2CH_2)_{23}$-OH (Brij 35®) and dendritic bromide. [b] Reaction product of monofunctional methyl PEG $CH_3(OCH_2CH_2)_{56}$-OH and dendritic bromide.

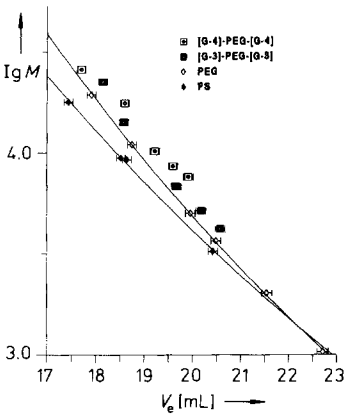

Fig. 1. SEC calibration curves for polystyrene (PS) standards, PEGs with narrow molecular weight distributions, and dendritic triblock copolymers [G]-PEG-[G]. THF, 30 °C, flow rate 1 mL min^{-1}; columns: PLGel 500 Å, 1000 Å, mixed-C.

In order to check the efficiency of the end-capping reaction, experiments with monofunctional PEGs were also performed (Table 1, Fig. 2). It is seen that the end-capping reactions of both mono- and bifunctional PEGs of similar molecular weight with a dendritic bromide proceed to completion. In the SEC traces of the monofunctional PEGs the shoulders at high molecular weights originate most probably from bifunctional impurities in the starting materials. Thus, it may be assumed that the lower values of the apparent molecular weights are caused not by incomplete functionalization (end-capping), but most probably by the smaller size of the resulting dendritic copolymers. A similar behavior was reported for dendritic versus linear macromolecules.[8, 9]

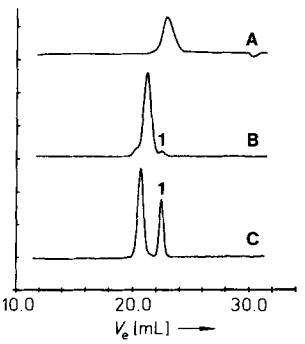

Fig. 2. SEC traces of the initial PEGs. **A**: H-$(OCH_2CH_2)_{24}$-OH, **B**: reaction mixture of H-$(OCH_2CH_2)_{23}OC_{12}H_{25}$ and **1**, **C**: reaction mixture of H-$(OCH_2CH_2)_{24}$-OH and **1**. THF, 30 °C, flow rate 1 mL min^{-1}; columns: PLGel 500 Å, 1000 Å, mixed-C.

Another factor contributing to the differences in the calculated and apparent molecular weights discussed above might be the formation of monomolecular micelles. The calibration curve for PEGs has a more negative slope compared to that for polystyrenes (PS) (Fig. 1), which confirms the well-known fact that the solubility of PEGs in THF decreases as their molecular weight increases. Thus, in copolymers with dendritic and linear blocks, the central PEG block should shrink in THF as its length increases, while the dendritic end blocks would undergo an intramolecular association. Since there are no other reports on copolymers consisting of linear and dendritic blocks, our results are best compared to those obtained for polyethylene oxide–polystyrene block copolymers. Indeed, a similar phenomenon was reported for polystryrene-*b*-polyethylene oxide-*b*-polystyrene.[10] Some authors have predicted a narrowing in the molecular weight distribution of block copolymers undergoing an association of their end groups.[11] However, with the copolymers in this study it would be very difficult to estimate quantitatively the contribution of both factors—collapse of the linear central block in solvents in which the PEGs are not well soluble (THF), and intramolecular association of the dense, hyperbranched endgroups—to the overall decrease in the molecular dimensions of the synthesized copolymers.

In order to gain qualitative information on the possible formation of micelles, we recorded ^{1}H NMR spectra in solvents selective for solubilizing the PEG and dendritic blocks. An interesting phenomenon is observed in [D_8]THF. At room temperature the initial PEG block with molecular weight of 19700 is obviously not soluble. Therefore, only signals for the protons of the groups -CH_2O- (δ = 3.28–3.58) and -CH_2CH_2- (δ = 1.57–1.73) of THF molecules are observed in the spectrum. The integrals of the two signals should be equal, but that of the CH_2CH_2 protons is greater ($I_{CH_2CH_2}:I_{CH_2O}$ = 1.35) due to the different isotopic distributions at the two positions. When the sample in the NMR tube is heated to 50 °C for 15 min, PEG visibly dissolves and the ratio of the integrals is strongly shifted towards the CH_2O protons ($I_{CH_2CH_2}:I_{CH_2O}$ = 0.17). The ^{1}H NMR spectra of dendritic copolymers having the same PEG as above for the central block are not temperature dependent. Theoretically, the ratio of the methylene PEG protons to the protons in the dendritic side-blocks for [G-4]-PEG19700-[G-4] should be equal to 4.84. In $CDCl_3$ the ratio of their integrals is about 4.9, but in [D_8]THF, the values obtained at room temperature and 50 °C are 2.49 and 2.30, respectively, after the integral intensity of solvent protons is subtracted. Thus, it may be assumed that attachment of dendritic blocks to PEG increases its solubility in THF to a certain extent; however, the screening of the PEG core by the dendritic outer shell in the micelles that are formed prevents further solubilization at higher temperatures.

Figure 3 presents the ^{1}H NMR spectra of [G-3]-$(OCH_2CH_2)_{243}$-O-[G-3] in $CDCl_3$ (**A**, both blocks are soluble) and CD_3OD (**B**, the PEG block is selectively soluble). It is noteworthy that while the signal for the methylene PEG protons remains sharp and is only slightly shifted downfield in CD_3OD (from δ = 3.32–3.72 to 3.29–3.70), the signals of the aromatic protons in the dendritic end blocks become very broad (δ = 7.06 ($\Delta\nu$ = 120 Hz), 6.38 (204 Hz), 4.72 (571 Hz) (Fig. 3, **B**.). It is quite surprising that the signals of the [G-3] block are observed, since the corresponding dendritic bromide and its derivatives are not soluble in methanol and consequently not evident in the NMR spectra recorded in

that solvent. The PEG block seems to carry its dendritic counterpart into solution as was observed for G blocks in [D_8]THF. However, the broadness of the signals is evidence of the limited flexibility of the dendritic blocks of the copolymers. When hyperbranched blocks of the next generation are attached to the same bifunctional PEG, the methanol solution of the resulting copolymer is milky and opalescent, and the aromatic signals are not seen in the NMR spectra (Fig. 3, **C**.). A similar behavior and the same values for $\Delta\nu$ are also

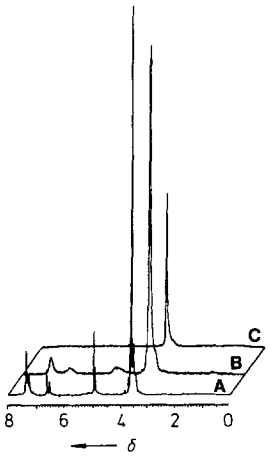

Fig. 3. ^{1}H NMR spectra of [G-3]-$(OCH_2CH_2)_{243}$-O-[G-3] in $CDCl_3$ (**A**), [G-3]-$(OCH_2CH_2)_{243}$-O-[G-3] in CD_3OD (**B**), and [G-4]-$(OCH_2CH_2)_{243}$-O-[G-4] in CD_3OD (**C**). 300 MHz, 22 °C, polymer concentration 1 wt%.

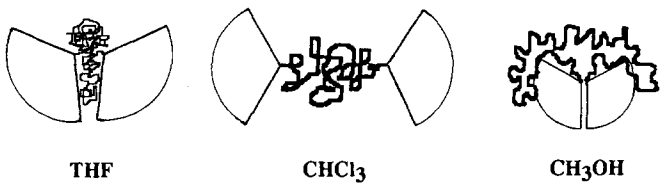
observed for dendritic copolymers of monofunctional PEGs. Thus, it could be assumed that in methanol both di- and triblock copolymers undergo the same type of transformation. Similar phenomena were reported for polystyrene-*b*-polyethylene oxide[12] and other micelle-forming copolymers[13] and were also interpreted as micelle formation. Although additional investigations are necessary to evaluate the number of molecules in the micelles formed, the results of SEC and ^{1}H NMR experiments strongly suggest that in selective and poor solvents the copolymers might undergo different size and shape transitions (Scheme 3).



Scheme 3. Left: Collapse of the central PEG block as the length increases. The dendritic G blocks are partially associated. Middle: Both blocks are soluble in the solvent. Right: Collapse and association of G blocks of higher generations. The PEG block expands.

The results show that the relatively bulky dendritic wedges, up to fourth generation, do not affect the reactivity and accessibility of the functional group at the core of the dendritic macromolecules. Thus, novel amphiphilic block copolymers of PEGs having different extents of hydrophobic and hydrophilic character can be formed in a single reaction under mild conditions. The preliminary characterization studies of these products show that they are able to form micelles in solvents in which both blocks are poorly soluble or in which one block is selectively soluble. Further investigations on their properties are in progress.

Experimental Procedure

A typical end-capping reaction was performed as follows: PEG of molecular weight 3800 [$H(OCH_2CH_2)_{86}OH$] (0.031 g, 8.3×10^{-6} mol) and **1** (0.029 g, 1.72×10^{-5} mol), synthesized according to ref. [8], were mixed and dissolved in dry THF (2 mL). To the solution was added NaH (0.001 g, 4×10^{-5} mol), and the reaction mixture was stirred at room temperature under nitrogen for a set time. The conversion was followed by SEC. After the PEG peak in the chromatogram had disappeared, the reaction mixture was filtered and purified by precipitation into acetone/methanol (1:3) and reprecipitation from THF into heptane. Yield: 0.056 g (93%). ^{1}H NMR (300 MHz $CDCl_3$, 22 °C): $\delta = 7.28-7.33$ (m, 80H; H in outer aromatic rings of [G-3]), 6.51–6.62 (m, 42H; H in inner aromatic rings of [G-3]), 4.89, 4.94 (d, 60H; benzylic CH_2 in [G-3]), 3.55–3.73 (m, 344H; CH_2CH_2O in PEG). All other experiments were performed by the same procedure with similar yields.

Indigoid *para*-Quinodimethanes**

By *Rudolf Gompper,** *Robert Kellner*, and *Kurt Polborn*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Indigo and indigoid compounds are important technical dyes because of their applications in coloration, especially in textile dying. The nature of the indigo chromophore was studied intensively and is now well understood.[1b, 2] However, the search for new indigoid compounds continues. The UV/VIS absorption of these systems at very long wavelengths makes them attractive materials for optical data storage,[3, 4] since such materials must absorb in the near-IR (>750 nm). This can be accomplished, for example, by complexation.[5] Alternatively, the indigo chromophore and structurally related chromophores can be fused to π electron systems to produce compounds with the desired bathochromic shift and the stability of the indigoid system. We have succeeded in synthesizing *para*-quinodimethane homologues of this type, **1**–**3**; their absorption is at a consider-

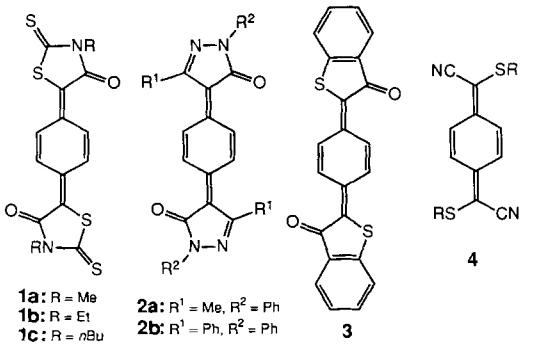
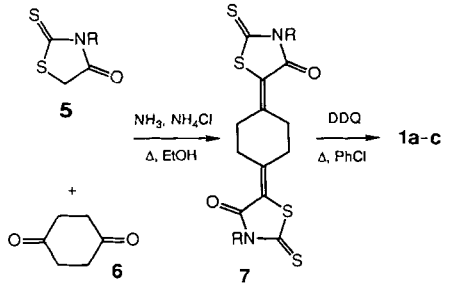
[**] This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ably longer wavelength than that of the related vinylogues. For example, the absorption of **3** (λ_{max}(*p*-xylene) = 626 nm) has a wavelength about 100 nm greater than that of **11** (λ_{max}(*p*-xylene) = 528 nm).[6]



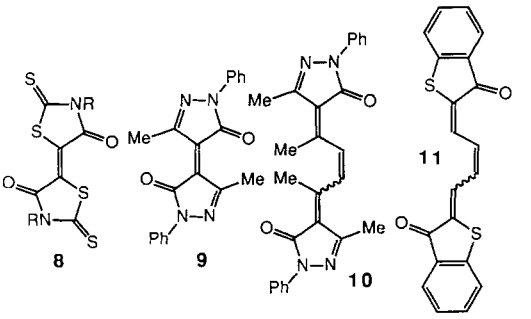
The first *para*-quinodimethane derivatives **4** with the donor(D)–acceptor(A) pattern of the indigo chromophore were reported during the course of our investigations by Iwatsuki et al.[7] ; however, these compounds are quite unstable and not suited for the applications we have in mind. The incorporation of the D-A functional groups into five-membered rings should increase the stability of the compounds and make the chromophore system more similar to that of indigo.

The rhodanines **5** were warmed with cyclohexane-1,4-dione (**6**) in ethanol. This solution was treated with concentrated ammonia followed immediately by a hot saturated solution of aqueous ammonium chloride to give the condensation product **7** (**7a**: m.p. 254–256 °C; λ_{max}(DMSO) = 356 nm (ε = 64600); **7b**: m.p. 280–282 °C; λ_{max}($CHCl_3$) = 357 nm (ε = 74100); **7c**: m.p. 262–264 °C; λ_{max}($CHCl_3$) = 357 nm (ε = 74100). In contrast to **7a–c**, compound **7d** is sufficiently soluble in deuterochloroform at room temperature; its ^{13}C NMR spectrum displays two sets of signals indicating that compounds **7** are mixtures of the (*E*) and (*Z*) isomers.

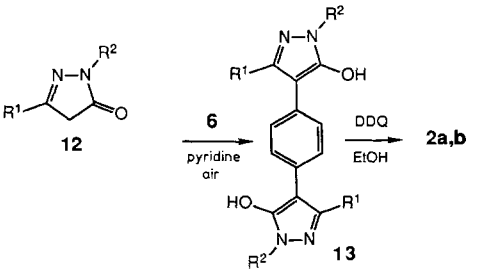


5,7: **a**: R = H ; **b**: R = Me ; **c**: R = Et ; **d**: R = *n*Bu

The dehydrogenation of **7b–d** to the amorphic quinodimethanes **1**, which range in color from dark violet to black (**1a**: m.p. 333–335 °C; λ_{max}($PhNO_2$) = 576 nm (ε = 97700)), was accomplished with an excess of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in refluxing chlorobenzene. **7a** could not be dehydrogenated to the corresponding quinodimethane with DDQ. In comparison to the birhodanines **8**[8, 9] the quinodimethane homologues **1** absorb at wavelengths about 140 nm longer. The extinction coefficients of **1** are larger than those of **8** (**8**, R = *n*Bu: λ_{max}($PhNO_2$) = 437 nm (ε = 36300), as is generally the case upon extension of the chromophore.

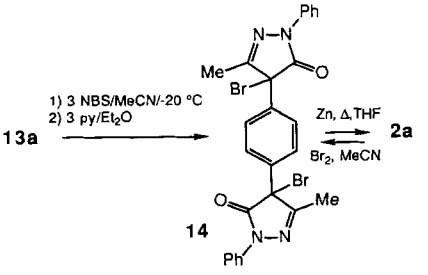


2-Pyrazolin-5-ones **12** reacted with **6** in pyridine in the presence of air to provide phenylenedipyrazoles **13** (**13a**: colorless, crystalline powder, m.p. > 340 °C (decomp); **13b**: m.p. 312–313 °C (decomp); **13c**: yellow, crystalline powder, m.p. 263–265 °C; **13d**: m.p. > 360 °C). The dehydrogenation of these compounds to the dark-blue to black *para*-quinodimethane derivatives **2a,b** proceeded best with DDQ (**2a**: small, dark-blue needles, m.p. 262 °C (decomp); λ_{max}($CHCl_3$) = 705 nm (broad, ε = 5750); λ_{max}(DMF) = 625 nm (ε = 2500), 705 (shoulder, ε = 1800); **2b**: small, black needles, m.p. 297 °C (decomp); λ_{max}(DMF) = 630 nm (broad, ε = 1000)).



12,13: **a**: R¹ = Me, R² = Ph ; **b**: R¹ = Me, R² = *n*Bu
c: R¹ = Ph, R² = Ph ; **d**: R¹ = Me, R² = CH_2Ph

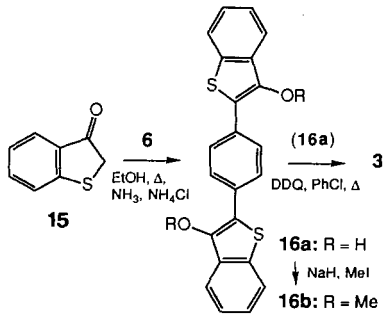
Alternatively, **13a** can be brominated to **14** with *N*-bromosuccinimide (NBS) and then reduced to **2a** with zinc powder. Treatment of **2a** with bromine regenerated **14** (yellow powder, m.p. 172–173 °C).



Compound **2a** is the quinodimethane homologue of pyrazole blue (**9**). The insertion of the quinodimethane system (**9** → **2a**) causes a bathochromic shift of the longest wavelength absorption of about 110 nm. In comparison to **10**,[10] the vinylogue of **9** described as red but not more thoroughly

analyzed, compounds **2a,b** absorb at considerably longer wavelengths.

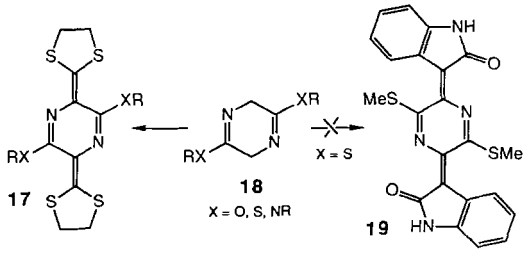
The reaction of oxobenzo[*b*]thiophene (**15**) with **6** in refluxing ethanol in the presence of a mixture of ammonia and ammonium chloride afforded the yellow phenylenebis(hydroxybenzothiophene) **16a** (yellow needles, m.p. 281 °C; λ_{max}(DMSO) = 387 nm (ε = 35 500)). The methylation of the Na salt of **16a** led to **16b** (yellow needles, m.p. 220–221 °C). Dehydrogenation of **16a** with DDQ yielded the new quinodimethane **3** (black microcrystals, m.p. 328 °C; λ_{max}(*p*-xylene) = 626 nm (ε = 57 500)).

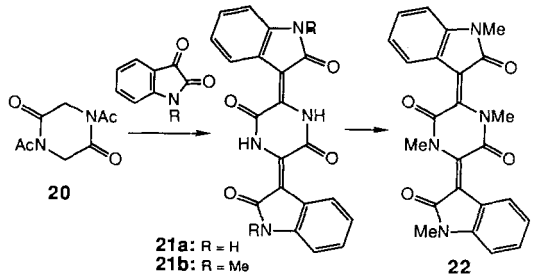


It is typical of the indigoid systems that upon extension of the central π electron system by one or two double bonds, the longest wavelength absorption maximum undergoes a hypsochromic shift,[11–13] rather than a bathochromic one as is seen for the cyanines, merocyanines, and polyenes.[1c, 14] The case is different for **3**, which absorbs at a wavelength 82 nm longer than that of *trans*-thioindigo (λ_{max}(*p*-xylene) = 544 nm[6]).

In cyclovoltammetric studies the quinodimethanes can be reduced reversibly to semiquinodimethanes which can be reduced further reversibly to dianions. Since the difference in potentials for the two redox processes is large enough (>100 mV), two single-electron transfer steps can be observed. The quinodimethanes **2** are somewhat stronger electron acceptors than the quinodimethanes **1**. Interestingly, tetracyanoquinodimethane with E_1 = 0.37 V (in dimethylformamide (DMF)) is only a slightly stronger electron acceptor than **2b** (E_1 = 0.28 V (in DMF)).

We were able to show previously that the dihydropyrazine derivatives **18**, obtained from diketopiperazine, can be treated with 1,3-dithiolium salts to provide tetradonor-substituted 2,5-diazaquinodimethanes **17**.[15] Thus, indigoid 2,5-diazaquinodimethane derivatives **19** should be accessible, for example from the analogous reaction of isatin and **18** RX = MeS. We were not successful with this reaction. The most promising candidates for the production of indigoid diazaquinodimethanes remain compounds related to the violet bis(oxindolylidene)diketopiperazine **21a**,[16] prepared from 1,4-diacetylpiperazine-2,5-dione (**20**) and isatin. We also obtained the violet bis(*N*-methyloxindolylidene)-





diketopiperazine **21b** (violet powder, m.p. > 360 °C; λ_{max}(solid) = 550 nm; λ_{max}(dimethyl sulfoxide) (DMSO)) = 490 nm (ε = 19 500); λ_{max}(H_2SO_4) = 469 nm) by treating **20** with *N*-methylisatin in DMF in the presence of triethylamine at room temperature. All attempts at converting **21b** into an RO-substituted 2,5-diazaquinodimethane derivative of type **19** failed. The reaction of the Na salt of **21b** with methyl iodide furnished the tetramethyl compound **22** (orange–red needles, m.p. 300 °C (decomp); λ_{max}(solid) = 357 nm; λ_{max}(DMSO) = 359 nm (ε = 24 000); λ_{max}(H_2SO_4) = 442 nm).

The electron spectra of **21a** and **21b** differ only slightly. The "medium effect" known for indigo is remarkably strong here: in the solid phase as a thin layer on a quartz plate **21a** absorbs at a wavelength 54 nm longer than when dissolved in DMSO, for **21b** even 60 nm longer. In contrast, the electron spectra of **22** as a solid (thin layer on a quartz plate) and dissolved in DMSO are almost identical. Yellow **22** absorbs

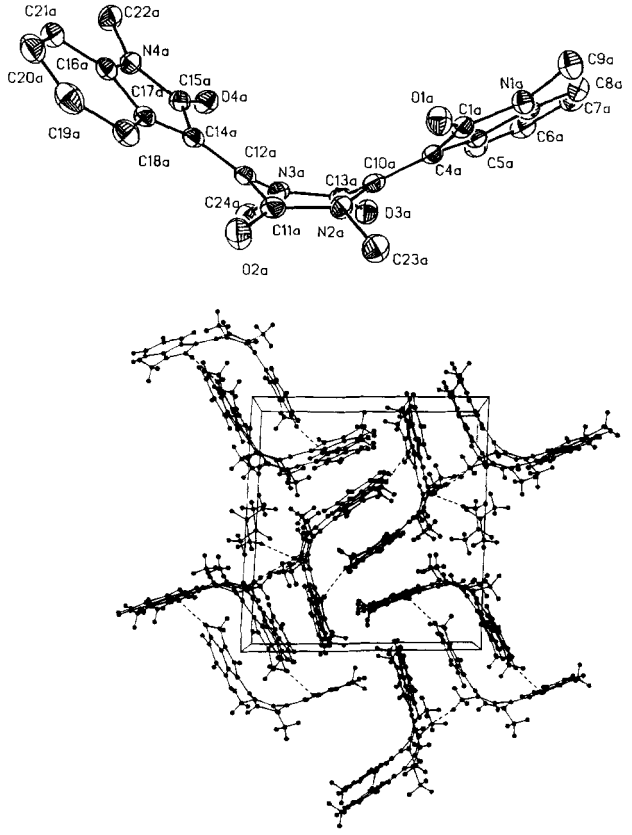


Fig. 1. Top: Crystal structure of **22** (ORTEP)[17]: Selected bond lengths [pm] and angles [°]: O1a-C1a 121.5(6), C1a-N1a 136.9(6), C1a-C4a 149.3(8), C14a-C17a 145.5(7), C4a-C10a 136.7(7), C10a-C13a 149.8(8), C10a-N2a 139.6(6), C13a-O3a 120.9(6), C13a-N3a 136.6(7), C11a-N2a 137.5(7), C23a-N2a 147.5(7); C11a-C12a-C14a 124.0(5), C12a-C14a-C15a 120.7(4), N3a-C12a-C11a 111.9(4), N2a-C11a-C12a 114.2(5), C12a-N3a-C13a 121.1(4), C12a-N3a-C24a 121.0(4), O2a-C11a-C12a 123.5(5). Bottom: Unit cell of **22**.

at a wavelength substantially shorter than **21a,b**. Thus, relative to the absorption maximum of **21b** in the solid state, that of **22** is shifted hypsochromically by 193 nm, in DMSO by 131 nm. The values measured for **21a** and **21b** in sulfuric acid display a slightly negative halochromism relative to those in DMSO; however, **22** shows a strongly positive halochromism. The longest wavelength absorption band of **22** in sulfuric acid is therefore only 27 nm shorter than that of **21b**.

Compound **21a** is planar, whereby intramolecular hydrogen bonds play an important role.[16] On the basis of the similar electron spectra of **21a** and **21b** one may assume that **21b** is also planar. The situation is different for **22**. The X-ray structure analysis reveals that the compound is in a concave "flagpole-boat" conformation (Fig. 1). The unit cell contains four molecules of **22** and two molecules of acetone (solvent). Channels are formed by the meshing of the molecules of **22** that surround the acetone molecules. The compound thus belongs to the group of channel inclusion compounds. Further investigations should show if host **22** is able to accomodate other guest molecules besides acetone.

Experimental Procedure

16a: To a solution of **15** (7.56 g, 50.3 mmol) and **6** (2.80 g, 25 mmol) in 75 mL of ethanol under N_2 were added first 3.50 mL of concentrated aqueous ammonia and then a hot solution of 3.50 g of ammonium chloride in 6 mL of water. The mixture was heated at reflux for 2h. The precipitate was filtered off and treated successively with boiling water, ethanol, and toluene, whereby the residue was vacuum-filtered each time while still hot. The crude product was dried under vacuum, and recrystallized from 75 mL of nitrobenzene. (Purification of the crude product was also possible by extractive recrystallization from toluene.) Yield 5.56 g (59%).

3: A solution of **16a** (2.50 g, 6.68 mmol) and DDQ (10.6 g, 46.5 mmol) in 200 mL of water-free chlorobenzene was heated at reflux for 6h under argon. The solvent was then removed by distillation, and the residue was treated with boiling ethanol and vacuum-filtered while still hot. The product was dried under vacuum and purified by extractive recrystallization from 75 mL of toluene over 27d. Yield 1.66 g (67%).

[Lithium Piperidide–Piperidine]$_4$: Crystal Structure of an Oligomeric 1:1 Lithium Amide–Amine Mixed Complex, an Intermediate in the *N*-Lithiation of Amines**

By *Gernot Boche,* Ira Langlotz, Michael Marsch, Klaus Harms,* and *Norma E. S. Nudelman**

The importance of lithium amides $LiNR^1R^2$ (R^1, R^2 = aliphatic and/or aromatic substituents) in organic synthesis is amply documented by the recent intensive investigations of their structures in the solid state and in solution, and by means of calculations; the same holds for lithium imides $LiN{=}CR^1R^2$.[1-5] There is, however, not much known about lithium amide–amine mixed complexes, although such species are likely to be formed during, for example, the preparation of lithium amides from amines (in excess) with organolithium compounds RLi, or the reactions of lithium amides with CH-acidic compounds R^1H to give R^1Li and amine. Lithium amide–amine complexes are also of special significance in the carbonylation reaction of lithium amides.[6-8] Crystal structure determinations have been performed on the monomeric [Ph(2-Pyr)NLi · HN(2-Pyr)Ph · hmpa] (= pyridyl, hmpa = hexamethylphosphoric triamide), though an extra hmpa donor ligand cocrystallizes,[9] and of the lithiated azomethine *N*-(cyclohexylidene)phenylamine, which crystallizes with diisopropyl amine to give [Ph(*cyclo*-C_6H_9)NLi · HN*i*Pr_2]$_2$.[3c] Very recently the crystal structure of a sodium ketimide that forms "an unexpected complex" with nonmetalated ketimine, [(*t*$Bu_2C{=}NNa)_4$ · (HN=C*t*Bu_2)$_2$], has been published.[10] Here we report on the crystal structure of lithium piperidide (**1**-Li), which crystallizes with piperidine (**1**-H) in a 1:1 ratio (see Fig. 1).[11]

$[H_2\overline{C(CH_2)_4}NLi \cdot H\overline{N(CH_2)_4}CH_2]_4$ [**1**-Li · **1**-H]$_4$

[**] We thank Dr. R. Snaith, University Chemical Laboratory, Cambridge, United Kingdom, for very valuable discussions. This work was supported financially by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 260) and the Fonds der Chemischen Industrie.

As can be seen from Figure 1, a limited-length "concave" (N4-Li4-N6 144.0(5), Li1-N4-Li4 117.6(4), N1-Li3-N2 143.0(5), Li2-N2-Li3 116.4(3)°) ladder is formed, and only the terminal lithium atoms are complexed. The same structural type was found in model calculations of $[H_2NLi \cdot H_2O]_4$ to be the most stable one; the alternative eight-membered ring structure is 17.1 kcal mol^{-1} higher in energy, while the ladder with H_2O molecules on each lithium atom is 62.9 kcal mol^{-1} less favorable.[15] This reflects the steric

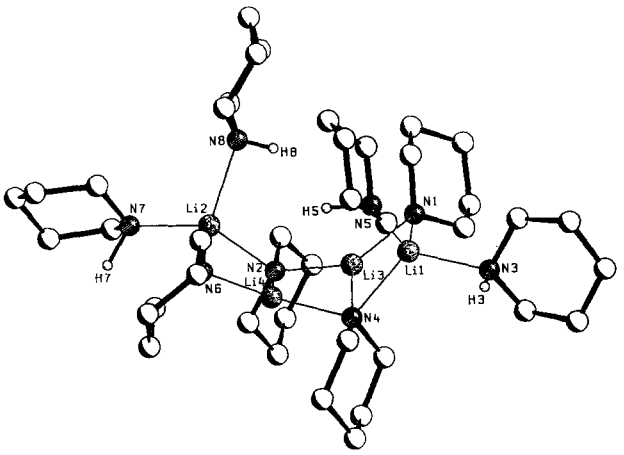

Fig. 1. Crystal structure of [**1**-Li · **1**-H]$_4$ [11]. Selected distances [pm] and angles [°] are: Li2-N2 216.8(12), N2-Li4 207.6(10), Li4-N6 193.3(12), N6-Li2 208.0(12), N2-Li3 203.5(11), Li3-N4 206.1(10), N4-Li4 205.6(10), Li3-N1 195.3(12), N1-Li1 204.1(13), Li1-N4 214.3(11), Li2-N7 210.0(13), Li2-N8 217.2(12), Li1-N3 213.9(13), Li1-N5 221.7(11), N4-N5 347.3(6), N4-H5 333.5(10), N4-N3 369.1(7), N4-H3 383.0(7), N4-N8 531.0(6), N4-H8 471(5), N4-N7 625.9(7), N4-H7 646(5), N2-N8 346.4(6), N2-H8 316(5), N2-N7 369.7(8), N2-H7 408(5), N2-N5 535.3(6), N2-N3 630.4(7), N2-H3 672.3(7), N1-N5 368.0(8), N1-H5 394(5), N1-N3 342.5(6), N1-H3 416.7(6), N1-N8 465.1(8), N1-H8 376(5), N1-N7 695.4(9), N1-H7 759(5), N4-Li4-N6 144.0(5), L1-N4-Li4 117.6(4), Li2-N2-Li3 116.4(4), N1-Li3-N2 143.0(5), Li1-N1-Li3 76.3(5), N1-Li3-N4 107.6(5), Li1-N4-Li3 71.9(4), N1-Li1-N4 101.5(5), N2-Li2-N6 99.1(4), Li2-N6-Li4 77.4(5).

crowding that would exist around the central Li atoms (Li3 and Li4 in the structure of [**1**-Li · **1**-H]$_4$) if ligand molecules (piperidine) were also coordinated there instead of exclusively at the outer Li atoms (Li1 and Li2). The internal ring N2-Li4-N4-Li3 is not planar. N2 and N4 lie 0.19(3) pm below, Li3 (0.19(3) pm) and Li4 (0.18(3) pm) above the best plane. Relatively short (Li3–N1 195.3(12) pm) and long (N1–Li1 204.1(13) pm) bonds are found alternating along the uncomplexed ladder edges (as at N1, for example). The Li3-N1-Li1 angle is 76.3(5); while the N1-Li1-N4 angle is much wider (101.5(5)°). A similar situation holds around Li2 and N6 (see Fig. 1). The internal ring has relatively long bonds (203.5(11) to 207.6(10) pm). The longest Li–N bonds occur at the complexed Li atoms such as Li1: Li1–N4 214.3(11), Li1–N3 213.9(13), and Li1–N5 221.7(11) pm. A similar situation is observed in the structurally related complex $[(H_2\overline{C(CH_2)_3}NLi)_4(tmeda)_2]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylene diamine), which also has 4 Li:4N donor centers, but a lithium:ligand ratio of 2:1 (furthermore, tmeda is a tertiary amine).[16] The crystal structure of the first oligomeric 1:1 lithium amide–amine mixed complex [**1**-Li · **1**-H]$_4$ therefore fits nicely the experimental and theoretical data so far collected for lithium amide structures.[1, 2] In addition, it is of special interest with regard to the mechanism of the formation of one of the two structural types of lithium amides, the ladders. $(R_2NLi)_n$ rings are formed when R is large or floppy; ladders of medium or long length are observed when R is small or tied together as in the case **1**-Li.[1, 2] Thus, the oligomeric [**1**-Li · **1**-H]$_4$ is almost a long ladder, but not fully; a long ladder would form if all the piperidine molecules were deprotonated: [**1**-Li · **1**-H]$_4$ is an intermediate in the formation of lithium amides from RLi and amines.[17]

Moreover, the crystal structure of [**1**-Li · **1**-H]$_4$ agrees completely with investigations on the carbonylation reactions of lithium amides in solution and with reactivity investigations on them, studied extensively by Nudelman et al.[6–8] Thus, the existence of a 1:1 complex of **1**-Li and **1**-H was concluded from ^{13}C NMR investigations of **1**-Li in THF in the presence of **1**-H. Furthermore, workup of the reaction mixture of **1**-Li (prepared from **1**-H) with CO under different conditions (hydrolysis, deuterolysis, oxidation, and reaction with cyclohexanone) likewise suggested an apparently very stable 1:1 mixed complex of **1**-Li and **1**-H to be the reactive intermediate.[6–8]

Experimental Procedure

Preparation of the crystals of [**1**-Li · **1**-H]$_4$: *n*-Butyllithium (1.00 mmol, 0.63 mL, 1.6 M in hexane) was added to a solution of piperidine (2.00 mmol, 0.17 g) in hexane (0.63 mL) under a nitrogen atmosphere at room temperature. The crystals were formed on cooling the solution to 4 °C. The solvent was removed and the crystals were washed with 2 mL of pentane and dried under vacuum at room temperature. Yield: 91.2 mg (62%); see also ref. [7f].

[17] It is probably long lithium amide ladders that precipitate from the solution immediately after the last complexing amine molecules have been lithiated [1, 2].

Interactions Between Acyclic and Cyclic Peralkylammonium Compounds and DNA**

By *Hans-Jörg Schneider** and *Thomas Blatter*

The quantification of electrostatic interactions between DNA[1] and positively charged effectors is as important for an understanding of the biological function of biogenic amines,[2] proteins, and peptides[3] as for the development of cytostatic agents.[4] Polyamines are bound predominantly in the strongly negatively charged larger groove of the double helix by coulombic interactions with the ribose phosphate groups and presumably also by formation of hydrogen bonds with the nucleobases.[5] We hoped to obtain further information on the mechanisms of molecular recognition relevant here by systematic variation of the structure of the polyamine – including hitherto little investigated[5d] peralkylated amines as well as amines conformationally restricted by cyclization. Using the principle of additive increments,[6] with which we have previously found a surprisingly uniform coulombic interaction energy of $\Delta G_{ES} = (5 \pm 1)$ kJ mol^{-1} for each salt bridge (at an ionic strength of about 0) for over 50 synthetic complexes,[6b] we first analyzed known equilibrium constants[7] for complexation of the biogenic amines **1** ($K = 3.2 \times 10^3$ M^{-1}); **2** ($K = 5.8 \times 10^4$ M^{-1}) and **3** ($K = 2.1 \times 10^5$ M^{-1}) with DNA (Scheme 1). When the differences in the number n of the salt bridges formed between N^+ (amine) and P-O$^-$(DNA), as evident from computer-supported molecular modeling,[5c] are taken into account, the following values for the coulombic increment ΔG_{ES} are obtained: **1** ($n = 3$, $\Delta G_{exp} = 20$) 6.7, **2** ($n = 6$, $\Delta G_{exp} = 27$) 4.5, and **3** ($n = 7$, $\Delta G_{exp} = 30$) 4.3 (all ΔG values in kJ mol^{-1}). The average value of 5.2 kJ mol^{-1} for the interaction with DNA lies in the same range as that of all previously analyzed salt bridges,[6] although molecular simulations[5c] indicate the presence of two to three additional N^+-H hydrogen bonds with the nucleobases. The existence of a largely constant bonding increment per N^+ group is in agreement with interactions between the DNA and protonated polyamines[8] and also between polylysine and polynucleotides.[9]

The comparison of the results of measurements on peralkylated polyammonium ions (Scheme 1) with those of the analogous compounds containing protonated nitrogen atoms makes it possible to estimate the contribution of the additional hydrogen bonds present for the protonated compounds in binding to DNA. By analogy to the comparable investigations of Stewart et al. with protonated polyamines,[8] we have used the polyamine concentration level (C_{50}), which leads to a 50% reduction in the fluorescence intensity of the intercalated probe ethidium bromide, as a measure of the interaction with the B-DNA double helix (calf thymus). These C_{50} values provide, at least approximately, a measure of the various equilibrium constants for complexation of the polyamines with the DNA.[8] The affinities of the *alkylated* open-chain compounds observed in this way generally lie only a little lower than those of the correspondingly charged *protonated* compounds (compare, e.g. **4** with **3**). The contribution of hydrogen bonds is therefore almost negligibly small; this result is in agreement with observations on amide hydrogen bridges, which are completely suppressed[11] by protic solvents,[10] especially water. This result does not, however, exclude small differences in selec-

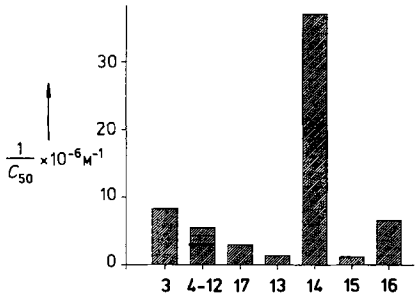
tivity arising from additional hydrogen bridges, for example, by a partial base-selective recognition.

Variation in the alkyl chains in the tetraammonium ions **4** to **12** leads to surprisingly small changes in the C_{50} values (Scheme 1), essentially in agreement with Stewart's results[8] for protonated polyamines. Even the introduction of an arene as spacer between the N^+ groups (**9**–**12**, Scheme 1) leads to similar constants, explicable by four largely undisturbed salt bridges. This obviously is a consequence of the small distance dependence of the coulombic potential, but also the high flexibility of the open-chain compounds.

Macrocyclic peralkylated tetraammonium compounds **13**–**17** can behave quite differently. These compounds display an effect towards DNA that is up to 15 times higher than that for the open-chain analogues (Scheme 1 and 2). (All the



Scheme 2. Affinities of the polyammonium derivatives **3**–**17** for B-DNA (shown as values of $1/C_{50} \times 10^{-6}\,M^{-1}$); the minimum and maximum values for the acyclic compounds **4**–**12** are indicated within the columns.

azoniacyclophanes[12] **13**–**16** employed were obtained by a one-pot cyclization of bistosylated bis(4-aminophenyl) methane with α,ω-dibromoalkanes, and subsequent permethylation after removal of the tosyl groups.[13]). For a given number of N^+ groups, azoniacyclophane **14** shows by far the highest interaction of a tetraamine with DNA that has been seen to date. Also, in contrast to the other cyclophanes, the change in melting point of the DNA complex is markedly higher for **14**, $\Delta T = 5.1\,^{\circ}C$ (Scheme 1).

What are the reasons for the particular high efficiency of an azoniacyclophane? Since the host compound **16**, for example, binds adenosine phosphate by enclosing the nucleobases within the cyclophane cavity with $K = 10^3$ to $10^4\,M^{-1}$,[14] and a larger acridinophane[15] has shown itself to be a potent intercalator[16] (by violation of the "neighbor exclusion" principle[17], according to which the inclusion of further intercalators between neighboring base pairs is not usually possible), an additional contribution to binding of the cyclophane to DNA by intercalation could not be ruled out. To examine this, we have conducted NMR and viscosity measurements, both of which exclude intercalation. Whereas intercalation typically causes shifts in the NMR signals of the intercalate of $\delta = -0.7$,[18] for example, by ring current effects, we have observed maximum differences of $\Delta\delta = 0.02$ for all aromatic protons. Moreover, the cyclophanes show similarly small changes in viscosity ($L/L_0 = 0.95$ to 1.05) with DNA as, for example. the open-chain spermine **3**, whereas intercalators cause considerable increases in viscosity[19] (e.g. for chinacrin: $L/L_0 = 1.16$). Both methods also show the lack of intercalation for the open-chain compounds containing aryl units (**11** and **12**). Electrostatic bonding therefore remains the dominating factor, also for the azoniacyclophanes. Molecular simulation shows that the particularly effective macrocycle **14** finds sufficient space in the large groove of the DNA double helix, thereby permitting predominantly ion-pair contact between the positive $^+$N-C-H protons and the ribose phosphate oxygen atoms.

In summary, the following results have been obtained: 1. Ionic bonding between polyamines and DNA can be described by additive increments of $5 \pm 1\,kJ\,mol^{-1}$ per salt bridge, thereby falling into the general range of numerous inorganic and organic ion pairs. 2. Peralkylated compounds have almost the same affinity for DNA as for example, biogenic amines, whereby the small contribution of hydrogen bonds to the bonding with DNA is also evident here. 3. Relatively rigid azoniacyclophanes show the same or higher affinities, although their arene units do not participate in intercalation.[20]

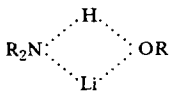
A Novel Six-Center Deprotonation–Lithiation Reaction Mechanism Supported by the X-Ray Structure Analysis of a Lithium Carbazolide**

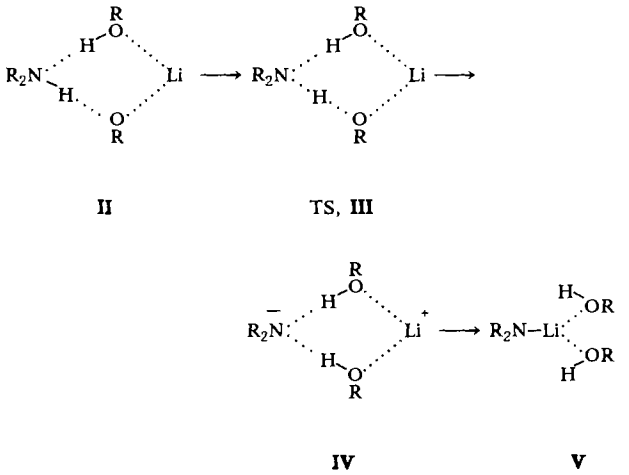
By *Christoph Lambert, Frank Hampel,* and *Paul von Ragué Schleyer**

Although deprotonation–metalation reactions of NH-acidic compounds with LiOR are important in organic chemistry,[1] details concerning the mechanism are scarce. Earlier experimental and theoretical investigations have assumed a four-center transition state (TS) **I**.[2]



TS, **I**

We propose an alternative *two-step* mechanism, which could occur in cases of similar NH and OH acidities in protic media (Scheme 1). This mechanism involves a precursor



II TS, **III** **IV** **V**

Scheme 1.

complex **II** (comprising the NH compound, the LiOR base, and an additional H-bound ROH solvent molecule), a six-center transition state **III** and a product complex **IV**. No direct Li–N contact is present in the transition state or in these complexes. Evidence for this pathway is given by a single X-ray structure of a lithium carbazolide (**1**,

$[Li(tBuOH)_2 \cdot (thf)_2][cb]$ **1**

Hcb = carbazole) (Fig. 1).[3] This complex was synthesized by deprotonation of carbazole in THF by a mixture of *t*BuOLi/*t*BuOH in THF. While the deprotonation with *n*BuLi in THF yielded a lithiocarbazole dimer,[4] a monomeric species with *t*BuOH as a ligand and without any Li–N contact (*d* Li-N = 3.636 Å) was obtained under the present conditions.

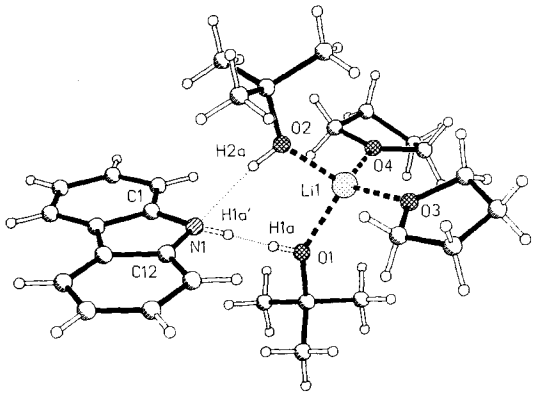


Fig. 1. Structure of **1** in the solid state. Selected bond distances [Å] and angles [°]: Li1-O1 1.924(12), Li1-O2 1.896(10), Li1-O3 1.939(11), Li1-O4 1.929(10), N1-O1 2.727(7), N1-O2 2.770(7), N1-Li1 3.636(10), O2-H2a 0.860(57) N1···H2a 1.913(56), O1-H1a 0.945(120), N1···H1a 1.844(103), N1-H1a' 0.851, O1···H1a' 1.877; O1-Li1-O2 95.8(4), O3-Li1-O4 101.0(4), O1-Li1-O3 111.4(5), O2-Li1-O4 112.7(4), O1-Li1-O4 114.0(7), O2-Li1-O3 112.4(7), Li1-O2-H2a 103.9(4.0), Li-O1-H1a 86.1(8.0), C1-N1-C12 105.7(5), C1-N1-H1a' 120.9, C12-N1-H1a' 125.5, N1-H2a-O2 174.8, N1-H1a-O1 154.4, N1-H1a'-O1 175.4.

The structural analysis of **1** exhibits disorder for a proton undergoing transfer. At 200 K the structure refinement gave ca. 40% occupation probability for the proton site at the carbazole nitrogen (H1a') and about 60% occupation probability for the site at a *tert*-butyl alcohol oxygen atom (H1a). The occupation probabilities correspond to a slightly asymmetric double minimum potential where the ΔG difference of the minima is about -0.4 kcal mol^{-1}. Therefore we reason that the acidity of carbazole and *tert*-butyl alcohol in the solid state must be quite similar. In fact, the differences in acidity are very small in protic media: pK_a (carbazole) = 17.06 in DMSO/H_2O (DMSO = dimethyl sulfoxide);[5] pK_a (*t*BuOH) = 16.54 in EtOH/EtO^-.[6] Hence, complex **1** provides a good structural model for both the precursor complex **II** and the product complex **IV**. The second *tert*-butyl alcohol molecule also incorporated into the structure obviously stabilizes the complexes **II** and **IV** (as well as the assumed transition state **III**) by forming of a six-center hydrogen-bridged arrangement. The X-ray structure supports a model in which hydrogen bonding is not only important in stabilizing anionic centers,[7] but may also be involved in the proton-transfer step. After proton transfer (first step) in solution, a rearrangement (second step) could take place to give an *N*-lithiated carbazole (as in **V**) by a stepwise rather than by a concerted mechanism.

Only a few structures of lithiated NH- or CH-acids complexed with ROH derivatives have been reported.[8] None of these, however, exhibit a partial transfer of the proton to the anionic (lithiated) center. The structure of a water-complexed lithiomalonodinitrile we reported recently[8e] also shows disorder, but this involves an H_2O proton and the ligand, and not the anionic center.

Furthermore, it is interesting that **1** is a solvent-shared ion pair rather than a contact ion pair as commonly observed for lithiated amines.[9] This preference of **1** is noteworthy, since

solvent-shared or solvent-separated ion pairs are expected to be less favorable for lithium amides than for lithium-carbon compounds due to the greater electrostatic Li–N interaction (stronger N–Li than C–Li bonding[10]) in amides.[11] Indeed, only few solvent-separated lithium amide structures are known.[12] In all these cases the ion-separation is induced by crown-ether complexation of the Li^+ ion, which is favored entropically over complexation by monodentate ligands like water, alcohols or ethers.[13]

Our direct experimental demonstration of a reaction pathway for proton transfer encourages the search for further examples.

Experimental Procedure

To a solution of 669 mg (4 mmol) carbazole in 4 mL THF a mixture of 2.5 mL (4 mmol) 1.6 M *n*BuLi/hexane and 1.5 mL (16 mmol) *tert*-butyl alcohol in 4 mL THF (the mixture was prepared at 0 °C and contains 1 equivalent *t*-BuOLi) was added dropwise at 0 °C. The colorless solution was stirred at room temperature for 1 day and kept at 5 °C for 1 day and at −18 °C for 1 day, during which time colorless crystals formed.

Dynamic Proton Exchange in the Hydrogen Dihydroxide Ion $H_3O_2^-$ of the Hydroxosodalite Hydrate $[Na_4(H_3O_2)]_2[SiAlO_4]_6$: ^{1}H MAS NMR Spectroscopic Evidence**

By *Günter Engelhardt,** *Peter Sieger*, and *Jürgen Felsche*

Structure and properties of the hydrogen dihydroxide ion $H_3O_2^-$, that is the monohydrate of the hydroxide ion, $[H–O\cdots H\cdots O–H]^-$, in which OH^- and H_2O can no longer be distinguished, have been of great interest both for theoreticians and also for experimenters in the last 15 years. Optimized structures were proposed by several authors from ab initio calculations, [1–3] and following experimental investigations into the hydration of OH^- in the gas phase[4] performed earlier several papers since 1979 have reported about crystal structures with discrete $H_3O_2^-$ ions (see, e.g., ref. [5–8] and references cited therein). Thus, in compounds of the natrocalcite type[6, 7] as well as in crystalline aqua hydroxo complexes of transition metals with organic ligands[5, 8] an (on average) symmetrical $[H–O\cdots H\cdots O–H]^-$ ion was observed, characteristic of which is a strong central hydrogen bond $O\cdots H\cdots O$ with $O\cdots O$ distances of 2.3–2.6 Å. In these compounds the $H_3O_2^-$ ion is coordinated by neighboring oxygen atoms and/or metal ions[6–8] or bonded to additional H_2O molecules by weak hydrogen bonds.[5]

Ardon and Bino discussed the significance of $H_3O_2^-$ as a bridging ligand in the primary hydrolysis products of metal salts and the possibility of its existence in aqueous solutions of aqua hydroxo complexes.[8] In the same work it is indicated that detailed investigations of the properties of the $H_3O_2^-$ ion can contribute to a deeper understanding of substitution and redox reactions, including enzymatic reactions, in which a hydrogen transfer via H_3O_2 bridges is conceivable. For such considerations apart from the static (or dynamically averaged) crystal structures, as obtained by X-ray or neutron diffraction, information about the dynamic proton exchange and reorientation processes of the $H_3O_2^-$ ion is of particular interest. Such information can be obtained, for example, from ^{1}H NMR spectroscopy, which was already widely used for the characterization of molecular dynamic processes in liquids occurring in a time interval of between approximately 1 s and 10^{-6} s. The investigation of solids however can be complicated by strong signal broadening due to dipole–dipole interactions of neighboring H atoms. This can be avoided (at least partly) by special measurement techniques (e.g. magic angle spinning (MAS), combined rotation and multipulse spectroscopy (CRAMPS)) as well as by the use of samples with only a few H atoms that experience no, or only weak, dipolar coupling. Therefore, as the first step towards the characterization of the dynamics of the $H_3O_2^-$ ion investigations on an isolated $H_3O_2^-$, that is, a $H_3O_2^-$ which is not or only weakly bound to other proton-containing species, would be desirable.

A suitable system for such investigations is sodium hydroxosodalite hydrate $[Na_4(H_3O_2)]_2[SiAlO_4]_6$, which according to the crystal structure recently published by Wiebcke et al.[9] contains discrete $H_3O_2^-$ ions, isolated in the sodalite cages. Figure 1 shows such a sodalite cage ($[4^6 6^8]$ polyhedron) built from alternating SiO_4 and AlO_4 tetrahe-

dra, from which the sodalite framework is formed by three-dimensional connections with identical cages via four- and six-membered rings. Each cage contains one $H_3O_2^-$ ion and four Na^+ ions tetrahedrally arranged over the six-membered ring windows, the latter are necessary for the charge compensation. Within the Na_4 tetrahedra the $H_3O_2^-$ ions show a six or twelvefold orientational disorder. One of the possible orientations is drawn in Figure 1. The short O2···O2 distance of only 2.36(4) Å in the ion determined from the X-ray diffraction data indicates the existence of a very strong central hydrogen bond, whereas the long H2···O1 and O2···O1 distances of 2.83 and 3.38 Å, respectively, definitely rule out hydrogen bonds between the terminal hydrogen atoms H2 and the framework oxygen atoms O1. Interactions between $H_3O_2^-$ ions in neighboring cages can also be ruled out because of the long distance and the mutual shielding by the Na^+ ions and the cage framework.

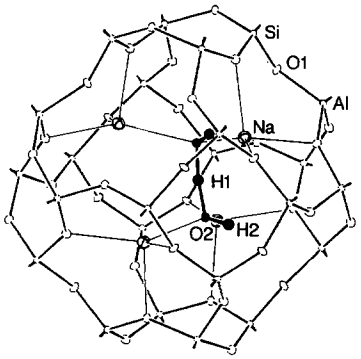

Fig. 1. Structure of $[Na_4(H_3O_2)]_2[SiAlO_4]_6$: $[4^66^8]$ sodalite cage with the $H_3O_2^-$ ion and four Na^+ ions as guest species [9].

A selection of the ^1H MAS NMR spectra of hydroxosodalite hydrate recorded in the temperature range between 365 and 155 K is reproduced in Figure 2. Apart from a sharp signal of an impurity (see below) whose position ($\delta = 5.0$) and line width up to 210 K remains unchanged, the spectra at 365 K and 335 K show only a broad signal at $\delta \approx 5$, superimposed with this sharp signal. With further decrease in temperature two signals at first broad, but up to 210 K becoming significantly narrower, occur at $\delta = -0.1$ and $\delta = 16.3$, which show an integral intensity ratio of 2:1. Thus, the spectra are typical for a dynamic exchange between two chemically nonequivalent kinds of protons occurring in the ratio 2:1; quite similar spectra are observed for analogous dynamic processes in the liquid phase.[10]

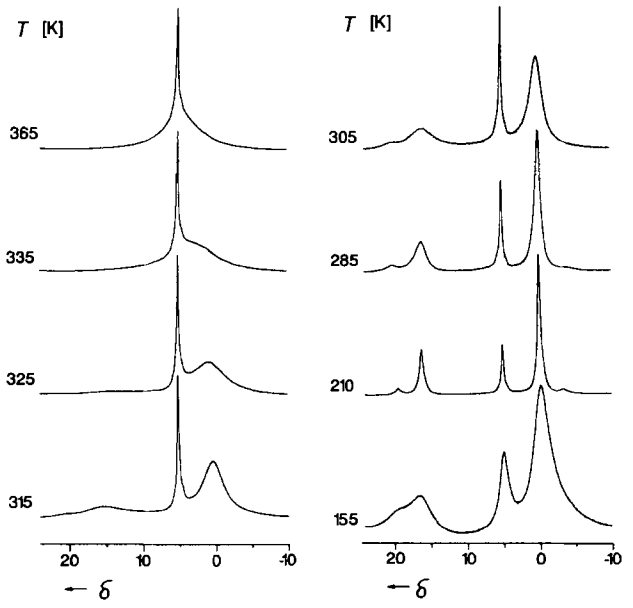

Fig. 2. ^1H MAS NMR spectra of the $H_3O_2^-$ ion in the sodium hydoxosodalite hydrate at several temperatures. The sharp signal at $\delta = 5$ stems from an impurity, the weak signals at $\delta \approx 20$ and $\delta \approx -4$ are spinning side bands.

On the basis of the chemical shifts and the relative intensities the signal at high field must be assigned to the two terminal H atoms H_t and the one at low field to the central H atom H_c of the $(H{-}O\cdots H\cdots O{-}H)^-$ ion.[9] The latter assignment is in excellent agreement with the results from ab initio calculations of the ^1H chemical shift of the free $H_3O_2^-$ ion. According to these calculations the central H atom has a chemical shift of $\delta = 16.3$[11] for a O···O distance of 2.42 Å. Furthermore, the assignment agrees with the linear correlation between OH···O distances and ^1H chemical shifts given by Yesinowski and Eckert.[12] The sharp signal at $\delta = 5.0$ is assigned to H_2O molecules found in small admixtures of hydrosodalite $[Na_3(H_2O)_4]_2[SiAlO_4]_6$, which is difficult to avoid during the preparation of the hyroxosodalite hydrate.[13] The narrow and up to 210 K unchanged line width of this signal shows that these H_2O molecules undergo a rapid dynamic reorientation and do not participate in the exchange process of the $H_3O_2^-$ protons.

Thus, the spectra in Figure 2 reveal unambiguously a dynamic exchange between the two terminal protons H_t and the central proton H_c of the $H_3O_2^-$ ion. On the NMR time scale this exchange occurs rapidly at 365 K (occurrence of only one signal) and becomes slower with decreasing temperature (two signals with decreasing line width). For such a dynamic process the position of the signal for rapid exchange (δ_{ct}) is the weighted population p average value of the positions of the signals at slow exchange: $\delta_{ct} = p_t\delta_t + p_c\delta_c$. With $p_t = 2/3$ and $p_c = 1/3$ $\delta_{ct} = 5.3$ is obtained which is in good agreement with the experimental value. Below 210 K an increasing broadening of all signals is observed (see spectrum at 155 K in Fig. 2), which in all probability is a result of the freezing of the dynamic reorientation of the whole $H_3O_2^-$ ion as well as the H_2O molecules of the impurity in the sodalite cage and the resulting increase of the dipole–dipole interaction of the H atoms.

From the half width $\Delta\nu$ of the signals measured at several temperatures the average life times τ_t and τ_c of the H atoms in the terminal and the central position respectively as well as the rate constants k and the activation energy E_a of the exchange process can be estimated. $\Delta\nu$ must be corrected for the residual line width occurring without exchange, for this the half width (80 Hz) of the signal of the water protons not participating in the exchange at $\delta = 5.0$ was used. For rapid exchange, that is, observation of only one signal $\tau_t = \Delta\nu/(4\pi p_t p_c^2 \Delta\delta^2)$ and $\tau_c = \Delta\nu/(4\pi p_c p_t^2 \Delta\delta^2)$ with $\Delta\delta = \delta_c - \delta_t$ (in Hz) is valid; in contrast, for slower exchange, that is, the occurrence of separate signals for H_t and H_c, $\tau_t = (\pi\Delta\nu_t)^{-1}$ and $\tau_c = (\pi\Delta\nu_c)^{-1}$ is valid.[14] Since the central H atom exchanges with two terminal H atoms, it follows that $\tau_c = \tau_t/2$. The rate constants k for the different temperatures T are given by $k = 2\tau_t^{-1} = \tau_c^{-1}$; from these the activation energy E_a of the proton exchange can be determined from the Arrhenius equation, $k = A \exp(-E_a/RT)$, by plotting lg k over $1/T$ (Fig. 3).

To avoid misrepresentations of the line widths as a result of the dipole–dipole interactions of the H atoms occurring at lower temperatures, only the ^1H MAS NMR spectra of the

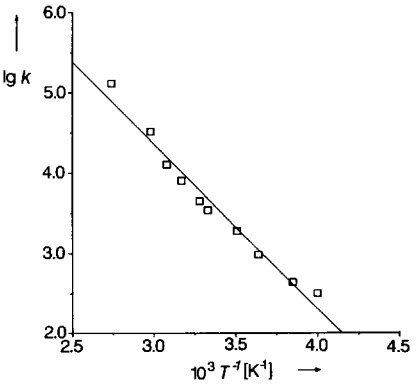

Fig. 3 Arrhenius plot of the rate constants k [s^{-1}] for the proton exchange in the $H_3O_2^-$ ion.

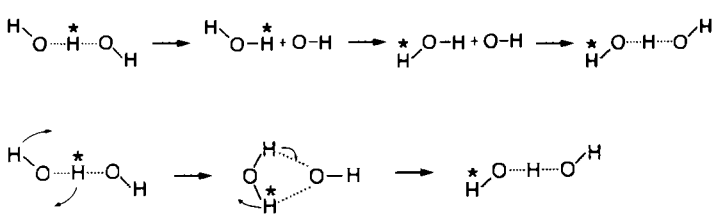
hydroxosodalite hydrate recorded between 365 and 250 K for ten temperatures were included in the evaluation. Average life times τ_c between 7.5×10^{-6} s at 365 K and 3×10^{-3} s at 250 K as well as an activation energy E_a for the exchange process of 39 ± 5 kJ mol^{-1} (estimation of the error according to [14]) were calculated this way. The activation energy lies significantly below the energy required for the dissociation of $H_3O_2^-$ into H_2O and OH^- (100 kJ mol^{-1}), determined experimentally[4] as well as by ab initio calculations.[3] Accordingly, the proton exchange in hydroxosodalite hydrate cannot occur via a complete splitting of the hydrogen bond and subsequent reorientation of the H_2O molecule (Scheme 1 top). Energetically more favorable and in better agreement with the estimated activation energy is the formation of a short-lived intermediate with bifurcated hydrogen bonds. According to ab initio calculations the energy of this intermediate is only 20–40 kJ mol^{-1} above the one of the structure of the $H_3O_2^-$ ion with a linear hydrogen bond.[1, 3] The exchange between terminal and central H atoms could thus occur as shown in Scheme 1 (bottom). Analogous ^{1}H MAS NMR investigations on the hydroxo alumogermanate sodalite hydrate $[Na_4(H_3O_2)]_2[GeAlO_4]_6$ showed that here a dynamic proton exchange within the $H_3O_2^-$ ion also occurs, for which an activation energy of 50 ± 10 kJ mol^{-1} was determined.

Our results show that even without the application of complicated multipulse techniques such as CRAMPS the ^{1}H MAS NMR spectroscopy of solids can produce highly resolved spectra, from whose temperature dependence detailed and selective information about the kinetics and mechanism of dynamic proton exchange and reorientation processes on the time scale of between approximately 10^{-2} and 10^{-6} can be derived. Recent investigations using inelastic and the quasi-elastic neutron scattering[15] showed that faster dynamic reorientation in the ps range, such as those proven for the OH group in the dehydrated hydroxosodalite $[Na_4(OH)]_2[SiAlO_4]_6$,[15, 16] do not occur in the $H_3O_2^-$ ion of the hydroxosodalite hydrate.



Scheme 1. Improbable (top) and probable (bottom) mechanism of the exchange process in the $H_3O_2^-$ ion.

Experimental Procedure

Crystalline sodium hydroxosodalite hydrate $[Na_4(H_3O_2)]_2[SiAlO_4]_6$ was prepared according to the procedure given in [13] from sintered Kaolin and carbonate-free, 16 M sodium hydroxide solution by hydrothermal synthesis at 623 K and 110 MPa. The crystals (0.5–1 mm) were ground into fine powders prior to NMR study. A microcrystalline powder of sodium hydroxoalumogermanate sodalite hydrate $[Na_4(H_3O_2)]_2[GeAlO_4]_6$ was obtained from GeO_2, γ-Al_2O_3, and carbonate-free, 16 M sodium hydroxide solution at 473 K and a reaction time of 14 days in teflon-coated steel autoclaves. The ^{1}H MAS NMR spectra were recorded at 400.13 MHz with a Bruker MSL-400 NMR spectrometer utilizing a double bearing MAS probe and ZrO_2 rotors with 4 mm diameter. Dry nitrogen was used as bearing and drive gas for the sample rotation, the rotation rate was kept constant at 8 kHz. For each spectrum 16 FIDs were accumulated, the length of pulse was 3 µs (corresponding to a flip angle of 65°), the pulse separation 3 s. The samples were thermostated with the bearing gas and the temperatures were corrected with a calibration curve, which was obtained by the ^{13}C NMR spectra of samarium acetate recorded at identical thermostated conditions and rotation rates [17].

Chelate Complexes of Tripodal, Aliphatic Triisocyanide Ligands**

By *F. Ekkehardt Hahn** and *Matthias Tamm*

For some time we have been occupied with the coordination chemistry of multidentate isocyanides with regard to the preparation of stable hexaisocyanide complexes of ^{99m}Tc as myocardium perfusion agents.[1, 2] Recently we were able to prove that aromatic, tripodal triisocyanides form chelate complexes of the form *fac*-[(triisocyanide)W(CO)$_3$] in spite of the linear M–CNR unit in the metal complex.[3] Depending on the ligand three 18- or 20-membered chelate rings were formed, which rank with the largest ring systems in organometallic compounds. We have now prepared the aliphatic triisocyanide Ctalc **1** and studied its coordination

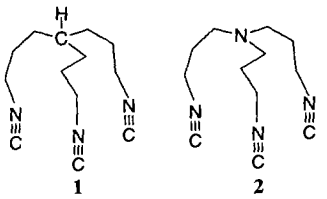
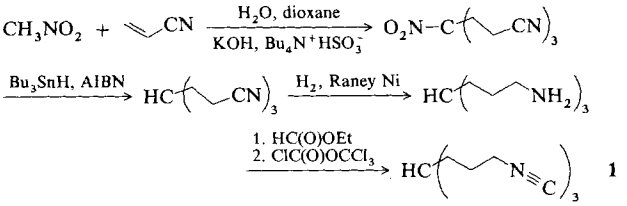
chemistry. Attempts to obtain chelate complexes with the similar ligand Ntalc **2**, led only to insoluble products. This behavior can be explained by the protonation of the central nitrogen atom[3] or by the formation of polymers as a result of the small number of framework atoms (rings with a maximum size of 12 atoms can be formed). Ctalc **1** can no longer be protonated at the central methine unit, so that the coordination chemistry of aliphatic triisocyanides with a small number of framework atoms can be studied with the preclusion of the protonation of the ligand.



1 **2**

Compound **1** was synthesized according to Scheme 1 and isolated as a colorless oil. It was completely characterized by elemental analyses and IR, ^{1}H, and ^{13}C NMR spectroscopy.[4] The ^{1}H NMR spectrum (400 MHz, in $CDCl_3$) of **1** shows three groups of signals.[4] The protons of the



Scheme 1. Synthesis of **1**.

methylene groups next to the isocyanide functions appear as a triplet of triplets at $\delta = 3.41$ by ^{14}N ^{1}H coupling. The signal for the proton of the central methine group and for the protons of the neighboring methylene group form a multiplet at $\delta = 1.45$. The remaining methylene protons appear as a broad multiplet at $\delta = 1.69$. The observed $^2J(^{14}\text{N}\ ^1\text{H})$ coupling in aliphatic isocyanides has already been described.[3, 6] The reaction of **1** with $[(C_7H_8)M(CO)_3]$ (C_7H_8 = cycloheptatriene, M = Cr, W) in CH_2Cl_2 leads to the colorless complexes **3** and **4**.

fac-$[HC(CH_2CH_2CH_2\text{-}NC)_3M(CO)_3]$
3, M = Cr; **4**, M = W

The new compounds were completely characterized by elemental analyses, mass spectrometry, and IR, ^{1}H, and ^{13}C NMR spectroscopy.[5] The ^{1}H NMR spectra for complexes **3** and **4** are very similar to each other but differ appreciably from the spectrum of the free ligand **1** (Fig. 1). In **4** the multiplicity of the signal for the methylene group D was reduced by the coordination of the isocyanide functions to the metal atom from a triplet of triplets in the free ligand to a triplet at $\delta = 3.65$. As expected, the ^{14}N ^{1}H coupling is removed by the coordination of the isocyanide function to the metal center. Hence, also for the signals of the methylene groups C (quint) and B (dt) only the expected $^3J(^1\text{H}\ ^1\text{H})$ coupling patterns are observed. The change of the signal for

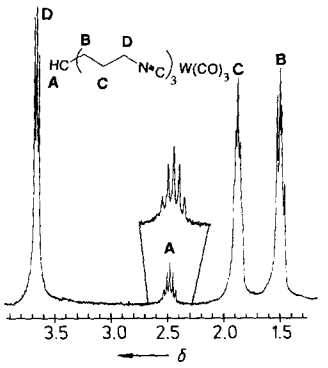


Fig. 1. ^{1}H NMR spectrum (270 MHz, CD_2Cl_2) of **4**.

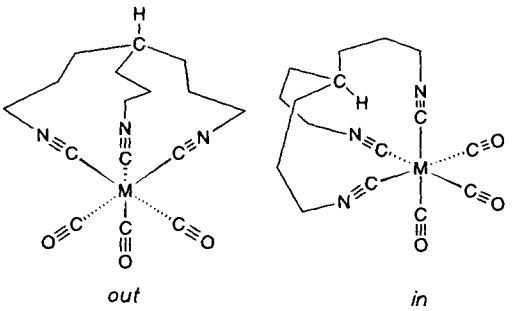
the proton at the central methine group is the most obvious. It experiences a low-field shift of more than $\Delta\delta = 1$ and appears as a septet at $\delta = 2.48$. To our knowledge the ^{1}H NMR signal of a methine group substituted with three propyl groups has so far never been observed at such low field. From the low-field shift of the signal for the methine group the structure of the presumably isostructural chelate complexes **3** and **4** can be deduced. From previous studies of metal complexes of tripodal ligands with a nitrogen atom as the central framework atom it is known that this atom can adopt the *in*[3, 7] or the *out* configuration.[3] Similar isomers are possible for the coordinated ligand **1** with a central methine unit (Scheme 2).



Scheme 2. The *in* and *out* isomers for complexes of the type *fac*-$[HC(CH_2CH_2CH_2\text{-}NC)_3M(CO)_3]$.

The low-field shift of the signal of the methine protons in **3** and **4**[5] can only be explained by the formation of *in* isomers since here the proton of the methine group would penetrate the deshielding region of the anisotropy cone of the NC triple bonds, which leads to the observed low-field shift. In the *out* configuration this proton should not be deshielded and thus its chemical shift approximates that of the free ligand. To gain support for this hypothesis and to show that also aliphatic triisocyanides with a low number of framework atoms can form chelate complexes a structural analysis of **4** was carried out.[8]

Single crystals of **4** were obtained from dichloromethane/hexane (1:1) by slow evaporation of the solvents at room temperature. The X-ray structural analysis shows that the conclusions drawn from the ^{1}H NMR spectrum are correct (Fig. 2 left). The ligand coordinates through three isocyanide groups to the tungsten atom forming three 12-membered chelate rings. Complex **4** and the probably isostructural **3** are the first chelate complexes with aliphatic tripodal triisocyanide ligands.

The quality of the X-ray diffraction data ($2\theta_{max}$ 55° at 100(5) °C) allowed for the determination and refinement

of the positional parameters of H1. Thus, the postulated *in* configuration of the central methine group in **4** was proven unequivocally. The C1–H1 vector points towards the W atom [angle C1-H1-W 177(3)°]. The distances of H1 to the nitrogen atoms lie between 2.69(4) and 2.78(5) Å, the H1–W distance is 3.56(5) Å. These data clearly explain the observed low-field shift of the signal for the methine proton by penetration of this proton into the deshielding region of the anisotropy cone of the NC triple bonds.

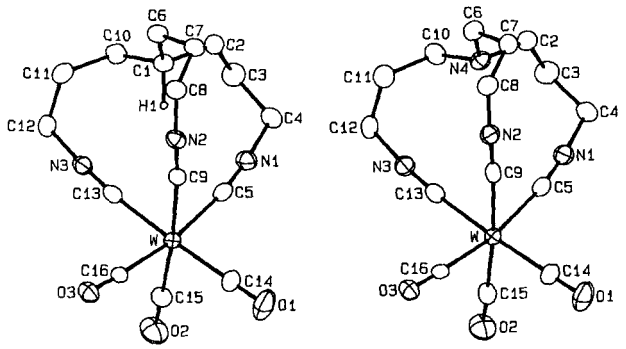


Fig. 2. Crystal structures of **4** (left) and **5** (right) (ORTEP) without hydrogen atoms (with the exception of H1 in **4**). Selected distances [Å] and angles [°] for **4** [**5**]: W-C5 2.138(3) [2.130(4)], W-C9 2.131(3) [2.125(4)], W-C13 2.119(3) [2.114(4)], W-C14 2.005(3) [1.999(4)], W-C15 1.994(3) [1.996(4)], W-C16 1.989(3) [1.983(4)], O1-C14 1.153(4) [1.157(5)], O2-C15 1.158(4) [1.157(5)], O3-C16 1.152(4) [1.160(5)], N1-C5 1.159(4) [1.158(5)], N2-C9 1.151(4) [1.165(5)], N3-C13 1.152(4) [1.157(5)], C1-H1 1.11(5); W-C5-N1 170.3(3) [170.1(3)], W-C9-N2 171.6(2) [171.3(3)], W-C13-N3 174.5(3) [173.6(3)], C5-N1-C4 174.7(3) [174.8(4)], C9-N2-C8 173.4(3) [174.6(4)], C13-N3-C12 174.1(3) [171.6(4)].

The influence on the chemical shift of protons by their interaction with aromatic ring systems have often been described, for example, the marked high-field shift of methine protons in certain cyclophanes.[9] In contrast, we report herein about the induction of a low-field shift, caused by the coordination of the ligand to a metal center and the resulting change of configuration of the ligand.

After we were able to show that also aliphatic tripodal triisocyanides such as **1** can form chelate complexes with only eleven framework atoms, the experiments with the Ntalc **2** ligand were repeated. If a very dilute solution of **2** is allowed to react with $[(C_7H_8)W(CO)_3]$, the polymers[3] originally postulated by us are not formed but a soluble monomeric complex, which was completely characterized. Microanalytical data and ^{1}H NMR and IR spectra[5] indicate the

fac-$[N(CH_2CH_2CH_2\text{-}NC)_3W(CO)_3]$ **5**

formation of complex **5**. This assumption is confirmed by the structural analysis of **5** (Fig. 2 right). This is also a chelate complex with three 12-membered rings. The central nitrogen atom is not protonated, and the ligand adopts the *in* configuration.

The bond parameters for **4** and **5** lie in the expected range. Corresponding parameters in these complexes are identical within the margins of error. The aliphatic triisocyanides are weaker π acceptors than the previously described aromatic triisocyanides.[3] Hence, the W–CN distances are longer than in compounds of the type *fac*[(aromatic triisocyanide)W(CO)$_3$]. The W-C-N angles deviate from linearity by up to 10° whereas the W-C-O angles are almost linear.

With the compounds **3**–**5** it could be shown that also aliphatic triisocyanides with a small number of framework atoms are able to form chelate complexes with low-valent transition metals. In comparison to the aromatic triisocyanides[3] it is noticeable that the marked reduction in the number of framework atoms (from 17 and 19) to 11 does not influence the ability to form chelates.

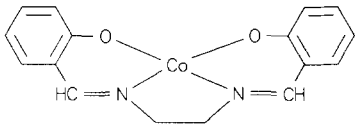
The Electrochemical Oxidation of [Co^{II}(salen)] in Solvent Mixtures—An Example of a Ladder Scheme with Coupled Electron-Transfer and Solvent-Exchange Reactions**

By *Emerich Eichhorn, Anton Rieker,* and *Bernd Speiser**

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

Recently Evans discussed electrode processes[1] in which electron-transfer (E) and chemical (C) reactions are coupled in such a way that a horizontal and vertical formulation of the E and C steps, respectively, leads to a closed, cyclic, so-called square scheme. Fence (more than two oxidation states, two structurally different compounds per oxidation state) and ladder schemes (more than two compounds linked by structural changes, in each case two oxidation states) are extensions of the square scheme. Evans emphasizes that ladder schemes are less common than fence schemes.[2] He quotes a series of systems[3] in which the different charge transfers of the ladder scheme could not be detected separately by experiment.

We now provide an example of a three-rung ladder scheme that we have discovered during a cyclic voltammetric study of *N,N'*-bis(2-hydroxybenzylidene)ethylenediaminatocobalt(II) ([Co(salen)], **1**) in several solvents and solvent mixtures. All electron-transfer reactions can be observed.



1

Compound **1** is used as oxygen carrier for the oxygenation of organic substrates[4] and is a model compound for enzymes with monooxygenase, dioxygenase, or peroxidase activity. The catalytic function of the oxygen transfer depends strongly on the nature of the solvent.[4, 5]

Earlier work has shown that **1** is oxidized in a relatively fast, quasi-reversible one-electron transfer [Eq. (a)],[6] for which the formal potential E^0 varies strongly with solvent.

$$[Co^{II}(salen)] \underset{}{\overset{e^-}{\rightleftharpoons}} [Co^{III}(salen)]^+ \qquad \text{(a)}$$
$$\mathbf{1} \qquad\qquad \mathbf{2}$$

Complex **1** interacts with the solvent; details, however, have not yet been elucidated. As regards the catalytic reaction, Carter et al.[7] demonstrated that a relationship exists between E^0 and the capacity of **1** to bind oxygen. A knowledge of the structure of each Co complex involved in each solvent and its electrochemistry is essential for the understanding and control of the catalytic reaction, in which the oxidation of **1** to the cationic Co^{III} complex **2** [Equation (a)] possibly also plays a role.[8] In order to define the various complexes in different solvents, we studied the oxidation formulated in Equation (a) at a Pt electrode by cyclic voltammetry.[9]

Both in dimethylformamide (DMF) and pyridine (py) only *one* couple of peaks is observed in the cyclic voltammograms. However, in mixtures of these two solvents three reducible compounds are formed successively on changing from L_1 (DMF) to L_2 (py). This can only be explained if *three* Co^{III} complexes are electroactive (formal potentials E_1^0, E_2^0, and E_3^0 in Scheme 1).

$$\begin{array}{ccc}
\mathbf{1}\cdot 2\,L^1 + 2\,L^2 & \overset{E_1^0}{\rightleftharpoons} & \mathbf{2}\cdot 2\,L^1 + 2\,L^2 + e^- \\
k_1 \Big\| k_{-1}K_1 = \dfrac{k_1}{k_{-1}} & & k_2 \Big\| k_{-2}K_2 = \dfrac{k_2}{k_{-2}} \\
\mathbf{1}\cdot L^1\cdot L^2 + L^1 + L^2 & \overset{E_2^0}{\rightleftharpoons} & \mathbf{2}\cdot L^1\cdot L^2 + L^1 + L^2 + e^- \\
k_3 \Big\| k_{-3}K_3 = \dfrac{k_3}{k_{-3}} & & k_4 \Big\| k_{-4}K_4 = \dfrac{k_4}{k_{-4}} \\
\mathbf{1}\cdot 2\,L^2 + 2\,L^1 & \overset{E_3^0}{\rightleftharpoons} & \mathbf{2}\cdot 2\,L^2 + 2\,L^1 + e^-
\end{array}$$

Scheme 1. Ladder scheme for the oxidation of [Co^{II}(salen)] (**1**) in a mixture of two solvents for two complexed solvent molecules L^1 and L^2, here DMF/pyridine, dichloromethane/pyridine, or acetonitrile/pyridine.

In the quasi-reversible voltammogram in DMF the formal potential is $E_1^0 = -471$ mV vs. ferrocene/ferrocenium (Fc/Fc$^+$). On addition of pyridine (excess of **1** relative to pyridine) the reduction peak splits into peak 1 and peak 2 (Fig. 1a). If complex **1** and pyridine are present in equimolar amounts, the dominant peak is peak 2, and on further addition of pyridine finally only peak 3 is found. With increasing pyridine concentration, at first **2**·2DMF, then **2**·DMF·py, and finally **2**·2py is formed after the electron transfer. These three complexes are reduced at sufficiently different potentials that separate peaks appear in the cyclic voltammograms. The oxidation peak broadens until about a 120-fold excess of pyridine over **1** is reached. Then, like peak 3, it shifts to more negative potentials (in pure pyridine, $E^0 = -871$ mV). This behavior is in fact anticipated for a preequilibrium (defined by K_3 in Scheme 1).[10] Possibly, after the reduction one of the two solvent molecules is cleaved to form the five-coordinate complex.

In DMF/py mixtures the oxidation peaks for the three complexes are not resolved. This is observed when L^1 is CH_2Cl_2 and L^2 is pyridine. The reaction in pure CH_2Cl_2 as solvent is complicated by adsorption phenomena (Fig. 1b). On addition of half an equivalent of pyridine (relative to **1**) the oxidation peak is resolved into two well-defined peaks 1 and 2 of equal intensity. Besides the reduction of the complex containing no pyridine ligands (peak 4), peak 5 appears at approximately -750 mV, which corresponds to the electron transfer to **2**·2py. Its intensity is relatively small, because the concentration of pyridine is still too small to convert all the cobalt(III) complex into **2**·2py. If the concentration of pyridine is increased, reduction peak 4 disappears, and simultaneously peak 2 grows at the expense of peak 1. Although an equimolar amount of pyridine should convert all of **1** to **1**·py·CH_2Cl_2, peak 1 still remains; some of the pyridine is used by the oxidized Co complex to form the bis(pyridine) complex. The equilibrium K_4 thus lies far to the side of **2**·2py. Finally a third oxidation peak (peak 3) forms the signal of a quasi-reversible electron transfer with the now more intense reduction peak 5, which shifts in the negative potential direction towards E_3^0 on increasing the pyridine concentration further. Although CH_2Cl_2 is usually a weak coordinating solvent, a quantitative assessment of the peak shift shows that the equilibrium constant K_3 has a value close

[**] Electrochemistry of Oxygenation Catalysts, Part 1. This work was supported by the Volkswagen-Stiftung (research funds), the state of Baden-Württemberg (graduate scholarship for E.E.), and the Deutsche Forschungsgemeinschaft (Heisenberg Fellowship for B.S.)

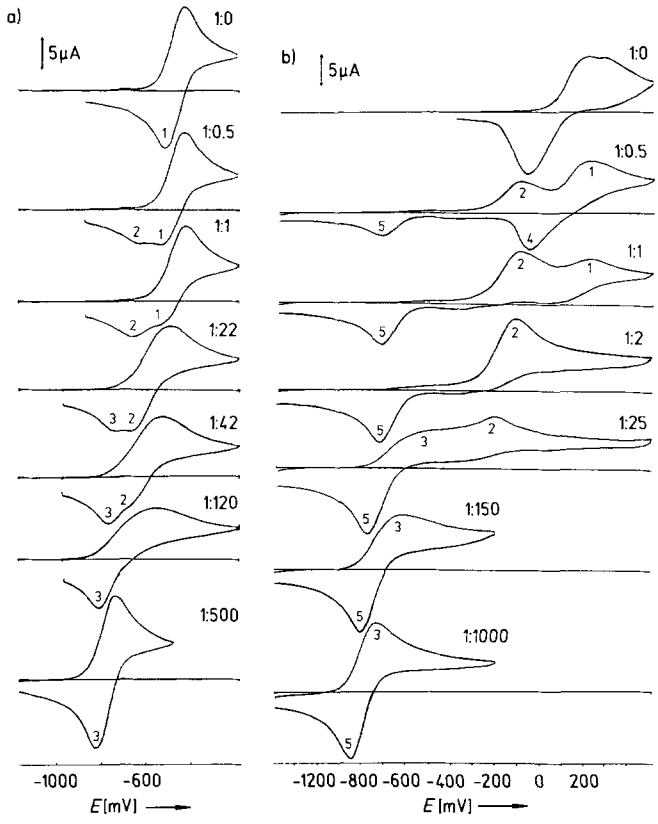

Fig. 1. a) Cyclic voltammograms of **1** in mixtures of DMF and pyridine; potential sweep rate $v = 100\ mVs^{-1}$, $c[\mathbf{1}] = 1.0$ mM; in each case the ratio of the concentrations of **1** to pyridine is given. Top curve: cyclic voltammogram in pure DMF; peak 1: $\mathbf{2}\cdot 2DMF \rightarrow \mathbf{1}\cdot 2DMF$, peak 2: $\mathbf{2}\cdot DMF\cdot py \rightarrow \mathbf{1}\cdot DMF\cdot py$, peak 3: $\mathbf{2}\cdot 2py \rightarrow \mathbf{1}\cdot 2py$. b) Cyclic voltammograms of **1** in mixtures of CH_2Cl_2 and pyridine; potential sweep rate $v = 50\ mVs^{-1}$, $c[\mathbf{1}] = 1.0$ mM; in each case the ratio of the concentrations of **1** to pyridine is given. Top curve: cyclic voltammogram in pure CH_2Cl_2; peak 1: $\mathbf{1}\cdot 2CH_2Cl_2 \rightarrow \mathbf{2}\cdot 2CH_2Cl_2$, peak 2: $\mathbf{1}\cdot CH_2Cl_2\cdot py \rightarrow \mathbf{2}\cdot CH_2Cl_2\cdot py$, peak 3: $\mathbf{1}\cdot 2py \rightarrow \mathbf{2}\cdot 2py$, peak 4: $\mathbf{2}\cdot 2CH_2Cl_2 \rightarrow \mathbf{1}\cdot 2CH_2Cl_2$, peak 5: $\mathbf{2}\cdot 2py \rightarrow \mathbf{1}\cdot 2py$.

to **1**. This points to a weak interaction of the second solvent molecule with the central atom of the Co^{II} complex.

Finally, in the solvent system CH_3CN/pyridine all six electron-transfer reactions could be observed separately (Fig. 2). The voltammogram in CH_3CN shows peaks 1 and 4 (redox reaction at $E_1^0 = -198$ mV). Already on addition of 0.25 equivalents of pyridine to the solution of the cobalt complex in acetonitrile a splitting of the reduction peak can be observed. With increasing pyridine concentration a shoulder grows out of the left flank of the oxidation peak (ratio of complex:py of 1:1). Simultaneously, the reduction of a third Co^{III} species becomes evident. On addition of more pyridine (excess 1:100) a continuous transition of the shoulder into oxidation peak 3 at still more negative potential occurs. Finally, the reduction of only the third species $\mathbf{2}\cdot 2py$ (process with E_3^0) can be observed (peaks 3 and 6).

Results of experiments, in which the potential scan rate v is varied and several successive cycles are recorded, are in accord with the proposed mechanism. A change in v shifts the reduction peak current ratio: increasing v in DMF at a **1**:py ratio of 1:0.5 increases peak 1 relative to peak 2; at higher concentrations of pyridine, peak 2 increases relative to peak 3. Apparently the exchange of DMF for pyridine at the Co^{III} stage takes place relatively slowly. Analogous effects are observed for the other solvent mixtures. If for a *multicycle experiment* the salt $[Co^{III}(salen)]Cl$ is dissolved in DMF and one equivalent of pyridine is added, a mixture of $\mathbf{2}\cdot 2DMF$ and $\mathbf{2}\cdot py\cdot DMF$ results. In such a solution reduction peaks 1 and 2 are observed as expected. On subsequent oxidation exclusively the electron transfer at E_1^0 takes place: at the Co^{II} stage $\mathbf{1}\cdot 2DMF$ forms predominantly because of the small pyridine concentration (equilibrium constant K_1). A second cycle shows only the redox behavior of the bis(dimethylformamide) complex. Ligand exchange reactions are thus very fast for the Co^{II} complexes, but slow for Co^{III} complexes.[11]

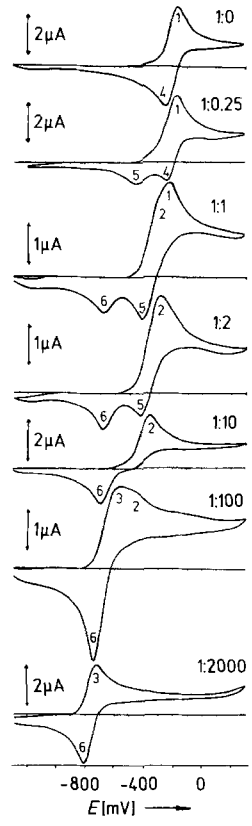

Fig. 2. Cyclic voltammograms of **1** in mixtures of CH_3CN and pyridine; potential sweep rate $v = 50\ mVs^{-1}$, $c[\mathbf{1}] = 0.25$ mM; in each case the ratio of the concentrations of **1** to pyridine is given. Top curve: cyclic voltammogram in pure CH_3CN; peak 1: $\mathbf{1}\cdot 2CH_3CN \rightarrow \mathbf{2}\cdot 2CH_3CN$, peak 2: $\mathbf{1}\cdot CH_3CN\cdot py \rightarrow \mathbf{2}\cdot CH_3CN\cdot py$, peak 3: $\mathbf{1}\cdot 2py \rightarrow \mathbf{2}\cdot 2py$, peak 4: $\mathbf{2}\cdot 2CH_3CN \rightarrow \mathbf{1}\cdot 2CH_3CN$, peak 5: $\mathbf{2}\cdot CH_3CN\cdot py \rightarrow \mathbf{1}\cdot CH_3CN\cdot py$, peak 6: $\mathbf{2}\cdot 2py \rightarrow \mathbf{1}\cdot 2py$.

The results discussed here are important for a detailed description of the catalytic activity of **1**. The redox behavior of the cobalt complex is relatively strongly influenced by variation of the solvent. The observed effect is larger than that of electronically and sterically active substituents on the arene rings of the ligand.[12] The voltammograms show that the change in the formal potential is linked to the change in the coordination sphere of the central atom. This could affect the catalytic activity of **1**, if the substrate for the oxygenation and—as postulated[4]—in some cases also the oxygen to be activated is bound to the complex. Furthermore, the analysis of the proposed exchange equilibria opens the way for an experimental investigation of the primary steps in the catalysis reaction and therefore the preparative oxygenation in the presence of **1**. Preliminary results with substrates such as aromatic amines suggest a connection between the ability of the substrate to expel a solvent molecule from the ligand sphere of cobalt and its tendency to be oxygenated.

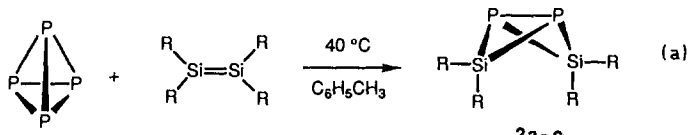
The Reaction of Tetramesityldisilene with As_4: Synthesis and Structure of a Novel Arsenic–Silicon Tricyclic Ring System**

By *Robin P. Tan, Nadia M. Comerlato, Douglas R. Powell,* and *Robert West**

Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

Tetramesityldisilene, $Mes_2Si{=}SiMes_2$ (Mes = 2,4,6-trimethylphenyl) (**1a**), and other disilenes react with many organic reagents and inorganic elements to form novel heterocyclic compounds.[1, 2] Recently we have been interested in the reactions of disilenes with group 5 elements. With phosphorus in the form of P_4, disilenes react to yield interesting butterfly structures, the 1,3-diphospha-2,4-disilabicyclobutanes,[3] **2a–c** [Eq. (a)]. We now report the results of the reaction of disilene **1a** with arsenic (As_4).

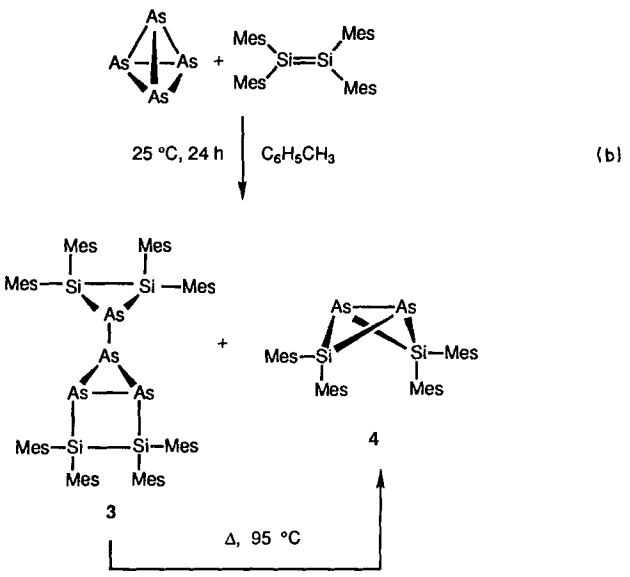


(a)

1a, R = 2,4,6-$Me_3C_6H_2$
1b, R = 2,6-$Me_2C_6H_3$
1c, R = 2,6-Me_2-4-tBuC_6H_2

2a–c

Tetramesityldisilene reacts with As_4 in toluene to give mainly a mixture of 5-(2,2,3,3-tetramesityl-1-arsa-2,3-disilacyclopropyl)-2,2,3,3-tetramesityl-1,4,5-triarsa-2,3-disilabicyclo[2.1.0]pentane (**3**) and 2,2,4,4-tetramesityl-1,3-diarsa-2,4-disilabicyclo[1.1.0]butane (**4**) [Eq. (b)]. Both compounds have been characterized by ^1H and ^{29}Si NMR spectroscopy, mass spectrometry, and elemental analysis. Furthermore,



(b)

the structure of **3** has been confirmed by a single-crystal X-ray analysis.[4] The tricyclic structure of **3** is quite remarkable (Fig. 1). This molecule contains: 1) the first example of a 1,2-diarsadisiletane ring, Si_2As_2, 2) the first example of an "open" cyclotriarsane, not incorporated in a cluster, and 3) the first arsadisilirane ring, Si_2As. This reaction also appears to be the first synthesis of a silicon–arsenic compound starting from elemental arsenic.

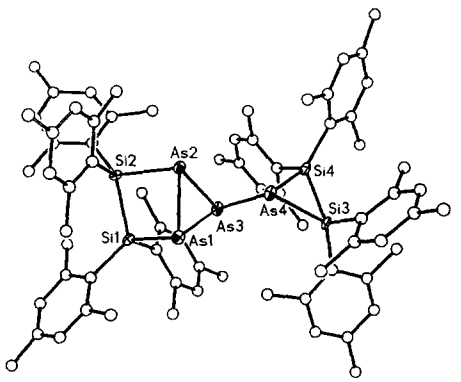


Fig. 1. Crystal structure of **3** (50% thermal ellipsoids for As and Si; hydrogens omitted for clarity). Selected bond lengths [pm] and angles [°]: As1–As2 245.6(3), As2–As3 245.0(3), As1–As3 246.3(3), As3–As4 245.6(3), As1–Si1 245.6(6), As2–Si2 239.2(5), As4–Si3 240.4(6), As4–Si4 240.1(6), Si1–Si2 241.7(7), Si3–Si4 231.5(7); As1–As2–As3 60.3(1), As1–As3–As2 60.0(1), As4–Si4–Si3 61.3(2), As4–Si3–Si4 61.1(2), As1–Si1–Si2 85.2(2), As2–Si2–Si1 90.3(2), As1–As2–Si2 85.7(1), As2–As1–Si1 87.9(1). Dihedral angles between planes: As1, Si1, Si2–As1,As2,Si2 34.6; As1,As2,Si2–As1,As2,As3 112.5; As1,As2,As3–As4,Si3,Si4 149.7.

The $^{29}Si\{^1H\}$ NMR spectrum of **3** shows two signals at $\delta = -6.6$ and -64.0; the latter can be assigned to the silicon atoms within the $AsSi_2$ three-membered ring, since there are several examples of disilacyclopropanes with resonances in this region.[2] The other product from this reaction, **4**, is analogous to the 1,3-diphospha-2,4-disilabicyclo[1.1.0]-butane **2a** obtained from the reaction of tetramesityldisilene

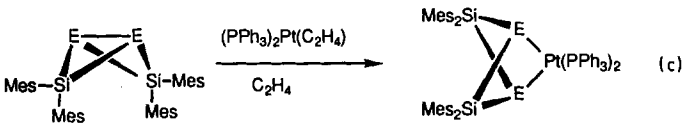
with P_4.[3] The ^1H NMR spectrum of **3** is very similar to that of the analogous phosphorus compound. The spectrum shows a total of six signals, corresponding to the two sets of chemically nonequivalent *exo* and *endo* mesityl groups. As expected, the $^{29}Si\{^1H\}$ NMR spectrum of **4** shows a singlet at $\delta = -35.1$.

The diarsadisilabicyclobutane compound **4** can be independently synthesized from compound **3** by heating in toluene at approximately 95 °C. This conversion from **3** to **4** is, however, quite slow; approximately 80% of the dimer is converted to **4** after 30 days of heating[5].

The cyclotriarsane ring is also an unusual structural feature of **3**. The other covalent, main group compounds containing cyclotriarsane rings are polycyclic cluster-type compounds, including a triarsatricycloheptane $As_3C_5H_9$[8] and a series of three heptaarsanes $As_7(MMe_3)_3$ (M = Si, Ge, Sn) with nortricyclene structures, reported by von Schnering et al.[9]

Like the phosphorus bicyclobutanes **2a–c**, compounds **3** and **4** may bind to transition metals, either as ligands or by insertion into the E–E bond (E = As, P). In a first attempt to explore such chemistry, we treated **4** with ethenebis(triphenylphosphine)platinum, which resulted in the formation of an adduct $[Mes_4Si_2As_2Pt(PPh_3)_2]$ [Eq. (c)]. The spec-



(c)

4, E = As
2a, E = P

5a, E = As
5b, E = P

troscopic properties of this compound are consistent with an asterane-like structure **5a**, entirely analogous to the corresponding compound **5b** formed from the phosphorus bicyclobutane **2a**.[10] In the $^{31}P\{^1H\}$ NMR spectrum of **5a**, the resonance of the phosphorus atoms of the triphenylphosphine groups is observed as a singlet ($\delta = 19.5$) with platinum satellite peaks; the $^1J_{P-Pt}$ coupling constant is equal to 2655 Hz. These values are similar to those of the phosphorus analog **5b** ($\delta = 22.5$, $^1J_{P-Pt} = 2523$ Hz).

Experimental Procedure

3: Tetramesityldisilene (400 mg, 0.93 mmol) was added to 120 mL of a toluene solution of As_4[11] (excess) in a drybox. The solution immediately turned orange. The reaction mixture was left in the box for 24 h, before the toluene was removed under vacuum. The residue was redissolved in toluene and decanted away from excess arsenic, present as a black precipitate. The toluene solvent was then stripped, leaving an orange residue which, according to its ^1H NMR spectrum, is made up of a 3:1 mixture of compounds **3** and **4**. About 10 mL of hexane was added to the residue, and the slurry was stirred for a few minutes. The residue was then transferred to a glass frit and washed with more hexane. The light yellow solid on the glass frit was identified as **3** (200 mg, 32%): m.p. 282–284 °C (decomp); ^1H NMR (200 MHz, C_6D_6): $\delta = 1.99–2.63$ (m, 72H, *o*-CH_3, *p*-CH_3), 6.58, 6.61, 6.65, 6.82 (16H, $C_6H_2Me_3$); $^{29}Si\{^1H\}$ NMR (INEPT, 99.4 MHz, C_6D_6): $\delta = -6.6$, -64.0; MS (FD), *m/z* calcd for $^{12}C_{72}{}^1H_{88}{}^{28}Si_4{}^{75}As_4$ 1364.283, found 1364.3. Correct elemental analysis. The orange mother liquor contained a mixture of **4** and other minor products.

4: Compound **3** (150 mg, 0.11 mmol) in 30 mL of toluene was sealed in a thick-walled glass ampule and heated at 95 °C for 30 d. The solvent was removed under vacuum, and a small amount of hexane was added to the residue. The slurry was stirred and then filtered; the light yellow residue (approximately 20 mg) was identified by ^1H NMR as compound **3**. The solvent from the yellow mother liquor was removed under vacuum, leaving an orange solid that was identified as **4** (126 mg, 85%): ^1H NMR (200 MHz, C_6D_6): $\delta = 2.01$ (s, 6H, *p*-CH_3), 2.05 (s, 6H, *p*-CH_3), 2.43 (s, 12H, *o*-CH_3), 2.77 (s, 12H, *o*-CH_3), 6.35 (s, 4H, $C_6H_2Me_3$), 6.68 (s, 4H, $C_6H_2Me_3$), $^{29}Si\{^1H\}$ NMR (INEPT, 99.4 MHz, C_6D_6): $\delta = -35.1$; MS (30 eV), *m/z* (rel. intensity) 682 (M^+, 94.3), 487 ($M^+ - Mes - As + 1$, 6.3), exact mass calcd for $^{12}C_{36}{}^1H_{44}{}^{28}Si_2{}^{75}As_2$ 682.1413, found 682.1420. Correct elemental analysis.

5a: A solution of **4** (26 mg, 0.038 mmol) in 5 mL of toluene was treated with $[Pt(PPh_3)_2(C_2H_4)]$ (28.4 mg, 0.038 mmol) at room temperature. Upon addition, the solution turned brown. After the solution was stirred overnight, the solvent was removed under vacuum, and a brown solid (**5a**) was obtained (23.8 mg, 45%): ^1H NMR (200 MHz, C_6D_6): $\delta = 2.02$ (s, 6H, *p*-CH_3), 2.21 (s, 6H, *p*-CH_3), 2.63 (brs, 24H, *o*-CH_3), 6.33 (s, 4H, $C_6H_2Me_3$), 6.76 (s, 4H, $C_6H_2Me_3$), 6.80–6.90 (m, 18H, PPh_3), 7.25–7.38 (m, 12H, PPh_3), $^{29}Si\{^1H\}$ NMR (INEPT, 99.4 MHz, C_6D_6): $\delta = -42.7$ (s, $^2J_{Si-Pt} = 116$ Hz); $^{31}P\{^1H\}$ NMR (202.5 MHz): $\delta = 19.5$ (s, PPh_3, $^1J_{P-Pt} = 2655$ Hz). MS (FAB, 3:1 mixture of dithiothreitol and dithioerythritol) calcd maximum mass for the signal for $C_{72}H_{74}Si_2P_2As_2Pt$ 1402.29, found 1401.3 $(M - H)^+$.

Matrix Isolation of Diisocyanogen CNNC**

By *Günther Maier,* Hans Peter Reisenauer, Jürgen Eckwert, Claudia Sierakowski,* and *Thomas Stumpf*

The ambident CN radical **1** can in principle dimerize to cyanogen **2**, isocyanogen **3**, and diisocyanogen **4**. After the initial synthesis of cyanogen **2** in 1815 by Gay-Lussac[1] 173 years passed until a second isomer was prepared.[2] On the

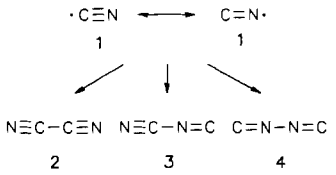
Heinrich-Buff-Ring 58, D-W-6300 Giessen (FRG)

[**] This research was supported by the Fonds der Chemischen Industrie.

basis of NMR[2] and photoelectron (PE)[3] spectroscopic data this compound was assigned the structure of diisocyanogen **4**. However, microwave[4] and infrared spectra[4, 5] soon showed that the new isomer must actually be isocyanogen **3**; in light of these results the PE[6, 7] and NMR spectra[8] were subsequently reinterpreted. If **3** is considerably higher in energy than **2** and only stable for a short time in the gas phase or at low temperature in the condensed phase,[8] then diisocyanogen **4** should have an even higher reactivity, as numerous theoretical studies have predicted.[9–13]

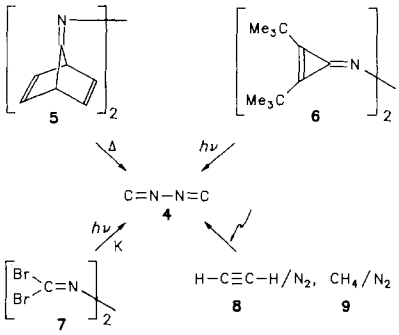


We obtained the first indication of the existence of **4** in our matrix spectroscopic investigations of the thermolysis of norbornadienonazine (**5**).[5] Besides the IR bands of the main product isocyanogen **3** and those of the by-product cyanogen **2**, an additional weak absorption at 1997 cm^{-1} was observed when the products were frozen in an argon matrix at 12 K immediately after passing the pyrolysis zone. This band did not arise when the reaction products were condensed first at 77 K, then evaporated, and isolated in a matrix at 12 K. Thus, this band must be due to a substance that is considerably more reactive than **2** and **3**.

The obvious assignment of this IR absorption at 1997 cm^{-1} to the antisymmetric CN stretching vibration (ν_3) of diisocyanogen **4**, the only IR-active stretching vibration of this linear molecule, is supported by the results of quantum mechanical calculations. If the calculated values are corrected with a suitable scaling factor, namely the mean quotient of the experimental (Ar matrix) and the calculated wavenumbers for the stretching frequency of **2**(ν_3) and **3**(ν_1, ν_2), then the values predicted for **4** (ν_3) are in good agreement with the observed position of the band (AM1: 1992 cm^{-1},[5] SCF/6-31G*: 1973 cm^{-1},[9] MP2/6-31G*: 2027 cm^{-1},[10] MP2/D95: 2048 cm^{-1},[11] ab initio CEPA: 1996 cm^{-1}[13]). The second IR-active fundamental band of **4** (bending, ν_5) is very weak in intensity according to calculations and should be in the far-IR region which we did not record. This band cannot be used for additional support of the assignment.

For unequivocal proof of our claims we not only prepared and isolated **4** in the matrix by independent routes from different precursors, but we also carried out specific isotopic labeling and compared the resulting shifts in the IR band with the theoretical values. Di-*tert*-butylcyclopropenonazine (**6**), accessible by condensation of di-*tert*-butylcyclopropenone with hydrazine dihydrochloride, proved to be a good precursor. The photolysis of **6** in an argon matrix at 12 K with a low-pressure Hg lamp ($\lambda = 254$ nm) causes a clean fragmentation into di-*tert*-butylacetylene, isocyanogen **3** (IR: 2295 cm^{-1}, ν_1; 2054 cm^{-1}, ν_2), and diisocyanogen **4** (IR: 1997 cm^{-1}, ν_3). Cyanogen **2** is not formed in the photolysis of **6**. The ratio of compounds **3**:**4** is estimated at 3:1 from the observed intensities of the bands when the calculated absolute intensities are taken into account.[13] The flash vacuum thermolysis (quartz tube, 600 °C, heating zone 8 × 50 mm) of **6** followed by matrix isolation does not proceed so cleanly. Isocyanogen **3** is the only CN dimer detectable by IR spectroscopy. In addition, the absorption bands of di-*tert*-butylacetylene, isobutene, and propene are observed.

In another approach, tetrabromoformaldazine (**7**) isolated in a matrix was irradiated with a low-pressure Hg lamp ($\lambda = 254$ nm) producing a very small amount of diisocyanogen **4** besides bromocyan and isocyanogen. We have previously observed an analogous photochemical elimination of bromine in the synthesis of isofulminic acid from dibromoformoxime.[14] The dehalogenation of **7** is also possible with potassium metal. Gaseous tetrabromoformaldazine (**7**) at room temperature and low pressure is allowed to pass through a glass tube filled with quartz wool and with a potassium mirror on its surface. When the resulting products are condensed with a large excess of argon on the spectroscopic window at 12 K the bands of of bromocyan, cyanogen **2**, and diisocyanogen **4** are detected by IR spectroscopy, however, not those of isocyanogen **3**.



A completely different and convenient access to all three CN dimers is possible from the microwave discharge of mixtures of acetylene **8** and nitrogen. We actually ran preliminary experiments hoping to be able to produce the unknown species diazodicarbon CCNN.[15] In a typical experiment a

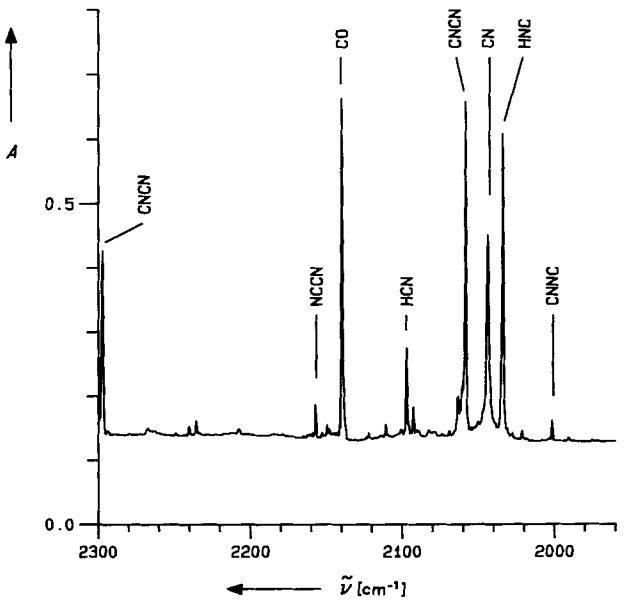


Fig. 1 Section of the FT-IR spectrum of the reaction products resulting from a microwave discharge in a mixture of acetylene and nitrogen (N_2 matrix, C_2H_2:N_2 = 1:500, 12 K).

discharge in a quartz tube (ca. 10×200 mm) through which the gas mixture flowed was maintained by a 2.45 GHz microwave generator. Immediately after the gas mixture passed out of the plasma zone it was frozen at 12 K on the spectroscopic window of the cryostat, and the condensate was examined by UV/VIS and IR spectroscopy. The characteristic IR absorptions, which are shifted roughly three or four wavenumbers relative to those measured in the argon matrix, indicate unequivocally the formation of all three CN dimers (**2**: 2157.0 cm^{-1}, ν_3; **3**: 2296.8 cm^{-1}, ν_1, and 2058.4 cm^{-1}, ν_2; **4**: 2001.3 cm^{-1}, ν_3). Based on the calculated intensities of the IR bands[13] the discharge delivers about 70% cyanogen **2**, 30% isocyanogen **3**, and very little ($\approx 1\%$) diisocyanogen **4**. Thus, this product distribution reflects the differing thermodynamic stabilities of the isomers. Their common precursor is likely to be the CN radical, which can be identified by its characteristic electron spectrum[16] as well as by its IR absorption at 2043.4 cm^{-1}.[16, 17] In addition, the bands of HCN, HNC, NH_3, NH_2, and other species are observed. Discharges in a mixture of methane (**9**) and nitrogen give rise to the same palette of products, although with a higher proportion of hydrogen-containing compounds (HCN, HNC, NH_2, and NH_3), as expected. Apparently the CN dimers are formed from C and N atoms (the connection to prebiotic processes is obvious). It is understandable then why the existence of the molecule actually hoped for, CCNN[15] (from the trapping of C_2 with N_2 molecules), could not be proved.

Isotopic labeling could be carried out easily with the microwave discharge technique. When a 1:1 mixture of $^{15}N_2$ and $^{14}N_2$ with 0.2% acetylene is employed, the nitrogen isotopes are found in a statistical distribution in the CN dimers. Accordingly, the unsymmetrical isocyanogen **3** shows four equally intense IR bands for the ν_1 as well as for the ν_2 stretching vibration. The symmetric diisocyanogen **4**, on the other hand, displays three IR absorptions as expected in the intensity ratio 1:2:1 for the isotopomers $C^{14}N^{14}NC$ (2001.3 cm^{-1}), $C^{15}N^{14}NC$ (1984.6 cm^{-1}), and $C^{15}N^{15}NC$ (1971.2 cm^{-1}), respectively. In other experiments we obtained the doubly ^{15}N-labeled CN dimers **2**, **3**, and **4** by flash pyrolysis of labeled norbornadienonazine **5**.[18] When this precursor is used (without or with double ^{15}N labeling), the observed bands of CNNC **4** are intense enough for the measurement of the $^{13}C^{14}N^{14}NC$ and the $^{13}C^{15}N^{15}NC$ isotopomers in their natural abundance. The vibrational frequency of the ^{13}C-labeled isotopomers may also be obtained by examination of the products arising from microwave discharge in a mixture of $^{13}CH_4$ or $^{13}C_2H_2$ and nitrogen. The wavenumbers of the ν_3 bands of the six observed CNNC isotopomers are compared to the calculated values from ab initio CEPA in Table 1. The good agreement leaves little doubt that our assignment is correct.

Table 1. Antisymmetric stretching frequencies (ν_3) of the observed CNNC isotopomers [cm^{-1}] in argon and nitrogen matrices.

Isotopomer	Experiment	Calculation [a]	
12-14-14-12	Ar: 1997.0 N_2: 2001.3	2019.9	
13-14-14-12	Ar: 1975.3 N_2: 1979.9	1998.0	(1975.3) [b] (1979.8) [c]
13-14-14-13	Ar: – N_2: 1960.1	1978.1	(1955.9) [b] (1960.1) [c]
12-14-15-12	Ar: 1979.9 N_2: 1984.6	2002.7	(1979.9) [b] (1984.5) [c]
12-15-15-12	Ar: 1966.6 N_2: 1971.2	1989.1	(1966.5) [b] (1971.0) [c]
13-15-15-12	Ar: 1944.3 N_2: –	1966.1 [d]	(1944.3) [b] (1948.2) [c]

[a] Ab initio CEPA 1/104 CGTOS[13]. [b] The value in parentheses is scaled with the factor 1997.0/2019.9 = 0.98876. [c] The value in parentheses is scaled with the factor 2001.3/2019.9 = 0.99079. [d] P. Botschwina, personal communication.

The upshot is that diisocyanogen **4** is extremely reactive, but is capable of existence under matrix isolation conditions.

Experimental Procedure

6: A solution of di-*tert*-butylcyclopropenone (6.3 g, 38 mmol) and hydrazine dihydrochloride (2 g, 19 mmol) in 150 mL of methanol was stirred at room temperature for 24 h. After the solvent was removed by rotary evaporation (aspirator pressure), the residue was washed in 150 mL of ether, dissolved in 300 mL of dichloromethane, filtered, and then concentrated to provide di-*tert*-butylcyclopropenonazine dihydrochloride (4.8 g, 12 mmol) as a colorless solid [m.p. 206 °C (decomp); MS (70 eV): *m/z* 328 ($M^{\oplus} - 2HCl$); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 16.2$ (s, 2H), 1.51 (s, 18H), 1.49 (s, 18H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 151.72$ (C=N), 150.87/147.82 (C=C), 33.50/33.14 (CMe_3), 28.44/27.85 (CMe_3); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1885 (C=C), 1540 (C=N); UV(C_2H_5OH): end absorption below 300 nm; correct elemental analysis. A suspension of di-*tert*-butylcyclopropenonazine dihydrochloride (516 mg, 1.29 mmol) in 15 mL of water-free THF at −78 °C was treated with a solution of 2.25 mmol of methyllithium in ether. The reaction mixture was stirred for 3 h at −78 °C before the solvent was removed by distillation. The residue was sublimed at 0.01 Torr/80 °C and washed with 1 mL of cold (−30 °C) water-free pentane to furnish **6** (325 mg, 0.99 mmol) as a colorless solid [m.p. 186 °C (decomp); MS (70 eV): *m/z* 328.2890 ($M^{\oplus}$, calc. 328.2870); ^1H NMR ($CDCl_3$): $\delta = 1.28$ (s, 18H), 1.23 (s, 18H); ^{13}C NMR ($CDCl_3$): $\delta = 150.47$ (C=N), 144.42/139.73 (C=C), 32.17/31.69 (CMe_3), 29.19/28.50 (CMe_3); IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 1828 (C=C), 1603 (C=N); UV (cyclohexane): λ_{max} [nm] (lg ε) = 228 (4.10); correct elemental analysis.

The Tandem Sakurai–Carbonyl–Ene Reaction: A New and Highly Stereoselective Sequential Transformation and Its Use for the Synthesis of Steroid Derivatives**

By *Lutz F. Tietze** and *Matthias Rischer*

Dedicated to Prof. Dr. Gerhard Quinkert on the occasion of his 65th birthday

The development of new sequential transformations[1] for the construction of organic molecules is of great interest since these procedures often open a short route to a very efficient and stereoselective assembling of complex molecules. In recent years we have elaborated several new sequences such as the tandem Knoevenagel hetero-Diels–Alder,[2] the tandem Knoevenagel–ene reaction,[3] the tandem Knoevenagel–allylsilane cyclization,[4] and the tandem Pictet–Spengler–ene reaction.[1a] In this paper we describe the tandem Sakurai–carbonyl–ene reaction and its use in the diastereoselective synthesis of the enantiomerically pure BCD part of steroids **1** with a methyl group in ring B according to the retrosynthetic scheme **1a** → **4**. In the Sakurai reaction[5] an α,β-unsaturated carbonyl compound reacts with an allylsilane to give a δ,ε-unsaturated carbonyl moiety, which yields a cyclic homoallylic alcohol in an intramolecular carbonyl–ene[6] reaction. Steroids with an additional methyl group at the steroid skeleton often show an increased biological activity; for example 6α-methylprednisolone is a five times more potent antiphlogistic agent than cortisone.[7]

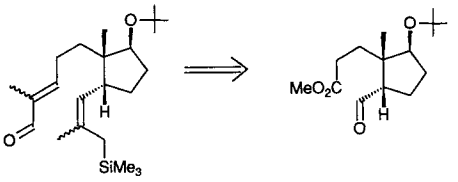
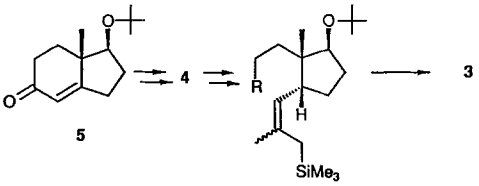
1b: β-CH_3 at C-9

2a
2b: β-CH_3 at C-6, β-OH at C-7
2c: β-OH at C-7



3 **4**

The starting material used for the synthesis of **1a** was the enantiomerically pure aldehyde **4**, which can be obtained from the ketone **5**[8] in a few steps by reduction and ozonolysis. Wittig reaction of **4** with **6**[9] generated in situ gives **8** (**6**, *n*BuLi, THF, −78 °C → 0 °C, 2 h; +**4**, −78 °C → 20 °C, 3 h, 50%, *E*/*Z* = 1:1). Reduction with lithium aluminium hydride (1 equiv, THF, 20 °C; reflux, 30 min, 90%) and oxidation with pyridinium dichromate (1.5 equiv, CH_2Cl_2, 20 °C, 15 h, 87%) afforded the aldehyde **9**, which was treated with **7** to yield **3** (THF, −78 °C → 20 °C, 4 h; HCl, THF, 3 h, 70%, four isomers 1:1:1:0.1).

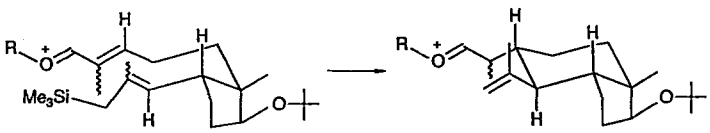


$Ph_3PC(CH_3)CH_2SiMe_3$ **6**
$H_3C(SiMe_3)C{=}NC(CH_3)_3$ **7**

8: R = CO_2Me
9: R = CHO

For the tandem Sakurai–carbonyl–ene reaction of **3**, several Lewis acids were investigated as mediators. The best results could be obtained with trimethylsilyl trifluoromethanesulfonate (TMS-OTf), which in a highly stereoselective fashion led to **2a** as the only cyclized product in 52% yield (1.1 equiv, CH_2Cl_2, −78 °C, 2 h; −30 °C, 2 h). The selectivity in this sequence is quite astounding since a mixture of all four geometrical isomers of **3** was used; we have to assume that the configuration of the double bonds in **3** has no influence on the selectivity of the Sakurai reaction; for the following carbonyl–ene reaction an epimerization of the new stereogenic center, presumably formed nonselectively, in the chain at C6 of the hydrindane 11 must be proposed. However, since the yield of **2a** is not quantitative, it is possible that one or two of the isomers do not cyclize under the reaction conditions. Amazingly, with $EtAlCl_2$ a different stereocontrol was observed; in this case the two diastereomers **2b** and **2c** were formed in a 3:1 ratio in 40% yield. Such a pronounced difference in selectivity with Lewis acids and Me_3SiOTf has recently been described for hetero-Diels–Alder reactions of 1-oxa-1,3-butadienes.[10]

As transition structures for the transformation of **3** into **2a** with Me_3SiOTf, conformations **10a** and **11a** with a chairlike arrangement of the chains and an equatorially oriented carbonyl group is assumed. The use of $EtAlCl_2$ as mediator may force the carbonyl group in the complexes **10b** and **11b** to take up an axial orientation and thus lead to the diastereomers **2b** and **2c**.



10a: R = $SiMe_3$
10b: R = $AlEtCl_2^-$

11a: R = $SiMe_3$
11b: R = $AlEtCl_2^-$

Homogeneous hydrogenation with $[(Ph_3P)_3RhCl]$ in benzene afforded **1a** as a single isomer in 96% yield. In contrast, with the heterogeneous catalyst $Pd/CaCO_3$ a 3:1 mixture of **1a** and **1b** as well as a small amount of the corresponding ketone was obtained.

The *trans*-axial arrangement of 5a-H, 9a-H, and 9b-H in **2a** could be deduced from the two large coupling constants of J = 12.5 Hz of the signal for 9a-H at δ = 1.53. The equatorial orientation of the hydroxy group at C7 and the axial orientation of the methyl group at C6, each displaying an α-configuration, is clearly seen from the two large couplings (J = 12 Hz) of the signal for 8-H_{ax} at δ = 2.16 and the large (J = 12 Hz) and two small couplings (J = 4.5 Hz) for 7-H at δ = 3.51.

Indirect $^{113}Cd,^{14}N$ Spin-Spin Coupling Constants as a Structural Probe of Solid Cadmium Thiocyanate Complexes**

By *Klaus Eichele* and *Roderick E. Wasylishen**

In the past decades the coordination chemistry of ambidentate ligands has seen explosive growth.[1] These ligands are sensitive chemical probes of their environment, and their response to electronic or steric effects is of synthetic and theoretical interest. The thiocyanate ion, in particular, has revealed a fascinating variety of coordination modes. In addition to the terminal *N*- and *S*-bonding modes, five different bridging modes have been established by single crystal X-ray diffraction.[1] Solution NMR studies have not been very informative in characterizing metal thiocyanate complexes. First, the structural integrity of these complexes is frequently lost in solution. Second, indirect spin-spin coupling constants, *J*, between NMR-active metal nuclei and ^{14}N often cannot be measured because of rapid ligand–metal exchange. Furthermore, efficient ^{14}N relaxation by the quadrupolar mechanism generally results in self-decoupling. The observation of $J(^{x}M,^{14}N)$ is important because the magnitude of *J* indicates the mode of bonding and the multiplicity provides information on the number of nitrogen atoms directly bonded to the metal.[2] The present study demonstrates that the aforementioned problems can be overcome, and $^{x}M-^{14}N$ coupling can be observed in solid-state magic-angle spinning (MAS) NMR spectra of the metal nucleus. For this purpose, the cadmium thiocyanate system is of particular interest. The Cd^{2+} ion is an acid of intermediate softness and forms many different linkage isomers with the thiocyanate ligand.[1] Moreover, cadmium, which has two isotopes of nuclear spin $I = \frac{1}{2}$, ^{111}Cd (12.8%) and ^{113}Cd (12.3%), offers the opportunity to use metal NMR to study the metal center directly.[3]

Figure 1 shows the ^{113}Cd CP–MAS NMR (CP = cross polarization) spectrum of a powder sample of tetra-*n*-propylammonium trithiocyanatocadmate(II) (**1**) together with

$(NnPr_4)[Cd(SCN)_3]$ **1**

the relevant part of the crystal structure as reported recently.[4] The central peak with isotropic chemical shift at $\delta = 310.9$ is flanked by several spinning sidebands, the intensity profile of which mimics the overall line shape that one would observe in the absence of MAS. Analysis of the spinning sideband intensities allows the reconstruction of the line shape of a static sample that is defined by the three principal components of the chemical shift tensor.[5] The magnitude of these components describes the dependence of the chemical shift on the orientation of the molecule with respect to the applied magnetic field. In the case of **1**, this orientation dependence is relatively large (components $\delta_{11} = 540$ and $\delta_{22} = \delta_{33} = 196$) and rules out a symmetrical tetrahedral or octahedral structure. This conclusion is in agreement with

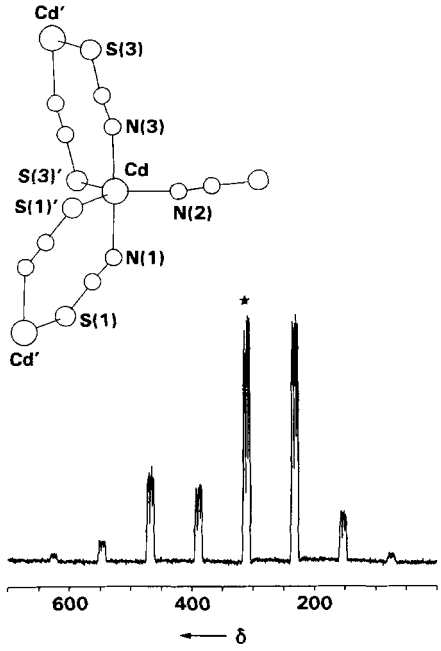

Fig. 1. Top: the relevant part of the crystal structure of **1** as reported in ref. [4]. Bottom: ^{113}Cd CP–MAS NMR spectrum (44.38 MHz) of **1**, obtained at a spinning speed of 3.5 kHz with 90° pulses of 5 μs duration after 9000 scans. The isotropic region is labeled by an asterisk. Chemical shifts are referenced with respect to $Cd(ClO_4)_2 \cdot 6H_2O$.

the reported crystal structure,[4] which indicates a trigonal-bipyramidal ligand arrangement around the cadmium center with a unique nonbridging *N*-bonded thiocyanate group in the equatorial position and four bridging ligands, *N*-bonded to the metal at apical and *S*-bonded at equatorial positions.

The most striking features of the ^{113}Cd CP–MAS NMR spectrum of **1** are the complex multiplets due to ^{113}Cd,^{14}N spin-spin interactions. An expansion of the isotropic region is shown in Figure 2. The slight asymmetry observed in the

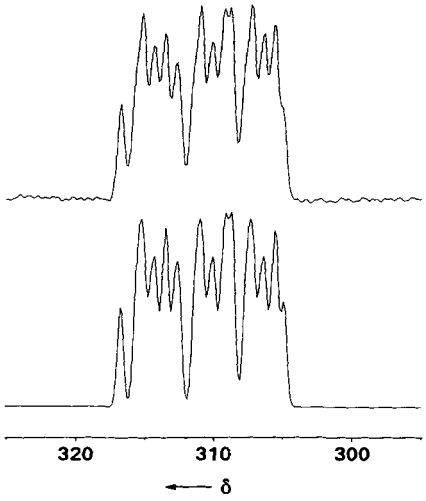

Fig. 2. Expansion of the isotropic region of the ^{113}Cd CP–MAS NMR spectrum displayed in Figure 1. The top trace shows the experimental, the bottom trace the simulated spectrum.

splitting pattern arises because of a breakdown of the high-field approximation for ^{14}N. It indicates that the quadrupolar coupling to the electric field gradient (EFG) causes a significant perturbation on the pure Zeeman energy term. Thus, the ^{14}N spin states are not solely quantized by the external field direction and the orientation dependence of the ^{113}Cd,^{14}N dipolar interaction differs from the usual $(3\cos^2\theta-1)$. As a result, MAS is unable to average the dipolar interaction completely, and the ^{113}Cd NMR frequencies are shifted relative to those in the pure high-field case.[6] A recently developed first-order perturbation approach,[7] for cases where the quadrupolar interaction with the EFG is smaller than the Zeeman interaction, has been successfully applied to analyze the MAS NMR spectrum of spin-$\frac{1}{2}$ nuclei coupled with a quadrupolar nucleus.[8] Application of this approach predicts three nonequidistant lines for ^{113}Cd coupled with one ^{14}N nucleus (Fig. 3), with frequencies $\nu_1 = |J| + d$, $\nu_2 = -2d$, and $\nu_3 = -|J| + d$, with respect to the Larmor frequency of the uncoupled ^{113}Cd nucleus. The residual dipolar coupling d is given by Equation (a)

$$d = -(3D\chi/20Z)(3\cos^2\beta - 1) \quad \text{(a)}$$

where D is the ^{113}Cd,^{14}N direct dipolar coupling constant, χ and Z are the ^{14}N quadrupolar coupling constant and Larmor frequency, respectively, and β is the angle between the Cd–N bond and the largest component of the ^{14}N EFG tensor. The dipolar coupling constant is given by Equation (b). For the case of thiocyanate complexes, the EFG at

$$D = (\mu_0/4\pi)\,\gamma_{Cd}\gamma_N r_{Cd-N}^{-3}(\hbar/2\pi) \quad \text{(b)}$$

^{14}N has been assumed to be axially symmetric.[9] Figure 3 shows, that the parameters J and d are readily obtained from

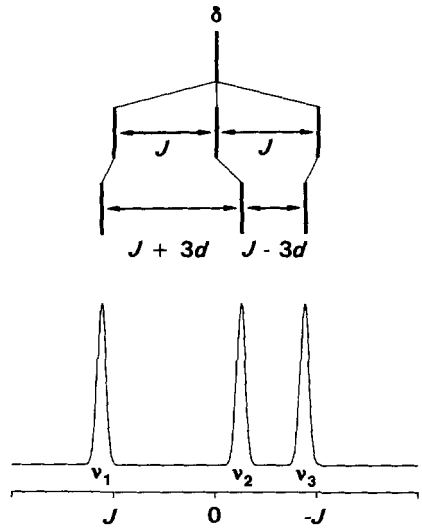

Fig. 3. Schematic representation of the CP–MAS NMR spectrum of ^{113}Cd coupled with one ^{14}N nucleus. Indirect spin-spin coupling results in three equally spaced lines. The perturbation on the ^{14}N spin states due to the quadrupolar interaction (shown here for $\chi < 0$) shifts the lines ν_1, ν_2, and ν_3 by d, $-2d$, and d, respectively, from their unperturbed positions at J, 0, and $-J$.

the separations within the asymmetric triplet. Interaction with a second ^{14}N will further split up each of the three lines into new asymmetric triplets. The simulated spectrum in Figure 2 has been calculated by expanding this simple approach to several ^{14}N nuclei coupled to ^{113}Cd, leading to three sets of values for J (and d): 178 (+ 3.8), 50 (+ 4.7), and 38 Hz (+ 4.2 Hz). As indicated by the multiplicity of this pattern and in agreement with the crystal structure, cadmium is bonded to three nonequivalent nitrogen atoms. Interestingly, $J(^{113}\text{Cd},^{14}\text{N})$ varies over a wide range, suggesting a significant dependence on subtle structural changes. Since the value of 178 Hz represents the largest $J(^{113}\text{Cd},^{14}\text{N})$ reported, it is reasonable to assign this value to the Cd–N2 bond, which shows the shortest reported bond distance, 216.3 pm. The much smaller values for $J(^{113}\text{Cd},^{14}\text{N})$, 50 and 38 Hz, are associated with the considerably longer Cd–N bond distances for Cd–N3, 233.8 pm, and Cd–N1, 236.3 pm. Similar correlations of $J(^{x}\text{M},^{31}\text{P})$ with M–P separations, r_{M-P}, have been reported for metal phosphine complexes.[10]

As indicated above, the parameter d contains information regarding the value of χ and the orientation of the largest principal component of the ^{14}N EFG tensor. Knowledge of the bond lengths leaves d dependent only on χ and β. The ^{13}C CP–MAS NMR spectrum of **1** also exhibits typical asymmetric line shapes characteristic of systems where the high-field approximation breaks down for the ^{14}N nucleus.[11] Combined analysis of the d values from ^{113}Cd and ^{13}C CP–MAS NMR spectra leads to the following values for χ (and β): -2.0 MHz (27°) for N1, -0.9 MHz (10°) for N2, and -1.9 MHz (22°) for N3. The errors in χ and β are estimated to be ± 0.2 MHz and $\pm 5°$, respectively. These values of χ are typical of those derived from nuclear quadrupole resonance (NQR) experiments for other systems containing *N*-coordinated thiocyanate ligands.[9] Noteworthy is the observation that χ for N2 is less than half χ for N1 and N3. The unique value of χ is associated with the nitrogen which exhibits the largest value of J(Cd,N) and the shortest Cd–N separation. The small value of β, 10°, is also consistent with the near linear arrangement of the Cd-N2-C2 moiety.

This analysis of the high-resolution ^{113}Cd CP–MAS NMR spectrum indicates the wealth of information available from such spectra. We have obtained the three principal

components of the ^{113}Cd chemical shift tensor and values of $J(^{113}Cd,^{14}N)$ for the three unique thiocyanate ligands in **1**. The magnitudes of $J(^{113}Cd,^{14}N)$ indicate a strong dependence on Cd–N bond length. Further studies are under way in our laboratory to examine the generality of such relationships in related compounds. In addition, the ^{14}N quadrupolar coupling constants and their respective orientations have been deduced from the ^{113}Cd and ^{13}C CP-MAS NMR spectra. None of this information is available from solution NMR studies of cadmium thiocyanate complexes. The techniques employed in this study should be applicable in characterizing other thiocyanate, cyanate, and selenocyanate complexes containing spin-$\frac{1}{2}$ metal centers.

The Structure and Stability Trends of Fluoro(methyl)plumbanes**

By *Martin Kaupp* and *Paul von R. Schleyer**

The dramatic differences in the stability of inorganic and organometallic Pb^{IV} compounds are best exemplified by comparing tetraalkyllead with lead tetrahalides: While Et_4Pb, for example, is a relatively stable compound with (still) considerable industrial use, $PbCl_4$ decomposes even at low temperatures.[1] On the other hand, Et_2Pb is unknown but $PbCl_2$ is perfectly stable. These remarkable differences between inorganic and organometallic compounds are of general importance in the chemistry of the heavy elements in groups 13 and 14 but do not yet seem to be fully understood.[2] We herein present ab initio pseudopotential calculations[3] on the structures of fluoro(methyl)plumbanes **1**–**3** which have the general formula $(CH_3)_nPbF_{4-n}$ ($n = 1-3$), as well as $(CH_3)_4Pb$ and PbF_4, and compare their stabilities with those of the corresponding divalent species $(CH_3)_2Pb$, CH_3PbF, and PbF_2.

$(CH_3)_3PbF$ **1** $(CH_3)_2PbF_2$ **2** CH_3PbF_3 **3**

The optimized geometries[3] of **1**–**3** are shown in Figure 1. The bond angles in all of these unsymmetrically substituted species deviate significantly from idealized tetrahedral values.[4] While the F-Pb-F angles are smaller than 109.5°, the

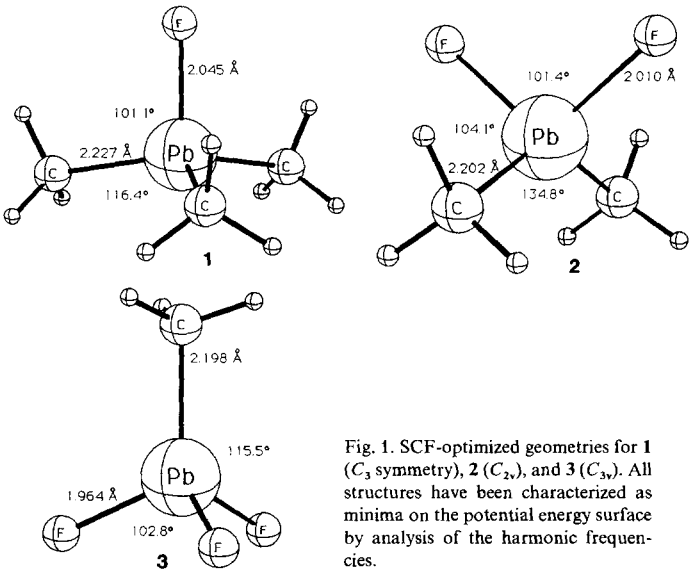

Fig. 1. SCF-optimized geometries for **1** (C_3 symmetry), **2** (C_{2v}), and **3** (C_{3v}). All structures have been characterized as minima on the potential energy surface by analysis of the harmonic frequencies.

C-Pb-C angles are considerably larger. This is most apparent in **2** with its C-Pb-C angle of approximately 135°. Similarly, the C_3Pb unit in **1** approaches planarity. These angle distortions have consequences for the polymeric arrangements found in the solid state: R_3PbX and R_2PbX_2 compounds (R is an alkyl or aryl group, X an electronegative substituent) usually form chain structures of types **4** and **5**, respectively.[1b] Note the almost planar PbR_3 arrangement in **4** (cf. **1**) and the *trans* orientation of the alkyl groups in **5** (cf. **2**). The calculated Pb–C and Pb–F bonds shorten when the number of fluorine substituents is increased,[5] consistent with the results of calculations on the fluoromethanes and -silanes.[6]

Both the distorted bond angles and the contracted bond lengths may be rationalized by hybridization arguments with

nonorthogonal hybrid orbitals.[6a, 7] Figure 2 displays the partial atomic charges on lead, the p:s ratio n of the Pb-sp^n hybridization of the hybrid orbitals used for Pb–C and Pb–F bonding, and the p:s ratio of the average Pb hybridization (Weinhold et al.'s "natural population/hybridization analysis" (NPA)[8] was employed). With increasing fluorine substitution, the positive charge on lead increases, and to the contributions of the p orbitals to the Pb hybrid orbitals and the bonding decrease. The larger contributions of the s orbitals to the bonds lead to the observed bond length contraction. Since the hybrid orbitals directed towards the electronegative fluorine substituents generally exhibit roughly twice as much p character as the hybrids used for Pb–C bonding (Fig. 2), the observed deviations from 109.5° angles follow expectations based on Bent's rule.[9]

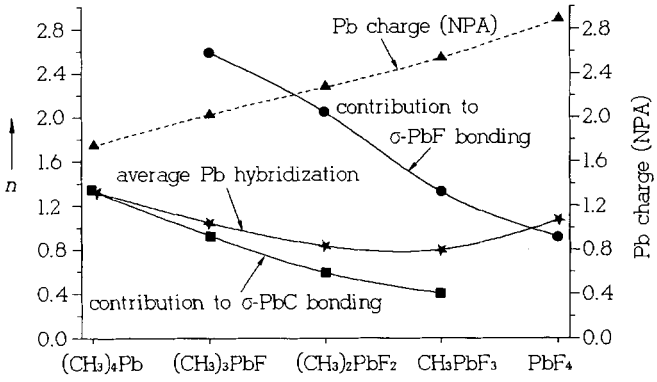

Fig. 2. p:s Ratio n of the Pb-sp^n hybridization (based on "natural population analysis" NPA[7]) and partial atomic charges on lead (NPA[7]) for the homologous series of fluoro(methyl)plumbanes (the average lead NPA hybridization and the p:s ratios of the contributions of the lead hybrid orbitals to the σ-bonding "natural localized MOs" (NLMOs)[7] are given). The differences between the average p:s ratio and the p:s ratio of the lead contributions to the σPb–F bonding NLMOs in PbF_4 are due to small hyperconjugative interactions.

The energies ΔE for the 1,1-elimination of F_2, methyl fluoride, or ethane from these Pb^{IV} compounds (to give Pb^{II} derivatives) are shown in Figure 3. In general, these reactions become less endothermic or more exothermic as the number of fluorine substituents increases. For example,

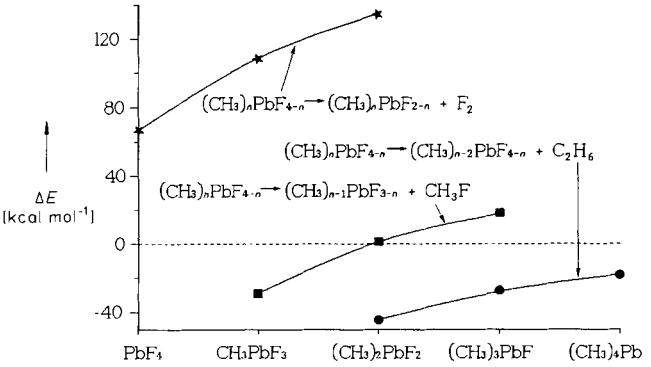

Fig. 3. Calculated energies ΔE [kcal mol^{-1}] for 1,1-elimination reactions (loss of F_2, C_2H_6, or CH_3F, respectively) of substituted Pb^{IV} compounds $(CH_3)_nPbF_{4-n}$ ($n = 0$–4). These reactions convert Pb^{IV} to Pb^{II} compounds. The MP4SDTQ single-point calculations at the SCF-optimized geometries [2,4] (cf. Fig. 1) used the same basis sets employed for the geometry optimizations [2] (the reaction $(CH_3)_4Pb \rightarrow (CH_3)_2Pb + C_2H_6$ was calculated at the MP4SDQ level).

elimination of CH_3F from $(CH_3)_3PbF$ (**1**) is *endothermic*, whereas loss of CH_3F is quite *exothermic* for CH_3PbF_3 (**3**). Obviously, the tetravalent lead compounds are destabilized in this sense by electronegative substituents. As a result, the disproportionation reaction $2\,(CH_3)_2Pb \rightarrow Pb(^3P) + (CH_3)_4Pb$ is exothermic, but the reaction $2\,PbF_2 \rightarrow Pb(^3P) + PbF_4$ is strongly endothermic.[10].

This destabilization of Pb^{IV} compounds by electronegative substituents may also be explained by the hybridization. The increasing metal charge contracts the lead 6s orbitals more strongly than the 6p orbitals.[11] Thus, the already significant differences in the radial extension of s and p orbitals in compounds of heavy main-group elements[7] become even larger. Since efficient hybridization requires the size of the orbitals involved to be similar, electronegative substituents increase the hybridization defects[7] (cf. Fig. 2) which leads to less efficient covalent bonding. A possible gain in ionic bonding contributions in the polyhalo compounds most probably is compensated by the increased electrostatic repulsions between the substituents.

In contrast to these Pb^{IV} compounds, alkanes and silanes are stabilized by geminal fluorine substitution.[6] This was shown to be due to negative hyperconjugation $n(F) \rightarrow \sigma^*(AH, AF)$ (A = C, Si).[6a] Due to less favorable orbital overlap, these hyperconjugative interactions which lead to a delocalization of the electron density do not contribute significantly to the stabilization of multiply fluorosubstituted alkylplumbanes. Preliminary calculations on the corresponding parent compounds (H instead of alkyl) with both quasi-relativistic and nonrelativistic lead pseudopotentials indicate that relativistic effects also contribute to the trends discussed here. We will present more detailed analyses of a larger set of such group 14 derivatives in a the full paper.

$[(\eta^5\text{-Cp})_2Sn(\mu\text{-}\eta^5\text{-Cp})Na \cdot PMDETA]$, a Compound with a Trigonal-Planar "Paddle Wheel" Triorganostannate Ion**

By *Matthew G. Davidson, Dietmar Stalke,* and *Dominic S. Wright**

Recently we have explored the bonding between early main group metals M (alkali or alkaline earth metals) and heavy p-block metals E such as In, Tl (group 3), Sn, Pb (group 4), and Sb, Bi (group 5).[1, 2] The monomeric complex $[Ph_3SnLi \cdot PMDETA]$ (PMDETA = $(Me_2NCH_2CH_2)_2$-NMe) was shown to be the first compound to contain such a bond in the solid state,[1] and the retention of such bonding in solutions of this complex was proved by the first observation of direct $^{119,117}Sn$–^7Li NMR coupling.[1] More recently our efforts have concerned the development of synthetic routes to complexes with M–E bonds (including M = Sn).[2]

Here we report the synthesis of the title compound **1** by the addition of sodium cyclopentadienide (CpNa) to bis(cyclopentadienyl)tin(II)[3] and PMDETA (mol ratio 1:1:1) in THF. Recrystallization of the crude product from toluene gives yellow crystals of **1** (see *Experimental Procedure*), which were investigated by X-ray diffraction.[4]

$[(\eta^5\text{-Cp})_2Sn(\mu\text{-}\eta^5\text{-Cp})Na \cdot PMDETA]$ **1**

Compound **1** is monomeric in solid state (Fig. 1 top). The structure contains an $(\eta^5\text{-Cp})_3Sn$ unit, a "paddle wheel" triorganostannate anion in which one Cp ligand is additionally involved in a $Sn(\mu\text{-}\eta^5\text{-Cp})Na$ bridge. The Sn center is nearly trigonal-planar (average angle Cp_c-Sn-Cp_c, 119.7(1)°, Cp_c = Cp centroid); Sn deviates approximately 0.14 Å from the plane of the three Cp centroids. The overall structure of **1**, and in particular the geometry of its Cp_3Sn unit, can be rationalized in terms of the competition by the Sn and Na centers for the electron density on the $\mu\text{-}\eta^5$-Cp ligand, through the slightly bent $Sn(\mu\text{-}\eta^5\text{-Cp})Na$ bridge (Sn(1)-Cp(A)-Na(1) 172.3(1)°). This competition weakens the interaction of the $\mu\text{-}\eta^5$-Cp contact with the Sn center (Cp(A)–Sn(1) 2.733(1) Å) compared to that between Sn and terminally attached Cp ligands (average value Cp(B,C)–Sn(1), 2.538(1) Å; cf. Sn–Cp, ca. 2.42 Å in $[Cp_2Sn]$[3]).

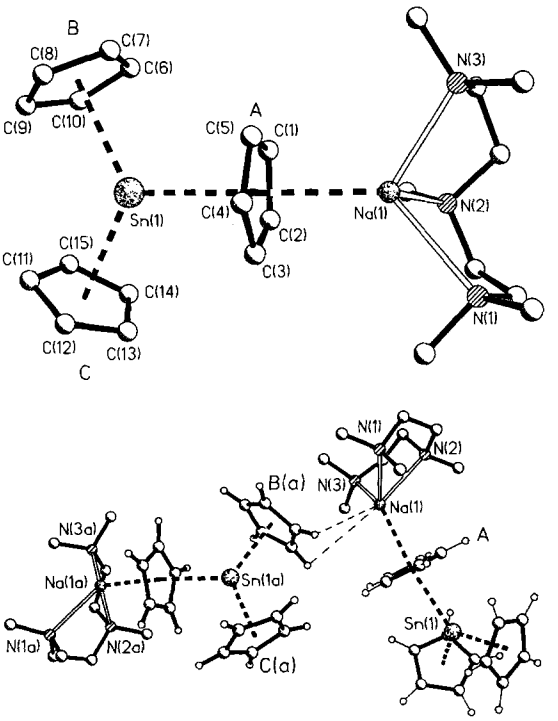

Fig. 1. Top: Crystal structure of **1**. Hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Cp(A)-Sn(1) 2.733(1), Cp(B)-Sn(1) 2.551(1), Cp(C)-Sn(1) 2.526(1), Cp(A)-Na(1) 2.550(1); Cp(A)-Sn(1)-Cp(B) 116.3(1), Cp(A)-Sn(1)-Cp(C) 118.9(1), Cp(B)-Sn(1)-Cp(C) 124.0(1), Sn(1)-Cp(A)-Na(1) 172.3(1). Bottom: Crystal packing of **1** determined by intermolecular C–H ··· Na interactions. Selected distances [Å]: H ··· Na 3.148(2), 3.490(2).

The deviation from linearity of the $Sn(\mu\text{-}\eta^5\text{-Cp})Na$ bridge (172.3(1)°) appears to be almost entirely a consequence of crystal packing. The Na–Cp_c vector is almost perpendicular (88.30(1)°) to the plane of the Cp ligand (Cp(A)–Na(1) 2.550(1) Å; cf. $(\mu\text{-}\eta^5\text{-Cp})$–Na in the polymer $[(\mu\text{-}\eta^5\text{-Cp})Na \cdot TMEDA]_\infty$ (TMEDA = $Me_2NCH_2CH_2NMe_2$) ca. 2.65 Å,[5] and Cp*–Na (Cp* = C_5Me_5) in molecular $[Cp^*Na(py)_3]$ (py = pyridine) 2.40 Å[6]). This bending of the $Sn(\mu\text{-}\eta^5\text{-Cp})Na$ bridge is caused by two long-range intermolecular C(H) ··· Na interactions (H ··· Na(1) 3.148(2) and 3.490(2) Å) with the $Na \cdot PMDETA^+$ unit. Thus, the apparently "naked" Na face is further coordinated and, as a result, units of **1** are linked into a polymeric array (Fig. 1 bottom).

Although a number of early main group metal stannates have been structurally characterized, only $[Ph_3SnLi \cdot PMDETA]$ contains a metal–Sn contact.[1] The role of the $\mu\text{-}\eta^5$-Cp ligand in **1** in holding the Sn and Na centers together is comparable with that of bridging heteroatoms (e.g., O, P, Cl) in other stannate complexes, for example O in $[Li(\mu_2\text{-}Ph_2C_6H_3O)_3Sn]$.[7] The planar geometry of the Sn center in **1** is unprecedented in the structures of triorganostannates.

[**] This work was supported by the British Science and Engineering Research Council (D. S. W., M. G. D.), the Associated Octel Co. Ltd., Ellesmere Port (M. G. D.), and the Deutsche Forschungsgemeinschaft (D. S.). We also thank S. Wilkinson (Cambridge) for recording NMR spectra.

All other such complexes, whether separated ions[8] or contact ion pairs are present,[1] have nearly pyramidal stannate ions as a result of the construction of σ bonds with substantial Sn p character and the lone pair on Sn having mainly s character. The geometry of the Sn center in **1** implies a very different use of orbitals than in other stannates.[9]

The title compound **1** is rare among organotin(II) compounds in containing three aromatic ligands π-bonded to Sn. Polymerically linked (μ-η^5-Cp)$_3$SnX units (X = μ-F-BF_3^- and THF) have been seen in the structure of $\{[(\eta^5\text{-Cp})_2\text{Sn}(\mu\text{-}\eta^5\text{-Cp})\text{Sn(thf)}]^+BF_4^-\}_\infty$, produced by the reaction of BF_3 with [Cp_2Sn] in THF (Cp–Sn, ca. 2.29–3.67 Å).[10] In orthorhombic [Cp_2Pb], (μ-η^5-Cp)$_2$(η^5-Cp)Pb units are present within its polymeric zigzag structure[11] (cf. the well-known bent structure of [Cp_2Sn][3]). Interestingly [Cp_2Pb] forms a 1:1 electrolyte in THF.[12] On the basis of our current work, it seems most likely that $[\text{CpPb(thf)}_x]^+[Cp_3Pb]^-$ is present in solution, rather than the suggested $[\text{CpPb}]^+$ and discrete Cp^- ions.[12, 13]

Finally, cryoscopic molecular mass determinations combined with variable-temperature ^{1}H NMR spectroscopy show that **1** is involved in a dissociative equilibrium in aromatic solvents.[14] At room temperature **1** is completely dissociated into $[(\eta^5\text{-Cp})_3\text{Sn}]^-$ and [Na · PMDETA]$^+$ ions. As the temperature is reduced (finally to ca. −80 °C) these ions pair up to give intact **1**. These results illustrate that the paddle wheel $[(\eta^5\text{-Cp})_3\text{Sn}]^-$ ion has a separate existence.

Previous work has concentrated on the reactions of electrophiles such as MeI with [Cp_2Sn].[13, 15] We are currently investigating the addition reactions (which produce mixed-ligand triorganostannates $[Cp_2RSn]^-$) and the substitution reactions (which produce mixed ligand organotin compounds [CpSnR]) of various nucleophiles, such as organolithium compounds, with [Cp_2Sn]. To our knowledge, these are new approaches to triorganostannate complexes and organotin(II) compounds. We are also investigating the use of $[Cp_3Sn]^-$ as a new ligand to other main group metals.

Experimental Procedure

1: CpNa (1.25 mL, 2.0 mol L^{-1} in THF, 2.5 mmol) was added to a solution of [Cp_2Sn] (0.623 g, 2.5 mmol) (preparation ref. [3]) and PMDETA (0.53 mL, 2.5 mmol) in THF (5 mL) at 20 °C under nitrogen. Stirring the reaction mixture (0.5 h) at 20 °C gave an orange-red solution. The THF was removed under vacuum, replaced with toluene (5 mL), and the solution was filtered to remove a faint precipitate. Storage of the orange-red filtrate at 20 °C (48 h) gave air-sensitive, yellow crystals, identified as **1**. First-batch yield 20%, m.p. 93–98 °C to a yellow oil. IR (solid): $\tilde{\nu}$ = 3079, 3061 cm^{-1} (s, ν, C-H, η^5-Cp), disappears upon exposure to air. ^{1}H NMR (25 °C, C_6D_6): δ = 6.00 (s, 15H; η^5- and μ-η^5-CpH; cf. δ = 5.78 (^2J(Sn,H) = 15.7 Hz) in [Cp_2Sn]), 1.80 (s, 15H; CH_3N and $(CH_3)_2N$), 1.65 (s, 8H; $(CH_2)_2$). Correct C, H, N analysis.

[14] Cryoscopic molecular mass measurements (in benzene) show that two solution species are present over a range of concentrations (n = 0.49 ± 0.02 (0.015 mol L^{-1}); 0.51 ± 0.02 (0.030 mol L^{-1})). ^{1}H NMR spectra of **1** at 25 °C (in $C_6D_5CD_3$) have, apart from signals due to PMDETA, just one sharp signal at δ = 5.97 due to discrete $[(\eta^5\text{-Cp})_3\text{Sn}]^-$ ions. No signals below this could be attributed to CpNa. Reducing the temperature to ca. −40 °C results in the splitting of the η^5-Cp signal. At ca. −80 °C these two resonances are fully resolved at a ratio of 2:1; δ = 6.02 (η^5-Cp, ^2J(Sn, H) = 29.4 Hz), and 6.00 (μ-η^5-Cp, ^2J(Sn, H) = 28.8 Hz).

Opening of an Aza-*closo*-dodecaborane to an Aza-*nido*-dodecaborate**

By *Franc Meyer, Jens Müller, Peter Paetzold,** and *Roland Boese*

Aza-*closo*-dodecaborane $NB_{11}H_{12}$ is isoelectronic with dicarba-*closo*-dodecaborane $C_2B_{10}H_{12}$.[1] Upon attack by base the icosahedral framework of $C_2B_{10}H_{12}$ is broken down into the open frame of dicarba-*nido*-undecaborate $C_2B_9H_{12}^-$.[2] We wanted to apply this reaction to $NB_{11}H_{12}$. Its N-bound proton is so acidic, however, that it is removed even by a weak base like NEt_3 forming $[HNEt_3][NB_{11}H_{11}]$ **1**.[1] Thus, before the examination of the attack of a base on the NB_{11} framework, it was imperative to protect the N atom by alkylation. The salt **1** was treated with the strong methylating agent methyltriflate, and $MeNB_{11}H_{11}$ **2** was obtained [Eq. (a)]. The three ^{11}B NMR signals of **2**, their intensity ratio of 5:5:1, and the characteristic B–H coupling constant leave no doubt that $NB_{11}H_{12}$ and its methyl derivative are structurally analogous.

$$\underset{\mathbf{1}}{[HNEt_3][NB_{11}H_{11}]} \xrightarrow[-[HNEt_3][O_3SCF_3]]{+MeO_3SCF_3} \underset{\mathbf{2}}{MeNB_{11}H_{11}} \qquad (a)$$

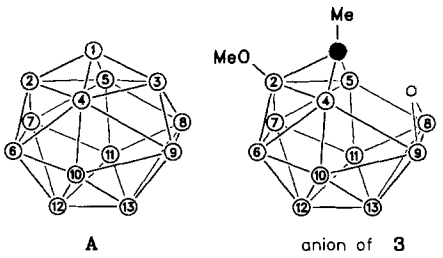
Compound **2** adds methanol in the ratio 1:1 and thereby forms the acid $H[MeNB_{11}H_{11}(OMe)]$, which is completely dissociated in dichloromethane solvent in the presence of an excess of methanol. The acid cannot be isolated in a pure form; when solvent is removed under vacuum, the acid decomposes completely to yet-unknown fragments. If the salt $[N(PPh_3)_2]Cl$ is added to a solution of the acid, one obtains product **3** [Eq. (b)], the anion of which is identical to that of the acid as is evident from their identical NMR spectra.

$$2 \xrightarrow{+MeOH} \xrightarrow[-HCl]{+[N(PPh_3)_2]Cl} [N(PPh_3)_2][MeNB_{11}H_{11}(OMe)] \qquad (b)$$

3

The structure of the anion of **3** is derived from the hypothetical *closo*-tridecaborate $B_{13}H_{13}^{2-}$ **A**[3] by removal of the B3 atom. Seven signals are seen in the ^{11}B NMR spectrum with the intensity ratio 1:2:2:2:1:2:1. Thus, three B atoms lie in one mirror plane, namely B2, B12, and B13, and one of these, B2, does not show B–H coupling. The 2D ^{11}B–^{11}B NMR spectrum reflects the connectivity of the B_{12} framework; the lack of a cross peak between B2 and B4/B5 is expected for a B–B bond bridged by an N atom.[4] The $^1H\{^{11}B\}$ NMR spectrum also consists of seven signals of the B-bound H atoms with the intensity ratio 1:1:2:2:2:1:2; they could be assigned with the help of the 2D ^{11}B–^1H NMR spectrum. Of special interest are the atoms B8/B9, each bound to a terminal H atom as well as a bridging H atom, and the atom B2, not bound to any H atom.



The unequivocal assignment of the spectroscopic data to the structure of the anion of **3** in solution is in agreement with the results of the X-ray structure analysis (Fig. 1).[5]

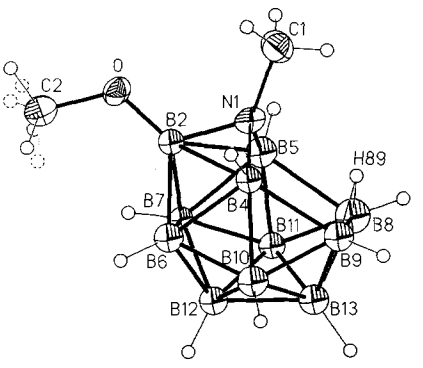


Fig. 1. Crystal structure of the anion of **3**. Selected distances [Å], standard deviations in parentheses: N1-B2 1.490(5), N1-B4 1.520(9), N1-B5 1.604(10), B2-B4 2.004(9), B2-B5 2.107(10), B2-B6 1.813(8), B2-B7 1.814(8), B4-B6 1.910(10), B4-B9 1.969(9), B4-B10 1.852(8), B5-B7 1.863(9), B5-B8 2.053(10), B5-B11 1.724(8), B6-B7 1.797(10), B6-B10 1.782(10), B6-B12 1.788(9), B7-B12 1.740(8), B7-B11 1.774(9), B8-B11 1.714(10), B8-B9 1.819(11), B9-B10 1.766(10), B9-B13 1.727(9), B10-B12 1.755(11), B10-B13 1.820(11), B11-B12 1.837(11), B11-B13 1.791(11), B12-B13 1.821(6), N1-C1 1.464(5); B2-O 1.356(4).

Whereas all 21 of the B–B distances remote from nitrogen fall within the range expected between 1.71 and 1.91 Å, the two distances B4–B9 and B5–B8 in the open pentagon of the cluster, as well as the distances B2–B4 and B2–B5, bridged by the N atom, are all especially long (1.97–2.11 Å). Accordingly, the triangles B2-B4-N and B2-B5-N deviate from equilateral with angles at the N atom of 83.5 and 85.8°, respectively. The further away the cluster faces are from the N atom, the closer they approach regularity.

The *nido* structure found for the anion of **3** is exactly that expected. Removal of the B3 atom from the hypothetical *closo* skeleton **A** eliminates the unfavorable connectivity $k = 6$ of the atoms B4 and B5 in the cluster framework, which means sevenfold coordination when the the *exo* H atoms are also taken into account. Simultaneously, an optimal place is made available for the electronegative N atom in position 1 with $k = 3$. Atoms B8 and B9 attain the connectivity $k = 4$, and are thus able to accommodate a bridging H atom on the mirror plane of the free anion of **3**, whereas all the other B atoms with $k = 5$ are not likely to form H bridges. Two other compounds set the precedent for the *nido* structure found here. One is the compound *nido*-$[(Cp^*Rh)OB_{10}H_8Cl(PMe_2Ph)]$ with the strongly electronegative O atom in position 1, the Rh atom surprisingly in position 8 (transition metals usually prefer positions with higher connectivity), and the ligands Cl and PMe_2Ph in the positions 5 and 9, respectively.[6] In the second example, $[(CpCo)Se_2B_9H_9]$, the Co atom and the two Se atoms occupy the respective positions 4, 1, and 9, so that the Se atoms have a minimum connectivity and the metal atom a maximum. In addition, the metal atom has the Se atoms as desirable neighbors.[7] The *nido* compound $Et_4C_4B_8H_8$ follows the same structural principle, but in this case the B4–B9 bond is opened so that the electronegative C atoms occupy positions 1, 4, 8, and 9 with two of these positions having $k = 3$ and the other two $k = 4$.[8] Other possibilities for obtaining *nido* derivatives of **A** arise from the removal of atom B5, or of B1 with simultaneous opening of the B5–B8 bond.[9]

The structure of the anion of **3** appears to be thermodynamically very stable, since **3** does not react solvolytically with either water or alcohols. The same anion is formed when **2** is treated with LiMe/tmeda, KO*t*Bu/[18]crown-6, or KF/[18]crown-6; however, instead of the base MeO^-, the respective bases Me^-, $tBuO^-$, and F^- are bound in the 2 position.[10] In the formation of these anions, the bridging H atom apparently comes from the formerly terminal position 2, having been displaced by the base. Methanol may also be considered as a source of the μ-H atom. However, in the methanolysis of **2** with CD_3OD no deuterium is transferred to the bridging position. This proves that it is the H atom in the 2 position of **2** that is apparently shifted intramolecularly to the bridging position during the methanolysis, and in addition that this H atom does not undergo exchange with either the excess of methanol or the protons of the medium.

The attack of base on *closo*-$MeNB_{11}H_{11}$ proceeds differently to that on *closo*-$C_2B_{10}H_{12}$. In the case reported, instead of the strongly basic alkoxide, weakly basic alcohol suffices; the twelve-vertex *closo* cluster is not broken down into an eleven-vertex *nido* cluster, but is rather opened to a twelve-vertex *nido* cluster.

Experimental Procedure

2: Methyltriflate (0.46 mL, 4.19 mmol) was added dropwise to a solution of **1** (1.02 g, 4.14 mmol) in 20 mL of CH_2Cl_2 at −50 °C. The reaction mixture was stirred at room temperature for 12h. The solvent was then removed under vacuum and the residue extracted with pentane (3 × 15 mL). The combined

pentane solutions were concentrated to 10 mL and cooled to −40 °C. A colorless solid crystallized (0.28 g, 42%), which sublimed at 20 °C/0.001 Torr.—NMR spectra measured in C_6D_6 at 25 °C; ^{1}H NMR (499.843 MHz, TMS): δ = 1.83 (s, Me), 2.16 (H2–H6), 2.47 (H7–H11), 3.03 (H12), measurement and assignment of the three B–H signals as cross peaks in the 2D ^{11}B–^{1}H NMR spectrum; ^{11}B NMR (160.364 MHz, $Et_2O{\cdot}BF_3$): δ = −11.2 (d, J = 147 Hz, B7–B11, cross peaks in the 2D ^{11}B–^{11}B NMR spectrum with B2–B6 and with B12), −5.1 (d, J = 183 Hz, B2–B6, no cross peak with B12), −0.1 (d, J = 147 Hz, B12).

3: To a solution of **2** (39.0 mg, 0.245 mmol) in 2 mL of CH_2Cl_2 at room temperature was added 0.10 mL of methanol. This mixture was stirred for 30 min and then treated with a solution of $[N(PPh_3)_2Cl]$ (140 mg, 0.256 mmol) in 3 mL of CH_2Cl_2. Pentane was added to the reaction mixture; **3** precipitated and was filtered, washed with pentane three times, and dried. Analytically pure bis(triphenylphosphoranylidene)ammonium [2-methoxy-1-methyl-8,9-μ-hydrodecahydro-1-aza-*nido*-dodecaborate] (**3**) was obtained (175 mg, 98%). Single crystals of **3** were obtained from hexane/dichloromethane at −40 °C. – NMR spectra were measured at 25 °C in $CDCl_3$ (same frequencies and standard as for **2**); ^{1}H{^{11}B} NMR: δ = −3.81 (broad, μ-H8/9), 0.32 (H13), 1.41 (H10/11), 1.52 (H4/5), 1.85 (H6/7), 2.15 (s, 3H, NMe), 2.44 (H12), 3.16 (H8/9), 3.80 (s, 3H, OMe), 7.42–7.68 (30H, Ph), assignment of the *exo* B-H signals as cross peaks in the 2D ^{11}B–^{1}H NMR spectrum; ^{11}B NMR spectrum: δ = −34.7 (d, J = 134 Hz, B13), −18.6 (d, J = 134 Hz, B6/7), −13.4 (d, J = 134 Hz, B4/5), −11.8 (d, J = 134 Hz, B10/11), −8.2 (d, J = 134 Hz, B12), 1.9 (d, J = 147 Hz, B8/9), 9.3 (s, B2), assignment with help of the cross peaks in the 2D ^{11}B–^{11}B NMR spectrum; ^{13}C NMR (125.697 Hz, TMS): δ = 37.7 (NMe), 53.4 (OMe), 126.9 (d, J_{PC} = 108 Hz, *ipso*-C of Ph), 129.6, 132.0, 133.8 (Ph).

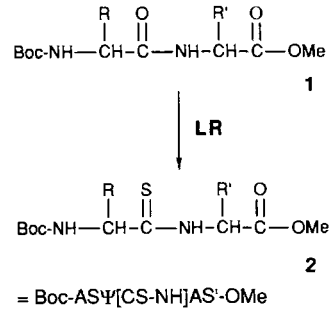
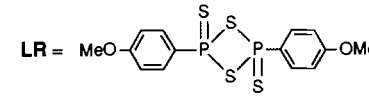
Chain Elongation of Thiodipeptides with Proteases**

By *Carlo Unverzagt,* Armin Geyer,* and *Horst Kessler**

The thioamide bond is a useful element for the structural variation of biologically active peptides to increase their activity and selectivity. Thiopeptides are attractive as peptidomimetics[1] because of their enhanced stability towards proteases[2] and the conformational changes they induce.[3] Their general application has been, however, prevented by insufficient synthetic availability. The O/S exchange in peptides by Lawesson's reagent[4] or its variants[5] may be selective in cyclic peptides[3, 6b] but its effectiveness is difficult to predict. Only protected dipeptides **1** allow the selective O/S exchange at the amide position (→ **2**) in high yields without affecting urethane or ester groups. Deprotection of thiopeptides **2** generally causes no difficulties.



= Boc-ASΨ[CS-NH]AS'-OMe

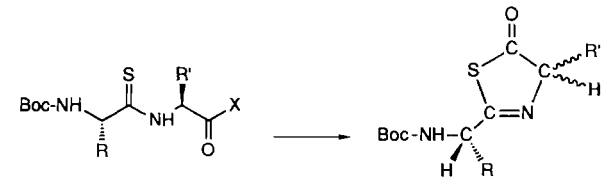


Boc-D-Ala-Ψ[CS-NH]Phe-OMe **2a**

Boc-LeuΨ[CS-NH]Leu-OMe **2b**

Boc-PheΨ[CS-NH]Gly-OMe **2c**

Peptide elongation at the C terminus of thiopeptides by means of classical peptide chemistry fails;[6] instead the activated thiopeptide **3** forms a sulfur-containing heterocycle **4**. These thiazolones **4** are poor acylating agents and are prone to racemization of the two chiral centers. Hence, only few elongations of thiopeptides have been performed with achiral C termini, such as glycine or α-aminobutyric acid.[6]



We report here on the enzymatic C-terminal elongation of thiopeptides **2a**, **b** and the N-terminal elongation of the derivative of **2c** deblocked at the N terminus (= **5c**). Subtilisin Carlsberg and subtilisin BPN′ accept **2a–c** as substrates: in 50% dimethylformamide (DMF) the corresponding free carboxylic acids are obtained in almost quantitative yield. Under these conditions proteases do not cleave amide bonds.[7, 8] Proteases can also be used to catalyze the elongation of amino acid esters and peptide esters at their C terminus.[8] We have successfully applied this mild synthetic method to sensitive thiopeptides. The subtilisin BPN′ catalyzed reaction of thiopeptide methyl ester **2a** with leucine amide H-Leu-NH_2 (**5c**) yields mainly the hydrolyzed dipeptide acid (60%) but also the desired tripeptide **6c** (24%) (see Table 1). Obviously the enzyme activates **2a** mildly, thereby allowing the elongation to thiopeptide **6c**, whereas the undesired side product (thiazolone) is not formed. The 250 MHz ^{1}H NMR spectrum of **6c** exhibits a characteristic signal for the thioamide proton at δ = 10.2 and the resonances of all three amino acids. It also proves the sterochemical uniformity of the peptide bond formation.

The yields in the enzymatic peptide elongation of **2a** with H-Leu-NH_2 (**5c**) could be increased with chymotrypsin as a biocatalyst (Table 1). Under the reaction conditions the thiodipeptides are completely converted into **6** by hydrolysis

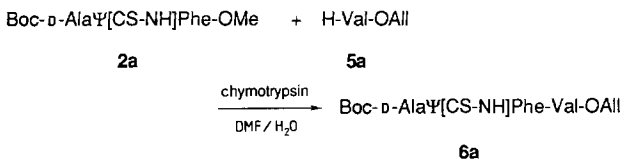
Table 1. Thiopeptides **6a–g** synthesized with chymotrypsin.

Starting materials [a]	Thiopeptides	Yield [%]
2a + **5a**	Boc-D-AlaΨ[CS-NH]Phe-Val-OAll **6a**	70
2a + **5b**	Boc-D-AlaΨ[CS-NH]Phe-Val-OMe **6b**	49
2a + **5c**	Boc-D-AlaΨ[CS-NH]Phe-Leu-NH_2 **6c**	48
2a + **5e**	Boc-D-AlaΨ[CS-NH]Phe-PheΨ[CS-NH]Gly-OMe **6d**	63
	+ Boc-D-AlaΨ[CS-NH]Phe-(PheΨ[CS-NH]Gly)$_2$-OMe **6e**	8 [b]
2b + **5d**	Boc-LeuΨ[CS-NH]Leu-Phe-NH_2 **6f**	66
2b + **5e**	Boc-LeuΨ[CS-NH]Leu-PheΨ[CS-NH]Gly-OMe **6g**	26

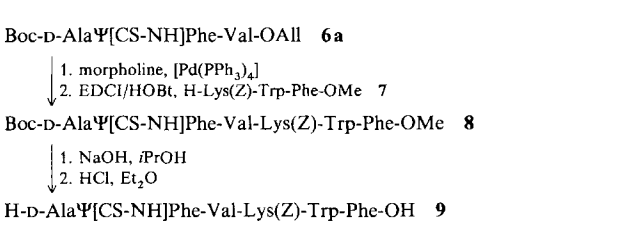
[a] **5a** = H-Val-OAll, **5b** = H-Val-OMe, **5c** = H-Leu-NH_2, **5d** = H-Phe-NH_2, **5e** = H-PheΨ[CS-NH]Gly-OMe. [b] Byproduct in the synthesis of **6d**.

or peptide elongation. Exceptions are the reactions of **2a** + **5c** and **2b** + **5e** in which 46 and 30% of the respective starting peptides were recovered. The results of the enzymatic reactions (Table 1) are not optimized, and yields may be increased by variation of cosolvent, substrate, and enzyme.

When thiopeptides such as **5e** are used as the amino component in peptide couplings, tetrapeptides with alternating thioamide bonds (**6d, g**) are formed. The hexapeptide **6e** containing three thioamide groups was isolated as a byproduct (8%) in the synthesis of **6d**. Apparently some of the amine **5e** dimerized to the tetrapeptide H-PheΨ[CS-NH]Gly-PheΨ[CS-NH]Gly-OMe, which was then preferentially elongated by chymotrypsin to **6e**.



Chymotrypsin cleaves peptides after aromatic amino acids and leucine with high specifity,[8] but does not attack valine esters.[9] Hence, the reaction of thiopeptide **2a** with valine allyl and methyl esters **5a, b** proceeds to thiotripeptides esters. It is remarkable that the slightly larger and more lipophilic allyl ester group in the nucleophile increases the yield by more than 20%. The resulting tripeptides **6a** (70% yield) and **6b** (49% yield) can be deprotected and incorporated into larger fragments. Removal of the allyl ester protecting group in thiotripeptide **6a** under Pd^0 catalysis was not affected by the nucleophilic thioamide sulfur atom (Scheme 1).[10, 11] Subsequent coupling with **7** in the presence of *N'*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride/1-hydroxybenzotriazole (EDCI/HOBt) gave thiohexapeptide **8** in 85% yield. Deprotection yielded **9** which is presently under investigation in cyclization reactions.



Scheme 1. Reactions sequence starting from thiopeptide **6a**.

The method described here for the enzymatic elongation of thiodipeptides can certainly be applied for the elongation of a number of other amino acids at the *C* terminus. The choice of suitable enzymes and appropriate protecting groups should allow the selective introduction of thioamide bonds in a variety of peptide linkages.

Experimental Precedure

N-tert-Butyloxycarbonyl-D-thioalanyl-L-phenylalanyl-L-valine allyl ester (**6a**): A 500 mg portion (1.37 mmol) of **2a** and 860 mg (5.48 mmol) of **5a** were dissolved in 21.2 mL of DMF/H_2O (1/1) in a plastic vessel. 250 mg of chymotrypsin was added, and the solution was stirred for 48 h. The mixture was concentrated in high vacuum and chromatographed on 30 g silica gel eluting with CH_2Cl_2/MeOH (100/1). Yield 472 mg (70%) **6a**. $[\alpha]_D^{22} = -4.0$ ($c = 1$, MeOH).

2,4-Didehydrophenol—First Proof of a *meta*-Aryne by IR Spectroscopy**

By *Götz Bucher, Wolfram Sander,* Elfi Kraka,* and *Dieter Cremer**

Dedicated to Professor Günther Maier on the occasion of his 60th birthday

Since the pioneering work of Wittig et al.[1] arynes have enjoyed a special status in mechanistic and preparative organic chemistry.[2] This area has received added impetus re-

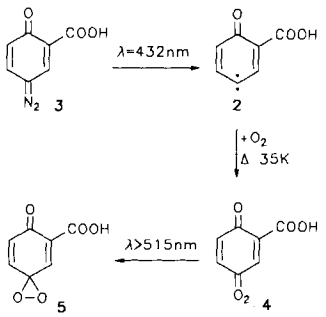
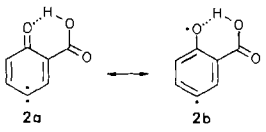
cently from the discovery that derivatives of *p*-dehydrobenzene play an important role in the mechanism of action of the enediyne anticancer agents.[3] Although *o*-dehydrobenzene has been well characterized,[4] unequivocal spectroscopic evidence for *m*- and *p*-dehydrobenzene is lacking. 9,10-Dehydroanthracene is the only derivative of *p*-dehydrobenzene to be characterized by spectroscopy.[5] Both *m*- and *p*-dehydrobenzene have already been investigated by mass spectrometry and UV spectroscopy,[6a, b] but the methods employed did not allow a definite assignment of the UV spectra. Recently, the heats of formation of *o*-, *m*-, and *p*-dehydrobenzene determined by mass spectrometry by measurement of the collision-induced dissociation (CID) were shown to be 106 ± 3, 116 ± 3, and 128 ± 3 kcal mol^{-1}, respectively.[7] According to these results *m*- and *p*-dehydrobenzene should be isolable in a matrix. Ab initio investigations of the dehydrobenzenes have not thoroughly treated *m*- and *p*-dehydrobenzene.[8] The *ortho* isomer has received more attention; its harmonic oscillation frequencies have been determined on the GVB,[9] MP2, and TCSCF levels.[10] Here we report on the first direct IR spectroscopic proof of 2,4-didehydrophenol (**1**), an *m*-dehydrobenzene, by means of matrix isolation.[11, 12]

In connection with our work on the vinylcarbene–cyclopropene rearrangement[13, 14] we also examined 3-carboxy-4-oxo-2,5-cyclohexadienylidene (**2**) and the isotopomer deuterated at the carboxyl group, [D$_1$]**2**. Irradiation of quinone diazide **3**[11] in a matrix with visible light (argon, 10 K, $\lambda > 470$ nm) did not lead to the expected carbene **2**, but rather by cleavage of CO_2 to a new compound, which we identified as aryne **1** (see below). Carbene **2** may be obtained from **3** by narrow-band irradiation ($\lambda = 432 \pm 10$ nm, 90 min) and subsequently investigated by IR and UV/VIS spectroscopy.[15] Proof of the existence of **2** in the matrix was provided by the very characteristic formation of carbonyl oxide **4**[16] in the diffusion-controlled reaction with molecular oxygen.[17] Carbonyl oxide **4** rearranges upon long-wavelength irradiation ($\lambda > 515$ nm) into dioxirane **5**,[18] which is transformed in turn into a lactone[19] when irradiated with blue light ($\lambda > 400$ nm; Scheme 1).

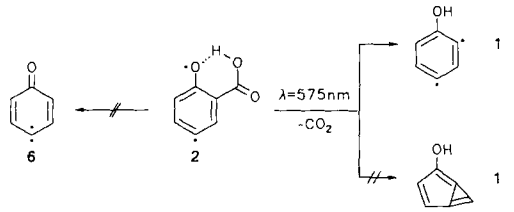


Scheme 1.

A notable feature in the IR spectrum of **2** is the low vibrational frequency of the C4 carbonyl group, which at 1415 cm^{-1} is red-shifted by 82 cm^{-1} relative to the parent compound **6**. This is evidence of the increased importance of the phenoxyl structure **2b** in describing the ground state of **2**. Structure **2b** is presumably stabilized by an intramolecular hydrogen bond. In the UV/VIS spectrum an absorption with a broad and very weak maximum at approximately 600 nm is observed as well as a narrow band with an absorption maximum at 390 nm , both characteristic for a 4-oxo-cyclohexadienylidene structure.[14, 20]



Irradiation of the long-wavelength absorption band of **2** ($\lambda = 575 \pm 10$ nm, 20 min) causes a rapid decarboxylation (intense absorption of CO_2 at 2347 cm^{-1}) and formation of a new compound, **1** (Scheme 2), with intense IR bands at



Scheme 2.

3612.0, 1516.3, 641.2, and 518.8 cm^{-1} (Fig. 1, Table 1). The IR bands assigned to **1** disappear upon irradiation with $\lambda > 420$ nm (see below).

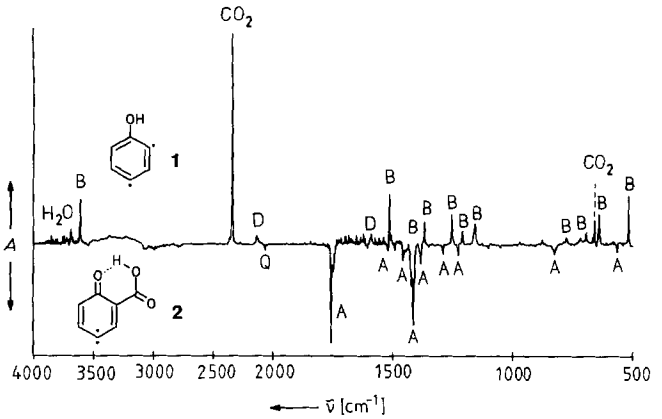


Fig. 1. Difference IR spectrum showing the photochemistry of carbene **2** ($\lambda = 575$ nm, Ar, 10 K). Bottom : bands that disappear upon irradiation; top: bands that arise. A: Carbene **2**, B: dehydrophenol **1**, D: unknown side product, Q: diazide.

The decarboxylation can also be observed in the UV/VIS spectrum: The bands assigned to carbene **2** disappear upon irradiation with $\lambda = 575 \pm 10$ nm, and a new band with a maximum at 344 nm and a shoulder at 356 nm arise.

Under the same conditions other 4-oxo-2,5-cyclohexadienylidenes undergo vinylcarbene–cyclopropene rearrangement to 1,3-bridged cyclopropenes;[13, 14] in our case this is of at most minor importance.[21] Irradiation of [D$_1$]**3**, the derivative of **3** deuterated on the carboxy group, provides a product with absorption bands at 3612.0 and 1157.6 cm^{-1} which are red-shifted relative to the non-deuterated product by 944 and 215 cm^{-1}, respectively. This allows the corresponding assignment of the O–H stretching and the C–O–H deformation vibrations. All the other IR bands show only small deuterium shifts. Analogous bands were observed for phenol at 3623 (− 973) cm^{-1} and 1180 (− 270) cm^{-1}, respectively, indicating the similarity of the hydroxyl groups in the decarboxylated product **1** and in phenol.

[a] Relative intensities. [b] Ratio of the vibration frequencies $\tilde{\nu}_i/\tilde{\nu}$ upon deuteration. [c] Scaling factor 0.9. [d] Approximate assignment based on the positions and the relative intensities of the bands. [e] Because of the large changes in intensities upon deuteration, $\tilde{\nu}_i/\tilde{\nu}$ cannot be determined reliably.

This unequivocal proof of the presence of a hydroxyl group and the absence of a carbonyl group greatly reduces the number of possible structures for **1** with the molecular formula C_6H_4O. Because of the very mild conditions in the synthesis of **1** (irradiation with $\lambda = 575$ nm, 10 K), a rearrangement of the carbon framework or a ring opening can be ruled out. (These would also cause a loss of phenol character.) The remaining reasonable structures are 2,4-didehydrophenol (**1**) and its bicyclic isomer, bicyclo[3.1.0]hexa-1,3,5-trien-1-ol (**1'**) (Scheme 2).

According to calculations (GVB/6-31G(d,p)//HF/6-31G(d,p)), in the singlet ground state the monocyclic biradical structure **1** is 17 kcal mol^{-1} more stable than the bicyclic structure **1'**.[23] In the geometry optimizations with GVB/6-31G(d,p) as well as with MP2/6-31G(d,p), **1'** is converted to **1**, indicating that **1'** most likely does not exist. In the GVB equilibrium geometry of **1** the C_{2v}-symmetric carbon framework of 1,3-didehydrobenzene is only slightly perturbed by the OH substituent (which is also indicated by the small dipole moment of 0.7 D). Thus **1** offers a realistic insight into the bonding relationships in 1,3-didehydrobenzene. **1** is planar, and the OH group points in the direction of the neighboring radical center (Fig. 2). Examination of the calculated electron-density distribution shows that the OH group is held in the plane of the ring by the electrostatic attraction between the partially positively charged H atom and the neighboring radical center.

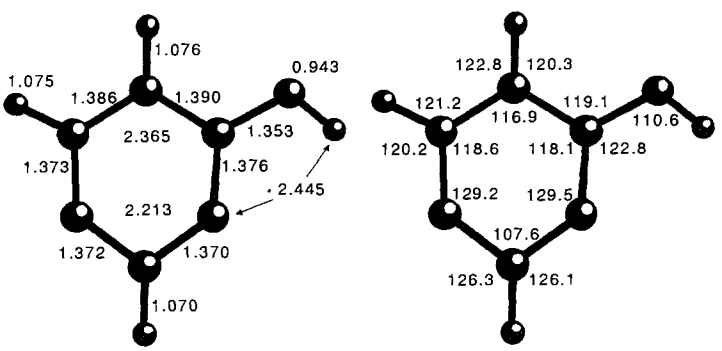

Fig. 2. Structure of 2,4-didehydrophenol (**1**) optimized by GVB/6-31G(d,p). Left, bond lengths [Å], right, bond angles [°].

An assignment of the experimental spectra to **1** or **1'** is possible by comparison with the calculated vibration spectra (Fig. 3). The calculated IR spectrum of **1** (GVB/6-31G(d,p,)) is in full agreement with the measured IR spectrum between 3600 and 800 cm^{-1}; only the bands at 641 and 519 cm^{-1} were not reproduced very well in the calculation. For [D_1]**1** the calculated isotopic shifts of 1027 and 207 cm^{-1} for the O–D stretching and the C–O–D deformation vibrations agree well with the corresponding experimental values (see Table 1).

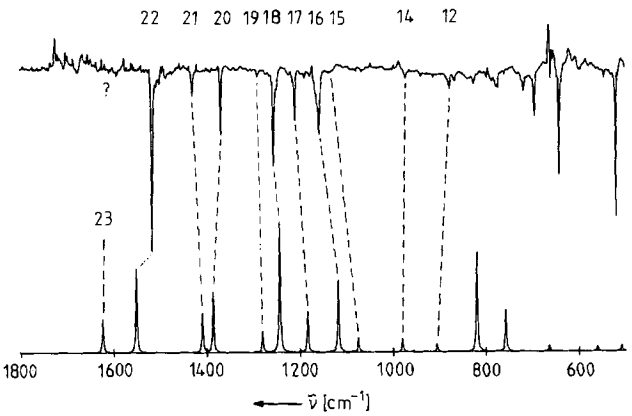

Fig. 3. Correlation between the experimental IR spectrum (top) and that calculated (GVB/6-31G(d,p); bottom). The assignment is only approximate and is based on the comparison of the positions and intensities of the bands. The calculated spectrum has been scaled by a factor of 0.9.

The alternative isomer, bicycle **1'**, can be ruled out by comparison of the experimental and theoretical spectra and by the fact that calculations with neither GVB nor with MP2 indicated its existence. The observed, intense long-wavelength absorption in the UV/VIS spectrum, which is about 80 nm red-shifted relative to the longest wavelength band for phenol, also supports to the diradical structure **1**.[25]

Dehydrophenol **1** is stable to irradiation with $\lambda > 570$ nm, but short-wavelength light ($\lambda > 420$ nm) will convert it into a ketene (IR, Ar, 10 K: $\tilde{\nu}$ = 2138.2 (s), 1419.4 (w), 1046.7 (w), 963.3 (w) cm^{-1}). Upon warming to 30 K in an O_2-doped matrix **1** reacts at a rate comparable to that of carbene **2** to give an oxidation product of unknown composition. Because of the small amount of **3** that could be sublimed into the matrix,[11] the ketene and the oxidation product of **1** could not be characterized further. However, the fast reaction with O_2 is further support for the diradical character of **1**. All experimental and theoretical findings can be explained only with the diradical structure **1**.

[11] An APD closed-cycle helium cryostat was used in the matrix experiments (see ref.[12]). IR spectra were recorded with a Bruker IFS 66 spectrometer between 4000 and 500 cm^{-1} with a resolution of 1 cm^{-1}, UV/VIS spectra with an HP 8452A diode array spectrometer with a resolution of 2 nm. **3** was deposited in the matrix at 25–30 K, the photolyses and the recording of spectra were conducted at 10 K. Because of the low volatility and the low thermal stability of **3** (ref.[24]) only small amounts could be sublimed onto the matrix window. **3**: IR (Ar, 10 K): $\tilde{\nu}$ 2113.6 (s), 2092.9 (w), 2057.2 (vw), 1740.9 (w), 1595.8 (vs), 1564.0 (vw), 1535.1 (w), 1481.1 (m), 1473.3 (s), 1458.4 (w), 1379.3(m), 1335.0 (vw), 1260.3 (vw), 1204.3 (w), 1164.8 (s), 1127.2 (w), 838.9 (vw), 528.9 (vw) cm^{-1} (rel. intensity).

[15] **2**: IR (Ar, 10 K): $\tilde{\nu}$ = 1758.3 (vs, 0.994), 1750.1 (m, –), 1523.5 (w, –), 1495.0 (m, 0.998), 1458.9 (w, 0.999), 1422.2 (s, –), 1415.0 (vs, 1.000), 1383.7 (w, 1.000), 1291.6 (w, 1.001), 1228.9 (w, –), 1053.9 (vw, –), 982.6 (vw, –), 826.3 (w, –), 565.0 (vw, 1.000), 542.9 (vw, –) cm^{-1} (rel. intensity, $\tilde{\nu}/\tilde{\nu}_i$); UV/VIS (Ar, 10 K): ca. 600 (vw, br), 390 (m), 316 (s), 306 (s), 236 (vs) nm (rel. intensity).

[16] **4**: IR (Ar, 10 K): $\tilde{\nu}$ = 1772.7 (s), 1766.0 (s), 1607.9 (m), 1601.6 (s), 1598.7 (s), 1583.3 (m), 1578.0 (m), 1573.1 (m), 1406.8 (vs), 1219.3 (m), 1082.4 (s), 888.5 (w), 849.0 (m), 844.2 (m), 658.6 (m), 655.2 (m) cm^{-1} (rel. intensity).

[17] W. Sander, *Angew. Chem.* **1990**, *102*, 362; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 344.

[18] **5**: IR (Ar, 10 K): $\tilde{\nu}$ = 1778 (vs), 1674.9 (s), 1657.0 (s), 1633.4 (w), 1405.9 (vs), 1395.2 (vs), 1391.9 (vs), 1321.5 (m), 1271.3 (vw), 1105.0 (m), 1039.0 (m), 1034.1 (m), 989.3 (vw), 953.1 (vw), 864.0 (w), 853.3 (m), 847.6 (m), 804.2 (w), 793.1 (w), 654.2 (m) cm^{-1} (rel. intensity).

[19] Because of the low concentration of **2** and the products of its subsequent reactions in the matrix, it was not possible to characterize unequivocally the isomeric lactones that formed. In the frequency range for carbonyl groups, absorptions were observed at 1783.8 (s, COOH), 1740.4 (s), 1724.5 (s), 1713.4 (s), 1672.9 (m), and 1623.8 (s) cm^{-1}. However, in analogy to the chemistry of *p*-benzoquinone-*O*-oxide, the formation of a 2,5-oxepinedione is expected (for the parent compound: $\tilde{\nu}$(C=O) at 1753 and 1660 cm^{-1}, ref.[13,14,20]).

[20] W. Sander, *J. Org. Chem.* **1988**, *53*, 2091.

[21] In the very slow decarboxylation with red light ($\lambda > 600$ nm) small amounts of an extremely photolabile compound also form with absorption bands between 1700 and 1800 cm^{-1}; this could be the cyclopropene.

[22] a) J. Gebicki, A. Krantz, *J. Am. Chem. Soc.* **1984**, *106*, 8093; b) J. H. S. Green, *J. Chem. Soc.* **1961**, 2236; c) G. T. Reedy, S. Bourne, P. T. Cunningham, *Anal. Chem.* **1979**, *51*, 1535; H. D. Bist, J. C. D. Brand, D. R. Williams, *J. Mol. Spectrosc.* **1967**, *24*, 402.

[23] GVB(1)/6-31G(d,p)//HF/6-31G(d,p) energies [Hartree]: −304.27655 (**1**), −304.248998 (**1'**); GVB(1)/6-31G(d,p): −304.27809 (**1**); RMP2/6-31G(D,p): −305.24500 (**1**). RMP2 and GVB geometries differ only slightly. Thus, the geometry does not depend on the calculational method. This does not hold for the reliable determination of relative energies and the vibration spectrum. In these cases an HF wave-function with corrections for dynamic correlation effects (estimated e.g. with MP2) is not sufficient. The GVB approximation is the simplest multiconfiguration (MC) method that provides a usable description of **1**. More exact data, especially for the low-frequency end of the IR spectrum, could be obtained with a larger MC formulation preferentially along with MP2 in order to account for both statistical and dynamic correlation effects.

[25] According to CNDO/S calculations the UV/VIS band of phenol with the longest wavelength λ_{max} lies at 282 nm, of **1a** at 362 nm. Another band calculated for **1** at λ_{max} = 476 nm is too weak in intensity to be observable under experimental conditions.

Hydride Transfer by Hydrido Transition-Metal Complexes. Ionic Hydrogenation of Aldehydes and Ketones, and Structural Characterization of an Alcohol Complex**

By *Jeong-Sup Song, David J. Szalda, R. Morris Bullock,* Christophe J. C. Lawrie, Mikhail A. Rodkin,* and *Jack R. Norton**

Transfer of hydrogen as a proton (H^+), hydrogen atom ($H^\cdot$), or hydride (H^-) is a decisive step in numerous catalytic and stoichiometric reactions utilizing metal hydrides.[1] The kinetics of proton transfer from metal hydrides[2] to metal-,[3] carbon-,[4] and nitrogen-centered[3] bases have been examined. Quantitative studies of the relative ability of carbonylhydridometal complexes to donate a hydrogen atom to olefins[5] or carbon-centered radicals[5, 6] have recently been reported. However, the little that is known about hydride transfer largely concerns substrates already coordinated to the metal atom.[7–9]

Direct hydride transfer to an uncoordinated substrate appears to be involved in the hydrogenation of sterically hindered olefins by transition-metal hydrides and triflic acid (CF_3SO_3H).[10] Such ionic hydrogenations (the addition to a double bond of H^+ from one source and H^- from another) are common in biological systems,[11] and probably occur in other organometallic reactions, e.g., the hydrogenation of aldehydes and/or ketones by acids and $[Mo_2(CO)_{10}(\mu\text{-H})]^-$,[12] $[Cr(CO)_5H]^-$,[13] $[Ru(bpy)_2(CO)H]^+$ (bpy = 2,2'-bipyridine),[14] $[Cp_2MoH_2]$,[15] or $[Cp_2Ta(CO)H]$.[16] These reactions offer a remarkable instance of kinetic selectivity: the H^+ and H^- are transferred to the same substrate more rapidly than they react with each other to form hydrogen gas.[17–19] In this communication we report on the scope and mechanism of the ionic hydrogenation of aldehydes and ketones by transition-metal hydrides and acids, and on the structure of the hydrogen-bonded alcohol complex that is formed upon hydrogenation of acetone with CF_3SO_3H and the hydrido tungsten complex **1a**.

When a pale yellow CD_2Cl_2 solution of acetone (0.10 M) and **1a** (1.5 equiv.) is treated with CF_3SO_3H (2 equiv.) at room temperature, the color changes to burgundy-red in less than 5 minutes, and the tungsten complex **2** is formed in quantitative (^1H NMR) yield [Eq. (a)]. The proton of the hydroxyl group of **2** gives rise to a doublet (J_{HH} = 7.6 Hz) at δ = 6.29 (^1H NMR in CD_3NO_2), significantly downfield from the position reported for the signal of the hydroxyl proton in the analogous complex with SbF_6 as counterion (δ = 4.90 in CD_3NO_2).[20] This shift suggests formation of hydrogen bond between the triflate anion and the alcohol ligand. A single-crystal X-ray diffraction study[21, 25] of **2** has verified that such a hydrogen bond is present in the solid state (Fig. 1). Especially informative in this connection is the short O···O distance of 2.63(1) Å, similar to the O–H···O distances found in other organometallic complexes that exhibit hydrogen bonding.[22] Only a few other alcohol com-

plexes with low-valent metal centers are known,[20, 23] and structural data for this unusual class of compounds are very scarce.

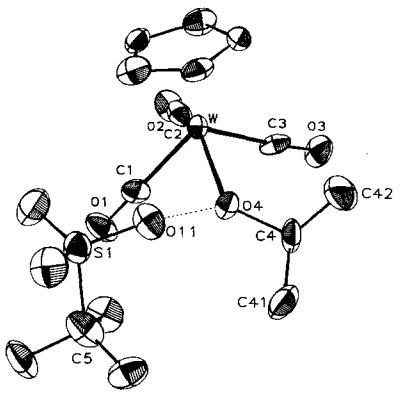

Fig. 1. ORTEP drawing of **2** showing 50% probability thermal ellipsoids. Selected bond lengths [Å] and angles [°]: O(4)···O(11) 2.63(1); W-C(1) 2.01(2); W-C(2) 1.99(2); W-C(3) 1.99(2); W-O(4) 2.186(9); O(4)-C(4) 1.47(2); C(1)-W-C(2) 76.1(5); C(2)-W-C(3) 77.2(6); C(1)-W-C(3) 110.6(6); C(2)-W-O(4) 139.8(5); C(1)-W-O(4) 78.2(5); C(3)-W-O(4) 83.7(4); W-O(4)-C(4) 131.2(7).

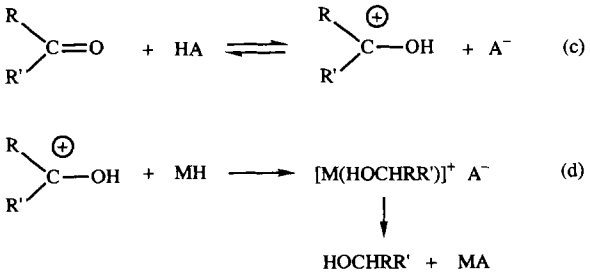
A variety of coordinatively saturated hydrido transition-metal complexes can serve as hydride donors in such reactions, examples being $[CpM(CO)_3H]$ (M = W, Mo), $[M(CO)_5H]$ (M = Mn, Re), and $[CpRe(NO)(PPh_3)H]$; in none of the cases examined does the hydride react with the ketone in the absence of acid. Ionic hydrogenation can also occur with acids of considerably different strengths (CF_3CO_2H, p-$CH_3C_6H_4SO_3H$, $C_6F_5CO_2H$, and CF_3SO_3H). With CF_3SO_3H/**1a** hydrogenation of propionaldehyde, 2-butanone, methyl benzyl ketone, 2,3-butanedione, adamantanone, or cyclohexanone gave high yields (>95% by NMR in CD_2Cl_2) of the $[Cp(CO)_3W(HOR)][OTf]$ complexes **3** with-in 5 minutes at room temperature, using 1.5–2 equivalents of both acid and hydride. For the synthesis of complexes **3**, typically about 1.5 equivalents of ketone (or aldehyde) and acid and 1 equivalent of **1a** were used; complexes **3** were obtained in 43–78% yield.

Despite the fact that these tungsten alcohol complexes can be isolated, they decompose slowly in solution, giving the free alcohol and the tungsten triflate complex $[CpW(CO)_3(OTf)]$ **4**. The decomposition half-life is about 14 hours at room temperature in CD_2Cl_2. The fact that an alcohol complex, rather than the more stable complex **4**, is the kinetic product suggests some W–O bond formation in the transition state of the hydride transfer.

When $(CH_3)_2CHCHO$ (0.049 M) was treated with excess $[CpMo(CO)_3H]$ **1b** (0.9 M) in the presence of CF_3CO_2H (0.23 M), at −30 °C in CD_2Cl_2, the apparent first-order rate constant k_{obs} for the disappearance of the aldehyde decreased as the reaction proceeded. However, with the acidity held constant by a quinuclidine-quinuclidinium buffer (total $[CF_3CO_2H] = 0.58$ M, total [quinuclidine] = 0.13 M), the rate of disappearance of the aldehyde was cleanly pseudo-first-order. The observed rate constant k_{obs} proved to be proportional to the concentration of **1b**, indicating that the reaction obeyed the rate law given in Equation (b). At −30 °C, $k = 3.5 \times 10^{-4}\ M^{-1}s^{-1}$.

$$\frac{-d[(CH_3)_2CHCHO]}{dt} = k[(CH_3)_2CHCHO][\mathbf{1b}] \qquad (b)$$

These results suggest that the reaction proceeds by rate-determining hydride transfer from the coordinatively saturated transition-metal hydride to the protonated form of the aldehyde or ketone [Eq. (c) and (d)]. This mechanism ac-



counts for the decrease of k_{obs} with time in the unbuffered reaction; since the reaction consumes protons as it proceeds, k_{obs} (which is a function of the acidity because it includes the equilibrium constant for Eq. (c)) will decrease. The acids effective in this hydrogenation range from those that protonate only a small amount of aldehyde at equilibrium (CF_3CO_2H) to strong acids (CF_3SO_3H) that protonate most of the aldehyde.

When p-$CH_3C_6H_4SO_3H$ is added to pivaldehyde and $[CpRe(NO)(PPh_3)H]$ in CH_2Cl_2, neopentyl alcohol is the only organic product formed. This implies that hydride transfer to the protonated pivaldehyde is occurring faster than the rearrangement of the protonated aldehyde to protonated isopropyl methyl ketone. The rate constant for this rearrangement has been estimated[24] as 0.6 s^{-1} at 25 °C in FSO_3H.

Selective incorporation of deuterium into the product alcohol can be effected under certain conditions, using deuterium labels on either the hydride or acid. For example, CH_3CHDOH results from ionic hydrogenation of acetaldehyde using $[CpMo(CO)_3D]$ and CF_3CO_2H. D^- transfer is thus faster than H/D exchange between the deuterido complex and trifluoroacetic acid under these conditions.[25]

Experimental Procedure

CF_3SO_3H (100 μL, 1.1 mmol) was added to a solution of **1a** (300 mg, 0.9 mmol) and acetone (80 μL, 1.1 mmol) in CH_2Cl_2 (10 mL) under Ar. The solution was stirred for 30 min at 22 °C, during which time the solution became burgundy-red. Et_2O (20 mL) and hexane (10 mL) were added by vacuum transfer, and the dark red microcrystalline product **2** (380 mg; 78%) was collected by filtration. ^1H NMR (CD_2Cl_2): $\delta = 7.49$ (d, $J = 7.3$ Hz, 1H, OH), 6.04 (s, 5H, Cp), 3.58 (d of septets, $J = 7.3$ Hz, 6.3 Hz, 1H, CH), 1.15 (d, $J = 6.3$ Hz, 6H, CH_3). ^{13}C NMR (CD_2Cl_2, 200 K): $\delta = 225.0$ (CO), 222.3 (2CO), 94.9 (Cp), 83.8 (CH), 22.2 (CH_3). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3444 (w, br; OH), 2062 (vs; CO), 1983 (vs), 1953 (vs); 1022 (s; CO); correct C,H analysis.

[17] Although the kinetic barrier to protonating a monohydride complex H–M at M [2], or evolving H_2 gas from H^+ and H–M, is usually substantial, there is evidence that the formation of *dihydrogen complexes* from H^+ and H–M is kinetically facile [2]. The existence of facile equilibria between H–M/H^+ and the corresponding dihydrogen complexes suggests that the hydrogenations with dihydrogen complexes (of acetone with $[(H_3N)_5Os(\eta^2\text{-}H_2)]^{3+}$ [18], and of dimethyl maleate with $[(P(CH_2CH_2PPh_2)_3)Co(\eta^2\text{-}H_2)]^+$ [19]) may occur by ionic mechanisms.

[25] Note added in proof (August 11, 1992): J. Milke, C. Missling, K. Sünkel, W. Beck have characterized a similar alcohol complex, $[Cp(CO)(PPh_3)Ru(HOEt)]^+BF_4^-$, by X-ray crystallography (submitted to *J. Organomet. Chem.*). The results indicate that a hydrogen bond is formed between the hydrogen atom of the hydroxyl group and one of the F atoms of the BF_4^- ion. We thank Prof. W. Beck for a preprint of this paper.

$[Nb\{B(\eta^6\text{-}C_6H_5)_2(C_6H_5)_2\}(\eta^2\text{-}H_3CC_2CH_3)]$: the First Compound with Bent Tetraphenylborate as 12-Electron Donor Ligand**

By *Fausto Calderazzo, Ulli Englert, Guido Pampaloni,** and *Lucia Rocchi*

We recently reported a simple synthesis of the metallocene $[Nb(\eta^6\text{-mes})_2]$, (mes = 1,3,5-trimethylbenzene) and demonstrated that this compound opens up a convenient entry to niobium(I) systems.[1] Herein we report on the preparation of the niobium complexes **1** and on their thermal conversion into the complexes **2**.

$[Nb(\eta^6\text{-mes})_2(RC_2R)]BPh_4$ **1** $[Nb\{B(\eta^6\text{-}C_6H_5)_2(C_6H_5)_2\}(\eta^2\text{-}RC_2R)]$ **2**

a, R = CH_3; **b**, R = C_6H_5

Oxidation of $[Nb(\eta^6\text{-mes})_2]$ with $[FeCp_2]BPh_4$ in toluene, followed by treatment with a stoichiometric amount of alkyne, affords red to brown microcrystalline solids which are sparingly soluble in the reaction medium and were identified by IR spectroscopy as **1a,b** ($\tilde{\nu}_{CC} = 1818$ and 1767 cm^{-1} for **1a** and **1b**, respectively).

$$[Nb(\eta^6\text{-mes})_2] \xrightarrow{[FeCp_2]BPh_4} [Nb(\eta^6\text{-mes})_2]BPh_4 \xrightarrow{RC_2R} \mathbf{1} \qquad \text{(a)}$$

Upon heating **1** in toluene at ca. 100 °C, red to orange solutions were obtained, which, after filtration from black pyrophoric materials, concentration, and cooling at ca. −30 °C, deposited red to orange crystals of compounds **2**.

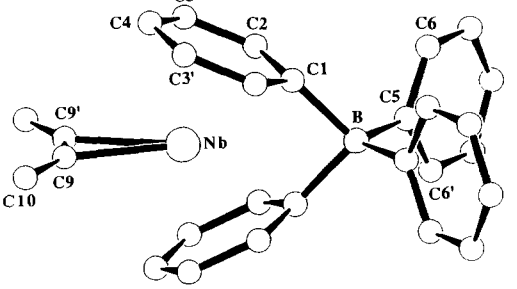

Fig. 1. SCHAKAL drawing of the crystal structure of **2a**. Selected bond lengths [Å] and angles [°]: Nb-C1, 2.369(3); Nb-C2, 2.373(2); Nb-C3, 2.420(2); Nb-C4, 2.420(1); C-C(η^6-C_6H_5, mean value), 1.419(3); C-C(other rings, mean value), 1.392(3); B-C1, 1.653(3); B-C5, 1.631(3); C5-B-C5', 112.8. For further data see text.

The structure of **2a** in the crystal[21] is shown in Figure 1. The niobium(I) atom is coordinated by two of the four phenyl rings of the tetraphenylborato ligand: the mean arene(centroid)–Nb distance is 1.931 Å, and the angle

[**] This work was supported by the Consiglio Nazionale delle Ricerche (CNR, Roma), and the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST).

formed between the arene centroids and the niobium atom is 131.6° (for comparison: 1.92 Å (mean value) and 147.7° in $[Nb(\eta^6\text{-mes})_2(CO)]BPh_4$[1b] and 1.91 Å (mean value) and 142.3° in $[Nb(\eta^6\text{-toluene})_2(PEt_3)]BF_4$[5]). The boron atom has a distorted tetrahedral geometry; the C1–B–C1′ angle is 92.3°.

The distances C9–C9′ [1.219(1) Å] and the Nb–C9 [2.269(3) Å] and the C10–C9–C9′ angle [150.8(3)°] are typical for niobium(I)–alkyne interaction with the alkyne behaving as a two-electron donor;[6] in contrast, longer C–C distances and shorter niobium(I)–carbon distances are generally observed in other disubstituted acetylene complexes,[7, 8] particularly when the ligand behaves as a four-electron donor.

Coordination of one[9] or more than one,[10] of the phenyl rings of the tetraphenylborate to transition metals in a 1:1 ratio has been reported in the literature; examples are $[Co\{B(\eta^6\text{-}C_6H_5)(C_6H_5)_3\}(py)_2]$[9b] and $[\{RuCp^*(\eta^6\text{-}C_6H_5)\}_4B]^{3+}$.[10] In the case of $Si(C_6H_5)_4$[11] two of the phenyl rings were found to be coordinated to the same metal atom in $[M\{Si(\eta^6\text{-}C_6H_5)_2(C_6H_5)_2\}]$, M = V, Cr.

To the best of our knowledge, compound **2** represents the first example of a metal complex containing two phenyl rings of the tetraphenylborate ligand coordinated to the same metal cation. The presence of the formal negative charge on the BPh_4^- ligand is important since its removal from the coordination sphere can be carried out only by ionization or by reduction in the presence of competitive ligands.

Experimental Procedure

2a: A suspension of **1a** (0.774 g, 1.09 mmol) in toluene (100 mL) was heated at 100 °C for 15 min and filtered. The volume of the orange-brown filtrate was reduced to ca. 25 mL, and the solution cooled at ca. −30 °C. Red crystals of **2a** (0.07 g) were isolated and dried in vacuo. Another crop of crystals (0.065 g) was isolated by further reduction of the volume of the solution to ca. 5 mL to give a total yield of 0.135 g (26%).—IR (nujol and poly(chlorotrifluoroethylene)): $\tilde{\nu}$ [cm^{-1}] = 3067w, 3047m, 2963m, 1919m, 1591s, 1481m, 1425s, 1347w, 1276w, 1261m, 1159m, 1089m, 1015m, 803m, 752s, 709s, 589m. Correct C, H and Nb elemental analyses.

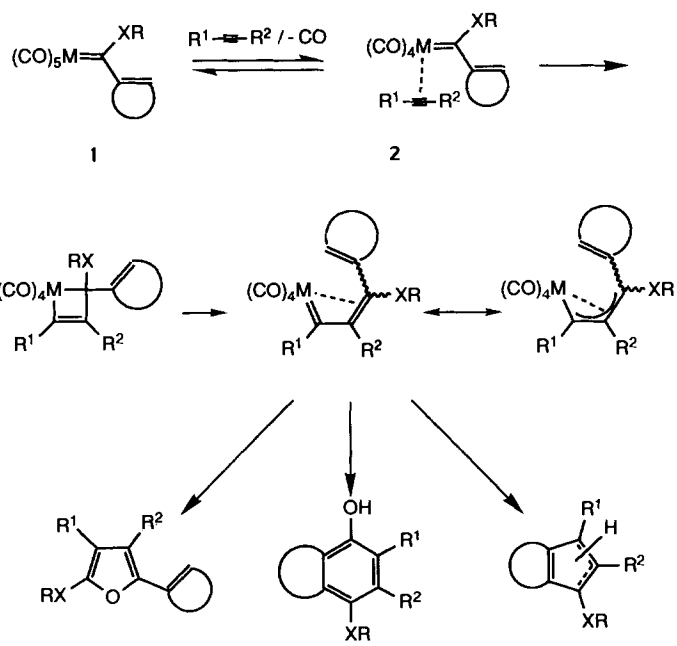
Alkyne(carbene) Complexes: Stabilization of an Intermediate of Carbene Annelation**

By *Karl Heinz Dötz,* Thomas Schäfer, Friedrich Kroll,* and *Klaus Harms*

Stable carbene complexes of the Fischer type are proving increasingly attractive reagents for organic synthesis.[1] Apart from established reaction patterns such as the cyclopropanation[2] and the Diels–Alder reaction,[3] they also undergo "nonclassical" cycloadditions, whose steps take place at the metal-template center.[4] A typical example for this is the chromium-induced coupling of an unsaturated carbene ligand with an alkyne and—in some cases—carbon monox-



Scheme 1. M = Cr, Mo, W; X = O, NR, S.

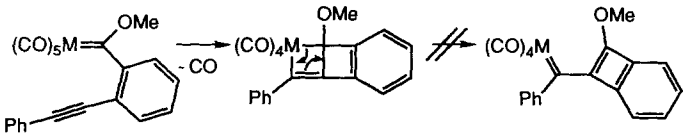
[**] Reactions of complex ligands, part 53. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 260), the Gradiertenkolleg "Metallorganische Chemie" and the Fonds der Chemischen Industrie.- Part 52: K. H. Dötz, A. Rau, K. Harms, *J. Organomet. Chem*, in press.

ide, which leads selectively to carbene annelation or to other cycloaddition products.[5]

According to a plausible proposal for the mechanism of the reaction based on the results of earlier kinetic investigations,[6] the reaction begins with the reversible decarbonylation of the pentacarbonyl(carbene) complex **1**, followed by the coordination of the alkyne.[7] Thereafter the alkyne(carbene) complex **2** undergoes a ligand coupling, as a result of which a σ,π allyl complex (alkyne insertion into the metal–carbene bond)[8] and a metallacyclobutene (alkyne addition to the metal–carbene bond)[9] are discussed. This step determines the regioselectivity with which the alkyne is incorporated into the final product (Scheme 1).

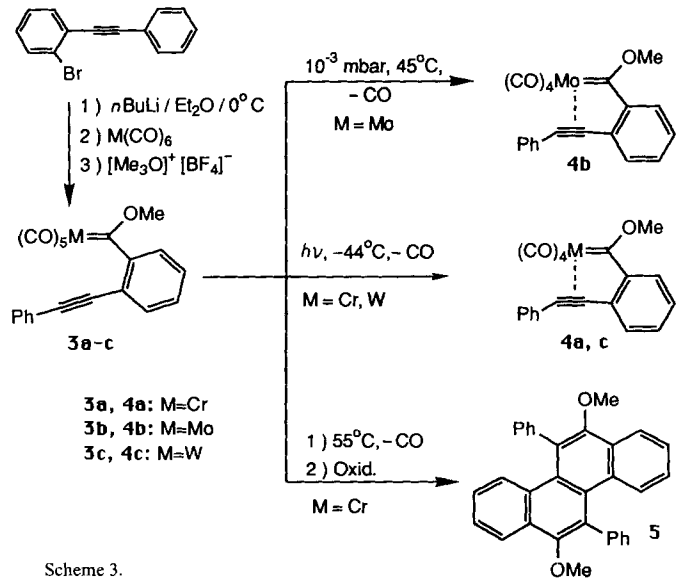
It has so far not been possible to isolate the alkyne(carbene) complex intermediate **2**, in which the alkyne behaves as a *two*-electron ligand, or to characterize it directly by spectroscopy;[10] a small metal–alkyne interaction was expected from calculations.[8, 9] We have now attempted to suppress the alkyne–carbene coupling by linking these two functions by a rigid C_2 arene bridge in the *ortho*-alkynyl carbene complex **3**. Here an insertion of the alkyne into the metal–carbene bond could occur only at the expense of the formation of an energy-rich benzocyclobutadiene intermediate (Scheme 2).



3

Scheme 2.

The *photochemically* induced low-temperature decarbonylation of the pentacarbonyl(*ortho*-alkynylarylcarbene) complexes of chromium and tungsten **3a,c** (accessible by the classical Fischer route[11]) affords the alkyne(carbene) complexes **4a,c**. In contrast, the molybdenum complex **3b** can be decarbonylated in a dark reaction under reduced pressure at 45 °C to give **4b** (Scheme 3). The X-ray structural analysis of the tungsten complex **4c**[12] (Fig. 1) shows unusually long



Scheme 3.

metal–C_{alkyne} distances (ca. 2.40 and 2.36 Å),[10] whereas the C_{alkyne}–C_{alkyne} bond (ca. 1.22 Å) is only lengthened slightly upon coordination. Together with the almost identical ^{13}C NMR chemical shifts for the alkyne carbon atoms in **3c** and **4c**,[13] these results prove a very weak coordination of the alkyne ligand.

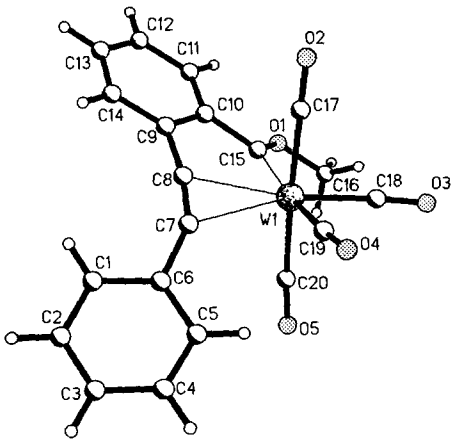


Fig. 1. Crystal structure of **4c**. Selected bond lengths [Å] and angles [°]: W1-C7 2.402(4), W1-C8 2.368(4), W1-C15 2.181(5), W1-C17 2.024(7), W1-C18 1.974(5), W1-C19 2.040(7), W1-C20 1.995(7), C7-C8 1.224(7), C15-O1 1.314(6); C7-W1-C8 29.7(2), C15-W1-C19 169.2(3), C17-W1-C20 176.1(2), C7-C8-C9 169.4(4), C6-C7-C8 151.9(4), C9-C10-C15 115.0(4), W1-C15-C10 118.2(0.4), W1-C15-O1 134.0(0.1), O1-C15-C10 107.6(0.4); torsion angle [°]: C15-W1-C8-C7 151.7(0.4), C9-C10-C15-O1 164.5(0.4), C8-C9-C10-C15 −2.6(0.7), C18-W1-C15-C10 −152.4(0.4).

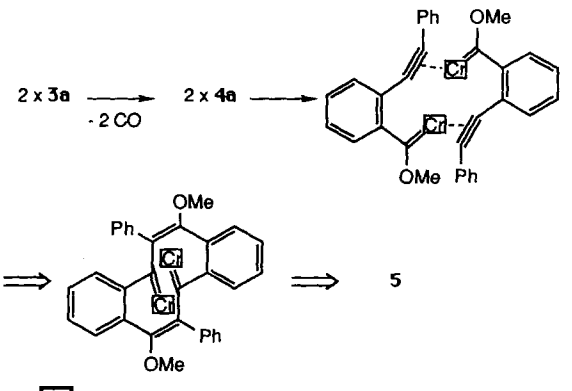
The known special suitability of chromium carbene complexes for carbene annelation is also evident from compound **3a**. Its *thermal* decarbonylation leads—without in this case being able to isolate the alkyne(carbene) intermediate **4a**—by the formal dimerization of the carbene ligand directly to the chrysene derivative **5**, which according to NMR spectra recorded during the reaction is initially coordinated to $Cr(CO)_3$. After oxidative demetalation in air **5** is obtained in the form of colorless crystals.[12]

A plausible explanation for the formation of **5** is based on a weak coordination of the alkyne, which is also proven for the chromium complex **4a** by NMR spectroscopy.[13] A decoordination of the alkyne could lead to the formation of a doubly alkyne-bridged dinuclear complex, which undergoes an alkyne insertion into the neighboring metal–carbene bond. Thus, a central ten-membered ring with carbene functions lying opposite one another is formed, whose coupling



Scheme 4. Cr = $Cr(CO)_4$.

("carbene dimerization") leads to the chrysene framework (Scheme 4).

Experimental Procedure

4c: A solution of pentacarbonyl[methoxy(2-phenylethynyl)phenylcarbene]-tungsten (**3c**) (0.94 g, 1.73 mmol) [prepared according to the Fischer route [11] from hexacarbonyl tungsten, 2-bromodiphenylacetylene, *n*-butyllithium, and trimethyloxonium tetrafluoroborate in a yield of 73%] in diethyl ether (80 mL) was irradiated at −44 °C with a Hg high-pressure lamp (TQ 150, Heraeus) for 150 min. After removal of the solvent and chromatography on silica gel (PE/Et_2O 3/1, −40 °C) dark brown metallic shiny crystals of **4c** were obtained (0.45 g, 51%).– IR (PE): $\tilde{\nu}$[cm^{-1}] = 2039, 1959, 1933, 1905 [W(CO)$_4$]; ^{1}H NMR (300 MHz, CD_3COCD_3): δ = 7.30–8.00 (m, 9 H, H_{aryl}), 4.87 (s, 3 H, OCH_3); ^{13}C NMR (75 MHz, CD_3COCD_3): δ = 308.9 (t, $J_{W,C}$ = 90 Hz, W=C), 212.9 (CO_{trans}), 210.3 (CO_{trans}), 198.3 (t, $J_{W,C}$ = 120 Hz, 2 $CO_{all-cis}$), 164.0 (C-1), 139.2 (C-2), 134.1 (C_{tert}), 132.9 (C_{tert}), 131.2 (C_{tert}), 130.1 (C_{tert}), 129.9 (C_{tert}), 129.6 (C_{tert}), 128.8 (C_{quat}), 121.5 (C_{tert}), 92.5, 88.7 (C≡C), 71.5 (OCH_3).

5: A solution of pentacarbonyl[methoxy(2phenylethynyl)phenylcarbene]-chromium (**3a**) (1.30 g, 3.15 mmol) in *tert*-butylmethyl ether (20 mL) was warmed under reflux for 2 h. After the addition of acetone (50 mL) the mixture was stirred for another 12 h with exposure to the air. Filtration and chromatography on silica gel (PE/Et_2O 3/1) afforded colorless crystals of **5** (0.58 g, 55%). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.20 (d, J = 7.8 Hz, 1 H, H_{aryl}), 7.20–7.60 (m, 7 H, H_{aryl}), 7.00 (d, J = 7.6 Hz, 1 H, H_{aryl}), 3.38 (s, 3 H, OCH_3); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 151.8 (C-6, C-12), 140.1 (C_{quat}), 131.6 (C_{quat}), 131.4 (C_{tert}), 129.3 (C_{tert}), 128.6 (C_{tert}), 128.2 (C_{quat}), 128.0 (C_{quat}), 127.8 (C_{quat}), 127.0 (C_{tert}), 126.0 (C_{tert}), 124.6 (C_{tert}), 122.5 (C_{tert}), 60.3 (OCH_3); EI-MS (70 eV): *m/z* 440 (M^+, 100%).

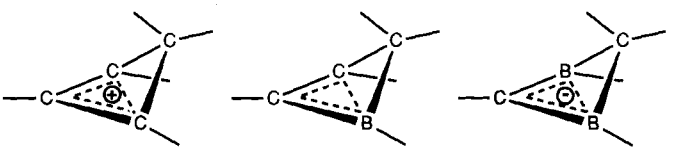
Homodiboriranides: The Simplest Negatively Charged Homoaromatic Compounds**

By *Peter Willershausen, Claudia Kybart, Nicolaos Stamatis, Werner Massa, Michael Bühl, Paul von Ragué Schleyer,* and *Armin Berndt**

While many positively charged homoaromatic systems are known,[1] and a few such neutral species have been described,[2] the existence of negatively charged analogues is still controversial.[3] The homodiboriranides **3** we report here are the simplest negatively charged homoaromatics and supplement the known series of isoelectronic analogues **1**[1a] and **2**.[2a]



1 **2** **3**

Compound **3a** is formed together with the 2-borataallene **8** by heating (110 °C, 3 h) a toluene solution of the boriranide **5a**. Compound **5a** is accessible from the borandiylborirane **4**[4] and phenyllithium (Scheme 1). The reaction of **4** with duryllithium (2,3,5,6-tetramethylphenyllithium) at room temperature only gave **3b**; **5b** was not detected. The carbenes **6**[5] are likely intermediates in the formation of **8** and **3**, while the 1-bora-3-boratabutadienes **7** might also be involved on the pathway leading to **3**. The constitution of **5a**, **3a,b**, and **8** follow from the ^{13}C and ^{11}B NMR data (Table 1).

The central C atoms of the 1,3-diboraallylanion moieties of the (*Z*) and (*E*) isomers of **5a** have chemical shifts (δ = 106.0 and 110.6, respectively) similar to that of the central C atom in **9** (δ = 99.7).[6] In contrast, the corresponding C atoms in **3a** and **3b** (δ = 162.9 and 155.1, respectively) are

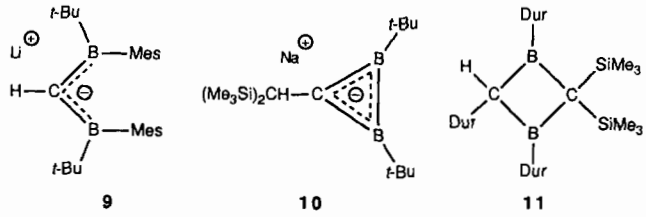
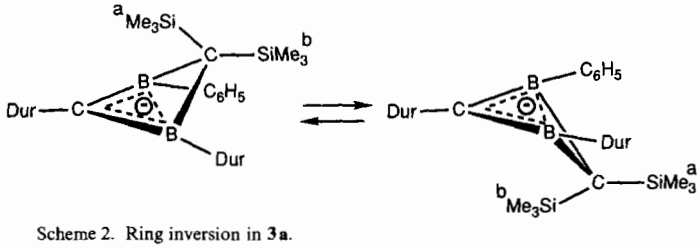
strongly deshielded. This deshielding indicates a cyclic homoaromatic delocalization of the π electrons as in the diboriranide **10** (δ_{BCB} = 147.8).[7]



The partial bonding between the boron atoms in **3** is facilitated by the folding of the four-membered ring. Although the trimethylsilyl substituents are diastereotopic, the ^{13}C NMR spectrum of **3a** in [D$_8$]THF/[D$_{10}$]Et$_2$O (4/1) at room temperature shows only one sharp signal. Upon cooling, this signal broadens and splits into four peaks at –120 °C, one for a trimethylsilyl group (which can still rotate freely) and three for the second trimethylsilyl group whose rotation is frozen. From the chemical shift difference with slow exchange ($\Delta\delta$ = 250 Hz) and the coalescence temperature (176 K), a 7.9 kcal mol^{-1} barrier to ring inversion of **3a** (Scheme 2) can be estimated approximately. This value, a measure of the homoaromaticity of **3**, is similar to that determined for the isoelectronic cation **1** (8.4 kcal mol^{-1}).[1a]



Scheme 2. Ring inversion in **3a**.

The crystal structure of **3a**[8] confirms the conclusions from the NMR data in solution (Fig. 1). The folding (147.1(9)°) at the B–B bond is similar to that found in derivatives of **1** (142.7, 143.6, 148.5°).[1c] The B–B distance (179.2(15) pm) is significantly shorter than the corresponding distance in **11** (203.1(7) pm), the product of the protona-

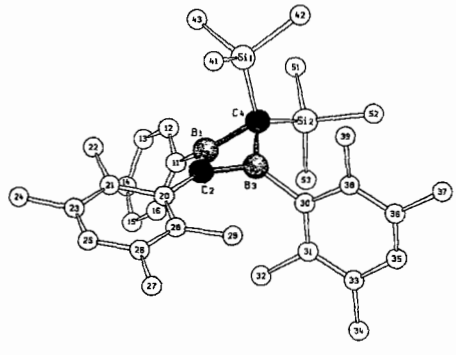


Fig. 1. Schakal drawing of the crystal structure of the anion in **3a**. Selected distances [pm] and angles [°]: B1-C2 148.4(13), C2-B3 148.2(13), B3-C4 160.4(14), C4-B1 158.7(13), B1-B3 179.2(15), B1-C11 161.4(12), C2-C20 145.0(13), B3-C30 161.9(14), C4-Si1 187.7(9), C4-Si2 185.1(9); B1-C2-B3 74.3(7), C2-B3-C4 102.0(8), B3-C4-B1 68.3(6), C4-B1-C2 102.8(7), Si1-C4-Si2 115.6(4).

tion of **3b**, for which the fold at the B–B bond is 153°. The Li^+ ion is far away from the charge-carrying centers B1, C2, and B3 (>700 pm) and is planar-coordinated with three partially disordered diethyl ether molecules.

The folding of **3a,b** is not due to steric interactions between the large substituents. This follows from ab initio calculations for the parent anion **3**, $C_2B_2H_5^-$ (C_s symmetry).[10] Fold angle (146°), B–B distance (185.9 pm), C–B distances (148.7 and 160.7 pm), energy difference to the planar conformation (7.4 kcal mol^{-1}), and the chemical shift for C2 (169) calculated with IGLO[11, 12] are in good agreement with the data for **3a** determined by experiment.

The 1,3 interaction in $C_2B_2H_5^-$ is evident from the calculated bond order of 0.23 (NPA, natural population analysis,[13] Wiberg's definition[14]). This value is somewhat smaller than that for the homocyclopropenium ion **1** (0.40). This can be explained as follows: In contrast to the usual descriptions with formal charges the boron atoms in $C_2B_2H_5^-$ are *positively* charged (NPA + 0.35). Fewer electrons are available for the transannular overlap than in **1** (NPA charge about 0). Analogously, in spite of the similar folding angle (145°) in **1**, a slightly higher inversion barrier is calculated (9.4 kcal mol^{-1}).[15]

The parent neutral compound **2**, C_3BH_5 (C_1 symmetry), shows the same evidence for a 1,3 interaction: the fold angle (147°) and the 1,3 bond order (0.24) are similar to the values for $C_2B_2H_5^-$, the inversion barrier (4.3 kcal mol^{-1}) is significantly smaller.

[8] X-ray crystal structure analysis of **3a**: $C_{34}H_{49}B_2Si_2Li \cdot 3Et_2O$, space group $P2/c$, $Z = 4$, $a = 1971.2(4)$, $b = 1345.0(3)$, $c = 1891.6(4)$ pm, $\beta = 104.84(3)°$, 3836 independent reflections with $F_0 > 3\sigma(F_0)$ measured on a four-circle diffractometer CAD4 (Enraf–Nonius) with $Cu_{K\alpha}$ radiation at −80 °C; no absorption correction ($\mu = 9.2$ cm^{-1}). The structure was solved by direct methods and with full matrix refinement [9]. Anisotropic temperature factors were used for all C, O, and Si atoms, for the rest isotropic. For the anion all the H atoms were included in calculated positions with groupwise refined temperature factors. There are two symmetry independent $[Li(OEt_2)_2]^+$ ions present, both with C_2 symmetry, i.e. Li^+ and an O atom lie on a twofold axis, and Li^+ is planar surrounded. Both cations have a disordered ethyl group, which was described by a "split atom" model with 1:1 occupation. Because of the uncertain geometry no H atom positions were included in the calculations for these ethyl groups. Apart from the numerous peripheral methyl groups of the anion this positional disorder appears to be the reason for the relatively low accuracy of the structure determination, which for 448 parameters gave $R = 0.098$, $wR = 0.077$ (weights $w = 1/\sigma^2(F_0)$). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56362, the names of the authors, and the journal citation.

Novel Cross-Conjugated Compounds Derived from Tetraethynylethene**

By *Armen M. Boldi, John Anthony, Carolyn B. Knobler,* and *François Diederich**

Recently, we reported the synthesis of tetraethynylethene (**1a**), the parent compound of an interesting class of highly unsaturated cross-conjugated hydrocarbons.[1] Besides **1a**, only the tetrasubstituted derivatives **1b–g** and compounds **1h,i** with two free ethynyl groups attached to the same ethene-carbon are known.[1–5] Tetraethynylethenes in which one or more alkyne units are functionalized became of interest to us for several reasons: 1) Compound **2a** ($R^1 = R^3$ = silyl protecting group, $R^2 = R^4 = H$) with a free *cis*-enediyne unit represents the precursor for oxidative coupling to hexaethynylhexadehydro[18]annulene derivatives and, ultimately, to a two-dimensional all-carbon network.[6] 2) Oxidative coupling of **2b** ($R^1 = R^4 \neq H$, $R^2 = R^3 = H$) with a free *trans*-enediyne unit should lead to linear chain polymers with pendant alkynyl groups along a poly(enebutadiyne) backbone. 3) Derivative **2c** ($R^1 = R^2 = R^3 \neq H$, $R^4 = H$) would be the first representative with a single terminal ethynyl group and provide access, via oxidative coupling, to extended cross-conjugated dimeric chromophores. In this communication, we present the first examples of compounds fitting the descriptions 2) and 3) and

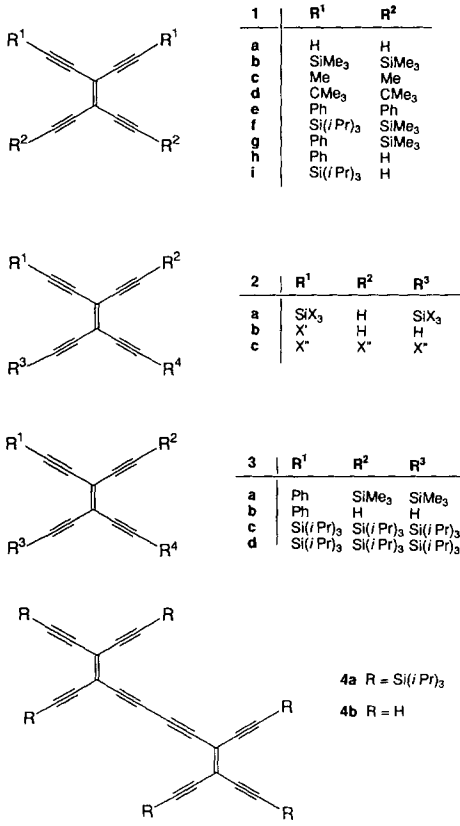
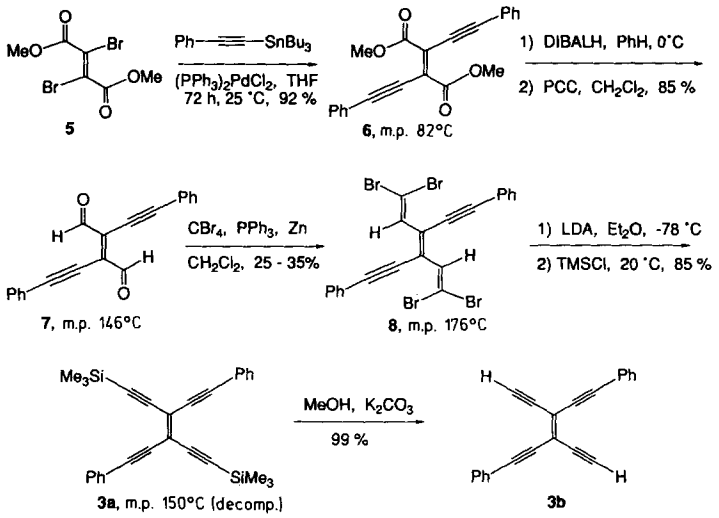
describe the synthesis and structural characterization of the tetraethynylethene derivatives **3a–d** and the dimerization products **4a,b**.



The seven-step synthesis of **3b** with a free *trans*-enediyne unit, which starts from dimethyl 2,3-dibromofumarate,[7] is shown in Scheme 1.[8] Upon slow evaporation of the solvent



Scheme 1. DIBALH = Diisobutylaluminium hydride, PCC = pyridinium dichlorochromate, LDA = lithium diisopropylamide, TMS = trimethylsilyl.

dichloromethane, the stable pale-yellow TMS-protected derivative **3a** afforded crystals suitable for X-ray analysis (Fig. 1).[9] Except for the methyl groups on the two silicon atoms, the molecule is perfectly planar. Deprotection of **3a** with K_2CO_3 in MeOH proceeded smoothly and yielded **3b** in quantitative yield. In the 360 MHz ^1H NMR spectrum of **3b** in $CDCl_3$, the signal for the terminal ethynyl protons appears at $\delta = 3.66$ [IR (neat): $\tilde{\nu}$ [cm^{-1}] = 3307, ≡C–H]. Like the isomeric compound **1h**, derivative **3b** is only stable at room temperature in dilute solutions. Upon concentration, solutions in $CHCl_3$ or CCl_4 darken rapidly, even at −5 °C, and in the solid state decomposition is instantaneous.

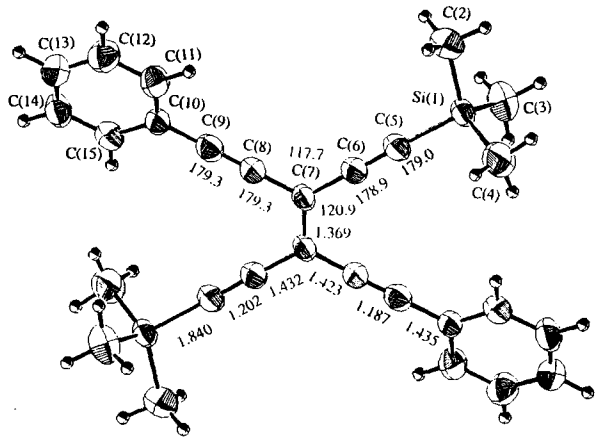


Fig. 1. X-ray crystal structure of **3a**.

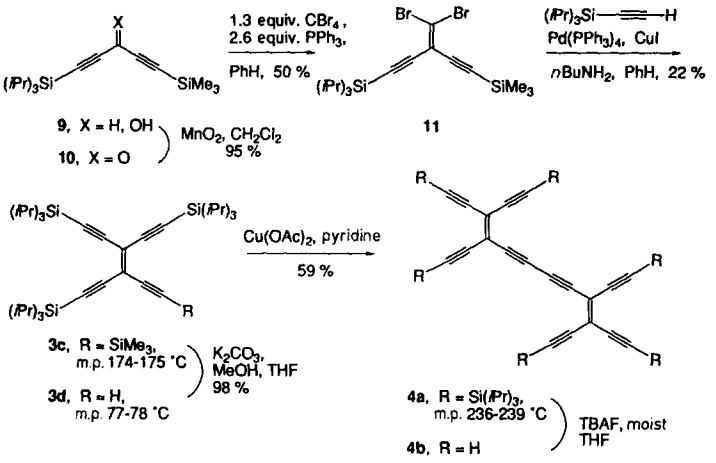
For the preparation of **4b**, a carbon-rich compound with the molecular composition $C_{20}H_6$, the terminally mono-deprotected tetraethynylethene **3d** was synthesized (Scheme 2).



Scheme 2. Compounds for which no melting point is quoted are oils at 25 °C. TBAF = tetrabutylammonium fluoride.

The starting material in this route, the unsymmetrically protected 1,4-pentadiyne-3-ol **9**, was prepared in 48% yield by reaction of TMS-propargylaldehyde in THF with $(i\text{Pr})_3\text{Si–C}{\equiv}\text{CH}$ and *n*BuLi. The mono-deprotected tetraethynylethene **3d** was obtained as a stable solid [IR (neat): $\tilde{\nu}$ [cm^{-1}] = 3307, ≡C–H] which was transformed through oxidative coupling in 59% yield into the fully silyl-protected yellow compound **4a**. This remarkably extended cross-conjugated π-system is very stable with a high melting point of 236–239 °C (!) and, upon recrystallization from hexane/EtOH, afforded crystals suitable for X-ray analysis.[9] The molecule is nearly planar (Fig. 2) with a maximum deviation

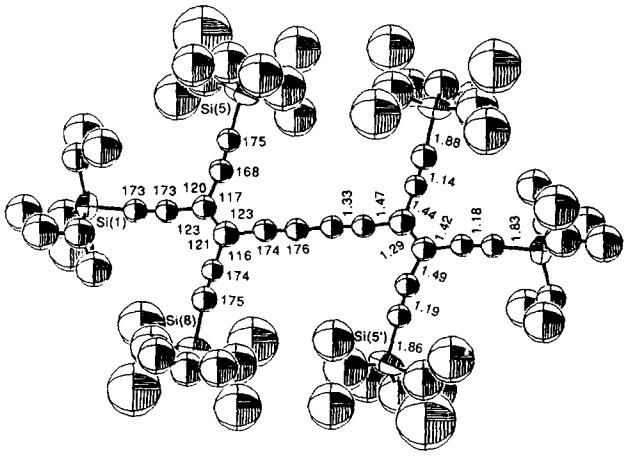


Fig. 2. X-ray crystal structure of **4a**.

from the least-squares plane through the dimeric framework including the six silicon atoms of 0.21(3) Å. Of two possible geometries, **4a** prefers the "transoid" alignment of the two ethenes with respect to the central butadiyne unit. The eighteen isopropyl groups are highly disordered, thus preventing a refinement of the structure beyond $R = 0.169$ ($R_w = 0.178$).

The extension of the π-electron conjugation in the new chromophore **4a** becomes clearly visible on comparison of its electronic absorption spectrum with that of the simple tetraethynylethene **1b** (Fig. 3). Both the location and the shape of the absorption bands of **4a** are very different from the bands in **1b**. In agreement with the planar molecular structure found by X-ray analysis, the UV/VIS spectrum of **4a** shows significant vibrational fine structure. Due to the extension of its chromophore, the end absorption of **4a** appears above 450 nm, and the longest wavelength band at $\lambda_{max} = 432$ nm is bathochromically shifted by 82 nm compared to the lowest energy absorption in **1b** ($\lambda_{max} = 350$ nm).

Deprotection of **4a** with tetra(*n*-butyl)ammonium fluoride in wet THF afforded the hexaethynyl derivative **4b** which is quite stable and soluble in pentane. The 360 MHz ^{1}H NMR spectrum of **4b** in [D$_6$]acetone showed three singlets of equal intensity for the terminal alkyne protons at $\delta = 4.51$, 4.57, and 4.60. Evaporation of the solvent yields a solid which, at room temperature even in the absence of oxygen and light, turns rapidly black yielding a polymer that is insoluble in organic solvents.

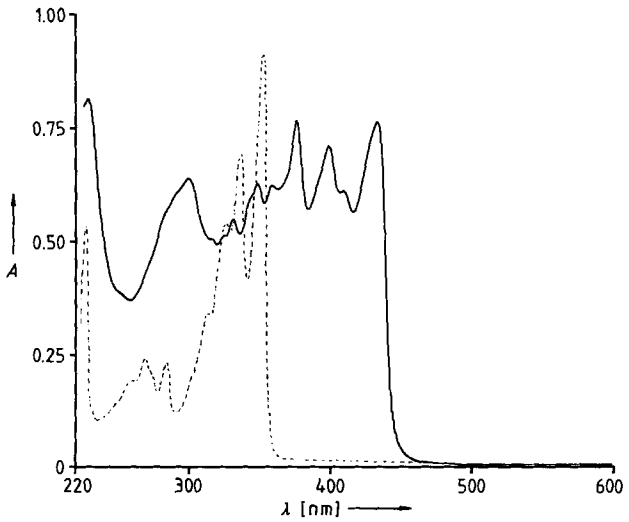

Fig. 3. Electronic absorption of **1b** (----) [1] and **4a** (——) in hexanes, $T = 25$ °C, $d = 1$ cm, $c = 2.74 \times 10^{-5}$ *M*. Spectrum of **4a**: $\lambda_{max} = 223$ sh ($\varepsilon = 36800$ cm^{-1}mol^{-1}L), 228 (37700), 253 sh (17500), 283 sh (25500), 291 sh (27800), 299 (29600), 316 (23200), 324 (23600), 331 (25300), 343 sh (27600), 347 sh (29000), 358 (28900), 374 (35600), 398 (33000), 408 (28300), 432 (35500).

The study of the polymerization chemistry of **3b** and **4b** as well as the preparation of tetraethynylethenes **2a** with free *cis*-enediynes are now under way.

Experimental

3a: To a solution of 3.2 g (5.4 mmol) of tetrabromide **8** in dry diethyl ether at −78 °C was added slowly 13.5 mL of a 2.0 M solution of LDA in THF (27 mmol). After 40 min, the stirred green solution was slowly warmed to 20 °C and 1.30 g (12 mmol) of TMSCl was added. After 3 h, the reaction was quenched with saturated NH_4Cl and extracted with water followed by saturated NaCl. The organic layer was dried and the solvent evaporated. The crude product was filtered through a short column of silica gel (CH_2Cl_2), and the solvent reduced to a volume of 5 mL. The residual solution was cooled to −5 °C, whereupon the product crystallized slowly to yield 1.9 g (85%) of **3a** as a pale yellow solid: m.p. 150 °C (decomp.). IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2205, 2141 (C≡C); ^{1}H NMR (360 MHz, $CDCl_3$): $\delta = 0.27$ (s, 18H, TMS), 7.36 (m, 6H, aryl), 7.54 (m, 4H, aryl); ^{13}C NMR (90.6 MHz, $CDCl_3$): $\delta = -0.23$, 87.24, 98.81, 101.14, 105.4, 118.1, 122.5, 128.3, 129.0, 131.9; UV/VIS (MeOH) λ_{max} [nm] = 232 (sh) ($\varepsilon = 17700$), 246 (18600), 256 (18900), 274 (24400), 380 (23500).

4a: To a solution of 266 mg (0.448 mmol) of **3d** in 45 mL of pyridine was added 1.6 g (8.96 mmol) of anhydrous $Cu(OAc)_2$. After stirring for 20 h at 20 °C, the solution was poured into 250 mL of pentane and 500 mL of 30% $CuSO_4$. The aqueous layer was extracted once with pentane, and the combined organic layers were washed twice with 500 mL of 30% $CuSO_4$, once with 250 mL of water, and once with 250 mL of saturated NaCl. After the organic layer was dried over $MgSO_4$, the solvent was removed to yield a brownish solid. The solid was re-suspended in pentane and filtered through flash silica gel. Removal of the solvent and recrystallization from MeOH/CH_2Cl_2 yielded 156 mg (59%) of **4a** as a yellow solid: m.p. 236–239 °C. IR (neat) $\tilde{\nu}$ [cm^{-1}] = 2156, 2125 (C≡C); ^{1}H NMR (360 MHz, $CDCl_3$): $\delta = 1.07$ (s, 126H, $CH(CH_3)_2$); ^{13}C NMR (90.6 MHz, $CDCl_3$): $\delta = 11.13$, 11.20, 11.24, 18.53, 18.61, 18.65, 82.34, 82.98, 101.55, 103.14, 103.34, 103.64, 103.70, 105.05, 115.91, 120.80.

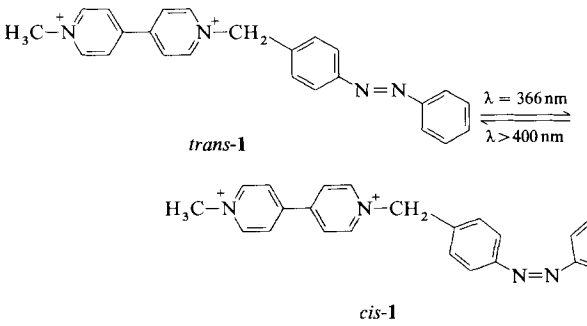
Photoswitchable Association of an Azobenzene–Bipyridinium Diad to Eosin: Photostimulated "On-Off" Guest Binding**

By *Itamar Willner**, *Sharon Marx*, and *Yoav Eichen*

Photoswitchable devices evoke continuous interest as information storage systems and signal amplification units of optical signals.[1, 2] Recent activities in photostimulation of macromolecules' functions[3] have demonstrated that physical properties of photochromic polymers such as permeability,[4] volume,[5] or viscosity[6] can be controlled by light. Similarly, catalytic[7] and binding properties of proteins containing photochromic components anchored to their backbones[8] can be activated by light (i.e., phototriggered).

Photostimulated "on–off" chemical reactivity at the molecular level has, however, been less explored. Photocontrolled binding of ions to photochromic ionophores such as azobenzene crown ethers[9] or "polyether spiropyran"[10] represent phototriggered chemical processes at the molecular level. Here we report on the photostimulated on–off binding of *N*-methyl-*N'*-[4-(phenylazo)benzyl]-4,4'-bipyridinium (Azo-V^{2+}, **1**) to eosin Y (Eo^{2-}, **2**).

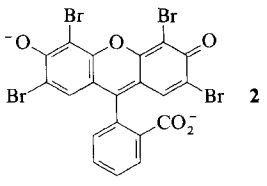
The diad *trans*-**1** was synthesized by the reaction of *trans*-1-(bromomethyl)-4-phenylazobenzene, with *N*-methyl-4,4'-bipyridinium. The resulting diad exhibits photochromic properties: Illumination of *trans*-**1** ($\lambda = 366$ nm) results in isomerization to *cis*-**1**, and upon illumination of *cis*-**1** ($\lambda > 400$ nm) *trans*-**1** is restored. Recently, we reported



trans-**1**

cis-**1**

on the structural and chemical properties of donor–acceptor complexes formed between bipyridinium salts and xanthene dyes, such as eosin.[11] We found that electrostatic interactions as well as π–π donor–acceptor and charge-transfer interactions play important roles in stabilization of these complexes.



2

Trans-**1** as well as *cis*-**1** form 1:1 complexes with **2**, but the complexes differ substantially in their association constants. Figure 1 shows the spectral changes of **2** upon addition of *cis*-**1**. By applying the Benesi-Hildebrand relation,[12] the derived association constant $K_a(cis)$ is determined to be 38000 M^{-1}. The association constant $K_a(trans)$ of *trans*-**1** to **2** is 3000 M^{-1}. Thus, functionalization of the bipyridinium

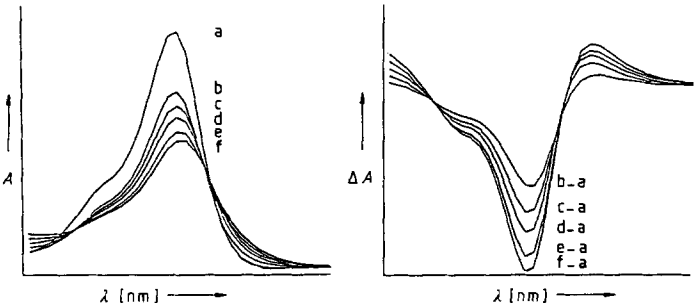


Fig. 1. Left: Spectral changes of Eo^{2-} (**2**, $c = 1.48 \times 10^{-5}$ M) at different *cis*-**1** concentrations. These concentrations for the different experiments are a) 0 M, b) 2.5×10^{-5} M, c) 5.02×10^{-5} M, d) 7.5×10^{-5} M, e) 1.0×10^{-4} M, f) 1.25×10^{-4} M. Right: difference spectra of **2** upon addition of *cis*-**1**. *A* = Absorption units.

component by an azobenzene unit results in a substantial difference in its association properties with **2**, and the association constant of **2** with *cis*-**1** is about twelve times greater than that with *trans*-**1**. A possible origin for this difference can be the changes in dipole moment associated with the isomerization of azobenzene. Isomerization of *trans*-azobenzene (0.5 D) is accompanied by an increase in the dipole moment (*cis*-azobenzene, 3.0 D). This larger dipole moment of the *cis*-azobenzene can participate synergetically in the stabilization of the charge-transfer complex between eosin and the bipyridinium unit. The association constant K_a of *N,N'*-dimethyl-4,4'-bipyridinium with eosin (in H_2O) is 4500 M^{-1}. This value implies that the enhanced binding of *cis*-**1** to eosin is associated with the increase in dipole moment of the azobenzene component.

The difference in the association constants of *trans*-**1** and *cis*-**1** to eosin allows us to design a molecular switch for association (Fig. 2). An aqueous solution of eosin ($c = 1.48 \times 10^{-5}$ M) and *trans*-**1** ($c = 6.2 \times 10^{-5}$ M) results in a system where the two components exhibit only weak mutual recognition and are essentially in a separated form. Upon illumination ($\lambda = 366$ nm), isomerization of *trans*-**1** to *cis*-**1** occurs. This results in the formation of a complex between *cis*-**1** and eosin, as evidenced by the decrease in the absorbance of the eosin dye [Eq. (a)]. Back isomerization of

$$\underset{\mathbf{2}}{Eo^{2-}} + \underset{trans\text{-}\mathbf{1}}{trans\text{-}Azo\text{-}V^{2+}} \underset{\lambda > 400\ nm}{\overset{\lambda = 366\ nm}{\rightleftharpoons}} [Eo^{2-} \cdots cis\text{-}Azo\text{-}V^{2+}] \qquad (a)$$

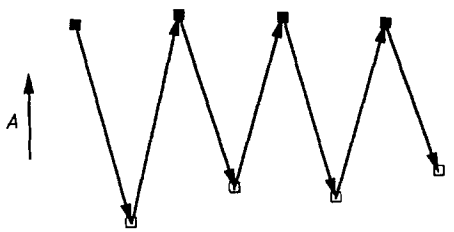

Fig. 2. Periodic complexation and decomplexation of diad **1** to and from eosin, followed by absorption differences of free and associated eosin. □: complexed Eo^{2-} in the presence of *cis*-**1**; ■: free Eo^{2-} in the presence of *trans*-**1**.

cis-**1** to *trans*-**1** ($\lambda > 400$ nm) results in separation of the complex, as evidenced by restoration of the absorption band of free eosin. Figure 2 shows the periodic complexation and separation [Eq. (a)] of the bipyridinium unit and eosin on remote photoinduced isomerization of the azobenzene component. In all photoinduced transformations of *trans*-**1** to *cis*-**1**, a photostationary state corresponding to 60% *cis* and 40% *trans* form is generated. Furthermore, the thermal reisomerization of *cis*-**1** is influenced by the complex formation, while transformation of *cis*-**1** to *trans*-**1** in dimethylsulfoxide (DMSO) proceeds at 323 K with a rate constant of $k = 4 \times 10^{-3}\ s^{-1}$. This is enhanced in the complex configuration, and the derived rate constant is $k = 3.9 \times 10^{-2}\ s^{-1}$.

We thus conclude that on–off photostimulated binding of the azobenzene-4,4′-bipyridinium diad to eosin proceeds by photoinduced isomerization of the photochromic component. The performance of this system resembles to some extent the functions of macroscopic machines. The separated form is analogous to the neutral position of a machine. Upon isomerization of *trans*-**1** to *cis*-**1** the system is geared into the complexed state. Further studies to modify the two complex components by including a catalytic site and a reactive site are now under way in our laboratory in an attempt to drive a catalytic transformation with the geared supramolecular assembly.

Solid-State Columns Made from Twisted, Self-Complementary Terpyridine Units**

By *Chia-Yu Huang, Vince Lynch*, and *Eric V. Anslyn**

One goal in the design of self-assembling molecular arrays[1] is to confidently predict solid-state structures. The assembly of organic molecules into predictable motifs has potential in the preparation of organic materials with useful optical or electronic properties.[2] To accomplish self-organization, two compounds are typically used which serve as complementary recognition units that guide the crystallization into a desired pattern.[3] Hydrogen-bond donors and acceptors are convenient for this purpose, since the directionality of the hydrogen bonds can be predicted,[4] and such donors and acceptors can be synthetically incorporated into the monomeric units used to form a polymeric array. In order to construct crystalline materials whose physical properties can be systematically varied, one strategy would be to form a scaffold with repeating units that allow the attachment of electron donors or acceptors,[5] or possibly structures with good nonlinear optical properties.[6] The α-helical scaffold of a protein is a particularly attractive design to mimic, since the amino acid side chains protrude from the helix in predictable and repeatable spatial positions.[7] The hydrogen bonds that direct the assembly of the secondary structure are colinear or directed toward the helix axis, and thus are not perturbed by the side chains.[8] The α-helix structure forms a columnar scaffold in which functional groups (the side chains) project from the column, and whose basic structural components may be mimicked by assembly of self-complementary monomers. A schematic representation of such a scaffold is shown in Figure 1. We report here a crystalline material with a structure that conforms to this conceptual design.

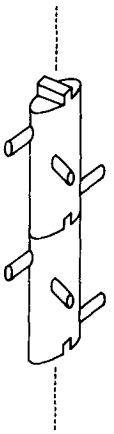

Fig. 1. A schematic representation of a columnar scaffold with sites for attachment of molecular units (the pegs). This scaffold is assembled by interactions of the recognition sites (the slots and teeth) along the column axis.

We reported recently on the complexation of nonplanar guests such as carbohydrates and their analogues with the polyaza cleft molecules **1** and **2**.[9] Since compounds **1** and **2** are twisted, we anticipated that in the solid state they might display the motif shown in Figure 1. The 2-aminopyridine groups could serve as the hydrogen-bond donors and acceptors to induce self-assembly, and the ethyl ester groups would point toward the outside of the scaffold. Herein, we show that compound **2** does indeed form such a structure, but compound **1** does not.

Both compounds **1** and **2** exist in solution as a mixture of *meso* as well as (+) and (−) isomers. According to molecu-

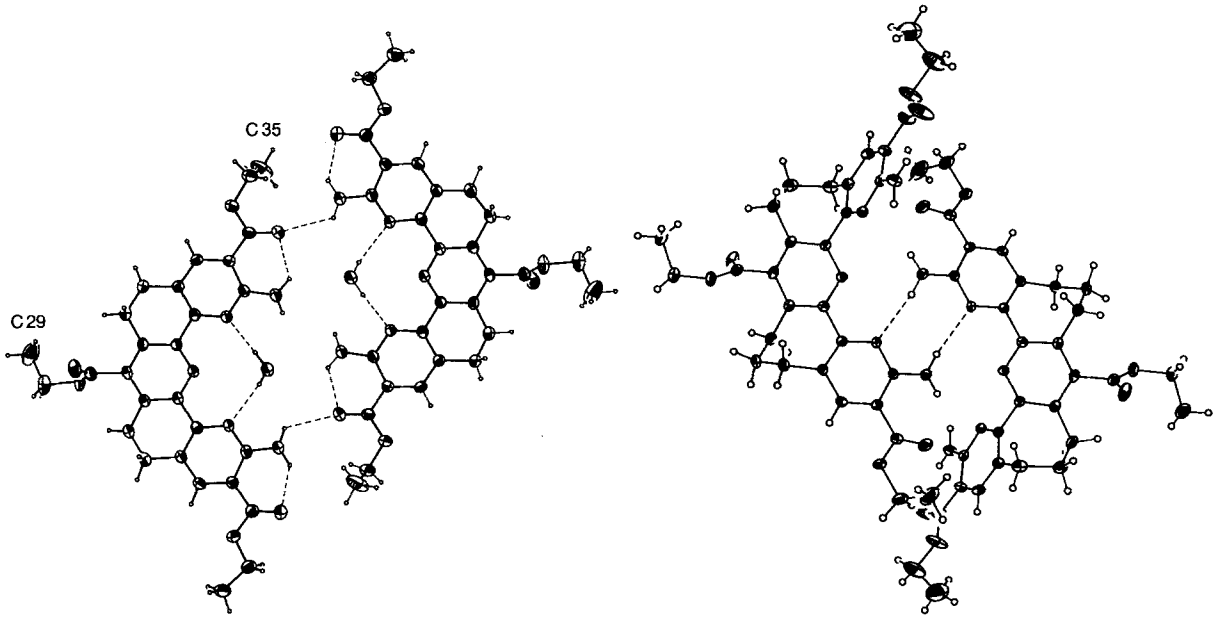

Fig. 2. Left: Dimeric structure of **1** in the solid state with two molecules of water. Right: Dimeric structure of **2** in the solid state showing the two intermolecular hydrogen bonds that ultimately lead to the columnar structure.

lar mechanics calculations,[10] the (+)/(−) isomers of **2** are typically 2 to 3 kcal mol^{-1} lower in energy than the *meso* isomer;[11] the energy difference for **1** is only about 1 kcal mol^{-1}. In the (+)/(−) isomers of **2** the angle formed by the two peripheral pyridine units is 80° in the calculated structure, and 79.8° in the crystal structure.[11] In contrast, the corresponding angle in **1** is calculated to be 24°, but is only 11° in the crystal structure. The discrepency between the calculated and the crystal structure is probably due to a water of crystallization found in **1** which would tend to make the host molecule less twisted so that it may form more linear hydrogen bonds with the water molecule (Fig. 2 left). Figure 2 shows the dimeric structures of compounds **1** and **2** in the solid state. In both cases the (+)/(−) isomers are found. In compound **2** (Fig. 2 right), the twist opens up the structure allowing each peripheral 2-aminopyridine moiety to associate with and form hydrogen bonds to an adjacent monomeric unit; this rigidifies the structure. Each hydrogen bond is close to linearity, and the N–N distance is nearly 3.0 Å. In contrast, compound **1** does not form a columnar scaffold but instead traps a water molecule between the peripheral 2-aminopyridine units. A molecular model of compound **1** suggests that a dihedral angle of only 24° between the peripheral 2-aminopyridines is not enough to allow dimerization of the monomers. "Polymerization" is thus prevented because of steric congestion.

Repetition of the hydrogen-bonding motif shown in Figure 2 leads to a columnar structure for compound **2** (Fig. 3). The ribbon (Fig. 3 middle) is drawn so as to depict the flow of the scaffold coplanar with the three pyridine rings of each

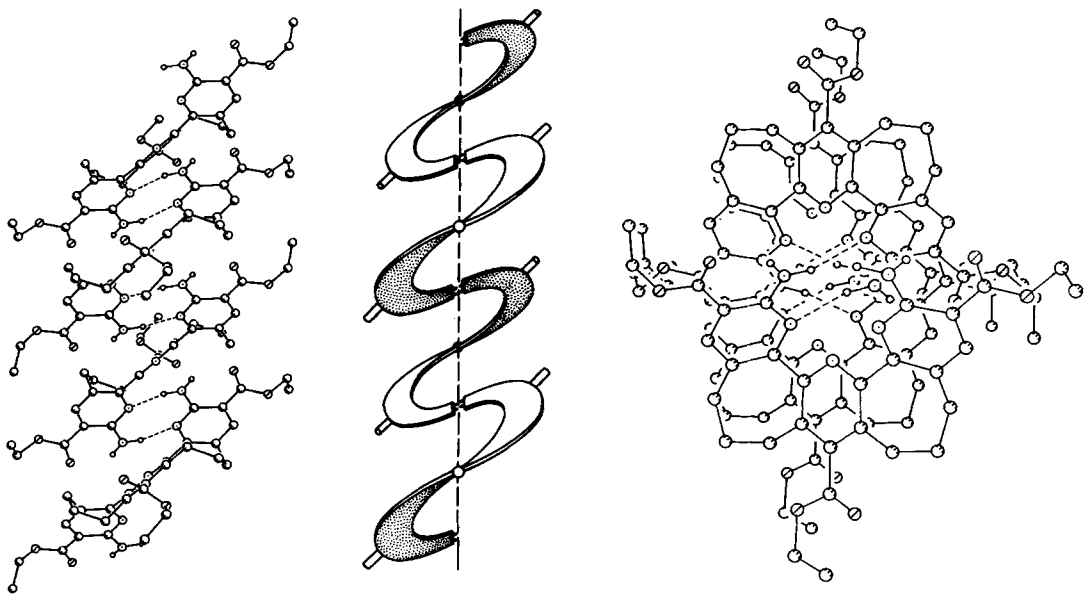

Fig. 3. Left: Four monomeric units of **2** of the self-assembled columnar scaffold. Middle: Schematic representation of the scaffold structure. Right: A view of the scaffold along the axis showing the interior hydrogen bonding that assembles the structure and the protruding ester groups.

monomer. The monomers are held together by two hydrogen bonds shown as two small dashed lines, and the ester groups are represented by pegs. The large dashed line drawn through the length of the ribbon is the column axis, and it passes through each pair of the hydrogen bonds. Two monomeric units are required to reach a translationally equivalent position along the column. The distance (the pitch of the helix) between equivalent positions is 10.8 Å. The perpendicular rise between the planes formed by the central pyridine rings is 3.74 Å, and the tilt angle of the central pyridines to the column axis is 48.2°. The tilt angle of the peripheral pyridines with respect to the column axis is 50°.

Figure 3 right shows a view of the scaffold down the column axis. Ethyl ester groups are oriented approximately 90° to each other when viewed down this axis. There are two types of ethyl ester groups: on two sides of the scaffold those of the peripheral pyridine units are stacked 5.4 Å apart and eclipse each other; on the other two sides the separation is also 5.4 Å but the ester groups of the central pyridine units are staggered. Thus on these sides of the scaffold, equivalent ester groups are 10.8 Å apart.

In summary, **2** forms a scaffold-type framework by self-complementarity, whereby the monomers are not covalently linked. Metal complexes of oligopyridine ligands have been extensively studied by Lehn et al. and Constable et al.[11,12] in an alternate approach to a similar helical columnar motif. We are currently testing if this structure is retained when the ethyl esters of **2** are derivatized. We are also preparing chiral monomers for the investigation of helix formation.

Experimental Procedure

Crystals of **1** [9] ($C_{28}H_{29}N_5O_6 \cdot H_2O$) were obtained as yellow plates from CH_2Cl_2/CH_3CO_2Et. One crystal was cut into a long needle $0.1 \times 0.2 \times 0.9$ mm. The X-ray data were collected at room temperature on a Nicolet P3 diffractometer with a graphite monochromator and $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å). Crystals of **2** [9] ($C_{30}H_{33}N_5O_6$) were obtained as pale yellow prisms and needles from $CHCl_3/CH_3CO_2Et$. The crystal selected for X-ray analysis was a prism of approximate dimensions $0.1 \times 0.2 \times 0.4$ mm. The data were collected at 173 K on a Nicolet R3 diffractometer, equipped with a Nicolet LT-2 low-temperature device and with a graphite monochromator and $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å). Four reflections were remeasured every 96 reflections to monitor the stability of the instrument and the crystal. A smoothed curve of the intensities of these control reflections was used to scale the data. The data were corrected for Lp effects but not for absorption. Data reduction and decay correction were performed with the SHELXTL-Plus software package. [13] Both structures were solved by direct methods and refined by full-matrix least-squares [13] with anisotropic thermal parameters for the non-H atoms. The hydrogen atoms were obtained from a ΔF map and refined with isotropic temperature factors. For **1**, the hydrogen atoms on C29 and C35 did not refine well and were idealized in the final refinement cycles (C–H 0.96 Å). The function, $\sum w(|F_o| - |F_c|)^2$ was minimized, where $w = 1/(\sigma(F_o))^2$ and $\sigma(F_o) = \{0.5\, kI^{-1/2}[(\sigma(I))^2 + (0.02\, I)^2]^{1/2}\}$. The intensity I is given by $(I_{peak} - I_{background}) \times$ scan rate, where 0.02 is a factor to downweight intense reflections and to account for instrument instability, and k is the correction due to Lp effects and decay. $\sigma(I)$ was estimated from counting statistics; $\sigma(I) = [(I_{peak} + I_{background})^{1/2} \times$ scan rate]. Neutral atom scattering factors for the non-H atoms were taken from Cromer and Mann, [14] with the corrections for anomalous dispersion taken from the work of Cromer and Liberman. [15] The scattering factors for the H atoms were obtained from Stewart, Davidson and Simpson. [16] Values used to calculate the linear absorption coefficient are from the International Tables for X-ray Crystallography (1974). [17] Other computer programs used in this work are listed elsewhere. [18] All figures were generated with SHELXTL-Plus. [13] Further details of the crystal structure investigation are availables on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

Pheromones of Marine Brown Algae; A New Branch of the Eicosanoid Metabolism**

By *Klemens Stratmann, Wilhelm Boland,** and *Dieter G. Müller*

Most of the semiochemicals (pheromones) in the sexual cycle of marine brown algae (Phaeophyceae) known today are acyclic or cyclic hydrocarbons with the molecular formulas $C_{11}H_{14}$, $C_{11}H_{16}$, $C_{11}H_{18}$, or $C_{11}H_{14}O$.[1,2] Fertile female gametes of the brown alga *Ectocarpus siliculosus*, a species found worldwide, release a mixture of ectocarpene (**A**), dictyotene (**B**), hormosirene (**C**), and finavarrene (**D**) to attract male gametes[3] (Fig. 1). The two most important pheromones are (+)-(*S*)-ectocarpene (**A**) and (−)-(1*R*,2*R*)-hormosirene (**C**); their threshold concentrations are in the range of 0.1 to 1 nM.

(+)-(*S*)-Ectocarpene (**A**), dictyotene (**B**), and finavarrene (**D**) are also produced by terrestrial plants. According to

modeling experiments with the South African *Senecio isatideus* (Asteraceae), these compounds arise in them from the multiply unsaturated C_{12} carboxylic acids **4** or **5** by oxidative decarboxylation[4, 5] (Scheme 1). We report here that in marine algae this class of compounds does not arise from the unsaturated C_{12} precursors **4** or **5** as previously thought, but is derived from the pool of polyunsaturated C_{20} fatty acids. Externally supplied [$^2H_8$]arachidonic acid **2** can be converted into labeled 6-butylcyclohepta-1,4-diene **1** (dictyotene **B**, Fig. 1) in high yield by female gametes of *E. siliculosus*. The relative amount of [$^2H_4$]-**1** obtained in the observed de novo synthesis from [$^2H_8$]-**2** under standard conditions[7] exceeds the amount of the natural accompanying component **1** by 800%, as is evident from the ratio of the signals of the respective molecular ions at *m/z* 150 and 154.

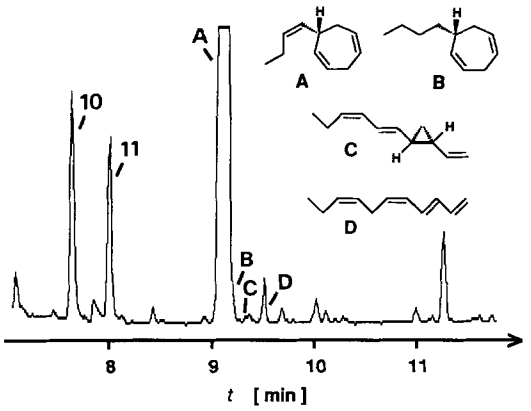

Fig. 1. Section of the gas chromatogram of the volatile compounds produced by the female gametes of the marine brown alga *Ectocarpus siliculosus*. **A**, **B**, **C**, and **D** are natural C_{11} compounds. **10** and **11** are the artificially derived C_{10} metabolites obtained after incubation with [$^2H_6$]-**7**. A similar product profile is observed after application of [$^2H_6$]-**7** to female gametes of *Sphacelaria rigidula*. GC conditions: RSL 300 (30 m × 0.32 mm; Alltech, Munich (FRG)) under programmed conditions (40 °C for 2 min, then heated at 10 °C min^{-1} to 250 °C); detector: Finnigan ion trap ITD 800.

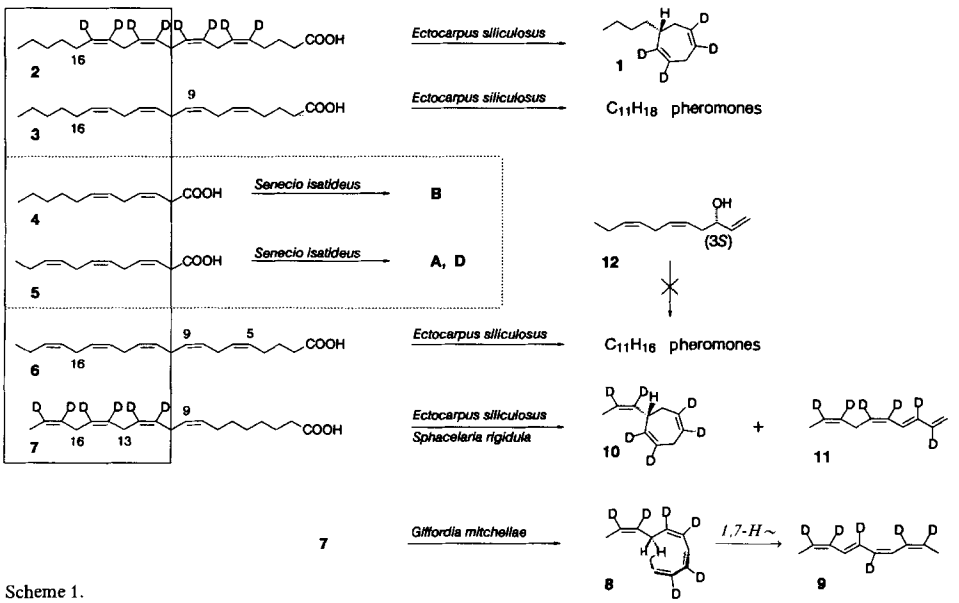
The deuteration pattern[4] and the structure of [$^2H_4$]-**1** indicate that this $C_{11}H_{18}$ hydrocarbon is formed from the C(10) to C(20) segment of the arachidonic acid [$^2H_8$]-**2**. Logically, a $C_{11}H_{16}$ hydrocarbon, for example **A**, **C**, or **D** (cf. Fig. 1), should arise from the aliphatic terminus of the yet more unsaturated eicosapentaenoic acid (**6**). This was established for ectocarpene (**A**) and finavarrene (**D**) with the [$^2H_6$]-C_{19} carboxylic acid **7**, which was designed as a short-chain analogue of natural eicosapentaenoic acid (**6**)[6] (Scheme 1).

[$^2H_6$]-**7** was metabolized very efficiently by female gametes of the brown alga *E. siliculosus* into the two deuterated C_{10} hydrocarbons **10** and **11**. The terminus of the metabolic probe, [$^2H_6$]-**7**, is one carbon atom shorter than in **6**, thus guaranteeing that the artificial metabolites **10** and **11** can be analyzed without interference from the natural products **A** and **D**. Figure 1 shows a profile of the substances formed in a typical incubation[7] with [$^2H_6$]-**7**. Relative to the natural pheromone **A** the production of **10** and **11** amounts to 10%! The mass spectrum of [$^2H_6$]-**10** displays the expected signal of the molecular ion (*m/z* 140) and a fragmentation pattern characteristic for cycloheptadienes like **10**.[4, 5] Careful analysis of the mass spectrum indicates that the ring closure to **10** occurs between C(10) and C(16) in the precursor [$^2H_6$]-**7** with retention of the positions of the deuterium atoms. The fragmentation pattern of the second C_{10} metabolite, [$^2H_6$]-**11**, corresponds to that of an acyclic olefin related to finavarrene (**D**).[4] The overproportional amount of [$^2H_6$]-**11** formed (Fig. 1) may be related somehow to the shorter chain, since the short-chained substrates of the terrestrial plant *S. isatideus* (e.g. nona-3,6-dienoic acid) are converted exclusively to acyclic olefins (e.g. 1,3,5-octatriene).[4] A metabolite corresponding to the trace component **C** was not found.

In experiments in which the gametes of the marine brown algae *E. siliculosus* are incubated with the C_{12} trienecarboxylic acid **5** or with a [$^2H_6$]-C_{11} analogue with a shorter terminal chain, the corresponding ectocarpene or [$^2H_6$]-**10** and [$^2H_6$]-**11** are not produced. According to this, the *intact* framework of the eicosanoids **3** or **6** is essential to the formation of the $C_{11}H_{18}$ and $C_{11}H_{16}$ hydrocarbons; a preceding degradation to **4** or **5** (4 × β oxidation) does not take place in the female gametes of marine brown algae.

The description above also holds for other members of the class Phaeophyceae. In experiments with female gametes from *Sphacelaria rigidula*, which also release primarily ectocarpene (**A**),[8] a spectrum of products analogous to that from *E. siliculosus* is obtained (cf. Fig. 1). Especially impor-



Scheme 1.

tant was the finding that [$^2H_6$]-**7** is transformed by the gametophytes of the brown alga *Giffordia mitchellae* into **9**, the C_{10} analogue of giffordene[9] (giffordene = (2*Z*,4*Z*,6*E*,8*Z*)-undeca-2,4,6,8-tetraene). In analogy to the biosynthesis of the acyclic tetraene **11**, which arises from **7** by loss of a hydrogen atom at C(13) and cleavage of the C(9)–C(10) bond, the formation of the intermediate (3*Z*,5*Z*,8*Z*)-decatetra-1,3,5,8-ene (**8**) must be postulated in order to account for the unusual geometry of **9**. Compound **8** is thermally labile and rearranges below room temperature into the isomeric tetraene **9** by an antarafacial [1,7] hydrogen shift.[9, 10] This electrocyclic reaction which otherwise occurs only in the biosynthesis of vitamin D[11] is now proven experimentally for the first time for the secondary metabolism of marine brown algae as well.

(3*S*,5*Z*,8*Z*)-Undeca-1,5,8-trien-3-ol (**12**),[12, 13] isolated from brown algae, was discussed by Moore and Jaenicke as an intermediate common to the fatty acid metabolism and the $C_{11}H_{16}$ pheromones.[14] A recently reported "biomimetic" synthesis of hormosirene (**B**) from **12** appears to support this hypothesis.[15] In analogy to the biosynthesis of the mushroom aroma oct-1-en-3-ol, **12** could be derived from a C_{20} polyene carboxylic acid.[16] Under standard conditions[7] all incubation experiments with a chain-shortened (5*Z*,8*Z*)-[5,6,8,9-$^2H_4$]-deca-1,5,8-trien-3-ol were negative. The expected [$^2H_4$]-propenylcycloheptadiene [$^2H_4$]-**10** was not found. Thus, we rule out the unsaturated alk-1-en-3-ols of type **12** as intermediates between the fatty acid metabolism and the C_{11} hydrocarbons. Because the eicosanoids are not catabolized into the multiply unsaturated C_{12} carboxylic acids **4** or **5**, we presume that 9-hydroxy- or 9-hydroperoxyeicosapentaenoic acid is the intermediate. In these compounds the functionalized C(9) of **3** and **6** corresponds to the carboxyl groups of **4** and **5** (Scheme 1), the precursors of the $C_{11}H_{18}$ and $C_{11}H_{16}$ hydrocarbons in higher plants. Thus, the group of C_{11} compounds in the brown algae could arise from the pool of eicosanoids according to the fragmentation $C_{20} \rightarrow C_{11} + C_9$, whereas in higher plants unsaturated fatty acids are converted to the olefins according to the scheme $C_{12} \rightarrow C_{11} + C_1$.

Separation of Overlapping Multiplets in Two-Dimensional NMR Spectra by Selective "Injection" of Magnetization**

By *Catherine Zwahlen, Sébastien J. F. Vincent,* and *Geoffrey Bodenhausen**

Broadly speaking, multidimensional NMR spectra can be interpreted at two different levels of sophistication. In many cases, it is sufficient to focus on chemical shifts, but a more thorough analysis must also address the information contained in the fine-structure of cross-peak multiplets.[1] There are three major obstacles that may impair such a detailed analysis: excessive complexity, poor digital resolution, and accidental overlap. Very complicated structures can be simplified either by some means of decoupling during signal acquisition, or by partial deconvolution of the multiplets once they have been recorded.[2] The problem of digital resolution can be solved very effectively by "zooming in" on multiplets with the help of "soft" two-dimensional methods such as selective correlation spectroscopy (soft-COSY).[3] However, these methods are unsuitable when the experimentalist is confronted with overlapping multiplets. Serious cases of overlap call for some way of increasing the dimensionality of the spectra. While three-dimensional spectra recorded with non-selective pulses have the advantage that multiplets rarely suffer from overlap, their digital resolution is usually very poor. Thus, it is desirable to record three-dimensional spectra with *selective* pulses,[4] but three-dimensional experiments are relatively cumbersome and time-consuming, and it is difficult to present the outcome in a graphically pleasing way.

Fortunately, it is possible to achieve a similar separating effect by a "poor man's" form of three-dimensional spectroscopy, which amounts to recording signals in a plane $S(\omega_2,\omega_3)$ of a hypothetical $S(\omega_1,\omega_2,\omega_3)$ data cube, where one of the three frequency variables (i.e. ω_1) is fixed. This can be achieved by a variant of relayed magnetization transfer, where coherence is "injected" in a selective manner at the beginning of the evolution period of a soft-COSY sequence. Consider a soft-COSY experiment that is set up to correlate multiplets resonating in the vicinity of Ω_A in ω_1 and Ω_X in ω_2. If there are several spins that resonate at nearly or precisely degenerate frequencies Ω_A, $\Omega_{A'}$,... and Ω_X, $\Omega_{X'}$,..., the soft-COSY spectrum will consist of a superposition of cross-peaks due to coherence transfer processes $A \rightarrow X$, $A' \rightarrow X'$,... Now suppose that each of the nearly degenerate nuclei A, A',..., has a coupling partner M, M',..., and suppose that these are *not* degenerate amongst each other. In such a case,

[**] We thank Dr. W. Bermel, Karlsruhe, and Prof. H. Kessler, Garching, for a sample of *cyclo*-(L-Pro^1-L-Pro^2-D-Pro^3). This work was supported by the Swiss National Science Foundation and by the Commission pour l'Encouragement de la Recherche Scientifique (CERS).

one may carry out experiments where the soft-COSY sequence is preceded by a selective coherence transfer step $M \rightarrow A$, or $M' \rightarrow A'$, etc. In this manner, the soft-COSY multiplets of the processes $A \rightarrow X$, $A' \rightarrow X'$, etc., can be unraveled.[5]

We have recently shown[6, 7] how a doubly selective homonuclear Hartmann-Hahn (HOHAHA) transfer can be used in one-dimensional spectra. Figure 1a shows the pulse sequence for one-dimensional applications. In-phase magnetization I_x^M is first excited by a self-refocusing 270° Gaussian pulse truncated at 2.5% with a typical duration of 30 ms for a peak amplitude of 55 Hz.[8] More sophisticated pulses such as Gaussian cascades optimized by quaternions[9] or E-BURP pulses[10] may also be used. In Figure 1, the doubly selective irradiation of duration τ_{DSI} is implemented by modulating a rectangular radiofrequency (rf) pulse with a function $\cos(\omega_a t)$, where $\omega_a = \frac{1}{2}(\Omega_M - \Omega_A)$. This modulation

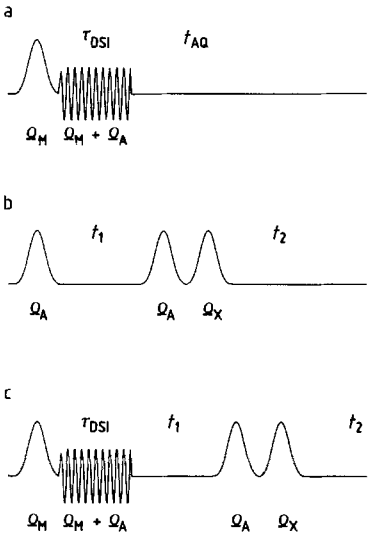

Fig. 1. a) Pulse sequence for selective in-phase coherence transfer in one-dimensional spectroscopy. The initial 270° Gaussian pulse, with a carrier frequency set at the chemical shift Ω_M, excites in-phase magnetization of spin M, which is transferred to spin A during the subsequent doubly selective irradiation period $\tau_{DSI} \approx 1/J_{AM}$, with two rf sidebands at Ω_M and Ω_A. The phase of the spin-locking field is orthogonal to the phase of the initial excitation pulse. b) Normal selective correlation experiment (soft-COSY) using three self-refocusing 270° Gaussian pulses, the first to excite A magnetization, the latter two for transferring magnetization from spin A to spin X. c) SPLIT-COSY sequence, consisting of a soft-COSY preceded by a doubly selective HOHAHA to inject in-phase coherence from spin M to spin A at the beginning of the evolution period. To suppress unwanted signals, the phases of the first pulse and of the receiver are alternated between 0 and 180° in all three sequences.

generates two sidebands at frequencies $\omega_{rf} \pm \omega_a$, which coincide with the chemical shifts Ω_M and Ω_A of the two chosen spins, provided the carrier frequency is placed at $\omega_{rf} = \frac{1}{2}(\Omega_M + \Omega_A)$. The optimum duration of the doubly selective irradiation is given by the inverse of the active coupling constant, $\tau_{DSI} = 1/J_{AM}$. The amplitude of the doubly selective irradiation must be optimized empirically to give the best in-phase transfer, as shown in Figure 2 for a transfer within the coupling network of L-proline[2] of *cyclo*(L-Pro[1]-L-Pro[2]-D-Pro[3]) **1**.[11]

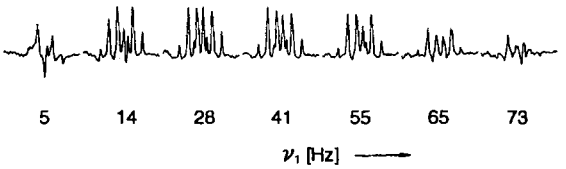

Fig. 2. Optimization of the rf amplitude ν_1 [Hz] for a HOHAHA transfer between the β^{cis} proton ($\delta = 2.10$) and the β^{trans} proton ($\delta = 1.62$) of L-proline[2] in **1** in $C_6D_6/CDCl_3$ (8/1) at 303 K. Since $J(\beta^{cis}\beta^{trans})$ is -12.8 Hz, τ_{DSI} is 78 ms. The experiments were performed on a Bruker MSL 300 spectrometer equipped with an Oxford Research Systems selective excitation unit.

Typically, the optimum radiofrequency amplitude ν_1 is 30 Hz for each sideband. If the amplitude is much weaker, it is impossible to lock all magnetization components within each multiplet simultaneously; if the rf amplitude is too large, various passive spins, some of which may have chemical shifts that lie accidentally in the vicinity of the rf sidebands, will also be perturbed.

Figure 1b shows the pulse sequence for normal selective correlation spectroscopy (soft-COSY). The in-phase magnetization I_x^A partly evolves into an anti-phase term $2I_x^A I_z^X$ during t_1.[12] The second and third pulses convert this term first into $2I_z^A I_z^X$, then into $2I_z^A I_x^X$, which evolves into observable magnetization I_x^X. The method can easily be adapted for soft-NOESY, by inserting a mixing period τ_m between the last two pulses.[8, 13] Figure 1c shows the sequence obtained by combining Figures 1a and 1b; in effect, the initial pulse of the soft-COSY experiment is applied at Ω_M rather than at Ω_A, and it is immediately followed by a doubly selective irradiation period τ_{DSI} for HOHAHA transfer from M to A. The only information needed prior to setting up the experi-

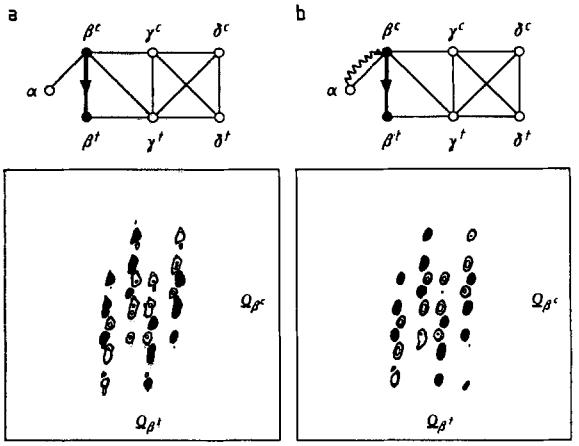

Fig. 3. a) Soft-COSY experiment correlating the β^{cis} proton (at $\delta = 1.23$ in the vertical ω_1 domain) and the β^{trans} proton ($\delta = 2.79$ in the horizontal ω_2 domain) of D-proline[3] in **1** obtained by exciting the magnetization of the β^{cis} proton by a simple 270° Gaussian pulse at the beginning of the evolution period. b) Same multiplet, but obtained by injection of magnetization from the α proton ($\delta = 4.49$) to the β^{cis} proton at the beginning of the evolution period, as indicated on the graph representing the coupling network. Since in D-proline[3] $J(\alpha\beta^{cis})$ is 6.5 Hz, τ_{DSI} is 154 ms. The spectral widths were 75 Hz in both ω_1 and ω_2. The matrices consisted of 128 × 1 K data points before and 256 × 1 K data points after zero filling. A Lorentz-Gauss transformation (LB = −0.3, GB = 0.05) was applied before Fourier transformation. With two scans for each t_1 increment and a relaxation delay of 10 s, the overall duration required for spectrum a was about 45 min; 16 scans were used for spectrum b.

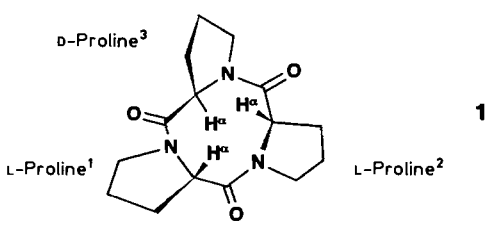
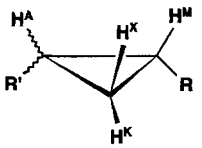


1

ment is the chemical shift Ω_M of a "passive" M spin which must be coupled to one of the A spins that we wish to distinguish. It is also desirable (though not essential) that we know the approximate value of the coupling constant J_{AM} to be able to estimate the optimum duration $\tau_{DSI} \approx 1/J_{AM}$ of the doubly selective irradiation period.

Before tackling difficult cases with overlapping multiplets, it appears advisable to check the efficiency of HOHAHA injection by an application to a harmless case within the coupling network of D-proline[3] of *cyclo*(L-Pro[1]-L-Pro[2]-D-Pro[3]) **1**.[11] The agreement of the patterns and pure absorption peak shapes in the multiplets shown in Figure 3 provides conclusive evidence that excitation by HOHAHA transfer, if done properly, is fully equivalent to excitation with a selective pulse. Figure 3 also shows graphs of coupling networks where the nodes represent the spins and the edges their mutual couplings.[14] To represent a soft-COSY experiment symbolically, a bold arrow runs from the spin that is active in t_1 to the one that carries the coherence in t_2, while HOHAHA transfer is represented by a wavy arrow.

Now consider a case where the multiplets appear to be hopelessly entangled. In earlier studies, the 1:3 mixture of the ethyl esters **2** of *cis*- and *trans*-2-phenylcyclopropanoic acid (R = $COOCH_2CH_3$, R' = C_6H_5) was used to test the limits of pattern recognition[14] and multiplet separation[15] procedures.



2

The protons A^{trans} and A^{cis} on the one hand, and X^{trans} and X^{cis} on the other, have pairwise nearly the same chemical shifts. This situation is very typical for a mixture of isomers. In a conventional soft-COSY experiment, one obtains two strongly overlapping multiplets due to the two transfer processes $X^{trans} \rightarrow A^{trans}$ and $X^{cis} \rightarrow A^{cis}$ (Fig. 4a). Fortunately, the existence of nondegenerate coupling partners M^{trans} and M^{cis} makes it possible to transfer magnetization selectively to either X^{trans} *or* X^{cis}. A soft-COSY sequence following selective transfer may provide pure cross-peaks of either $X^{trans} \rightarrow A^{trans}$ *or* $X^{cis} \rightarrow A^{cis}$, as illustrated in Figures 4c and 4b, respectively. We dubbed this novel experiment *S*eparation of *P*atterns by *L*ifting the *I*mbroglio of *T*ransfer in *Co*rrelation *S*pectroscop*y* (SPLIT-COSY).

Figure 5 illustrates an interesting case where our technique failed to split two overlapping cross-peaks due to an unforeseen case of degeneracy. In the normal soft-COSY spectrum corresponding to the region shown in Figure 5, one observes two severely overlapping multiplets due to $\gamma^{trans} \rightarrow \beta^{trans}$ and $\beta^{cis} \rightarrow \beta^{trans}$ in L-proline[1]. We hoped to split these by using a selective HOHAHA transfer to γ^{trans} from two other strongly coupled protons of the same amino acid, δ^{cis} and δ^{trans}. To our disappointment, the SPLIT-COSY spectrum obtained in this manner, which is shown in Figure 5, is virtually identical to the corresponding soft-COSY spectrum. This experiment shows that the magnetization received by γ^{trans} is in part transferred to β^{cis}, although the J coupling constants between β^{cis} and both δ^{cis} and δ^{trans} are vanishingly small. In general, when two coupled spins have nearly the same chemical shift, it is not possible to transfer magnetization to one of them selectively. Indeed, two such spins will always be irradiated at the same time by one of the rf sidebands, so that

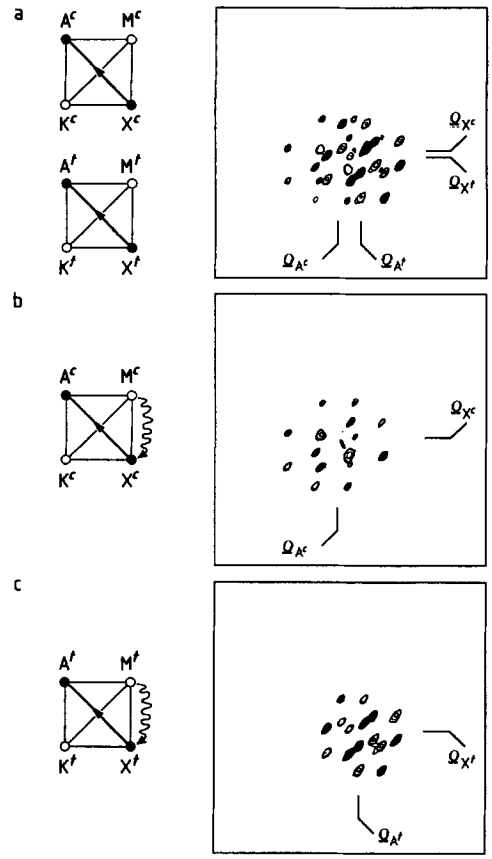


Fig. 4. a) Normal soft-COSY spectrum of **2** in $CDCl_3$ showing overlapping cross-peaks $X^{cis} \rightarrow A^{cis}$ and $X^{trans} \rightarrow A^{trans}$. The symbols A^c and A^t stand for the H^A protons of the *cis* and *trans* isomers of **2**. b) Clean $X^{cis} \rightarrow A^{cis}$ multiplet (centered at $\delta = 1.16$ and 2.42, respectively) obtained by SPLIT-COSY with injection from M^{cis} ($\delta = 1.95$) to X^{cis} with $\tau_{DSI} = 130$ ms. c) Clean $X^{trans} \rightarrow A^{trans}$ multiplet (centered at $\delta = 1.18$ and 2.40) obtained by an injection from M^{trans} ($\delta = 1.79$) to X^{trans}, with $\tau_{DSI} = 108$ ms. Experimental conditions were the same as for the spectra in Figure 3.

if any magnetization is transferred to one of them, it will automatically be transferred to the other, in the manner of total correlation spectroscopy (TOCSY).[16]

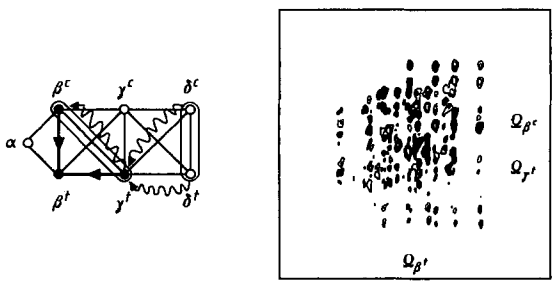

Fig. 5. SPLIT-COSY spectrum of **1** centered at $\delta = 1.59$ in ω_1 and 2.27 in ω_2, showing a superposition of two cross-peaks $\beta^{cis} \rightarrow \beta^{trans}$ and $\gamma^{trans} \rightarrow \beta^{trans}$ in L-proline[1]. In this case, a doubly selective HOHAHA period led to a transfer from δ^{cis} *and* δ^{trans} (which are nearly degenerate at $\delta = 3.55$) to γ^{trans} *and* β^{cis}, the latter being coupled and nearly degenerate in the vicinity of $\delta = 1.59$. Experimental conditions were the same as for the spectra in Figure 3.

Although the two-step transfer from $\delta^{cis} + \delta^{trans}$ to β^{cis} represents an obstacle to the separation of the two overlapping multiplets in Figure 5, the same phenomenon can be put to use in a constructive fashion to separate the multiplets in Figure 6a. These two multiplets originate from two different

proline residues. The L-proline[2] multiplet can be separated easily by a transfer from β^{cis} to β^{trans} as shown in Figure 6b. In order to excite only the β^{cis} proton of L-proline[1], magnetization was transferred from the strongly coupled pair $\delta^{cis} + \delta^{trans}$ to the strongly coupled pair $\beta^{cis} + \gamma^{trans}$. The resulting multiplet is represented in Figure 6c and corresponds perfectly to the pattern in Figure 6a obtained by soft-COSY.

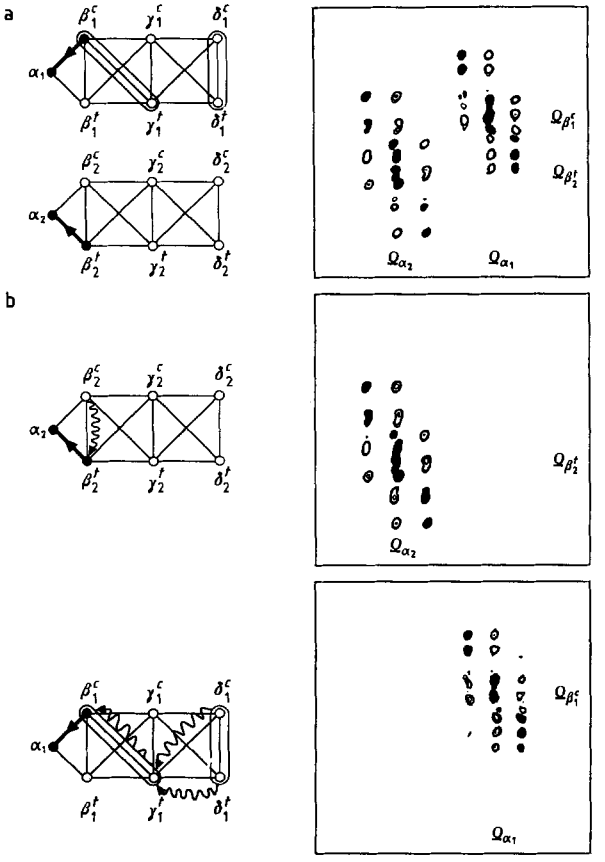

Fig. 6. a) Multiplets obtained with normal soft-COSY of **1**, centered at $\delta = 1.60$ in ω_1 and $\delta = 4.28$ in ω_2. To the left, cross-peak correlating the β^{trans} proton (at $\delta = 1.62$) and the α proton ($\delta = 4.32$) of L-proline[2]; to the right, cross-peak connecting the β^{cis} proton ($\delta = 1.58$) and the α proton ($\delta = 4.23$) of L-proline[1]. b) SPLIT-COSY multiplet of L-proline[2] alone obtained by injection of magnetization from β^{cis} ($\delta = 2.10$) to β^{trans} via $J(\beta^{cis}\beta^{trans}) = -12.8$ Hz with $\tau_{DSI} = 78$ ms. c) SPLIT-COSY multiplet of L-proline[1] alone obtained by injection of magnetization from the two nearly degenerate protons δ^{cis} ($\delta = 3.52$) and δ^{trans} ($\delta = 3.57$), with $J(\delta^{cis}\delta^{trans}) = -11.7$ Hz, to the two nearly degenerate and strongly coupled protons γ^{trans} and β^{cis} ($\delta = 1.61$ and 1.58, with $J(\gamma^{trans}\beta^{cis}) = 3.4$ Hz) via $J(\delta^{cis}\gamma^{trans}) = 3.1$ Hz and $J(\delta^{trans}\gamma^{trans}) = 6.7$ Hz. The cleanest in-phase magnetization was obtained for $\tau_{DSI} = 220$ ms. In this case, the double irradiation period was followed by a hard purging pulse in order to remove antiphase terms [6]. Experimental conditions were the same as those for the spectra in Figure 3.

Our new SPLIT-COSY technique allows one to separate overlapping multiplets in crowded parts of COSY spectra in order to extract hidden information. The structure of the resulting multiplets is the same as in soft-COSY, unlike the multiplets obtained in *S*electively *I*nverted *S*oft COSY (SIS-COSY).[15] In general, samples containing mixtures of isomers, which are likely to give overlapping cross-peaks, should become amenable to investigation, provided each isomer has at least one site with a distinct chemical shift. If necessary, several consecutive HOHAHA transfer steps may be used.

Se_2NCl_3 and $[Se_2NCl_2]^+[GaCl_4]^-$, Chloride Nitrides of Trivalent Selenium**

By *René Wollert, Antje Höllwarth, Gernot Frenking, Dieter Fenske, Helmut Goesmann,* and *Kurt Dehnicke**

The chemistry of selenium–nitrogen compounds has only livened up in the last few years, mainly because of the development of new synthetic processes.[1] Nevertheless, the research in this field is often limited by the properties of the starting materials: the explosive character of tetraselenium tetranitride or by the low solubility of the more stable tetraselenium dinitride.[2] We report herein about a readily accessible chloride nitride of trivalent selenium, which is soluble in organic solvents and stable, but at the same time is very reactive and suitable as a synthetic reagent.

Diseleniumtrichloride nitride (**1**) is formed by the action of tris(trimethylsilyl)amine on a suspension of selenium tetrachloride in boiling dichloromethane [Eq. (a)]. Upon cooling

$$2\,SeCl_4 + N(SiMe_3)_3 \longrightarrow \underset{\mathbf{1}}{Se_2NCl_3} + 3\,ClSiMe_3 + Cl_2 \qquad (a)$$

moisture-sensitive crystals can be isolated from the red solution. **1**, which when viewed against light appear red but viewed against a background appear a shiny, metallic green.

According to the X-ray crystal structure analysis[3] **1** forms planar molecules shaped like dividers and with almost C_{2v} symmetry (Fig. 1). The two symmetry-independent molecules are only slightly different from each other. The Se–N bonds in **1** (174 pm) are significantly shorter than the values expected for a Se–N single bond (186 pm [4]); thus π bonding contributions can be assumed. Similar short distances are

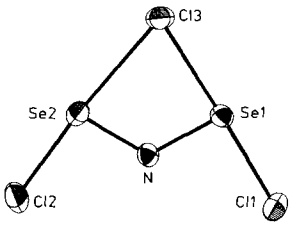

Fig. 1. Crystal structure of **1**.

also observed for other Se–N compounds with delocalized π bonding,[1] for example, in the cyclic anions $[SeN_2Se_2]_2^{2+}$ and $[SeN_2Se_2]^{2+}$ available from Se_4N_4 and arsenic pentafluoride.[5] The bond angle at the N atom in **1** (119.9°) is in accordance with sp^2 hybridization. The Se–Cl distances to the terminally bonded chlorine atoms in **1** are slightly longer (average value 223.4 pm) than the terminal Se–Cl bonds in the cubane structure of $[SeCl_4]_4$ (average value 216.4 pm);[6] in contrast the two bridging Se–Cl bonds in **1** are much shorter (average value 259.8 pm) than the Se–Cl bridging bonds in $[SeCl_4]_4$ (average value 279.4 pm). Nevertheless, the bridging chlorine atom in **1** is readily removed as chloride by the action of strong Lewis acids such as aluminum or gallium trichloride leading to the formation of **2** [Eq. (b)]. Com-

$$\mathbf{1} + GaCl_3 \longrightarrow \underset{\mathbf{2}}{[Se_2NCl_2]^+[GaCl_4]^-} \qquad (b)$$

pound **2** forms orange, moisture-sensitive crystals, which according to the X-ray crystal structure analysis[7] are ionic. The cation of **2** is formed by the rearrangement of the framework atoms of **1** (Fig. 2) and has a U-shaped structure. The

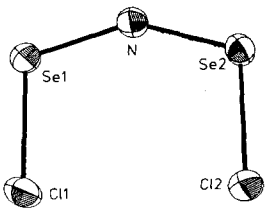

Fig. 2. Crystal structure of the cation of **2**.

cation is almost planar, and the Se–N and Se–Cl distances are the same within standard deviations, fulfilling the criteria for C_{2v} symmetry. As expected, all the bond lengths in **2** are slightly shorter than in **1**. The shortening of the Se–N bonds is accompanied by an opening of the Se-N-Se bond angle of 119.9° in **1** to 146.6° in **2**. This is also apparent in the IR spectra[8] from the shift of the υ_{as}Se-N-Se band from 830 cm^{-1} in **1** to 922 cm^{-1} in **2**.

Whereas the sulfur compound analogous to **1** is unknown, the $[N(SCl)_2]^+$ cation analogous to the cation of **2** is known with various counterions.[9–12]

Both **1** and **2** are diamagnetic; the ground state is thus a singlet state. In the ^{77}Se NMR spectra[13] in acetonitrile **1** shows a resonance signal at $\delta = 961$, the corresponding signal in the spectrum of **2** is shifted to $\delta = 1699$, which is explained by the deshielding of the selenium atoms in the cation of **2**. This signal lies in the range between that of **1** and those of the cations of $[Se_4^{2+}][AsF_6^-]_2$ ($\delta = 1936$ [14]) and $[SeN_2Se_2^{2+}][AsF_6^-]_2$ ($\delta = 2434$ [6]).

The results of quantum chemical ab initio calculations[15] of **1** and of the cation of **2** are in good agreement with the average values of the bond lengths and angles determined by experiment (Table 1). The deviations between the theoretical and the experimental values can partly be explained by crystal packing effects.

Table 1. Experimentally determined and theoretically calculated bond lengths [pm] and angles [°] of Se_2NCl_3 (**1**) and of $Se_2NCl_2^+$ the cation of **2**. Calculated partial charges q from the Mulliken population analysis.

Cl3-Se1-N1	87.1(2)	82.2		
Cl3-Se2-N1	82.4(2)	82.2		
q(Cl3)		−0.61		
q(Cl1)		−0.21		−0.01
q(Se1)		+0.69		−0.70
q(N1)		−0.35		−0.38

The analysis of the occupied orbitals supports the assumption that the Se–N bonds in **1** and those in the cation of **2** have π bonding contributions. The orbital occupation shows five occupied valence orbitals with π symmetry for **1** and four occupied π orbitals for the cation of **2**. Of those, three and two, respectively, can be assigned to the π orbitals of the lone pairs at the chlorine atoms of **1** and in the cation of **2**, respectively. This means that the Se-N-Se unit in **1** and in the cation of **2** has two doubly occupied π orbitals and is therefore, with regard to the π bonds, valence isoelectronic with the allyl anion, which could be an explanation for the bond shortening. The bonding in **1** can be described with the mesomeric structures shown in Figure 3.

A topological analysis of the calculated wave function[16] of **1** indicates significant differences between the terminal

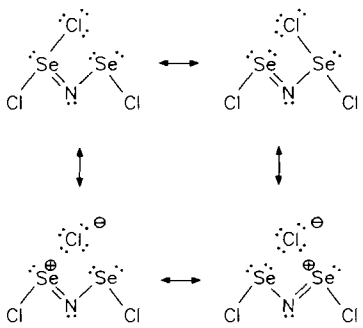

Fig. 3. Description of the bonding in **1** with mesomeric limiting structures.

Se–Cl bonds and the Se–Cl bridging bond. Figure 4 (left) shows the Laplacian distribution of the electron density of **1**. Whereas the electron density distribution of the bridging Cl atom is spherically symmetrical, the terminal Cl atoms show a significant distortion of the electron density distribution and an overlap with the electron density of the Se atoms. This indicates a covalent character for the terminal Se–Cl bonds, whereas the bridging Cl atom is rather ionically bound. The calculation of the charge distribution according to Mulliken[17] supports this interpretation (Table 1). The bridging Cl atom with a partial charge of -0.61 is clearly more negatively charged than the terminal Cl atoms (-0.21). The Se atoms in **1** have a positive partial charge ($+0.69$), which in the cation of **2** is almost identical ($+0.70$). The Laplacian distribution of the U-shaped cation (Fig. 4 right) shows that the only significant difference to the corresponding structural unit in **1** is the orientation of the Se-N-Se unit. Obviously the repulsion between the in-plane orbitals of the lone pairs at Cl and at N in the W-shaped structure of the cation of **2** is greater than that between Se and N in the U-shaped structure.

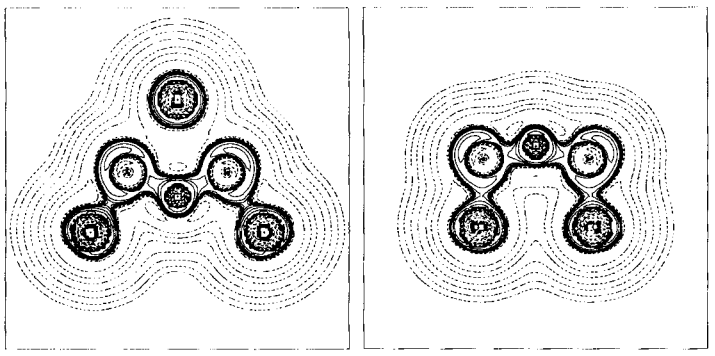

Fig. 4. Laplacian distribution of the electron density in **1** (left) and in the cation of **2** (right).

The calculated frequency spectra for **1** and for the cation of **2** show that the optimized structures are minima on the potential energy hypersurface (no negative eigenvalues of the Hessian matrix). In agreement with the experiment a frequency shift to higher wavenumbers is calculated for the highest positioned band (ν_{as}(Se-N-Se), b_2) from 862 cm^{-1} (**1**) to 909 cm^{-1} (cation of **2**) during the formation of **2** from **1**.

Experimental Procedure

1: A solution of tris(trimethylsilyl)amine (2.2 g, 9.4 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a suspension of $SeCl_4$ (4.1 g, 18.7 mmol) in CH_2Cl_2 (30 mL) and stirred. This was refluxed for 12 h, filtered to remove small amounts of unreacted $SeCl_4$, and after concentration to 10 mL cooled to 5 °C. The red crystals were separated by filtration, washed with a little cold CH_2Cl_2, and dried in vacuum (yield 1.5 g, 57%, based on $SeCl_4$, m.p. 69 °C). The chlorine formed by this reaction reacted with a part of the tris(trimethysilyl)amine. An improvement in the yield strived for by the addition of larger quantities of amine is not advisable since explosive by-products are formed.

Pyridine-2-thiolato Complexes of V^{II}, V^{III}, and V^{IV} with Unusual Structural Features**

By *John G. Reynolds,* Shawn C. Sendlinger, Ann M. Murray, John C. Huffman,* and *George Christou**

One of the stimuli for our continuing interest in vanadium–sulfur chemistry is the relevance of this area to industrial petroleum refining. Certain crude oils contain large amounts of vanadyl (VO^{2+}) impurities categorized into two types according to their ligands.[1] These are the vanadyl petroporphyrins, which have been well studied and characterized,[2] and the vanadyl nonporphyrins whose ligand environment is thought to contain S, N, and/or O donor atoms.[3] The presence of these vanadyl impurities leads to the formation of

[**] This work was supported by the Office of Basic Energy Sciences, Division of Chemical Sciences, U.S. Department of Energy, Grant DE-FG02-87ER13702 (to G. C.) and Contract No. W-7405-ENG-48 (to J. G. R.)

vanadium sulfides (primarily V_2S_3 and V_3S_4) under the reducing and sulfur-rich hydrotreating conditions.[4] These sulfides have deleterious consequences on the activity and lifetime of the heterogeneous catalyst (e.g., Mo/Co/S on alumina) employed for upgrading crude oil. To model the progressive reduction, sulfide incorporation, and aggregation of VO^{2+} impurities in crude oil, we have studied a variety of vanadium–sulfur compounds which contain a number of thiolato ligands and range from mono- to tetranuclear in oxidation states from III to V.[5–11] More recently we have used the ligand pyridine-2-thiol (pytH) because it contains functional groups common in crude oils (thiolate S and arene N) and also has the ability to both chelate and bridge transition metals.[12] We herein report the syntheses of V^{II}, V^{III}, and V^{IV} complexes with pyt^- ligands which have unusual structural features; we also describe an extremely rare example of a thiolatovanadium(II) complex.

The addition of two equivalents of Na(pyt) to a solution of $[VOCl_2(thf)_2]$ in THF yields the vanadium(IV) compound **1**.[13] The structure of **1** (Fig. 1)[14, 23] displays an unusual

$[V_2O_2(pyt)_4]$ **1**

bridging arragement of two $\mu_2:\eta^1:\eta^2$-pyt^- ligands in which the N6 atom of pyridine makes up part of the base of the square-pyramidal coordination of V1 (vertices N6, N5, S2, S3′, O4) and the sulfur atom S3 of the same pyt^- unit occupies a basal position at V1′ [V1′–S3 = 2.457(4) Å]. In addition, the sixth position of the V1 coordination sphere *trans* to the oxo ligand is occupied by S3 [V1–S3 = 2.798(3) Å]. This complex is an extremely rare example of a compound with an unsymmetrical pyt^- bridge.[15] Two chelating pyt^- ligands complete the coordination sphere at each metal center. The V–O distance [1.583(6) Å] is normal for a triply bonded vanadyl unit, and the whole molecule has imposed C_i symmetry. The X-band EPR spectra of **1** dissolved in CH_2Cl_2 or THF recorded at room temperature show only the typical isotropic 8-line signals characteristic of mononuclear VO^{2+} species; this suggests that either the dinuclear arrangement is not retained in solution, or that the metal centers are noninteracting.

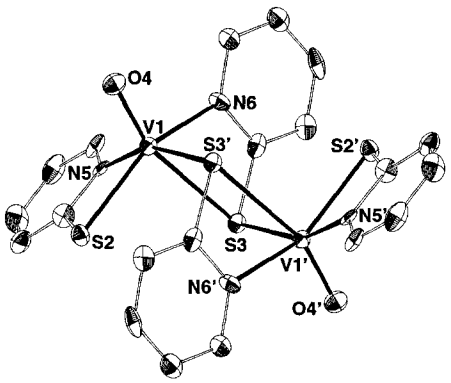

Fig. 1. ORTEP representation of complex **1** (ellipsoids at the 50% probability level). Primed and unprimed atoms are related by the inversion center. Selected interatomic distances [Å] and angles [°]: V1···V1′ 3.989(2), V1-S2 2.427(3), V1-S3 2.798(3), V1-S3′ 2.457(4), V1-O4 1.583(6), V1-N5 2.088(7), V1-N6 2.106(7); V1-S3-V1′ 98.65(9), O4-V1-S2 108.92(24), O4-V1-S3 158.99(24), O4-V1-S3′ 99.47(22), O4-V1-N5 101.13(28), O4-V1-N6 96.7(3), N5-V1-S3′ 158.11(19), S2-V1-N6 150.68(21), S2-V1-N5 68.51(19), S3-V1-N6 62.35(21).

Addition of four equivalents of Na(pyt) to a solution of $[VCl_3(thf)_3]$ in THF yields the vanadium(III) complex **2**.[16]

$[Na(thf)_2V(pyt)_4]$ **2**

The crystal structure of **2** (Fig. 2)[17, 23] shows a rare example of a vanadium(III) center with sevenfold coordination[18] which consists of three chelating pyt^- ligands and a fourth bound to the V atom by its sulfur atom (S23). The nitrogen

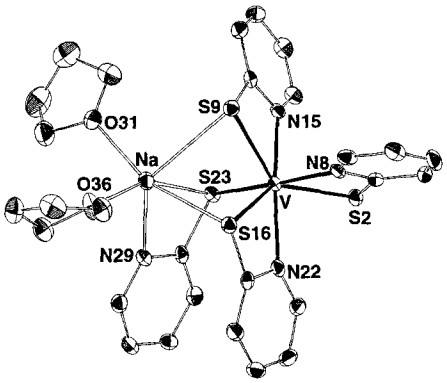

Fig. 2. ORTEP representation of complex **2** (ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: V-S2 2.526(1), V-S9 2.567(1), V-S16 2.543(1), V-S23 2.495(1), V-N8 2.121(3), V-N15 2.178(3), V-N22 2.187(3), Na-S9 3.042(2), Na-S16 2.887(2), Na-S23 2.951(2), Na-N29 2.400(3), Na-O31 2.286(3), Na-O36 2.325(3); S9-V-N15 64.39(9), S2-V-N8 66.59(9), S16-V-N22 64.57(9); Na-S9-V 77.15(7), Na-S16-V 80.44(7), Na-S23-V 79.96(7); N8-V-S23 168.14(9).

atom (N29) of this fourth pyt^- ligand is bound to a second metal center, the Na atom. There are also bonding interactions between the Na atom and S9, S16, and S23. Two THF molecules complete the coordination sphere of the Na atom. Complex **2** may best be described as a triply bridged heterobimetallic species because of the ligation mode of three of the four pyt^- ligands (particularly that containing S23 and N29). The formulation as an ion pair, $[Na(thf)_2]^+[V(pyt)_4]^-$, would be less accurate. In **2** the three pyt^- ligands are also in the rare μ_2: $\eta^1:\eta^2$ ligation mode.

Addition of two equivalents of Na(pyt) to a solution of $[VCl_2(tmeda)_2]$ (tmeda = tetramethylethylenediamine)[19] in CH_2Cl_2 or THF yields the vanadium(II) complex **3**,[20] an

$[V(pyt)_2(tmeda)]$ **3**

extremely rare example of a thiolatovanadium(II) complex.[22] Compound **3** (Fig. 3)[21, 23] is a mononuclear trischelate which has a distorted octahedral geometry because of the small bite angle of the pyt^- ligand. The molecule has imposed C_2 symmetry, and the S2-V-S2′ angle is 156.05(4)° rather than 180°. X-band EPR spectra of **3** dissolved in toluene recorded at room temperature show a broad signal near $g = 2$. At 115 K, an additional broad signal at $g = 4$ is observed, consistent with an $S = 3/2$ ground state.

The pyt^- complexes of V^{II}, V^{III}, and V^{IV} display unusual structural features and provide a useful family of related compounds for reactivity studies. Preliminary results show that both compounds **2** and **3** react with O_2 and S_8 to yield complex **1** and $[V_2S_2(pyt)_4]$, respectively. Also, dissolution of

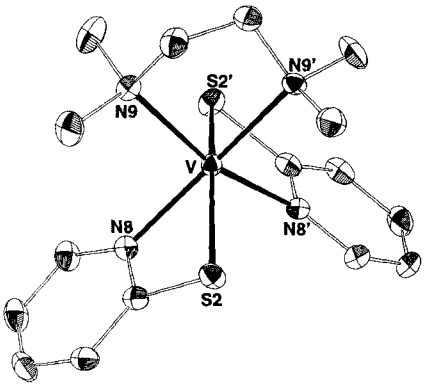

Fig. 3. ORTEP representation of complex **3** (ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: V-S2 2.547(1), V-N8 2.124(2), V-N9 2.252(2); S2-V-S2′ 156.05(4), S2-V-N8′ 97.24(6), S2-V-N8 66.85(8), S2-V-N9 97.63(6), S2-V-N9′ 100.45(6), N8-V-N8′ 99.89(13), N8-V-N9 90.65(9); N8-V-N9′ 164.27(8), N9-V-N9′ 81.64(12).

compound **2** in CH_2Cl_2 yields a white precipitate [Na(pyt) according to IR spectroscopy]. Efforts are currently underway to characterize this material, since mononuclear "$[V(pyt)_3]$" may be unstable with respect to aggregation.

Complexes **1** and **2** were studied by electron ionization mass spectrometry to determine gas-phase fragmentation pathways and probe possible C–S bond cleavage reactions. These transformations may serve as a models for some of the high-energy reactions occurring during hydrodemetallation/hydrodesulfurization of petroleum. Under normal ionization conditions, both compounds show one or more fragmentation pathways involving C–S bond cleavage, as previously detected in $[V(StBu)_4]$, in which the C–S bonds are more easily cleaved.[11] For example, $[VO(C_5H_4NS)_2]^+$ (*m/z* 287; 100% intensity) gives fragment ions assigned to $[VO(C_5H_4NS)(C_5H_4N)]^+$ (*m/z* 255; 4%), $[VO(C_5H_4N)_2]^+$ (*m/z* 223; 38%), and $[VO(C_5H_4NS)S]^+$ (*m/z* 208, 209; 10%) which appear to form through a one- or two-step process involving C–S bond cleavage. The ion $[V(C_5H_4NS)_3]^+$ responds similarly under the same conditions. Further details of both the mass spectrometric investigation and the reactivity studies will be reported in due course.

Aromatic Boron Heterocycles: The Generation of 1 H-Borepin and the Structure of Tricarbonyl(1-phenylborepin)molybdenum**

By *Arthur J. Ashe III,* Jeff W. Kampf, Yasuhiro Nakadaira,** and *Jennifer M. Pace*

Dedicated to Professor William von E. Doering on the occasion of his 75th Birthday

1*H*-Borepin (**1**) is of great interest because it is isoelectronic with tropylium (**2**).[1, 2] Prior work over thirty years has

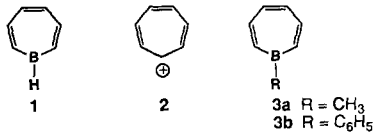
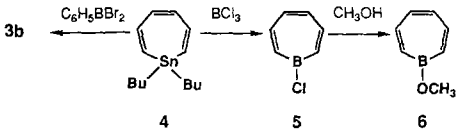
[**] This work was supported by the Research Corporation and the donors of the Petroleum Research Fund, administered by the American Chemical Society.

produced a number of imaginative syntheses of highly substituted borepins,[3-9] while the minimally substituted 1-methylborepin (**3a**) has only recently been synthesized.[10] We report here on the first synthesis of the parent heterocycle **1** and on structural data which show that 1-substituted borepins can serve as η^7 aromatic ligands for transition metals.



Borepins are most conveniently prepared by an exchange reaction of the appropriate stannepin with boron halides.[4,8-10] Thus, the reaction of 1,1-dibutylstannepin (**4**)[11] with phenylboron dibromide in benzene affords 1-phenylborepin (**3b**) in 30% yield. The reaction of **4** with excess BCl_3 in refluxing liquid butane affords 1-chloroborepin (**5**) as a volatile liquid (67% yield), which is easily purified by pot-to-pot distillation. Reaction of **5** with CH_3OH in CH_2Cl_2 gives 1-methoxyborepin (**6**) in 73% yield. These



borepins are air sensitive and **5** is particularly sensitive, but they can be easily handled using Schlenk techniques. The NMR data for these compounds is summarized in Table 1.

When an excess of Bu_3SnH (50 mg) is added to a frozen solution of 10 mg of **5** in 500 μL of C_6D_6 in an NMR tube at −78 °C and then warmed to 25 °C, the ^1H NMR spectrum of the reaction mixture shows that the signals of **5** decrease over 15 min and new signals simultaneously appear. The spectrum after the reaction is complete is shown in Figure 1.[18] We assign this spectrum to 1*H*-borepin as discussed below. Since 1*H*-borepin is extremely moisture, oxygen, and heat sensitive, it has not been isolated. However, in a reaction characteristic of secondary boranes[13] **1** reacts with methanol to afford the methoxy derivative **6**.

The proof of the existence of 1*H*-borepin rests largely on the analysis of the ^1H, ^{11}B, and ^{13}C NMR spectra (Table 1). The ^1H NMR spectra of the four borepins **1**, **3b**, **5**, and **6** show virtually identical patterns of peaks, since the observed

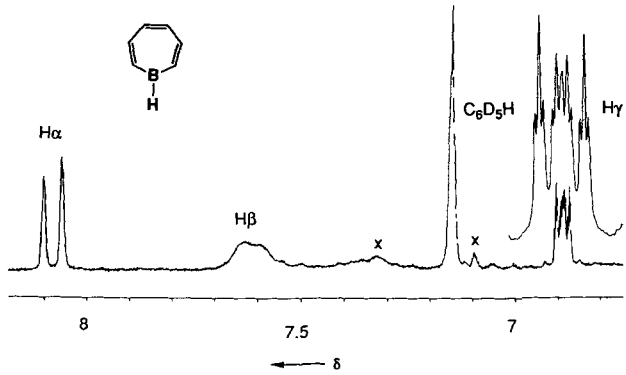


Fig. 1. The low-field region of the 300 MHz ^1H NMR spectrum of 1*H*-borepin in C_6D_6. The signals due to excess Bu_3SnH and Bu_3SnCl are not seen. The insert shows an expansion of the signal at $\delta = 6.89$ arising from the γ protons. Signals for unidentified oxidation products are marked with an x.

ring H–H coupling constants are all nearly equal.[14] The signals of the β protons are very broad doublets without fine structure because of strong quadrupolar coupling to ^{11}B, while the signals of the α protons are also somewhat broadened due to a weaker coupling. Only the signals for the remote γ protons are sharp. For **1** the signal of the proton bound to the boron atom was not observed presumably due to the signal width.[15] However, the ^{11}B NMR spectrum shows a broad doublet ($J = 99$ Hz), which collapses to a singlet on ^1H broad-band irradiation, indicating B–H coupling.

The ^{13}C NMR spectra of borepins **1**, **3b**, and **5** show that the α and β carbon atoms are almost identically deshielded while the signals of the γ carbon atoms are in the normal region for aromatic and olefinic carbon atoms. The STO-3G MO calculations on **1** give p–π orbital populations of 0.94, 0.94, and 0.98 electrons for the α, β, and γ carbon atoms, respectively.[2a] Since the ^{13}C NMR shifts are sensitive to changes in π electron density, the observed shifts are consistent with the calculations.

The low-field ^1H NMR shifts of the ring protons of substituted borepins have been taken as evidence of a diamagnetic ring current.[4,8-10] The low-field signals of **1**, particularly the signals of the α protons, also fit this pattern. Analysis of the ^1H NMR spectrum of **1** permits a discussion of its conformation. The Karplus relationship between the magnitude of the vicinal coupling constant $^3J_{H3,H4}$ and the torsion angle H3-C3-C4-H4 applies to cycloheptatriene and heterocycloheptatrienes.[16-18] The observed value of $^3J_{H3,H4}$ of 8.3 Hz is very close to that calculated from the torsion angle of 0° which is required for the planar conformation predicted by

Table 1. ^1H, ^{11}B, and ^{13}C NMR shifts of the new borepin derivatives and the borepin complex **7** (C_6D_6, 25 °C, coupling constants in Hz).

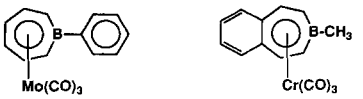
[a] Assignment uncertain.

MO calculations.[18, 2a] Thus, the data suggest that borepin is a planar aromatic compound.

In order to explore further the aromaticity of borepins, we have prepared the $Mo(CO)_3$ complex **7** by the reaction of **3b** with tricarbonyltris(pyridine)molybdenum and $BF_3 \cdot OEt_2$. The NMR signals of the orange, air-stable complex **7** are shifted markedly upfield in comparison to those of the free ligand **3b**. Therefore the borepin ring is η^7-coordinated to Mo.[19] Since prior structural data are available only for complex **8** with the fused benzene ring,[4c] it was of interest to obtain a crystal structure for **7**.[20]



7 **8**

The structure of **7** (Fig. 2) shows a nearly planar borepin ring which is η^7-coordinated to the $Mo(CO)_3$ moiety. The B–Mo distance (2.523(3) Å) is somewhat larger than the C–Mo distances of 2.33–2.42 Å; the boron atom is slightly displaced (0.04 Å) from the plane of the ring. This is consistent with the larger size of the boron atom and conforms to a pattern shown by other heterocyclic boron ligands.[21] The uncoordinated phenyl ring is canted by 28° relative to the boron ring.

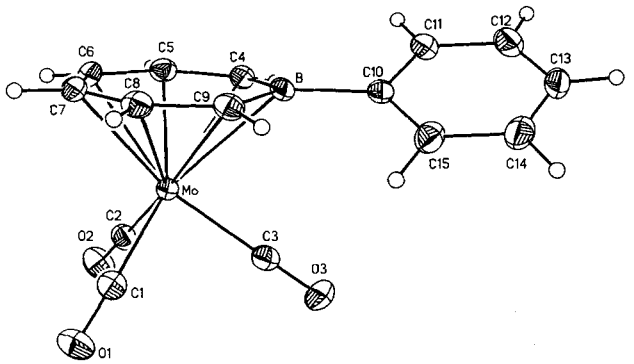


Fig. 2. Solid-state structure of 7 (ORTEP). Selected distances [Å]: MoB 2.523(3), MoC4 2.400(3), MoC5 2.346(3), MoC6 2.327(3), MoC7 2.348(3), MoC8 2.380(3), MoC9 2.416(3), BC4 1.525(4), BC9 1.532(4), BC10 1.578(4), C4C5 1.390, C5C6 1.421(4), C6C7 1.408(5), C7C8 1.423(4), C8C9 1.391(4).

The C–C bonding distances of the borepin ring (1.39–1.42 Å) are typical of those found for complexed monocyclic ligands containing boron. The small range of bond lengths (deviation 0.04 Å) indicates that the π bonds are not very localized. Interestingly, this range is identical to that shown by the C–C bond lengths of the phenyl ring (1.36–1.40 Å). The intraring B–C bond length (1.53 Å) is significantly shorter than the exocyclic B–C_6H_5 distance of 1.58 Å, indicating B–C π bonding in the borepin ring. These structural data clearly demonstrate that borepin can serve as an aromatic ligand.

Experimental

3b: Phenylboron dibromide (0.84 g, 3.4 mmol) in 5 mL of benzene was added dropwise with stirring to **4** (1.0 g, 2.4 mmol) in 5 mL of benzene at 25 °C. The reaction mixture turned green on addition. After 5 min the solvent was removed under reduced pressure, and the residue was subjected to pot-to-pot distillation (120 °C/0.05 Torr) giving 1.35 g of product. Analysis by ^{1}H NMR indicated that the product was approximately 10% 1-phenylborepin (30% yield), and the remainder was largely dibutyltin dibromide. This mixture can be used in subsequent reactions. Careful redistillation gave 70 mg (15%) of **3b** (b.p. 95 °C/0.05 Torr). – EI-MS: *m/z* (rel. intensity): 166 (45, M^+ for $C_{12}H_{11}{}^{11}B$), 165(100).

5: To a gently refluxing solution of BCl_3 (1.0 g, 8.5 mmol) in 10 mL of butane at 0 °C, **4** (1.0 g, 2.4 mmol) was added dropwise with stirring. On addition, the rate of reflux increased and the color of the reaction mixture turned green-brown as a brown precipitate formed. The mixture was allowed to stir as the butane and excess BCl_3 were removed by distillation. The reaction mixture was allowed to warm to 25 °C and finally heated to 50 °C. The brown residue was then subject to pot-to-pot distillation (50 °C/0.5 Torr) giving 200 mg (67%) of product which formed colorless crystals at −78 °C. EI-MS: *m/z* (rel. intensity): 126 (17, M^+, for $C_6H_6{}^{11}B\ {}^{37}Cl$) 123(100). High-resolution EI-MS: calcd for $C_6H_5{}^{11}B^{35}Cl$: 123.0173; found: 123.0171.

6: A solution of methanol (55 mg, 1.72 mmol) in 1.0 mL of CH_2Cl_2 was added to **5** (200 mg, 1.61 mmol) at −78 °C. The mixture was allowed to warm to 25 °C with stirring for 15 min. The solvent and excess methanol were removed under vacuum leaving an oil which was distilled pot-to-pot (50 °C, 1 Torr) to give 140 mg (73%) of **6**. EI-MS: *m/z* (rel. intensity): 120 (33, M^+ for $C_7H_9{}^{11}BO$), 119(100). High-resolution EI-MS: calcd. for $C_7H_8{}^{11}BO$: 119.0668; found: 119.0666.

7: A solution of 1.35 g of the mixture of **3b** and dibutyltin dibromide (0.8 mmol of **3b**) above in 5 mL of Et_2O was added to a suspension of $[(C_5H_5N)_3Mo(CO)_3]$ (0.38 g, 0.9 mmol) in 5 mL of Et_2O. The $BF_3 \cdot OEt_2$ (0.4 mL, 2.8 mmol) was added dropwise with stirring over 5 min. The reaction mixture gradually darkened to a golden brown. After 2 h the solvent was removed under vacuum, and the residue was extracted with hexane (2 × 25 mL). The yellow-brown extracts were washed with 10 mL H_2O and dried over anhydrous Na_2SO_4. Removal of solvent left a thick yellow oil (0.54 g) which solidified on cooling. ^{1}H NMR showed the material to be about 20% product. Recrystallation from pentane gave 10 mg bright orange crystals, m.p. 75–76 °C.

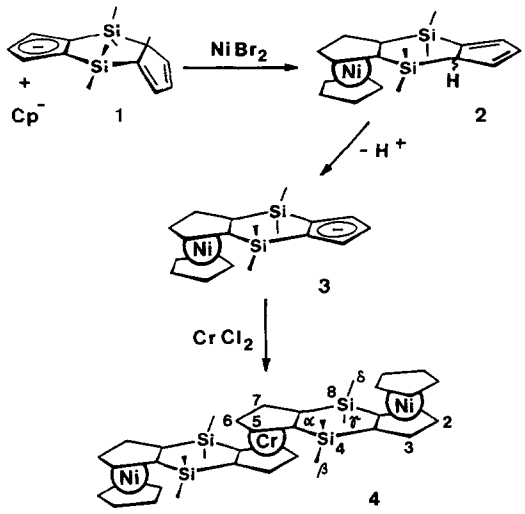
Stepwise Stacking of Three Paramagnetic Metallocene Units: [CpNiCp(SiMe$_2$)$_2$CpCrCp(SiMe$_2$)$_2$CpNiCp]**

By *Pierre Bergerat, Janet Blümel, Monika Fritz, Johann Hiermeier, Peter Hudeczek, Olivier Kahn,* and *Frank H. Köhler**

Molecular materials which are ferro-, ferri, or antiferromagnetic as a result of interactions between spin-carrying metal centers are currently subjects of intensive research.[1] A particularly rich chemistry is derived from chelate compounds in which like and—more promisingly—unlike metals are assembled in close proximity.[1c] Other spin sources are organometallic compounds. Thus, the reactions of polyalkylmetallocenes with tetracyanoethylene and related electron acceptors yield the salts $[Cp^*_2M]^+$ [π anion]$^-$ which crystallize as stacks and exhibit spontaneous magnetization at low temperature when the metal is iron, manganese, or chromium.[2] In these materials the stacks are linear, that is, vertical with respect to the plane of the π ligands, and their stability is determined by ionic interactions. This organometallic/organic concept implies that different metal centers cannot be introduced in one stack by using simple sandwich molecules.

We wished to explore an alternative concept concerning pure organometallic compounds with stacking orientations other than vertical, with covalent bonding between the metallocenes, and with two different paramagnetic metal centers. We therefore synthesized biscyclopentadienyl ligands that may serve to link different metallocenes in a stereochemically well-defined manner.[3] After testing less reactive diamagnetic synthetic building blocks and their complexation behavior[4] we report here on the title compound **4**, the prototype of a heteronuclear compound containing three paramagnetic metallocene units.

The synthesis (Scheme 1) is based on the stepwise metalation of two doubly bridged cyclopentadienes.[4] Thus the cyclopentadienide **1**[3b] reacted with $C_5H_5^-$ and solvated nickel(II) bromide to give the nickelocene **2** (two pairs of enantiomers *syn*-**2a/b** and *anti*-**2a/b** in the ratio 5:1).[5] Deprotonation of **2** yielded the green anion **3**,[5] a key compound for further reaction with transition metal ions. The title compound **4**[5] was obtained after addition of solvated chromium(II) chloride to a solution of **3** in THF. **4** is an air-sensitive compound isolated as mossy green crystals of **4** · toluene from toluene and solvent-free olive-green glittering platelets from hexane (42% yield).



The cyclic voltammogram of **4** (Fig. 1) shows five electron transfers leading to a pentacation. An interaction between the two terminal nickelocenes is disclosed by splittings of 65 and 190 mV[6] associated with the potentials for the oxidation to the nickelocene monocations (near 1 V) and dications (near 2 V), respectively. Not surprisingly for highly charged

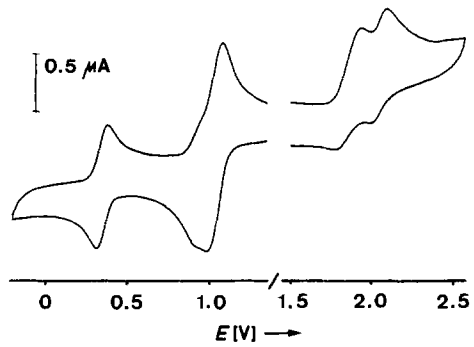


Fig. 1. Cyclic voltammogram of **4** in propionitrile, 8×10^{-4} mol L^{-1}, −20 °C, scan rate 200 mV s^{-1}, potential E vs internal Cp_2Co/Cp_2Co^+. Electron transfers from left to right: $E_{1/2}$ (ΔE_p) 340(65), 980(80), 1045(80), 1850(170), 2040(105) mV; assignment see text.

species, the electron transfers leading to the tetra- and pentacation are chemically not reversible. The central chromocene is oxidized more easily ($E_{1/2}$ = 340 mV) in accord with what is known from the parent metallocenes.[7] In addition, a broad, unresolved wave with $E_c = -1140$ mV indicates the irreversible reduction to 4^{3-}.

From the paramagnetic compound **4** we have obtained ^{13}C NMR signals in the range from $\delta = -400$ to $+1600$ (Fig. 2). Their number and their approximate areas are in

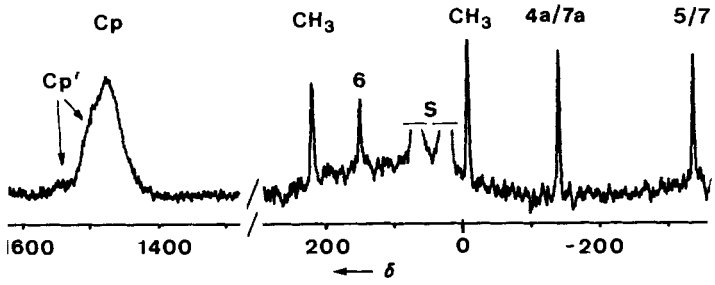

Fig. 2. ^{13}C NMR spectrum of **4** in [D$_8$]THF at 298 K; the two sections have different vertical scales. S = solvent, Cp' = C1-3, C3a, and C8a.

agreement with the structure shown in Scheme 1,[8] while their shifts are characteristic of substituted nickelocenes (weighted average $\delta \approx 1400$ to 1500[9]) and chromocenes (weighted average $\delta \approx -300$ to -400[9]). It follows that, at ambient temperature, **4** has six unpaired electrons with each metallocene unit accommodating two of them. This is confirmed by the ^1H NMR spectrum.[5] Surprisingly, however, the signals of H1-3 at $\delta = -221.6$ are shifted about 10% less than the Cp protons of mononuclear nickelocenes.[9] Since it was not clear whether this points to spin exchange between the metallocenes, we performed solid-state magnetic measurements.

The magnetic behavior is illustrated by the plot of $\chi_M T$ vs T (Fig. 3). At 250 K, $\chi_M T$ is equal to 2.94 cm^3 K mol^{-1}, which corresponds to what is expected for three uncoupled ions with $S_{Ni1} = S_{Ni2} = S_{Cr} = 1$[10] and is in agreement with the NMR results. When the temperature is lowered, $\chi_M T$ decreases more and more rapidly and reaches 0.83 cm^{3}Kmol^{-1} at 1.9 K. Such behavior may arise from the

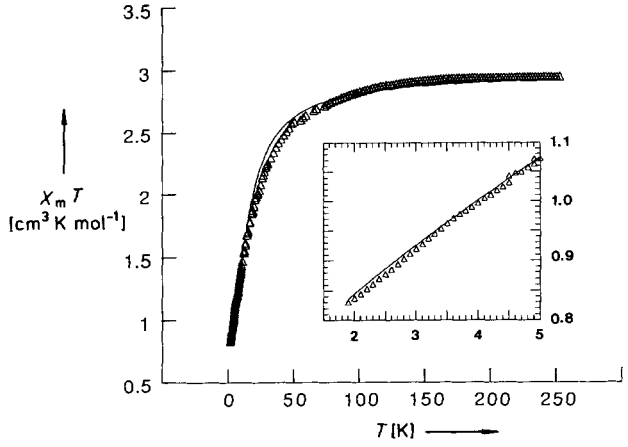

Fig. 3. Magnetic properties of **4** represented as a plot of $\chi_M T$ vs T with χ_M being the molar magnetic susceptibility and T the absolute temperature. Δ: Experimental values, solid line: calculated curve. Inset: expansion of the low-temperature range.

local anisotropies D_{Ni} and D_{Cr} of the metal(II) ions, and the isotropic intramolecular magnetic interaction J between the central Cr^{II} and the terminal Ni^{II} ions. Based on the pertinent spin Hamiltonian[11] the respective role of the two contributions becomes evident from the plot of $\chi_M T$ vs T when T approaches zero: neglecting J would result in $\chi_M T > 1.3$ cm^3 K mol^{-1}; neglecting D_{Ni} and D_{Cr} would result in a plateau with $\chi_M T \approx 1$ cm^3 K mol^{-1}. The latter corresponds to the temperature range in which only the triplet ground state is thermally populated. It turns out (Fig. 3) that both contributions are operative. These contributions are not correlated below 50 K, although they are correlated above 50 K, so that the fitting of the magnetic susceptibility χ_{Mu} along the direction u by Equation (a)[12] is expected to

$$\chi_{Mu} = \frac{N\beta \, \Sigma_i(-\partial E_{i,u}/\partial H_u) \exp(-E_{i,u}/kT)}{H_u \quad \Sigma_i \exp(-E_{i,u}/kT)} \qquad \text{(a)}$$

provide a reliable value of J. Since both D_{Ni} and D_{Cr} contribute to the zero-field splitting within the magnetic pair state they cannot be determined separately. We therefore assumed that D_{Cr} is negligible with respect to D_{Ni}. With somewhat idealized symmetry[13] the fitting yielded a Zeeman factor of $g = 1.98$, a zero-field splitting of $D_{Ni} = 28.7$ cm^{-1} (both are close to the values for nickelocene itself[14]), and the Ni^{II}–Cr^{II} interaction parameter $J = -1.95$ cm^{-1}; the agreement factor[12] was $R = 3.8 \times 10^{-4}$. The corresponding theoretical curve is given in Figure 3. Considering that D_{Cr} is not negligible leads to the same energy spectrum for the low-lying states with a different value for D_{Ni} but the same for J.

The magnetic properties are the crucial proof that the silyl bridges in **4** function as "valves" that allow a limited electron-exchange interaction. In this particular case it is antiferromagnetic. Other metal combinations and the manipulation of the silyl bridges are conceivable so that the magnetism of trinuclear metallocenes should be adjustable.

The properties of the title compound **4** illustrate that the approach discussed at the beginning, the stepwise stacking of metallocene units, actually works. Compound **4** is a good model for analogous polymers, since here structure, redox behavior, and interactions between the metallocene units, in particular magnetic exchange, may be investigated conveniently.

[10] Calculated from $\chi_M T = (N\beta^2/3k)\ (4g_{Ni}^2 + 2g_{Cr}^2)$ where g_{Ni} and g_{Cr} are the local Zeeman factors and the other symbols have their usual meaning.

[11] $H = -J\ (S_{Ni1} + S_{Ni2})\ S_{Cr} + S_{Ni1}\ \boldsymbol{D}_{Ni}\ S_{Ni1} + S_{Ni2}\ \boldsymbol{D}_{Ni}\ S_{Ni2} + S_{Cr}\ \boldsymbol{D}_{Cr}\ S_{Cr} + \beta(S_{Ni1} + S_{Ni2})\ \boldsymbol{g}_{Ni} + S_{Cr} \cdot \boldsymbol{g}_{Cr} \cdot H$, where $\boldsymbol{D}_{Ni}$ and $\boldsymbol{D}_{Cr}$ are the local anisotropy tensors and $\boldsymbol{g}_{Ni}$ and $\boldsymbol{g}_{Cr}$ are the local Zeeman tensors.

[12] In Equation (a) the summation runs over the 27 levels $E_{i,u}$ in the presence of the magnetic field H_u. The powder magnetic susceptibility was calculated by averaging over 15 directions of the magnetic field. The energies $E_{i,u}$ were obtained by diagonalizing the spin Hamiltonian of ref. [11] using the $|M_s(Ni1), M_s(Cr), M_s(Ni2)>$ functions as a basis set. Then the parameters J, $\boldsymbol{D}_{Ni}$, and g were determined by minimizing the agreement factor $R = \sum[(\chi_M T)^{cal} - (\chi_M T)^{obs}]^2 / \sum[(\chi_M T)^{obs}]^2$.

[13] $\boldsymbol{D}_{Ni}$ and the zero-field splitting parameter D_{Ni} (= $3D_{Ni,zz}/2$) were assumed to be axial, and $\boldsymbol{g}_{Ni}$ and $\boldsymbol{g}_{Cr}$ to be isotropic with the same principal g value.

Chelate Stabilization of a Monomeric Lithium Tellurolate**

By *Heinz Gornitzka, Susanne Besser, Regine Herbst-Irmer, Ulrike Kilimann*, and *Frank T. Edelmann**

Metal complexes with alkoxide (RO^-) and thiolate ligands (RS^-) have been well studied.[1–3] However, only a few with selenolate and tellurolate ligands (RSe^- and RTe^-, respectively) are known.[4–6] They are of interest as precursors for metal chalcogenides,[7,8] and also play an ever increasing role as reagents in organic synthesis.[4–6,9–11] In both cases alkali metal chalcogenolates act as intermediates. Sodium tellurolates are for example accessible by the reduction of the corresponding ditellurides with sodium amalgam or sodium in liquid ammonia.[12] They can undergo reactions to give transition metal tellurolates[13] as well as compounds with Te–C bonds.[9–11] Very little is known about the structural chemistry of alkali metal tellurolates: only $[Li(thf)_3][2,4,6\text{-}tBu_3C_6H_2Te]$[14] as well as $[Na(tmeda)][2,4,6\text{-}Me_3C_6H_2Te]$ and $[K([18]crown\text{-}6)][2,4,6\text{-}iPr_3C_6H_2Te]$[15] have been structurally characterized. In all three cases bulky substituents led to a kinetic stabilization of the alkali metal tellurolate. We have now found that the stability of alkali metal chalcogenolates can also be increased dramatically by chelation. Crystalline lithium chalcogenolates are readily accessible also in the case of the higher homologues by incorporation of a Li–E unit (E = S, Se, Te) into a six-membered chelate system.

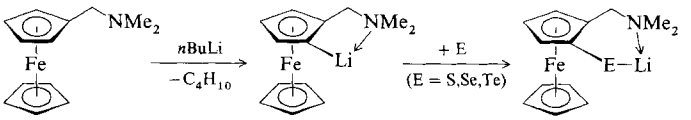
2-(Dimethylaminomethyl)ferrocenyllithium (**1**) served as the starting material, which is readily accessible by metalation of (dimethylaminomethyl)ferrocene[16] with *n*-butyllithium.[17] In THF solution **1** rapidly reacts with elemental sulfur, selenium, or tellurium under insertion of a chalcogen atom into the lithium–carbon bond. The crystalline lithium chalcogenolates **2**–**4** can be isolated in high yield from the resulting solution. The yellow-brown solids are readily soluble in THF, but almost insoluble in diethyl ether and hydrocarbon solvents.



1

2, E = S (73%)
3, E = Se (84%)
4, E = Te (100%)

Red-brown single crystals of the composition [Li(dme)][CpFe{$C_5H_3(CH_2NMe_2)$Te}] were obtained by recrystallization of **4** from dimethoxyethane (DME). In contrast to other alkali metal tellurolates, which are very sensitive to oxidation, crystalline [Li(dme)][CpFe{$C_5H_3(CH_2NMe_2)$Te}] can be handled in air for a short period of time without noticeable decomposition. The X-ray structure analysis[18] reveals that the Li–Te unit is stabilized by intramolecular chelate formation (Fig. 1). The six-membered chelate ring

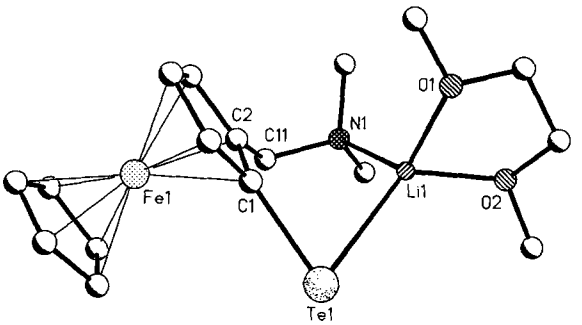


Fig. 1. Crystal structure of [Li(dme)][CpFe{$C_5H_3(CH_2NMe_2)$Te}]. Selected bond distances [pm] and angles [°]: Te1-Li1 273.4(4), Li1-N1 207.9(4), N1-C11 147.8(3), C11-C2 149.0(3), C2-C1 144.0(3), C1-Te1 212.2(2), Li1-O1 195.3(5), Li1-O2 201.0(4), C1-Fe1 206.3(2), C2-Fe1 203.9(2); C1-Te1-Li1 74.2(1), Te1-Li1-N1 103.7(2), Li1-N1-C11 111.0(2), N1-C11-C2 111.2(2), C11-C2-C1 124.5(2), C11-C2-C3 127.1(2), C2-C1-Te1 125.5(2), C5-C1-Te1 127.9(1), C2-C1-C5 106.6(2), Te1-C1-Fe1 128.1(1), C11-C2-Fe1 126.6(2).

adopts a slightly distorted boat conformation, in which Te1, C1, C2, and C11 are found almost in a plane. Noteworthy is the relatively small angle at the tellurium atom (74.2(1)°). The Te–C bond length (212.2(2) pm) lies in the normal range.

Their easy accessibility and unusual stability render the lithium chalcogenolates **2**–**4** of interest for subsequent reactions. Air oxidation of THF solutions leads to the corresponding dichalcogenides [{CpFe[$C_5H_3(CH_2NMe_2)$E]}$_2$] (E = S, Se, Te) as yellow crystalline solids.[19] Initial experiments show that the new ferrocenyl chalcogenolate ions are suitable ligands for transition metals and rare-earth elements. Thus, the ytterbium(III) thiolate [{CpFe[$C_5H_3(CH_2NMe_3)$S]}$_2$Yb] is accessible from **2** and $YbCl_3$.[20] As a typical example the reaction of **4** with $HgCl_2$ is outlined, which leads to the mercury(II) tellurolate **5**. The orange crys-

tals of **5** are stable in air and thermally stable up to about 170 °C.

$$HgCl_2 + 2\,\mathbf{4} \longrightarrow [\{CpFe[C_5H_3(CH_2NMe_2)Te]\}_2Hg] + 2\,LiCl$$
$$\mathbf{5}$$

Experimental Procedure

General Procedure: To a suspension of 2-(dimethylaminomethyl)ferrocenyllithium (**1**) (4.71 g, 18.9 mmol) in THF (100 mL) was added chalcogen (21.2 mmol) [S_8 was dissolved in THF (50 mL) and added dropwise at −20 °C]. The mixture was stirred at room temperature for 24 h (**2**: 1 h). After filtration and removal of the solvent in vacuo the residue was washed with ether (20 mL) and dried in vacuo.

2: Yellow solid, m.p. 190 °C (decomp.); yield 3.90 g (73%); IR (Nujol): ν[cm^{-1}]: 1268 m, 1166 m, 1105 s, 1036 m, 1006 m, 795 m; ^{1}H NMR (250 MHz, CD_3CN): δ = 4.10 (d, 1 H; J = 13 Hz, CH_2N), 4.05 (s, 1 H, C_5H_3), 3.92 (s, 1 H, C_5H_3), 3.81 (s, 5 H, C_5H_5), 3.70 (s, 1 H, C_5H_3), 2.51 (d, 1 H, J = 13 Hz, CH_2N), 2.07 (s, 6 H, NMe_2); ^{7}Li NMR (97 MHz, THF, C_6D_6): δ = 0.43 (s); FI-MS: m/z (rel. int. 1,3-Dimetallabenzene Derivatives of Niobium or Tantalum**

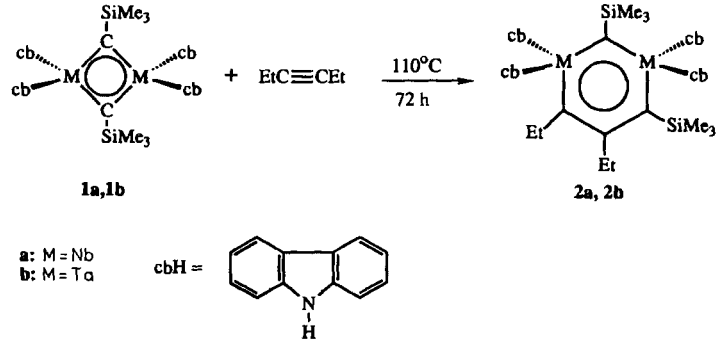
By *Robert D. Profilet, Phillip E. Fanwick,* and *Ian P. Rothwell**

Interest in the structure, bonding, and reactivity of six-membered metallacyclic compounds that may be considered quasiaromatic has surged in the last few years.[1] We report here on the synthesis and structure of a series of novel six-membered dimetallacyclic derivatives of niobium and tantalum that appear to be a new class of 1,3-dimetallabenzenes.

We have recently shown that the alkylidyne-bridged dimer **1b** is a useful starting material for the synthesis of polyhydridoditantalum compounds.[2] We have also investigated the reaction of **1b** and its niobium analogue **1a** with various substituted alkynes in order to assess their potential as catalysts (or precursors) for alkyne metathesis.[3] Reaction of **1a** or **1b** with 3-hexyne does not occur over weeks at 25 °C. However, these sparingly soluble compounds will react with one equivalent of 3-hexyne at 110 °C over 3 days in toluene to produce new metallacyclic compounds **2** in 60% yield as dark red (**2a**) or red (**2b**) crystals from toluene/hexane.[4]



1a,1b **2a, 2b**

a: M = Nb
b: M = Ta

The solid-state structure of **2b** in Figure 1[5] shows a six-membered dimetallacycle formed by insertion of one hexyne molecule into one of the alkylidyne bridge groups in **1**. The coordination environment about each nonequivalent tantalum center is pseudotetrahedral involving two carbazole ni-

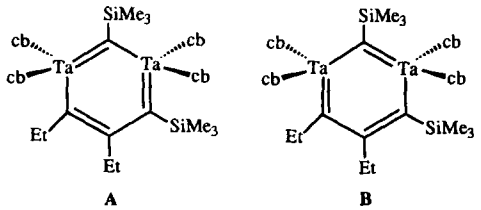
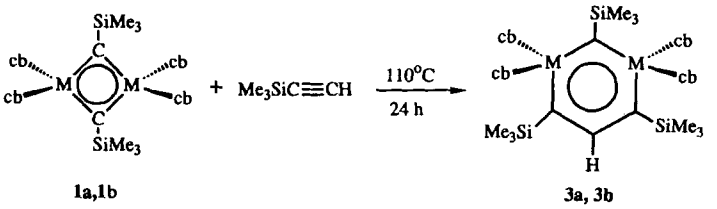
Distances [pm] and angles [°]: Ta1-N119 203(1), Ta1-N129 208(2), Ta2-N219 202(1), Ta2-N229 207(2), Ta2-C4 204(2), Ta2-C21 204(2), Ta1-C11 211(2), Ta1-C21 199(2), C3-C11 140(3), C3-C4 148(3); Ta1-C21-Ta2 90.5(7), C21-Ta2-C4 99.6(7), Ta2-C4-C3 98(1), C4-C3-C11 119(2), C3-C11-Ta1 93(1), C11-Ta1-C21 102.8(7), N119-Ta1-N129 105.8(7), N219-Ta2-N229 104.9(7).

trogen atoms and two carbon atoms within the ring. The six-membered dimetallacycle is distorted from planarity. The distortion can best be described as a twist (53°) of the $EtCC(Et)CSiMe_3$ and $(cb)_2TaC(SiMe_3)Ta(cb)_2$ units relative to each other. Inspection of the bond lengths within the dimetallacycle does indicate some localization of the (double) bonds, indicating more contribution from resonance form **A**.



The observed solid-state structure of **2b** is maintained in solution as evidenced by ^1H and ^{13}C NMR spectra. The deviation from planarity is demonstrated in the ^1H NMR spectrum (25 °C) by the presence of diastereotopic methylene protons for the two ethyl substituent groups.[6] When the temperature of the solution is increased, the ABX_3 multiplets collapse into a simpler A_2X_3 pattern. From the coalescence temperature an estimate of the barrier for exchange of these protons of 16.1(5) kcal mol^{-1} at 328 K can be made. This barrier corresponds to the energy needed for the nonplanar ditantallacycle **2b** to achieve planarity before flipping into the other enantiomeric form. There is no evidence at 70 °C for exchange of nonequivalent Et, $SiMe_3$, or $Ta(cb)_2$ groups in **2b**, indicating that more extensive, reversible fragmentation or rearrangement of the dimetallacycle does not occur on the NMR timescale. The ^{13}C NMR spectrum of **2b** is also informative. The resonance of the carbon atom bound to both tantalum centers lies at $\delta = 393.0$, while those of the carbon atoms bound to only one tantalum center are found at $\delta = 253.9$ and 257.3. These latter two signals are in a region typical for α carbon atoms in tantalum alkylidene complexes.[7]

The alkylidyne-bridged compounds **1a** and **1b** both react over 24 hours at 80 °C with the terminal alkyne $Me_3SiC{\equiv}CH$ to produce a single regioisomer, **3a** and **3b**, respectively.[8] The presence of only the 2,4,6-trisubstituted regioisomer is indicated by both the ^1H and ^{13}C NMR spectra.[9] The most important feature of the spectroscopic data on **3a** and **3b** is the chemical shift of the proton directly attached to the six-membered ring. These protons resonate at $\delta = 8.43$ and 8.64 for **3a** and **3b**, respectively. The downfield position of these signals may be indicative of a ring current within compounds **3**, although the fact that this proton is in a position β to two high-valent metal centers complicates this assessment.



The isolation of these new dimetallacycles **2** and **3** allows the proposal of a possible new pathway for alkyne metathesis.[10, 11] Preliminary studies have shown that reaction of **1a** and **1b** with 2-pentyne at 100 °C leads to a mixture of regioisomeric dimetallacycles, but no evidence of alkyne metathesis has yet been found. Further work on these and related dimetallacycles continues.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Host-Guest Molecular Interactions. From Chemistry to Biology. (Series: Ciba Foundation Symposium No. 158.) Wiley, Chichester, 1991. IX, 278 pp., hardcover £ 39.50.—ISBN 0-471-92958-1

Under the auspices of the Ciba Foundation, a symposium on molecular recognition was held in London at the beginning of July 1990. The 15 papers presented at this small but illustrious gathering have provided the material for the book reviewed here. Following an introduction by I. Sutherland, the first paper is a contribution by J. F. Stoddart on the application of charge-transfer interactions to the synthesis of catenanes and rotaxanes. Next G. W. Gokel reports on experiments aimed at creating artificial ion channels based on crown ether derivatives. This is followed by an application-orientated contribution by D. N. Reinhoudt, on the problem of converting chemical information into electrical signals. The required selectivity can be obtained by using synthetic host molecules; for example, calixarene is the basis for a field-effect transistor responding to potassium ions. However, it is also possible to use enzymes for specifically converting substrates into products that can be detected electrochemically, and W. J. Albery describes how this method has been successfully used for in-vivo determination of blood sugar content. Next comes a report by J. P. Waltho and D. H. Williams on complexes between antibiotics of the vancomycin family and peptides, then an article on J. Rebek's well-known receptor molecules for adenine etc., which are derived from Kemp's tricarboxylic acid. The contribution by R. Breslow describes cooperative effects of bifunctional molecules in the binding of substrates, in the catalysis of supramolecular reactions, and in connection with the triggering of differentiation processes in tumor cells.

The second half of the book is mainly concerned with biopolymers, starting with nucleic acids and their complexes with antibiotics (M. Waring). N. T. Thuong and C. Hélène describe conjugates of oligonucleotides with acridine that make possible sequence-selective binding to DNA through the formation of triple helices. This topic is taken further in a report by M. H. Caruthers on the preparation and properties of dithioate-modified DNA. The next four articles are concerned with the structural self-organization of proteins and enzyme–substrate complexes. G. C. K. Roberts describes NMR studies on dihydrofolate reductase, R. I. Carey and M. Mutter report on synthetic proteins with template-controlled folding behavior, A. B. Edmundson contributes an article on the binding of peptides to immunoglobulins, and R. U. Lemieux describes studies on the stability of complexes between various modified tetrasaccharides and a lectin. The lectin results reported by Lemieux generated new speculations concerning the role of associated water molecules in the association of amphiphilic surfaces, and the discussion of this is reported here. The book concludes with an article by J. G. Vinter on molecular modeling approaches to the description of host–guest interactions.

Conference reports published in book form have certain unavoidable drawbacks, namely the lack of uniformity in the individual contributions, a relatively high price due to small print runs, and above all the fact that similar articles by the same authors can often be found in the regular journals, and sometimes already exist when the book appears. This volume is no exception in the latter respect, and, moreover, the articles are all very brief. However, this certainly does not mean that the book is superfluous, since by including an account of the discussions it achieves something that an individual paper cannot do, that is to convey something of the spirit of a conference in which the lively exchange of views reveals new aspects of the work reported. These discussions, which also include literature references and diagrams to make the main points clear, are given an appropriately large amount of space. In addition three "General Discussions" on important topics of interest are included. The volume is completed by a list of participants, an author index, and a brief subject index. The material has been carefully put together, and the standard of printing and production is good. This book is certainly of value for everyone interested in the subject.

Cyclobutarenes. The Chemistry of Benzocyclobutene, Biphenylene, and Related Compounds. (Series: Studies in Organic Chemistry, Vol. 44.) By *M. K. Shepherd.* Elsevier, Amsterdam, 1991, XIV, 322 pp., hardcover HFl 320.00.— ISBN 0-444-88171-9

Benzocyclobutene, biphenylene, and related compounds are of interest because of the rigidity of the four-membered ring linking the benzenoid parts of the structure, which confers planarity on molecules of this type and makes possible a mesomeric interaction between the individual π-systems. Furthermore, various higher analogues have recently been successfully synthesized, and heterocyclic compounds of this type can also be prepared. Against this background the publication of the book "Cyclobutarenes" by M. K. Shepherd, which gives a comprehensive survey of this class of compounds, is a welcome development.

The book contains eight chapters, two short appendices, and a subject index. In Chapter 1 the author describes the electronic configurations and physical properties of the cyclobutarenes. The chapter begins with an introduction discussing aromaticity, nonaromaticity, and antiaromaticity, starting with benzene and cyclobutadiene then moving on to the cyclobutarenes. A brief section on nomenclature is followed by sections on benzocyclobutene and annelated systems such as biphenylene, benzobiphenylenes, and lastly their heterocyclic and ionic analogues. Chapter 2 describes methods for preparing benzocyclobutene and related compounds, classified according to reaction types, with similar compounds grouped together in tables. The following chapter gives a thorough description of the chemistry of benzocyclobutene and related compounds. The main reactions discussed are dimerizations, cycloadditions with dienes and dienophiles, insertions, additions, metal complex formation, and redox reactions. Chapter 4 is concerned with methods for preparing biphenylene and related compounds, again subdivided according to reaction types; these include the dimerization of arynes, dehalogenation of 2,2′-biaryls, extrusion reactions from bridged biaryls, cyclotrimerization of alkynes, cycloaddition reactions with benzocyclobutene, the Wittig reaction, and condensations with benzocyclobutenedione. Chapter 5 then describes the chemistry of biphenylene and its derivatives, again arranged according to reaction types, namely electrophilic, nucleophilic, and homolytic substitutions, additions, insertions, cycloadditions, heat-induced reactions, photochemical reactions, and redox reactions. The following chapter deals with substituted biphenylenes, classified according to substituents: alkyl and aryl derivatives, carbonyl compounds, halides, nitrogen compounds, hydroxybiphenylenes, metalated derivatives, transition metal complexes, and lastly biphenylenequinones. Chapter 7 is devoted to annelated biphenylene derivatives, starting with the strained cyclopropane-anellated systems, then moving on to systems with four- and five-membered anellated rings, and continuing with a longer section on systems with six-membered rings, which also include the larger fully conjugated systems. The series then continues in the same way up to annelated systems with twelve-membered rings. The final chapter deals with heterocyclic biphenylenes and their derivatives, distinguishing between azabiphenylenes that are electron-deficient and those with an electron excess, and also covering furan and thiophene analogues. The book ends with two appendices listing ^1H and ^{13}C NMR data for many of the compounds mentioned, followed by a detailed subject index.

M. K. Shepherd has carried out a formidable task in writing this book, as is evident from the more than 1200 literature references. It is a mine of information for everyone working in this field, especially as it also includes many reactions that only give a specified compound in low yields. The subject matter is systematically arranged, although in some cases this reviewer felt that it would have been better to combine sections that are very short. In view of the wealth of information provided, the criticisms mentioned below are only of minor importance. For example, the author should have been aware that P. J. Garratt's book "Aromaticity" (Ref. 1a in Chapter 1), which first appeared in 1971, was succeeded in 1986 by a thoroughly revised new edition. In the appendix listing ^1H NMR data it is unfortunate that the solvent is not always given. It is especially regrettable that the publishers have not afforded the book a quality of production commensurate with the author's hard work and with the price. The text is directly reproduced (which no doubt accounts for the fact that it is noticeably free of errors), but the quality of the type and of the formula diagrams leaves something to be desired. Considering the facilities that are available with modern text processing, it would have been helpful if, instead of printing the formula numbers in normal type in parentheses, they were in bold type for easier readability. Substituents attached to arene rings should be shown joined on by lines. It would also have been helpful to include details of reagents, reaction conditions, and yields alongside the arrows in the reaction schemes, rather than mentioning them only in the text.

The book is of great value for chemists whose work is concerned with cyclobutarenes, but the high price will probably deter many potential private buyers. It has often been demonstrated by other publishers that books comparable in content to this one can be offered at a lower price and with a better standard of production.

August Wilhelm Hofmann—"Reigning Chemist-in-Chief"**

By Christoph Meinel*

One hundred and twenty-five years ago, on November 11th, 1867, the German Chemical Society of Berlin held its inaugural meeting. The main purpose of the Society was to unite pure and applied chemistry and to foster cooperation between academic research and the chemical industry. And, indeed, it soon became the major forum of German and even European chemistry. Its program clearly bears the hallmark of a single individual: August Wilhelm Hofmann, the Society's first president, who died 100 years ago. For his contemporaries, Hofmann represented a new type of chemistry professor. At no time since have professional chemists felt as abundantly endowed with potential for the future and with public esteem. Hofmann's portrait was monumental even then, and still today it would belong in any gallery devoted to our distinguished forebears.

Anniversaries provide an opportunity to direct our attention toward the past—and thus to ourselves as well. We are, after all, heirs to that period from which the modern world derives its profile. Questions from our own time lead us to reacquaint ourselves with one of the founders of modern chemistry, but we may also benefit from a fresh look at an epoch which, beneath the surface of prosperity and progress, was as contradictory as our own, an epoch struggling to understand the role of science in the new industrial era.

In Liebig's Laboratory

We must envision the young Hofmann as a sensitive individual, rather inclined toward literature and the arts—and the direct opposite of someone with a clear plan for the future.[1] He was stamped with impressions gathered in educational travel, especially to Italy, where the boy was accompanied by his father, Johann Philipp Hofmann, privy councillor and provincial architect to the court of Darmstadt. "This awakened his early interest in the study of modern languages and a certain facility for expressing himself in tongues other than his native German, a factor not without its influence on his later career."[2] Hofmann registered as a student in his native city of Giessen at the age of eighteen. His father would have liked to have seen him study architecture, but the son found himself drawn rather to languages, "an idea contested vigorously by the father on the grounds that it could not lead to any satisfactory goal." The resolution of this dilemma was a decision in favor of law, a study "to which the next few years were dedicated, with occasional interruptions and little notable success." As far as the pursuit of a utilitarian education was concerned, Hofmann found it difficult to develop any enthusiasm, "always wavering between philology, law, and even architecture." In those days, preparing oneself to become an administrative official included learning the fundamentals of chemistry, so Hofmann became acquainted with the basic tenets of analytical chemistry in Liebig's laboratory. The name Liebig was already on

[**] This essay appears here as a preprint from *Die Allianz von Wissenschaft und Industrie: August Wilhelm Hofmann (1818–1892)–Zeit, Werk, Wirkung* (Eds.: C. Meinel, H. Scholz), VCH, Weinheim, November **1992**. In this volume, historians, historians of science, and chemists from industry and academia discuss Hofmann's life and work in the context of the society and economy of his time. They also trace those traditions that led to today's chemical research. The authors of this bilingual volume come from Germany, Great Britain, the USA, Czechoslovakia, the Netherlands, and Israel.

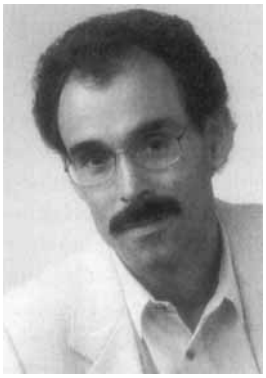
every tongue—his novel didactic methods had in fact attracted students to Giessen from all over Europe. It had already been necessary to expand the facilities of Liebig's institute on two occasions, and even to open a second branch, with construction activities carried out under the supervision of Hofmann's father. The resulting frequent—indeed, friendly—interchange between Herr Hofmann and Liebig was not without its effect on the son. According to one anecdote, Hofmann's father was moved to provide Liebig with an account of his son's indecisiveness and lack of academic success, to which Liebig is supposed to have responded: "give him to me, and I'll see what can be made out of him; he's a good lad, and he's certainly no fool; perhaps he just hasn't found the right path."[3]

Once within the sphere of attraction of the great master, he soon felt an irresistible pull toward the natural sciences, which confronted him with the lure of the novel in contrast to the singular course of his own previous studies. Thus began a new life, the study of law forgotten, philology relegated to the leisure hours, and the major part of his efforts dedicated to the study of chemistry, physics, and finally mathematics. Soon we see the young man working as a zealous pupil in the laboratory and ultimately taking part as an assistant in the research of the revered professor.[4]

Liebig's institute in Giessen is regarded as the prototype of the modern university laboratory. Here experimental research became incorporated directly into the educational function of the university, and laboratories were transformed into work stations dedicated to the production of new knowledge. It was also here that the idea of a division of labor was first applied to research activities, with distinctive roles assigned to the group leader, one or more assistants, and the research students. Moreover, contacts were established between university research and industry, and the organizational form of the university "institute" as a large-scale enterprise had its beginnings. It all began with a single piece of methodology: the elemental analysis of organic compounds, which was developed to the level of a routine procedure in 1832. This proved the key to organizing research along new lines: "turning out the most audacious discoveries in a factorylike fashion," as Liebig once described it.[5] These were also decisive years for the discipline of chemistry itself. Organic and physiological chemistry emerged from the context of "plant and animal chemistry" as distinct fields of research. Fundamental concepts, the notions of elements and molecules, nomenclature and formulas: all demanded clarification. The question of chemical "vitalism"—which was supposed to provide a distinction between the "organic" and the "inorganic"—was transported into the realm of experimental answers. Commercial applications promised to furnish the discipline with improvements in obsolete techniques in addition to attractive profits.

Liebig's recipe for success included introducing his gifted students to research at a very early stage.[6] There was no such thing as a fixed curriculum, and passing an oral examination was the sole requirement for a doctorate. Outstanding performance on the latter, as in Hofmann's case, constituted grounds for certification as a qualified university lecturer *(Habilitation)*. Within a very short time we find Hofmann working as an assistant, and entrusted with editing the *Annalen der Chemie und Pharmacie*. His own first research results appeared in this journal in 1843 under the title "Chemische Untersuchung der organischen Basen im Steinkohlen-Theeroel" ("Chemical Investigation of the Organic Bases in Coal-Tar Oil").[7]

How often does it happen that a young chemist takes on as his first research topic a substance that will become the basis for his later fame—and for an entire industry as well? And how often does he succeed at the same time in locating a substrate open to almost infinite variation? The owner of a tar distillery in Offenbach, himself a former student of Liebig, sent a sample of the material to Giessen for analysis, and Hofmann was assigned the task of its investigation. He found in this tar two previously described bases, known as "kyanol" and "leukol" [quinoline],[8] and after a great deal of effort extracted from it sufficient material to demonstrate that the "kyanol" was actually identical to substances also characterized in the literature as "krystallin," "benzidam," and "anilin." Moreover, he showed that it bore a relationship to phenol, one which could be expressed in terms of the common radical "phen" or $C_{12}H_{10}$ [C = 6]. Shortly thereafter it became apparent that the other base, "leukol," was identical to Gerhardt's quinoline. The latter was of considerable interest as a degradation product of quinine. Once Hofmann succeeded in obtaining larger quantities of aniline from the benzene in coal tar, he subjected it to nitration and subsequent reduction with zinc in acid, after which he began



Christoph Meinel, born in Dresden in 1949, studied chemistry in Marburg. After receiving his Diplom, he turned toward the history of science and completed his Ph.D. in 1977 with a dissertation on the history of chemistry. Following a postdoctoral year at the University of Kent at Canterbury, he held positions at the Universities of Marburg and Hamburg and conducted research in the United States. In 1987 he completed his Habilitation in the field of history of science in Hamburg. He was Fellow at the Institute for Advanced Study, Berlin, in 1987/88, and later Heisenberg Fellow of the Deutsche Forschungsgemeinschaft and coordinator of the Verbund für Wissenschaftsgeschichte in Berlin. In 1990 he was appointed professor for history of science at Mainz but moved on to a chair for history of science at the University of Regensburg that same year. Since 1990 he has been chairman of the History of Chemistry Group in the Gesellschaft Deutscher Chemiker. His research interests include 18th- and 19th-century chemistry and early modern natural philosophy and theory of matter. He has published books on the history of chemistry at the University of Marburg, on the work of the 17th-century Hamburg naturalist and philosopher Joachim Jungius, and on the history of alchemy.

a systematic investigation of the various transformations. Indigo attracted his attention in this context, since it also led to aniline upon alkali fusion. A paper describing the properties of this dye[9] served as impetus for the preparation of its halogenated derivatives, in analogy to the chloro and bromo derivatives of isatin.

The matter proved to be of considerable interest. Accepted theory—in the Liebig school as elsewhere—held that a chemical compound should be regarded as a pairing of a stable, electropositive group of atoms, the "radical," with an electronegative element or group. It was recognized in the meantime, however, that an organic radical might incorporate electronegative elements like chlorine or bromine without altering its electropositive character. This observation was the starting point for a new "substitution theory," put forward and defended by Laurent and Dumas. The substitution theory made it possible for the first time to regard a molecule as a single entity, in which individual atoms might be replaced by other elements without fundamentally changing its chemical nature. This theory, championed by Liebig's bitterest opponents, had been the subject three years earlier of a malicious piece of satire formulated by Wöhler and Liebig and published in the *Annalen* under the pseudonym S. C. H. Windler ("swindler"). The alleged author reported that, thanks to the new French doctrine of "types and substitution," he had succeeded in replacing, one after another, all the atoms in cotton by chlorine, and that there was no significant change evident in the material's characteristics. Indeed, clothing manufactured from "spun chlorine" was said to be already on the market in London, where it was avidly sought by consumers! Was Liebig now expected to allow Hofmann's bromo- and chloroanilines to reignite this old controversy?

Facts

Hofmann must have known that he could never come to Liebig with a new theory. This was especially true since his mentor's research program had just recovered from a very serious crisis. Its origin can be traced to nearly insurmountable difficulties presented by the chemistry of nitrogen metabolism in animals. Liebig had struggled for a decade with the explanation for this phenomenon, using all the means available from a contemporary perspective. If chemistry were to satisfy the demands of the neo-humanist interpretation of science then it must demonstrate its powers in the context of a theoretical interpretation of natural phenomena.[10] And now his program was threatened with failure because of the complexity of the subject! The dilemma could only be resolved in one of two ways. Either the discipline must succeed in breaking new ground and convincingly translate its insights into practical results, thereby displaying to the world the utility it claimed to possess, or else the demand for a scientific interpretation of nature must be reduced to "hard" numbers and facts, with studious disregard for any speculative elements.

Hofmann chose the second path, adopting a compromising stance with respect to those aspects of his research that impinged upon bonding theory. Thus, while he acknowledged that hydrogen had been replaced by halogen, he emphasized at the same time the fact that the introduction of increasing amounts of bromine or chlorine caused the electrochemical character of the radical to be displaced in an electronegative direction. This left Liebig free to present this work in a footnote—not as evidence supporting the views of Dumas, but as a strike against Berzelius. Hofmann's own reserved attitude with respect to broad generalizations and theories is also apparent from the fact that he coupled his cautious compromise proposal with an express warning: "Nothing is more dangerous than attempting to draw general conclusions without the ability to stand on a mass of facts."[11] And when he submitted the work in a competition sponsored by the Société de Pharmacie in Paris, he took steps to ensure that he would not be accused of taking sides in the bonding theory controversy by adding the motto of the English author Edmund Burke: "Facts are to the mind what food is to the body."[12]

As it happens, this motto reveals to us one of the important characteristics of Hofmann's approach to research. To a much greater extent than most of his contemporaries, and comparable in this respect only to Wöhler, Hofmann avoided becoming involved in controversies surrounding the fundamental theories of chemistry. His papers speak instead the dispassionate language of "chemical facts." When confronted with the need to adopt a text for use in his classes in London, Hofmann chose to translate Wöhler's *Beispiele zur Übung in der analytischen Chemie* (Göttingen, 1853), a work that progresses through 122 chapters—very pragmatically, without any theory—proceeding from simple materials to complex situations involving applications. The translator's preface leaves no room for questioning the motive behind his choice: "General statements, general instructions, will always remain more or less unintelligible to the student, as long as he fails to have a sufficient number of facts at his disposal."[13] Thomas Gradgrind, director of the model school in *Hard Times*, would have taken a great deal of satisfaction from this textbook, which was published in precisely the same year as Charles Dickens' famous critique of the impending machine age, with its obsession for numbers and facts—a book that begins with the classic enjoinder: "Now, what I want is, Facts. Teach these boys and girls nothing but Facts. Facts alone are wanted in life. You can only form the minds of reasoning animals upon Facts: nothing else be of any service to them ... Stick to Facts, Sir!"[14]

Four years later, at the suggestion of Kekulé, chemists from all over the world assembled in Karlsruhe in an attempt to clarify the fundamental uncertainties surrounding the concept of atoms and molecules. Hofmann's was among the 45 signatures on the invitation, but he chose, in fact, not to make a personal appearance at this first congress of chemists. While others were publishing ambitious theoretical compendia, such as Kekulé's *Lehrbuch der organischen Chemie* (Erlangen, 1861–1887), Hofmann produced only a single small volume, almost conversational in style, entitled *Einleitung in die moderne Chemie*. This work does testify to his "conversion to 'Gerhardtism'"[15] and to the "types" notation, but otherwise maintains a very pragmatic tone, with commitment to clear, didactic presentation and to "extreme moderation, the most measured reserve"[16] with respect to theory. The most original part of the work—a computational method based strictly on gas volumes ("Krithen") rather than mass units, with the corresponding

formulas expressed graphically—was never copied by anyone else, and must have seemed, only six years after the Karlsruhe congress, oddly positivistic. When the sixth and last edition of the *Einleitung* appeared in 1877 it still contained no reference whatsoever to the periodic table, and the list of atomic weights of the elements is simply presented alphabetically! And yet, Hofmann was anything but "A man of realities, a man of facts and calculations" in the mold of Gradgrind. Precisely the tension arising between the bold geometrical speculations of a Kekulé or a van't Hoff and the massive production of tangible "chemical facts" by a Hofmann, the latter outrunning every theory—it is this dichotomy that explains the incredible dynamic of chemistry at that time.

What Marvelous Opportunities!

Giessen offered no place for Hofmann over the long term. Assistants with greater seniority had priority in terms of acquiring a professorship. Liebig played his cards close to the chest when it came to personnel matters. Consequently, Hofmann cleverly contrived during the master's absence to become engaged to his niece, at the same time transferring his activities to Bonn. Understandably enough, Liebig was "painfully moved" to discover that his protégé had seized the initiative "without consulting me and without telling me about it," in the process frustrating his own plan for establishing Friedrich Mohr in the Bonn position, which had already been proposed to him.[17] In the spring of 1845 Hofmann became a *Privatdozent* (instructor) in Bonn. What he had in mind was nothing less than establishing a copy of the successful Giessen model on Prussian soil. This should necessarily have appealed to Liebig, since it would have been equivalent to an intellectual-political triumph over the latter state, where Liebig had recently claimed there was not a single university offering practical training in chemistry.[18] Or did Liebig have an even more audacious plan in mind?

Exactly one month prior to Hofmann's introductory lecture in Bonn, Liebig set out on his fourth visit to England. Ever since the first wave of British students arrived in Giessen in 1836, Liebig had found himself irresistibly fascinated with this country.[19] Great Britain must have seemed a "land of unlimited opportunity" to a chemist. Liebig had even toyed with the idea of emigrating there in order to devote himself exclusively to his agrochemical experiments. The lightning visit in the spring of 1845 was intended as preparation for such a move. Under a seal of absolute secrecy, Liebig entrusted his friend Wöhler with the news that he wished this time to undertake "an enormous experiment" to verify his agrochemical ideas.[20] In fact, jointly with two British partners he had established a fertilizer factory in Liverpool.[21] Despite the fact that this firm was not blessed with great success, it is quite clear that an interest in practical applications was what Liebig was pursuing in England.

The date of the trip coincided with a decisive phase in British chemistry. After decades of stagnation the discipline had achieved a leading role in the modernization of science, in no small measure due to demands of the economy. Public recognition and professionalization in chemistry were much further advanced in England than on the continent; missing, however, was an appropriately modern educational facility. William Gregory, chemistry professor at Aberdeen and a former student of Liebig, had been stressing this point since 1842. Bullock and Gardner, also former Liebig students, made a public suggestion in 1844 that a private institution be founded, on the Giessen model, for education and research in chemistry.[22] The motives of these clever, business-oriented young men were an elevated status for the discipline and the promise of rich profits. They attracted support in a circle of wealthy landowners interested in improvements in agriculture and mining, as well as among physicians, druggists, and industrialists. The plan gained an important advocate in the person of the queen's physician, with whom Liebig also had close contacts. Before long a nucleus of subscribers had been assembled, and even the support of the crown had been won. Needless to say, only a student of Liebig could be considered for the role of director of such an institute. And so it was that Hofmann was offered the directorship of the Royal College of Chemistry in London. The proposal sounded not only speculative but even visionary.[23]

Fig. 1. A. W. Hofmann in his 28th year (1846), heliogravure from an (unknown) drawing, 116 × 91 mm, from Jacob Volhard and Emil Fischer, "August Wilhelm von Hofmann: Ein Lebensbild," *Ber. Dtsch. Chem. Ges.* **1902**, *35* (special issue), prior to p. 33.

The moment of decision came at a meeting in August 1845, when Queen Victoria and the Prince Consort were visiting Schloss Brühl as guests of the Prussian court. From there they made a trip to Bonn, where Prince Consort Albert was anxious to see once again the building in which he had lived as a student. In the meantime, who but Hofmann should have installed his laboratory in that very building! This favorable coincidence led to the confirmation of the appointment at the highest possible level, since both the Prussian ambassador and the Minister of Education were also in attendance. One formal obstacle—the fact that instructors were not employed members of the faculty, and thus not eligible for leaves of absence—was dealt with in an elegant fashion: the Minister of Education simply promoted Hofmann on the spot to the rank of assistant professor *(ausserordentlicher Professor)*, and then granted him a leave of absence. Hofmann was offered a laboratory with space for

40 students, assistants, and technicians, free lodging, and an annual income of £ 400 with a £ 2 supplement from the tuition of each student. After two years he was promised an annual raise of £ 100, up to a maximum stipend of £ 700—and in the interest of security, 600 talers [equivalent to £ 51] to permit him to return to Bonn. With ten times the income that a professor at Bonn could anticipate, Hofmann planned to return in two years as a successful man with 10000 talers in his pocket, suitably prepared for marriage. Full of self-confidence he wrote back to Giessen:

My dear professor, what will you say when you hear that in all probability I will be going to England. It may be that I overestimate my abilities, since recently all my investigations have been so crowned with splendid success, but I believe I am the man who can make something of the situation there. Once in a lifetime each of us is offered a very special chance, and the daring man seizes it. What marvelous opportunities to move forward in science and establish a reputation for oneself are not offered in England![24]

A Conspiracy

The outcome of this situation was hardly inopportune from Liebig's perspective. Or might it not be that he arranged the whole thing himself? At the very least it is noteworthy that Hofmann's contract became valid only after Liebig had approved the conditions. Having a reliable bridgehead in England was almost preferable to emigrating there himself. It would appear, however, that Liebig and Hofmann secretly pursued designs that none of their contemporaries could have imagined.[25] It may have been Hofmann's work on the bases in coal tar that gave Liebig the idea to investigate more closely the residues from cinchona bark and quinine production known as "quinoidine," which was discovered in 1822 to contain an amorphous mixture of alkaloids. Liebig discovered that this quinoidine could serve as a source for crystalline quinidine [a stereoisomer of quinine], with a composition identical to that of pure quinine itself and displaying equivalent therapeutical activity. This led to a scheme to buy up supplies of quinoidine from all over Europe, then patent the process, publish the analytical results, and finally sell the now valuable material at a good profit. Capital was of course required, but also important—from the standpoint of patent rights—were British comrades-in-arms. A consortium was therefore established in which Liebig, Hofmann, Bullock, and Gardner each held one-sixth shares. The chancellor of the University of Giessen, on the other hand, had two-sixths, since he represented the actual source of the funds. All but the latter belonged to the narrow circle around the founders of the Royal College of Chemistry. They must have felt rather like conspirators preparing to join in the new game of "capitalism." A sum of 50000 gulden had already been invested in the project when, through carelessness, the affair came out and the whole scheme collapsed.

The stereotype of Hofmann as one who ventured forth "from the spiritual heights of a German university ... inflamed" with "a pure passion for knowledge of the true and the beautiful, unsullied by the pursuit of material advantages,"[26] who arrived in a materialistic England and there capitulated against his will to the forces of industry—this stereotype is clearly due for revision. Indeed, it reveals all too openly the handwriting of its author, who was a master of stylization. In any event, Hofmann must have recognized in the quinidine affair a warning against future direct participation in business risks. He never succumbed to the "founders' fever" that later struck so many chemists. When his assistant William Perkin produced his first synthetic dye and—having just turned 18—wanted to try his luck in industry, Hofmann reacted "much annoyed, and spoke in a very discouraging manner ... Hofmann perhaps anticipated that the undertaking would be a failure, and was sorry to think that I should be so foolish as to leave my scientific work for such an object."[27] Nevertheless, to see Hofmann as the archetype of the pure scientist[28] would be a mistake. "Whatever you now do," he once advised Liebig (hardly an inexperienced bystander in such matters), "don't lift a finger unless there is financial compensation."[29]

Branching Off

Conceived originally as an educational institution, the Royal College of Chemistry was also a testing laboratory, which was supposed to provide its private financiers with certifications and analyses. Landowners and mine operators, apothecaries and druggists, industrialists and businessmen, all anticipated that their investments would be rewarded in productivity and the jingling of coins. But Hofmann was quite conscious of the dangers in an overly shortsighted, utilitarian operation. The fact that the Giessen model of research-oriented education had been transplanted into the more utilitarian climate of Britain meant that the character of the institution would necessarily change as well. London was not the place for the selfless pursuit of pure science. It was important instead to justify the research imperative as a pedagogic vehicle directed toward scientific results in the form of new laws and compounds that could in turn be applied in a beneficial way within industry and commerce. The gap between theory and practice, the tension between the demands of commerce and the ideals of scholarship—Hofmann dealt with these through a rhetoric that treated the utilitarian as a more or less inevitable spin-off from the scientific quest for knowledge.

Even though the curriculum of the College[30] offered a fixed three-year course of studies, what made it attractive was the fact that the extent and intensity of the required work could be tailored to the individual, who could enter the program at any stage. Fully half the students enrolled for only a single semester, often to conduct investigations important to their own particular professions. Others came to seek the qualifications necessary for carrying out research. Hofmann's ability to recognize talent and provide each applicant with an appropriate assignment from his rich storehouse of ideas was as famous as his knack for selecting outstanding associates. In this way the focus of the College shifted more and more in the direction of pure organic chemistry.

It is nearly impossible to describe all the projects undertaken by Hofmann and his students. As in any research

program, detours, special opportunities, and outside commissions played a role, and one substance or another inevitably resisted the will of the chemist. Nevertheless, Hofmann succeeded in developing a characteristic research style in London. One of his earliest projects, executed in Giessen but presented before the Chemical Society in April 1845, was introduced with the remarkable assertion that a new direction had become apparent in organic chemical research. Whereas in the past one had always operated in a purely analytical mode, and rarely "with the goal of preparing particular compounds postulated through prior speculation," now the groundwork had been laid to conduct targeted "synthetic experiments" for the artificial preparation of organic compounds. "If a chemist were to succeed in transforming naphthalene in a simple way into quinine, we would quite properly honor him as a benefactor of humanity. Such a transformation has not yet been accomplished, but that alone does not imply that it is impossible."[31]

The concept of synthesis is a key to Hofmann's way of thinking. If the analytical phase of organic chemistry began with Liebig, in Wöhler's synthesis of urea Hofmann saw the threshold to the next higher step: an "era of synthetic chemistry."[32] A decisive shift in emphasis for the discipline had thus been recognized. This change is associated in no small measure with the name of another man who also traveled to London in the fall of 1845: Hermann Kolbe. With acetic acid, Kolbe succeeded in completing the first targeted synthesis of an indisputably organic compound starting from its elements.[33] In fact, the synthetic program of modern chemistry evolved in very important ways from the work undertaken by Kolbe and Frankland at the Royal School of Mines in the 1840s. The idea of "synthesis," for which popular accounts had predicted so much, reached its programmatic summit in the work of Berthelot. But as early as 1858 Kolbe had prophesied:

> *In the present state of our still-youthful discipline one may make the bold claim that as soon as the chemical constitution of substances such as indigo, alizarin, quinine ... has been correctly diagnosed, we will be in a position to assemble these materials artificially from their more intimate components.*[34]

It was left to Hofmann to transform this agenda into practice, and this he did with spectacular success. At the same time, however, for Hofmann the concept of synthesis held more than a mere chemical connotation: consistent with his creative, esthetic, nonanalytical way of looking at things, synthesis appeared to offer a vision of creativity in the face of the emerging machine age, and the prospect of wholeness as opposed to a science increasingly dominated by division of labor and a narrow-minded concentration on detail.

It is certainly characteristic that Hofmann's research program was eminently product-oriented. His positivistic, theory-abstaining stance corresponded to the spirit of the new age itself, the spirit of goods and the marketplace. Hofmann thought strictly in terms of *classes* of substances, which were to be investigated systematically and thoroughly once a pilot study had revealed some synthetic access. Analogy was his leading heuristic principle; his method was to systematically chart possible derivatives, toward which targeted syntheses were then directed. Hofmann operated strategically, in accordance with the expansionism of his time. Extension and diversification were key words for him. He described chemistry as a "magical tree, reaching out in every direction with its branches and twigs and infinite ramifications."[35] His central and often repeated metaphor of the tree comprises three crucial aspects: the nineteenth-century notion of evolution, the image of motion and vitality, and the many ramifications of Hofmann's own research program, at the heart of which was the researcher, supplying both guidance and planning. That, at any rate, is how his students saw it, and they extolled "the fertility of mind which, while he himself was conducting simultaneously several investigations, continually branching off into new ramifications, enabled him to suggest a multitude of fresh subjects for work to his students ... and to hold the guiding strings of all firmly within his grasp."[36]

There is no need to explain to chemists that Hofmann could not have selected a better starting point for such an endeavor than aniline. This particular venture led to a series of ten "Contributions to an Understanding of the Volatile Organic Bases." The goal was to investigate the "remarkable analogy" between aniline and its derivatives, on the one hand, and ammonia, on the other.[37] Reactions with the halogens and alkyl halides were especially interesting. It became clear that the premise of the radical theory, according to which preformed ammonia must constitute one member of a "pair" in such compounds, was no longer tenable. In fact, the alkylated anilines could better be viewed as compounds in which the various hydrogen atoms of ammonia were successively replaced by organic residues. Application of the principle of homology permitted the number of possible combinations and their isomers to be increased almost without limit.

> *Here I find it impossible to avoid pointing out the wonderful versatility of isomeric compounds, to which a continuation of this investigation must necessarily lead. One sees at first glance that substances with the formula $C_{18}H_{13}N$ can be obtained by introduction of 1 equiv of methyl into xylidine, or 2 equiv of methyl into toluidine, or finally by attaching to aniline the radical (propyl) derived from the missing alcohol of propionic acid. We obtain in this way six alkaloids with the same formula, yet differing significantly in their constitution.*

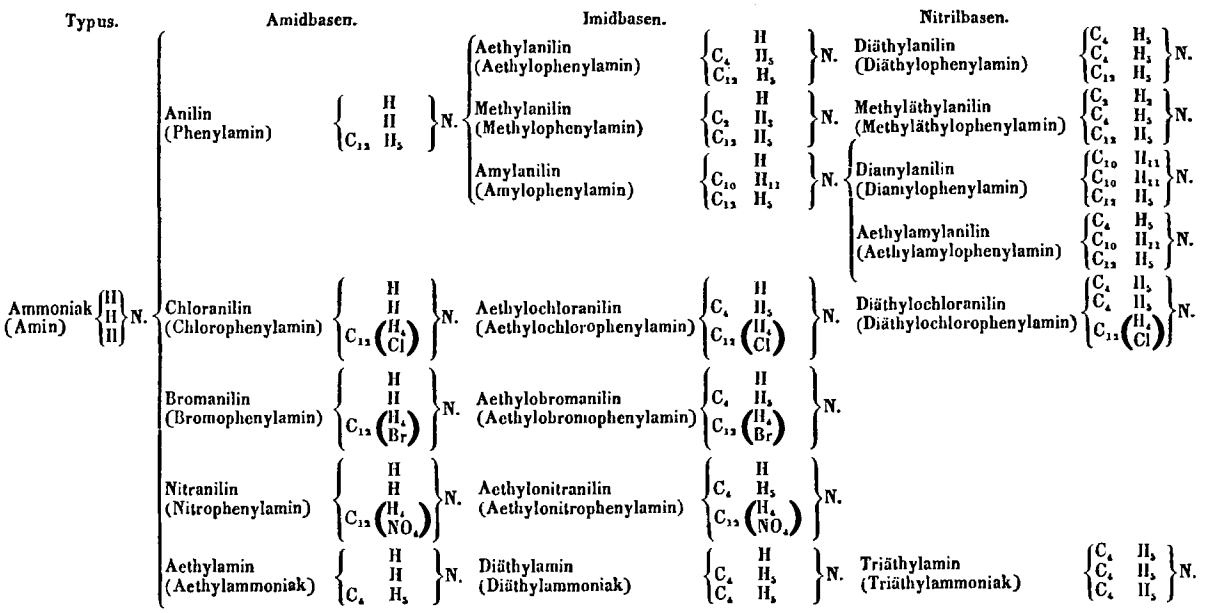
$$\left.\begin{array}{ll}
\text{Cumidin} & \left\{\begin{array}{ll} & H \\ & H \\ C_{18} & H_{11} \end{array}\right\} N \\
\text{Methyloxylidin} & \left\{\begin{array}{ll} & H \\ C_2 & H_3 \\ C_{16} & H_9 \end{array}\right\} N \\
\text{Aethylotoluidin} & \left\{\begin{array}{ll} & H \\ C_4 & H_5 \\ C_{14} & H_7 \end{array}\right\} N \\
\text{Dimethylotoluidin} & \left\{\begin{array}{ll} C_2 & H_3 \\ C_2 & H_3 \\ C_{14} & H_7 \end{array}\right\} N \\
\text{Propylanilin} & \left\{\begin{array}{ll} & H \\ C_6 & H_7 \\ C_{12} & H_5 \end{array}\right\} N \\
\text{Methyläthylanilin} & \left\{\begin{array}{ll} C_2 & H_3 \\ C_4 & H_5 \\ C_{12} & H_5 \end{array}\right\} N
\end{array}\right\} = C_{18}\,H_{13}\,N.$$

> *This number, of course, increases the higher we climb up the ladder of organic compounds. Two members are added at each rung, so that when we reach diamylaniline $C_{32}H_{27}N$ we*

are confronted with no less than twenty bases, the calling into existence of which will not be overlooked in the progress of science. —A striking example of simplicity in variety, which characterizes the creations of organic chemistry.[38]

Types, Colors, Alliances

Substitution reactions had convinced Hofmann of the advantages of utilizing the notation of "types" for expressing



The basic structure of ammonia permits one to obtain in this way a complete range of homologous substitution products, which Hofmann later designated as primary, secondary, and tertiary amines. Even though individual twigs were still unknown on this tree of possibilities that had unfolded itself in Hofmann's mind's eye, he remained confident that their existence "should be supportable by facts without difficulty;"[39] indeed, the synthesis of complicated natural products appeared to have moved into the realm of the possible.

The natural bases [quinine, morphine, etc.], may possess a more entangled composition. But a series of well-conceived experiments will not fail to cast light on the constitution of these compounds, and in this way place us in the position of constructing them in the same way it has been possible with the alcohol bases.[40]

Before Hofmann no one had ever conducted chemistry in this way. His approach represents an anticipation of basic strategies of industrial research, with the development and variation of entire spectra of products.[41] The program was to prove its worth a hundred times over in the broad field of organic nitrogen compounds. It is thus no wonder that Hofmann once compared his role as director of the institute with "the position of an industrialist in command of a splendid machine."[42] Instead of following Liebig's ingenious principle of basing research on an instrumental method, elemental analysis, Hofmann transformed the laboratory into a gigantic piece of machinery for the systematic synthesis of "chemical facts" in the form of new compounds and derivatives.

chemical formulas. Substances with similar reactivities could thereby be assigned to a small number of basic types, in which atomic groupings were bound to one another in identical ways. Nevertheless, this was not meant to be an assertion regarding the true nature of either intramolecular groupings or bonding relationships; rather, the formulas were regarded simply as tools to aid in the classification of reactivity, and to assist in the search for analogies—a taxonomic model with no correlation with a reality that was assumed to be fundamentally unintelligible.[43] Compounds derived formally from a given inorganic primary substance all belonged to a single "chemical type." Hofmann seized upon this approach more firmly than his contemporaries as a guide to synthesis. He pictured it as a "type of construction" and a form of "template" in whose empty spaces atoms or atomic groups could be inserted like building blocks.[44] Hofmann's own model substance was of course ammonia.

Relative to all the other approaches to expressing chemical formulas, the type theory offered the tremendous advantage of permitting for the first time predictions regarding possible compounds of a given type. For this reason, type formulas were to provide the basis—along with the principles of analogy, homology, and variation—of the most important heuristic instrument and classification scheme in the new synthetic chemistry. Without his type theory, Hofmann's research program would have been impossible. He therefore remained true to the type notation even after it had been superseded by structural formulas. Entire series of publications on the volatile and nonvolatile organic bases [amines], the analogous phosphorus bases [phosphines] (17 papers, 1857–1860), and the "polyammonias" [polyamines] (24 pa-

pers, 1858–1863) testify to the effectiveness of the approach. Always pursuing several series of investigations simultaneously, and attacking across a broad front, Hofmann carried the art of serial publication to its first high point. He preferred to describe his method of operation as "analogic or template work."[45]

It was destined to prove its worth best in that field which to this day is still associated with Hofmann's name: coal-tar dyes. The corresponding history is too familiar to be repeated here in detail.[46] In 1856 Hofmann's assistant William Perkin oxidized aniline in the hope of obtaining quinine. The result was the first synthetic organic dye prepared in a research laboratory, aniline purple or mauve. This was followed two years later by Hofmann's discovery—and Verguin's independent discovery in Lyon—of fuchsin (magenta). The brilliance of these substances enchanted the ranks of high society, and they quickly acquired the status of "fashionable" colors. Industry and science instantly became conscious of the potential inherent in coal tar. Coal-tar dyes, together with their corresponding starting materials and intermediates, came to occupy the center of attention, leading in turn to a new relationship between chemical research and industry. The complexity of the substrate demanded the availability of professional chemists with both theoretical and analytical training, while translating results from the laboratory into industrial-scale ventures required the experience of industrialists. Virtually all the important subsequent innovations would come from the collaboration between these two worlds.

Hofmann himself first entered the new territory in 1860 in the context of his work on the polyamines.[47] The decisive factor was his contact with Edward Chambers Nicholson, whose company in London was one of the leading producers of chemical intermediates.[48] Studies related to aniline red (fuchsin), "chrysaniline," "rosaniline," and their derivatives, which we recognize today as triphenylmethane and acridine dyes, constituted thereafter the core of Hofmann's efforts. Systematically applying the principles of analogy and variation, he provided access to an enormous number of potential dyes and intermediates, at the same time clarifying their relationships to one another. Of outstanding significance was his discovery that the introduction of substituents into a dye molecule could lead to systematic changes in the dye's properties, facilitating the targeted development of specific nuances of color.

> *The facts elicited by the study of the action of iodide of ethyl upon rosaniline open a new field of research, which promises a harvest of results. The question very naturally suggests itself, whether the substitution for hydrogen in rosaniline of radicals other than methyl, ethyl, and amyl, may not possibly give rise to colours differing from blue; and whether chemistry may not ultimately teach us systematically to build up colouring molecules, the particular tint of which we may predict with the same certainty with which we at present anticipate the boiling-point and other physical properties of the compounds of our theoretical conceptions?*[49]

The chemical knowledge of the times, of course, set up certain barriers preventing the thorough classification and theoretical interpretation of the diversity of new dyes. This becomes especially apparent in Hofmann's case, since he remained firmly committed to thinking in terms of the ammonia type, which prevented him from ever understanding the true nature of the rosaniline dyes with respect to their triphenylmethane skeleton. Hofmann himself did not regard this as a particularly serious obstacle. Oriented in his thinking and in his work toward substances and away from theories, he saw it as precisely the point at which a purely scientific view must be supplemented by the pragmatic and problem-oriented approach of industry. "Though proud of her office as guide of industry, science acknowledges without blushing that there are territories on which she cannot advance without leaning on the strong arm of her powerful companion. Joint labours of this kind cannot fail to seal the pledge of alliance between industry and science."[50] Educated in a tradition that recognized a clear division of responsibilities and an even clearer intellectual priority of "pure" over "applied" chemistry,[51] Hofmann learned in England that the new era demanded new ways of thinking. In his report on the World's Fair of 1862, he concluded that industrial research constituted the highest and noblest activity, and should be accorded an equal status with pure science:

> *In the course of this review he [the reporter: Hofmann] has become more and more disposed to assign to the pursuit of industrial chemistry ... an equal rank with the very highest and noblest of the learned professions; and, in particular, to place it fully on a par with the pursuit of purely scientific investigations of any kind .... He desires to record it as his firm persuasion that pure and applied science will, hereafter, in an increasing degree, go hand in hand.*[52]

"To seal the pledge of alliance between industry and science"[53] was to become the equivalent of a magical formula for Hofmann.

In the Marketplace of Life

The London Great Exhibition[54] of 1851, a prestige project of the Prince Consort, marked a turning point in Hofmann's life. World's Fairs amounted to stages for the century itself, with commercial interests resplendent in a shimmer of glass and steel, light and national banners: masterpieces of consumption, shrines dedicated to the idolization of merchandise.[55] A vision of paradise on earth, offering glitter and luxury even to the masses—here it became truly palpable. Hofmann was active in the preparations for this first World's Fair, which was to set the pattern for those that followed. He was a member of both the German exhibition commission and the jury, and he edited the official report on "miscellaneous manufacture and small wares." The impetus to innovation emanating from the exhibition was of direct benefit to chemistry. A whole complex of new research establishments came into existence, and the Royal College of Chemistry was made a part of the School of Mines. As a result, Hofmann became director of a state institute of higher education as well as a British subject, and soon thereafter was named Assayer of the Royal Mint. Government agencies thought highly of him as a consultant, and he was an indispensable adviser to industry. In 1851 he was designated a Fellow of the Royal Society. The Chemical Society,

of which he had been a member since 1845, elected him in 1847 to the post of foreign secretary, and then in 1861 to the presidency.

Fig. 2. A. W. Hofmann as professor at the London Government School of Mines, engraving by [John William] Cook, 16 × 11 cm from James Sheridan Muspratt, *Chemistry, Theoretical, Practical and Analytical as Applied and Relating to the Arts and Manufactures*, Mackkenzie, Glasgow/Edinburgh/London/New York, **1853–1861**.

Aristocratic landowners introduced Hofmann into the ranks of high society. The climax appears to have been an invitation to the estate of Lord Ashburton in the company of Thomas Carlyle.[56] Hofmann sparkled as an orator, delivering popular scientific lectures in front of the laboring classes in London as well as to the Crown Prince and Princess of Prussia at Windsor Castle—and finally even before the Queen and her children. As Hofmann himself perceived it, the interests of science were no longer subjects reserved exclusively for scientists; they had passed out of the laboratories to take their stand "in the market-place of life."[57] And in their company Hofmann himself became a recognized figure in public life: courted, honored, and influential.

At the apex of Hofmann's fame an opportunity arose to return to Germany. Bismarck's Prussia was on the point of backing up its political and military pretensions to leadership by modernizing institutions at home. Professorial chairs in chemistry had come available at two of the important centers of the land: those of Bischof in Bonn and Mitscherlich in Berlin. Chemistry at both institutions had fallen behind the level of development characterizing even the smaller universities, to say nothing of Munich and Leipzig, but Prussia was determined to set a new tone by issuing calls to prominent professorial candidates. Even the names Wöhler and Liebig were discussed. In 1863 Hofmann received an offer from Bonn, shortly thereafter one from Berlin.

Hofmann did not hesitate about returning to Prussia, which was beginning to take the lead in the modernization of Germany. His move was carefully prepared in advance.[58] Nevertheless, few at the time would have been able to appreciate his true motives. Friends advised him not to relinquish his prominent position in England. Liebig, who would perhaps have gladly received the offer himself (if only to be able to reject it), warned him against "transporting himself into the misery of German university conditions."[59] Actually, Hofmann probably foresaw that the traditional structures of British society, business, and education were soon to become a hindrance to further progress in industry and science,[60] and he was one of the first to draw the obvious conclusion. Caro, Böttinger, König, Leonhardt, Martius, Meister, and other industrialists who had sought their fortunes as chemists in Britain during the 1840s and 1850s followed his example.[61]

The Germany to which Hofmann returned had little in common with the quiet land of his youth. The country was awakening. Within a few decades it would experience a modernization unparalleled in history. Provincialism and customs barriers were falling, and railroads and factory chimneys were reshaping the agrarian landscape of the "belated nation,"[62] which was preparing itself under Prussia's leadership to surpass its rivals. The era of factories and machines was dawning: the era of Borsig, Krupp, and Siemens. A wave of new incorporations reached its culmination in the chemical industry in the 1860s. Europe watched spellbound by the incredible tempo with which a new industrial sector arose, one that was destined in a short time to dominate the world market.[63]

Palaces and Temples

Universities also derived their share of spoils from the economic upturn. The Humboldt formula of "seclusion and freedom," once purchased dearly with a renunciation of political and economic power, was displaced by a new self-assurance in science that relied on the scientists' power to actually reshape the world. Chemistry assumed the leading role in the modernization of the universities. A new generation of magnificently equipped institutes came into being.[64] Bonn and Berlin represented a prelude. While still in London, Hofmann was assigned the task of preparing a report on the building plans. He accepted this commission with obvious pleasure, since he was very well aware of the symbolic significance of such "palaces and temples"[65] dedicated to progress and the religion of science. They gave clear expression to the new claims of scientists to validity and prestige: the "splendid suite of apartments for the director" at the institute in Bonn with its "imposing entrance hall, illuminated by a glass cupola above, and the splendid ball-room, extending through two stories, and amply satisfying the social requirements of a chemical professor of the second half of the nineteenth century!"[66] The proposed institute in the Dorotheen- and Georgenstrasse in Berlin was impressive on the basis of its size alone.[67] A total of 954000 marks had been allotted to the construction, two and one-half times as much as for the institute in Bonn. New standards were to be set here for modernity, albeit hidden again behind the type of Renaissance facade so dear to the industrialists and upper middle-class. Their economic power no longer bore any relationship to their political standing, and this led them to hide their historical perplexity behind historicizing pretense.[68] Hofmann was especially concerned to include terra-cotta medal-

lions of the great chemists between the window arches, as well as busts of Liebig, Wöhler, and Faraday in the foyer.[69]

On May 7th, 1865, Hofmann commenced his lectures in Berlin, establishing himself temporarily in Heinrich Rose's old laboratory. Three years later the new building was ready. It boasted three large work rooms for beginning and advanced students; spectroscopy and photometry rooms; clean-up, weighing, and titration areas; metallurgical and forensic laboratories; workshops; and a roomy, private laboratory for the director. Hofmann was now in a position to pursue a research program along the broadest possible front.[70] He supervised more than 150 doctoral dissertations in Berlin, and his co-workers must have handled an equal number. The unprecedented dimensions of the resulting intellectual productivity are attested to by 899 scientific publications "Aus dem Berliner Universitäts-Laboratorium," 150 of them from Hofmann himself. Applying the principles of analogy, homology, and variation to the targeted synthesis of derivatives and to the discovery of new classes of compounds, here he was able to develop his working style to perfection. At the center remained as always organic compounds containing nitrogen, together with dyes, especially the rosaniline and quinoline dyes, but also dyes derived from beechwood tar. Reactive starting materials and intermediates for synthetic purposes also became important. Aromatic diamines, benzidine, xylidine, and methylated aniline derivatives were among the key substrates. Using the analogy between alcohols and amines as a heuristic tool, Hofmann prepared the aliphatic amines from C_9 to C_1, for which purpose he devised a general technique of amide degradation involving bromine and base. Systematic studies were also conducted on the derivatives of guanidine, isonitriles, and aliphatic mustard oils. A synthesis of formaldehyde permitted Hofmann to prove the existence of this long-sought molecule.

Reigning Chemist-in-Chief[71]

The close connection between the university research program and practical application was apparent in constant efforts to supply the dye and fine-chemical industries with new classes of substances and derivatives. An intimate, virtually symbiotic relationship soon joined the laboratory in Berlin with the chemical industry through former students who had accepted industrial appointments. The central figure was Carl Alexander Martius, one of Hofmann's assistants in London. In Berlin Martius assumed leadership of the Aktiengesellschaft für Anilinfabrikation (AGFA), thereafter enjoying a virtual monopoly with respect to the discoveries in Hofmann's laboratory and the placement of his graduates.[72] Hofmann also maintained ties with the inorganic bulk-chemicals industry through Hugo Kunheim, and with the developing pharmaceutical industry through Ernst Schering. The "alliance between industry and science" of which Hofmann had once dreamed was now a reality, albeit in a form very much in keeping with the patriarchal structure of the Wilhelmian era. The result was a complex interplay of give and take, interests and powers, gains and concessions, which—due to problems with the relevant source materials—eludes even today the grasp of the historian. Only in limited areas, such as the role played by professors in the various World's Fairs,[73] has it so far been possible to analyze the relationships with greater clarity.

Hofmann remained a master of "synthesis" when it came to matters of influence and power, always willing to accept nominations for new offices. His work load was incredible.

> *When he was seized by a new challenge, bodily needs seemed for him no longer to exist. A long lunch break was a useless waste of time, and hours devoted to sleep were reduced to a minimum. Even younger associates found it difficult in those days to keep pace with Hofmann at work, and I venture to doubt whether the occasional invitations to his assistants at two or three in the morning to join him in a glass of punch in order then 'to finish the job just like that' were always received as an unmixed blessing.*[74]

Institute director and professor at the Friedrich-Wilhelms-Universität, as well as its rector (1880/1881), Royal Privy Councillor Hofmann was at the same time a professor in the Military Academy, full member of the Academy of Sciences, full member of the Scientific Delegations for Medical and Educational Affairs (from 1864) as well as the Delegation for Trade and Commerce (from 1864), member of the directorate of the Patent Rights Society (from 1873), member of the Imperial Patent Office (1877–1882), full member of the Imperial Office of Public Health (from 1880), chemical adviser to the Chancellor of the Reich, and an expert witness before the courts. When the Assembly of German Natural Scientists and Physicians *(Versammlung Deutscher Naturforscher und Ärzte)*, with all its rich tradition, survived a stormy controversy in 1890 that resulted in a new set of by-laws intended to enhance its professional standing, it was once again Hofmann who was entrusted with the delicate position of the presidency.

Nevertheless, it was the German Chemical Society *(Deutsche Chemische Gesellschaft)* that emerged as the true focal point for the diverse interests of chemical industry and chemical science.[75] The Society constituted an imaginary stage upon which Hofmann was to perform as the star in a production that seemed written just for him. Martius and Wichelhaus, his closest associates, took the initiative in founding the organization, but it is tempting to think that Hofmann himself was the source of the idea. He described its purpose as follows: "the new Society is actually designed to provide an opportunity for the mutual exchange of ideas between representatives of the speculative and applied branches of chemistry in order to seal anew the alliance between science and industry."[76] Founded on November 11th, 1867, in the Great Hall of the Institute of Trade, the Society elected August Wilhelm Hofmann to be its first president. He would occupy this chair fourteen times in the next twenty-five years. But even during the eleven years in which he was "only" vice-president, Hofmann held the reins of power in his own hands. "It is self-evident," he assured Wöhler when the latter was proposed for the presidency, "that your assumption of this office will not cause you the slightest worry, or trouble you in any way. We ask nothing more than the honor of seeing your name at the pinnacle of this Society."[77] Indeed, Wöhler's only obligation was that of adding his signature to documents presented to him by the secretary "in a cozy portfolio."[78] Hofmann appears to have directed the course of elections in other cases as well. Thus, when the

election of Hermann Kopp was under consideration, Hofmann turned to Bernhard Tollens with the request that he "add the weight of your voice, along with those of your friends, colleagues, and students, to the scales" in the interest of his friend.[79]

Hofmann maintained his leading role in the German Chemical Society for a quarter of a century by exercising incomparable diplomatic adroitness, and by using this instrument he helped to determine the overall development of chemistry in Germany. Walter Ruske acknowledged as "a phenomenon difficult to understand for a contemporary observer" the degree to which the style and image of the Society was stamped in the image of a single man: "It almost appears as though Hofmann was literally forced into the role of a hero of German chemistry by his admirers, and the descriptions they provided of their master bear all the marks of a patriarchal model."[80] Hofmann knew how to make full and ceremonial use of all the authority that flowed in his direction. With eloquence and politeness, coupled with an almost youthful charm, he was an expert at transforming tension into a communal sense of self-assurance, preventing conflicts from ever developing, and finding common ground where there appeared to be a direct conflict of interests—a master at synthesis in this context as well.

Dissonance and Jubilation

The chemists tried very hard to convey an impression of self-confidence, both progressive and imperial, but in reality they felt a certain insecurity. Ever since the declaration of the Reich, worries and skepticism with regard to "progress" had merged with the fervor of the "founders' years" *(Gründerzeit)*. The belated and correspondingly accelerated modernization threatened to redraw the established boundaries of class and status. Modernization and industrialization also made their appearance within the universities. In no other discipline was the new role played by the natural sciences in the industrial era so apparent as in chemistry. Conflict with the traditional self-image of the universities was unavoidable. It peaked with a demand that chemistry and the other applied natural sciences be excluded from the universities altogether and banished to polytechnics or appropriate specialist institutions.[81] "The 'spirit of New York' now making its way into Berlin," wrote Heinrich von Treitschke in 1873 in reference to the University of Berlin, "threatens to endanger the life of the nation; it would be impossible to take action too strong in establishing an optimum counterbalance against the forces of consumption and pleasure," especially since some of the faculty already perceived themselves as part of a "university *en décadence*."[82] Anyone hesitant to retreat into the "ivory tower of academics" could escape the trials of the time only in aesthetic ventures with the vision of a more perfect, nobler world. Idealization and tendencies toward harmonization left their distinctive mark on the picture of the imperial Reich. What followed was an era of pomp and posturing, festivals and parades.

Hofmann was a genius at staging, at careful and exacting preparation, and the grand gesture. Even his lectures were recognized as histrionic masterpieces, "very dramatic, indeed theatrically honed."[83] For example, in order to demonstrate the bleaching effect of chlorine he once ordered an entire basket of violets and robbed them of their color, after which "with friendly jests and charming grace Hofmann threw the bouquets to his pupils."[84] But his *pièces de résistance* were the celebrations of the German Chemical Society. The new building for the Chemical Institute at the University had barely been completed when Hofmann invited the members to a "club night with the President." His intent was to make up for the spirit of elegance and consecration that had been absent when work first commenced in the "halls of the new temple": "None of those distinguished and eminently distinguished gentlemen in whose radiance we might on this occasion have shone, no bemedalled dignitaries of the Reich with their followers, no blossoming wreath of white-clad maidens to greet us on the steps of the sanctuary!"[85]

In 1870 after two years in office as president of the German Chemical Society, Hofmann passed the position on to Rammelsberg. In doing so he invited all the members, together with colleagues from the academy and the university, ministers, state officials, and diplomats, to a banquet that was to become a model for all their future ceremonial gatherings: a veritable firework of speeches, witty toasts, and congratulatory telegrams from all over the world. The purpose of the event was obvious: the effusive ovations served no other end than to portray Hofmann's return to Germany and the renunciation of his magnificent position in London to become a "simple German professor" as a rejection of the banal utilitarianism of the English, a yearning for the "higher, more ideal interpretation of things" found only in the German universities—remarkable testimony to the posturing and pretense of the founders' years. Hofmann edited the ceremonial report himself, and distributed it at his own expense as a special issue of the *Berichte der deutschen Chemischen Gesellschaft*.[86] Its title page portrayed Hofmann posing as an Olympian; in place of the goddess Victory he held in his right hand a bottle of aniline as he reigned sovereign over a multitude of profitable dye-putti bearing sacks bursting with talers. We must not let ourselves be disappointed by the antiquated Germanic frame and the clumsy lines of the artist: had any German professor ever before appeared in such an undisguised imperial attitude, or assumed so shamelessly the attributes of political and economic power?

This was not to pass without protest, and one of the greatest scandals in the intellectual history of the imperial Reich followed in its wake.[87] From Leipzig, a stronghold of middle-class mistrust of the upstart capital Berlin, Kolbe raged against the "arrogance of that Society, which calls itself 'German.'"[88] His colleague, the astrophysicist Zöllner, launched an unbridled attack against Hofmann and the modern scientific establishment in general. Hermann Cochius, one of the founding members of the German Chemical Society, resigned in protest against the dominant tone soon after the Hofmann celebration, distancing himself explicitly from the "clique of Berlin *raisonneurs*."[89] Friedrich Mohr wrote quite openly: "There prevails in the German Chemical Society in Berlin an attitude of toadyism and subservience that would make anyone nauseous.... I myself have fought for some time ... against the patented science of the current leaders."[90] Friedrich Rüdorff, chemistry professor at the Berlin Archi-

tectural Academy, feared nothing could be altered by criticism: "at the least they are likely to proceed with undiminished strength about the business of the great European society founded for the purpose of mutual and self-adulation (of which I myself am one of the oldest members)."[91]

Rüdorff turned out to be right. The success of the experiment in "modernity" was increasingly called into question, contradictions began to intrude into business and society as a result of the ebbs and flows of economic cycles and the so-called founders' crises, societies and special-interest groups were organized, complaints were voiced over depersonalization and declining quality, and disputes arose concerning academic versus vocational education, universities versus technical colleges, culture versus civilization. Yet, the more differentiated and dissonant this Wilhelmian Germany became, the more brilliant and jubilant were the festivities of the German Chemical Society: expressions of a deep desire to rise above the conflicts of the day, to compensate for dissonance in society with the harmony of a community.

Harmony and Luster

No excuse for celebration was wasted. A drinking party was held for 1500 students in Berlin's largest ballroom in 1878 in honor of Hofmann's 60th birthday, followed by a magnificent dinner for 200 guests. Hofmann arranged for participation by delegates from the four corners of the earth.[92] A convention was held in 1886 by the Assembly of German Natural Scientists and Physicians, at which Virchow and Hofmann were named managing directors. The German Chemical Society was responsible for organizing the chemical sections. A ceremonial reception was included, and the Society distributed to all in attendance a witty publication called the *Berichte der durstigen* ("thirsty") *Chemischen Gesellschaft*,[93] from the same publisher and in the same format as its staid journal, the *Berichte der deutschen Chemischen Gesellschaft*. The light-hearted tone and coarse jokes of this "journal" were in stark contrast to the otherwise solemn demeanor of the distinguished assembly of professors, directors, and industrialists. For Hofmann's 70th birthday the Society contributed a marble bust, together with the initial funds for a Hofmann Foundation. A student fête followed in imperial Germany's great ceremonial style.

Finally, a stunning culmination was arranged in the form of an elaborately coordinated double event for the year 1890: a "benzene festival" in the chambers of the City Hall and an "aniline festival" in the Hotel Kaiserhof. The Kaiser himself was invited, together with the "highest dignitaries of the Reich"—of course to no avail.[94] The former celebration was a tribute to the 25th anniversary of the formula for benzene, as well as to Kekulé, its inventor. The latter saluted Hofmann's return to Germany 25 years previously, and the impact that had on industrial development. The centerpiece at the first festival was the brilliant architect of a courageous idea who, in the words of Hofmann in his laudation, "never had a dye in his hands, and yet ... by proposing his theory of benzene may have given the coal-tar dye industry a greater impetus than all of us together, who have devoted years of our lives to the investigation of dyes."[95] Meanwhile, at the other celebration, tribute was paid to the man of action, one whose syntheses had provided industry with building blocks for the future, "who carried the light of science into the workshops of technology, ... who raised Technology to a status equivalent to that of its sister: Science," in the words of Heinrich Caro, representing the dye manufacturers.[96] The question of academic standing versus practical application, which had sounded as a leitmotiv throughout chemistry's history as an academic discipline, was thus provided with a dual answer: "pure" science scatters applications in its wake, even if unintentionally, but only industry blessed with an equal share of rights is in a position to make science productive. The coal-tar dyes, products of the most complex of all industrial syntheses up to that point, would have been unthinkable in the absence of an alliance between science and industry. But even more was at issue with these magical substances.

The founders' years of the chemical industry were not a time for treating men and materials with velvet gloves. Sulfuric acid, chlorine bleach, and sulfite pulping operations produced hazardous emissions at a level scarcely imaginable today. Exploitation reached its height, and plumes belching from the smokestacks of the factories were the pride of every entrepreneur. Coal tar was recognized as a particularly repulsive by-product, and it was produced in vast quantities during the gasification of coal. And yet it was precisely this scourge that was to become the starting point for a blossoming industry. It is certainly no coincidence that whenever the occasion arose to illustrate the utility of chemistry, Hofmann chose as his example not the mass-produced chemicals or the metals, not the dramatic improvements achieved in soda and mineral-acid manufacture, not the crucial fertilizer sector, not the introduction of wood-based cellulose as the basis of a new mass culture, but always dyes—a field that in the 11th edition of Rudolf Wagner's *Handbuch der chemischen Technologie* (Leipzig, 1880) warranted a scant 72 out of 1100 pages. It was not actual utility that was here thrust into the debate: many of the early dyes were primarily used in the treatment of silk, purely a luxury item. Much more at issue was fascination with the transformation of a detestable raw material into shining offspring steeped in elegance and luxury: "the way from coal to colour,"[97] a scientific fulfillment of the alchemist's ancient dream of transmutation.[98] It was this theatrical display that had occupied the center of public attention at the Internation Exhibition of 1862. Some of the glow is reflected in Hofmann's report:

> *In these cases is displayed a series of most attractive and beautiful objects, set in sharp contract with a substance particularly ugly and offensive. This latter is a black, sticky, fetid semifluid, equally repulsive to sight, smell, and touch: one of the most noisome, as it is also one of the most abundant and (heretofore) embarrassing, of the gas manufacturer's waste products. It is, in a word, gas tar.*
> *The beautiful objects amidst wich [sic] the tar is placed are a series of silks, cashmeres, ostrich plumes, and the like, dyed in a diversity of novel colours allowed on all hands to be the most superb and brilliant that ever delighted the human eye. Language, indeed, fails adequately to describe the beauty of these splendid tints. Conspicuous among them are the crimsons of the most gorgeous intensity, purples of more than Tyrian magnificence, and blues ranging from light*

azure to the deepest cobalt. Constrasted with these are the most delicate roseate hues, shading by imperceptible gradations to the softest tints of violet and mauve.[99]

The aesthetic of shine and luster was as much a part of the image of Wilhelmian Germany as its inclination toward the decorative and colorful. The sober reality of power and material acquired a second and artificial skin, appearing to be ennobled to culture. It was a remarkable (but for the times typical) preference for the ceremonial over the commonplace that conferred such a high symbolic value on iridescence drawn from tar. Gottfried Semper had extolled the introduction of gas illumination for its enrichment of the festive,[100] and in a similar way the conspicuous rhetoric surrounding the coal-tar dyes constituted a part of the apparatus of idealization and ennoblement with which the aspiring profession of chemistry freighted its vision of the future: science could help transform the inhospitability of cities and their industries into a festival of bright colors. Critics have described the reign of Wilhelm II as an "age of festivals."[101] The monarch himself, with his peculiar inclination to the operatic, represented precisely what the public desired: pomp and glory. "Even the simplest of things was transformed in Bengalic illumination," observed Nicolaus Sombart.[102] The same words could almost have been used to characterize Hofmann's style in his later years.

Prestige and Effect

Through their unique mix of glorification of the free life of the student, of whimsical superabundance, of that drive to impress so characteristic of the founders' years, and of the general national pathos, the chemists' celebrations betrayed all too clearly how little this band of professionals had established its footing in the new role to which it had ascended on the strength of its academic and economic might. Status and acceptance were dominant social values of the time,[103] but in chemistry a wide gulf separated pretension from reality. Avoidance of things political after all constituted the core of that silent compromise into which intellect and capital had entered under the protective mantle of state authority. Neither party—scientists nor industrialists—had any serious part to play at the real center of power. The greatest height to which a scientist could hope to rise was to become a model for the educated middle class, the "Bildungsbürgertum," but chemistry rested on one of the lower rungs of the disciplinary ladder. Status in Prussia was measured on a prestige scale shaped by the aristocracy and the military. Professors were not even represented on the court's list of high-ranking individuals. This made all the more important the carefully crafted system of titles and honors with which the traditional elite attempted to ensnare members of the aspiring middle class. In the year 1888 Hofmann, too, was rewarded with a title of nobility by Kaiser Friedrich, whose brief reign was the subject of so many hopes.

The impression of a leading role for natural scientists in German society of the second half of the nineteenth century, conveyed so often by sources close to the scene, is simply a myth.[104] In Imperial Germany the truth lay elsewhere. Chemistry was never blessed with a du Bois-Reymond or a Helmholtz. Chemists rarely ventured beyond the bounds of their own discipline and its closely allied industry; even marriages were commonly arranged within this social group. The circle surrounding Hofmann was also curiously limited. Shortly after his arrival in Berlin he admittedly communicated to his brother what he perceived to be compensation for the shabbiness and pettiness with which he was otherwise confronted at every step: "In the circles in which I travel, an academic enjoys encounters with industry and high finance, with the highest officials of the state, officers of every rank, artists in every field;"[105] but in truth his association was essentially limited to industrialists, co-workers, and "special colleagues" from the natural-science branch of the philosophical faculty. Few prominent figures appeared even at the numerous celebrations held in Hofmann's honor, leaving aside those from closely related disciplines. It is therefore reasonable to suggest that the ostentatious celebrations were intended primarily to shape and enhance the self-image of a profession that was in fact still somewhat insecure with respect to its true significance in society.

Fig. 3. A. W. Hofmann, ca. 1871, photograph by Carl Günther, Berlin, 90 × 56 mm, Staatsbibliothek Preussischer Kulturbesitz, Berlin, Coll. Darmstaedter, G2 1858 (5), f. 162.

The impression made on the outside world was correspondingly weak. Hofmann seldom appeared as a public lecturer except among chemists. Only when his duties required it did he take a position in daily affairs. The speech he delivered upon assuming the position of Rector of the Friedrich-Wilhelms-Universität attracted wide attention, but what he actually had to say on that occasion regarding division of the Faculty of Philosophy into separate faculties of science and humanities came across as weak and conventional: a rearguard action in the attempt to maintain the advantages associated with university status. Hofmann never followed a true policy in science, let alone in politics. In 1880 when he opposed the recognition of an antisemitic student fraternity—but at the same time pressed for the dissolution of a student "Committee Opposed to Antisemitic Agitation"—he was acting merely in his role as rector, attempting to keep the university free of politics and party confrontation.[106] Hofmann had no head for politics. He accepted the notions of monarchy and dynasty as pivotal, and he dis-

played an almost childish veneration for Friedrich's empress, who as a princess in London had once eavesdropped on his chemistry lectures. One searches in vain among Hofmann's speeches and writings for the name of Bismarck. To characterize him as a liberal nationalist would be something of an overstatement. Indeed, the widely traveled Hofmann had been a British subject for twelve years, and he always refused to be a participant in the growing nationalism. As for the German Chemical Society, with its high percentage of foreign members, he governed it according to the age-old model of the transnational community of scholars, and in England this "denationalisation of chemical science" was praised as one of the Society's most lofty achievements.[107]

Monuments

The restless Reich attempted with the help of historical myths to obscure the impositions of modernity. An excessive cult of monuments was the result. The monument to Arminius (*Hermannsdenkmal*) in the Teutoberger Forest (1875) and the Niederwald monument near Rüdesheim (1883) set the national tone. In the following years monuments were erected everywhere. In a world of expanding markets, of proliferating cities and industrial landscapes, materials and materialism, greed and profits, in a world characterized by horizontal expansion, monuments offered an element of verticality and meaning, pointing upward toward the sublime and away from the crudely materialistic, toward a realm of culture in which all historical contradictions were resolved.[108] It was unthinkable that the chemists should be immune to this passion for monuments.[109] Hofmann's laboratory in Berlin was probably the first building of its type to incorporate in its facade a rich sculptural program honoring the traditions of European chemistry.[110] Hofmann attached great importance to the busts of Liebig, Wöhler, and Faraday displayed in the entrance hall. But it was important that the world outside take notice as well. April, 1873, marked the death of Liebig, and the German Chemical Society decided immediately that a monument should be dedicated to him. In that very year, though it was also to witness the first of the founders' crises and an economic depression, a collection for the purpose was initiated among the chemists, energetically pursued by Hofmann.[111] Meanwhile, the German population as a whole was engaged in a collection to build a great national monument. The two monuments were unveiled within a few weeks of each other in the summer of 1883: the Kaiser doing the honors for a victorious Germania atop the Niederwald, and Hofmann for the Liebig statue in Munich. A second monument was erected to Liebig in Giessen, in July of 1890, and two days later one to Wöhler in Göttingen. It goes without saying that Hofmann delivered both dedication addresses. The tradition he thereby initiated continued for many years: by 1911 the German Chemical Society had erected no less than 21 monuments throughout the Reich.

Perhaps no preceding era had ever felt a greater need for history. Historicized styles of every imaginable type literally blossomed. It is no coincidence that an independent historiography of the natural sciences developed at the same time. Hermann Kopp set the standards with his *Geschichte der Chemie* (*History of Chemistry*; 1843–1847), a work that Hofmann greatly respected. Other descriptions followed from the hands of Gerding (1867), Wurtz (1868), and Ladenburg (1869).[112] Whether motivated by fundamental principles of a historiographic concern for source criticism, or by those of a panegyric, all these works shared one common characteristic: they invested a young discipline devoid of a history of its own with a mantle of tradition and permanence. Spurred on by both expedience and inclination, Hofmann contrived to make history an integrating element within the German Chemical Society. His genre was necrology; his preferred source, correspondence. Beginning with a commemorative address for Thomas Graham in 1869, Hofmann created a colorful bouquet of life histories—no less than 51 in number—which now adorns the yellowing volumes of the *Berichte*. The finest were collected in 1888 as three sumptuous volumes of *Erinnerungen an vorausgegangene Freunde* (*Remembrances of Departed Friends*), where they were accompanied by selections from the correspondence between Liebig and Wöhler. Lively, and displaying a fine sense of cultural history, the portrayals by Hofmann are testaments to a culture of affirmation, projecting the contrasting world of a pre-industrial idyll in which at the end of the day's toil one might seek after-hours consolation. But they also preserve the vision of a science at the heart of which stood the individual researcher, with all his hopes and disappointments; a science in which the ideal was most important, and financial gain was irrelevant; the vision also of a community of scholars, far removed from nationalistic delusions and the arsenals of the present day.

Under the Protection of the Patriarchy

Hofmann's portrait gallery, indeed the world of the founders' years quite generally, must be envisioned as a male phenomenon. Women played at most a decorative role, as when a "blossoming wreath of white-clad maidens"[113] adorned the formal opening of an institute, or during a social evening "a rich garland of lovely ladies looked down into the colorfully animated room from the loges and balconies."[114] Even as the wives of professors, corporate directors, and privy councillors, women were absent from the chemists' circles. Prussia was a bastion of male chauvinism. Nowhere else was opposition to women students so powerful and so enduring. Initially tolerated only as auditors in 1895, women were first allowed to matriculate or acquire the doctorate in 1908.[115]

And yet there existed certain isolated niches under the protection of this patriarchy, although it required a patriarch with the stature of a Hofmann to employ a female private assistant for almost three years, subsequently going so far as to help her acquire a doctorate—all without the news ever leaking out in Berlin. This case is documented in confidential correspondence.[116] In the summer of 1874 Hofmann wrote a letter to Wöhler enjoining the latter to be of assistance to his "not only charming, but also thoroughly educated pupil, Fräulein Julie Lermontoff," whose knowledge far exceeded the norm and who had the singular ambition "to take home with her from Germany a doctorate." Fräulein Lermontoff wished to apply for this purpose to Göttingen. "With our severe regulations here we are unfortunately not in a position

to introduce to the scene something so unheard of as a doctoral degree for a woman." Shortly thereafter Hofmann once again requested that special considerations be accorded her due to the unusual circumstances: "despite her considerable knowledge Fräulein Lermontoff is naturally very shy, and would consider herself fortunate if the chalice of an examination might pass her by."[117] In October 1874, 28-year-old Julie Lermontoff from St. Petersburg received her doctorate in chemistry at Göttingen with physics as a minor, albeit not without standing for the usual examination.[118] This was certainly the first doctorate in chemistry for a woman in Germany, indeed the first by many years.[119]

The End of an Epoch

If we may accept the word of his brother-in-law and longtime co-worker Ferdinand Tiemann, Hofmann's image evolved in a contrapuntal way:[120] from that of a fiery combatant in the battle for science in a Germany only beginning to awaken from its Philistine repose; to one serious and strict in respecting his obligations, out of a regard for public welfare, as the new Reich contemplated assuming a strong-man posture on the way to becoming a modern state. He ultimately came to represent the one constant factor in the chemical world: cheerful, benevolent, of sparkling humor, and always mindful of conciliation as the epoch reeled in a *fin-de-siècle* fever toward its demise.

In 1890 the whole atmosphere of Wilhelmian Germany was transformed. Ever since Bismarck's withdrawal, the Reich had perceived itself facing an uncertain future. The supremacy of the past gave way to a labile equilibrium. Industrialization, fragmentation of the middle class, and a developing labor movement produced dangerous cracks in the apparent solidarity of a patriarchal order. Rampant materialism, specialization, and "professionalism": these were the bywords of the cultural crisis of the decade. The instruments of the founders' years, the program of conservative reform, no longer struck a resonant chord; even the vision of industrialism as conveyed by the literature of the times became inverted and assumed a distinctly negative character.[121] The contrasting image of the creative genius, as conjured up for example by Julius Langbehn's *Rembrandt als Erzieher* (*Rembrandt as Educator*, 1890) began to attract enthusiastic throngs. A diffuse and ambiguous critique of modernity established itself.[122] The Reich of Bismarck had gambled away the opportunity for modern industrialized society to guide a new elite toward new forms of scientific-economic-political cooperation.

Such circumstances called for one more grand celebration by the chemists in an attempt to promote unity: in honor of the 25th anniversary of the German Chemical Society. Preparations were well underway when, on May 5th, 1892, Hofmann died, in the fullness of life and with a completed manuscript lying on his desk: it was to be the 887th contribution "Aus dem Berliner Universitäts-Laboratorium."[123] His funeral was worthy of a prince.

Hofmann's death marked the end of an epoch. The generation of the founders had retired from the scene. Siemens, who had coined the phrase "scientific era," died six months later. A new generation of academic mandarins,[124] the privy councillors and grandiose professors, rejected exaggerated display and monumentality. Emil Fischer, Fritz Haber, and Walther Nernst, leading reformers and protagonists of a new style, distanced themselves through coolness, matter-of-factness, and precision from the exuberance of their predecessors. Their own plans for the future were based on complexity and competitiveness, not on hierarchies and a sense of community.[125] They no longer felt able to plaster over the rents and tensions plaguing the scientific establishment. In conflicts about state examinations, rights of the technical institutes, questions related to untenured faculty and instructors or the integration of research and teaching—everywhere the tones became harsher and more strident.

Is it any wonder that the times held fast to their image of Hofmann? That they in fact inflated it until it acquired monumental proportions, because modern scientists—and industrialists—were threatened with disappearance as individuals due to a new division of labor in the workplace? That they drew comfort from Hofmann's enormous vitality, because their era seemed powerless, hectic, and a primary cause of its own illness? That they rejoiced in the memory of Hofmann's unpretentious humor and winning charm, because times were now bad and the mood had become strident? That they swore by his ability to integrate and to synthesize, because industrial society had lost that unanimity and clarity that had characterized traditional society? "In times of almost feverish growth in activity in science and industry," began Tiemann in his obituary address before the German Chemical Society, "it is appropriate for us to look back more often than in the past in order not to lose sight of the broader perspective."[126] A biography that the Society commissioned Tiemann to prepare was not completed until 1902, and then by Volhard and Fischer. It finally appeared in the form of an impressive special issue of the *Berichte*: a testament of the preceding century, laid at the threshold of a new age.

Hofmann would be remembered once again. In April 1918, the German Chemical Society gathered to celebrate its own 50th anniversary and the 100th birthday of its founder.[127] Few were present because of the war, and indeed only a single foreigner. The atmosphere was one of dejection; achievements from the past were urgently recalled to counter the uncertainty of the future. Cabinet ministers and representatives of government agencies, the rectors of the university and the Technische Hochschule, presidents of the professional associations and of the Kaiser Wilhelm Society—all were duly in attendance, and tributes to the contributions of chemistry recorded "in the golden book of this war" were just as obligatory as telegrams praising Ludendorff and the "heroic" Kaiser. Only one of the seated dignitaries apparently maintained his silence through all the speeches and toasts: Fritz Haber, who came to represent the minister of war.

*

Speaking out of the feverish restlessness of the *fin de siècle*, from the deep strife characterizing the turn of the century, and from the trauma of war, the German Chemical Society and chemists individually swore their allegiance repeatedly to the image of Hofmann. And it is this image that tradition has handed down to us. The accomplishments of this remarkable man were phenomenal for the time. In the stormy

phase of economic rebirth and through the crises of the founder's years he was the central integrating figure, the figurehead. Hofmann's powers of synthesis were enviable. But must we therefore be envious of an era that stood in desperate need of such men?

The Chemistry of GALLEX—Measurement of Solar Neutrinos with a Radiochemical Gallium Detector

By Edmund Henrich and Klaus H. Ebert*

In the GALLium EXperiment, GALLEX, low-energy solar neutrinos produced in the main hydrogen fusion reaction inside the Sun are being counted for the first time in a radiochemical gallium detector. In this way, the theories about stellar structure may be verified and the question of the existence of a neutrino rest mass be brought closer to a solution. The experiment is being carried out with international collaboration at the Gran Sasso underground laboratory (LNGS) in the Abruzzi mountains in Italy. In this paper we survey the planning, construction and initial experimental operation of the gallium detector, paying special attention to the chemical aspects of the experiment. The chemical problem to be solved is the separation of very few ^{71}Ge atoms from 100 metric tons of a highly concentrated $GaCl_3$ solution acidified with hydrochloric acid. In addition, these Ge atoms must be isolated and converted into germane, GeH_4, for low-level counting of ^{71}Ge in a gas proportional counter. After extensive preparatory work to meet the extreme requirements of the experiment, the first results have now become available.

1. Introduction

Direct information about the interior of the Sun, where fusion reactions take place in which energy is generated, can be obtained only by way of solar neutrinos. While it takes photons roughly a million years to diffuse to the surface of the Sun, undergoing profound changes in the process, neutrinos travel from the interior of the Sun to the Earth within 500 seconds. According to the Standard Solar Model (SSM),[1] there are essentially two types of solar neutrinos: 1) pp neutrinos, arising in the main reaction of the fusion cycle, with a maximum energy of 0.42 MeV; 2) higher energy neutrinos from side reactions, with maximum energies of up to 18.8 MeV.

So far, it has only been possible in sophisticated experiments to demonstrate the existence of the higher energy neutrinos, but the readings obtained are at least 50% below the calculated values from the SSM. This discrepency has fueled much discussion and speculation both about the correctness of the SSM and the problem of the rest mass of the neutrino.[2, 3] The solution to this riddle of the solar neutrinos is now expected to come from experiments in which pp neutrinos are counted in a radiochemical gallium detector.

Two such experiments have been under way for some time: SAGE,[4] a Russian–American collaboration in the Baksan underground laboratory[5] in the Caucasus mountains, and GALLEX,[6–8] an international collaboration carried out in the Gran Sasso underground laboratory in Italy.[9] All experiments conducted to prove the existence of solar neutrinos must be optimally shielded against cosmic radiation and, for this reason, are performed in laboratories below ground.

Neutrinos are difficult to detect because of their extremely weak interactions with matter. With low-energy neutrinos, these interactions are even less pronounced than with higher energy neutrinos. The higher energy neutrinos can be detected in real-time experiments, but this requires extremely large detectors. One such detector contains 680 tons of water as the scattering medium and detects the neutrinos, after collisions with electrons, by the Cerenkov radiation; it has been in operation in the Kamioka mine in Japan since 1987. In that experiment, Kamiokande, neutrinos with an energy >7.3 MeV have been detected.[10]

Neutrinos can also be detected by radiochemical detectors; the reaction is based on the capture of a neutrino by a nucleus corresponding to an inverse β-decay (as is well known, neutrinos are emitted in β-decays). This transmutation gives rise to the nucleus of a different element, which can be separated in a chemically selective way. At the present time, there are three radiochemical detectors which can be used for the detection of solar neutrinos: one chlorine detector and two gallium detectors.

The chlorine detector is based on the conversion of chlorine-37 into argon-37. This detector offers a number of excellent preconditions: 1) there are many cheap liquid compounds with high fractions of chlorine which may serve as targets; 2) argon-37 decays by electron capture with a half-life of 35 d; 3) the separation of argon from the liquid and its subsequent purification are relatively easy. Several hundred tons of chlorine are required to ensure that the number of argon-37 atoms is still large enough to be detected reliably by low-level counting techniques. The chlorine detector suffers from the disadvantage of responding only to neutrinos with an energy in excess of 0.81 MeV and, thus, is not sensitive to lower energy solar neutrinos. The chlorine detector was set up in the Homestake gold mine in South Dakota more than twenty years ago by pioneers in the field of radiochemical neutrino detectors, namely Raymond Davis and his colleagues from Brookhaven National Laboratory (BNL). It has been in operation since 1970.[11] The result of Davis's extensive measurements, shows that roughly only one third of the value expected from the SSM[12] is detected.

The gallium neutrino detector was proposed by Kuzmin as early as 1964.[13] It is based on the conversion of gallium-71 into germanium-71, and it is sensitive to neutrinos above an energy as low as 0.23 MeV. For many years, the gallium

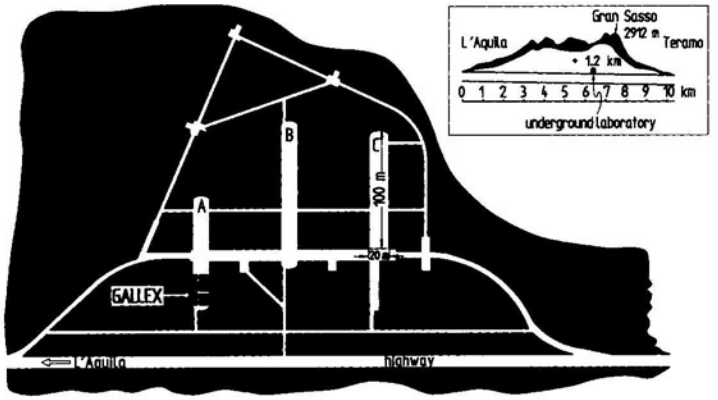

Fig. 1. Floor plan of LNGS underground laboratory with location of GALLEX in hall A.

detector was a utopian proposition because the worldwide annual production of gallium was far below the minimum of thirty tons required for the experiment. Only in the past decade, as the commercial demand picked up, has production increased.

The studies of the concept of a gallium neutrino detector were begun at BNL as long ago as the seventies; the chemical target selected was a concentrated $GaCl_3$ solution acidified with hydrochloric acid.[14, 15] The experiment was intended to be run in the underground laboratory of the Homestake mine, where access is limited by the main shaft. The approximately 100–150 tons of detector solution was to be contained in twenty or more tanks of approximately 3 m^3 each, and desorption was to be used to separate the $GeCl_4$ from this battery of tanks. The project[16] was abandoned in the USA in the mid-eighties due to lack of funding to purchase the large quantity of gallium required.

Upon the initiative of the Max-Planck-Institut für Kernphysik (MPIK), the GALLEX Collaboration was set up next. The decisive factors in favor of GALLEX were the ability to finance the amount of gallium needed, and the guarantee of space in the underground laboratory, being built in the Gran Sasso mountains by the Italian Istituto Nazionale di Fisica Nucleare (INFN). Figure 1 shows a floor plan of the LNGS underground laboratory[9] and the location of GALLEX.

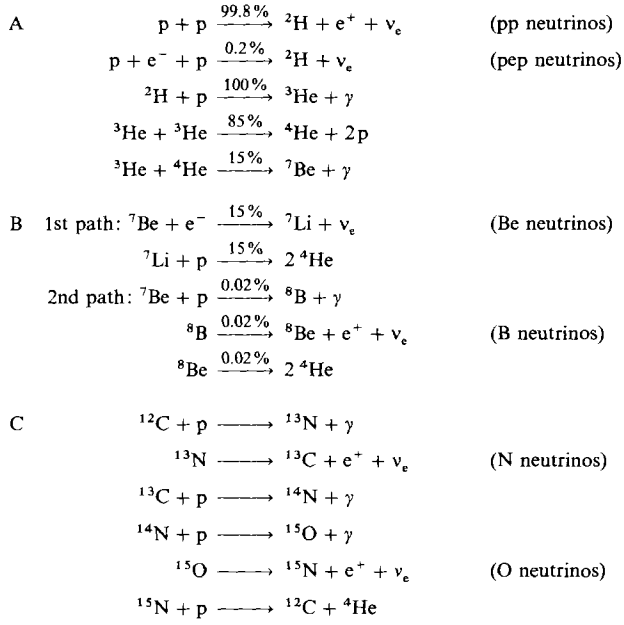
The Standard Solar Model (SSM) and the Mass of Neutrinos

The most important fusion reactions in which hydrogen (protons p) is converted into helium can be subdivided into the main cycle (Scheme 1 A), secondary reactions (Scheme 1 B), and the CNO cycle with carbon-12 as "catalyst" (Scheme 1 C). The main cycle provides some 83% of the total energy of the Sun, while the secondary cycles produce 15% and the CNO cycle contributes only 1.6%. The various solar models[1, 17] differ in the contributions made by main and secondary reactions and, consequently, in the temperature assumed to exist in the Sun. At higher tempera-

Klaus Ebert, born in Berlin in 1928, studied chemistry in Vienna, where he gained his doctorate in 1953 for work on the properties of chemically altered silicate surfaces. In 1957, after carrying out postdoctoral work with Professor Paneth at the University of Durham (UK), and a spell as assistant at the Max-Planck-Institut für Chemie in Mainz (FRG), he took up an appointment as assistant to Professor F. Patat at the Institut für Technische Chemie der Technischen Hochschule München (FRG), where he habilitated in 1964 with work on the mechanism and kinetics of enzymatic dextran polymerization. In 1969, following a short period of employment in industry at BASF (1968–1969), he was appointed Professor for Applied Physical Chemistry at the University of Heidelberg, where he was also Dean of the Faculty for Chemistry and Natural Sciences (1969–1972) as well as vice-president. In 1980 he was appointed head of the Institut für Heisse Chemie des Kernforschungszentrum Karlsruhe (FRG) (on leave from the University of Heidelberg) and worked on the development of technology for the reprocessing of nuclear fuels. Since 1984 he has worked on the GALLEX project. Further research areas range from the influence of cosmic radiation on meteorites to the kinetics and modeling of complex chemical gas reactions (pyrolyses) and the degradation mechanisms of high-polymer materials to investigations of the chemistry of supercritical fluids. Klaus Ebert is a founder member of the Sonderforschungsbereich "Modeling of Complex Reactions", author of the VCH textbook "Computer Applications in Chemistry", and was a member of the "Studienreformkommission Chemie".

Edmund Henrich was born in 1941 in Kaiserslautern (FRG). From 1961 to 1967 he studied chemistry at the Universities of Mainz and Heidelberg and spent a period of time doing research at GERN in Geneva. After gaining his doctorate in 1971 for work on the preparation and properties of heptavalent transuranics under the supervision of Franz Baumgärtner he remained at Heidelberg until 1974 as research assistant. Since 1974 he has been employed as scientist at the Kernforschungszentrum Karlsruhe (FRG). His work focusses on the applicational development of new methods for the safer management of volatile radionuclides during reprocessing of spent nuclear fuel, especially in off-gas purification, the treatment of fission product iodine, the removal of fission product noble gases and refining by crystallization. Besides his contribution to the design, construction, and operation of the process engineering plant for GALLEX he has in recent years turned his interests to low waste technology.

tures, the contribution by secondary cycles increases. On the other hand, narrow limits are imposed by the total energy emitted, whose absolute level is known very precisely from the solar constant.



Scheme 1. Main reactions in the fusion of hydrogen. A) main cycle, B) secondary reactions, C) CNO cycle.

Six of the fusion reactions outlined above (Scheme 1) give rise to neutrinos (ν_e). These neutrinos are distinguished by prefixes indicating the elements from which they originate, e.g., pp neutrinos from the reaction of two protons, or Be neutrinos from the decay of the beryllium nucleus. The solar neutrino flux is made up of all neutrinos leaving the Sun. Their intensities are calculated by the SSM (Table 1). The neutrinos produced in the various fusion reactions have very different energies, partly discrete values, partly continuous energy spectra (Table 1, Fig. 2). For the total neutrino flux impinging on the Earth, the SSM produces a calculated value of 66 billion neutrinos per cm^2 per second.

Neutrinos are assumed to have no rest mass and no charge. As they are subject only to weak interaction, their interaction with matter is extremely rare, which makes measuring difficult. The cross-section decreases greatly as the energy decreases (Fig. 3), i.e., the low-energy neutrinos are even more difficult to detect than the high-energy variety. On

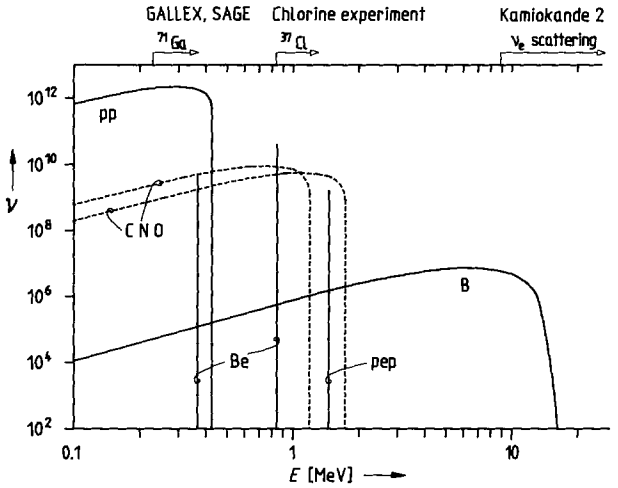


Fig. 2. Solar neutrino spectrum (for abbreviations see Scheme 1). E = neutrino energy; ν = solar neutrino flux to earth per cm^2, second and MeV; detection limits of the neutrino detectors are given above. Kamiokande 2 = neutrino detector in the Kamioka mine.

the other hand, the low-energy pp-neutrinos make up 91% of the neutrino flux according to the SSM. Only the gallium neutrino detector is sensitive to pp neutrinos, but, again, only above its 0.23 MeV threshold. The other detectors

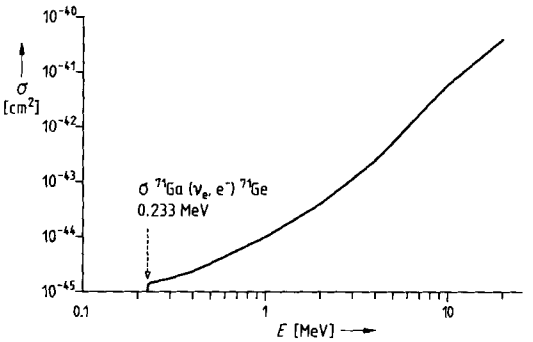

Fig. 3. Neutrino capture cross-section σ of gallium as a function of the neutrino energy E (after Ref. [1]). The dotted arrow indicates the threshold energy for neutrino detection.

(chlorine detector, Kamiokande) can count only the higher energy neutrinos from the secondary reactions, which contribute but slightly to the total fusion cycle. The limits of detection are indicated in Figure 2.

In recent years, the assumption that neutrinos have no mass has been doubted more and more seriously. The prob-

The GALLEX Collaboration

An experiment posing such extreme requirements in several areas of chemistry, physics, and process engineering can be carried out successfully only by collaboration among various working groups.

The GALLEX Collaboration was set up in 1984 following an initiative by the Max-Planck-Institute for Nuclear Physics in Heidelberg (MPIK),[*] soon after collaboration for the same research purpose between the Brookhaven National Laboratory (BNL) and MPIK had been wound up after BNL had reduced its solar neutrino program for financial reasons.

GALLEX was initiated with mainly West European collaboration in mind. It very soon became apparent that scientists from this region showed a very keen interest in the experiment, and that there was a real chance of raising the funds for the necessary investments. A decisive fact improving the prospects of GALLEX in the early stage was that the 30 tons of gallium, which amounted to almost one worldwide annual production, were purchased and financed thanks to grants from the Bundesministerium für Forschung und Technologie (BMFT), the Alfried-Krupp-von-Bohlen-und-Halbach-Stiftung, and the Max-Planck-Gesellschaft, and that sufficient space was offered by the Istituto Nazionale di Fisica Nucleare (INFN) in the Laboratorio Nazionale del Gran Sasso in the Abruzzi mountains (LNGS), the word's largest underground laboratory.

The GALLEX Collaboration was ready to start in 1986; it is made up of scientists from ten institutions. Its present members are:

P. Anselmann, W. Hampel, G. Heusser, J. Kiko, T. Kirsten, E. Pernicka, R. Plaga, U. Rönn, M. Sann, C. Schlosser, R. Wink, M. Wójcik (Max-Planck-Institut für Kernphysik (MPIK), Heidelberg (FRG)), R. von Ammon, K. H. Ebert, T. Fritsch, K. Hellriegel, E. Henrich, L. Stieglitz, F. Weirich (Institut für Heisse Chemie, Kernforschungszentrum Karlsruhe (IHCH-KFK), Karlsruhe (FRG)), M. Balata, E. Bellotti, N. Ferrari, H. Lalla, T. Stolarczyk (INFN—Laboratori Nazionali del Gran Sasso (LNGS), L'Aquila (Italy)), C. Cattadori, O. Cremonesi, E. Fiorini, S. Pezzoni, L. Zanotti (Dipartimento di Fisica, Università di Milano, and INFN—Sezione di Milano, Milan (Italy)), F. von Feilitzsch, R. Mössbauer, U. Schanda (Physikalisches Institut der Technischen Universität München (TUM), Garching (FRG)), G. Berthomieu, E. Schatzman (Observatoire de la Côte d'Azur, Nizza (France)), I. Carmi, I. Dostrovsky (Department of Environmental and Energy Research, Weizmann Institute of Science (WIS), Rehovot (Israel)), C. Bacci, P. Belli, R. Bernabei, S. d'Angelo, L. Paoluzi (Dipartimento di Fisica II Università di Roma, and INFN—Sezione di Roma 2, Rome (Italy)), S. Charbit, M. Cribier, G. Dupont, L. Gosset, J. Rich, M. Spiro, C. Tao, D. Vignaud (DAPNIA, CEN Saclay: Gif-sur-Yvette (France)), R. L. Hahn, F. X. Hartmann, J. K. Rowley, R. W. Stoenner, J. Weneser (Brookhaven National Laboratory (BNL), Upton, NY (USA)).—In addition, the following KfK staff members were instrumental in the construction and operation of the technical installation: J. Amend, O. Brenk, P. Fischer, W. Habicht, D. Heidt, M. Kluth, G. König, F. Koch, M. Persohn, J. Römer, W. Rösch, G. Schnabel, F. Schübel, P. Schwab, J. Unk, R. Will.

A collaborative venture of this size can succeed only if, on the one hand, responsibilities in planning, buildup, and execution are clearly delineated and, on the other hand, communication functions smoothly. Over the whole period of time, the GALLEX Collaboration has met every six months for GALLEX meetings from the beginning of the experiment, always at LNGS. At these meetings, the program has been discussed and defined in detail. Throughout the year, important information has been made accessible to each member of the Collaboration as "GALLEX News" by electronic mail, and the local GALLEX Coordinator appointed by each group on a basis of rotation ensured that GALLEX was always present at LNGS for ongoing business and for taking care of numerous visitors. In appointing Till Kirsten its Spokesman, the GALLEX Collaboration succeeded in finding a scientist who not only acted as a promoter of the project from the beginning, but also has been its Coordinator from the early days on. Special mention must be made of the excellent equipment available at the underground laboratory, which is in no way inferior to that of a modern experimental facility. In addition, the generous support offered by the staff of LNGS and its Director, Enrico Bellotti, must be emphasized. Cooperation within the Collaboration has been exemplary; all members have at all times given their full support to the experiment. Indeed, it was quite customary to see physicists participate in the operation of the chemical plant by running night shifts.

The main activities within the project are assigned to certain groups. Frequently, new problems and duties arose in the course of the experiment, which needed to be solved quickly; in most cases they were handled by interdisciplinary cooperation. In this way, collaboration has become closer and closer as the experiment went on. This should be taken into account when going through the list below of tasks assigned to the institutions:

- Scientific and technical infrastructure, and measurement of background radiation in the underground laboratory: INFN-LNGS; University and INFN Milan; University and INFN Rome
- Supply of the gallium chloride solution and specification control: MPIK.
- Planning, construction, and operation of the detector and technical process equipment; IHCH KfK
- Specification and chemistry of the detector solution: MPIK, KfK, BNL, TUM
- Side reactions in the detector: INFN, CEN Saclay, MPIK, KfK
- Conversion of $GeCl_4$ into GeH_4; purification and transfer into the counter: BNL, MPIK, and WIS
- Development and operation of the low-level counting systems; trace analysis (detector solution, in-plant analyses): MPIK
- Planning and construction of the 1.5 MCi ^{51}Cr neutrino source; neutron measurement in the process buillding: CEN Saclay.

All member groups of the Collaboration took part in the evaluation and assessment of measured results. It has been a particularly good idea of the initiators of GALLEX to include, from the outset, particle physicists and astrophysicists in the collaborative venture. At the GALLEX meetings and in many specialized discussions, they time and again have motivated the experimentalists, by their imaginative contributions, and it is largely due to their efforts that the publication of the first measured results [6] of GALLEX has been accompanied by an evaluation [7].

[*] T. Kirsten, *Jahresbericht des Max-Planck-Instituts für Kernphysik*, Heidelberg, **1984**, p. 139.

lem is of eminent importance to particle physics and astrophysics alike. Modern physics tells us that elementary particles can be grouped into three identical families, which differ only in their masses. The leptons (electrons and neutrinos) are classified in the electron, muon and tauon families. For the quarks it was proved that transformations—so-called oscillations—among the families are possible. However, such oscillations are confined to elementary particles with a rest mass. If proof can be obtained that also neutrinos oscillate, they are bound to have a mass, albeit a very small one.[2, 3, 18]

The fusion reactions in the Sun give rise only to electron neutrinos (ν_e). All radiochemical detectors of solar neutrinos are sensitive only to electron neutrinos. The rate at which neutrinos are converted into a different species, e.g. muon neutrinos, is very much a function of their energy. The experiments conducted so far to detect solar neutrinos, which are sensitive only to the higher energy neutrinos, have produced only one half to one third the signal expected. This has been interpreted as an indication of neutrino oscillations.[19] Consequently, it is of great interest to know whether such indications exist also for low-energy neutrinos. Only the gallium detector can tell us this, because it is the only instrument that is also sensitive to low-energy neutrinos.[20]

Should neutrinos be found in fact to have a finite rest mass, its value would give a strong boost to the grand unified theories (GUTs), especially by providing an indication of the scale of energy at which all electroweak and strong interactions can be described by a unified force.

In astrophysics it is also important to know whether neutrinos have a mass. Even if it were less than 10^{-4} the mass of an electron, it could contribute to the missing mass in the universe, as the number of neutrinos present in space is enormous. However, they do not disturb measurements of solar neutrinos on Earth, as their energy is much lower, and their interaction with matter is many orders of magnitude weaker than that of the pp neutrinos.

2. Basic Principles of GALLEX

2.1. ^{71}Ge Production from ^{71}Ga

In principle, gallium as a neutrino detector can be used in any chemical form. Germanium-71 is produced by the capture of an electron neutrino: $^{71}Ga(\nu_e, e^-)^{71}Ge$. The rate of production P of ^{71}Ge is given by the product of the number n of gallium-71 atoms, the neutrino capture cross-section σ, and the neutrino flux Φ [Eq. (a)]. The 30.3 t of natural gallium, the quantity available to GALLEX, contains 12 t, i.e. 1.037×10^{29} atoms, of ^{71}Ga.[21]

$$P = n \int_0^{E_{max}} \sigma(E_i)\Phi(E_i)dE \qquad \text{(a)}$$

As seen in Figure 2 the solar neutrino flux, Φ_i, is made up of fractions of various neutrinos with different energy spectra; the capture cross-sections also depend on energy.[1] The relatively complex calculation ends up in a production rate for GALLEX of 1.18 ^{71}Ge atoms a day. After four weeks, there are roughly 16 atoms of ^{71}Ge, as ^{71}Ge decays at a half-life of 11.4 d. These Ge atoms must be separated from the gallium target with a high yield and high selectivity, and must be counted by way of their radioactive decay. At a separation yield of 90% and a counting yield of 66%, the counting system would measure an average of 9.5 ^{71}Ge pulses. These procedures must be repeated again and again until the statistical error of measurement is so small that a reliable value is reached. This ultimately requires four years of measurements, in which a total of approximately 500 ^{71}Ge pulses will be registered. A first result based on ca. 70 ^{71}Ge pulses has been published recently by GALLEX.[6]

It must be ensured that all ^{71}Ge atoms have originated from the neutrino-capture reaction and not from other nuclear reactions. The most important side reaction of ^{71}Ga occurs with fast protons ($E_p \geq 1.02$ MeV), in which ^{71}Ge atoms are also produced[16, 22]: $^{71}Ga(p,n)^{71}Ge$.

Protons can be generated in three ways: 1) by fast muons from cosmic radiation; 2) by fast neutrons (>0.4 MeV) produced in the local environment of the gallium neutrino detector by α-radiation and spontaneous fission; 3) by α-radiation inside the detector. The side reactions must be kept so small as not to have a major impact on the value of the measured production rate of ^{71}Ge. This implies a number of requirements with respect to the purity of the detector solution, to the materials used for the equipment, and to the environment.

2.2. Separation of $GeCl_4$ from a $GaCl_3$ Solution

The sequence of experimental steps in GALLEX is shown in a simplified way in Figure 4. The process comprises three steps: 1) Separation of $GeCl_4$ from the detector tank and transfer into ca. 1 L of an aqueous solution. 2) Further concentration; conversion into germane (germanium tetrahy-

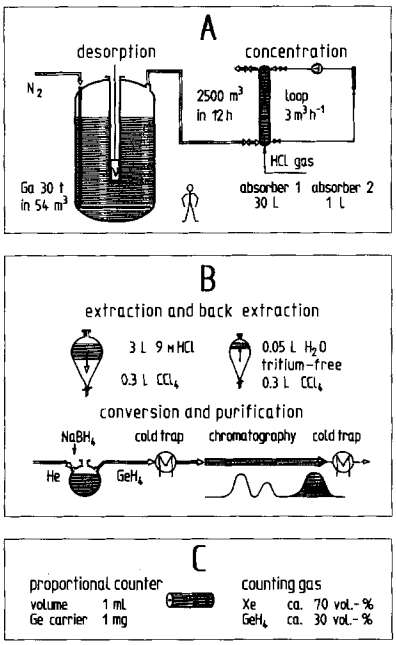

Fig. 4. Sequence of process steps of GALLEX. A: desorption, absorption and concentration in 1 L solution; B: extraction, conversion, and purification; C: counting of $^{71}GeH_4$.

dride, GeH_4); purification by gas chromatography; introduction into the 1 mL-volume counter. 3) Low-level counting and identification of the counting pulses.

Germanium tetrachloride, which is volatile in a solution acidified with hydrochloric acid, is desorbed from the detector solution by an inert gas (nitrogen) and reabsorbed in a small volume of liquid. The volatility of $GeCl_4$ depends very much on the HCl concentration (Fig. 5): at low acid concentrations, $GeCl_4$ hydrolyzes and dissolves, while it is volatile and can be expelled easily at high acid concentrations. In the target solution, however, a lower concentration of HCl is sufficient, as $GaCl_3$ contributes considerably to the volatility of $GeCl_4$.[16, 23] This is shown in Figure 6, which indicates the partition coefficients of Ge^{IV} as contours as a function of the $GaCl_3$ and HCl concentrations. The region of high volatility is shown by the grey area, reaching down to a nearly 1 M HCl concentration for an 8 M $GaCl_3$ solution. At this point, the volume of the solution, the concentration and the partial pressure of hydrochloric acid are all at a minimum. For this reason, only little inert gas is needed for desorption, and only a small amount of hydrochloric acid is discharged.

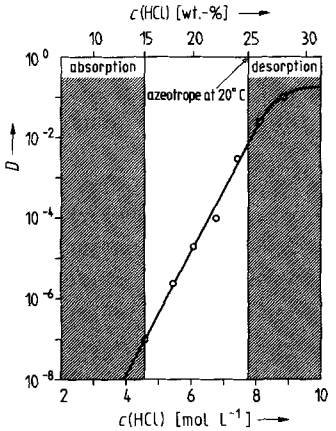

Fig. 5. Ge-partition coefficient D of Ge^{IV} in hydrochloric acid solution. D is defined as the ratio of the concentrations in the gas phase and in the liquid.

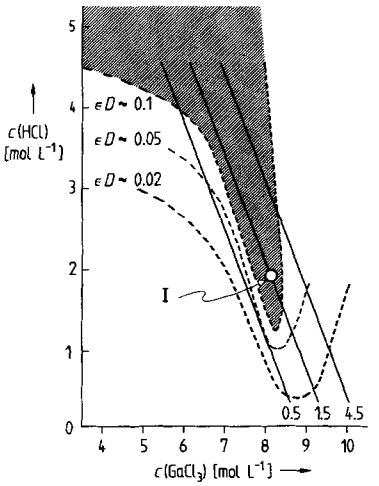

Fig. 6. Dynamic partition coefficients εD (broken curves) of Ge^{IV} as a function of the $GaCl_3$ concentration and HCl concentration; I = composition of the GALLEX detector solution; solid curves: partial concentration of the HCl over the solution. The values on the straight portions of the curves hold for 20 °C and are given in $g \cdot m^{-3}$.

When calculating desorption, it must be borne in mind that ^{71}Ge both decays and is growing-in during the desorption process. As a consequence, desorption time should be kept as short as possible. The amount of Ge is not important initially; if the desorption yield is to be determined, however, non-radioactive germanium carrier must be added; because of the small counters, this addition is limited to a quantity of 1 mg.

At a constant desorption rate, the concentration, c, of the germanium carrier in the detector solution decreases exponentially with time, t_d [Eq. (b)]; c_o is the initial concentration and τ_d is the mean residence time of Ge during desorption; it can be either measured or calculated from operating data [Eq. (c)], where $G(m3/h)$ = desorption gas flow, $L(m^3)$ = solution volume, D = Ge partition coefficient, and ε = gas phase saturation (normally between 0.5 and nearly 1).

$$R = c/c_o = e^{-t_d/\tau_d} \tag{b}$$

$$\tau_d = \frac{L}{G\varepsilon D} \tag{c}$$

When looking at processes involving only a small number of atoms, one must not forget that concentration data are mean values of a Poisson distribution.

The decrease of the ^{71}Ge concentration initially parallels that of the Ge carrier, but then flattens out at longer times.

The residual ^{71}Ge concentration ^{71}R is given by Equation (d) with R defined by Equation (b) and $A = \exp(-t_e/\tau)$, $B = \exp(-t_d/\tau)$; t_e is the exposure time, and τ is the mean lifetime of ^{71}Ge (16.5 d).

$$^{71}R = \frac{B-A}{1-A}R + \frac{\tau_d}{\tau_d+\tau} \cdot \frac{1-BR}{1-A} \tag{d}$$

The minimum concentration $^{71}R_{min}$ of ^{71}Ge in the target is found for $t_e = t_d$ to be approximately

$$^{71}R_{lim} \approx \frac{\tau_d}{(\tau_d+\tau)(1-A)} \tag{e}$$

The calculated desorption curves for the Ge carrier and ^{71}Ge from the detector tank are shown in Figure 7. They indicate that a desorption period of 12 hours is in the optimum range at a rate of 200 m^3/h; longer times will not add much more to the ^{71}Ge yield. At lower desorption rates, the desorption curve shows a correspondingly flatter shape, and the residual concentration of ^{71}Ge levels off at higher absolute concentrations. Thus, at an inert gas flow of 95 m^3/h and 20 h of desorption—the conditions prevailing in tank B in the first test series—a ^{71}Ge desorption yield of 97–98% is achieved.

The absorption of $GeCl_4$ from the inert gas in a scrubber is calculated by the model of transfer units.[24] As the $GeCl_4$ partial pressure is negligibly low over water and diluted hydrochloric acid, it decreases exponentially over the packing height. In a (1:9 scale) pilot plant the height of a transfer unit was determined and, in this way, the packing height of the absorbers in the plant was designed for a yield of 99.8%.

In the absorption process, $GeCl_4$ losses can arise also by desorption from the scrubbing acid, by entrainment of small droplets, and by condensation mist. Conditions were determined experimentally at which these losses remain below 1%; this is a very low level for a 10^5 ratio of gas throughput to scrubbing acid volume.

In the process, only the Ge-carrier can be measured to determine separation yields. While, in the detector solution, ^{71}Ge and the Ge carrier cannot be readily assumed to behave identically, after desorption, the carrier and ^{71}Ge are present in the same chemical form, $GeCl_4$, and at almost constant ratio (see Fig. 7).

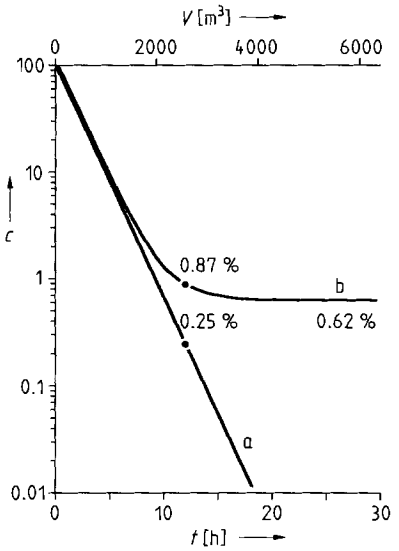

Fig. 7. Desorption of Ge carrier (a) and $^{71}GeCl_4$ (b) for a standard run in tank A (t_e = 27 d, τ_d = 2 h); c = Ge in solution in %, t = desorption time, V = initial gas volume. The percentages on the curves give the residual content of Ge carrier and ^{71}Ge relative to the initial concentration.

H_2GeO_3 solution is added as a carrier to the detector solution; however, ^{71}Ge is produced in a nuclear reaction. It is well known that recoil atoms from nuclear reactions are often present in another chemical form in an inert surrounding than the same species in a thermal equilibrium.[25] In the detector solution, which contains some 50 wt-% of chlorine, it is very probable for a ^{71}Ge atom initially to produce $GeCl_4$ after neutrino capture. As the carrier is present in the same form, also the chemical behavior ought to be the same. In addition, it was verified experimentally that ^{71}Ge atoms produced in the solution as a result of the β-decay of ^{71}As (EC, β^+, half-life 64 h), can be desorbed just as easily as a stable Ge carrier added at the same time.[16, 26]

2.3. Counting Gas and Low-level Counting Technique

The chemical procedure for quantitatively converting the separated germanium into GeH_4 was developed at BNL and, in contrast to the process steps up to this point, can be carried out on a laboratory scale. After acidifying the 1 L of concentrate, the Ge is transferred into 50 mL of low-tritium water by extraction with CCl_4 and back-extraction. Low-tritium $NaBH_4$ is added to convert it quantitatively into 0.3 mL of GeH_4 gas at a temperature of 90 °C and at a pH of 11. The GeH_4 is purified by gas chromatography and the gas volume is then measured for yield determination. Finally, the 0.3 mL of GeH_4 is mixed with 0.7 mL of xenon, and counted for six months in a gas proportional counter. Roughly 8 h pass from the beginning of extraction to the start of counting.

Counting these few ^{71}Ge atoms requires a special effort. The Heidelberg MPIK developed the miniaturized gas proportional counters of the Davis type to the ultimate level worldwide, especially in terms of low background count rates and high counting yields.[27] The high standard of the HD2 Fe/Si type GALLEX counters has contributed decisively to the possibility of running GALLEX on only 30 t of Ga.

^{71}Ge atoms decay by electron capture (K 87.7%, L 10.3%, M 2.0%), emitting Auger electrons and X-rays.[28] Because of their low energies of 10.4 (K capture) and 1.2 keV (L capture), these produce point-type ionization events in the counting gas which result in a rapid pulse rise. Pulse shape analysis allows these pulses to be differentiated from the slowly rising pulses of the high-energy Compton electrons or β-particles which produce extended ionization tracks. Figure 8 is a plot of counting pulses versus energy and rise time. The ^{71}Ge pulses are located in the K and L counting windows with a probability of 95%. The background count rate in the windows is approximately 2 pulses per month or even less in a few selected counters.

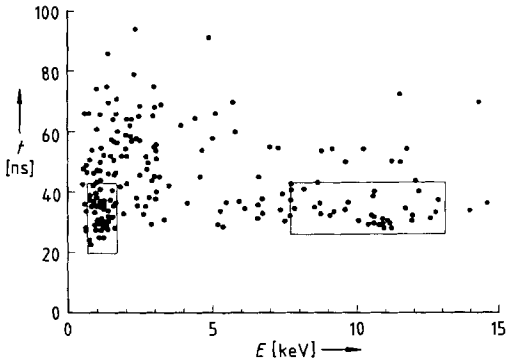

Fig. 8. Plot of pulses as a function of the energy E of the pulse and pulse rise time; as rise time t, the time for the pulse energy to increase from 10% to 70% of the maximum value was taken. The diagram shows all ^{71}Ge pulses of the first ^{71}Ge series of measurements during the first ^{71}Ge half-life (16.5 d) (after Ref. [6]).

Where counters are operated in the well of a large NaI pair spectrometer for simultaneous γ-counting, additional information about the types of decaying nuclides can be obtained by coincidence measurements from the γ-quanta emitted, albeit at the expense of a slightly higher background of ca. 1 pulse per week. Consequently, ^{68}Ge-decays can be distinguished from ^{71}Ge not only by their longer half-lives, but also by the delayed coincidence of the γ-radiation of the ^{68}Ga daughter. Decays of ^{69}Ge can be identified by direct γ-coincidence.

3. Process and Equipment

3.1. Process Concept

For the chemical form of the Ga target, either gallium metal (melting point, 29.8 °C) or a $GaCl_3$ solution can be used. Preparatory earlier work at BNL had decided in favor of the $GaCl_3$ solution, and a number of experiments were run, some of which were on a pilot scale, with 1.3 t of $GaCl_3$. The two types of target were evaluated primarily in terms of the simpler chemistry and process technology associated with the separation of ^{71}Ge from the $GaCl_3$ target. On the other hand, two advantages of the metal target are its ten times lower specific volume and lower sensitivity to trace impurities.

Modern technology in the making of containers of fiberglass-reinforced vinyl ester lined with PVDF (polyvinylidene fluoride) allowed the entire 100 t of $GaCl_3$ solution to be accommodated in one tank, which greatly facilitated the process engineering and operational aspects of desorption.[30] The properties of fiberglass-reinforced tanks with respect to corrosion resistance and weight exhibit clear advantages compared to enamel tanks. As hydrochloric acid has to be handled in an underground laboratory with a low rate of air exchange, and earthquakes had to be taken into account as well, a second tank, a large spill tray and emergency dump tanks (100 m^3) were necessary.

For desorption, a choice had to be made between a loop system and an open once-through system. The loop system seems to offer advantages because of its insensitivity to external impurities. The advantage is bought, however, at the expense of a more complicated process flowsheet. Consequently, that option was not pursued further, especially because of the impossibility of obtaining a suitable compressor (approx. 30 kW) resistant to hydrochloric acid. For this reason, a once-through flow system was designed in which liquid nitrogen is evaporated to provide the required desorption gas.[29, 30]

For the absorber system, three commercial glass columns with coolers in the circulating scrubbing acid were used. A three-column version is also easy to adapt to a loop mode of operation.[30] Concentration, i.e., the desorption of $GeCl_4$ from the scrubbing solution and reabsorption in a small column, was mainly carried out in laboratory-scale equipment; care had to be taken to minimize holdup and dead volumes.

All the materials used must be examined for corrosion, compatibility with germanium, and also for α-emitters; the latter can produce fast neutrons. Special attention had to be paid to the glass fibers used for the tank construction, and also to the substances to be put into the tank. For the glass fibers, so-called S2-type glass manufactured by Corning (USA) was used; it had by far the lowest contents of uranium and thorium among all glass fibers available.

3.2. Process Flowsheet

At the beginning of a run a carrier solution containing 1 mg of an enriched stable Ge isotope is added to the $GaCl_3$ solution. After three or four weeks of exposure time, desorption is carried out with 2500 m^3 of nitrogen over a period of 12 hours. Approximately 0.2% oxygen is added to keep the oxidation potential high enough to prevent the reduction of Ge^{IV} to non-volatile Ge^{II}. In each run, desorption is monitored by measuring the gas throughput and the amount of HCl in the scrubbers. $GeCl_4$ and HCl (roughly 4 kg) are absorbed from the gas flow by circulating water at 10–12 °C. In this step, the HCl content in the scrubbers must not exceed 15% if losses of Ge are to be avoided reliably. After the desorption process, all of the germanium is contained in the first scrubber in a volume of 25–30 L. The scrubber is then detached from the system and connected to the small concentration loop. After evacuation to 0.1 bar and acidification to 30% with electronic grade HCl gas, $GeCl_4$ is expelled from the scrubbing acid by means of a recirculating gas flow of 3 m^3/h and transferred to the small absorber of the concentration loop. After careful rinsing of the small absorber, all Ge is contained in ca. 1 L of diluted hydrochloric acid. The Ge yield is determined by atomic absorption spectrometry. Additional chemistry further concentrates the germanium, which is finally converted into germane.

To minimize ^{71}Ge losses due to radioactive decay, roughly 1% decays within four hours, all process steps must be performed as quickly as possible. Losses of ^{71}Ge can be tolerated if a faster operation ultimately results in the same amount of ^{71}Ge to be filled into the counters.

3.3. Yield Determination

The yield of the Ge carrier must be high and amenable to reliable predetermination. Since the chemical behavior of ^{71}Ge and Ge carrier is identical, the ^{71}Ge yield can be calculated from the carrier yield.

The yield is related to the amount of Ge carrier added at the beginning of each run. In a sequence of identical runs, losses caused by incomplete desorption are offset by the amounts left over from earlier runs, which affects the yield of an individual run as determined from the GeH_4 volume. Because carriers containing Ge isotopes enriched to different levels (^{72}Ge, ^{74}Ge, ^{76}Ge) are used, mass spectrometry can be used to determine whether Ge has been carried over from earlier experiments or from some outside source. This mass spectrometric examination of the counting gas is done at the end of the counting period. Consequently, the ultimate yield is not known until six months after completion of counting.

3.4. Technical Equipment

The entire facility is located in the process building in the southern wing of hall A (Fig. 9); only the supply of nitrogen gas is situated outside the building. The counters are installed in an adjacent low-level building. The process building is 14.6 m long, 9.2 m wide, and 9.6 m high. It includes the two detector tanks, the absorber system, the laboratory apparatus for the production and purification of germane, and a number of auxiliary systems (Fig. 10). The exhaust air of the building ventilation system and the building atmosphere

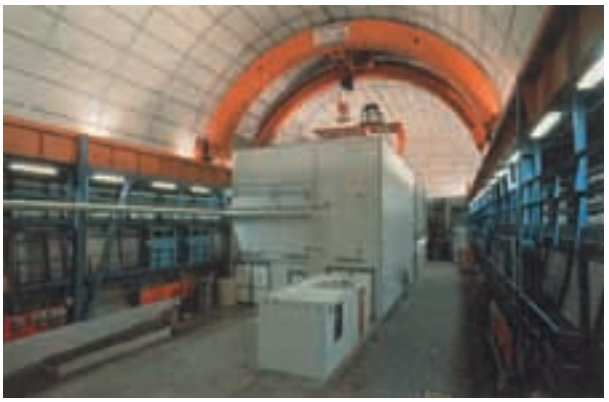

Fig. 9. GALLEX process building in hall A of the LNGS underground laboratory.

are passed through scrubbers and continuously monitored for HCl.

A general overview of the technical equipment is given in Figure 11. The detector tanks are two 70 m^3 vessels of vinyl ester resin reinforced with fiberglass, with an inner lining of 4 mm of PVDF; the outer dimensions are 3.9 m diameter and 7.8 m overall height. These dimensions just barely allow the tanks to be transported inside the tunnel (Fig. 12). The central tube to accommodate a calibration neutrino source exists only in tank A. The sparging system in tank A has been designed for a gas flow of 250 m^3/h and is made up of four concentric pipe rings perforated at the bottom. The sparging system in tank B consists of only one pipe ring and has been designed for ten times lower gas throughputs. The

solution contained in the tank can be thermostated at temperatures between 10 °C and 60 °C by means of tube bundle heaters; for thermal insulation, the tanks are enclosed in plastic film jackets. The inner surfaces of the tank, the supply ducts and pumps are all made of PVDF.

The absorber system consists of three commercial glass columns with diameters of 0.3 m and heights of 3.5 m, connected in series. The exchange regions are filled with 12 mm glass helices and have been designed for a maximum gas throughput of 250 m^3/h (gas flow rate, approx. 1 m/s). The scrubbing water can be thermostated to a temperature slightly above the dew point of the environment (8 °C) by means of heat exchangers made of tantalum.

4. The $GaCl_3$ Detector Solution

4.1. Supply and Specification

Purchasing the very large quantity of 30.3 t of gallium as a highly concentrated $GaCl_3$ solution that met special purity criteria was difficult to achieve in a relatively short period of time. The $GaCl_3$ solution was prepared at a Rhône-Poulenc facility in Salindres (France) and delivered to LNGS between December 1988 and May 1990; a total of 46 batches of roughly 2.2 t each arrived in specially designed shipping casks. All batches were carefully examined for weight, composition, and critical impurities before they were added to the contents of the interim storage tanks in the outer experimental hall. All of the batches met GALLEX acceptance criteria. The chemical analyses performed in three different laboratories yielded results which were in surprisingly good agreement. The specifications and the measured mean values

Table 2. Comparison of the measured and specified values of the GALLEX detector solution.

	Measured	Specified
Ga content [g L^{-1}]	567 ± 2	565 ± 10

[a] These values give a ^{71}Ge contribution of 1% according to the SSM.

are listed in Table 2, while the composition and the characteristics of the detector solution are shown in Table 3. The

^{68}Ge done at KfK and TU-Munich. The initial ^{68}Ge concentration roughly corresponded to the Ge-carrier concentration in a run. The desorption curve initially shows an exponential decrease but then flattens out below 0.1% (Fig. 13).[33] This less volatile fraction of germanium, which is also called the tail, is a sensitive indicator of trace impurities difficult to detect in any other way. Additional checks indicated the tails to have most likely been caused by traces of silicic acid.[31-33]

In an experiment conducted at such an extremely low level, the presence of a mere 60 atoms of ^{68}Ge, a figure eight orders of magnitude below the detection level of contamination monitors, can still double the counting background. This exemplifies the special care that must be exercised when working in the GALLEX facility.

Table 3. Composition and properties of the detector solution; 8.13 M $GaCl_3$, 2.0 M HCl.

composition of the solution, with approx. 76 wt-% $GaCl_3$, is rather like that of a "molten salt"; physicochemical data of diluted $GaCl_3$ solutions can be extrapolated only with great reservations. The solution carbonizes organic material, very much like concentrated sulfuric acid does, and is highly corrosive in the presence of air. This was taken into account in designing the process flowsheet by reducing all operations with the solution to the absolute minimum. Radioactive trace impurities due to the natural decay series in all of the delivered batches were measured by means of activation analyses for U-238 and Th-232, and Rn-222 desorption for Ra-226.[22, 32] In many instances, the radioactive impurity levels were far below specifications (see Table 2).

The existence of chemical impurities critical to $GeCl_4$ desorption was checked in samples of the detector solution by measurements of the desorption behavior of carrier-free

4.2. Predesorption of Cosmogenic Germanium

As soon as the installations in the underground laboratory permitted, the detector solution temporarily kept in the outer experimental hall was transported into the tunnel in a 10 m^3 container. Germanium produced by cosmic radiation was outgassed shortly before the transport. Figure 14 shows an interior view of the outer experimental hall with the technical equipment, the transport tank, an absorption column, and tanks for interim storage. Desorption of each of the eight transport batches was performed with 1000 m^3 of nitrogen during 24 hours. Desorption was monitored with a few mg of Ge carrier by concentration assays of the scrubbing acid with atomic absorption spectrometry. As is shown

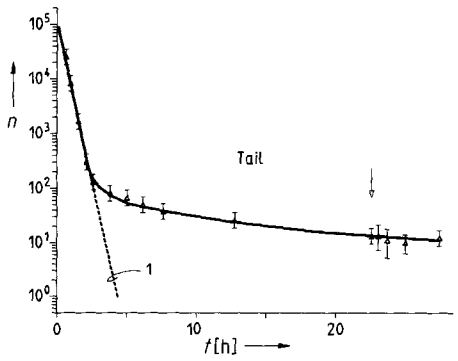

Fig. 13. Plot of ^{68}Ge-stripping from the detector solution; 1 = ideal stripping. n = number of ^{68}Ge pulses per mL. Values plotted after the arrow were recorded after 80 d.

Fig. 14. Interior view of the outer experimental hall with transport and storage tanks and weighbridge in foreground.

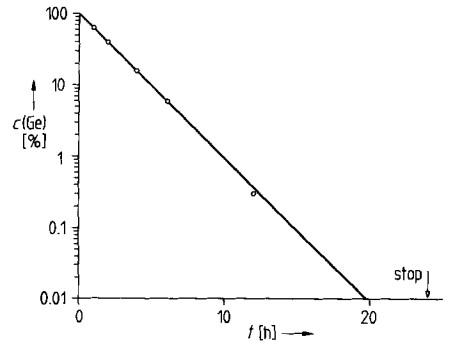

Fig. 15. Decrease in concentration of the Ge carrier during pre-desorption.

in Figure 15, an exponential desorption curve over two and a half orders of magnitude was obtained.

Only rough estimates can be made of the quantities of cosmogenic Ge radioactivity removed in the pre-desorption and of the fraction carried on into the tunnel. Existing measurements[16, 34] estimate the cosmogenic production of ^{71}Ge at sea level to be some 1000 atoms per day per ton of gallium. The production of ^{68}Ge and ^{69}Ge is roughly two and three times larger, respectively.[16, 35] In the outer experimental hall located roughly 1000 m above sea level the entire rate of Ge production is higher by a factor of two.[36]

When the gallium solution was manufactured, also the cosmogenic germanium was separated; but new cosmogenic germanium was produced in the solution during transport and storage. Averaging over the post-production periods of all 46 batches results in nearly saturation activity for the shorter lived ^{69}Ge and ^{71}Ge isotopes, and in a value of roughly 30% of the saturation level for the long-lived ^{68}Ge. The ^{68}Ge desorbed was measured in three pre-desorption steps. Extrapolation to the total quantity indicated about 18×10^6 ^{68}Ge atoms at the end of the storage period, or a saturation level of approx. 6×10^7 atoms, which is in good agreement with the estimate.

After pre-desorption, less than 0.1% of the volatile cosmogenic ^{68}Ge remains in solution. However some Ge activity grows in during desorption in the transport tank (six hours germanium mean residence time) and over the approximately four hours of transport into the tunnel; this corresponds approximately to 10 hours of exposure time. On the basis of these data, the number of cosmogenic ^{68}Ge atoms carried into the tunnel can be estimated at some 60000 (ca. 1 atom/L). Even this quantity upsets the measurement of ^{71}Ge; consequently, pre-desorption must be completed underground. If all ^{68}Ge atoms existed in a volatile form, three outgassing steps would be sufficient. If there are tails, the desorption is delayed and requires additional measures to be taken. For the short-lived ^{69}Ge, and for ^{71}Ge, this problem is solved automatically by the decay within a few months.

4.3. ^{68}Ge Desorption in the Detector Tank

The entire detector solution had been transferred to tank B by June 1990. The procedure employed to remove the residual ^{68}Ge activity was identical with that used in ^{71}Ge runs. After the first few runs, the release of ^{68}Ge was seen to be persistent at a level of 100–200 atoms/d, which was considerably higher than the tolerable amount of ≤ 3 atoms/d (Fig. 16). Blank tests were carried out to verify that the release was not simulated by memory effects in the absorbers or other parts of the equipment. The sparging system in tank B was run far into the overload range at a throughput of up to 95 m^3/h in order to attain the necessary desorption yields over a period not exceeding 20 hours. The resultant absorption losses due to solution entrainment and condensation mist amounted to a few percent. For the purpose of ^{68}Ge removal such losses were tolerable.

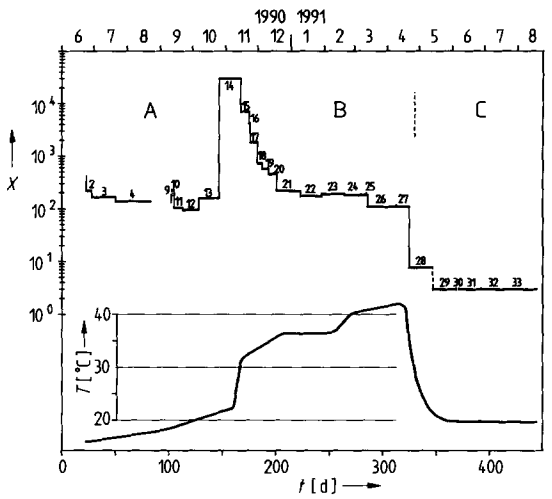

Fig. 16. Release x of ^{68}Ge in atoms per day in tank B (runs B2–B33) during the temperature treatment of the tank solution (lower curve). A: cold runs; B: warm runs; C: cold runs, ^{71}Ge measurement. The measurements relate to the period from June 1990 to July 1991 (upper scale).

The properties of the ^{68}Ge tails in the detector tank do not have to agree with those examined in the laboratory, as their concentrations differ by several orders of magnitude, and as they also have different histories. Consequently, an attempt was made to characterize the release rates by adding more carrier (four runs (B5–B8) with 10 mg each of Ge carrier), and by conducting runs with different exposure times (B9–B13). The persistent high release level (Fig. 16) documents the inertness to isotopic exchange of the tail species and is indicative of a uniform release from a deposit of ^{68}Ge which, at room temperature, does not decrease greatly beyond the lifetime of ^{68}Ge.

This was followed by thermal treatment; the solution was heated to 42 °C over a period of six months, left at that temperature for some time and then cooled again. Desorptions were carried out periodically during this period. When the solution was first heated to a temperature above 30 °C, some 600000 ^{68}Ge atoms were removed, which corresponds to some 5% of the original cosmogenic ^{68}Ge inventory. Despite further heating, the release rate then gradually dropped to the original level of approximately 100 ^{68}Ge atoms/d. Under the assumption that the release originated from the decomposition of a Ge tail species with an activation energy of approx. 100 kJ/mol, it was to be expected that the release of

^{68}Ge would drop back to the desired low level of ≤ 3 ^{68}Ge atoms/d after cooling (runs B27 and B28). After this was verified, it was possible to start the first measurement of ^{71}Ge produced by solar neutrinos. It was decided to continue these runs in tank B.

5. First Experimental Operation

5.1. Germanium Yields

When measuring the ^{71}Ge production rate in tank B, attention had to be devoted again to attaining high absorption yields. The absorption yields of $GeCl_4$ and HCl in the three columns are listed in Table 4 for various operating conditions. The numbers are averaged over runs conducted under the same operating conditions. In normal operation in tank A, $GeCl_4$ and HCl are absorbed at a rate in excess of 99% in the first column. Overload operation of the sparging system in tank B results in the formation of condensation mist and partly transfers these compounds to the second and third columns, where they are completely retained. The cause of mist formation is the sharp gas jet from the perforated sparging pipes in the overload regime; per 1 m^3 of gas, approx. 0.14 mL of solution is entrained in the form of droplets approximately 1 μm in size. In the wet gas phase of the scrubbers, supersaturated with HCl, they constitute good condensation nuclei which grow in the scrubber packing to roughly four times their original diameter, thus forming a condensation mist of 8 mL/m^3. If the pressure losses are low and the gas velocities ≤ 0.4 m/s, the mist droplets can pass the scrubber packing.[37] If the pressure losses are high the last scrubber is operated slightly below the flooding point, thus reliably retaining the mist.

Table 4. Percentage absorption yields of $GeCl_4$ and HCl.

Column	1	2	3
Tank A: Gas throughput ca. 200 $m^3 h^{-1}$			
$GeCl_4$	>99	<0.5	<0.5
HCl	>99.2	<0.7	<0.1
Tank B: Gas throughput ca. 95 $m^3 h^{-1}$			
$GeCl_4$	88.5	3.4	8.1
HCl	74.3	9.1	16.6
$GeCl_4$ [a]	88.6	9.3	2.1

[a] With acidification of the mist after column 1.

$GeCl_4$ and HCl are carried over from the first column exclusively by mist. For this reason, feeding HCl gas (4 kg in 7 h) downstream of the first column acidifies the mist so that $GeCl_4$ is released into the gas phase. It is then reabsorbed in the second column. After some 80% of $GeCl_4$ from the tank had been desorbed, the HCl feed was stopped to keep the HCl concentration in the scrubbing acid of the second column below 15 wt-%. The effectiveness of this simple measure can be seen from Table 4: instead of 8–9%, only some 2% of the $GeCl_4$ is carried over into the final column and, thus, is lost to the measurement.

The yield of germanium put into the counters, as determined from the GeH_4 volume, has an average value of 91.8 ± 2.2% for all runs after B35. These values still need to be corrected for the Ge residues from the previous run, which is obtained from the isotopic composition of the germanium in the counting gas. In most of the runs conducted so far, a fraction of 98.5–99% of the carrier used was removed during desorption, which is in good agreement with the value calculated on the basis of operating data (see also equations in Section 2.2).

Table 5 summaries the Ge mass balance for the Ge carrier and ^{71}Ge for the runs performed under standard conditions in tanks A and B. The decay losses of ^{71}Ge (difference between Ge carrier and ^{71}Ge yields) depend on the time required to perform the operations. The carrier residue (and the ^{71}Ge contained) must be taken into account when estimating desorption losses. Table 6 is a summary of the yields of all runs in the ^{71}Ge series.

Table 5. Mass balance for the Ge carrier and ^{71}Ge in tanks A and B.

	Tank B	Tank A
GeH_4 yield [%]		
Ge carrier	91 ± 2	$95 + \pm 2$

Absorption	3	1
Concentration	1	1
Sampling	1	0.5
Preparation of counting gas	2.5	2

[a] Determined from operational data.

5.2. ^{71}Ge Production in Side Reactions

Contributions to ^{71}Ge production by side reactions were estimated from a number of additional investigations. The fluxes of cosmic muons and fast neutrons were measured directly in the underground laboratory.[38, 39] The integral ^{71}Ge production cross-sections in the detector solution were determined from irradiations with muon beams[35] and Pu-Be neutron sources of known intensity.[16] On the basis of the reaction cross-section and the particle flux, the ^{71}Ge production rate is calculated for the muons in the underground laboratory, which increases the expected SSM value by 2.9 ± 0.9%. For fast neutrons, the correction was found to be less than 0.2%.

The integral ^{71}Ge production rate of α-particles was measured directly in an 8 M $GaCl_3$ solution.[14, 16] On this basis, the number, Z, of α-particles required for the production of one ^{71}Ge atom was calculated by means of the approximation Equation (f).

$$\log_{10} Z = 15.36 - 0.67\, E_\alpha, \quad E_\alpha\ 4\text{–}9\ \text{MeV} \qquad \text{(f)}$$

The calculation indicates that, e.g., 1% of the value expected in the SSM is produced by 0.2 g of ^{232}Th in equilibri-

Table 6. Carrier yields in the first ^{71}Ge runs.

um with its daughters. The more effective short-lived higher energy α-emitters are generated as daughters of long-lived nuclides, which is why the long-lived radioelements of the natural decay series must be monitored very accurately. In our present environment, transuranium elements should also be included in these checks. Consequently, α-spectrometric assays for transuranium elements and for ^{210}Pb, ^{210}Po, and ^{228}Ra were carried out.[40] Investigations conducted so far have shown the sum total of all known contributions by side reactions caused by α-emitters to be below 0.2% of the expected standard solar signal.

The gallium detector solution is much more sensitive to fast neutrons ($\geq$0.4 MeV) than to α-particles. In the case of heavy nuclei, such as ^{244}Pu and ^{252}Cf, the emission of neutrons in spontaneous fission contributes more to the production of ^{71}Ge than do the α-particles emitted at the same time. As α-spectrometric analysis is too insensitive, global detection of spontaneous fission events in the tank by separating and measuring the ^{133}Xe fission product (half-life, 525 d) is currently being organized. In addition, more information about spurious side reactions is to be obtained by way of measuring the production of ^{69}Ge.

5.3. Results of the Series of ^{71}Ge Measurements[6]

Between May 1991 and April 1992, 16 runs with either 3 or 4 weeks of exposure time and five runs with short exposure times (ca. 1.2 d) were performed (runs 29 to 50). The short runs serve as blank tests in which Ge activity carried over is detected; they were spread over the entire measurement period and provided very low levels of 6(+12, −6)% of the SSM signal, consistent with a null result.

The counting gas yields (Table 6) comprise all operations, including filling of the counting gas into the counters. The counting periods of 13 runs had not been completed by June 1992, which means that precise determination of the counting background has not yet been accomplished. The results obtained in the first counting period comprise a total of 295 days of exposure.

The counting pulses due to ^{71}Ge were selected on the basis of pulse energy and rise time. Figure 8 shows all the pulses registered during the first lifetime of ^{71}Ge. The two "counting windows" for the K and L peaks were determined by calibration for each counter. A maximum-likelihood-analysis was applied in calculating the rate of ^{71}Ge production from the pulses within the two windows.[41] The original number of ^{71}Ge atoms was obtained by assuming a half-life of 11.43 d for ^{71}Ge and a constant background. The results are summarized in Figure 17; the diagram contains the count rates (in pulses/d) of all L and K pulses of 14 runs plotted as a function of counting time. The solid line represents the best fit with the measured value of the counting background. Figure 18 shows the results of the individual ^{71}Ge counting runs. Monte Carlo simulations showed deviations to be within the statistical error range which, because of the small total number of pulses (an approximate aggregate of 70), is still relatively high.

Analysis of the counting pulses indicated a mean rate of ^{71}Ge production in the detector tank of 0.80 ± 0.17 ^{71}Ge atoms per day. As, in astrophysics, one neutrino capture per second per 10^{36} target atoms is called 1 SNU

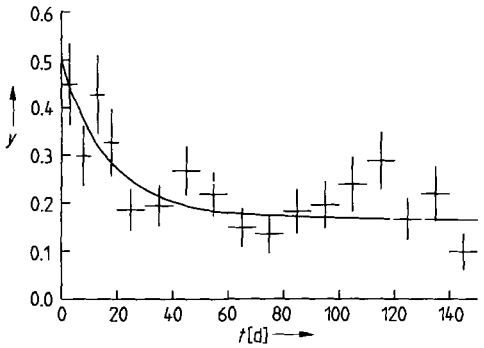

Fig. 17. Decrease in ^{71}Ge count rate (number of pulses per day y) averaged over 14 runs (after Ref. [6]).

(Solar Neutrino Unit), the resultant value is 90 ± 19 SNU. The corrections to be subtracted from this value are: 1) induced by muons, 3.7 ± 1.1 SNU; 2) due to α-emitters in the detector solution, 0.2 SNU; 3) due to fast neutrons, 0.15 ± 0.1 SNU; 4) due to radon, 2 ± 1 SNU; 5) because of ^{69}Ge from muons and ^{8}B neutrinos, 1 ± 1 SNU.

In addition, contributions to the systematic error by the counting yield ($\pm 3.6\%$), the definition of the limits to pulse rises ($\pm 1.6\%$), and the chemical yield ($\pm 1.5\%$) must also be taken into account. The result then obtained for the flux of solar neutrinos is given by (g) or (h).

$(83 \pm 19$ [statistical] ± 8 [systematic]/SNU (for 1σ error) (g)

$(63 \pm 14$ [statistical] ± 6 [systematic])% of the expected value of 132 SNU in the SSM (h)

This average SNU value is shown on the far right in Figure 18. A fit to the measured values in Figure 17 produced a value of the lifetime of ^{71}Ge of 13.5 ($+5.2 - 3.5$) d, which is in statistical agreement with the known value of 16.5 d.

Evaluation of this result[7] in the light of the theories about stellar structure and the fusion reactions inside stars as well as the properties of neutrinos allows the conclusion to be drawn that GALLEX, for the first time, has proved the existence of low-energy pp neutrinos originating in the main reaction of the Sun. The result of GALLEX may be in agreement with the SSM if the error, which is still relatively large, is taken into account. As far as the question of whether neutrinos have a rest mass is concerned, the findings are not that unequivocal. However, it is possible to indicate limits to the neutrino mass together with the results of the chlorine experiment[11,2] and the measurements conducted in the Kamioka detector[10] and, perhaps even more important, to exclude certain ranges of mass. Consequently, the most probable region of the difference between the squared masses of electron neutrino the muon neutrino seems to be around 10^{-5} eV, which would lead to a mass of a few 10^{-3} eV for the heavier muon neutrino. For astrophysical purposes, this value is too small to explain the "missing" mass in the universe.

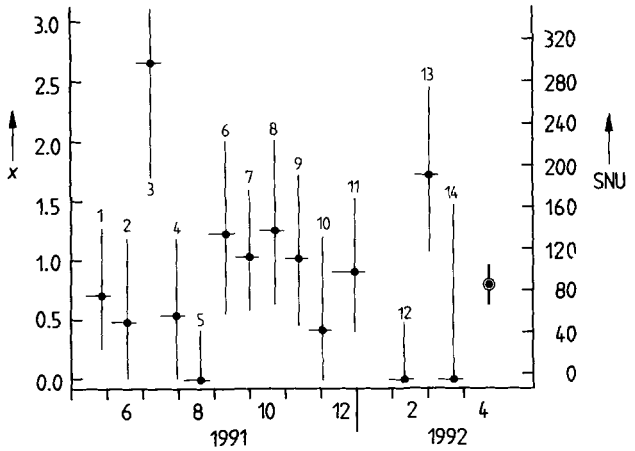

Fig. 18. Results of the first series of measurements (May 1991 – April 1992, 14 runs). The mean value is given on the extreme right (after Ref. [6]). x = ^{71}Ge production in atoms per day (after Ref. [6]).

6. Outlook

The GALLEX experiment is scheduled to run for a period of four years. The accuracy of the final result depends critically on high yields of ^{71}Ge and on tight checks being kept on all credible side reactions. The latter aspect will continue to be worked on intensively. However, even checks on further side reactions are not expected to lead to any fundamental change in the results obtained so far. As far as yields are concerned, we have reached a satisfactory point beyond which no significant improvements are possible, especially now (since June 1992) that desorption is being performed in tank A, specifically designed for that purpose.

Measurements of the ^{71}Ge production by solar neutrinos were continued after August 1992 (2nd period of operation) and are planned to continue for another year. At intervals of four weeks, runs with 27 d and runs with 1 d of exposure are to be performed alternately. A large number of short runs allows, by extrapolation to zero exposure time, a background level for the production of ^{71}Ge to be measured and spurious effects due to extraneous Ge activity to be excluded.

An important confirmation of the measured results is the calibration of the GALLEX detector with a chromium-51 neutrino source (half-life 28 d), which is produced by the irradiation of enriched chromium-50 metal in the Grenoble high-flux reactor. It will have an intensity in excess of 1.5 MCi and produce a ^{71}Ge signal in the detector solution which, initially, will be ten times stronger than that produced by the solar neutrinos. Preparations for the two calibration experiments planned after the second period of operation, for late 1993 and 1994, are on schedule. These calibration experiments are to check once more the correct conceptual design of the experiment, its setup, and the execution of all operations. Afterwards, there will be another two years of solar exposures in order to reduce further the statistical error in the result.

When, after four years, a final result about the fusion reactions in the Sun will be in hand, this certainly will not be the end of the GALLEX mission. The question of a relationship between longer-term fluctuations of the neutrino flux and the eleven-year sunspot cycles may be another worthwhile activity for GALLEX.

Scanning Tunneling Microscopy and Atomic Force Microscopy in Organic Chemistry

By Jane Frommer*

When Kekulé awoke from dreams of snakes biting their own tails, he didn't have the benefit of a scanning tunneling microscope (STM) image to confirm that his vision of benzene as a cyclic molecule was accurate. References to STM in the chemical literature increase steadily, although the technique was perhaps oversold in its early days of the 1980s, with such promises as DNA sequencing and tailored bi-molecular chemical reactions (literally, two molecules). Publications alternate between attempting to explain the process by which images of traditional insulators are obtained and simply presenting the end images themselves as stunning views of atoms and molecules. While imaging mechanisms are still being debated, these instruments' ability to "see" single molecules has been established, albeit at the fringes of our expectations. For example, whereas STM studies at present might not be able to answer the question of why adsorption of CO doubles the density of platinum atoms on the surface of a single crystal of the metal, the images go far in illustrating that this *is* a process which platinum undergoes. As with any emerging analytical tool, these scanning, very localized microscopic methods are undergoing the growing pains of irreproducible results and mis-marketed artifacts. Nonetheless, we assemble here, primarily for the uninitiated, a collection of careful and credible studies to mark the progress of scanning tunneling microscopy and atomic force microscopy into chemistry, and to encourage a healthy blend of idealism and skepticism toward future work.

1. Introduction to the Scanning Tunneling Microscope

In 1986 a Nobel prize was awarded for scientific progress made five years earlier: a microscope based on electron tunneling.[1] What about this instrument endowed it with such recognition? This new imaging technique enabled *direct atomic-scale* measurements to be made. This high-resolution measuring and imaging technique afforded an enormous magnification, allowing atomic information not from an average over many atoms, but rather recorded locally, atom by atom. The development of this method continues in new directions; it is a dynamically evolving method rather than a mature one.[2]

The operating principle of the scanning tunneling microscope (STM; this abbreviation is used for the instrument and the technique) takes advantage of an electrical current that flows between two conductors that are separated by very small distances, typically angstroms. This current, known as the tunneling current, is an electrical current through an extremely thin, insulating layer such as vacuum, air, or liquid. The electrons "tunnel" through this electrically insulating layer, giving rise to a measurable current which displays an exponential dependence on the distance between the two conductors, that is, the thickness of the insulating layer [Eq. (a)] where I is the tunneling current, V is the voltage applied across the two conductors, φ is the effective tunneling barrier (eV), c is a constant, and s is the spacing between the two conductors (Å).[3]

$$I \propto V \exp(-c\sqrt{\varphi}s) \qquad \text{(a)}$$

It is the *exponential* dependence of the tunneling current on the distance between the two conductors (STM tip and the analyzed surface) that provides the sensitivity of the measured current that can be interpreted as the surface structure. As the equation shows, other factors influence the current as well, such as the electron band structure of the two conductors (φ).

At the time of the STM's conception,[4] the theories of tunneling were not new. Indeed, experimental setups were already in operation, mostly in the form of planar tunnel junctions.[5] The novelty of the STM arose when the mechanics of piezoelements became refined enough to allow control over motion on the subangstrom scale.[6] This control enables positioning a probe over an individual atom and scanning it over an array of atoms, thereby providing a surface analysis with atomic resolution (Fig. 1). In the STM, the probe is one of the two conductors, configured as a tip. A very localized stream of electrons tunnels from it to the second conductor, the surface being analyzed. As the tip is scanned over the surface, the tunneling current is collected

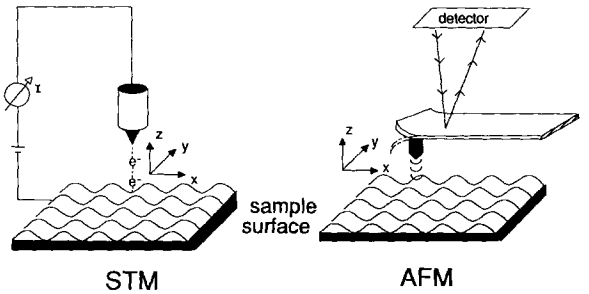

Fig. 1. Schematic illustration of the scanning tunneling microscope and the atomic force microscope, highlighting their common feature of a localized probe that scans a surface composed of atomic or molecular features and collects data directly over very localized sites of angstrom or nanometer dimensions.

from a series of points, angstrom by angstrom, that is, on the level where atoms are joined together. When this atomic information is pieced together laterally, like the pieces of a puzzle, an image of the whole is obtained, be it the face of a crystal lattice or the backbone of a hydrocarbon chain.

By monitoring the tunneling current over each point (x, y) on a surface, the electronic topography of a surface is recorded experimentally. In cases of homogeneous materials, such as a metal single crystal, this current map reflects the surface topography; atoms appear as "hills" of higher current and the bonds between them as "valleys" of lower current. Figure 2 is a map of the tunneling current that flows between the tip and surface as the tip is scanned piezoelectrically over a (7×7) reconstructed[*] silicon (111) surface.[7] It reflects the atomic surface structure of the sample displayed as an array of single atoms that make up the sample. The STM's atomic resolution arises from the extremely narrow stream of tunneling electrons which is spatially confined between a few atoms on the tip and a few atoms in the sample.

Lattice parameters are available from other techniques, such as X-ray and neutron scattering. Where, then, does the STM offer an advantage, or an improvement in our previous knowledge? A fundamental difference is the scale on which the STM collects its data: an STM image is not the result of averaging over large areas containing many atoms; rather it is a composite picture of data points collected separately and directly over each individual atom. By avoiding both the averaging of data from many sites and the Fourier transform from reciprocal space, information can be obtained for very localized features such as an irregular atomic defect, a grain boundary, or small, irregularly shaped domains. Figure 2b contains two examples of defects in a silicon lattice: a shifted atom and a vacancy or reacted atom These details would be lost in analytical techniques that provide atomic information from averaging data from many sites.

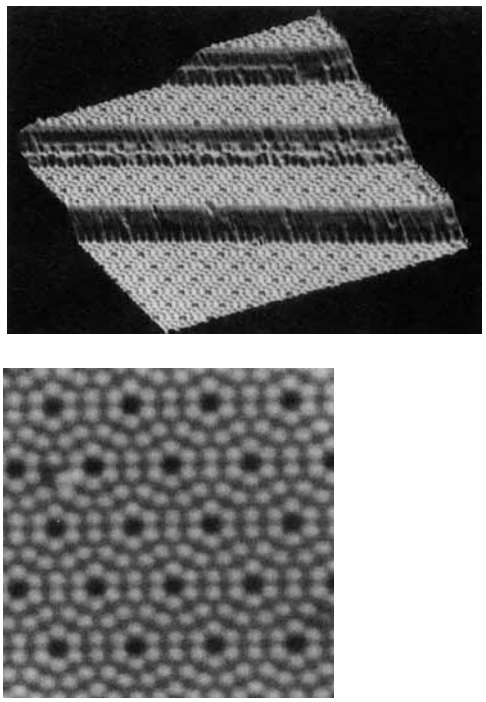

Fig. 2. STM images of a silicon (111) crystal (7×7) reconstructed surface resolving atomic spacing[7]: a) a 3-D rendition of a scan (size 320×360 Å^2) showing three steps of varying heights up to about 12 Å high. The step heights are multiples of the silicon (111) double-layer height of 3.13 Å. b) Top view of a $(100 \times 100$ Å^2) scan. Two defects can be seen in this image: a shifted adatom (top left) and a reacted adatom or surface impurity (bottom right).

1.1. Units

In this article, measurements will be discussed that have been performed with the STM on organic molecules, rendering information from the angstrom scale to the submicron scale, that is, from intramolecular features such as bond lengths and angles to intermolecular spacings and long-range packing. Data from the atomic force microscope (AFM) are collected over nanometers to microns (Section 9). Resolution with the AFM is currently limited, principally by tip geometries, to molecular resolution on organic molecules; however, interatomic spacing is often obtained for inorganic salts.

Results are reported in units of angstroms (10^{-10} m) or nanometers (nm, 10^{-9} m). For reference, examples of bond lengths are 1.4 Å between lithium and fluorine atoms in a LiF crystal, 2.2 Å between silicon atoms in a Si single crystal, 1.5 Å between adjacent carbon atoms in an alkane, and 1.4 Å between carbon atoms in benzene. Within the context of organic solids, intermolecular spacings (e.g., noncovalent bonding interactions due to van der Waals forces) are on the order of 3 to 10 Å.

[*] On reconstructed surfaces the surface atoms are arranged differently from the bulk crystal to minimize energy. In the case of Si(111), (7×7) reconstruction means a rhombohedral unit cell, the sides of which are seven atoms long (see also ref. [1]).

Jane Frommer was born in 1952 in New England (USA). She obtained her Bachelor of Science degree in chemistry in 1975 from Tufts University (Massachusetts) after carrying out an undergraduate research project at MIT in mechanistic organic chemistry. Following a year of research in Vitamin D photobiochemistry at Massachusetts General Hospital Endocrine unit, she entered California Institute of Technology (Pasadena) where she obtained a Ph.D. in organometallic chemistry in 1980 under R. G. Bergmann. Since 1980 she has been active in industrial research laboratories, first at the Allied Corporation (New Jersey) and then at IBM (Almaden Research Laboratory, San Jose, CA, USA). Her research areas have included electronically conducting polymers and STM and AFM investigations of molecular interfaces. Since 1990 she has been on sabbatical from IBM at the Physics Institute of the University of Basel, Switzerland.

1.2. The Scanning Tunneling Microscope

An STM workstation consists of several components (Fig. 1). The actual measuring device is mounted on a stable surface (for example, a vibration isolation table). At the heart of the device, a delicate metal tip scans over the sample surface. The scanning is controlled electronically with piezoelectric transducers, over spans of hundreds of microns to several angstroms. During the scan the tunneling current is recorded over each point on the sample, the signals are digitized, and an image is assembled from the collection of these points with a computer. The contrast in STM images is based on an arbitrarily chosen scale of shades of grey to indicate the magnitude of the measured currents, where high currents are typically assigned light shades and low currents dark shades. Artificial coloring is occasionally used to render data from different atoms or molecular moieties separable to the eye. The STM workstation is completed with associated hardware and software to drive the data acquisition, to convert the electronic signals into images that can be displayed in various formats, such as line scans or 3-D renderings, and finally to store the scanned information.

The electrode fashioned into a tip rarely terminates in a single-atom point; instead the effective operating area is provided by several atoms at the end of a fortuitous protrusion on the macroscopic tip. STM tips are commonly prepared by electrochemically etching a tungsten wire (about 0.25 mm in diameter) partially immersed in an NaOH solution until the end of the wire has a conical shape.[8] Platinum/iridium (80/20) wire, cut with pliers, can also serve as a tip. Ultimately it is the dependence of the tunneling process on s, the separation between the two electrodes [Eq. (a)], that defines the *functional* tip as the point on the macroscopic tip that is closest to the scanned surface. Regardless of the tip preparation method, its geometry can influence the collected image and introduce artifacts (see Section 1.5 and Fig. 3).
