At room temperature, the crystal structure of In_4Br_7 may be characterized in the trigonal space group $R\bar{3}m$, the crystal chemical formula is $(In^{3+})_3(In^+)_5(Br^-)_{14} = In_8Br_{14} = 2 \times In_4Br_7$.[6] Along the long c axis (4658 pm) are a total of five distinct coordination polyhedra stacked on top of each other. The two trivalent indium cations are found both in an approximately octahedrally shaped polyhedron, In(1), and also in an approximately tetrahedrally shaped polyhedron, In(2), coordinated through Br^- ions; the average bond lengths of $In^{3+}-Br^-$ are 267 and 247 pm, respectively.[7] Both polyhedra are already known from the structures of $InBr_3$ (octahedron) and $InBr_2$ (tetrahedron) with very similar distances of 267 and 250 pm. In comparison, the univalent indium cations exhibit very different and enlarged types of coordination polyhedra (Fig. 1), as a consequence of the special electronic configuration of In^+.[2] The In^+-Br^- bond lengths cover a typically greater range between 330–440 pm, and none of these three polyhedra has been observed up to now in the known structures of the reduced indium bromides. Simple counting of the bromide ions gives the following coordination numbers: for In(3) $3+1+6=10$, for In(4) $3+6+3=12$, and for In(5) likewise $6+6=12$. Furthermore, with aid of the recently optimized bond length–bond strength parameter ($r_0 = 266.7$ pm)[2] for the In^+-Br^- combination, the empirical valences for the different univalent indium atoms are deter-

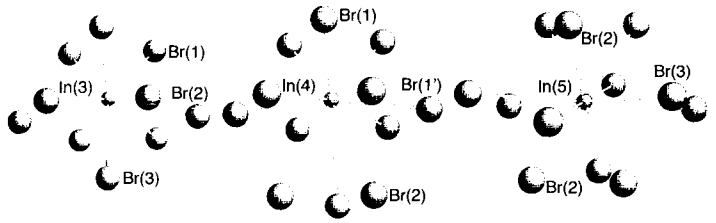

Fig. 1. Coordination of univalent indium cations in In_4Br_7. The interatomic distances [pm] are for In(3), left, 3×327.6 (−Br(1), head), 1×340.9 (−Br(3), foot), and 6×390.6 (−Br(2), waist); for In(4), middle, 3×337.6 (−Br(1), head), 6×382.0 (−Br(1'), waist), and 3×436.4 (−Br(2), foot); for In(5), right, 6×350.6 (−Br(2), head and foot) and 6×439.2 (−Br(3), waist). The standard deviations for the interatomic distances are about 0.5 pm.

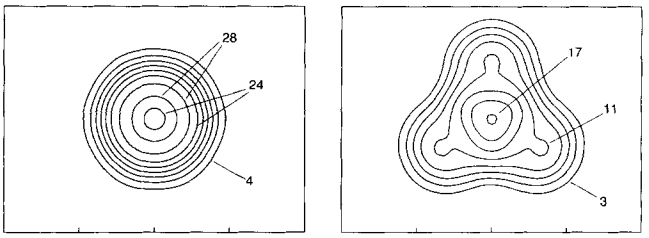

Fig. 3. Difference Fourier synthesis for In_4Br_7 at 90 K (single crystal data, $Mo_{K\alpha}$ radiation) based on the phases of the atoms In(1–4) and Br(1,2). Shown are cuts (400×300 pm^2) parallel to the *ab* plane, in the direct neighborhood of In(5), left, and Br(3), right. The contours of the electron density are given in multiples of e Å^{-3}.

mined to be 0.92, 0.74, and 0.68 for In(3), In(4), and In(5), respectively. An unusual bonding situation is already apparent from this classical description since the sums of the bond orders of the univalent indium cations are too low most noticably for In(5). Self-consistent, semiempirical calculations of the band structure[8] indeed prove that the average In^+-Br^- overlap populations are slightly lower than that of the typical In^+-Br^- interactions of +0.07[2] with values of +0.066 for In(3), +0.061 for In(4), and most significantly the value of +0.049 for the strongly reduced In(5). The shortest indium–indium interaction ($In(1)^{3+}-In(3)^+$ = 397 pm) is weakly antibonding (−0.051), which is consistent with an electrostatic interpretation.

The previously mentioned chemical and physical sensitivity of In_4Br_7 can be explained by a theoretical analysis. A calculation of atomic reactivity increments[9] makes it clear that In(5) is mainly responsible for the additionally reduced absolute electronic hardness of only 1.97 eV, compared to all other reduced indium bromides;[10] one origin for the sensitivity of this phase can thus be spatially localized in the crystal. The simple reason for this lies in the lowest lying unoccupied crystal orbital (LUCO), which is almost completely centered at the univalent In(5) ion, and which possesses $5p_{x,y}$ character (Fig. 2). The small energy gap of this LUCO from the occupied levels of the density of states leads, in connection with the weak In^+-Br^- bonding and the local symmetry $\bar{3}m$, to structural consequences:

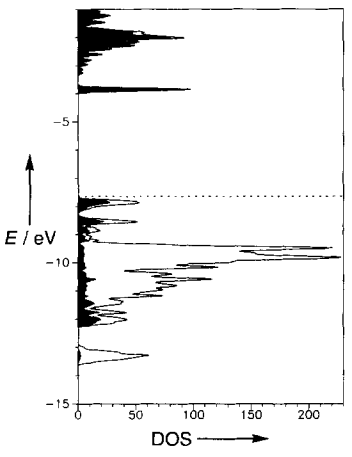

Fig. 2. Density of states (DOS) for In_4Br_7 with local projections of the univalent indium cations in black. The peak at −3.8 eV possesses nearly exclusively In(5)-$5p_{x,y}$ character.

The first low-temperature crystallographic studies prove that at 90 K In(5) is no longer found on the special position 3*a* (i.e. on the threefold rotoinversion axis), but moves away from the center of its coordination polyhedron by around 40 pm (!) (Fig. 3). As already theoretically predicted,[2] such a distortion can be easily understood as a consequence of second-order Jahn–Teller instability. This second-order effect is exactly what would be expected if the mixing of a formerly unoccupied orbital or energy band with *p*-character is possible by an atomic displacement under energy reduction. This result is achieved for In(5) at very low temperatures. Additionally, Br(3), which lies nearly in the same plane, is affected by this unprecedented structural instability of In^+ (Fig. 3).

However, a similar effect may be observed already at room temperature under different conditions. In Rietveld refinements on In_4Br_7, which continuously undergoes decay due to light and stress, and whose primary decomposition product can easily be identified and refined as $InBr_2$ (in superb agreement with the previously published data[11]), greatly enlarged displacement parameters result for In(5) and Br(3), indicating the very high mobility of these atoms in their coordination polyhedra. It is very likely that it is at this specific point that the decay of In_4Br_7 to $InBr_2$ begins through the exuding of amorphous indium. In accordance with this, an expected enhanced chemical reactivity of solid In_4Br_7 could be observed in the first attempts at reactions with likewise solid organic substances at room temperature. Currently, we are investigating these reactions which occur in just seconds or minutes.

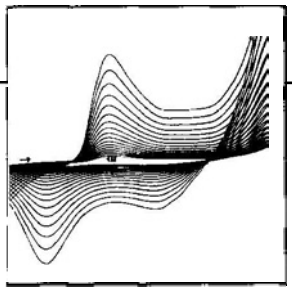
Surface Electron Transfer Processes

1995. XII, 368 pages
with 137 figures and 3 tables.
Hardcover. DM 128.00.
ISBN 1-56081-036-X
(VCH, New York)

This book gives an extensive theoretical treatment of its theme. The emphasis is on electronic coupling of molecular potentials to conducting band states. The essential role of surface electron transfer in catalysis, electrochemistry, photo imaging, and virtually all charge transfer solid state devices make this process one of the most important single chemical events.



Sandifer, J. R.

Ion-Transfer Kinetics

1995. X, 142 pages with
38 figures and 16 tables.
Hardcover. DM 165.00.
ISBN 1-56081-508-6
(VCH, New York)

In six concise, well-referenced chapters, this book covers the essentials of ion-transfer principles and applications, including computer simulation techniques for ion-transfer kinetics models.

It is addressed to chemists in academia and industry, to physical chemists and to chemical engineers.

Mechanistic Heyday

The Adventure Playground of Mechanisms and Novel Reactions. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *R. Huisgen.* American Chemical Society, Washington, 1994. 279 pp., hardcover $ 24.95.—ISBN 0-8412-1832-3

This book is one of a series in which chemists who have had an important influence on chemistry during the postwar years look back over their life's work; 22 have contributed to the series so far. For each of these authors the award of a Nobel Prize (if that had not occurred already) would come as no surprise to the scientific world. Remarkably, the list includes only one German chemist, Rolf Huisgen. This book therefore has a special importance, since it was Huisgen above all others who, through his fundamental work on reaction mechanisms which gained worldwide recognition, played a decisive role in establishing the high standing of German chemistry in the immediate postwar period.

One approaches the book with curiosity to discover which aspects of Huisgen's research he regards in retrospect as the most important and elaborates on. There are the classical studies which established arynes as important reactive intermediates. Then there are the chapters on azoles, azides, and azomethynimines, work which pointed the way to studies of 1,3-dipolar cycloadditions. At the time when the concept of the conservation of orbital symmetry in pericyclic reactions was being developed by Havinga and Oosterhoff and by Woodward and Hoffmann, it had scarcely been formulated when Huisgen tested it in the field of electrocyclic reactions applied to cyclooctatrienes, aziridines, and many other substrates. This is followed by chapters on [2+2]-cycloadditions, mainly applied to ketenes and to donor- and acceptor-substituted alkenes. Equally interesting is the insight into the beginnings of Huisgen's research, which was in the area of azo and diazo compounds and prepared the way for mechanistic studies in free radical chemistry. Of all the work described, only that in the chapter on effects in medium-sized rings no longer seems to find an echo in present-day research topics, but here too, as in all the rest of the chapters, we find physical organic chemistry in its purest form. The skillful exploitation of the physical properties of compounds to facilitate their analysis, and the masterly way in which kinetic studies are used to analyze reaction mechanisms, are hallmarks of Huisgen's research which stand out very clearly in this book. From Husigen's school there emerged a whole generation of German university teachers, and their contributions during that period are impressively described here. No less than thirteen of Huisgen's students hold, or have held, professorial chairs in German universities. This contribution that the researches summarized in this book have made to the intellectual standing now enjoyed by organic chemistry in the universities of the Federal Republic cannot be overstated.

The book is literally a historic document of the history of the period concerned. On the one hand Huisgen documents, in his characteristically perfectionist style, the milestones of his research career, and evaluates their significance in the context of the state of knowledge and the ideas of other research groups at that time. On the other hand the book also describes the heyday of mechanistic organic chemistry in Germany, before it was superseded by other lines of research. How quickly time has passed on can be seen from the way in which present-day textbooks treat arynes and 1,3-dipolar cycloadditions, citing well-established principles and giving just one or two representative examples. Huisgen's book describes the considerable intellectual and experimental efforts that were originally needed to arrive at these clear and unambiguous statements.

Nevertheless, after reading this book one's curiosity remains unsatisfied in some respects. What was the information that led to a start being made on a new area of study? What key development prompted the thoughts that eventually parted the fog and led to a clear understanding of a particular reaction mechanism? If these insights emerged from each chapter the book would give us a clearer understanding of Rolf Huisgen's enquiring mind. But Huisgen concentrates so much on thoroughly analyzing a problem and presenting the result in a polished form that the researcher himself, learning from the lessons of false trails as the work proceeds, remains hidden, despite the inclusion of many of the author's personal experiences. One hardly expects anecdotes about a scientist of these qualities—although, on the other hand, perhaps there ought to be some for that very reason.

The book is well worth reading, not only for those who have lived through the period described and wish to be reminded of the adventures in the "playground of mechanisms and novel reactions". It is equally important that it should be read by those who wish to gain a brief insight, through these examples, into how results that now belong to the established canon of knowledge in organic chemistry were arrived at. Furthermore, since there is now a renewal of interest in the study of reaction mechanisms, this book has an important function in showing where the connections to the past are to be made.

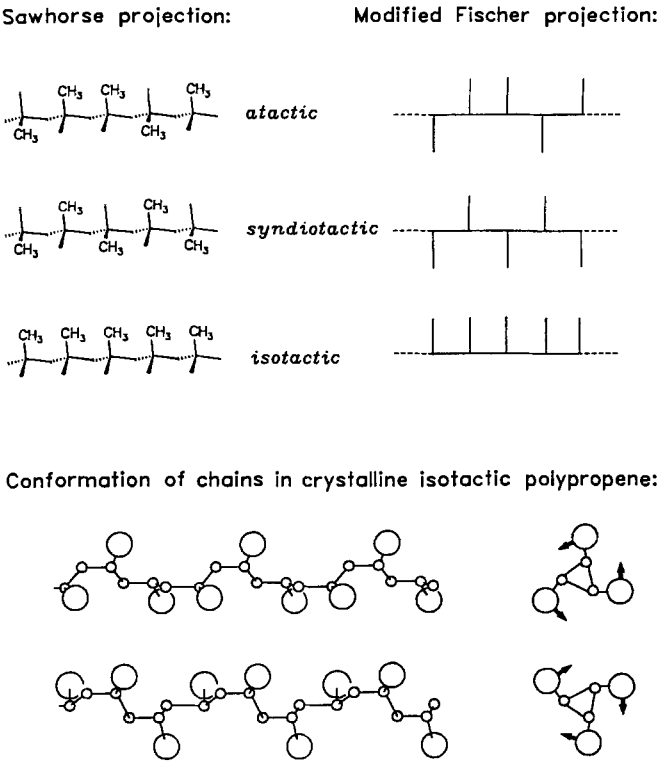
Stereospecific Olefin Polymerization with Chiral Metallocene Catalysts

Hans H. Brintzinger,* David Fischer, Rolf Mülhaupt, Bernhard Rieger, and Robert M. Waymouth

Dedicated to all those excellent graduate students who are the true heroes of this story

Current studies on novel, metallocene-based catalysts for the polymerization of α-olefins have far-reaching implications for the development of new materials as well as for the understanding of basic reaction mechanisms responsible for the growth of a polymer chain at a catalyst center and the control of its stereoregularity. In contrast to heterogeneous Ziegler–Natta catalysts, polymerization by a homogeneous, metallocene-based catalyst occurs principally at a single type of metal center with a defined coordination environment. This makes it possible to correlate metallocene structures with polymer properties such as molecular weight, stereochemical microstructure, crystallization behavior, and mechanical properties. Homogeneous catalyst systems now afford efficient control of regio- and stereoregularities, molecular weights and molecular weight distributions, and comonomer incorporation. By providing a means for the homo- and copolymerization of cyclic olefins, the cyclopolymerization of dienes, and access even to functionalized polyolefins, these catalysts greatly expand the range and versatility of technically feasible types of polyolefin materials.



Keywords: alkenes · catalysis · metallocenes · polymerizations

1. Introduction

Forty years after Karl Ziegler's invention of transition metal catalyzed polyinsertion and Giulio Natta's discovery of the stereoselective polymerization of α-olefins,[1–4] we are witnessing the evolution of new generations of catalysts and polyolefin materials, which originate from studies on homogeneous, metallocene-based polymerization catalysts. In the following, we will attempt to review some of these recent developments.[5–7]

Research on metallocene-catalyzed olefin polymerization has derived much of its impetus from the desire to model the reaction mechanisms of heterogeneous polymerization catalysts. In the evolution of Ziegler–Natta catalysis, an empirical approach has proven highly successful. Modern $MgCl_2$-supported catalysts have tremendous activities for the production of polypropene and other polyolefins; at the same time, they are

Scheme 1. Structure of isotactic, syndiotactic, and atactic polypropene in sawhorse and modified Fischer projections [107] (top), and conformation of the chains in crystalline isotactic polypropene, determined by Natta and Corradini [2] (bottom).

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995* *0570-0833/95/1111-1143 $ 10.00+.25/0*

highly stereoselective, forming practically only the isotactic, most useful stereoisomer of the polymer[8] (Scheme 1). Still unsatisfactory, however, is our understanding of the reaction mechanisms that are the basis of this advanced catalyst technology. Plausible hypotheses concerning these mechanisms have certainly been advanced, most notably Cossee's model of polymer chain growth by *cis*-insertion of α-olefins into a Ti–C bond on the surface of crystalline $TiCl_3$.[9, 10] Based on Natta's early ideas about the role of chiral surface sites in the formation of isotactic polyolefins,[6, 11] very adequate models were proposed to explain the induction of stereoregular polymer growth by the chiral environment of the catalyst centers[9b, 12] (Scheme 2).

The relationship between the properties of a particular catalyst and the coordination geometry of its reaction centers, however, leaves many questions open,[8g, h] due to the notorious nonuniformity of active sites in these heterogeneous catalysts and the limited experimental access to their structural details. In a review written in 1980, Pino and Mülhaupt summarized this shortcoming:[4b] "Up to now, there is no direct proof for the structures proposed; most of them are the result of speculations or derived from indirect experimental indications."

In this situation, related developments in other fields of catalysis nourished the hope that homogeneous organometallic catalysts capable of stereoselective olefin polymerization might eventually allow more direct observations on the catalyst species

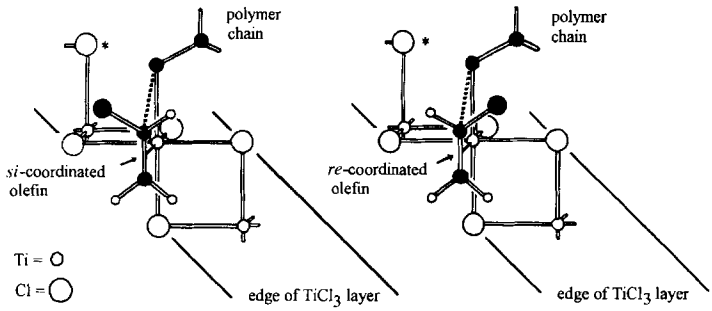
H.-H. Brintzinger

D. Fischer

R. Mülhaupt

B. Rieger

R. M. Waymouth



Hans-Herbert Brintzinger, born in Jena, Germany, in 1935, studied chemistry in Basel, where he received his Ph.D. in 1960 with Hans Erlenmeyer and his Habilitation in 1964. After teaching chemistry at the University of Michigan for several years, he moved to the University of Constance in 1972, where he holds a professorship for General Chemistry and Coordination Chemistry. His fields of interest are organometallic chemistry and reaction mechanisms in homogeneous catalysis.

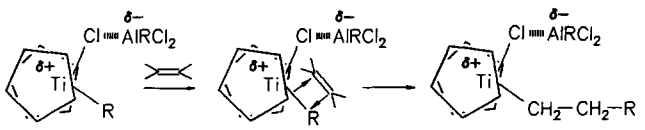
David Fischer, born 1963 in Cologne, Germany, studied chemistry at the University of Cologne. After earning his diploma in physical chemistry, he joined Rolf Mülhaupt's group at the University of Freiburg as a graduate student. He received his Ph.D. in 1992 for studies on propene polymerization with homogeneous zirconocene catalysts. After a postdoctoral period with Robert Waymouth at Stanford, he joined the plastics laboratory of BASF AG in 1993, where he is still working on stereospecific propene polymerization with metallocene catalysts.

Rolf Mülhaupt was born in Waldshut-Tiengen, Germany, in 1954. From 1973 to 1978 he studied chemistry in Freiburg; he received his Ph.D. in 1981 with Professor Pino at the Laboratory for Technical Chemistry at the ETH in Zürich. Following industrial research positions at the Central Research and Development Experimental Station of Dupont in Wilmington, Delaware, from 1981 to 1985 and at Ciby-Geigy AG in Marly, Switzerland, from 1985 to 1989, he was appointed professor of Macromolecular Chemistry at the University of Freiburg in 1989. Since 1992 he has been director of the Material Research Center in Freiburg. His research interests include, besides transition metal catalyzed polymerization, new polymer structural materials, material compounds, dispersions and specialty polymers.

Bernhard Rieger was born in Augsburg, Germany, in 1959. He studied chemistry at the University of Munich and received his Ph.D. in 1988 for studies on enantioselective hydrogenations with rhodium–phosphane catalysts. After research appointments at the Institute for Polymer Science and Engineering of the University of Massachusetts at Amherst and in the plastics laboratory of BASF AG, he received his Habilitation in 1995 at the University of Tübingen, where he presently holds a faculty position in chemistry.

Robert M. Waymouth was born in Warner Robins, Georgia (USA), in 1960. He received bachelor's degrees in mathematics and chemistry at Washington and Lee University and his Ph.D. from California Institute of Technology in 1987, where he worked with Professor R. Grubbs. Following a year's postdoctoral appointment at the ETH in Switzerland with Professor Pino, he joined the faculty at Stanford in 1988, where he is now an Associate Professor of Chemistry. His research interests are in stereoselective catalysis.

Scheme 2. Model for the stereospecific polymerization of propene at a chiral Ti center on the edge of a $TiCl_3$ crystal, as proposed by Corradini and co-workers [12b]. The growing polymer chain occupies the open sector of the chiral coordination sphere; the olefin adopts that enantiofacial orientation which places the olefin substituent *trans* to the polymer chain at the incipient C–C bond (left); a *cis* orientation of olefin substituent and polymer chain is disfavored (right).



involved and, hence, on the mechanisms of polymer growth and its stereochemical control.[13] This sentiment was expressed, for example, by Boor in the concluding chapter of his book on Ziegler–Natta catalysts.[3c]

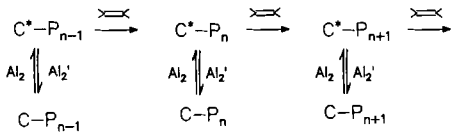
Particularly attractive as model systems of this kind appeared alkylaluminum-activated metallocene complexes of the Group 4 transition metals, which have been known since 1955 to catalyze the polymerization of ethene[14, 15] and have since been the topic of many studies. The simple coordination geometry of Group 4 metallocene complexes—only two reactive, *cis*-positioned ligand sites—promised opportunities for identifying and characterizing essential intermediates of homogeneous polymerization catalysts and providing more direct experimental verification for some of the hypotheses in the field of Ziegler–Natta catalysis.

2. Activation of Metallocene Halides for α-Olefin Polymerization

In 1957, patents and publications by Breslow and Newburg[14] at the Hercules Research Center and by Natta, Pino, and their co-workers[15] reported that homogeneous reaction mixtures of dicyclopentadienyltitanium dichoride (Cp_2TiCl_2) and diethylaluminum chloride (Et_2AlCl) catalyze the formation of polyethene under conditions similar to those used with heterogeneous Ziegler catalysts. Numerous subsequent studies were aimed at the identification of reaction intermediates and reaction mechanisms of this homogeneous catalysis. The results obtained have been summarized previously;[4a, b, 16] some are particularly noteworthy in the context of the following discussion.

Formation of (alkyl)titanocene complexes Cp_2TiRCl (R = Me or Et) by ligand exchange with the alkylaluminum cocatalyst, polarization of the Cp_2Ti–Cl bond by Lewis-acidic aluminum centers in an adduct of the type $Cp_2Ti(R)$–$Cl \cdot AlRCl_2$, and insertion of the olefin into the Cp_2Ti–R bond of this (or some closely related) electron-deficient species, had been deduced by 1960 from spectroscopic, kinetic, and isotope labeling studies done at the Hercules laboratories by Breslow, Newburg, and Long and by Chien[17, 18] (Scheme 3). These early metallocene studies contributed to the ideas put forth by Cossee[9a] with regard to the mechanisms of heterogeneous Ziegler–Natta catalysis.

Scheme 3. Polymerization of ethene by *cis*-insertion into the Ti–C bond of an alkylaluminum halide activated titanocene complex, as proposed by Breslow, Newburg, and Long [17].



2.1. Metallocene Cations in the Polymerization of Ethene

An interesting question remained unresolved by this early research: does olefin insertion occur in a bimetallic species, in which an alkyl group or a halogen bridges the titanium and aluminum centers, as advocated by Natta and his group,[19] by Patat and Sinn,[20] by Reichert and co-workers,[21] and by Henrici-Olivé and Olivé?[22] Or does it require the formation of a truly ionic species $[Cp_2TiR]^+$ by abstraction of a halide anion and its incorporation into an anion $R_xCl_{4-x}Al^-$, as proposed by Shilov, Dyachkovskii, and Shilova?[23]

Crystal structures of complexes that were occasionally isolated from reaction mixtures containing Cp_2TiCl_2 and an alkylaluminum chloride[24, 25] were not conclusive in this regard, as they represented degradation products, which require either reoxidation[17] or renewed alkyl exchange with alkylaluminum cocatalysts[4a] for reactivation. In 1986, however, Jordan and co-workers isolated the tetraphenylborate salts of cations such as $[Cp_2ZrCH_3 \cdot THF]^+$ and $[Cp_2ZrCH_2Ph \cdot THF]^+$ and demonstrated their capability to polymerize ethene without addition of any activator.[26] These and related findings in the groups of Bochmann,[27] Teuben,[28] and Taube[29] and by Hlatky and Turner at Exxon[30] lent general credence to the proposal that (alkyl)metallocene cations are crucial intermediates in homogeneous polymerization catalysis.

A useful concept for the description of alkylaluminum-activated metallocene catalyst systems goes back to kinetic studies in Reichert's group.[21] During the growth of a polymer chain, each metal–polymer species appears to alternate between a "dormant" state and a state in which it actively grows. This "intermittent-growth" model was further elaborated by Fink[31] and by Eisch[32] and their co-workers in extensive kinetic and reactivity studies. Consecutive equilibria appear to convert alkylaluminum and (alkyl)metallocene halides first into Lewis acid–base adducts equivalent to inner (or contact) ion pairs and then into dissociated (or separated) ion pairs. In these highly dynamic equilibria, only the cation of a separated ion pair appears to be capable of interacting with an olefin substrate and, hence, of contributing to polymer growth.[33] Contact ion pairs, which appear to dominate in these equilibria, can then be termed "dormant" in this regard[34, 35] (Scheme 4).

This model would explain the inability of metallocenes activated by alkylaluminum halides to catalyze the polymerization of propene and higher olefins[4a, 36] by the insufficient capability of the more weakly coordinating, substituted α-olefins to form

Scheme 4. "Intermittent-growth" model involving equilibria between polymer-bearing, but inactive primary complexes (C–P$_n$) and active catalyst species (C*–P$_n$), generated by excess alkylaluminum halide, as proposed by Fink and co-workers [31]. $Al_2 = (AlEtCl_2)_2$, $Al_2' =$ unknown, $P_n =$ polymer chain with n monomer units; C–P$_n$ here $Cp_2TiP_nCl \cdots AlCl_2Et$.

reactive, olefin-separated ion pairs by displacement of an aluminate anion from the metal center. At any rate, the limitation of homogeneous catalyst systems to the polymerization of only ethene was a crucial obstacle for progress in this field for many years. Fortunately, this impediment was overcome by a series of serendipitous observations,[37–39] which led, around 1980, to the discovery by Kaminsky, Sinn, and co-workers that metallocenes are activated for the catalytic polymerization of propene and higher olefins by methyl aluminoxanes.[4a, 39]

2.2. Polymerization of Propene and Higher Olefins

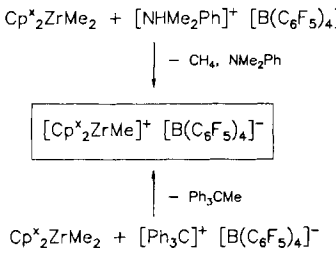
Water, which had long been considered to be a "poison" for Ziegler–Natta catalysts, was first reported by Reichert and Meyer to cause a surprising increase in the rate of ethene polymerization by the catalyst system $Cp_2TiEtCl/AlEtCl_2$.[37] Subsequent studies by Long and Breslow on the effects of water in the otherwise inactive system Cp_2TiCl_2/Me_2AlCl led to the notion that formation of a dimeric aluminoxane, ClMeAl–O–AlClMe, by partial hydrolysis of Me_2AlCl might generate an exceptionally strong Lewis acid and, hence, a potent activator for $Cp_2TiMeCl$ toward ethene polymerization.[38]

While studying halogen-free systems such as $Cp_2ZrMe_2/AlMe_3$, Sinn and Kaminsky noticed that addition of water imparts to this otherwise inactive reaction system a surprisingly high activity for ethene polymerization which was, furthermore, unprecedentedly constant over extended reaction times.[39a, b] Sinn and Kaminsky observed that an interaction between Cp_2ZrMe_2 and $AlMe_3$ occurred only when water had been added. The suspected formation of methyl aluminoxane (MAO) by partial hydrolysis of $AlMe_3$ was subsequently supported by its direct synthesis and characterization as a mixture of oligomers of approximate composition $(MeAlO)_n$. Activation of Cp_2ZrMe_2 and Cp_2ZrCl_2 with preformed MAO did indeed yield exceedingly active catalysts for the polymerization of ethene.[39b] Similar activities were obtained with MAO-activated Cp_2TiCl_2; however, at temperatures above 0 °C this catalyst system is rapidly deactivated, most likely by reduction to the Ti^{III} stage.[40]

Sinn, Kaminsky, and co-workers noticed furthermore that MAO-activated homogeneous metallocene catalysts were—in contrast to previously studied metallocene catalysts activated by aluminum halides—capable of polymerizing propene and higher olefins.[4a, 39c–g] Although the achiral metallocene catalysts were still lacking the stereoselectivity of heterogeneous Ziegler–Natta systems, aluminoxane-activated metallocene catalysts now came to be most promising as model systems.

While oligomeric alkyl aluminoxanes have been known for more than 30 years, for example as initiators for the polymerization of oxiranes,[41] their exact composition and structure are still not entirely clear. When the hydrolysis of $AlMe_3$, which is highly exothermic (and indeed potentially dangerous[39j, 42b]), is conducted under controlled conditions, it appears to generate mostly oligomers $Me_2Al–[O-AlMe]_n–OAlMe_2$ with $n \approx 5–20$.[39j]

Investigations in quite a number of research groups by cryoscopy, UV, vibrational and NMR spectroscopy, chromatography, and other means[38, 39j, 42–50c] yield the following picture for aluminoxane solutions. Residual $AlMe_3$ in MAO solutions[42b, 43] seems to participate in equilibria that interconvert different MAO oligomers[42b, 43–46] and possibly also cyclic and branched oligomers.[39e–j, 46] Cross-linking by methyl-free oxoaluminum centers has been proposed to generate a microphase with an Al_xO_y core.[47] Aluminoxane clusters $[RAl(\mu_3\text{-}O])_n$, with R = *tert*-butyl and $n = 4$, 6, or 9, have been isolated and structurally characterized by Barron and his group.[48a] Complexes with four-coordinate Al centers seem to predominate in MAO solutions[48a, 49] and might contain intramolecular $Al_2O \rightarrow Al$ or $Al–CH_3 \rightarrow Al$ bridges.[42b] The presence of three-coordinate Al centers in MAO solutions has been deduced by Siedle and co-workers from ^{27}Al NMR data.[50b, c] While species of exceptional Lewis acidity are certainly present in MAO solutions, their exact composition and structure is still not adequately understood.[51]



When toluene solutions of Cp_2ZrCl_2 are treated with MAO, a fast, initial ligand exchange reaction generates primarily the monomethyl complex $Cp_2ZrMeCl$;[39i, 44b] excess MAO leads to Cp_2ZrMe_2.[39i] These systems become catalytically active when the concentration of excess MAO is raised to Al:Zr ratios of about 200:1 or higher.[39] The ways in which excess MAO induces this activity have been investigated largely by spectroscopic methods.[39i, 50–52, 53a] It is generally assumed that some of the Al centers in MAO have an exceptionally high propensity to abstract a CH_3^- ion from Cp_2ZrMe_2 and to sequester it in a weakly coordinating ion $CH_3–MAO^-$. A fast, reversible transfer of $^{13}CH_3$ groups from Cp_2ZrMe_2 to the Al centers of a MAO activator was observed by Siedle et al.[50b, c] Barron and coworkers[48b] obtained NMR spectroscopic evidence that Cp_2ZrMe_2 and alumoxane clusters like $(\mu_3\text{-}O)_6Al_6tBu_6$ form complexes of the type $[Cp_2ZrMe^+ \cdots (\mu_3\text{-}O)_6Al_6(tBu)_6Me^-]$ in $[D_8]$toluene solution, which polymerize ethene. The tendency of four-coordinate Al centers in these aluminoxane clusters to abstract a methyl anion is ascribed by these authors to the relief of ring strain upon formation of the methyl complex.

^{91}Zr and ^{13}C NMR spectra of Cp_2ZrMe_2/MAO solutions[50b, c] and solid-state XPS[52] and ^{13}C NMR[53a] studies indicate formation of a cation $[Cp_2ZrR]^+$, which is most likely stabilized by coordinative contact with its $CH_3–MAO^-$ counterion, for example through bonding like that in $Al_2O \rightarrow Zr$ or $Al–CH_3 \rightarrow Zr$. These contacts appear to give way, in the presence even of substituted olefins, to olefin-separated ion pairs $[Cp_2ZrR(olefin)]^+ CH_3–MAO^-$, the presumed prerequisite for olefin insertion into the Zr–R bond. This hypothesis—that the unusually low coordinating capability of the anion A^- in the ion pair $[Cp_2ZrMe]^+ A^-$ is crucial for catalytic activity[50e]—led to the discovery of a series of highly active cationic metallocene

catalysts for the polymerization of propene and higher α-olefins.

Even for large, weakly coordinating anions such as $(C_6H_5)_4B^-$ and $C_2B_9H_{12}^-$ fairly strong interactions have been observed with cationic (alkyl)zirconocene species.[30, 53b, 58a] Reaction systems containing $[Cp_2ZrMe]^+$ together with $(C_6H_5)_4B^-$, $C_2B_9H_{12}^-$, or other carborane anions thus polymerize propene only at low rates, if at all.[26f, g, j, 27–30]

A breakthrough in this regard was the introduction of perfluorinated tetraphenylborate as a counterion by Hlatky and Turner[54] and by Marks and co-workers.[53b] An ion pair $[Cp^x_2ZrMe]^+(C_6F_5)_4B^-$ (where Cp^x is some substituted Cp or indenyl ligand) is formed by reaction of $Cp^x_2ZrMe_2$ with dimethylanilinium tetrakis(perfluorophenyl)borate or by abstraction of CH_3^- from a (dimethyl)zirconocene complex by trityl tetrakis(perfluorophenyl)borate[55, 56] (Scheme 5). These were the first well-defined zirconocene catalysts capable of polymerizing propene and higher olefins at high rates without addition of a further activator. Similar activities for propene polymerization were subsequently observed also with other base-free or weakly stabilized[53, 57, 58] (alkyl)metallocene cations. Cations obtained by abstraction of CH_3^- from a (dimethyl)zirconocene complex by the powerful Lewis acid $B(C_6F_5)_3$ were likewise found to be highly active catalysts for α-olefin polymerization.[59, 60]

Scheme 5. Alternative ways to generate a propene-polymerizing (alkyl)zirconocene cation (associated with the weakly coordinating $B(C_6F_5)_4^-$ anion) as reported by Hlatky, Upton, and Turner [54], by Marks and co-workers [53b], by Ewen and Elder [55], and by Chien and co-workers [56]. Cp^x represents a variety of substituted and/or bridged cyclopentadienyl and indenyl ligands (see Section 3.1).

Crystal structures obtained by Marks and co-workers,[60] for example that of $[(Me_2C_5H_3)_2ZrCH_3^+ \cdots H_3C-B(C_6F_5)_3^-]$, reveal residual coordinative contacts between the cationic Zr center and its counterion (Fig. 1). This contact appears to resemble those yet unidentified interactions that stabilize an (alkyl)-metallocene cation in contact with a H_3C-MAO^- counterion.

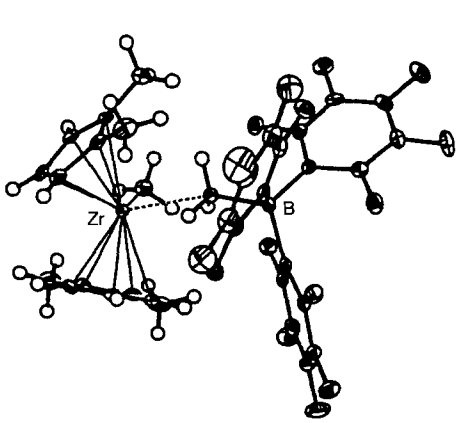


Fig. 1. Crystal structure of the zirconocene catalyst $[(Me_2C_5H_3)_2ZrCH_3^+ \cdots H_3C-B(C_6F_5)_3^-]$, as determined by Marks and co-workers [60]. The bridging $Zr \cdots CH_3B$ bond is substantially longer (255 pm) than the terminal $Zr-CH_3$ bond (225 pm).

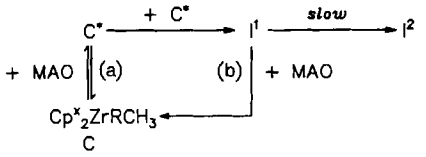
In both cases, a fast methyl exchange occurs between the cationic and anionic complex moieties;[50, 60] most importantly, both types of contacts appear to be weak enough to allow an α-olefin to displace the anion from its coordination site at the Zr center.

Cationic metallocene complexes, particularly those that arise by in situ activation of a stable zirconocene precursor,[56] yield catalysts with very high activities. They are easily deactivated, however, probably by minute traces of impurities. Addition of $AlMe_3$ or $AlEt_3$ has been shown to stabilize these cationic metallocene catalysts[55, 56b] by formation of AlR_3 adducts.[57d]

Of even greater simplicity, at least conceptionally, are catalysts based on an (alkyl)metallocene complex containing a Sc^{III}, Y^{III}, or a trivalent lanthanide center. As shown by Ballard et al.[61] and by Watson et al.,[62] neutral complexes of the type $Cp_2M^{III}R$ act as single-component catalysts for the oligomerization of α-olefins.[63, 64] While generally more difficult to prepare and to handle than the Group 4 metallocene catalyst systems described above, catalysts such as $(C_5Me_5)_2ScR$ (R = Me, Et) provided Bercaw and his co-workers detailed information on the rates and mechanisms of individual olefin insertion steps.[63] The results of these studies lent additional support to the concept that an analogous olefin insertion into the isoelectronic species $[Cp_2ZrR]^+$ is responsible for the growth of polymer chains in zirconocene-based catalyst systems.

2.3. Kinetics and Mechanisms of α-Olefin Polymerization



Because of many practical advantages, activation of zirconocene dichloride derivatives by methyl aluminoxane still appears to be the generally favored route to homogeneous polymerization catalysts. Substantial efforts have been made, therefore, to identify intermediates arising in the resulting, relatively complex reaction systems and to clarify the kinetics of the polymer chain growth they induce.

At propene pressures of 1–2 bar and ambient temperatures these reaction systems produce roughly 100–1000 kg polypropene per hour and mol of Cp_2ZrCl_2. This corresponds to about 2000–10000 olefin insertions per hour at each Zr center. T is equivalent to the production of 500–5000 polymer chains with average molecular weights on the order of $M_n = 200–2000$. Ethene is polymerized by these catalyst systems with still higher turnover numbers of 10–100 insertions per second, which approach those of C–C bond forming enzymes.[39b, c, g]

Attempts to identify the species involved in the rate-determining step of the polymerization process by kinetic methods (i.e. by determining the rate of polymer formation as a function of the concentrations of zirconocene, MAO, and olefin reagents) have been hampered by the complex time-dependence of the catalytic reaction. Relatively high initial values, reached shortly after the components are mixed, decrease to much lower steady-state values.[65–69] This decrease occurs within minutes at temperatures of 40–60 °C; at lower temperatures, it can take hours until the steady-state rate is reached.

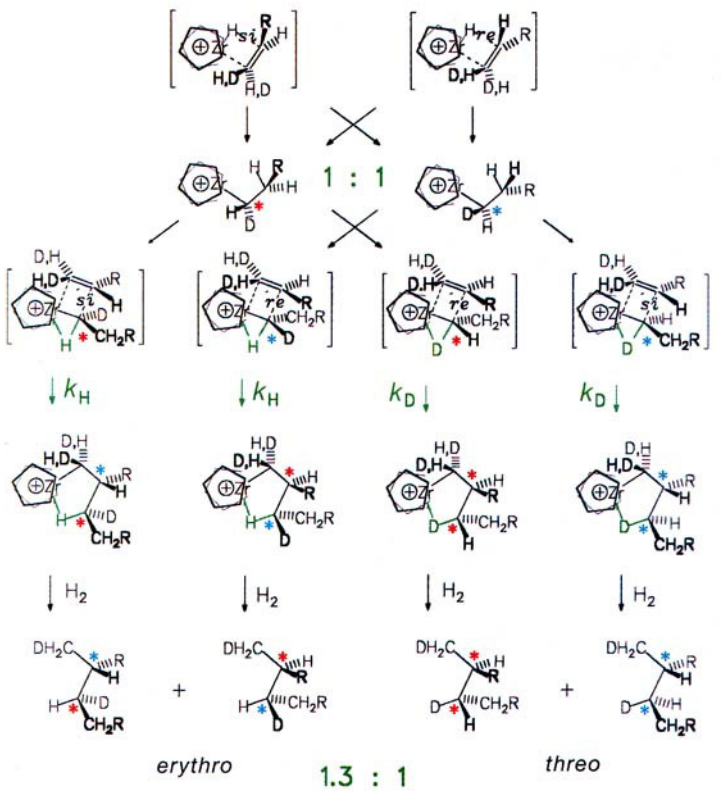
In kinetic studies, Fischer and Mülhaupt[69a, b] describe the steady-state activity of a Cp_2ZrCl_2/MAO catalyst system as a sequence of reversible and irreversible processes. A reactive species C* appears to be generated in a fast equilibrium reaction

involving excess MAO and an (alkyl)zirconocene complex C (Scheme 6).[70] Another, slower reaction, which shows a second-order dependence on the concentration of the active species C*, converts C* to some inactive species I^1. This inactive species I^1 is constantly reconverted to the catalyst species C and C* by reaction with excess MAO; this was demonstrated by the effects of MAO additions on the catalytic activity of a system that had already reached steady-state conditions.[69c] A further, still slower reaction converts I^1 to another inactive species I^2 from which C* is not regenerated in these reaction systems. Since the transformation of C* to I^1 is bimolecular, the steady-state fraction of the inactive species I^1 decreases at low concentrations of C*. Accordingly, specific activities are observed to increase at lower zirconocene concentrations.[39, 69]

Scheme 6. Dual effect of MAO on the steady-state activity of a zirconocene-based polymerization catalyst, derived from kinetic studies by Mülhaupt and Fischer [69a, b]. (a) Generation of active species C* in a fast equilibrium with a (dialkyl)zirconocene complex and (b) reactivation of an inactive intermediate I^1 arising from a second-order deactivation reaction of C*; I^1 slowly decays to another inactive species I^2, from which the active catalyst is not regenerated.

The reaction that converts C* to I^1 is undoubtedly connected with the known propensity of (methyl)zirconocene cations to react with a wide variety of C–H units by means of σ-bond metathesis and release of CH_4.[26d–f, 28, 30, 50, 71] Kaminsky and co-workers have indeed observed a steady liberation of CH_4 from MAO-activated zirconocene catalysts, which reached up to 50 molecules of CH_4 per Zr center.[39i] The inactive, dominant steady-state species is proposed to be a binuclear complex with CH_2 bridges between a Zr and an Al center. Binuclear species with C_2H_4 bridges between two Zr centers were isolated by the same authors from ethene-polymerizing catalyst systems.[4a, 39] Regeneration of active polymerization catalysts from these binuclear, C_xH_y-bridged deactivation products by MAO is proposed to occur by alkyl exchange reactions, for instance between a $Zr-CH_2-Al$ species and the alkylaluminum activator;[72] the latter will thus be consumed gradually under formation of $Al-CH_2-Al$ units. Evidence for the formation of binuclear cations of the type $[Cp_2ZrMe(\mu\text{-}CH_3)MeZrCp_2]^+$ is now firmly established.[53a, 57d, 60a, 73, 120e, 132b] Further insights with regard to their identity and their involvement in deactivation processes[74] can be expected from studies on MAO-free, cationic zirconocene catalysts.

The question of why such a huge excess of MAO is required to induce catalytic activity for α-olefin polymerization is still unanswered. Catalytic activities are found to decline dramatically for MAO concentrations below an Al:Zr ratio of roughly 200–300:1. Even at Al:Zr ratios greater than 1000:1, steady-state activities increase with rising MAO concentrations,[75] approximately as the cube root of the MAO concentration.[39d, 69b] MAO appears to be involved in a fast equilibrium $C + MAO \rightleftharpoons C^{*+} + CH_3-MAO^-$ as well as in the slower reactivation process $I^1 + MAO \rightarrow C^*$. The concentration of the most Lewis-acidic Al centers must be related, furthermore, to the total MAO concentration through complicated equilibria. To date, it has not been possible to model the overall effects of MAO concentrations on catalytic reaction rates by a plausible, comprehensive system of kinetic equations.



The effect of olefin concentration on the reaction rates is likewise complicated by catalyst deactivation. Since the reactive species appears to be stabilized by excess olefin, rates of polymer production under steady-state conditions are not proportional to propene concentrations, but approximately to $c(\text{olefin})^{1.3}$.[69b] Related observations (see for example refs. [50b, c]) that polymerization rates depend on olefin concentration to a fractional order between 1 and 2 have led to the proposal that two olefin molecules are involved in the insertion transition state.[76] While initial rates of polymer production, determined before the onset of catalyst deactivation, have been reported in two instances to increase in proportion to ethene[65c] or propene concentration[69b] (i.e. as $c(\text{olefin})^{1.0}$), this point requires further clarification (see Section 3.3).

For the present we will assume, in accord with general opinion, that the productive reaction complex in MAO-activated zirconocene catalysts is a cationic alkyl(olefin)zirconocene complex of the type $[Cp_2ZrR(\text{olefin})]^+H_3C-MAO^-$, which is generated by displacement of an anion H_3C-MAO^- from its $[Cp_2ZrR]^+$ counterion by an olefin molecule.

The reaction step by which such an alkyl(olefin)zirconocene cation is finally converted to the olefin-insertion product has been further characterized by kinetic isotope effects. Laverty and Rooney,[77] and Brookhart and Green[78] had proposed that an agostic interaction of one of the α-H atoms of the metal-bound alkyl chain with the metal center of a Ziegler–Natta catalyst[79] facilitates the insertion of an olefin into the metal–alkyl bond. To test this hypothesis, Krauledat and Brintzinger[80] investigated the catalytic hydrodimerization of α-deuterated hexenes to the *threo* and *erythro* diastereomers of $5\text{-}CH_2D\text{-}6\text{-}[D]$-undecane by MAO-activated Cp_2ZrCl_2. Diastereomer ratios in accord with a value of $k_H/k_D \approx 1.3$ were observed with *cis* and *trans* α-deuterated 1-hexene. This indicates—along a line of reasoning developed earlier by Grubbs and co-workers[81]—that the transition state for the insertion of hexene into the Zr–C bond of the initially formed $Zr-CHD-(CH_2)_4CH_3$ unit involves considerable weakening either of its α-C–H or of its α-C–D bond. In other reaction systems agostic interactions with H atoms have been shown to be preferred over those with D atoms by a factor of about 1.2–1.5.[79a] The stereokinetic isotope effect $k_H/k_D \approx 1.3$ associated with the insertion of an α-olefin into the metal–CHD–R unit of a MAO-activated zirconocene catalyst can thus be regarded as evidence that this reaction requires the agostic interaction of one of the α-H atoms with the metal center (Scheme 7).

Similar results were obtained by Piers and Bercaw[82] in studies on hydrocyclizations and hydrodimerizations induced by single-component scandocene catalysts. It remains to be tested whether this notion can be generalized or whether olefin insertions into metal–alkyl species might occasionally occur without agostic assistance.[83]

Olefin insertion into the metal–alkyl bond of a cationic metallocene complex of the type $[Cp_2MMe(\text{olefin})]^+$ (M = Ti,

Scheme 7. Stereokinetic isotope effects in the $(C_5H_5)_2ZrCl_2$/MAO-catalyzed hydrodimerization of (*E*)- and (*Z*)-1-[D]-1-hexene (R = *n*-C_4H_9) favor the *erythro* over the *threo* products in a ratio of 1.3:1 [80]. While the achiral starting compounds must give the Zr–CHD–CH_2R enantiomers in a 1:1 ratio, the second olefin insertion is influenced by α-agostic interactions. A H–C(α) bond is weakened in the formation of the *erythro* isomers, a D–C(α) bond in the formation of the *threo* isomers of the hydrodimer product.

Zr) has been the subject of numerous theoretical studies.[84–89] Calculations with ab initio and density functional methods depict the transition state as a planar[84e,g,85,87,88] or slightly puckered[84f,86] four-membered ring with Ti–C and Zr–C distances of 2.1–2.3 and 2.3–2.5 Å, respectively, an incipient alkyl–olefin C···C distance of 2.1–2.3 Å, and a slightly increased olefin C=C bond length of roughly 1.4 Å[84e–g,85–88] (Fig. 2).

Most of these studies concur with the view that in the insertion transition state one α-H atom of the migrating Zr–CH_2–R

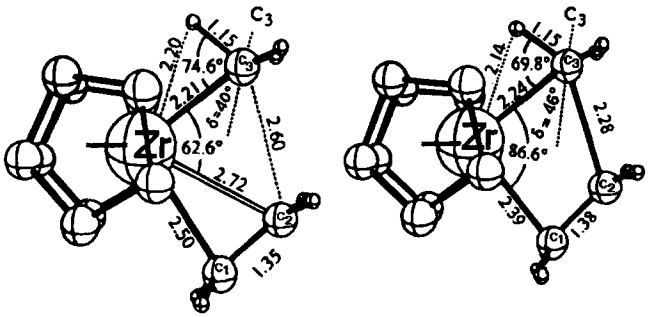


Fig. 2. Structures of a cation $[(C_5H_5)_2ZrMe(C_2H_4)]^+$ (left) and of the transition state for insertion of the ethene ligand into the Zr–Me bond (right), as determined by Ziegler and co-workers by density functional methods [87]. A shortening of the agostic Zr–H(α) contact helps align the C_3 axis of the CH_3 group for interaction with the ethene π* orbital.

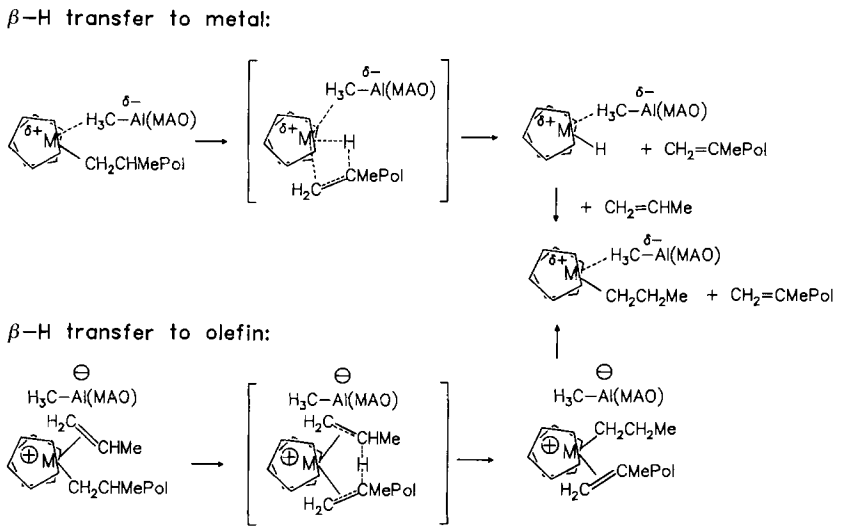
group is in close proximity to the metal center and that this Zr–H interaction is due to an α-agostic bond.[86–88] An Extended-Hückel MO study[89] indicates that the α-agostic interaction of a Zr–CH_2–R unit with the Zr center is linked to the increasing electron deficiency of the reaction complex as it progresses along the olefin-insertion coordinate from a 16-electron to a 14-electron species. The size of the contribution of the agostic interaction to the stabilization of the olefin-insertion transition state is still a matter of debate.[89]

These studies also indicate that the Zr–*n*-propyl unit at the end of the insertion path is stabilized by the agostic interaction of one of its γ-C–H bonds with the Zr center.[84g,85–89] A yet more stable structure appears to be a product in which one of the β-C–H bonds of the Zr–*n*-propyl unit interacts with the electron-deficient Zr center.[85–88] The γ-agostic species initially arising from the insertion process is thus likely to rearrange into a structure with a β-agostic bond;[79] the latter probably represents something like a resting state for a $[Cp_2Zr–alkyl]^+$ ion (see ref. [63]). Theoretical studies indicate that the $\gamma \rightarrow \beta$ rearrangement might be relatively slow.[85b,87b]

Effects of the solvent and counterions, neglected so far in these theoretical studies, might be of more than peripheral concern. In an ion-cyclotron resonance study, Richardson and co-workers[74] showed that $[Cp_2TiCH_3]^+$ and C_2H_4 react in vacuo to form the allyl complex $[Cp_2TiC_3H_5]^+$ and H_2, rather than the insertion product $[Cp_2TiC_3H_7]^+$. It remains to be clarified which interactions induce the more useful course to polymers in the analogous condensed-phase reaction systems.



2.4. Molecular Weights and Chain Termination Reactions

An important aspect in which homogeneous olefin polymerization by metallocene catalysts differs from heterogeneous Ziegler–Natta catalysis is the narrow molecular weight distribution of homogeneously produced polymers. While polyolefins obtained with heterogeneous catalysts have broad molecular weight distributions with large polydispersities of $M_w/M_n \approx 5–10$,[8] homogeneous catalysts produce polymers with polydispersities M_w/M_n close to 2.[39f] A polydispersity of 2 is predicted by Schulz–Flory statistics[90] for polymers arising from identical catalyst centers with fixed rates of chain propagation and chain termination, v_P and v_T. A polydispersity of 2 is thus regarded as evidence that only a single catalyst species contributes to polymer growth in a homogeneous catalyst system. Even though the deactivation and reactivation reactions discussed above are likely to generate a diversity of complex species in these catalyst systems under steady-state conditions, only one of these species, presumably the cation $[Cp_2Zr–alkyl(olefin)^+]$, appears to contribute to polymer growth.

While ethene is polymerized by MAO-activated or cation-type Cp_2Zr-based catalysts to give polymers with high molecular weights in the range of 100 000 to 1 000 000,[39] propene polymers obtained at room temperature with these catalysts have rather low degrees of polymerization, with molecular weights in the range of 200–1000.[39e,g,69b] The relatively low molecular weights of the polymer products must be due either to an increased rate of chain termination or to a decreased rate of olefin insertion (or both), since the average degree of polymerization

P_N is determined by the ratio of the rates of chain propagation and chain termination, $P_N \approx v_P/v_T$.[90]

^1H and ^{13}C NMR analyses show that polypropene chains produced with zirconocene-based catalysts bear *n*-propyl and 2-propenyl end groups.[91] The 2-propenyl end groups could arise by transfer of a β-H atom from the polymer chain to the metal center (Scheme 8). The Zr–H unit generated by this process can then react with propene to form a Zr–*n*-propyl unit, from which a new polymer chain can start to grow.[96] Another conceivable chain termination mechanism is the transfer of a β-H atom from the Zr-bound polymer chain directly to the β-C atom of a coordinated olefin molecule. In this case, the 2-propenyl-terminated polymer chain and a new Zr–*n*-propyl unit are generated without the intermediacy of a Zr–H species (Scheme 8).

Scheme 8. Chain termination by β-H transfer to the metal (top) and to a coordinated olefin (bottom). A polymer chain with a 2-propenyl end and a metallocene complex with a *n*-propyl chain result from both of these processes, but the rate of the latter increases with olefin concentration in parallel to that of olefin insertion, while the rate of the former is olefin-independent. Molecular weights of the polymers will thus increase with olefin concentration in the case of β-H transfer to the metal, while molecular weights independent of olefin concentration indicate β-H transfer to an olefin ligand.

Evidence for direct β-H transfer to a coordinated olefin was obtained by Kashiwa and co-workers[97] from studies on ethene–propene copolymers. A Zr–H intermediate would be expected to react at least as fast with ethene to give a Zr–ethyl unit as with propene to give a Zr–propyl unit; ethyl end groups should thus be found at the head of a polymer chain with the same frequency as *n*-propyl ends. In fact, very few ethyl ends were formed at comparable concentrations of ethene and propene. The most plausible explanation for this observation is that β-H transfer to a coordinated propene molecule occurs more often than that to a coordinated ethene molecule, since the rate of insertion of propene into a Zr–polymer bond is lower than that of ethene.[97]

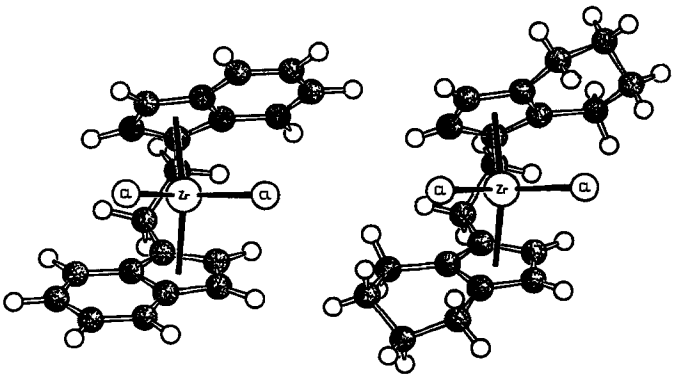
This mechanism does not appear compatible, on the other hand, with observations that polymer molecular weights increase linearly with ethene[65c] or propene[69b] concentrations. For chain termination by β-H transfer to a coordinated monomer one would expect v_T like v_P to depend linearly on monomer concentration. In this case, the mean degree of polymerization, $P_N \approx v_P/v_T$, is expected to be independent of the monomer concentration. This discrepancy obviously needs to be readdressed; we will return to it in the discussion of stereoselective polymerization catalysis in Section 3.3.

Molecular weights of polyolefins obtained with MAO-activated zirconocene systems generally increase with the concentration of the MAO cocatalyst,[39, 69b, 98] in parallel with increased rates of chain growth. Effects of zirconocene concentrations on polymer molecular weights again parallel those on catalytic activities: molecular weights increase substantially as zirconocene concentrations are decreased.[39, 69b, 98] This might be due to dilution effects favoring the dissociated or olefin-separated ion pairs C* relative to their associated precursors C, and hence the rate of chain propagation over that of chain termination.[99] As an alternative, Kaminsky and co-workers[39, 98] advocate that a bimolecular reaction of the active complex with a second zirconocene species terminates growth of the polymer chain in a manner possibly related to the second-order deactivation process discussed in Section 2.3. Further clarification of these questions can be expected from future studies on MAO-free, cationic metallocene polymerization catalysts.

3. Stereoregular Polymers from Chiral Metallocene Catalysts

The discovery of homogeneous catalysts capable of polymerizing propene and higher α-olefins around 1980 revived a long-standing question:[13] Would it be possible to induce these homogeneous polymerizations in a stereoregular fashion, so as to produce isotactic polymers, by using suitably designed chiral metallocenes as catalysts?

Chiral metallocenes suitable for this purpose[100] became available, not quite accidentally[101] just at that time. Using ethylene-bridged ligands,[102] Wild and Brintzinger[103] obtained ethylenebis(indenyl)- and ethylenebis(tetrahydroindenyl)titanium complexes, *rac*-(en)(ind)$_2$TiCl$_2$ and *rac*-(en)(thind)$_2$TiCl$_2$, and their zirconium analogues. The conformationally constrained indenyl and tetrahydroindenyl ligands give these complexes chiral structures (Fig. 3) which



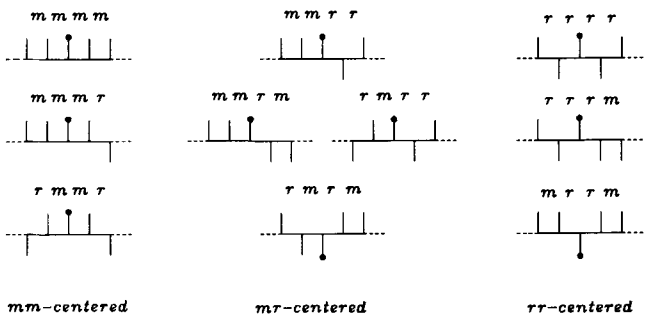


Fig. 3. Prototypical *ansa*-zirconocene complexes prepared by Wild et al. [103]: *rac*-(en)(ind)$_2$ZrCl$_2$ (left) and *rac*-(en)(thind)$_2$ZrCl$_2$ (right).

could be expected to be retained even under catalysis conditions. When activated with MAO in the manner described above, these *ansa*-metallocenes[104] were indeed found, in independent studies by Ewen with (en)(thind)$_2$TiCl$_2$/MAO[105] and by Kaminsky and Külper with *rac*-(en)(thind)$_2$ZrCl$_2$/MAO,[106] to polymerize propene and other α-olefins to give highly isotactic polymers. These findings led to extensive exploration of the mechanisms by which these catalysts control the stereochemistry of polymer growth and the effects of different metallocene structures on the tacticities and other properties of the polymers produced.

3.1. Catalyst Structures and Stereoselectivities

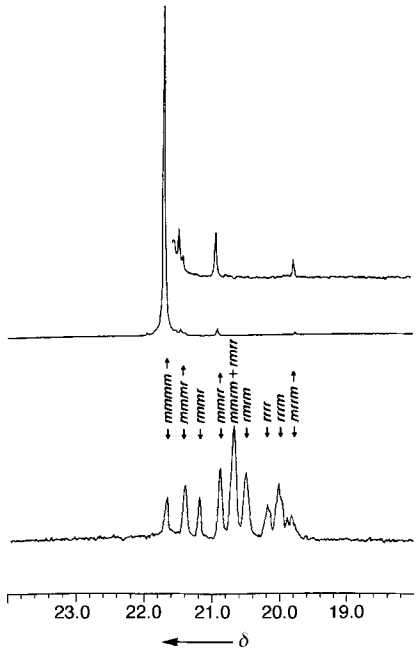
Polypropene produced by MAO-activated chiral *ansa*-zirconocenes such as *rac*-(en)(ind)$_2$ZrCl$_2$ or *rac*(en)(thind)$_2$ZrCl$_2$ has similar isotacticity to polymers produced with heterogeneous Ziegler–Natta catalysts. For a more quantitative discussion of these relations, we consider briefly the ^{13}C NMR spectroscopic methods[107] currently used to characterize the stereoregularity of poly(α-olefins).

The ^{13}C NMR signals of a polymer are most conveniently related to its microstructure by a stereochemical notation developed by Bovey.[107a] Relative configurations of neighboring units (or "dyads") are designated as *m* (*meso*) for equally and *r* (*racemo*) for unequally positioned substituents in a Fischer-type projection of the polymer chain. In polypropene, the ^{13}C NMR shift of each CH_3 group is determined by the configurations of two neighboring repeat units on either side;[108] each CH_3 signal is thus assignable to a particular "pentad" pattern, represented by the four consecutive *m* or *r* designators framing the CH_3 group under consideration (Scheme 9). All ten possible

Scheme 9. The ten possible stereochemical pentads of a polyolefin [107].

pentad signals (*mmmm*, *mmmr*, *rmmr*, *mmrr*, *mmrm*, *rmrr*, *rmrm*, *rrrr*, *rrrm*, and *mrrm*)[109] are observed for the randomly configurated repeat units of atactic polypropene[110] (Fig. 4). Isotactic polypropene, on the other hand, is ideally characterized by a single ^{13}C NMR signal for *mmmm* pentads, since its repeat units have identical configuration over long segments of the polymer chain.

The degree of isotacticity of such a polymer is usually expressed as the ratio of the *mmmm* pentad integral to the integral sum of all pentad signals observed; it will be designated in the following as [*mmmm*].[111] Isotactic polypropene produced by modern heterogeneous Ziegler–Natta catalysts[8] is highly



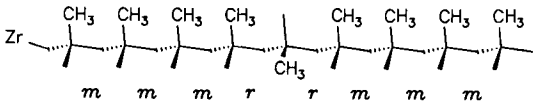


Fig. 4. ^{13}C NMR spectra of isotactic polypropene (CH_3 region) with [*mmmm*] > 90% obtained with *rac*-Me$_2$Si(1-benz[*e*]indenyl)$_2$ZrCl$_2$/MAO [117h, 120d] (top), and of atactic polypropene with random pentad distribution obtained with the *meso* isomer of the same catalyst (bottom).

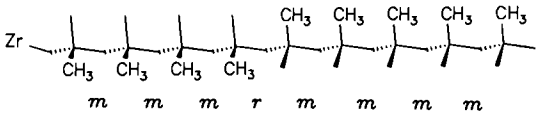
stereoregular with [*mmmm*] > 0.95. At ambient temperatures, typical MAO-activated chiral *ansa*-metallocene catalysts yield polypropene with stereoregularities of [*mmmm*] ≈ 0.8–0.9.[106, 112, 113] At increased polymerization temperatures, however, most of these homogeneous catalysts are distinctly less stereoselective than typical heterogeneous Ziegler–Natta catalysts.[114a]

The ^{13}C NMR signals associated with occasional stereoerrors in the isotactic polymers produced by metallocene catalysts indicate that stereoregularity is controlled by the chirality of the metallocene catalyst and not by the asymmetry of the last inserted unit: Such "chain-end" control would give rise to the single-inversion pentad *mmrm* as a main error signal, since an occasionally inverted chain-end configuration would generally be followed by units of the same configuration. For this chain-end control one would expect an error pentad ratio close to *mmmr*:*mmrr*:*mmrm*:*mrrm* = 1:0:1:0. In fact, an error pentad distribution close to *mmmr*:*mmrr*:*mmrm*:*mrrm* = 2:2:0:1 is observed for these polymers (Scheme 10). As previously established for heterogeneous catalysts,[12] this pentad pattern is expected when olefin insertion is indeed under "catalytic-site" control.[105, 115] In this case, *r* dyads due to stereoinversions will occur in pairs, since a catalyst center of fixed chirality forces the enantiofacial orientation of subsequent olefin insertions to return to the previous preference immediately after an occasional mistake (Scheme 10).



How the stereoselectivities of chiral catalysts depend on the structure of the complex, in particular on different bridging units and substituent patterns, has been the subject of comparative studies in several research groups.[116–120] In investigations of this kind, it is crucial to take into account the polymerization temperature T_p.[121] Even an unbridged metallocene catalyst with unsubstituted ring ligands, Cp_2TiPh_2/MAO, has been

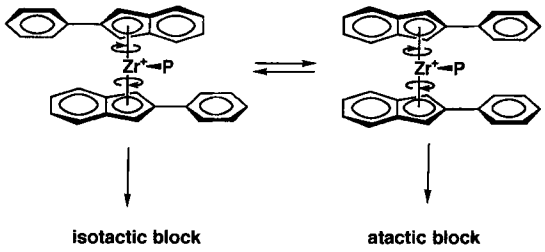
Catalytic–site control

mmmr : *mmrr* : *mmrm* : *mrrm* = 2 : 2 : 0 : 1

Chain–end control

mmmr : *mmrr* : *mmrm* : *mrrm* = 1 : 0 : 1 : 0

Scheme 10. Pentad distributions of stereoerrors in isotactic polypropene characteristic for catalytic-site stereocontrol (top; see also insert in Fig. 4) and for chain-end stereocontrol (bottom).



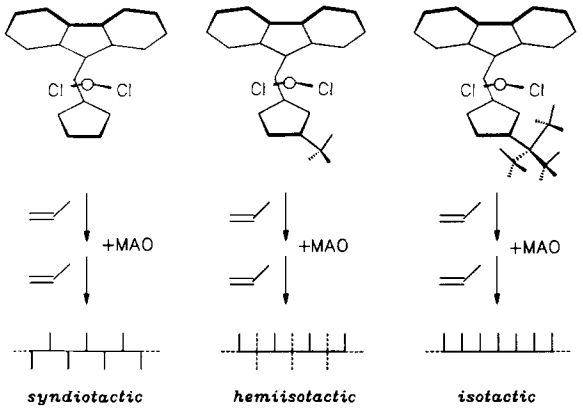
shown by Ewen[105] to yield partially isotactic polypropene with [*mmmm*] ≈ 0.5 at temperatures below −40 °C. In this case, the nearly equal intensities of the *mmmr* and *mmrm* pentad signals indicate a chain-end control mechanism.[105, 122]

Similar observations were reported by Erker and co-workers[123] for unbridged zirconocenes with substituents containing an asymmetric C atom; these were found to give isotactic polymers with [*mmmm*] ≈ 0.4–0.8 at polymerization temperatures of −50 °C or lower. This partial control by the configuration of the last inserted unit over the stereochemistry of the next olefin insertion is almost completely lost at ambient temperatures. Apparently, insufficiently restricted rotations of the C_5 ring ligands and their substituents and the increasing conformational mobility of the growing polymer chain abolish this stereocontrol mechanism at ambient temperatures.

An unbridged, chiral zirconocene that produces an isotactic polymer even at T_P = 60 °C was described by Razavi and Atwood.[124] MAO-activated (1-methylfluorenyl)$_2$ZrCl$_2$ generates polypropene with [*mmmm*] = 0.83 and a catalytic site controlled pentad distribution. The fluorenyl ligands of this complex are chirally disposed, due to their methyl substituents, and apparently so strongly hindered in their mutual rotation that the enantiomers of this complex are not interconverted during the growth of a polymer chain.

Waymouth and co-workers recently reported on an unbridged metallocene catalyst, (2-phenylindenyl)$_2$ZrCl$_2$/MAO, which appears to isomerize, by restricted rotation of its indenyl ligands, between chiral and achiral coordination geometries during chain growth; this catalyst yields a highly stretchable atactic–isotactic stereoblock polypropene with elastomeric properties (Scheme 11).[125]

A short interannular bridge will necessarily restrict rotation of the C_5 ring ligands. Accordingly, high stereoselectivities are found for all chirally substituted *ansa*-metallocene catalysts with one-atom or two-atom bridges,[116–120] at least at lower polymerization temperatures. At temperatures of 50–70 °C, typical for technical polymerizations, stereoselectivities are often substantially decreased. Incorporation of the ethylene bridge of (en)(ind)$_2$ZrCl$_2$ (which can fluctuate between δ and λ chelate ring conformers[126a]) into a carbocyclic system[127] or its replacement by a one-atom silanediyl or germanediyl bridge[114b, 116c, 117b] increases stereoselectivities, but only to a limited extent.[117g] Even in metallocenes with a short Me_2Si bridge, the ZrX_2 and ligand framework moieties appear to retain substantial degrees of mobility.[126b] Molecular mechanics studies indicate that much of this mobility is restricted by substituents placed in α-position to the bridgehead atom.[126b] Chirally substituted *ansa*-zirconocene catalysts with α-CH_3 groups at each C_5 ring do indeed show increased stereoselectivities.[118–120]



Scheme 11. Reversible isomerization of an unbridged zirconocene catalyst between chiral and achiral geometries found by Waymouth and co-workers [125] to yield isotactic and atactic blocks alternating along each polymer chain. The resulting polypropene is an elastomer.

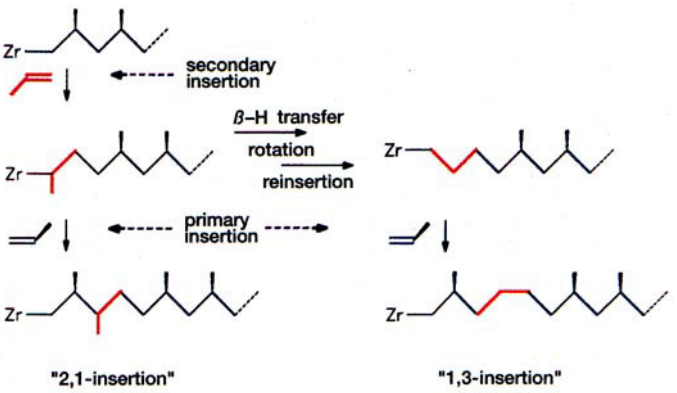
Most interesting with respect to their effects on polymer stereoregularities, however, are the substituents in β-position to the bridgehead atom of an *ansa*-zirconocene. These β-substituents are in close proximity to the coordination sites at which the growing polymer chain and the α-olefin substrate are bound. In the chiral complexes (en)(ind)$_2$ZrCl$_2$, (en)(thind)$_2$ZrCl$_2$, and Me_2Si(ind)$_2$ZrCl$_2$, CH or CH_2 groups of the annelated C_6 ring function as β-substituents and flank each of the adjacent coordination sites. If the β-substituents are very bulky, as in Me_2Si(2-Me-4-*t*Bu-C_5H_2)$_2$ZrCl$_2$[120a, b] or in Bercaw's [Me_2Si(2-$SiMe_3$-4-*tert*-butyl-C_5H_2)$_2$YH]$_2$,[144] or particularly protruding, as in Spaleck's Me_2Si(2-methyl-4-aryl-1-indenyl)$_2$ZrCl$_2$,[117h] polypropenes with stereoregularities of [*mmmm*] > 0.95 are generated even at polymerization temperatures of 70–80 °C.

Chiral *ansa*-zirconocene complexes with two identical ligand moieties have C_2 symmetry. Both coordination sites of such a C_2-symmetric complex are thus equivalent; each is framed by the β-substituents in such a manner that olefin insertions at the Zr center occur with equal enantiofacial preference at both sites. *Unilateral* coverage of each coordination site is essential for this stereoselectivity; this is documented by the observation that atactic polypropene is produced if both coordination sites are flanked by *two* β-substituents, as in C_2H_4(3-methyl-1-indenyl)$_2$ZrCl$_2$/MAO or in its silyl-bridged analogue Me_2Si(3-methyl-1-indenyl)$_2$ZrCl$_2$/MAO.[116c, 117h] The bilateral coverage of each coordination site in these complexes, by a CH and a CH_3 group, appears to render them indifferent with respect to the enantiofacial orientation of an entering olefin. The same result, production of essentially atactic polymers, was also observed for the *meso* isomers of each *ansa*-metallocene catalyst.[105]

The relationship between the stereoselectivity of *ansa*-metallocene catalysts and the spatial disposition of their β-sub-

Scheme 12. Relationship between catalyst structure and stereoselectivity discovered by Ewen and co-workers [116d–h]. Syndiotactic polypropene is produced by $Me_2C(C_5H_4)$(9-fluorenyl)$ZrCl_2$/MAO; introduction of a β-CH_3 group on the C_5 ring results in formation of hemiisotactic polymer in which every other repeat unit is randomly configurated; introduction of a β-*tert*-butyl group gives highly isotactic polypropene.

stituents has been most elegantly utilized by Ewen and co-workers in a series of studies on Me_2C-bridged fluorenyl complexes (Scheme 12).[116d–h] The complex Me_2C(Cp)(9-fluorenyl)-$ZrCl_2$, for example, is not a C_2-symmetric but a C_s-symmetric structure with one unsubstituted C_5 ring ligand and, in its fluorenyl ligand, one C_5 ring ligand with *two* β-substituents.[124b, c] In the presence of MAO or cationic activators this complex produces highly syndiotactic polypropene.[116d–g, 117d]



Syndiotactic polypropene is ideally characterized by a ^{13}C NMR spectrum with a single *rrrr* pentad signal, as configurations alternate here from one repeat unit to the next.[128] Ewen's syndiospecific catalyst provided this polypropene isomer for the first time in substantial quantities, with stereoregularities of [*rrrr*] > 0.9 and with a pentad intensity distribution in accord with catalytic-site control.[116d] The alternating enantiofacial orientation of subsequent olefin insertions, which gives rise to this particular tacticity, is undoubtedly due to the fact that the two coordination sites in this C_s-symmetric complex are no longer homotopic, as in a complex with C_2 symmetry, but enantiotopic.[129c]

The correlation between the substituent pattern of a metallocene and the stereoregularity of its polymer products is further extended by Ewen's finding that still another polypropene stereoisomer is formed with MAO-activated $Me_2C(3\text{-}MeC_5H_3)$-(9-fluorenyl)$ZrCl_2$.[116e–g, 117d] This catalyst, with one coordination site framed by one β-substituent and one by two β-substituents (Scheme 12), produces hemiisotactic polypropene[129] in which every other repeat unit is of identical configuration while the remaining units are randomly configurated. By totally blocking one of the coordination sites in the catalyst $Me_2C(3\text{-}t\text{Bu}C_5H_3)$(9-fluorenyl)$ZrCl_2$/MAO with a *tert*-butyl group and a fluorenyl C_6 ring, while keeping the other site unilaterally framed by the other fluorenyl C_6 ring, Ewen and Elder finally obtained isotactic polypropene again.[116h]

The stereoselectivity of a C_2-symmetric isotactic polymerization catalyst such as $Me_2Si(ind)_2ZrCl_2$ is practically independent of zirconocene and MAO concentrations[131] and essentially unaffected even by the replacement of MAO by a borane or borate activator.[116f, g, 132a, b] The C_s-symmetric syndiospecific catalyst Me_2C(Cp)(9-fluorenyl)$ZrCl_2$/MAO, however, behaves differently in this regard: its syndiotactic polymers show more frequent *rmrr* errors when either MAO or olefin concentrations are decreased.[116e, f, 132a]

Ewen et al.[116f] and Herfert and Fink[132a] showed that this dependence must indeed result from a crucial requirement for syndiotactic polymerization: each olefin insertion has to occur at the coordination site opposite to the previous one. This requirement can only be met when the polymer chain remains at the coordination site of the previous olefin unit until the next olefin insertion occurs. Stereoerrors with single-*m* dyads must result whenever the polymer chain moves to the opposite coordination site before the next olefin inserts. Such an event[133] will become more likely when the rate of olefin insertion is decreased by low olefin or MAO concentrations. Similar changes in the stereoregularity of hemiisotactic polypropene, recently reported by Herfert and Fink[132c] and by Farina and co-workers,[129b] and of partly isotactic polypropene obtained with several asymmetric catalysts,[130] underscore the importance of the relative rates of olefin insertion and chain migration between coordination sites for these non-C_2-symmetric metallocene catalysts.

While olefin insertion in metallocene-based homogeneous catalysts, as in heterogeneous Ziegler–Natta systems,[10, 12] generally occurs with 1,2-regioselectivity so as to generate primary Zr–alkyl units, polyolefins produced with metallocene-based catalysts contain varying fractions of regioinverted units.[114a, 135, 136] Depending on the polymerization temperature and on the metallocene catalyst used, one finds either head-to-head concatenations resulting from primary olefin insertion into regioinverted secondary Zr–alkyl units, or tetramethylene units (1,3-insertions). The latter arise from an isomerization of a secondary Zr–alkyl unit to one with a terminal Zr–alkyl bond prior to insertion of the next olefin[114a, 136] (Scheme 13).

Scheme 13. Alternative sequences arising from a secondary olefin insertion [114a, 136]. A (relatively slow) primary insertion gives the tail-to-tail and head-to-head pattern typical of a 2,1-insertion; rearrangement of the secondary Zr–alkyl unit into its terminal isomer, followed by a primary insertion, yields a tetramethylene or 1,3-insertion unit.

Different zirconocene catalysts produce the regioirregularities in different ratios:[69b] only 1,3-misinsertions (ca. 1%) are found in polymers made with (en)(thind)$_2ZrCl_2$/MAO; with (en)(ind)$_2ZrCl_2$/MAO both types of misinsertions are present; and $Me_2Si(ind)_2ZrCl_2$/MAO forms polymers with only 2,1-misinsertions (ca. 0.6%) at 40 °C. With "fast" catalysts, misin-

sertions are generally of the 2,1-type; slower catalysts produce mainly 1,3-misinsertions.[117h, 120d] Effects of these misinsertions on catalyst activities will be considered in Section 3.3.

The irregularities introduced into a polypropene chain by 2,1- or 1,3-misinsertions decrease its melting point considerably (see Section 3.4); these misinsertions are thus of practical concern. Their frequency seems to depend mainly on the steric demands of the substituents on the C_5 ring. Rather frequent misinsertions are found for metallocenes with bulky β-substituents, while α-methyl substituents appear to suppress these regioirregularities.[120a–c]

Steric relationships in a metallocene complex can be described by its "coordination-gap aperture", the largest possible angle spanned by two planes through the metal center which touch the van der Waals surfaces of the β-substituents at the C_5 ring ligands, and by its "lateral extension angle", which is limited by the two α-substituents protruding into the coordination gap (Fig. 5).[137a]

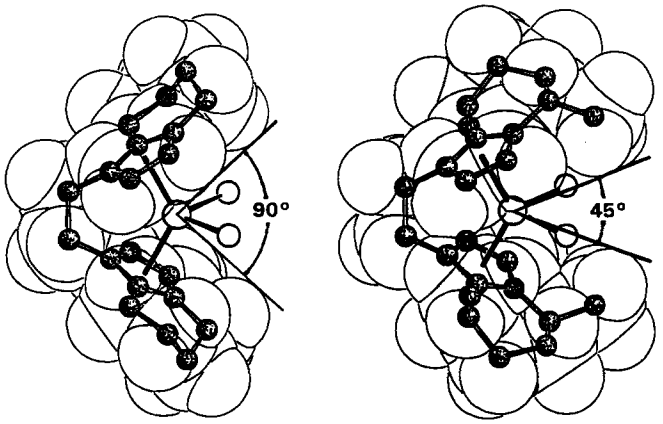


Fig. 5. Right: Narrow coordination gap aperture [137] of *rac*-C_2H_4(4,7-dimethyltetrahydroindenyl)$_2ZrCl_2$ was found by Spaleck and co-workers [117i] to produce unusually large fractions (ca. 24%) of 1,3-misinsertions (molecular model). Left: Crystal structure of unsubstituted *rac*-C_2H_4(tetrahydroindenyl)$_2ZrCl_2$ [103] for comparison (see Fig. 3).

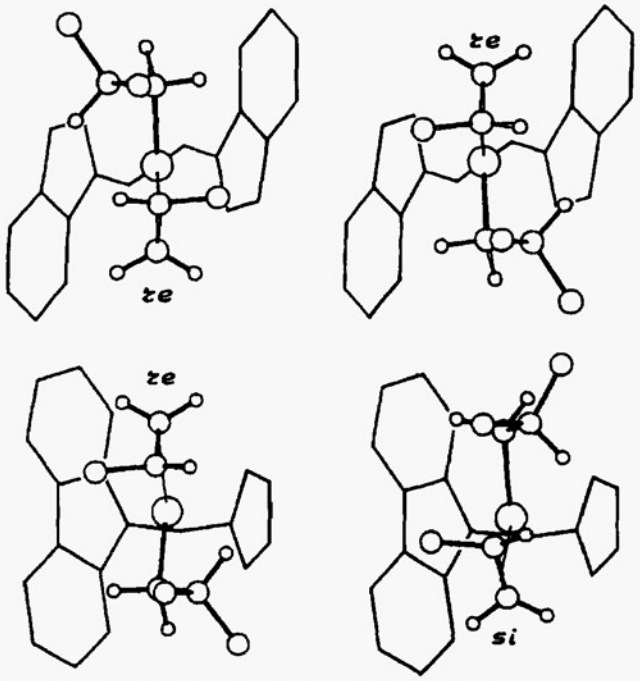
A secondary olefin insertion (2,1-insertion) is expected—due to the lateral orientation of the olefin substituent—to require less space in the aperture direction but more space in the lateral direction than a regular 1,2-insertion. Regioinversions are thus favored by those zirconocene catalysts whose β-substituents strongly limit the gap aperture, provided that the lateral extension angle is not restricted also by α-substituents protruding into the coordination gap.[137b, c] Polypropene with an unusually high fraction of 1,3-misinsertions has been reported by Spaleck and co-workers[117i] to arise from the catalyst C_2H_4(4,7-dimethyl-thind)$_2ZrCl_2$/MAO, whose *endo*-oriented 4-methyl groups severely restrict the coordination gap aperture (Fig. 5).

3.2. Mechanisms of Stereochemical Control

The mechanisms by which chiral *ansa*-metallocenes control the stereochemistry of polymer growth are reasonably well-understood today. As usual, stereochemical analysis affords more reliable information on a reaction mechanism than most other methods. This analysis is simplified, furthermore, by the observation that the stereoregularity of isotactic polymers is rather insensitive to MAO or zirconocene concentrations[120c, 132a] (see, however, ref. [131]) and even to the type of activator used to generate the reactive cationic species.[116f, g, 132b, 151b]

First important clues as to the factors governing the stereoselectivity of C_2-symmetric, chiral metallocene catalysts came from ^{13}C NMR studies of Zambelli and co-workers. These authors followed the course of propene and 1-butene insertions into ^{13}C-enriched CH_3 and CH_2CH_3 end groups, which were introduced into a MAO-activated (en)(ind)$_2TiMe_2$ catalyst by alkyl exchange with Al($^{13}CH_3$)$_3$ or Al($^{13}CH_2CH_3$)$_3$.[138] The results of these studies can be summarized as follows:

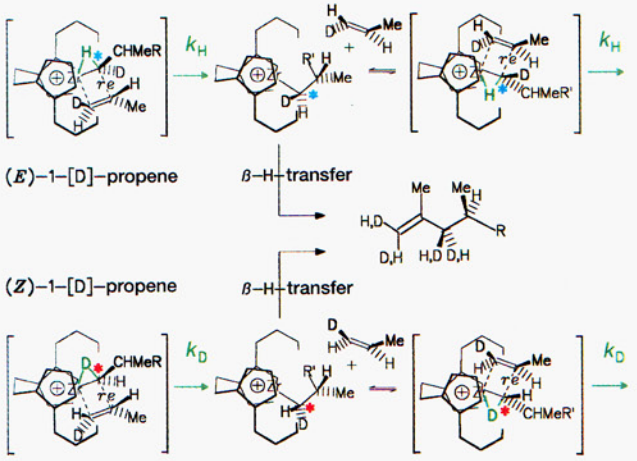


1. Propene inserts into (en)(ind)$_2$Ti–$^{13}CH_3$ bonds without significant stereoselectivity, as shown by signals of diastereomeric end groups with almost equal intensity.
2. Butene insertion into (en)(ind)$_2$Ti–$^{13}CH_3$ bonds occurs with slight (2:1) selectivity.
3. Complete stereoselectivity prevails when either propene or butene inserts into (en)(ind)$_2$Ti–$^{13}CH_2CH_3$ bonds.
4. All these results resemble those obtained before with analogously activated heterogeneous polymerization catalyst systems.[12]

Efficient control of the chiral catalyst over the enantiofacial orientation of the entering olefin is thus clearly contingent on the presence of a metal–alkyl segment with at least two C atoms. This segment appears to act as a sort of lever in transmitting the effects of the β-substituents on the orientation of the prochiral α-olefin.

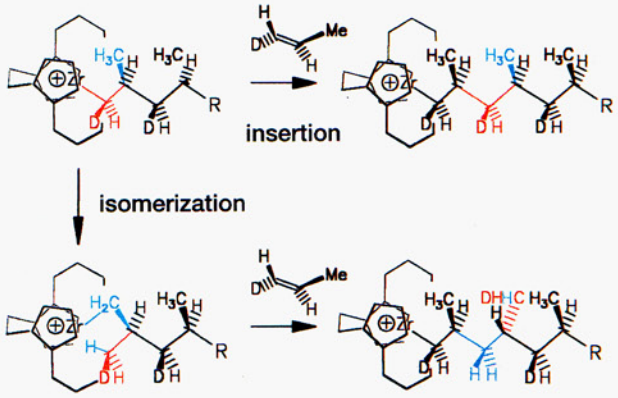
The nature of this stereocontrol mechanism was clarified by molecular mechanics calculations by Corradini, Guerra, and co-workers.[139] As previously proposed for heterogeneous Ziegler–Natta catalysis,[12b] repulsive interactions were shown to force an olefin into that enantiofacial approach to the metal–alkyl unit which places the olefin substituent *trans* to (i.e. away from) the β-C atom of the metal-bound alkyl chain. The metal–alkyl chain, in turn, was proposed to favor an orientation in which its C(α)–C(β) segment is in the most open sector of the chiral *ansa*-metallocene ligand framework (Scheme 14). Subsequent model studies in other groups by means of more elaborate force field and ab initio methods[85, 86] support this proposal.

Analogous considerations hold for stereocontrol mechanisms for *ansa*-metallocene derivatives that produce syndiotactic and hemiisotactic polymers.[116e–g, 139e, g–i, 140] In each case, the C(α)–C(β) segment of the polymer chain appears to orient itself so as to avoid interaction with the C_5 ring substituents in β-position adjacent to its coordination site (Scheme 15); an entering olefin is then forced into that orientation in which the two alkyl substituents at the incipient C···C bond are *trans* to each other.[141]



Experimental proof for this catalytic-site control by means of chain-segment orientation was provided by Pino and co-workers.[142] Chiral hydrotrimers and hydrotetramers with the predicted absolute configurations were obtained when propene was hydrooligomerized[143a] with enantiomerically pure[103, 125] (en)(thind)$_2ZrMe_2$ activated by MAO in the presence of H_2. Formation of asymmetric oligomers with olefinic end groups in similar reaction systems without H_2 were studied by Kaminsky and co-workers[143b] and found to follow the same rules.

Scheme 14. Models for the stereocontrol of olefin insertions in *ansa*-zirconocene catalysts, proposed by Corradini, Guerra, and co-workers [139]. The growing alkyl chain occupies an open sector of the ligand framework; the olefin enters the reaction complex with its substituent *trans* to the C(α)–C(β) chain segment. For C_2-symmetric complexes identical enantiofacial olefin orientation at both coordination sites results in isotactic polymer formation (top); for C_s-symmetric complexes the enantiofacial orientation alternates between coordination sites and leads to syndiotactic polymers (bottom).



The origin of stereoselectivity in *ansa*-metallocene catalysts was further examined by use of α-deuterated olefins. In studies similar to those previously reported for achiral zirconocene and scandocene catalyst systems,[80, 82] stereokinetic isotope effects of $k_H/k_D \approx 1.4$ were observed for hydrodimerization of (*E*)- and (*Z*)-1-[D_1]-1-hexene by chiral *ansa*-zirconocene and scandocene catalyst systems.[144–146] This indicates that the insertion reaction favors a transition state in which the α-H and not the α-D atom of initially formed Zr–CHD–R unit is in a position suitable for α-agostic interaction with the metal center. Recently stereokinetic isotope effects of $k_H/k_D \approx 1.3$ were determined directly for isotactic propene polymerizations catalyzed by (en)(thind)$_2$ZrCl_2/MAO and other chiral *ansa*-zirconocene catalysts from the mean chain lengths of polymers produced from either (*E*)- or (*Z*)-1-[D_1]-propene (Scheme 15).[145b] These results indicate that α-agostic interactions control the stability of alternative transition states for the insertion of an olefin into a metal–alkyl bond.

These α-agostic interactions can thus be considered to be the origin of the stereoselectivity of chiral *ansa*-metallocene catalysts. Of the two alternative Zr–C(α)–C(β) orientations resulting from binding one of the α-H atoms to the metal center, one orientation is sterically inaccessible since it would cause the growing chain to collide with a β-substituent of the chiral ligand framework; the other one is sterically unencumbered and in fact practically indistinguishable from that proposed by Corradini and co-workers[139] on the basis of nonbonding van der Waals repulsions alone (see Scheme 14). The α-agostic model would thus describe the *re* or *si* orientation of an inserting olefin as being controlled by the required placement of the β-C atom of the growing chain in the more open of the two possible positions at a rigid three-membered Zr–H(α)–C(α) ring.

Scheme 15. Stereokinetic isotope effects in isotactic polypropene formation indicate α-agostic interactions in the olefin insertion transition state [145]. Chain growth with (*E*)-1-[D]-propene proceeds faster, due to its Zr ← H–C(α)-stabilized transition state, than that with (*Z*)-1-[D]-propene, which proceeds via a transition state with a Zr ← D–C(α) interaction; this is manifested in polymer chain lengths that are ca. 1.3 times longer for (*E*)- than for (*Z*)-1-[D]-propene.

The exclusion of one of the possible Zr–H(α) interactions implied by this model raises questions as to the origin of the stereoerrors produced by homogeneous catalysts especially at higher reaction temperatures. Increased stereoerror frequencies at decreased olefin concentrations, recently observed by Cipullo and Busico, and by Resconi and co-workers,[131] were ascribed to an epimerization of the last inserted unit, which competes with olefin insertion. Direct evidence for stereoerror formation by chain-end isomerization was obtained by Leclerc and Brintzinger from a study of D-label distributions in isotactic polypropene obtained from (*E*)- or (*Z*)-[D_1]-propene with chiral *ansa*-zirconocene catalysts.[145b] The appearance of CH_2D instead of CH_3 groups in the *mrrm* stereoerror positions indicates that most of these errors arise from the isomerization represented in Scheme 16. *ansa*-Zirconocene catalysts with par-

Scheme 16. Formation of stereoerrors by chain-end isomerization [145]. Isolated (*mrrm*-framed) stereoerrors are associated with CH_2D instead of CH_3 groups in isotactic polypropene made from (*E*)- or (*Z*)-1-[D]-propene with (en)(thind)$ZrCl_2$/MAO. The stereoinverted CH_2D groups must originate from the α-CHD olefin terminus by an isomerization process, the exact mechanism of which is still being debated [131a, b].

ticularly high stereoselectivity[117h, i, 120b, d] thus appear to owe this property to their suppression of chain-end isomerization relative to olefin insertion.

3.3. Activities of *ansa*-Zirconocene Catalysts

The rate of a reaction is normally expected to decrease when it is made stereoselective by imposing steric restrictions on some of its possible reaction modes. Yet even the first studies on propene polymerization with the chiral *ansa*-zirconocene catalyst *rac*-(en)(thin)$_2$ZrCl$_2$/MAO showed its catalytic activity to be substantially higher than that of the stereochemically unselective, unsubstituted catalyst Cp$_2$ZrCl$_2$/MAO.[106, 107g] Even the sterically strongly congested chiral catalyst *rac*-Me$_2$Si(2-Me-4-*t*Bu-C$_5$H$_2$)$_2$ZrCl$_2$/MAO produces polypropene at higher rates than Cp$_2$ZrCl$_2$/MAO system.[120c]

Apparently, some favorable effects compensate for the steric congestion of a β-substituted *ansa*-metallocene. β-Substituents might favor formation of active, olefin-separated ion pairs at the expense of the presumably dormant contact ion pairs or, alternatively, facilitate access to an α-agostic insertion transition state by destabilizing the β-agostic interactions that otherwise compete.

With regard to the effects of different bridging units linking the C$_5$ ring ligands, one finds that zirconocenes with the one-atom bridge Me$_2$Si yield somewhat more active catalysts than otherwise comparable complexes with the two-atom bridge C$_2$H$_4$,[116f, 117g] most likely because such a short bridge widens the coordination-gap aperture.[137] Zirconocenes with three-atom or four-atom bridges have so far all been found to be practically inactive for propene polymerization in the presence of MAO.[117b, 148–150a] The same is true for chiral zirconocenes containing two Me$_2$Si bridges.[150b] Structural studies on these inactive complexes reveal that the geometrical constraints of their interannular bridges place at least one and, in some cases, two of the substituents on the C$_5$ ring in a central position close to the meridional centroid–Zr–centroid plane (Fig. 6). Substituents in this position appear to interfere with the course of the otherwise facile insertion of an α-olefin into the Zr-bound alkyl chain, most probably by colliding with the alkyl substituent of the olefin substrate, which has to be close to this meridional position in the insertion transition state. In accord with this view, these propene-inactive catalysts are generally found to be active in the polymerization of ethene, which is unobstructed by a substituent.[117b, 150, 151a]

Different ring substituents also affect catalyst activities to a substantial degree. Low activities in MAO-activated propene polymerization are obtained with the *tert*-alkyl-substituted *ansa*-zirconocenes Me$_2$Si(2-Me-4-R-C$_5$H$_2$)$_2$ZrCl$_2$ with R = *tert*-butyl or 1-methyl-cyclohexyl.[120c] A kinetic study by Fischer and Mülhaupt revealed, however, that these catalyst systems show even higher initial activities than some of the most productive bis(benzindenyl) catalysts, but differ from these by a very fast deactivation to rather low levels of residual steady-state activity.[69d]

Annelation of further six-membered rings as in Me$_2$Si-(benz[*e*]indenyl)$_2$ZrCl$_2$ results in three- to fourfold increases in productivity.[117h, i, 120d] These high activities are likely to stem

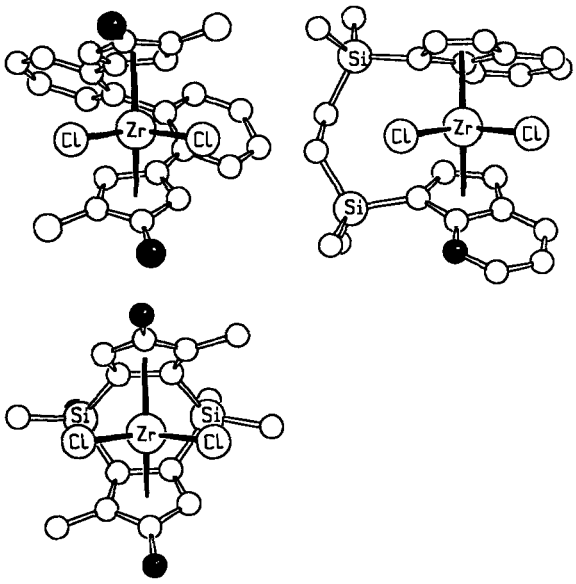


Fig. 6. Crystal structures of *ansa*-zirconocene complexes that are inactive for propene polymerization in the presence of MAO [117b, 150]. A substituent on the C$_5$ ring close to the meridional centroid–Zr–centroid plane appears to block the insertion of propene (but not that of ethene).

from steric or electronic shielding of the cationic reaction center against coordination of MAO-bound anions or other metallocene units by the extended annelated ring systems. Overall, little is known about the effects of electronic factors on catalyst activities.[119b, 152]

Isospecific metallocene catalysts usually polymerize propene at rates four to five times slower than those for ethene.[132a] This preference for ethene is less pronounced, however, than that observed with the unsubstituted system Cp$_2$ZrCl$_2$/MAO.[39e, f] Ewen's C_s-symmetric, syndiospecific catalyst is unique in that it polymerizes propene with higher activity than ethene.[132a] Higher α-olefins such as 1-butene[106] and 1-hexene,[50c] and even α-olefins branched at their 4-position such as 4-methyl-1-hexene[152] are polymerized by *ansa*-metallocene catalysts at rates only moderately lower than those for propene. The rather low degree of chemoselectivity of these catalysts is essential for their properties as copolymerization catalysts (cf. Section 4.1).

Studies with chiral olefins such as 4-methyl-1-hexene have shown that an enantiomeric catalyst center—both in homogeneous[152] and in heterogeneous catalyst systems[153a]—tends to incorporate preferentially one of the olefin enantiomers into the growing polymer chain.[153b, c]

With α-olefins branched in 3-position such as 3-methyl-1-pentene, *ansa*-zirconocene catalysts generally have negligible activities.[154] Styrene, formally also an olefin branched in 3-position, has not yet been polymerized at any worthwhile rate by MAO-activated metallocene catalysts.[36] The CpTiR$_3$/MAO systems that catalyze this reaction[7b] appear to polymerize styrene through a 2,1-concatenation, that is, by formation of secondary insertion products.[138b, 155] Apparently, the regioselectivity of *ansa*-zirconocene-based polymerization catalysts for 1,2-insertions is incompatible with the preference of styrene for 2,1-insertion.

Occasional regioerrors appear to inhibit the polymerization of normal α-olefins by MAO-activated metallocene catalysts

significantly.[114, 120, 136, 156, 157] Kashiwa, Tsutsui, and co-workers[156] found that the rates of propene and butene polymerization by (en)(ind)$_2$ZrCl$_2$/MAO increase in the presence of H_2 roughly 10- and 60-fold, respectively. These polymers were found to be free of misinserted units; hydrogenolysis apparently eliminates the slowly inserting 2,1-units and allows the start of a new, fast-growing polymer chain.

Busico, Cipullo, and Corradini[157] determined the frequency with which oligomers having primary and secondary end groups are liberated from zirconocene centers by hydrogenolysis in propene hydrooligomerization catalyzed by (en)(ind)$_2$ZrCl$_2$/MAO. Their data indicate that insertion of propene into a secondary Zr–alkyl unit is about 100 times slower than into a primary one.[158] As a consequence, 2,1-insertions with an incidence frequency of only 1% are sufficient to tie up about 90% of the catalyst in secondary Zr–alkyl units when polymerizations are conducted in the absence of H_2. Based on Busico's estimate, substantially increased activities can be expected for a catalyst that would be unimpeded by occasional 2,1-misinsertions.

Activities of chiral zirconocene catalysts are also affected by MAO concentrations. Increasing activation occurs at Al:Zr ratios of up to roughly 1–5000:1, while inhibition is observed at still higher Al:Zr ratios.[75, 132a] For propene polymerization with (en)(thind)$_2$ZrCl$_2$/MAO,[106, 116b] Me$_2$Si(ind)$_2$ZrCl$_2$/MAO,[116c, 117c] or Me$_2$C(Cp)(9-fluorenyl)ZrCl$_2$/MAO activity maxima are found at Al:Zr ratios between about 1000:1 and 10000:1.[116d–f] Apparently, yet unknown types of equilibria interconnect a diversity of species in these reaction systems.

Puzzling is also the dependence of catalyst activities on the monomer concentration. In several recent studies[69c, 120d, 132c] polymerization rates have been observed to increase more than linearly with olefin concentrations, for example, as [olefin]$^{1.4-1.7}$. Whether these observations indicate the participation of more than one olefin molecule in the insertion transition state[76]—a notion diverging from most of the current thinking about this reaction—or whether they arise from the participation of a second olefin in another reaction step that augments the overall activity of the catalyst, such as reactivation following a 2,1-insertion,[156, 157] remains to be clarified.

3.4. Polymer Chain Lengths and Crystallinity

Molecular weight is another property of polyolefins that is strongly influenced by the metallocene catalyst employed. Initial studies with (en)(ind)$_2$ZrCl$_2$/MAO and (en)(thind)$_2$ZrCl$_2$/MAO yielded polypropene with molecular weights ranging from $M_w \approx 50000\ g\,mol^{-1}$ at ambient polymerization temperatures down to $M_w \approx 10000\ g\,mol^{-1}$ at 60–70 °C.[106, 112, 114, 116c, 117g] These molecular weights are almost two orders of magnitude higher than those of the atactic polypropene obtained under otherwise identical conditions with Cp$_2$ZrCl$_2$/MAO. This effect is probably due, at least in part, to an increased rate of chain propagation v_P for *ansa*-metallocene catalysts.[117g] In addition to an increased v_P, β-substituents in these complexes might also cause a decreased rate of chain termination v_T, for example by sterically hindering the tertiary β-CH group of the growing chain in its approach to the Zr center. Bulky β-*tert*-butyl substituents as in Me$_2$Si(2-Me-4-*t*Bu-C$_5$H$_2$)$_2$ZrCl$_2$/MAO lead to rather low molecular weights at elevated temperatures[69b, 120a–c] A relatively high fraction of isopropyl end groups indicates that chain growth is frequently terminated here by transfer of the polymer chain to an Al center, presumably of the trimethylaluminum component of the MAO cocatalyst.[120c]

The molecular weights initially accessible with metallocene-based catalysts were far lower than those obtained with heterogeneous Ziegler–Natta catalysts. Higher molecular weight polymers were obtained with the analogous hafnium complexes (en)(ind)$_2$HfCl$_2$/MAO and (en)(thind)$_2$HfCl$_2$/MAO, albeit at the expense of substantially decreased catalytic activities.[116b, c, 135] Further studies revealed that additional α-methyl substituents at each C$_5$ ring ligand increase molecular weights of the polymers produced by factors of 3 to 5.[118, 120a–c] With α-methylated complexes such as Me$_2$Si(2-Me-ind)$_2$ZrCl$_2$ and Me$_2$Si(2-Me-benzind)$_2$ZrCl$_2$, polypropene can be obtained at $T_P = 50$ °C with molecular weights of $M_w = 100000–400000\ g\,mol^{-1}$.[117f, h, 120d] Polypropene with M_w close to $1000000\ g\,mol^{-1}$ is accessible with the catalyst Me$_2$Si(2-methyl-4-naphthyl-1-indenyl)$_2$ZrCl$_2$/MAO developed by Spaleck and co-workers.[117h]

β-Hydride transfer from the growing polymer chain directly to a coordinated olefin (see Scheme 8) has been implied as a dominant chain termination process by studies on end-group distributions in ethene–propene copolymers[97] and on hydrooligomer distributions at different olefin concentrations.[157c] In *ansa*-zirconocene catalysts without α-methyl substituents, direct β-H transfer from the growing polymer chain to a coordinated olefin does indeed appear to predominate, as indicated by a near-constancy of molecular weights with increasing olefin concentration.[120d, 157c] For *ansa*-metallocene catalysts with α-methyl substituents, however, a strong increase of molecular weight almost proportional to olefin concentration[117h, 120d] indicates that the remaining chain termination arises almost exclusively from β-H transfer to the metal. α-Methyl substituents thus appear to block a relatively large fraction of chain terminations that would otherwise arise from β-H transfer directly to a coordinated olefin.

Narrow molecular weight distributions, as measured by polydispersity ratios of $M_w/M_n \approx 2$,[105, 106, 112, 114, 117g, 118, 120] are as typical for these stereoregular polyolefins as for the atactic polymers produced with MAO-activated Cp$_2$ZrCl$_2$.[39e, g] Substituted *ansa*-zirconocene catalysts thus also appear to induce the growth of their respective polymer products at a single type of active center.

A polydispersity of $M_w/M_n \approx 1$, which indicates a "living" polymerization system (i.e. polymer chains permanently attached to the metal centers on which they simultaneously start to grow),[90] are typically observed for ring-opening metathesis[159, 160] and group-transfer polymerization catalysts,[161a, b] but so far not with either heterogeneous Ziegler–Natta catalysts or with zirconocene-based catalysts for normal α-olefin polymerization. Polymerization systems with a finite life span have been obtained with scandium-based metallocene catalysts.[62] Their utilization for the formation of ethene–methacrylate block copolymers as well as partially living polymerizations of cycloolefins with zirconocene-based catalysts will be discussed

in Sections 4.1 and 4.2, respectively. Development of truly living α-olefin polymerization systems remains a challenge.[162]

Stereoregularity, regioregularity, and chain length of a polypropene all appear to influence its crystallinity as well as its melting behavior and mechanical properties. Heterogeneously produced isotactic polypropenes normally crystallize in a regular packing of parallel helices, the classical α-modification.[163] In contrast, isotactic polypropenes produced by homogeneous, C_2-symmetric *ansa*-zirconocene catalysts often crystallize from their melts with sizeable fractions of a heretofore infrequently observed[164] γ-modification,[114, 165–167b] which was found by Brückner and co-workers to contain alternate layers of helices oriented at an angle of 81° to each other.[166] For a given polypropene sample, the fraction of this γ-modification, as measured by wide-angle X-ray diffraction (WAXD), appears to be inversely related to the average length of isotactic chain segments, n_{iso}, if one takes into account that stereoerrors as well as regioinversions and chain ends limit the length of the isotactic segments.[69b, d, 168]

Statistical factor analysis has been used to correlate the melting points of isotactic polypropenes with the substituent patterns of the *ansa*-zirconocene catalysts used, without differentiating between effects of regio- and stereoerrors and chain lengths variation.[169a] Melting points and total crystallinity both appear to be directly correlated with the average length of isotactic chain segments in these polyolefins.[69d] A finite fraction of noncrystalline segments within each polypropene chain appears to augment the toughness of the polymer materials.[117e, 169b] These segments apparently function as flexible links between the crystalline polymer domains (Fig. 7).

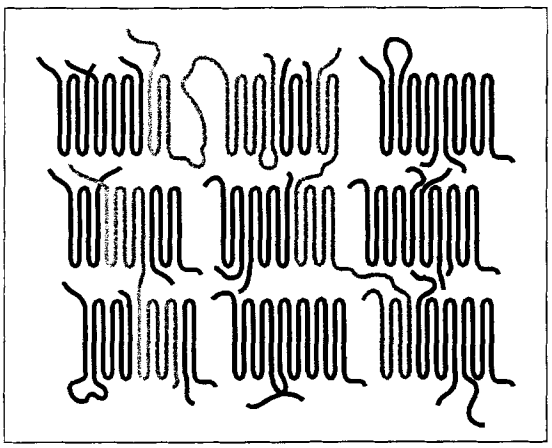

Fig. 7. Noncrystalline segments within longer polymer chains act as flexible links; they connect the crystalline polymer domains and render the polymer tougher (less brittle).

Several crystal modifications have now also been characterized for the syndiotactic polypropenes formed with C_2-symmetric metallocene catalysts.[167c, 170–173] Their crystallinity appears to correlate again with the length of uninterrupted syndiotactic chain segments;[174] a large proportion of an amorphous phase, together with a small crystallite size, appears to cause the high transparency of this material.[169b] Syndiotactic polypropene can slowly form highly crystalline solids with a melting point of about 160 °C when kept just slightly below the melting temperature.[171b] Correlations between the structures of polyolefin materials produced with different homogeneous catalysts and their respective thermal, mechanical, and optical properties are presently being studied in more detail than can be accounted for within the limits of this review.[167, 175]

4. Olefin Copolymerization and New Polyolefin Materials

While the development of homogeneous, chiral metallocene catalysts can be seen mainly as an opportunity for in-depth studies on the fundamental principles of stereoselective α-olefin polymerizations, two examples of homogeneously produced polymers encountered already, syndiotactic and hemiisotactic polyolefins, are inaccessible with heterogeneous Ziegler–Natta catalysts. In the following chapter, we summarize additional examples for the formation of polyolefin materials by homogeneous metallocene catalysts which extend beyond the capabilities of classical heterogeneous polymerization catalysts.

4.1. Copolymers from Ethene and Higher Olefins

Olefin copolymers, especially those of ethene with propene and/or another α-olefin, are of great practical interest; their total production volume is comparable to that of the homopolymers. New possibilities for controlling the properties of olefin copolymers with metallocene-based catalysts have recently caught the interest of industrial chemists and will thus be summarized here.

Linear polyethene with short-chain branches, which has low crystallinity and, hence, low density (*l*inear *l*ow-*d*ensity *poly*ethene, LLDPE) is obtained by copolymerization of ethene with 1-butene, 1-hexene, and/or 1-octene.[176] Its mechanical properties, which differ from those of the long-chain branched LDPE (*l*ow-*d*ensity *poly*ethene) produced by high-pressure radical polymerization, make LLDPE one of the largest volume polyolefin products. Copolymerization of propene with small amounts of ethene gives copolymers of lower crystallinity;[177] increased fractions of ethene lead to amorphous materials with rubber-like elasticity (EP-rubbers). Blending of these EP-rubbers with the stiffer but brittle polypropene yields heterophase materials with balanced toughness–stiffness properties which have opened new ranges of practical applications for these polyolefin blends.[178, 179]

Mechanical, thermal, and optical properties of these copolymers obviously depend on their comonomer content; however, to a significant degree they also depend on the distribution of the comonomers between and within individual polymer chains. If a catalyst distributes the comonomers randomly along each chain, an amorphous polymer is to be expected, whereas partially crystalline polymers are likely to result when the monomers are collected into separate blocks.

The comonomer selectivity of a given catalyst, in other words its tendency to insert one of two competing monomers into each type of metal–chain-end bonds, is expressed by its copolymerization parameters r_1 and r_2 (the subscripts specify the monomer).[176a, 180] These are defined as $r_i = k_{ii}/k_{ij}$, the ratio of

the rate constant for a homopolymerization step (k_{ii}) over that for a copolymerization step (k_{ij}).[181, 182] The product r_1r_2 is an indicator for the distribution of two monomers along each chain.[176] Values of $r_1r_2 > 1$ indicate that a catalyst tends to collect at least one of the comonomers into separate blocks, while a catalyst with $r_1r_2 < 1$ tends to alternate isolated comonomer units along each chain.[183]

Values of $r_1r_2 > 1$ are typical for ethene–propene copolymers made with heterogeneous polymerization catalysts[177b, 184b] (Table 1) and indicate that these catalysts tend to collect each

Table 1. Copolymerization parameters r_1 and r_2 for ethene and a second α-olefin. For heterogeneous catalysts (entries 1–3) values of $r_1r_2 > 1$ indicate that the monomers are incorporated in blocks; for metallocene-based catalyst systems (entries 4–9), random or alternating monomer sequences are indicated by values of $r_1r_2 \leq 1$.

Entry	Catalyst	r_1	r_2	r_1r_2
1	δ-$TiCl_3$/$AlEt_3$ [176c]	7.3	0.76 [a]	5.5
2	$MgCl_2$/$TiCl_4$/$AlEt_3$ [184a]	–	– [a]	4
3	SiO_2/$MgCl_2$/$TiCl_4$/$AlEt_3$ [184a]	5–10	0.2–0.34 [a]	1.9
4	$(C_5H_5)_2ZrCl_2$/MAO [190]	48	0.015 [a]	0.72

[a] Ethene/propene. [b] Ethene/1-hexene.

type of monomer into separate blocks. In addition, the nonuniform centers of heterogeneous polymerization catalysts have in general different copolymerization characteristics.[6, 176b, 185] Analysis of the copolymer products by *t*emperature-*r*ising *e*lution *f*ractionation (TREF) and cross-fractionation[186] (Fig. 8) shows that the higher α-olefin is preferentially incorporated at the centers that produce shorter chains; higher olefins are thus enriched in the low molecular weight fractions of these copolymers.[187] This increases the content of extractables and tends to make these materials sticky, two generally undesirable properties.

In their early studies on chiral, metallocene-based catalysts such as (en)$(thind)_2ZrCl_2$/MAO, Kaminsky and co-workers had noticed that these catalysts polymerize propene or 1-butene with only modestly lower rates than ethene.[39c–h, 188] Accordingly, copolymers obtained with these catalysts contain larger fractions of higher olefins than those obtained with heterogeneous catalysts under comparable conditions.[176, 177] These and additional studies,[189–193] particularly by the groups of Zambelli,[122, 136b] Chien,[194] Soga,[195] and Kashiwa,[66, 97] showed that copolymers produced by metallocene-based catalysts consist of uniform chains with narrow molecular weight distributions typical of single-site catalysts. The copolymer chains contain the comonomers in nearly random placement,[196] as indicated by copolymerization-factor products of $r_1r_2 \approx 1$ (Table 1); their TREF characteristics (Fig. 8) show that comonomer distributions are essentially independent of chain lengths, an important aspect for applications of these copolymers, for instance in films or sealant layers.

The copolymerization characteristics of metallocene-based catalysts vary with the metallocene complex used.[197] Higher

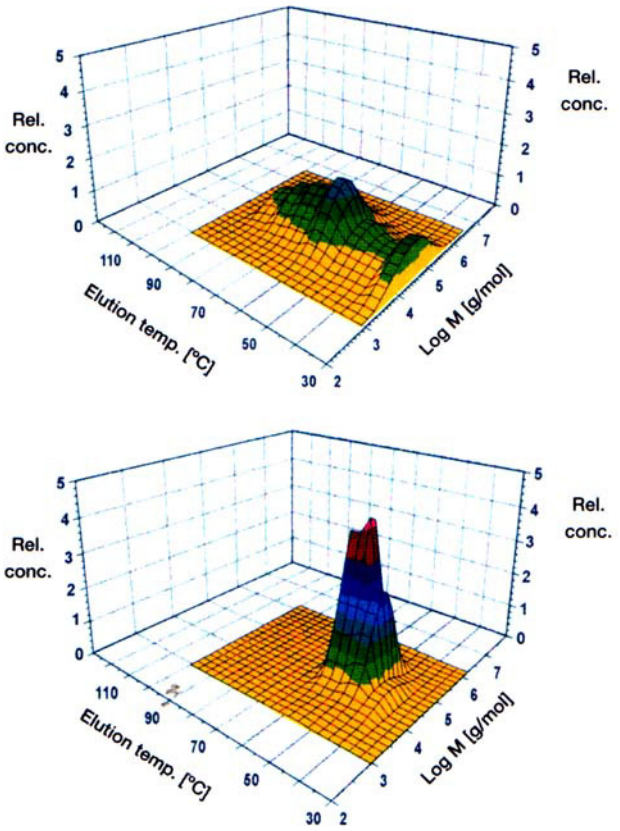

Fig. 8. Holtrup cross-fractionation of a conventional (top) and a metallocene-derived (bottom) ethene–butene random copolymer (LLDPE). Whereas LLDPE produced by classical heterogeneous catalysts contains a mixture of polymer chains with different composition and chain lengths, LLDPE produced by metallocene catalysts shows chemical uniformity and a very narrow molecular weight distribution.

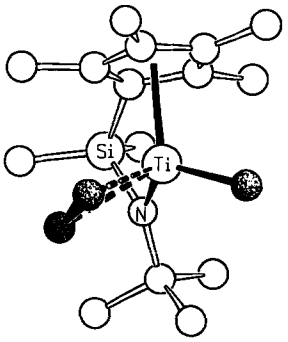
α-olefins are taken up more readily by isospecific, chiral *ansa*-metallocenes than by unbridged complexes. An even greater tendency for the incorporation of higher α-olefins is evident for the syndiospecific catalyst $Me_2C(Cp)$(fluorenyl)$ZrCl_2$/MAO. This trend reflects the rising activities in this series of catalysts for the homopolymerization of higher α-olefins as compared to that of ethene.[132a] But even monomers that are not homopolymerized by metallocene catalysts, for example isobutene,[188f] styrene, and 1,3-dienes,[188e, 191] are incorporated, albeit in minor amounts, into various copolymers.[39c, 188, 189d, 191, 194d]

Even less restricted than the metallocene-based catalysts with regard to comonomer selection are monocyclopentadienyl complexes such as MAO-activated dimethylsilyl-bridged amidocyclopentadienyltitanium complexes.[7a, 189c, 198] These catalysts (Fig. 9) incorporate into their polymer products even the vinylic end groups of polymer chains terminated by β-hydrogen transfer; they can thus generate copolymers with long-chain branches, in contrast to the strictly linear LLDPE copolymers produced by metallocene-based catalysts.[189c, 198a] These catalysts can also copolymerize styrene with ethene;[7a] styrene units in these copolymers are mostly isolated and of low regioregularity. Whether styrene–ethene and styrene–1,3-diene copolymers can be obtained also with the unbridged titanium system $CpTiCl_3$/MAO,[199–201] which catalyzes the syndiotactic homopolymerization of styrene,[7b] needs further clarification.[202]



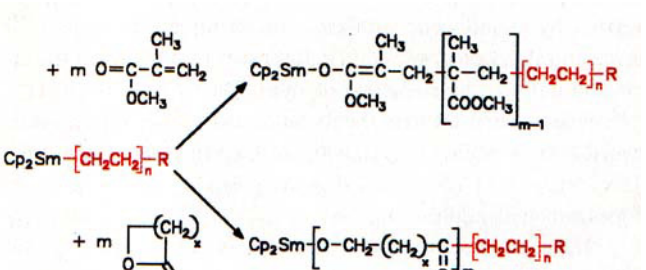


Fig. 9. Monocyclopentadienyltitanium complex with an Me_2Si-bridged alkylamido ligand framework [7a] which catalyzes, in the presence of MAO, formation of long-chain branched copolymers [198] (ab initio model for the C_2H_4 complex of $Me_2Si(Me_4C_5)(tBuN)Ti-CH_3^+$) [87b, 88b].

A long-standing goal in olefin polymerization catalysis is the copolymerization of ethene or propene with olefins bearing polar functional groups such as acrylate esters or vinyl ethers. Copolymers of this type might endow polyolefins with some of the useful properties of polyvinyl esters or ethers such as their adhesiveness. While most metallocene-based polymerization catalysts appear to be as sensitive to oxygen-containing functional groups as their heterogeneous predecessors, advances toward the goal of incorporating olefins with polar functional groups into Ziegler–Natta polymerization systems have recently been made and will be discussed in Section 4.3.

Living polymerizations, briefly mentioned in Section 3.4, would allow the formation of block copolymers, with polar olefins as well as with other alkenes. Advances in this regard—catalyst systems with polymer chains bound to the central metal atom for at least some minutes—have recently been reported. Ethene–propene block copolymers, prepared by Turner and Hlatky with cationic hafnocene catalysts at lower temperatures, indicate that Hf–polymer bonds have a finite lifetime at these temperatures.[203] Yasuda and co-workers[204] utilized the persistence of lanthanide–alkyl bonds[62] to prepare ethene copolymers with polar polyacrylate or polyester blocks. They first polymerized ethene with a samarocene catalyst and used this system then to initiate the polymerization of the polar monomer by group-transfer polymerization or by ring-opening polymerization of a lactone (Scheme 17).

Scheme 17. Block copolymers from ethene and polar monomers obtained by Yasuda and co-workers [204] with a samarocene catalyst. A living Sm–polyethene system is utilized to initiate group-transfer or ring-opening polymerizations of unsaturated or cyclic esters.

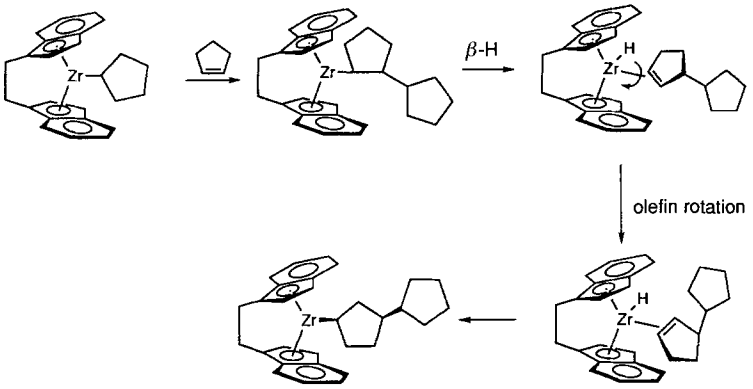
Studies on ^{13}C NMR characteristics of ethene–propene copolymers have led to rather complete assignments of their repeat patterns and end group signals.[97, 205] Isospecific *ansa*-zirconocene catalysts generate copolymers with mainly *m*-oriented side chains, as expected from their stereoselectivity.[197] Studies by Zambelli and co-workers on propene copolymers with ^{13}C-labeled ethene showed furthermore that the stereoselectivity of the catalyst system is undiminished by incorporation of ethene, thus proving that this stereoselectivity is indeed caused by the chirality of the metallocene centers and not by that of the last inserted monomer unit.[122]

End group distributions in ethene–propene copolymers were studied by Kashiwa and co-workers by ^{13}C NMR spectroscopy.[97] The strong prevalence of *n*-propyl ends and the near-absence of ethyl end groups were taken as evidence that chain termination occurs mainly by β-H transfer directly to a coordinated propene molecule rather than to the metal followed by monomer insertion into the Zr–H bond, as discussed in Section 2.4.

As with heterogeneous Ziegler–Natta catalysts,[176b] a distinct comonomer effect is generally observed with MAO-activated zirconocenes.[66, 182, 188, 206] Under otherwise identical conditions, the rate of copolymerization of ethene with higher α-olefins often exceeds that of the homopolymerization of ethene. This effect is difficult to reconcile with the fact that homopolymerization rates are higher for ethene than for other α-olefins and that ethene is always preferentially incorporated into the copolymer. It remains to be clarified whether these comonomer effects are due to increased rates of ethene insertion into a $Zr-CH_2-CHR-$ rather than into a $Zr-CH_2-CH_2-$polymer bond (e.g. by destabilization of a β-agostic resting state of the former[26i, 63, 89, 120a]), to cooperative effects of both olefins (e.g. in insertion transition states involving two olefins[76]), or simply to a higher solubility of a copolymer in the reaction medium[206b] (which might allow for higher rates of diffusion of the monomers to the catalyst centers).

4.2. Cycloolefin Polymerization and Diolefin Cyclopolymerization

A distinctive property of homogeneous, metallocene-based polymerization catalysts is their capability to induce the polymerization of cyclic olefins without inducing ring-opening metathesis, which is characteristic of those heterogeneous Ziegler–Natta catalyst systems that polymerize cycloolefins.[4a] As noted by Kaminsky and co-workers,[207a] cyclobutene, cyclopentene, norbornene, and dimethanooctahydronaphthalene but not cyclohexene (Scheme 18) are polymerized with remarkably high activities by chiral *ansa*-zirconocene catalysts such as $(en)(ind)_2ZrCl_2$/MAO and its Me_2Si-bridged analogue.

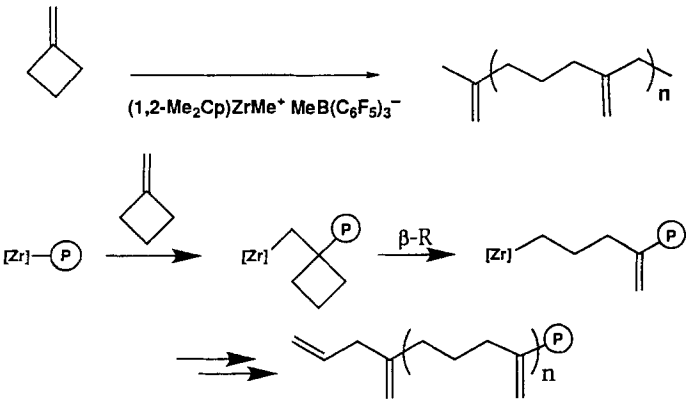


The homopolymers obtained from these reactions are highly crystalline with melting points around or above 400 °C,[207] close to their respective decomposition temperatures. Structural assignments for these polymers are rendered difficult by their

DMON

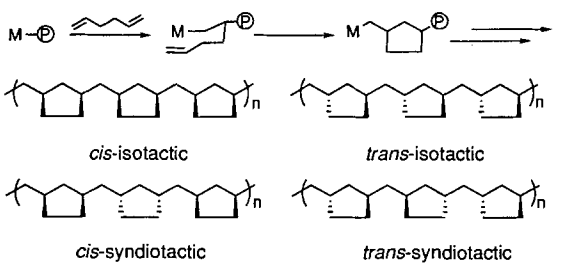
Scheme 18. Cyclic olefins used by Kaminsky and co-workers [207] in ring-preserving polymerization reactions with *rac*-$(en)(ind)_2ZrCl_2$/MAO or *rac*-$Me_2Si(ind)_2ZrCl_2$/MAO.

insolubility in all common solvents. Instead of a 1,2-enchainment as originally proposed by Kaminsky and co-workers for polymers of cyclopentene,[207b] a 1,3-enchainment was revealed in a recent study by Collins and Kelly[208a] on the corresponding zirconocene/MAO-catalyzed hydrooligomerization. The mechanism proposed for this enchainment—1,2-insertion followed by β-H elimination, olefin rotation, and reinsertion—is analogous to that assumed to lead to the minor fraction of 1,3-inserted propene units in propene polymerization with these catalysts.[114, 136a, b, 208b] Apparently, the intermediate derived from 1,2-insertion of cyclopentene is sterically too demanding to permit insertion of another cyclopentene and has to isomerize before another olefin inserts (Scheme 19). This system is an interesting example for an insertion–isomerization type of polymerization with metallocene-based catalysts.[209]



Scheme 19. Mechanism for the formation of 1,3-linked polycyclopentene proposed by Collins and co-workers [208].

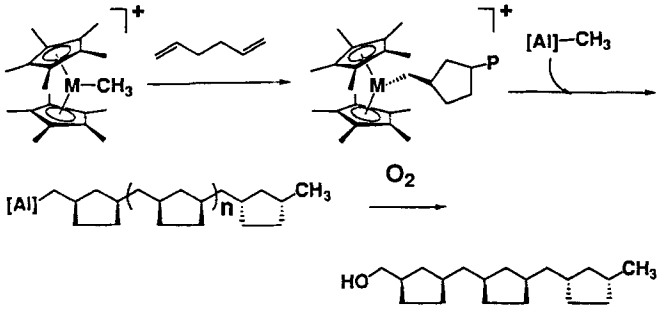
The cycloolefin polymers prepared with chiral (en)(ind)$_2$-$ZrCl_2$/MAO as catalyst are undoubtedly stereoregular;[208, 209] whether they have an isotactic structure like that of the other olefin polymers produced by this catalyst could not yet be established unequivocally.



Studies on the copolymerization of cyclic monomers with ethene or propene[207, 210] showed that all of the cycloolefins mentioned above, as well as cycloheptene and cyclooctene, are incorporated into copolymers. While ethene is vastly more reactive than cyclopentene in the catalyst system (en)(ind)$_2$$ZrCl_2$/MAO, with a comonomer selectivity factor of $r_1 = 80-300$, norbornene is quite readily incorporated, with $r_1 = 1.5-3.2$, such that a broad range of ethene/norbornene copolymers can be obtained with this system.[207] The cycloolefin copolymers are mostly amorphous (rather than crystalline like the respective homopolymers) and have a relatively high glass transition temperature. A 1,2-enchainment, rather than a 1,3-enchainment has been determined for the copolymers of cyclopentene and ethene.[207] Apparently, insertion of ethene is faster than isomerization of the cyclopentyl group at the zirconium center. In contrast to cyclopentene homopolymers, these copolymers are mostly amorphous; however, they often have relatively high glass transition temperatures.

An interesting ring-opening polymerization, which contrasts the ring-preserving polymerizations of internal cycloolefins discussed above, was recently reported by Marks and co-workers,[211] who observed that polymerization of exomethylenecyclobutane by [(1,2-$Me_2C_5H_3)_2$-$ZrMe^+ \cdots MeB(C_6F_5)_3^-$] yields a polymer with mainly ring-opened 2-methylene-1-buten-4-yl rather than the expected 1-methylenecyclobutan-1-yl units (Scheme 20). Apparently, insertion of the disubstituted olefin into a Zr–alkyl unit with a quarternary β-C atom is so slow that rearrangement of the latter by β-alkyl transfer to give a secondary Zr–alkyl unit is the preferred process. Kinetic data indicate that insertion of the disubstituted olefin into the latter—rather than the β-alkyl transfer—still limits the overall rate of this process, which has turnover numbers of about 400 h^{-1} at 25 °C.

Scheme 20. Ring-opening polymerization of methylenecyclobutane reported by Marks and co-workers [211]. Ring-opening β-alkyl transfer appears to be faster than insertion of methylenecyclobutane into the sterically hindered cyclobutylmethyl–Zr bond.

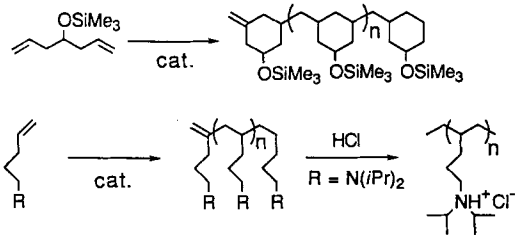


Another polymerization process that leads to 1,3-cycloalkanediyl units, connected this time by methylene groups, is the cyclopolymerization of nonconjugated dienes.[93, 95b, 212–217] It involves 1,2-insertion of one of the vinyl functions into a metal–carbon bond followed by an intramolecular cyclization (Scheme 21). The microstructure of the resulting polymers concerns the *cis*/*trans* stereochemistry of the rings and the relative stereochemistry between rings. The latter, i.e. the tacticity of the polymer, is determined by the enantiofacial selectivity of the metallocene catalyst in the first insertion step; the *cis*/*trans* stereochemistry of the rings, on the other hand, arises from the diastereoselectivity of the cyclization step.

Scheme 21. Cyclopolymerization of nonconjugated dienes studied by Waymouth and co-workers [93, 95, 213–217]. The *trans*-isotactic form represents an effectively chiral polymer; polymers with substantial molar optical rotations are obtained with *R*- or *S*-(en)(thind)$_2$$ZrCl_2$/MAO.

While the *cis/trans* diastereoselectivity can hardly be controlled with heterogeneous catalysts,[212] it is strongly influenced by substituents at the cyclopentadienyl ligands in metallocene-based catalysts.[93] Cyclopolymerization of 1,5-hexadiene by MAO-activated $(C_5H_5)_2MX_2$ (M = Ti, Zr, Hf; X = Cl, CH_3) leads to polymers containing predominantly *trans* rings, while cyclopolymerization with the more hindered catalyst $(C_5Me_5)_2MX_2$/MAO yields predominantly *cis* rings.

The melting points of the resulting polymers proved to be quite sensitive to the *cis/trans* ratio of the carbocycles.[213] *trans* Polymers are waxes with melting points $\leq 70\,^{\circ}C$; polymers containing $>90\,\%$ *cis* rings are crystalline and melt at 189 °C. Cyclopolymerization of unsymmetrical dienes such as 2-methyl-1,5-hexadiene with catalysts such as $Cp_2^*ZrMe_2$/MAO or with $[Cp_2^*ZrMe^+\cdots X^-]$ (X = $B(C_6F_5)_4$ or $H_3CB(C_6F_5)_3$) affords highly regioregular cyclopolymers.[215] The perfectly alternating head-to-tail microstructure must arise from the regioselective insertion of the less hindered terminus of the diene into the metal–polymer bond, which is sterically encumbered by its quarternary β-C atom. Cyclization of the disubstituted olefin yields a methylene-1-methylcyclopentan-3-yl intermediate (Scheme 22). This insertion appears to be greatly facilitated by its intramolecular nature; intermolecular insertions of disubstituted olefins into Zr–alkyl bonds are at best quite sluggish.



Scheme 22. Hydroxy-terminated cyclopolymers formed by alkyl exchange with a methylaluminum activator [95b].

Cyclopolymerization of 1,5-hexadiene generates polymers with substantially higher molecular weights than polymerization of 1-hexene with the same catalysts,[93] undoubtedly due to some hindrance of the β-H transfer that normally terminates growth of a polymer chain. For the cyclopolymerization of 1,5-hexadiene with a $Cp_2^*ZrCl_2$/MAO catalyst at $-25\,^{\circ}C$, chain transfer to aluminum was found to be the only chain termination process.[95b] The resulting poly(methylene–cyclopentane) was shown to bear an alkylaluminum end group, which could be oxidized with O_2 to give hydroxy-terminated polymers (Scheme 22). Cyclopolymerization of 2-methyl-1,5-hexadiene with the catalysts $[Cp_2^*ZrMe^+\cdots X^-]$ (X = $B(C_6F_5)_4$ or $H_3CB(C_6F_5)_3$), for which neither β-H transfer nor chain transfer to aluminum are feasible, gave a polymer with end groups derived from a β-CH_3 transfer process.[95b]

Although optically active olefin oligomers of low molecular weight can be obtained with enantiomerically pure *ansa*-metallocene catalysts,[140, 141b, 143b] stereoregular polyolefins of high molecular weight contain an effective mirror plane perpendicular to the molecular axis in the middle of the molecule and are thus achiral.[107c] Chiral polymers have now become available by metallocene-catalyzed cyclopolymerization of 1,5-hexadiene. Coates and Waymouth recognized that the *trans*-isotactic form of poly(methylene-1,3-cyclopentane) is chiral.[213, 217] Using MAO-activated, resolved (1*R*)-(en)(thind)$_2$Zr-binaphtholate as a catalyst, they obtained optically active poly(methylene-1,3-cyclopentane) with a molar optical rotation of $[\Phi]_D^{20} = +51.0$ ($c = 0.8$ in $CHCl_3$). Cyclopolymerization with the (1*S*) enantiomer of the catalyst gave the enantiomeric polymer. Cyclopolymers of 1,5-hexadiene obtained with (en)(thind)$_2$Zr-derived catalysts contain a mixture of *cis* and *trans* rings. Despite the presence of roughly 32 % *cis* rings, the molar optical rotation of the polymer ($[\Phi]_D^{20} = +22.8$) is considerably higher than that of the model compound *trans*-(1*R*,3*R*)-1,3-dimethylcyclopentane ($[\Phi]_D^{20} = +3.1$), presumably due to the presence of helical polymer conformations in solution. Interesting insights in this regard might come from X-ray diffraction studies on these chiral polymers. A ^{13}C NMR analysis of the microstructure of the polymer at tetrad resolution provided an estimate of 91 % for the enantiofacial selectivity of this cyclopolymerization reaction.[217]

4.3. Functionalized Polyolefins

Advances toward the goal of polymerizing polar monomers by Ziegler–Natta catalysis have recently been made with cationic metallocene catalysts. Waymouth and co-workers found that these catalysts are considerably more tolerant of functional groups than either conventional heterogeneous catalysts or homogeneous catalysts activated by MAO. Catalysts of the type $[Cp_2^*ZrMe^+\cdots X^-]$ (X^- = $B(C_6F_5)_4^-$ or $H_3CB(C_6F_5)_3^-$) are indeed capable of polymerizing a variety of functionalized α-olefins and dienes such as 4-*tert*-butyldimethylsiloxy-1-pentene, 5-*N*,*N*-diisopropylamino-1-pentene, and 4-trimethylsiloxy-1,6-heptadiene[218] (Scheme 23).

Scheme 23. Formation of polymers with O- or N-functional groups by use of borane-activated zirconocene catalysts reported by Waymouth and co-workers [218, 219]. R = $NiPr_2$, OTBDMS; cat = $[Cp_2^*ZrMe^+MeB(C_6F_5)_3^-]$.

Activities for the polymerization of 4-*tert*-butyldimethylsiloxy- and 5-*N*,*N*-diisopropylamino-1-pentene by the catalyst $[(C_5Me_5)_2ZrMe^+\cdots X^-]$ were lower than for 1-hexene, with average turnover numbers (at ca. 40–50 % conversion) ranging from 2700 h^{-1} for 1-hexene to 190 h^{-1} for 4-*tert*-butyldimethyl-siloxy-1-pentene and 130 h^{-1} for 5-*N*,*N*-diisopropylamino-1-pentene. Chiral $[rac$-(en)(thind)$_2$ZrMe$^+\cdots$X$^-]$ catalysts are active for the polymerization of 5-*N*,*N*-diisopropylamino-1-pentene, but not for that of 4-*tert*-butyldimethyl-

siloxy-1-pentene. Preliminary ^{13}C NMR analysis of poly-(5-*N*,*N*-diisopropylamino-1-pentene) obtained in this manner indicates an isotactic microstructure.[219]

Another approach toward functionalized polyolefins is the generation of α-olefin polymers capped by polar end groups. Polymers of this kind are principally accessible through living polymerizations. Living polymers of α-olefins have been obtained so far only in rare instances, at low temperatures[220, 221] (see Section 4.1). Complete transfer of polymer chains to aluminum centers of the cocatalyst, also useful for this purpose, has been observed in only one special case, again at temperatures below ambient.[95b]

In contrast to heterogeneous polymerization catalysts, which afford shorter propene oligomers only in the presence of H_2, that is, only with saturated chain ends, metallocene catalysts give easy access to propene oligomers with olefinic end groups, which can be converted to various other functional groups.[222, 223] Thiol-terminated oligopropenes have been used as chain transfer reagents in methacrylate polymerization to form poly(propene-*block*-methylmethacrylate). A new class of polymers containing pendant polypropene chains such as polymethylmethacrylate-*graft*-polypropene is derived from methacrylate-terminated oligopropene macromonomers, which are copolymerized with various acrylic esters, acrylonitrile, or styrene.[224a]

These polypropene block and graft copolymers are efficient blend compatibilizers. By enhancing the dispersion of otherwise incompatible polymers and improving their interfacial adhesion, these copolymers allow the formation of "alloys" of isotactic polypropene, for example, with styrene–acrylonitrile or polyamides.[224b, c] Polymer blends of this type afford property synergisms such as improved stiffness combined with improved toughness. They are obtained by way of the short isotactic polypropene chains with unsaturated end groups formed by the *ansa*-metallocene catalyst $Me_2Si(2\text{-}Me\text{-}4\text{-}t\text{Bu-}C_5H_2)_2ZrCl_2$/MAO.

5. Perspectives

The most remarkable aspect of metallocene-based catalysts appears to be that they can produce an unprecedented variety of polyolefins. The range of stereo- and regioregularities, molecular weights, and polydispersities of copolymers and cyclopolymers available with these catalysts exceeds that accessible with classical heterogeneous Ziegler–Natta catalysts and opens new possibilities for producing tailored polyolefin materials.

Much of our knowledge in this area has been acquired by application of rational conceptional models to the design of new metallocene structures and catalyst activators. Some traits of these catalysts, in particular their stereoselectivity, are now close to being predictable, based on our understanding of the essential elementary reaction steps in these homogeneous reaction systems. Other traits such as the formation of cyclic or functionalized polyolefins have been and continue to be discovered by testing our understanding of the basic reaction mechanisms of these catalysts against increasingly demanding tasks. This approach derives substantial support from the rapidly advancing methods for modeling even large metallocene reaction systems by ab initio and density functional methods.[84–88] These methods can also provide a calibration for useful molecular mechanics models for these catalysts,[86, 139, 225] which may eventually allow estimates of steric effects on the course of essential reaction steps, for example on competing insertion and chain termination reactions.

The evolution of advanced catalysts and catalytic processes based on rational model hypotheses is now beginning to carry over to heterogeneous Ziegler–Natta catalysis as well. Practical application of metallocene catalysts requires their preadsorption on solid supports such as alumina or silica gels.[189c, 200, 226–228] Instead of the polymer dust produced by a homogeneously dissolved metallocene catalyst, the solid catalyst particles generate coherent polymer grains.[117e, 229] As with classical heterogeneous catalysts, these grains appear to be enlarged replicas of the catalyst particles[117e, 228] (Fig. 10). Metallocene catalysts that are heterogenized, for example on a silica gel support, can thus be readily used in existing Ziegler–Natta production facilities, for instance in solvent-free slurry or gas-phase reaction systems.[227, 228]

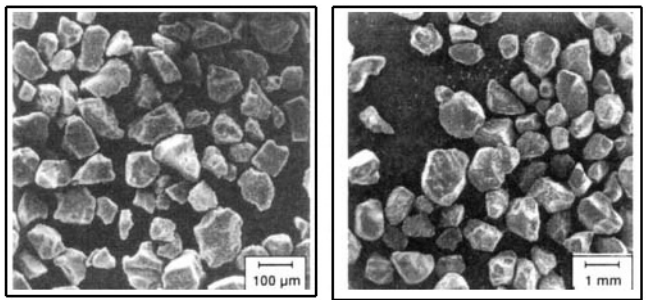


Fig. 10. Catalyst grains containing $Me_2Si(2\text{-}Me\text{-}benz[e]indenyl)_2ZrCl_2$/MAO on a silica gel support (left) and polymer grains grown on these in a gas-phase reactor at 70 °C (right, note different scale) [228].

Detailed guidelines have been developed for the selection of supports with optimal composition, particle size, pore size distribution, and surface OH group density, and for their treatment with various alkyl aluminum and aluminoxane activators[227, 228] prior or subsequent to adsorption of the metallocene complex. The more advanced of these protocols require only limited excess ratios of alkylaluminum activators per zirconocene unit; Al:Zr ratios of roughly 100–400:1, much below those used for homogeneous catalyst systems, appear to give entirely satisfactory activities for these surface-supported metallocene catalysts.[228, 230] In contrast to modern $MgCl_2$-supported heterogeneous Ziegler–Natta catalysts, silica gel supported metallocene catalysts are practically free of chlorine. This could be an advantage from a ecological standpoint when the chemical or thermal recycling of polymer products reaches a larger scale.[231]

Despite the practical advantages of supported catalysts, interactions between support materials and catalyst complexes are only partly understood on a molecular level. Based on the generally close resemblance of the polymer microstructures produced by a metallocene catalyst in homogeneous solutions and on solid supports, even in solvent-free gas phase systems,[228, 232] it appears likely that the active catalysts are quite

similar, in other words that the (presumably cationic) metallocene catalyst is only physisorbed on the alkylaluminum-pretreated (possibly anionic) catalyst surface. Based on this model, "microreactors" might be fabricated by immobilizing different types of single-site metallocene catalysts—or even catalyst cascades[193]—on suitable supports for in situ production of novel polyolefin blends and other environmentally friendly polyolefin materials.

Polymers with properties distinctly different from those produced in homogeneous solution—with unusually high molecular weights—have recently been obtained by fixing a metallocene catalyst on unpretreated supports[233] and by synthesizing covalently linked *ansa*-metallocenes directly on a SiO_2 support.[234] These observations are probably connected with the site-isolation effects, that is, with the strict suppression of all binuclear reaction intermediates, known to arise from linking catalyst centers covalently to a solid support.[235] If methods become available for a controlled synthesis of such covalently supported metallocenes and for their structural characterization, one could imagine another round of developments toward novel metallocene-based Ziegler–Natta catalysts that are heterogeneous, like their predecessors discovered forty years ago, yet endowed with wider process and product variability and with superior environmental properties.

We thank Dr. A. Reinmuth and Ms. S. Kyncl for checking the text and the references of this article and for help in composing the table and figures. We are grateful to BASF AG for providing graphs and figures, and for financial support.

[33] Since an olefin complex of the type $[Cp_2MR(olefin)]^+$ (M = Ti, Zr) has not been observed by spectroscopic or kinetic means so far [32], it is doubtful whether it should be regarded as a reaction intermediate.
[34] These "dormant" species might still be quite reactive, however, with regard to other important transformations, such as chain termination or catalyst deactivation reactions.
[35] Reagents such as $^{131}I_2$, ^{14}CO or CH_3OT, which are used to determine the number of active sites in a given reaction system [18], react also with these "dormant" sites; these methods will thus count all transition metal alkyl species as "active": P. J. T. Tait, B. L. Booth, M. O. Jejelowo, *Makromol. Chem. Rapid Commun.* **1988**, *9*, 393; P. J. T. Tait in ref. [6b], p. 309.
[36] Besides ethene, styrene has been reported to be polymerized by Cp_2TiCl_2/$AlEt_2Cl$ catalyst systems (C. G. Overberger, F. S. Diachkovsky, P. A. Jarovitzsky, *J. Polym. Sci.* **1964**, *A2*, 4113; C. G. Overberger, P. A. Jarovitzsky, *ibid.* **1965**, *A3*, 1483); it cannot be excluded that the presence of minor amounts of mono-Cp titanium compounds in these reaction systems are responsible for this catalysis (cf. ref. [7b]). Recently, polymerization of styrene has been found to occur also with $CH_2(C_5H_4)_2TiCl_2$/MAO: A. Miyashita, M. Nabika, T. Suzuki, *Abstr. Int. Symp. Synthetic, Structural and Industrial Aspects of Stereoselective Polymerization* (Ed.: L. Porri), Milan, **1994**, p. 88.

[70] Such an equilibrium explains that increasing MAO concentrations cause further increases in activity even though ^{14}CO or CH_3OT radio-tagging methods represent most of the Zr centers as "active", i.e. as carrying a polymer chain, even in homogeneous catalyst systems with moderate MAO concentrations [18, 35, 65, 67].
[71] A. D. Horton, A. G. Orpen, *Organometallics* **1992**, *11*, 8; *Angew. Chem.* **1992**, *104*, 912; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 876; A. D. Horton, *Organometallics* **1992**, *11*, 3271.
[72] Added $AlMe_3$ increases the steady-state activities in reaction systems of this kind: S. Srinivasa Reddy, G. Shashidhar, S. Sivaram, *Macromolecules* **1993**,

26, 1180; I_1 might thus be reconverted to C by alkyl exchange with the $AlMe_3$ content of MAO.

[89] M. H. Prosenc, C. Janiak, H. H. Brintzinger, *Organometallics* **1992**, *11*, 4036. This study yields a—probably exaggerated—estimate of ca. 20 kJ mol^{-1} for the agostic stabilization of the insertion transition state.

[90] P. J. Flory, *Principles of Polymer Chemistry*, Cornell University Press, Ithaca, **1986**, p. 317.

[91] Other end groups, which arise from β-alkyl transfer to the Zr centers [58, 92–94], from σ-bond metathesis with the olefin substrate [50b, c], or from alkyl exchange between Zr and Al centers [43, 65c, 95], are occasionally observed, in particular with sterically strongly hindered (e.g. permethyl) metallocene catalysts (cf. G. Sini, S. A. Macgregor, O. Eisenstein, J. H. Teuben, *Organometallics* **1994**, *13*, 1049). These reactions do not appear to contribute significantly to chain termination in propene polymerization by MAO-activated Cp_2ZrCl_2 systems.

[96] Such an *n*-propyl unit is observed at the head of most polypropene chains, except for a small fraction, which is initially formed by propene insertion into the $Zr-CH_3$ units generated during activation of Cp_2ZrCl_2 by the MAO cocatalyst [97].

[97] T. Tsutsui, A. Mizuno, N. Kashiwa, *Polymer* **1989**, *30*, 428.

[98] W. Kaminsky, K. Külper, S. Niedoba, *Makromol. Chem. Macromol. Symp.* **1986**, *3*, 377.

[99] This would imply that v_T is not significantly affected by MAO concentrations, i.e. that chain terminations arise predominantly) from "dormant" (i.e. associated) zirconocene ion pairs. Facile olefin isomerizations with Schwartz's hydrozirconation reagent Cp_2ZrHCl indicate that olefin extrusion from neutral zirconocene alkyl species is fairly fast: J. Schwartz, J. A. Labinger, *Angew. Chem.* **1976**, *88*, 402; *Angew. Chem. Int. Ed. Engl.* **1976**, *15*, 333.

[100] Previously prepared chiral titanocene and zirconocene complexes: H. Brunner, H. D. Schindler, *J. Organomet. Chem.* **1973**, *55*, C71; J. Tirouflet, A. Dormond, J. C. Leblanc, F. Le Moigne, *Tetrahedron Lett.* **1973**, 257; J. Besancon, F. Huq, M. Colette, *J. Organomet. Chem.* **1975**, *96*, 63; P. Renaut, G. Tainturier, B. Gautheron, *ibid.* **1978**, *148*, 43; J. C. Leblanc, C. Moise, J. Tirouflet, *ibid.* **1978**, *148*, 171; S. Couturier, B. Gautheron, *ibid.* **1978**, *157*, C61; E. Cesarotti, H. B. Kagan, R. Goddard, C. Krüger, *ibid.* **1978**, *162*, 297.

[101] Studies on metallocene-based polymerization catalysts in Kaminsky's group [39a, b] as well as syntheses of chiral *ansa*-metallocenes in Brintzinger's group (H. Schnutenhaus, H. H. Brintzinger, *Angew. Chem.* **1979**, *91*, 837; *Angew. Chem. Int. Ed. Engl.* **1979**, *18*, 777) were supported from 1973 to 1978 by Deutsche Forschungsgemeinschaft through a special program for research in homogeneous catalysis.

[102] Fixation of ligand geometries by an ethanediyl bridge had been found to be beneficial for other types of stereoselective homogeneous catalysts, see e.g.: M. D. Fryzuk, B. Bosnich, *J. Am. Chem. Soc.* **1978**, *100*, 5491; B. Bosnich, M. D. Fryzuk, *Top. Stereochem.* **1981**, *12*, 119.

[103] a) F. R. W. P. Wild, L. Zsolnai, G. Huttner, H. H. Brintzinger, *J. Organomet. Chem.* **1982**, *232*, 233; F. R. W. P. Wild, M. Wasiucionek, G. Huttner, H. H. Brintzinger, *ibid.* **1985**, *288*, 63; b) more recent syntheses and structural studies: J. A. Ewen, L. Haspeslagh, J. L. Atwood, H. Zhang, *J. Am. Chem. Soc.* **1987**, *109*, 6544; R. M. Waymouth, F. Bangerter, P. Pino, *Inorg. Chem.* **1988**, *27*, 758; S. Collins, B. A. Kuntz, N. J. Taylor, D. G. Ward, *J. Organomet. Chem.* **1988**, *342*, 21; S. Collins, W. J. Gauthier, D. A. Holden, B. A. Kuntz, N. J. Taylor, D. G. Ward, *Organometallics* **1991**, *10*, 2061; R. B. Grossman, R. A. Doyle, S. L. Buchwald, *ibid.* **1991**, *10*, 1501; G. M. Diamond, S. Rodewald, R. F. Jordan, *ibid.* **1995**, *14*, 5; F. Piemontesi, I. Camurati, L. Resconi, D. Balboni, A. Sironi, M. Moret, R. Zeigler, N. Piccolrovazzi, *ibid.* **1995**, *14*, 1256.

[104] The prefix *ansa* (lat. ansa = bent, handle), first used for compounds with an alkane bridge across an arene ring (A. Lüttringhaus, H. Gralheer, *Justus Liebigs Ann. Chem.* **1942**, *550*, 67), was adopted as a short notation for metallocene derivatives with an interannular bridge (J. A. Smith, J. von Seyerl, G. Huttner, H. H. Brintzinger, *J. Organomet. Chem.* **1979**, *173*, 175).

[105] J. A. Ewen, *J. Am. Chem. Soc.* **1984**, *106*, 6355.

[106] W. Kaminsky, K. Külper, H. H. Brintzinger, F. R. W. P. Wild, *Angew. Chem.* **1985**, *97*, 507; *Angew. Chem. Int. Ed. Engl.* **1985**, *24*, 507.

[107] a) F. A. Bovey, *High Resolution NMR of Macromolecules*, Academic Press, New York, **1972**; A. Zambelli, P. Locatelli, G. Bajo, F. A. Bovey, *Macromolecules* **1975**, *8*, 687; F. A. Bovey, *Chain Structure and Conformation of Macromolecules*, Academic Press, New York, **1982**; b) J. C. Randall, *Polymer Sequence Determination by the Carbon 13 NMR Method*, Academic Press, New York, **1977**; in *Polymer Characterization by NMR and ESR* (Eds.: A. E. Woodward, F. A. Bovey) (*ACS Symp. Ser.*; **1980**, *142*); c) M. Farina, *Top. Stereochem.* **1987**, *17*, 1; d) A. E. Tonelli, *NMR Spectroscopy and Polymer Microstructure*, VCH, Weinheim, **1989**; e) J. L. Koenig, *Spectroscopy of Polymers*, American Chemical Society, Washington, **1991**.

[108] Today, polymer NMR spectra can be analyzed at even higher resolution levels: A. E. Tonelli, F. C. Schilling, *Acc. Chem. Res.* **1981**, *14*, 233; T. Hayashi, Y. Inoue, R. Chujo, T. Asakura, *Polymer* **1988**, *29*, 138; A. De Marco, P. Sozzani, G. Di Silvestro, M. Farina, *Macromolecules* **1989**, *22*, 2154; M. Farina, G. Di Silvestro, P. Sozzani, *Prog. Polym. Sci.* **1991**, *16*, 219.

[109] The *mmrm* and *rmrr* pentad signals have identical chemical shifts.

[110] Essentially atactic polypropylene was first obtained with a homogeneous catalyst containing VCl_4 and $AlClEt_2$ at $-78\,^\circ C$ (G. Natta, A. Zambelli, G. Lanzi, I. Pasquon, E. R. Mognaschi, A. L. Segre, P. Cantola, *Makromol. Chem.* **1965**, *81*, 161). Strictly atactic polypropene is obtained from isotactic polypropene by epimerization with Pd catalysts at elevated temperatures: U. W. Suter, P. Neuenschwander, *Macromolecules* **1981**, *14*, 528.

[111] Alternative measures for polyolefin stereoregularity are the relative triad probabilities $[mm] = [mmmm] + [mmmr] + [rmmr]$, $[mr] = [mmrr] + [mmrm] + [rmrr] + [rmrm]$ and $[rr] = [rrrr] + [rrrm] + [mrrm]$, and the average lengths of isotactic and syndiotactic sequences, $n_{iso} = 2[mm]/[mr] + 1$ and $n_{syn} = 2[rr]/[mr] + 1$ [107]. For typical isotactic polymers with $[mmmm] \approx 0.95$, the mean length of an isotactic sequence is $n_{iso} \approx 100$ units.

[112] T. Tsutsui, N. Ishimaru, A. Mizuno, A. Toyota, N. Kashiwa, *Polymer* **1989**, *30*, 1350.

[113] Since [*mmmm*] > 0.9 corresponds to a diastereomer excess of > 95% for each insertion step, these homogeneous polymerization catalysts are roughly comparable to the most highly stereoselective organometallic catalysts employed for other C-C coupling reactions: H. Brunner, *Top. Stereochem.* **1988**, *18*, 129; *Synthesis* **1988**, 645; D. Seebach, *Angew. Chem.* **1990**, *102*, 1363; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 1320.

[114] a) B. Rieger, J. C. W. Chien, *Polym. Bull. (Berlin)* **1989**, *21*, 159; B. Rieger, X. Mu, D. T. Mallin, M. D. Rausch, J. C. W. Chien, *Macromolecules* **1990**, *23*, 3559; b) Y. X. Chen, M. D. Rausch, J. C. W. Chien, *Organometallics* **1994**, *13*, 748.

[115] a) H. N. Cheng, M. A. Bennett, *Makromol. Chem.* **1987**, *188*, 135; H. N. Cheng, J. A. Ewen, *ibid.* **1989**, *190*, 1931; H. N. Cheng, G. N. Babu, R. A. Newmark, J. C. W. Chien, *Macromolecules* **1992**, *25*, 6980; H. N. Cheng, *Makromol. Chem. Theory Simul.* **1993**, *2*, 561. b) Recently, the term "catalytic-site control", which is applicable also to metal centers of C_s symmetry, appears to be used more frequently instead of the previously used term "enantiomorphic-site control".

[121] Comparison of results from different laboratories is difficult not only because of variations in T_p and other catalysis parameters, but also because of inexplicit corrections of signal intensities for contributions from various end group and regio-irregularity signals and by use of different stereoregularity measures [111].

[181] Equation $r_1 = k_{11}/k_{12}$ thus pertains to a catalyst center which had previously inserted monomer 1, $r_2 = k_{22}/k_{21}$ to one with monomer 2 as the last inserted unit.

[182] For the metallocene-catalyzed copolymerization of ethene and 1-hexene Fink and Herfert observed deviations from this "terminal model"; these authors report that the probabilities of inserting either one of the comonomers depend on the last two previously inserted units ("penultimate effect"), ref. [132d]; N. Herfert, G. Fink, *Polym. Mater. Sci. Eng.* **1992**, *67*, 31; N. Herfert, P. Montag, G. Fink, *Makromol. Chem.* **1993**, *194*, 3167; N. Herfert, Dissertation, Universität Düsseldorf, **1992**; cf. also ref. [69e].

[183] In the case of $r_1 r_2 = 1$, the probability of inserting either monomer is independent of the last inserted unit; the comonomer distribution along each chain will then correspond to a Bernoullian random distribution.

Y. Ohashi (ed.)

Reactivity in Molecular Crystals

1993. XII, 348 pages. Hardcover. DM 198.00.
ISBN 3-527-29098-2

Do you need to design syntheses that are
- highly selective
- fast
- enantioselective with quantitative enantiomeric yield?

This book describes in detail how best to exploit the enormous synthetic potential of solid state reactions. Written by leading experts, it provides in depth information on
- the theoretical and physico-chemical approach to solid state reactions
- solid-to-solid organic reactions
- stereoselective solid state photoreactions
- reactivity and crystal structure

An ideal companion to Bürgi and Dunitz's *Structure Correlation*, this book will be highly useful to synthetic organic chemists, stereochemists, crystallographers, and solid-state chemists.

Basic Principles of Thermoanalytical Techniques and Their Applications in Preparative Chemistry

Heiko Karl Cammenga* and Matthias Epple*

The investigation of thermodynamic properties and reactivity yields interesting insights into the chemistry of newly synthesized substances. With thermal analysis extensive information can be gained from small samples (often only a few milligrams). In addition, the data obtained by thermal analysis can be used to plan and optimize a synthesis. Among the most important applications are identification and purity analysis, and the determination of characteristic temperatures and enthalpies of phase transitions (melting, vaporization), phase transformations, and reactions. Investigations into the kinetics of consecutive reactions and decomposition reactions are also possible. With the instruments available today such analyses can usually be performed quickly and easily. In this review the fundamentals of thermoanalytical methods are described and illustrated with selected examples of applications to low and high molecular weight compounds.

Keywords: analytical methods · phase transformations · kinetics · thermal analysis

1. Introduction

In general, thermal analysis describes the examination of temperature-dependent properties of materials. In this respect a feature of thermoanalytical methods is the large variety of possibilities. Common fields of application range from the generation of thermodynamic and kinetic parameters in basic research, through the characterization of materials, to routine quality control and maintenance in industrial practice.

As thermally induced processes (phase changes, phase transitions, reactions, decompositions) and temperature-dependent material properties (heat capacity, thermal stability, mechanical properties) are very important in chemistry, the potential amount of information is substantial. For this reason increasing numbers of chemists are using thermal analysis. The extensive range of commercially available instruments and their easy operation are further reasons for the growing popularity of thermal analysis. Unfortunately the potential from the information extracted from the recorded graphs is often not fully exploited.

Thermal analysis has had only a minor impact on preparative chemistry so far. This is probably because scientists active in the field of synthesis are not familiar with the many and diverse possibilities of these methods. In this article, therefore, the basic principles and potential applications will be expounded. The user should also know the limits of the methodology, because the computer-assisted data processing commonly used today often leads to wrong conclusions and thus to incorrect results, which could have been avoided had the basic principles behind the program for evaluation been known.

An important aid that thermal analysis can offer preparative chemists is, for instance, the rapid determination of purity, phase state, and stability of newly synthesized substances as well as of adduct formation with the solvent. Such information can often be obtained easily from a single measurement. Different polymorphous forms of solids can be identified. Table 1 collates

Table 1. Some of the variables obtainable from thermoanalytical measurements.

Variable or Process	Symbol [a]	Method [b]
melting point	T_{fus}	DTA, DSC
enthalpy of fusion	$\Delta_{fus}H$	DSC
mixed melting point	T_{fus}^{mix}	DTA, DSC
boiling point	T_{vap}	DTA, DSC, TG
enthalpy of vaporization	$\Delta_{vap}H$	DSC
decomposition temperature	T_{dec}	DTA, DSC, TG
enthalpy of decomposition	$\Delta_{dec}H$	DSC
purity	x_1	DSC
enantiomeric purity	% *ee*	DSC
heat capacity	$C_p(T)$	DSC
expansion coefficient	α	TMA, thermal X-ray
phase transition temperature	T_{trs}	DTA, DSC, TMA
phase transition enthalpy	$\Delta_{trs}H$	DSC
glass transition	T_g, $\Delta C_{p,g}$	DSC, TMA, DMA
enthalpy of reaction	Δ_rH	DSC
reaction kinetics	E_A, $\lg(k_\infty)$, n [c]	DTA, DSC, TG, TOA, thermal X-ray

[a] The physical quantity determined directly or indirectly. [b] The abbreviations are explained in the text. [c] From these variables deductions on the mechanism can be made.

a number of variables that can be obtained from thermodynamic measurements.

Apart from thermodynamic parameters (heat capacities, phase transition temperatures, enthalpies), kinetic data (rates of transition, reaction, and decomposition) can often also be obtained from the quantitative evaluation of the data. The precise evaluation of the shape of a melting peak can enable the determination of the total concentration of impurities even in a range below 1 mol%, a concentration range in which the usual analytical methods (for example spectrometric methods) reach their limits. The examination of the enantiomeric purity of newly synthesized pharmaceuticals is an important application.

Applications in the extensive field of the chemistry of high molecular weight substances (polymers) include, for instance, the determination of thermal and mechanical properties in addition to the measurement of the degree of crystallinity and of the kinetics of polymerization, crystallization, and decomposition. An interesting branch of thermal analysis is biocalorimetry. In this field the thermal behavior of living beings (from protozoa to large mammals, even humans) is examined. The change in the rate of heat generation of living cultures can be employed, for instance, in screening procedures to test the effectiveness of pharmaceuticals.

2. Basic Principles of Methods of Thermal analysis

In this section the basic principles of thermal analysis will be introduced briefly. Detailed information can be found in a series of more recent monographs.[1-11]

The German Industrial Standard (DIN) 51005 defines thermal analysis as follows:

> Thermal analysis (TA): Generic term for methods in which the physical and chemical properties of a substance, a mixture of substances, and/or reaction mixtures are measured as a function of temperature or time, for which the sample is subjected to a controlled temperature program.[12]

This definition also includes isothermal temperature programs (that is, measurements at constant temperature) and the observation of free (that is, unregulated) heating and cooling processes. In almost all cases, however, measurements are carried out at a constant heating rate $\beta = dT/dt$ (scanning mode), which strictly speaking also includes isothermal measurements ($\beta = 0$).[14]

For a given sample property a potentially large number of variables may be considered. The most common methods follow the mass m (thermogravimetry TG), the temperature difference ΔT (differential thermal analysis DTA), the change in enthalpy dH/dt (differential scanning calorimetry DSC),[18] and the linear expansion of a sample l (dilatometry and thermomechanical analysis TMA).

These four most important methods are illustrated in Figure 1. In the case of thermogravimetry (TG, Fig. 1a) the change in the weight of a sample is measured as a function of time and/or temperature (example: monitoring the thermal decomposition of a hydrated salt). The sample masses lie in the mg to g range depending on the particular instrument and problem. Typically 10 to 20 mg of a substance is sufficient. As a rule it is

H. K. Cammenga

M. Epple

Heiko K. Cammenga, born 1938 in Bremen, studied chemistry in Braunschweig and Helsinki. Following his doctorate on precision measurements of low vapor pressures at the Technische Hochschule Braunschweig in 1967, he first became assistant, then senior assistant there at the "Institut für Physikalische Chemie". From 1970 to 1971 he visited the University of Rochester, NY, USA, as assistant professor on the invitation of Professor K. C. D. Hickman. There he worked on a project of the U. S. Office of Saline Water on the basic principles of sea water desalination processes. In 1973 he habilitated in physical chemistry with studies on the kinetics of vaporization and sublimation. Since 1977 he has been professor and director of the Department of Applied Physical Chemistry at Braunschweig. Since its foundation in 1985 he has also been a member in the collaborative project SFB 179 "Water and Matter Dynamics in Agro-Ecosystems". His areas of research are many and diverse. Main focuses are the kinetics and mechanisms of reactions of (above all organic) solids, kinetics of phase transition processes, chemistry of and damaging processes in building materials, development and improvement of analytical methods, and ecological-chemical processes. He is author or coauthor of several books and more than 120 contributions to journals. In 1988 he received the prize of the "Schweizer Gesellschaft für Thermoanalytik und Kalorimetrie".

Matthias Epple, born 1966 in Reutlingen, studied chemistry from 1984 to 1989 at the Technische Universität Braunschweig. In 1992 he completed his doctorate under the supervision of Professor H. K. Cammenga on the investigation of the kinetics of the solid-state reactions and of solid–solid phase transitions by time- and temperature-resolved X-ray diffraction. During 1993 he was postdoctorate fellow with Professor J. C. Berg at the Department of Chemical Engineering at the University of Washington in Seattle, USA, and worked in the area of recycled paper fiber recovery by flotation processes. Since January 1994 he has been working on his habilitation (chemistry of organic solids) at the "Institut für Anorganische und Angewandte Chemie der Universität Hamburg" with Professor A. Reller.

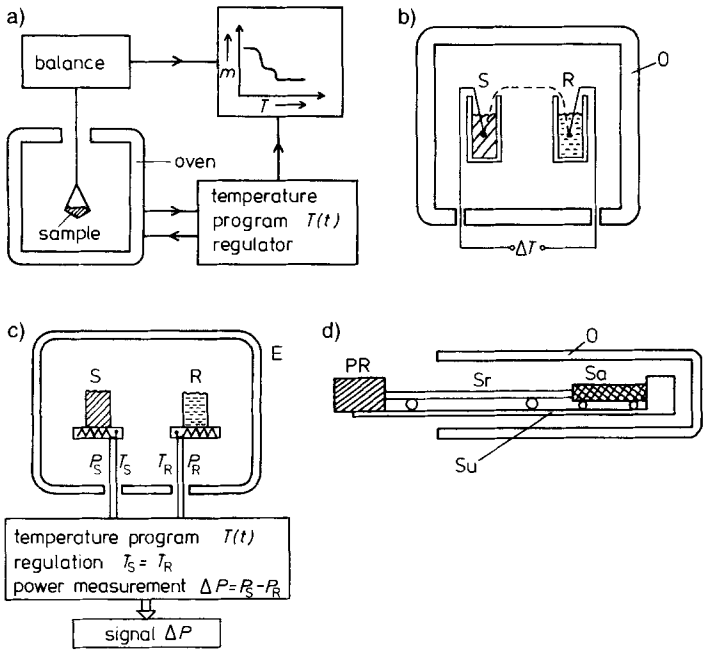

Fig. 1. The four most commonly used methods of thermal analysis presented schematically. a) Thermogravimetry (TG). b) Differential thermal analysis (DTA): S sample, R reference sample, O oven, ΔT temperature difference between sample and reference sample. c) Differential scanning calorimetry (DSC): S sample, R reference sample, E environment, T_S sample temperature, T_R reference sample temperature, P_S electrical heating power supplied to sample, P_R electrical heating power supplied to reference sample, ΔP difference in power. d) Thermomechanical analysis (TMA): Sa sample, O oven, Sr steering rod, Su support, PR displacement recorder (from refs. [1, 19]).

possible to detect changes in relative weight in the order of parts per thousand without difficulty. The purge gas in the sample chamber can usually be varied, and measurements in inert or reactive gases and even measurements in a vacuum are possible. Temperatures of approximately 1500 °C are attained, and in specially designed equipment more than 2000 °C are possible. With cooling systems low-temperature measurements to −150 °C can be conducted.

Differential thermal analysis (DTA, Fig. 1b) is based on the measurement of the temperature difference between the test sample *S* and an inert sample (reference *R*) during a temperature program. Both samples are placed as symmetrically as possible in an oven *O*. The temperatures of the test and reference samples can be measured either directly inside the samples or near the samples. At thermal equilibrium, the oven and the test and reference samples should have the same temperature. If the oven is heated at a constant rate, a constant temperature difference ΔT, which is smaller the more symmetric the experimental setup, is established following an initial transition period caused by the thermal lag within the system. In general, ideal thermal symmetry is not possible because of different heat capacities of the test and reference samples and the asymmetries caused by instrument design. As a result the temperature difference does not reach zero but is constant (stationary state). This results in a constant signal from the calorimeter (giving rise to the base line, see Section 3.1 and ref. [20]).

To reach the stationary state the system requires a certain amount of time during which the signal approaches the base line asymptotically. Such transient processes also always occur on changing the heating rate during the course of a measurement program and at the beginning of a measurement in every case (see for example, Figs. 10 and 12). Under no circumstances may they be confused with thermal events or even integrated!

If a thermal event (change in heat capacity, melting, boiling, phase transformation, reaction) now occurs in the test sample, the stationary state will be disturbed. The temperature of the test sample is then higher than (exothermic reaction) or lower than (endothermic reaction) the temperature of the reference sample; in other words, the signal recorded deviates from the base line. The temperature difference is plotted against time or temperature. Depending on the design of the calorimeter the recorded signal ΔT can be evaluated qualitatively or quantitatively. For DTA the feasible temperature range is approximately −190 to 3000 °C.

Differential scanning calorimetry (DSC, Fig. 1c) is based on a related principle for measurement. In this case the temperature difference arising from thermal activity is balanced by two independent compensatory heaters, which are positioned underneath the test sample and the reference sample. The heater power required to compensate for the temperature difference is recorded. In this arrangement the heat used or released (q) is obtained directly. Differential scanning calorimetry conducted with this type of setup is therefore described as "power-compensated DSC" (temperature range approximately between −180 and 800 °C).[23]

For DSC measurements the samples are filled into small containers ("crucibles"; made for example from aluminum, high-grade steel, gold, or glass), so that the measurements are not dependent on the different sample forms (heat radiation and dissipation varies depending on sample surface and form) and also to prevent a reaction between the sample and calorimeter (corrosion!). Attention must, however, be paid to possible reactions between the sample and crucible material, such as, for instance, an attack by acids and bases on the frequently used aluminum crucibles. A compilation of the compatibility of important calibration substances (see below) with crucible materials has been published.[24] Special high-pressure crucibles are also available for several instruments. In general the required sample quantity is only a few mg.

In dilatometry and thermomechanical analysis (TMA, Fig. 1d) the sample length is the property examined. The simplest procedure consists of heating the sample in an oven and measuring only the change in length. Expansion coefficients can be determined and transformations detected (for example, the glass transition in polymers). Whilst in dilatometry as little pressure as possible is applied to the sample, a constant force is applied in thermomechanical analysis (usually one of pressure, more rarely one of tension).

In an extension of the method, namely dynamic mechanical analysis (DMA), the applied force is changed with time, for instance sinusoidally. The mechanical response of the sample to the change is observed. Important viscoelastic sample characteristics (storage modulus E', loss modulus E'', $\tan\delta = \tan(E'/E'')$) can be calculated from the penetration depth of the test plunger and the time delay. DMA plays a particularly important role in the characterization of polymers.

Besides these four classical techniques a large number of procedures are based on monitoring the temperature dependence of other variables. Some of these are listed here as examples:

- Thermooptical analysis (TOA)[7, 25] is based on following the optical properties of a sample (absorption, emission of radiation). Thermomicroscopy is a special case, which can be used to gain important supplementary information.[26–31] Changes in grain size (structural alterations), phase changes, phase transitions, nucleation processes, precipitation processes in solids, recrystallizations and solid-state reactions are often investigated with thermomicroscopy. In thermophotometry, the temperature dependence of optical properties (for example, IR, VIS, UV, index of refraction, polarization, luminescence) is measured.[7, 32]
- In evolved gas analysis (EGA) the gases released by a sample are detected and, if applicable, analyzed quantitatively, for example by gas chromatography/mass spectrometry or FTIR-spectroscopy.[7, 33] Evolved gas analysis is often applied simultaneously with thermogravimetry.
- Emanation thermal analysis (ETA)[34, 35] concerns the detection of the release of radioactive radon from samples that have been appropriately pre-treated. With this method, for instance, structural changes of a sample (microscopic cracking, phase transformations, sintering, melting) can be detected with high sensitivity.
- Thermoconductometry[7] involves the measurement of the temperature-dependence of electrical conductivity. It is particularly suitable for the detection of phase transformations in the solid state.
- Thermal X-ray methods[36–42] involve the study of the X-ray diffraction pattern of a sample. This method enables numerous conclusions to be drawn about solid–solid phase transitions and solid-state reactions. This method can be applied to powders as well as single crystals (with synchrotron radiation).[43] Expansion coefficients can also be determined.[2]

Thermoanalytical methods are often combined. Such procedures are described as simultaneous methods. For example, the widespread, simultaneous analysis of a sample by TG and DTA enables a specific change in mass to be attributed to a thermal event. In contrast, comparative measurements are often limited when two different methods are used in succession because of the different conditions under which they are performed (sample container, oven type, temperature sensor allocation, atmosphere, etc.). Sample-to-sample variations that generally occur in solids can be avoided. A disadvantage of simultaneous methods is that the sensitivity of the measurement system is frequently reduced relative to (optimized) single methods. All other procedures which may contribute towards the characterization of a sample are described as supplementary methods. This term covers, in particular, the more rarely applied thermoanalytical methods listed above.

Finally, a brief comment on the calibration of thermoanalytical instruments is necessary. As in virtually all procedures the temperature is not directly measured at the sample site, a certain doubt arises over the "true" temperatures that should be attributed to the processes observed. These can be determined by examining well-known reference materials (with known melting temperatures, phase transition temperatures, heat capacities, expansion coefficients, heats of melting etc.; see for example, reference [44]) by the method concerned and correlating the temperatures measured with the thermodynamic equilibrium temperatures. A calibration function calculated from the observed deviations[45] can be used to correct the measured temperatures.

3. Measurements on Low Molecular Weight Materials

The preparative chemist is primarily interested in the properties of low molecular weight materials. Thermoanalysis enables the determination of diverse thermodynamic and kinetic data, which can, for instance, be used for the identification of synthesized materials and the optimization of syntheses (see Table 1). This section will highlight and, using representative examples, demonstrate the different applications.

3.1. Phase Transformations and Phase Transitions of Pure Substances

Knowledge of phase transition temperatures and enthalpies is important for the design of syntheses and for industrial manufacture. In particular, phase transition processes are exploited in purification processes (distillation, sublimation, crystallization). It is important to avoid the decomposition of a substance in the process and to achieve as good a separation as possible.

The determination of phase transition temperatures counts among the oldest applications of thermal analysis (construction of phase diagrams from cooling curves). The DSC instruments available today enable a quick and precise analysis when using temperature programs. Only a little time is required for an overview. Characteristic temperatures and enthalpies of thermally induced processes count primarily among the information accessible.

DSC is generally used for the determination of thermodynamic parameters. Figure 2 shows a typical melting peak. The change in heat capacity on melting generally gives rise to a change in the base line, and accordingly, an interpolation must be carried out.[20] From the shape of the peak the five temperatures T_i (initial peak temperature), T_e (extrapolated peak-onset temperature), T_p (maximum peak temperature), T_c (extrapolated peak-offset temperature) and T_f (final peak temperature) can

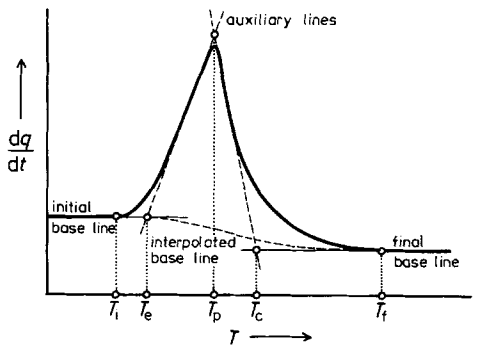

Fig. 2. An endothermic peak as obtained by the melting of a pure substance by DSC. The five characteristic temperatures T_i, T_e, T_p, T_c, and T_f can be determined from the peak shape; refer to text (from ref. [46]).

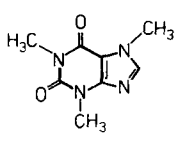
be deduced. For the characterization of melting and phase transformation temperatures the peak-onset temperature T_e is generally recommended.[46] This temperature is defined as the intersection of the tangent to the ascending peak slope and the linearly extrapolated initial base line. The peak-onset temperature is (in contrast to T_p) almost independent of the heating rate and the sample quantity, and is easier to determine than the initial peak temperature T_i.



The enthalpies related to the phase changes and transitions can easily be obtained by integration of the appropriate peak (the product of heat flow and time gives a quantity of heat). This procedure naturally presents the problem of the base line construction underneath the peak.[20] A linear interpolation is usually undertaken; however, other constructions may also be appropriate.[22]

In routine operation, melting points of pure materials can usually be reproduced to within 0.5 K; enthalpies can be accurately measured to within several percent, depending on the quality of the instrument and the calibration performed.[22] For the determination of boiling points the normally sealed DSC crucibles may be pierced with a fine needle in order to enable the evolved vapor to escape. To limit the extent of vaporization below the boiling temperature, a small ball may be placed on the perforation to act as a "valve" which "opens" when the boiling point is reached, thus giving rise to sharper boiling peaks. The variation of boiling point with pressure of the environment can be ascertained by performing DSC at different selected pressures.[50, 51] The enthalpy of vaporization can be calculated from the vapor pressure curve obtained by this method and the Clausius–Clapeyron equation.

Liquid crystalline phases are primarily formed by long, asymmetric molecules. Their properties lie between those of crystalline and liquid phases. To investigate transitions between the different liquid-crystalline phases, DSC, temperature-resolved X-ray diffraction (often with synchrotron radiation), and polarization microscopy (TOA) may be used to advantage.[48, 49]

Solid–solid phase transitions occur quite often.[5, 52, 53] Different orders of transitions are recognized. According to Ehrenfest a phase transition is of the same order as the lowest derivative of Gibbs energy G that exhibits a discontinuity at the transformation. For example, G is continuous in a first-order transition, while the derivatives of G with respect to T and p are discontinuous (for example, S, V, H). The enthalpy–temperature curve of a first-order transition therefore exhibits a discontinuity at the transition temperature (examples: melting, vaporization). Among other characteristics, higher order transitions have $C_p(T)$ curves that often increase long before the transformation, ending in a maximum at the transition temperature (examples: λ transformation, magnetic transformation).

Figure 3 shows a DSC curve of caffeine (**1**). The low-temperature phase, β-caffeine, is converted into the high-temperature phase, α-caffeine, at 141 ± 2 °C in a first-order phase transition ($\Delta_{trs}H$ = 4.1 ± 0.2 kJ mol^{-1}). α-Caffeine melts at 236.0 ± 0.2 °C ($\Delta_{fus}H$ = 21.6 ± 0.5 kJ mol^{-1}).[1, 54, 55] The phase transition peak is not as "sharp" as the melting

1

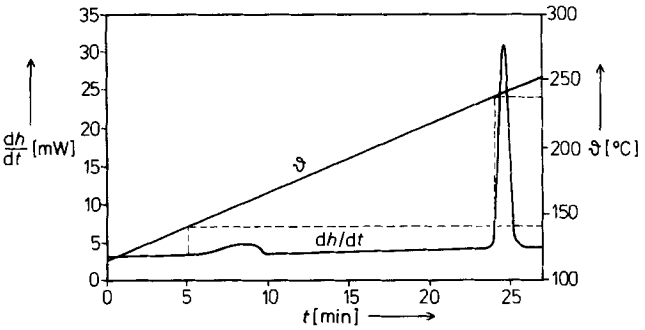


Fig. 3. DSC curve of caffeine (**1**, heating rate 5 K min^{-1}). At 141 °C the phase transition $\beta \rightarrow \alpha$ occurs and at 236 °C the melting process. The temperature is plotted on the right, the heat flow on the left (endothermic peaks point upwards, exothermic peaks downwards).

peak, as nucleation processes during a phase transition in the solid state require time. Dilatometric measurements were performed to establish whether this transition was first order. Figure 4 shows the change in length l with temperature of a pressed pellet of β-caffeine. There is a distinct discontinuity in l at the transition temperature; in other words, it is a first-order transition.

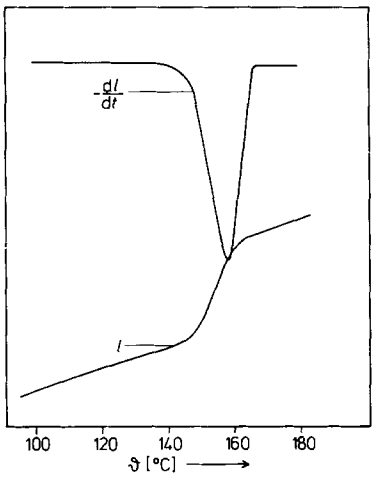

Fig. 4. Graph showing the linear expansion of a β-caffeine pellet with increase in temperature. The lower curve shows the change in length l, the upper curve the differentiation of the lower curve with time dl/dt. At approximately 140 °C the phase transition $\beta \rightarrow \alpha$ begins. The heating rate was 1 K min^{-1} (from ref. [1, 54]).

Phenanthrene undergoes a higher order transition between 72 and 74 °C. Figure 5a illustrates a DSC curve, and Figure 5b the lattice parameters determined by temperature-resolved X-ray diffraction. In both methods the transformation already begins to show at low temperatures and comes to an end with a sharp rise in the transformation rate between 72 and 74 °C. The nature of this transformation was elucidated by X-ray structure determination on single crystals at elevated temperatures.[56] The transition is one of order–disorder, in which the individual phenanthrene molecules have two different orientations in the high-temperature phase (Fig. 6). At room temperature all phenanthrene molecules lie in the orientation drawn in black. In the high-temperature phase the positions drawn in white and in black are taken up with the same probability; in other words,

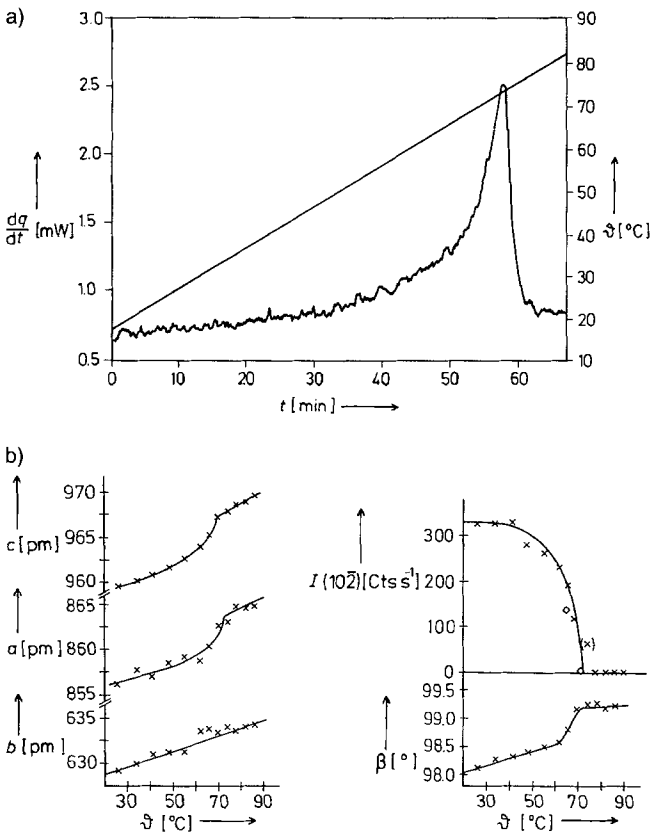

Fig. 5. Graph showing the solid–solid phase transition of phenanthrene. a) DSC curve (heating rate 1 K min^{-1}; according to ref. [1]). b) Crystallographic monitoring of the lattice parameters a, b, c, and β, and X-ray reflection (10$\bar{2}$) characteristic of the transition (temperature program: isothermal steps). The values for the (10$\bar{2}$) reflection gathered from examinations of single crystals [56] are plotted as ◇ (from ref. [41]).

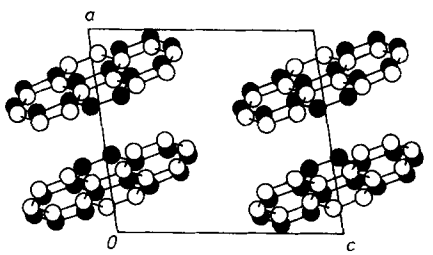

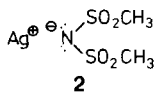

Fig. 6. Projection of the arrangement of phenanthrene molecules in a crystal onto the a/c plane. In the high temperature phase the molecules lie with the same probability either in the black or the white orientation (from ref. [56]).

the structural symmetry of the individual phenanthrene molecule in the crystal increases.

If the samples to be examined exhibit a more complex thermal behavior, or if nothing is known about the samples, the information from DSC is often insufficient, because DSC only yields the rather unspecific variable "enthalpy change". It is not possible to differentiate clearly between an endothermic phase transition, a melting process, and an endothermic reaction by DSC alone. Supplementary methods of measurement must be employed in cases that are not clear-cut. In particular the examination of solids could prove to be difficult due to the widespread appearance of polymorphism: approximately one third of organic solids have two or more polymorphic forms. Other thermoanalytical procedures can be used as additional methods (see Section 2). This approach was demonstrated here for the analyses of caffeine (Fig. 4, use of dilatometry) and phenanthrene (Fig. 5, use of temperature-resolved X-ray methods).

Cases where only small changes in enthalpy, no change in mass, and little change in length are associated with the events in progress (for example, some solid–solid phase transitions) present problems. This situation arises in a solid–solid phase transition of higher order in anhydrous silver dimesylamide (**2**), which takes place with only very small thermal effect, shows no discontinuity in its thermal expansion behavior, and is, of course, not associated with a mass loss.[57]

2

Thermoconductometry and temperature-resolved X-ray diffraction were therefore the methods chosen for this investigation. In Figure 7 the logarithm of conductivity is plotted against the reciprocal temperature. The kink at about 142 °C pointing to a phase transformation is clearly visible. The measurements carried out by X-ray diffraction enabled the quantitative determination of this higher order transition.[58]

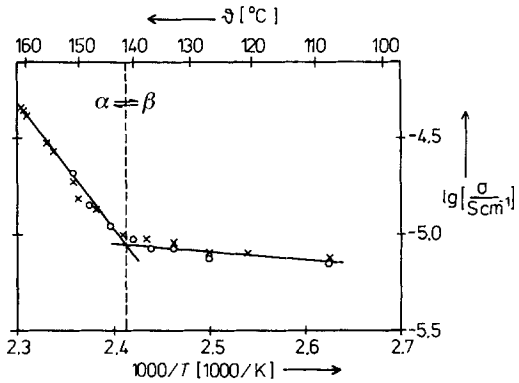

Fig. 7. Thermoconductometric study of the phase transformation $\alpha \rightleftharpoons \beta$ in anhydrous **2** (pressed pellet, 2000 Hz). The quarter hydrate **2**·1/4H2O was the starting material, which was dehydrated by heating. The subsequent cooling curve (○) and second heating(×) were recorded.

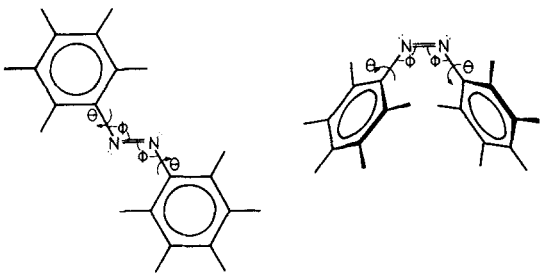
3.2. Determination of Phase Diagrams of Mixtures



As already mentioned, a classical application of thermal analysis is the determination of phase diagrams of mixtures or alloys from cooling curves (monitoring the temperature while allowing the sample to cool freely). Knowledge of the phase state is also important in syntheses, because the materials obtained are often more or less contaminated.

One of the simplest methods for checking the identity and purity is the determination of the mixed melting point T_{fus}^{mix}, which can easily be obtained from a DSC measurement. The classical van't Hoff method for the determination of purity provides more extensive information. This method is based on the lowering of the melting or freezing point, which occurs if a pure substance is contaminated with an impurity (cryoscopy). A tacit condition for this procedure is the existence of a eutectic phase diagram (cf. physical chemistry textbooks), in which the contamination of a pure component always leads to depression of

the melting point. If however a solid solution is formed between the two components (mixed crystals), the melting point of the mixture always lies between the melting temperatures of the pure substances; in other words, the method of melting temperature depression cannot be used. This situation is not rare, but is often not considered.

Such simple, and even more complex, phase diagrams can easily be determined using thermoanalytical methods. For this purpose different compositions of mixtures of pure materials are examined. DSC is the method normally used for these measurements. For more complicated problems, X-ray diffraction (if necessary temperature-resolved), thermooptical methods, and temperature-dependent measurements of electrical conductivity or electrode potential[59] are also often used.

The pseudo-binary phase diagram of *cis*- and *trans*-azobenzene will be used to demonstrate the procedure. At elevated temperature *cis*-azobenzene (**3b**) is slowly transformed into *trans*-azobenzene (**3a**) in the solid state as well as in the melt.[60-63]

3a, *trans* **3b**, *cis*

By repeatedly melting a sample of pure *cis*-azobenzene, allowing partial isomerization in the melt, and then cooling, the entire phase diagram can be established in small stages. In addition of course, mixtures can also be weighed out and measured.

Melting curves of some *cis*/*trans*-azobenzene mixtures with different compositions are shown in Figure 8. The change in the melting peaks for the pure substances as well as the eutectic peak for a mixture containing different portions of the components is clearly visible. The phase diagram shown in Figure 9 can be constructed from the melting temperatures of the mixtures. The eutectic of *cis*- and *trans*-azobenzene containing 52% of *trans*-azobenzene melts at 41.4 °C. When quenching molten mixtures of *cis*- and *trans*-azobenzene presumably a further modification of *cis*-azobenzene occurs, which also forms a eutectic with *trans*-azobenzene (eutectic temperature 36.7 °C). The melting temperature of the *cis*-azobenzene is also lowered (broken liquidus curve).[61-63] The agreement with additional data obtained by TOA[62] and by the Kofler contact method[30] is good. This example shows that unexpectedly complex phenomena can also occur in (seemingly) simple systems.

3.3. Identification and Determination of Purity

The purity of synthesized substances is often of crucial importance for the subsequent synthetic step. While the previous section dealt with larger quantities of foreign substances (impurities), this section outlines the calorimetric determination of small concentrations of impurities.

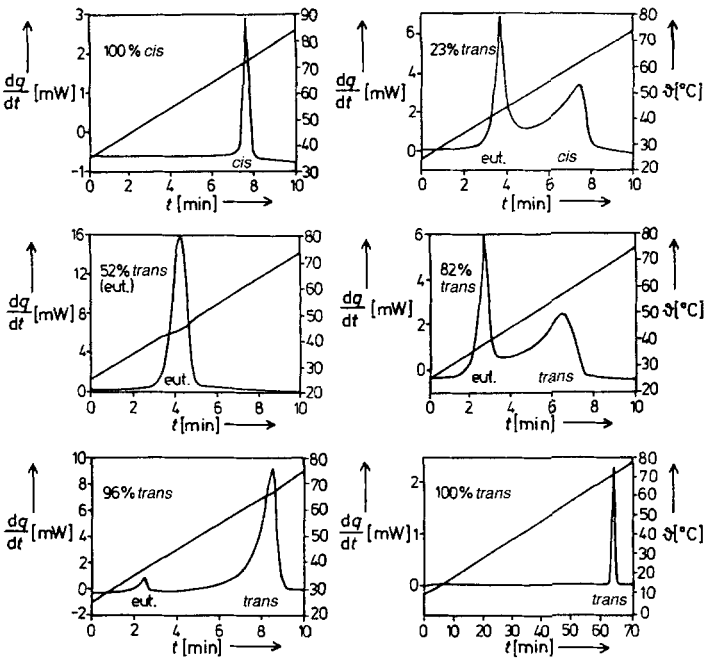


Fig. 8. Melting curves of some mixtures of *cis*- and *trans*-azobenzene (**3**). The melting temperature of the eutectic (eut.) is 41.4 °C, of *cis*-azobenzene (**3b**) 71.6 °C, and of *trans*-azobenzene (**3a**) 68.3 °C.

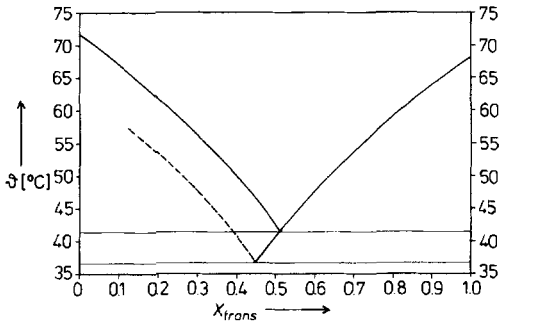

Fig. 9. The pseudo-binary phase diagram of *cis*- and *trans*-azobenzene (**3**). For details see text.

A DSC curve of a sample can be recorded quickly. The purity can already be roughly estimated by visual inspection of the shape of a melting peak. Figure 10 exhibits melting curves of naphthalene which was definitely contaminated with *trans*-azobenzene. Pure naphthalene has a very sharp melting peak with a very steeply ascending left slope. The melting peak becomes broader and flatter with increasing concentration of contaminant (the peak area remains approximately constant!). The extrapolated peak-onset temperature (described here as T_m) decreases. This effect is due to the increasing depression in melting temperature with increasing concentration of contaminant according to the Schröder–van-Laar equation and the van't Hoff law [Eq. (a)], where T_0 is the melting point of pure substance A

$$T_0 - T_m = \frac{R T_0 T_m}{\Delta_{fus} H_A} \ln x_A \approx \frac{R T_0^2}{\Delta_{fus} H_A} x_B = \frac{R T_0^2}{\Delta_{fus} H_A} x_B^* \frac{1}{F_m} \qquad (a)$$

(naphthalene in example), T_m the melting point of contaminated substance A, x_A the fraction of main component A in the liquid phase (melt), x_B the fraction of contaminant B (*trans*-azoben-

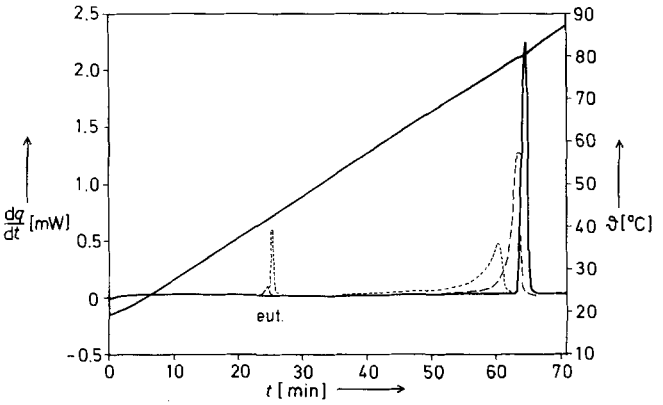

Fig. 10. The effect of contaminant concentration x_{3a} on the DSC melting curve of naphthalene. The solid curve represents zone refined (highly pure) naphthalene, the broken curve naphthalene containing 0.98 mol% **3a**, and the dotted curve naphthalene containing 5.01 mol% **3a** (from ref. [1]). eut. = eutectic.

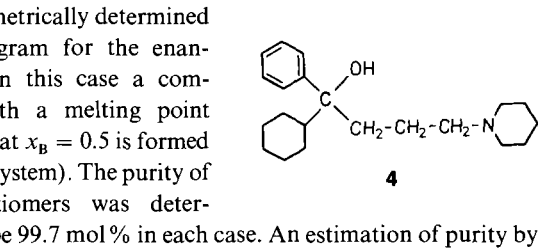
zene in example) in the liquid phase, and $\Delta_{fus}H_A$ the enthalpy of fusion of pure substance A. The basic prerequisite for the use of this equation is the formation of a eutectic between A and B. In addition, this equation is only valid under certain conditions (see ref. [66]), which primarily include an adequately low concentration x_B, thermal stability of the components even after melting, and thermodynamic equilibrium (neither temperature nor concentration gradients). The last of these requirements results in the use of a low heating rate β (normally 1 to 2 K min^{-1}) and a small sample quantity (a few mg). As a rule of thumb, a substance is of high purity if the ascending (left) side of the melting peak is steeper than the descending (right) side.

Quantitative analysis of the melting peak shape provides more precise values for purity. In this method it is assumed that the eutectic of A and B initially melts. The pure component A (in this case naphthalene) then gradually dissolves in the eutectic with increasing temperature, and as a result the concentration of B (in this case *trans*-azobenzene) steadily decreases. Thus one moves along the solubility curve of B in A, which is approximately given by the van't Hoff equation. When all of A has melted, the melt has a contaminant concentration of x_B.



By suitable plotting of the melting temperature versus the corresponding fraction that has melted (F_m), which can easily be determined from the ratio of the integral of the curve up to the particular melting temperature to the integral of the whole curve, the fraction x_B^* of contamination in the original sample can be calculated by linearization: the gradient gives the contaminant concentration x_B^*. The intercept of the extrapolated line with the temperature axis yields the melting temperature of pure component A.[1, 64, 65] The small but measurable total concentration of contaminants (less than 0.1 mol%), which can often no longer be quantitatively determined by the usual procedures such as NMR, UV, IR, and MS, is a particular advantage of this method.

As the reduction in melting temperature, being a colligative property, depends not on the type of dissolved particles but on their number only, the concentration of contaminant x_B must be regarded as a summated variable. All foreign substances which form eutectics with the main component are detected together. This feature differentiates this method from other sensitive methods (GC, HPLC, etc.), which can only detect individual impurities but do not directly yield the purity of the sample. The requirement that all components behave ideally in the melt limits the safely detectable concentration range to $x_B \approx 5$ mol% (for an estimation of the error resulting from approximations associated with the van't Hoff and Schröder–van Laar equations, see ref. [66]).

Another method that so far has hardly been used is based on a mathematical simulation of a measured curve by allocating suitable thermal resistances and time constants for the calorimeter and calculating the rate of enthalpy change in the sample.[66, 67] In this procedure calculated melting curves are compared with an experimentally obtained melting curve. The concentration of contaminant is mathematically varied in the simulation process until optimal agreement between the calculated and measured curves has been reached.

An important practical application of the calorimetric purity analysis is the determination of enantiomeric purity of newly synthesized substances. This type of analysis is particularly important for pharmaceuticals. In these cases calorimetric analysis can provide valuable results.[68–71]

The example of the selective antimuscarine agent 1-cyclohexyl-1-phenyl-4-piperidino-1-butanol (hexahydro-difenidol, **4**) will be used to illustrate this application. Figure 11 exhibits the calorimetrically determined phase diagram for the enantiomers. In this case a compound with a melting point maximum at $x_B = 0.5$ is formed (dystectic system). The purity of the enantiomers was determined to be 99.7 mol% in each case. An estimation of purity by melting point determination alone would lead to completely incorrect results here. The course of the curve between the melting temperatures of the pure enantiomers and the eutectics was calculated with the unsimplified Equation (a) (Schröder–van-Laar equation; middle partial equation). The course of the curve between the two eutectics arises from the Prigogine–Defay equation $\ln 4x_B(1 - x_B) = \Delta_{fus}H_{rc}(1/T_{max} - 1/T)$ Enantiomeric purities are frequently quoted as %*ee*. The relation to molar fraction is $\%ee = 100(2x - 1)$.[68, 70]

4

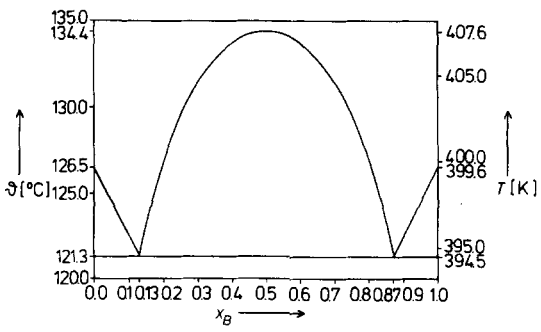


Fig. 11. The calorimetrically determined phase diagram of the two enantiomers of **4**. Both components form a dystectic (from ref. [70]).

3.4. Determination of Thermochemical Parameters

Besides the properties of pure, thermally unreactive materials, the measurement of which was discussed in the previous three sections, chemical reactions can also easily be examined with

thermoanalytical methods. These methods enable thermodynamic data (heat capacity change $\Delta_r C_p$, enthalpy of reaction $\Delta_r H$, equilibrium constant K_p, and Gibbs energy $\Delta_r G$) as well as kinetic data to be determined. The study of reaction kinetics is discussed extensively in the separate Section 3.5 because of the large significance of this field of application.

Differential scanning calorimetry (DSC) on small sample quantities (2–4 mg) can provide a general analysis of an unidentified or newly synthesized material within a few hours. An analysis by this method provides information on phase transformations and on reactions, among these also decomposition reactions. Although the temperature and enthalpy values obtained are usually still rather inaccurate, valuable conclusions on the identity, purity, and stability of the sample can still be drawn.[72–74] Unexpected effects such as phase transitions and reactions are often found. These easily obtainable results should be of interest to the preparative chemist in particular. Experience shows that a quantitative determination of the effects taking place requires a larger number of measurements. However, a quantitative description of the system is not always necessary, depending on the specific research task.

The determination of different thermochemical parameters is demonstrated here with the silver dimesylamide quarter-hydrate ($\mathbf{2}\cdot 1/4\,H_2O$) as example. Figure 12 shows the DSC curve of a

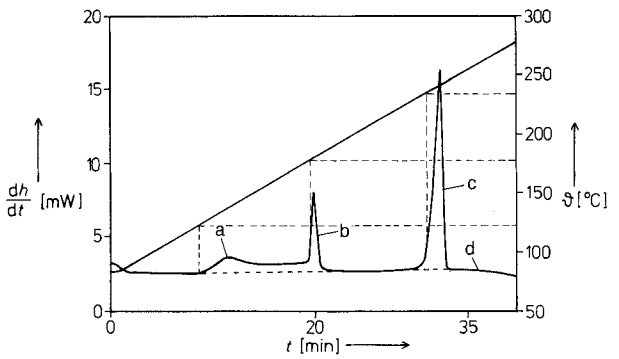

Fig. 12. DSC curve of $\mathbf{2}\cdot 1/4\,H_2O$. The dehydration a begins above 100 °C and ends with a very rapidly occurring phase transition b at 174 °C. At 238 °C the now anhydrous substance melts (c). In the melt, exothermic decomposition d occurs. The heating rate was 5 K min^{-1} (from reference [75]).

heating event. Dehydration a appears above 120 °C as a broad, endothermic peak. At 174 °C the dehydration is concluded by a rapid phase transition, during which the remainder of the water of hydration is released (sharp endothermic peak b). The sum of the enthalpy of dehydration and phase transformation was calculated by integration to be +18.42 kJ mol^{-1}.[75] After the dehydration and phase transition the substance is yellow because the crystals shatter into many small fragments while maintaining the external morphology.[75]

From the fusion peak c the melting temperature can be calculated to be 237.7 °C. The calorimetrically determined purity of the sample is 99.6 mol% (enthalpy of melting 26.48 kJ mol^{-1}). Exothermic decomposition d begins only in the melt and is seen in the falling base line.

At this point it becomes clear how information obtained from thermal analysis data can be useful in the planning of a synthesis. Silver dimesylamide is used as a starting material for further syntheses and must be available in an anhydrous form; in other words, it must be dehydrated.[58] The optimal dehydration temperature lies approximately between 180 and 190 °C, as the entire amount of water of crystallization is released quickly at this temperature without decomposition. Thermal analysis also shows that the yellow coloration after dehydration is not due to decomposition, as may have been assumed upon superficial examination. Knowledge of the high purity is of considerable value for further synthesis planning.

3.5. Kinetic Parameters from Thermoanalytical Measurements

The variables measurable by thermoanalytical methods can often be correlated with the progress of reaction. In the case of thermogravimetry the quotient from the loss in mass $\Delta m(t)$ at time t with the total mass loss $\Delta m(t = \infty)$ equals the proportion which has reacted so far, the degree of conversion. The degree of conversion is generally defined by using the extent of reaction ξ and is described as α [Eq. (b), see physical chemistry textbooks]. For a reaction proceeding to completion the degree of conversion lies between 0 and 1. The relationship between the degree of conversion and loss in mass is given by Equation (c), where $\Delta m(t)$ is the mass loss by time t, $\Delta m(t = \infty)$

$$\alpha = \frac{\xi}{\xi_{max}} \tag{b}$$

$$\alpha(t) = \frac{\Delta m(t)}{\Delta m(t = \infty)} = \frac{m(t = 0) - m(t)}{m(t = 0) - m(t = \infty)} \tag{c}$$

the total mass loss at the end of the reaction, $m(t)$ the sample mass at time t, $m(t = 0)$ the sample mass before reaction, and $m(t = \infty)$ the sample mass at the end of the reaction.

This simple equation is, of course, only valid for one-step reactions proceeding to completion ($\alpha(t = \infty) = 1$) in which the starting material used has not yet undergone decomposition ($\alpha(t = 0) = 0$). An example is the thermal decomposition of $Li_2SO_4\cdot H_2O$, which takes place without the formation of lower hydrates.[76] For the dehydration of $CuSO_4\cdot 5\,H_2O$ to $CuSO_4$, which is known to have intermediate steps, this equation must be applied to the individual steps.

A similar equation applies to DSC for the relationship between the enthalpy of reaction and degree of conversion. In this case the partial area of the reaction peak up to time t is compared with the total peak area [Eq. (d)], where $\Delta_r H(t)$ is the

$$\alpha(t) = \frac{\Delta_r H(t)}{\Delta_r H} = \frac{\int_{t_i}^{t}\left(\frac{dH}{dt}\right)dt}{\int_{t_i}^{t_f}\left(\frac{dH}{dt}\right)dt} \tag{d}$$

enthalpy of reaction (= partial peak area) up to time t, $\Delta_r H$ the total enthalpy of reaction (= total peak area between t_i and t_f), t_i the initial peak time (temperature T_i), t_f peak-end time (temperature T_f), and dH/dt enthalpy change (= heat flow) at time t.

Besides those conditions mentioned for thermogravimetry, additional conditions apply to DSC. No other thermal event (phase transition, melting, evaporation) may take place during

the reaction, and furthermore the enthalpy of reaction, which is dependent on the amount of material, must be independent of the degree of conversion. This means, for instance, that the enthalpy changes by the same amount when the degree of conversion changes from $\alpha = 0$ to $\alpha = 0.1$ as it does when the degree of conversion changes from $\alpha = 0.6$ to $\alpha = 0.7$.

Thermogravimetry and DSC are the methods most frequently used for the determination of kinetic data. Other methods such as thermooptical analysis, evolved gas analysis, and X-ray diffraction can also be used in kinetic measurements.

A particular feature of thermoanalytical methods is their suitability for the study of the kinetics of nonisothermal reactions. Conventionally, kinetic measurements are performed isothermally at different temperatures. The calculated rate constants are plotted according to Arrhenius ($\ln(k)$ versus $1/T$) to give the activation energy and collision factor (providing the plot forms a straight line). This procedure can be time consuming and requires substantial amounts of material.

Nonisothermal measurements enable, in principle, the activation parameters E_A and $\lg(k_\infty)$ to be determined from a single experiment.[25, 78–80] This procedure considerably reduces the measurement time. Although some procedures for evaluation have been available for over thirty years, this method of analysis is used comparatively seldom and is therefore unfamiliar to many chemists. For this reason the most important procedure for the evaluation of nonisothermally obtained data (the Borchardt and Daniels method),[81] which is also frequently included in the commercially marketed TA program packages, will be introduced briefly here. The rate of reaction is defined by using the previously introduced degree of conversion α [Eq. (e)],

$$\frac{d\alpha}{dt} = k(T)f(\alpha) \qquad (e)$$

where $d\alpha/dt$ is the rate of reaction, $k(T)$ the temperature-dependent rate constant, and $f(\alpha)$ a function characteristic of the reaction mechanism. For a first-order reaction, for instance, $f(\alpha) = 1-\alpha$; for an nth order reaction $f(\alpha) = c_0^{n-1} \times (1-\alpha)^n$, where c_0 is the initial concentration.[82]

For determining the temperature dependence of the rate constant k the Arrhenius equation [Eq. (f)] is applied. k_∞ is the collision factor (preexponential factor, often also denoted as k_0, A, or Z) and E_A the activation energy.

The combination of the two equations gives Equation (g). Equation (h) is thus valid for an nth order reaction. By taking logarithms the Equation (i) is obtained.

$$k(T) = k_\infty \exp\left(-\frac{E_A}{RT}\right) \qquad (f)$$

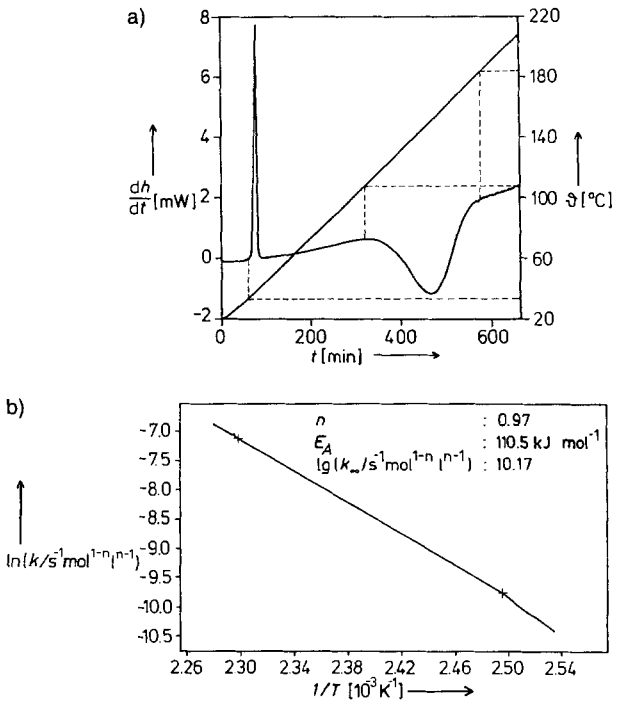
$$k(T) = \frac{d\alpha/dt}{f(\alpha)} = k_\infty \exp\left(-\frac{E_A}{RT}\right) \qquad (g)$$

$$k(T) = \frac{d\alpha/dt}{c_0^{n-1}(1-\alpha)^n} = k_\infty \exp\left(-\frac{E_A}{RT}\right) \qquad (h)$$

$$\ln k(T) = \ln(d\alpha/dt) - (n-1)\cdot\ln(c_0) - n\cdot\ln(1-\alpha) = \ln k_\infty - \frac{E_A}{RT} \qquad (i)$$

In the most favorable case the order n of the reaction is known. In this situation $k(T)$ can be calculated from the variables $d\alpha/dt$, c_0, and α for all temperatures. The value of $\ln(k(T))$ is plotted versus $1/T$, and after linear regression the activation energy E_A can be calculated from the gradient and the collision factor k_∞ from the intercept, providing n has been chosen correctly. If the order of reaction n is not known, an optimal fit of the three parameters E_A, k_∞, and n can be achieved by multiple linear regression (MLR) or nonlinear regression.[84, 85]

This procedure is demonstrated in Figure 13. The thermally induced rearrangement of (diphenylsilyl)methyl benzoate (**5a**)



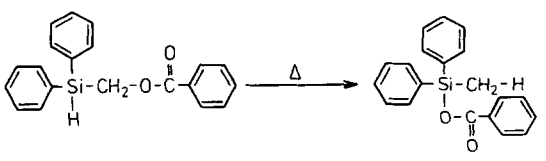


Fig. 13. Determination of the kinetics of the rearrangement of benzoic acid ester **5a** to **5b** by DSC. a) DSC curve (heating rate 0.3 K min^{-1}). At 39.4 °C the substance melts (sharp endothermic melting peak). Between 105 and 180 °C the exothermic rearrangement reaction takes place. b) Kinetic plot, obtained by multiple linear regression (MLR) for an n-th order reaction. The calculated fit parameters are included. The crosses mark the range used for MLR. The reaction only starts at elevated temperatures. Even ten cycles of melting and resolidification do no lead to any conversion.

was studied. This compound melts at 39.4 °C (enthalpy of fus $\Delta_{fus}H = 25.74$ kJ mol^{-1}). Rearrangement to the silyl ester **5b** takes place in the melt in the temperature region between 105 and 180 °C. The enthalpy of reaction calculated as described in Section 3.4 is $\Delta_r H = -169.1$ kJ mol^{-1}. Kinetic analysis of the exothermic reaction peak by multiple linear regression resulted in a first-order reaction ($n = 0.97$) with an activation energy E_A of 110.5 kJ mol^{-1} and a collision factor $\lg(k_\infty/s^{-1}\,mol^{1-n}\,l^{n-1}) \approx \lg(k_\infty/s^{-1})$ of 10.17. These results agree well with the

5a **5b**

results obtained by conventional methods (NMR, isothermal) and by theoretical calculations.[86, 87]

Besides the Borchardt and Daniels method, a series of other methods for the evaluation of nonisothermal measurements exist. The following categories of procedures can be differentiated:[1, 25]

- *Direct methods* employ the degree of conversion α and the rate of reaction $d\alpha/dt$. They are particularly suitable for DTA and DSC measurements in which the signal recorded is proportional to $d\alpha/dt$. The most important method is that of Borchardt and Daniels.[81]
- *Integral methods* employ only the degree of conversion α.[88–90] They are particularly suitable for the thermogravimetric and temperature-resolved X-ray diffraction methods, as in these cases the signal recorded (mass, intensity) is directly related to the degree of conversion.
- *Differential methods* involve the derivative of the reaction rate $d\alpha/dt$ with respect to time or temperature.[91–93] These methods naturally react very sensitively to noisy curves and are therefore not applicable in many cases except after curve smoothing.
- Some methods make use only of *specific points* on the experimental curve, such as the maximum in the rate of reaction $d\alpha/dt$.[94–100] Usually several measurements with different heating rates are necessary. These methods are often based on simplifying assumptions, which are not always justified.

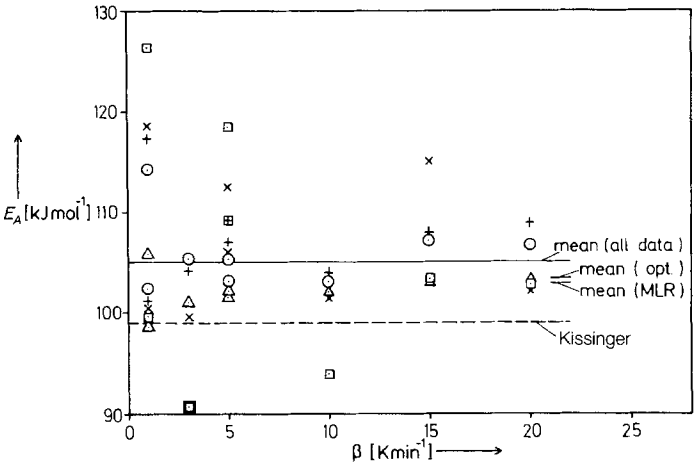

Fig. 14. Isomerization of *cis*-azobenzene **3b** in the melt analyzed by DSC with different methods of data processing. The calculated isomerization activation energy (first-order reaction) is plotted against the heating rate, β. The points ⊙ were determined by the Borchardt and Daniels method [81], × by the Ellerstein method [92], + by the Coats and Redfern method [88], △ by multiple linear regression [84], and ⊡ by the Freeman and Carroll method [91]. In addition, the values determined by the Kissinger method [96] and by discontinuous (isothermal) spectrophotometric measurements [60] are also plotted. The mean values from multiple linear regression and the mean of all non-isothermal measurements are also included (from ref. [102]). Very recently Flammersheim and Eckert, using samples we provided, obtained $E_A = 103 \pm 1$ kJ mol^{-1} by multivariate nonlinear regression (heating rate 1–40 K min^{-1}). The reaction and its data may thus be used as a kinetic reference.

As these methods always deal only with different mathematical variants of the same basic kinetic equations (see above), they should, in principle, produce identical activation energies and collision factors for a given reaction. However, the chosen method of evaluation may depend on the heating rate β as a result of different approximations made when differentiating the equations and of varying signal-to-noise ratios. Nonlinear methods of curve fitting are therefore being increasingly used (for consecutive, equilibrium, and parallel reactions as well), which perform a numerical optimization without approximations.[101] However, caution is advised here if the process investigated is not well known. Clearly, the more variables (i.e., kinetic parameters of assumed partial stages of a reaction) that are fitted to a curve, the better the mathematical fit will be. This should, however, not encourage a noncritical acceptance of the calculated activation parameters and reaction mechanisms.

Different methods of evaluation were applied to the example of the thoroughly investigated thermal isomerization of *cis*- to *trans*-azobenzene in the melt (**3b** → **3a**; enthalpy of isomerization according to DSC: $\Delta_{iso}H^{\ominus}_{298} = -48.2$ kJ mol^{-1}).[61–63] DSC measurements were performed at six different heating rates. The results for the activation energy obtained are depicted in Figure 14.[102] Besides the results determined by the methods of Borchardt and Daniels,[81] Ellerstein,[92] Coats and Redfern,[88] Freeman and Carroll,[91] and Kissinger,[96] and by multiple linear regression from the DSC curves, results arising from isothermally performed spectrophotometric measurements (discontinuous, classical Arrhenius evaluation)[60] are also plotted.

The "classically" performed optical measurements conform well to the mean value from the calorimetric measurements. It is, however, clear that the methods always produce slightly differing results. At low heating rates the signal-to-noise ratio of the DSC curve increases, which manifests itself in a greater scatter of the activation energies obtained. The differential procedures of Ellerstein, and also of Freeman and Carroll, react particularly sensitively to the increasing noise. The selected heating rate can therefore have considerable impact on the result.

In summary, the nonisothermal methods deliver results consistent with those from isothermal measurements. In each individual case the heating rate must always be varied and the calculated kinetic data analyzed critically to avoid serious errors in conclusions. This is all the more important because programs for kinetic data processing with a convenient and easy operation that can lead to an all too uncritical handling of the data are offered by instrument manufacturers today.

The examples given so far concern homogenous chemical reactions. In general the applicability of kinetic procedures and their agreement with results obtained by "classical isothermal" methods is good in these cases.[63, 78, 86, 102] The examination of heterogenous reactions (for instance, when at least one participant in the reaction is a solid) proves to be more difficult.

Whilst the possible mechanisms for homogenous reactions (expressed by the functions $f(\alpha)$[82]) are usually zeroth, first, or second order, the circumstances surrounding the reactions of solids are completely different. Because of the fixed orientation of the molecules or atoms, nucleation, diffusion, and thermal conduction phenomena play crucial roles. The resulting rate laws are often complicated even though numerous simplifications were involved in their derivation.[82] Selection and verification of the "correct" reaction mechanism is difficult. As yet no successful unified theory for solid-state reactions has been developed, despite extensive theoretical and practical efforts. The basic principles of the kinetics of these reactions as understood today can be found in several monographs.[5, 103–108]

The significance of the kinetic parameters E_A and k_∞ in the solid-state reactions is controversial.[109–113] Increasingly, the

view is taken that the calculated variables are artifacts; in other words, they have no physical significance.[114] In fact, the concept of an "activation energy" was originally developed for collision-induced reactions in the gas phase and is already not valid without reservation in liquid phases.

The extensive characterization of solid-state reactions is considerably more difficult (and therefore more laborious) than that of a homogeneous reaction. Additional analyses by optical, electrical,[59] and diffraction methods, amongst others, must usually be performed.

Figure 15 illustrates an example of the application of a supplementary method to a solid-state reaction. Lithium sulphate

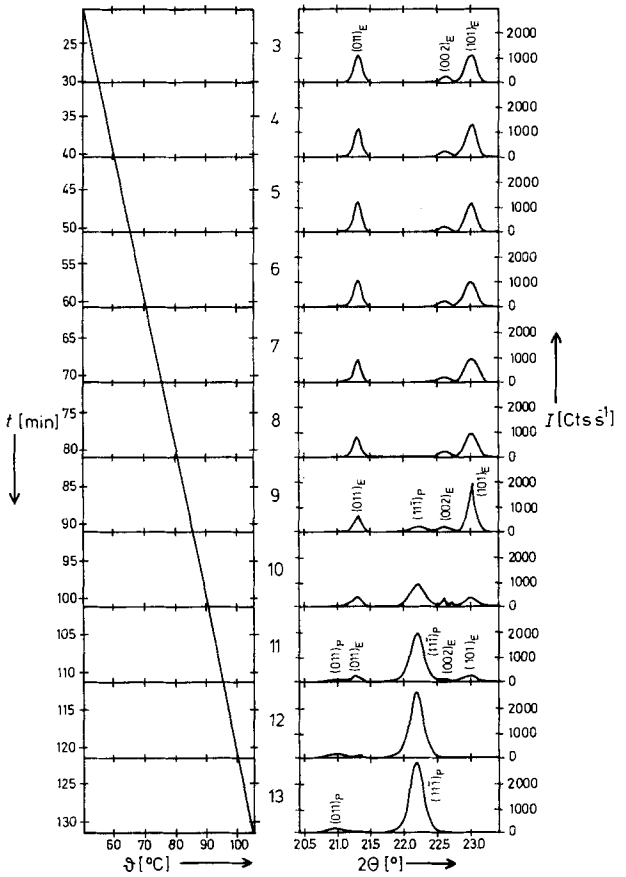

Fig. 15. Analysis of the dehydration of lithium sulphate monohydrate by temperature-resolved X-ray diffraction (TXRD). On the left the temperature is plotted against time; on the right the recorded diffractograms (scans 3 to 13) are portrayed. The heating rate was + 0.5 K min^{-1}, the angular velocity relative to 0.3° 2θ min^{-1}. The reflections from starting material E (= $Li_2SO_4 \cdot H_2O$) and product P (= Li_2SO_4) are marked (from ref. [77]).

monohydrate was discussed as a potential kinetic standard for solid-state reactions.[76] Here we discuss the study of the dehydration of lithium sulphate monohydrate by time- and temperature-resolved X-ray powder diffraction.[77] During the heating process performed at a constant heating rate, powder diffractograms of the sample are recorded continually. During dehydration the reflections of the hydrate (E) become smaller until they have completely disappeared. The reflections of the anhydride (P) develop concurrently. The reflections could be indexed.[115] The quantitative ratio of hydrate to anhydride can be calculated from the intensities of the reflections, from which the degree of conversion can be determined.[41] It is then possible to draw conclusions on the kinetics of the solid-state reaction from the temperature- and time-dependent degree of conversion data. The data recorded point to a nucleation mechanism A_2 according to Avrami–Erofeev.[82]

However, the X-ray reflections of the hydrate do not decrease monotonically as would be expected. Instead, for instance, the intensity of the (101) reflection suddenly increases in scan 9, and decreases again in the following scan. Such effects can also be observed with other hydrate reflections. They indicate that during the dehydration, processes are taking place that cannot be explained by simple kinetic models. Neither DSC nor TG measurements gave any indication of such processes.[77] Such observations show that solid-state reactions involve very complicated processes that can only be explained after analysis by as many methods as possible (see for example, ref. [116]).

For this reason nonisothermal kinetic measurements should preferably be performed in a homogeneous (liquid) phase. In this case DSC is usually the method of choice. In favorable cases all energetic and kinetic parameters of a reaction can be determined from very few measurements by this method with mg quantities, as shown in Sections 3.4 and 3.5. Naturally, the nonisothermal procedure can also be applied advantageously to other techniques (for example, the large variety of spectrometric methods[117, 118]), an option that unfortunately has only been used very sporadically as yet.

4. Measurements on High Molecular Weight Substances (Polymers)

An important field for the application of thermoanalysis is the examination of high molecular weight substances.[10, 119–122] The main methods used are DSC, thermogravimetry, and thermomechanical procedures. The processes and variables examined include glass transition temperatures (DSC, TMA, DMA), degrees of crystallinity and melting processes (DSC), rates of polymerization (DSC), heat capacities (DSC), rates of crystallization (TOA), softening processes (TMA, DMA), mechanical variables such as expansion coefficient, elasticity, storage modulus, loss modulus (TMA, DMA), thermal stability (TG, DSC), and the determination of the composition and compatibility of multicomponent mixtures (DSC, TG, TMA, DMA). In the following examples will be used to illustrate these applications.

Glass transitions appear as a shift in the base line (in an endothermal direction, change in heat capacity ΔC_p) during a DSC measurement. The glass transition in polyethylene terephthalate (PET) is illustrated in Figure 16 (78.7–83.7 °C). Knowledge of glass transition temperatures is important for the assessment of elastic properties and estimation of the compatibility of the individual components in polymer mixtures (polymer blends).

The exothermic crystallization of amorphous regions (peak temperature 157.6 °C) and the melting process (peak-onset temperature 239.6 °C) can also be seen in Figure 16. By comparing the measured enthalpy of melting with the enthalpy of melting tabulated for an entirely crystalline polymer, the crystalline fraction of the sample can be estimated (polymers generally contain crystalline as well as amorphous regions).

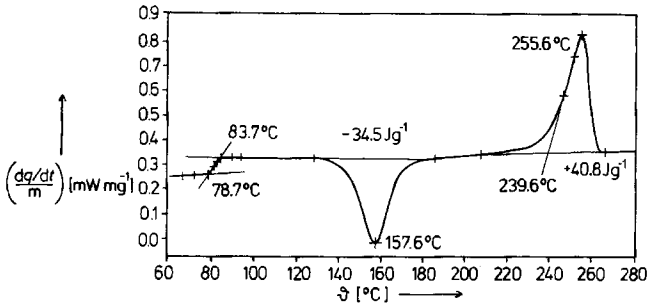

Fig. 16. Melting curve of PET by DSC. From 78 to 84 °C the glass transition appears as an endothermic step. At a peak temperature of 158 °C exothermic recrystallization takes place (enthalpy of crystallization $-34.5\ J\,g^{-1}$), at a temperature of 240 °C (onset) and 256 °C (maximum) melting takes place (enthalpy of melting $+40.8\ J\,g^{-1}$). The heating rate was $10\ K\,min^{-1}$ (from ref. [123]).

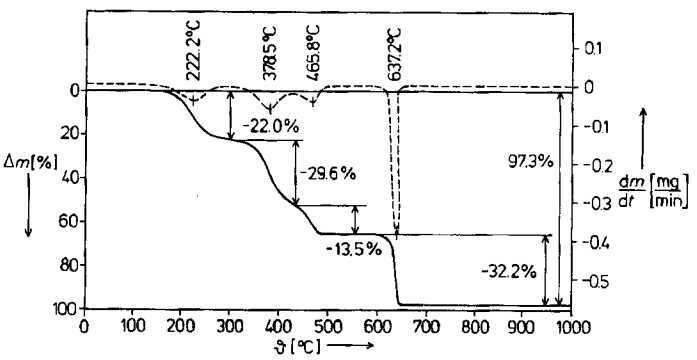

Fig. 17. TG curve of the decomposition of a natural rubber/ethylene–propylene copolymer blend. The solid line illustrates the mass curve (lefthand scale, Δm), the broken line the differential mass signal dm/dt (righthand scale). For details see text (from ref. [126]).

The ratio of the glass transition temperature T_g to the melting temperature T_{fus} can provide information on the type of polymer. For highly symmetrical, highly crystalline homopolymers made from very small monomer components (for example, polyethylene, polyoxymethylene), T_g/T_{fus} lies below 0.5; for certain unsymmetrical polymers T_g/T_{fus} lies above 0.76. For the large majority of polymers the ratio T_g/T_{fus} is approximately 2/3.[123]

Rates of polymerization can be accurately measured by DSC.[124] Important information on the treatment necessary for complete curing (length of time, temperature, type and quantity of catalyst) can be gained from the position and shape of the normally exothermic reaction peak. In addition, the reaction peak can be analyzed by the kinetic methods of evaluation introduced in Section 3.5.

TMA and DMA are used to measure the temperature-dependent mechanical properties.[125] Besides the expansion coefficient, the response of a sample to the application of a force that is changed with time (for example, a sinusoidal oscillation) can also be measured. Glass transition temperatures can often be recorded more clearly by this method than by DSC (the elasticity increases markedly when the polymer is heated beyond the glass transition temperature).

The thermal stability of polymers can be estimated by DSC or TG measurements. Decomposition manifests itself as an exothermic or endothermic peak during DSC analysis or as mass loss in thermogravimetric analysis. An important application of this thermal decomposition of polymeric materials is the determination of the composition of samples containing several components. Thermogravimetry is the selected method of analysis. By quantitative analysis of the dependence of the mass loss on temperature and type of purge gas, the mass fractions of the individual components are determined. This procedure can, for example, be used for quality control of polymers.

Figure 17 portrays the TG curve of the decomposition of a mixture of natural rubber and an ethylene–propylene copolymer. The measurement is begun in a stream of nitrogen. Between approximately 150 °C and 300 °C the plasticizer (a low-boiling ester of adipic acid) is given off (22.0 wt%). Pyrolysis of the rubber (29.6 wt%) and the ethylene–propylene copolymer (13.5 wt%) follows. At 600 °C the purge gas is switched from nitrogen to air. A sharp peak corresponds to the combustion of the soot contained in the sample (32.2 wt%). An occasional residue (here: 2.7 wt%) consists of ash and filler, in this case of zinc oxide ZnO.

The individual components can be determined with good accuracy. Naturally the method has its limits if the decomposition reactions of the individual components overlap strongly. Reducing the heating rate in this instance often gives a better separation of the peaks. If even this measure does not lead to success, other methods of analysis (for example, simultaneous TG/DTA, EGA with mass spectrometry or FTIR) must be used.

5. Possible Applications of Thermal Analysis in Industry

The potential applications of thermal analysis in industrial production and routine analysis are manifold. Possibilities are quality control of raw materials on delivery, continuous control of production by analysis of aliquots, and the examination of products for quality assurance.[111] The methods of analysis used essentially are:

- differential scanning calorimetry (DSC) for the determination of melting point, boiling point, vapor pressure, purity, heat capacity, heat of reaction, thermal stability
- thermogravimetry (TG) for the determination of moisture content, fractions of volatile components, and thermal stability, as well as the released gases and remaining residues after combustion or pyrolysis (if necessary coupled with gas chromatography, FTIR, or mass spectrometry)
- dilatometric methods of analysis (dilatometry, TMA, DMA), for the determination of mechanical behavior (expansion coefficients, glass transition temperatures, elasticity, plasticity), especially of polymers (see Section 4).

Besides production control and quality assurance, thermal analysis can provide important information on the potential hazards of decomposable materials.[127–132] The data obtained by these methods are not only important for large scale production, but also for the preparative chemist, as the prevention of accidents in pilot plants and even in the laboratory is imperative. The following text gives a brief summary of the possibilities for technical safety.

Exothermic decomposition reactions present a considerable risk. Potentially hazardous organic compounds are, for example, nitrenes, isocyanates, azo and hydrazo compounds, azides, amino-halide compounds (for example, halogen-substituted anilines), oximes, epoxides, peroxides, and *N*-oxides. The danger

arises from the high exothermic decomposition energy resulting from the formation of small, very stable molecules (N_2, H_2O, CO_2). Most decompositions of this type are also autocatalytic.

The enthalpy of decomposition $\Delta_{dec}H$ (p = constant) can be determined by DTA and DSC measurements. It can, in many cases, also be calculated from the tabulated thermodynamic enthalpies of formation, which, however, always involves uncertainty about the assumed reaction products and the complete conversion required. For organic compounds an approximate calculation by incremental methods is usually possible. In ref. [129] the chemical structure is compared with the decomposition energy $\Delta_{dec}U$ (V = constant), enabling an approximate estimation. The enthalpy of decomposition is expediently related to the mass of the chemical substance and is given in $J\,g^{-1}$. Typical values are, for instance, $-1740\,J\,g^{-1}$ for nitrobenzene, $-1882\,J\,g^{-1}$ for 4-nitroaniline, $-800\,J\,g^{-1}$ for azobenzene, $-830\,J\,g^{-1}$ for 3,5-dimethoxyaniline, $-920\,J\,g^{-1}$ for maleic anhydride, $-406\,J\,g^{-1}$ for glucose, and $-835\,J\,g^{-1}$ for sodium azide.[128]

The adiabatic temperature rise ΔT_{ad}, which is defined as the quotient of the enthalpy of decomposition and heat capacity, is more significant [Eq. (j)]. An adiabatic temperature rise of 50 to

$$\Delta T_{ad} = -\frac{\Delta_{dec}H}{C_p} \qquad \text{(j)}$$

100 K is generally regarded as safe.[127] If the heat capacity C_p is not known, the approximation $C_p \times \rho \approx 1.7\,J\,cm^{-3}\,K^{-1}$ (ρ is the density in $g\,cm^{-3}$) can be used for organic materials.[127] C_p can also be determined by DSC or approximately calculated by incremental methods.[10]

Nonexplosive materials can easily be examined by DSC and TG for the risk of an exothermic decomposition. A quick general analysis scanned at $10\,K\,min^{-1}$ to approximately 500 °C is performed. If the DSC analysis reveals no exothermic peak and the TG analysis no great loss in mass, the substance may be regarded as safe.[127]

If an exothermic peak appears, the hazard potential must be further assessed by performing additional investigations (measurements using a low heating rate, adiabatic thermal storage experiments, estimation of the adiabatic temperature rise and adiabatic induction time).[127, 128] Conclusions on the long-term storage behavior of unstable materials can be drawn by performing adiabatic temperature experiments, in Dewar flasks for example.

In this context it is interesting that the heat transfer behavior of a $2\,m^3$ agitated reactor is approximately the same as that of a $500\,cm^3$ Dewar flask.[133] A powder exhibiting similar heat transfer behavior as reactor occupies an even smaller volume of $0.1\,m^3$.[127] This makes it clear how quickly dangers resulting from difficulties with heat dissipation can arise when scaling up chemical syntheses from the laboratory to industrial production (or even only on storage of chemicals).

The decomposition temperature may be considerably lowered by additives and impurities. Figure 18, which portrays DTA curves of 3-nitrobenzoic acid in a pure form and with different additives, makes this point clear. A shift of the decomposition peak to lower temperatures results, especially following the addition of heavy metals.

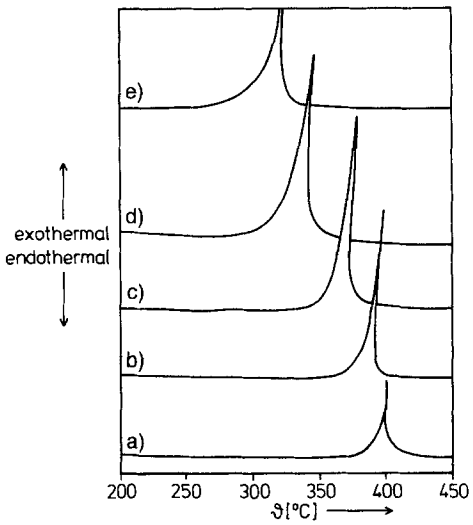

Fig. 18. DTA curves of the decomposition of 3-nitrobenzoic acid contaminated with different salts. a) Pure substance, b) 3-nitrobenzoic acid contaminated with 1.6 wt.% NaCl, curve c) 3-nitrobenzoic acid contaminated with 1.3 wt.% $FeCl_3$, d) 3-nitrobenzoic acid contaminated with 1.5 wt.% VCl_3, and e) 3-nitrobenzoic acid contaminated with 1.6 wt.% $MoCl_5$. In contrast to the other figures, the exothermic signal points upwards (from ref. [128]).

6. Biocalorimetry

Biocalorimetry involves the use of calorimetric methods for the study of biological processes. The application of calorimetry to living organisms is already very old. As far back as 200 years ago Lavoisier and Laplace examined the heat production of guinea-pigs with their newly developed ice calorimeter.[3] As heat exchange with the environment belongs to the fundamental characteristics of living systems, biocalorimetry with its methods of measurement, which meanwhile have become considerably more sensitive, today offers applications for the examination of a wide variety of subjects ranging from microorganisms, through plants and insects, to man.[134–137]

An example taken from the examination of microorganisms demonstrates the potential for the application of this method. Figure 19 illustrates the growth of a strain of *Escherichia coli* bacteria without and with the addition of antibacterial agents. The addition of amoxycillin and clavulinic acid causes strong bacterial growth inhibition, which manifests itself in a drop in heat generation. Control experiments showed that the addition of amoxycillin or clavulinic acid alone had no effect on bacterial growth.[138, 139] Such measurements can produce important contributions towards judging the effectiveness of pharmaceuticals.[138, 140]

7. Summary and Outlook

We hope we have shown that the reputation of thermal analysis as merely a qualitative method for measurement is unjustified. Providing investigations are performed carefully and the data evaluated critically, thermal analysis can provide quantitative results on material properties, thermodynamics, and kinetics. As is the case with all analytical methods, a certain basic knowledge of the operation of instruments, algorithms, and programs for

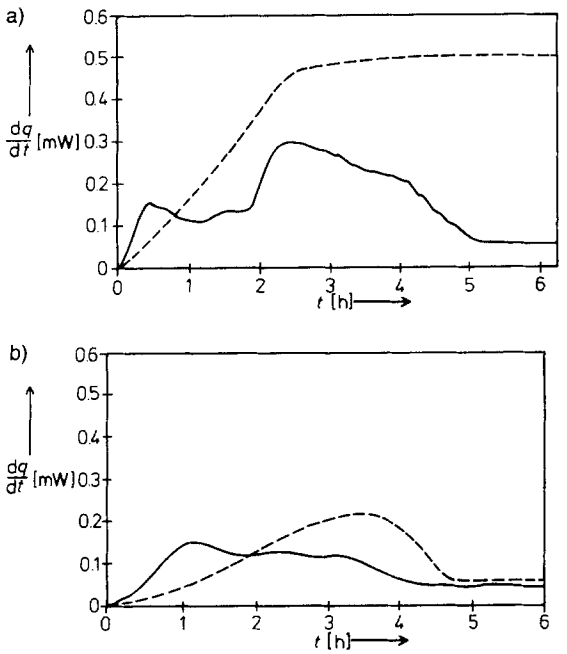

Fig. 19. Heat flow–time diagrams of the growth of *Escherichia coli* bacteria (solid line: heat evolution, broken line: growth curve). a) Undisturbed growth. b) Inhibited growth following the addition of antibacterial agents (amoxycillin, clavulinic acid) (from to ref. [138, 139]).

the data processing is required. Thermal analysis is a method for the measurement of thermodynamic and kinetic properties of materials that is easy to operate. The four most frequently applied methods, thermogravimetry, differential thermal analysis, differential scanning calorimetry, and dilatometry can be used in many different ways to characterize synthesized materials. The range of possible applications in technical practice is extensive. Special advantages are the speed and small samples required.

Besides these established methods, an increasing number of other methods are being developed. As virtually all physical methods of measurement can also (at least potentially) be performed with temperature programming, this trend will certainly continue. Investigations into kinetics in particular should profit from such new developments. Although most procedures of this type are (still?) not commercially available, we have purposely included a series of examples to demonstrate the variety of results obtainable. In addition, the intention was to expound the limits beyond which results obtainable by current methods are no longer reliable for a definite characterization.

We would like to thank Henning Arnecke, Sigurd Bauerecker, Dr. Heino Bothe, Dr. N. Eckardt, Dr. Sabine Eligehausen, Prof. Dr. Claus Führer, Dr. Peter Gabel, Dietmar Hamann, Erwin Kaisersberger, Dr. Kerstin Martin, Gerlind Öhlschläger, Dr. Joachim Reichelt, Dr. Stefan M. Sarge, Petra B. Schneider, Axel Steer, Dr. Ingeborg Steppuhn, Manfred Steppuhn, Prof. Dr. R. Tacke, Dr. Uwe Ulbrich, and Martin Welzel for their contributions towards this study as well as the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Arbeitsgemeinschaft Industrieller Forschungsvereinigungen (AIF) for their financial support.

[12] The standard valid in Germany is German Industrial Standard (DIN) 51005 "thermal analysis (TA), concepts" dated August 1993. Further standards relevant here are DIN 51004 (determination of melting temperature by DTA), DIN 51006 (thermogravimetry), DIN 51007 (differential thermal analysis), and DIN 51045 (thermal expansion in solids) (in part initially published as preliminary paper). The German standards can be obtained from Beuth Verlag, Berlin. Definitions and instructions were also published by the "International Confederation for Thermoanalysis and Calorimetry" (ICTAC) and the "American Society for Testing and Materials" (ASTM) [13]. Important ASTM instructions are E473-85 (definition of concepts in TA), E472-86 (presentation of thermoanalytical data), E1142-90 (terminology), E967-83 and 968-83 (calibration of DSC), E914-83 and E1131-86 (thermogravimetry), E793-85 and E794-85 (melting and solidification), E831-86 (thermal expansion), E928-85 (determination of purity by TA), E537-86 and E487-79 (thermal stability), E698-79 (kinetics), D3417-83 (melting and solidification of polymers), and D3418-32 (phase transformations of polymers).

[14] Besides the generally used temperature programs with a constant heating rate (including isothermal measurements) there are a series of other temperature–time programs. Of some significance are stepwise isothermal temperature programs, during which the oven temperature is increased in a series of stages and held constant at each temperature for a predetermined period of time [15]. Specifically developed for the study of reactions were the quasi-isothermal temperature control and the establishing of a constant rate of reaction, which often enable a better kinetic evaluation of reactions of solids [15, 16, 17]. Furthermore, most instruments also offer heating–cooling programs as well as the cycling of temperature programs (important in investigations into the reversibility of processes). A newly developed version of DSC is oscillating DSC (ODSC), also called modulated DSC (MDSC) in which an oscillating (for instance, sinusoidal) temperature profile is superimposed on a constant heating rate. This results in better resolution of reversible and irreversible phenomena, especially in polymers and polymer blends. P. J. Gill, S. R. Sauerbrunn, M. Reading, *J. Therm. [20] For instruments used in scanning operations a differentiation must be made in thermoanalysis between the zero line (German standardized term: Nullinie), the reference line (German: Grundlinie), and the base line (German: Basislinie). The signal blank, that is, when the instrument does not contain a sample crucible, is described as the zero line. The reference line is the signal recorded when the instrument contains an empty sample crucible. The signal recorded during a period of measurement in which no thermal event takes place is described as the base line. In the case of a single peak as illustrated in Figure 2, the base line before and after the thermal event is known. Naturally, the base line cannot be measured during the thermal event and must therefore be constructed. Different methods have been developed for this purpose [1, 21, 22]. Normally only a linear interpolation is used as the simplest method in the construction of a base line.

[23] The likewise frequently encountered "heat flux DSC" or "quantitative DTA" is based on a measurement principle similar to that of DTA. The specific design here ensures that the temperature difference is proportional to the difference between the flow of heat to each sample. By assuming a constant flow of heat to the reference sample the thermal flow $\dot{q}$ from or to the sample can then be calculated from the signal ΔT; in other words, a quantitative measurement of the change in enthalpy is possible, as it is in power-compensated DSC. The maximal attainable temperatures of 1500 °C are considerably higher than they are in power-compensated DSC. Whether this method can be classified as DTA or DSC is a question of definition (see for example, ref. [1] for more details).

[45] Substances which were selected as fixed points on the International Temperature Scale of 1990 (ITS-90) are particularly suitable for temperature calibration. A procedure for temperature calibration for DTA and DSC is suggested in ref. [46,24]. Ref. [24] contains a selection of recommended materials for calibration in the temperature range 120 K to 1350 K. See ref. [47] for ITS-90. Besides the temperature calibration, a mass calibration can be performed for TG instruments, a heat calibration and heat flow calibration for DSC instruments, and a length calibration for dilatometers. The procedure for heat calibration and heat flow calibration of DSC instruments recommended by the Gesellschaft für thermische Analysis (GEFTA) is illustrated in ref. [22]. Factors influencing the calibration of heat flux calorimeters are discussed, for example, in H. K. Cammenga, A. Steer, *Thermochim. Acta* **1993**, *229*, 15–25.

[76] The dehydration of lithium sulphate monohydrate proceeds in one stage without the formation of intermediates according to measurements carried out to date. Other hydrates are not known. For this reason it was considered for a while as a kinetic reference material for solid-state reactions by the "Kinetics Committee" of the ICTAC. For more recent measurements on lithium sulphate regarding kinetics, see V.B. Okhotnikov, N. A. Simakova, B. I. Kidyakov, *React. Kinet. Catal. Lett.* **1989**, *39*, 345–350; H. Tanaka, N. Koga, J. [82] Reactions in homogeneous phase are predominantly simple n-th order, in which $f(\alpha) = (1-\alpha)n$, where n is the order of reaction. The introduction of the function $f(\alpha)$ is primarily justified by the fact that considerably more complex time laws appear in the kinetics of heterogeneous reactions, which may be due to nucleation or diffusion processes, for example. For three-dimensional diffusion (Jander equation), the function is, for instance: $f(\alpha) = [1-(1-\alpha)^{1/3}]^{-1}(1-\alpha)^{2/3}$. The different equations for the rates of heterogeneous reactions are quoted (ref. [1, 7]) or derived (refs. [2, 83, 105, 107]) in several papers.

Synthetic Ribozymes and the First Deoxyribozyme**

Petra Burgstaller and Michael Famulok*

The principal aims of the early stages of protein engineering were limited to understanding how enzymes work. Today's greatest challenge is the de novo design of synthetic enzymes. Since the discovery of natural catalytic RNAs more than ten years ago,[1] however, progress in this field is no longer limited just to proteins. The development of methods for in vitro selection and in vitro evolution have made it possible not only to alter and improve the functionality and specificity of natural ribozymes, but also to develop RNA catalysts with new functionalities. The strategies by which this is achieved differ—with one exception[2]—from those used, for instance, to isolate catalytic antibodies. In this case, antibodies that specifically bind to transition state analogues (TSAs) are isolated. Such antibodies contain a binding site that fits better to the structure of the transition state of a particular chemical reaction than to the structures of the products or starting materials, and hence catalyze the corresponding reaction.[3] In contrast to this, catalysts based on nucleic acids are isolated by the method of "direct selection", whereby a randomized, highly complex pool of nucleic acids is subjected to a competitive situation in which only those molecules survive that can catalyze a particular reaction. The principles applied are similar to those that play a role in Darwinian evolution, and are based on in vitro selection and in vitro evolution, techniques whose function has been described several times, also in this journal.[4] In this highlight we will present some of the newest, most exciting results in this field, which is developing at a truly astonishing rate.

Bartel and Szostak made a major step forward two years ago. They succeeded in isolating ribozymes from a synthetic RNA pool which were capable of ligating an oligonucleotide to their 5'-end with cleavage of pyrophosphate.[5] The mechanism of this reaction corresponds to the mode of action of RNA-dependent RNA polymerases. The selection strategy started with a pool with a very long randomized synthetic sequence of 220 nucleotides. This length was chosen to increase the probability of isolating catalytically active sequences (Scheme 1).

To bring the 3'-hydroxyl group of the oligonucleotide in proximity to the triphosphate at the 5'-end of the RNA pool, a sequence in the constant region of the 5'-primer was constructed such that the substrate oligonucleotide could hybridize to the 5'-end of the pool. Catalytically active molecules were enriched

Scheme 1. Selection strategy for the isolation of an RNA ligase ribozyme. 1) The defined region at the 5'-end of a synthetic RNA pool with 220 randomized nucleotides forms a hairpin structure which allows binding of the oligonucleotide to be ligated. This binding reaction brings the 3'-end of the oligonucleotide into close proximity to the triphosphate unit (ppp) at the 5'-end of the RNA pool. To prevent aggregation of the RNA molecules, they are immobilized on streptavidin agarose by hybridization of the 3'-primer binding site of the pool to a biotinylated oligonucleotide. 2) After successful ligation and release of pyrophosphate (pp), the pool is enriched in two steps. 3) First, the ligated tag sequence is hybridized to an immobilized, complementary oligonucleotide, whereby ligated and unligated sequences are separated. After removal of unligated sequences from the oligonucleotide affinity column by washing, the bound sequences are eluted by denaturation, and reverse-transcribed. 4) A further enrichment follows, using PCR with a primer which is also complementary to the ligated region. 5) By means of a second PCR the original unligated sequence is regenerated, and the T7 promoter for the subsequent in vitro transcription is added. Transcription with T7 RNA polymerase (not shown) adds a triphosphate group to the 5'-end of the RNA pool, and the resulting RNA can then be subjected to a further selection cycle.

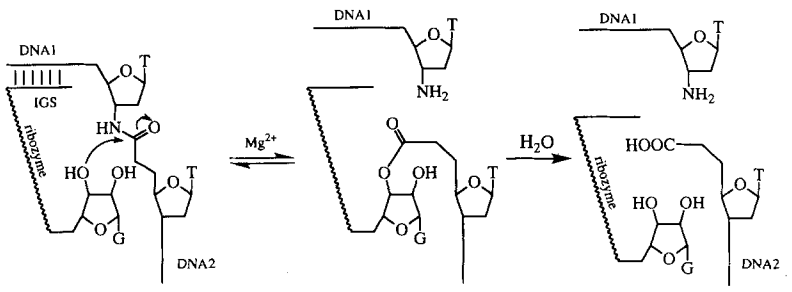
in two steps. Following incubation with the oligonucleotide, the pool was purified by passage through an oligonucleotide affinity column, to which only successfully ligated sequences could bind. These were then eluted, reverse transcribed, and amplified in a PCR reaction with a primer that was complementary to the sequence of the ligated oligonucleotide. In a second PCR reaction the original, unligated structure was then regenerated, from which an enriched RNA pool was transcribed for the next round of selection. Three of the ten selection rounds contained a mutagenic PCR step, so that "worse" catalysts had the chance to develop into "better" ones. This strategy led to an increase in the ligation rate from $3 \times 10^{-6}\,h^{-1}$, for the uncatalyzed rate, to $8\,h^{-1}$.

A characteristic trait of many enzymatic catalysis mechanisms is their specific substrate recognition and their cofactor requirements. In order to study whether RNA can also carry out a substrate- or cofactor-dependent catalysis, Lorsch and Szostak started from a specific ATP-binding RNA, which had been previously selected by affinity chromatography on ATP agarose,[6] and used this as the basis for the evolution of an ATP-dependent oligonucleotide kinase[7] (Scheme 2). An RNA pool was synthesized in which the central sequence of the ATP binder had been 15% randomized and was surrounded by three completely randomized sequences of a total of 100 bases. This pool was incubated with ATP-γ-S. RNAs onto which the γ-thiophosphate group of the ATP had been transferred could be separated from the rest of the pool on activated thiopropyl agarose, since they specifically formed a disulfide bond between the thiophosphate group and the agarose. These covalently bound RNAs were then eluted by washing with an excess of 2-mercaptoethanol, amplified, and reselected.

After thirteen cycles of selection, seven classes of ribozymes were characterized which catalyzed various reactions. Five of these RNA classes catalyzed the transfer of the γ-thiophosphate onto their own 5′-hydroxyl group and are therefore 5′-kinases. The other two classes phosphorylated the 2′-hydroxyl groups of specific internal base positions. Starting from one of these sequences, a ribozyme was developed which can phosphorylate oligonucleotides at their 5′-end in an intermolecular reaction. In this way a multiple, ATP-dependent transfer reaction could also be demonstrated, and it was shown that the kinetics of the catalysis followed the Michaelis–Menten equation.

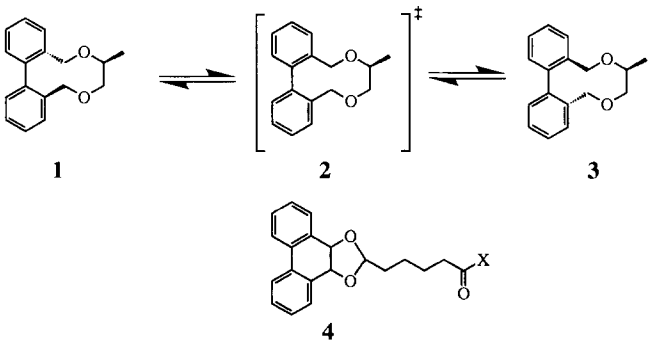


The novel synthetic ribozymes developed up to now all carry out phosphodiester transfer reactions and hydrolyses, as do all known natural, catalytically active RNA molecules. However, Joyce et al. recently demonstrated a far broader catalytic potential for RNA, by describing a ribozyme that catalyzes the cleavage of an amide bond.[8] For this purpose a DNA-cleaving RNA molecule was chosen that had previously been isolated by in vitro evolution from a pool of variants of the *Tetrahymena* ribozyme.[9] It was assumed that the DNA-cleaving ribozyme should also be capable of hydrolyzing an amide bond, since the transition state of amide hydrolysis corresponds exactly to the tetrahedral structure of the phosphate group. In addition, Piccirilli et al. had previously shown that the wild-type group I intron from *Tetrahymena* can also catalyze the hydrolysis

Scheme 2. Selection of a ribozyme with polynucleotide kinase activity. The RNA pool, which is based on the ATP-binding aptamer [6] of Sassanfar and Szostak, is incubated with ATP-γ-S. Molecules that have been successfully thiophosphorylated bind to activated thiopropylsepharose by formation of a disulfide bond and can be separated by chromatography. The disulfide bond is then cleaved with an excess of β-mercaptoethanol, so that the molecules can be amplified and subjected to the next round of selection.

of a carboxylic ester if this is presented as substrate to the ribozyme in the form of an aminoacyl-oligonucleotide.[10] The substrate used for the amide hydrolysis was an oligonucleotide (DNA1), which contained an amide group and could hybridize to a particular region of the ribozyme, the "internal guide sequence" (IGS). The ribozyme contained 17 mutations in comparison with the wild-type sequence of the *Tetrahymena* intron and catalyzed the amide cleavage, whereas the wild-type sequence was inactive (Scheme 3).

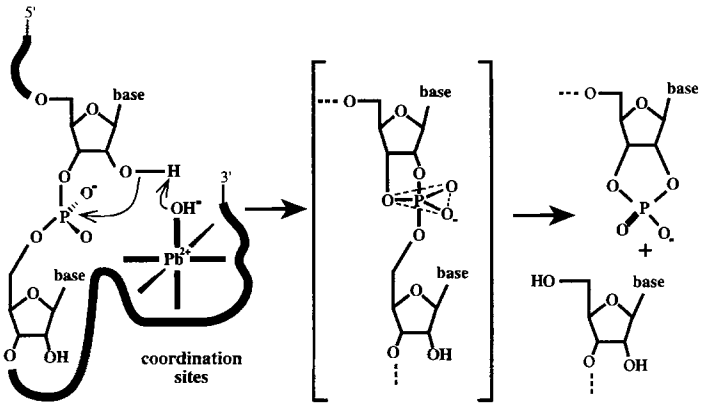
Although the reaction rate of the hydrolysis in the presence of the ribozyme was only $10^{-6}\,min^{-1}$, this nonetheless corresponds to a 100-fold acceleration over the uncatalyzed reaction. The cleavage is independent of the nature of the substituents on the amide group, which was tested with four different sub-



Scheme 3. Mechanism for the RNA-catalyzed cleavage of an amide bond. The region upstream of the amide bond (DNA1) is complementary to the internal guide sequence (IGS) of a DNA-cleaving variant of the *Tetrahymena* ribozyme. The amide bond is thereby brought close to the guanosine at the 3′-end of the ribozyme, and the 2′-hydroxyl group can carry out a nucleophilic attack of the amide bond. Spontaneous hydrolysis of the resulting ester bond regenerates the ribozyme and releases DNA2.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1190 $ 10.00+.25/0

strates, DNA1-methionine and DNA1-(arginine)$_n$ ($n = 1$, 2, or 3). All four substrates were hydrolyzed selectively at the amide group immediately following DNA1. Peptide bonds within the (arginine)$_2$ or (arginine)$_3$ moieties were not attacked.

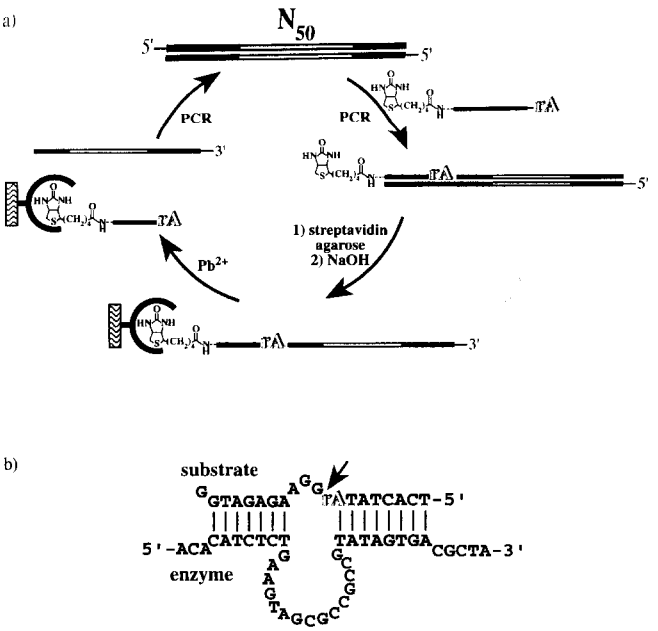


An indirect selection of ribozymes is also possible, as has been shown by Prudent et al.[2] They isolated RNA aptamers that could bind specifically to the TSA **4** of the isomerization of an asymmetrically substituted biphenyl derivative. The selection was performed by affinity chromatography of a randomized pool on the TSA immobilized on agarose. A selection scheme of this nature has already been applied in several cases in order to isolate RNA aptamers for various molecular ligands.[6, 11] After seven rounds of selection, the RNA pool was able to bind to the TSA column. Of the 20 sequenced clones, one sequence made up 75% of the selected pool and was able to accelerate the reaction by a factor of 100 over the uncatalyzed reaction (Scheme 4).

Scheme 4. Isomerization reaction of the biphenyl derivative **1** to its diastereomer **3**. This reaction is catalyzed by a ribozyme that was selected by binding to TSA **4**, which mimics the planar transition state **2** of this reaction.

The kinetic study showed that a Michaelis–Menten complex is formed initially, followed by the isomerization reaction and release of the reaction product. The reaction was completely inhibited by the planar TSA **4**. This strategy is analogous to the principle that has been used successfully many times for the isolation of catalytic antibodies. The isolation of ribozymes by selection of TSA-binding RNAs constitutes a highly efficient method for investigating the diversity of available chemical reactions that can be catalyzed by RNA. In a very recent publication, however, RNA aptamers are described which bind to the TSA of a Diels–Alder reaction but are not able to catalyze the corresponding reaction.[12]

A new departure in the development of nucleic acid based catalysts was made by Breaker and Joyce, who recently reported the isolation of the first deoxyribozyme.[13] This proof that DNA can also catalyze chemical reactions is not completely unexpected, especially since it was shown shortly after the development of the in vitro selection technique that single-stranded DNA molecules can also be selected to bind to a variety of ligands.[14] However, the selection technique used by Breaker and Joyce is remarkable. Their aim was the isolation of a DNA enzyme that could specifically cleave the phosphodiester bond of a ribonucleotide. The DNA pool synthesized for this purpose contained a single ribonucleotide at a specific position within a primer binding site, in order to avoid a possible effect of RNA on the catalysis. In addition, they assumed that a DNA-dependent RNA cleavage at pH 7 would require a cofactor, possibly a metal ion. All ribozymes whose reaction mechanisms have been studied are metalloenzymes. Metal ions such as Mg^{2+}, Mn^{2+}, or even Pb^{2+} in the case of the self-cleaving yeast tRNA^{Phe} were always involved in the catalytic mechanism and also served to maintain the correct folding of the RNA. Pan and Uhlenbeck had shown that new ribozymes with Pb^{2+}-dependent phosphodiesterase activity could be isolated from a randomized pool of tRNA^{Phe} molecules.[15] The specificity of the reaction depends on the coordination of a Pb^{2+} ion to a defined position within the RNA (Scheme 5).



Scheme 5. Possible mechanism of RNA cleavage by Pb^{2+} ions. The $Pb(OH)^+$ ion is brought close to the 2'-hydroxyl group by specific coordination to the RNA. Abstraction of the H^+ ion of the 2'-hydroxyl group facilitates nucleophilic attack of the oxygen atom on the neighboring phosphorus atom. This leads to a transition state with a fivefold coordinated phosphorus atom with trigonal-bipyramidal coordination, which in turn generates a 2',3'-cyclic phosphate and a 5'-hydroxyl group.

Breaker and Joyce also used Pb^{2+} as the cofactor in their selection. They generated a pool of about 10^{14} double-stranded DNAs with a randomized region of 50 nucleotides. One of the strands contains a biotin group at the 5'-end, followed by a defined 43-mer base sequence containing a ribose adenosine unit at position 28. The double-stranded DNA was immobilized on streptavidin agarose, and the non-biotinylated strand was removed by increasing the pH. The immobilized single-stranded DNA was then incubated in Pb^{2+}-containing buffer. In active sequences this led to cleavage of the phosphodiester bond to the ribose phosphate group, and hence to loss of the covalent attachment to the biotin-bearing 5'-end. The catalytically active sequences were thereby specifically eluted from the column, and were subsequently amplified and selected once more (Scheme 6a). Five rounds of selection afforded a population of single-stranded DNAs that could catalyze the Pb^{2+}-dependent cleavage of the ribose residue. These DNAs also showed similarities in their sequences. Like the hammerhead and hairpin ribozymes, they contain two conserved, unpaired regions between two sequences which can pair with bases upstream and downstream of the splice site. This structural motif served as the basis for the construction of a shortened version of the catalytic and substrate domains.

In this way, it was shown that the 38-nucleotide long catalytic domain could cleave the 21-mer substrate specifically and with high turnover rates. The deoxyribozyme is, however, not capable of cleaving a pure RNA substrate, although the substrate

Scheme 6. a) In vitro selection of a deoxyribozyme that cleaves the phosphodiester bond of a ribonucleotide group. PCR is used to introduce a single ribonucleotide (rA) into the defined region at the 5'-end of a synthetic DNA pool with 50 randomized nucleotides, and also a biotin group on the same strand. By immobilization on streptavidin agarose and raising the pH, a single-stranded pool is obtained, which is subsequently incubated in the presence of Pb^{2+} ions. Sequences that are cleaved at the rA are eluted, amplified by PCR, and subjected to the next cycle. b) Secondary structure of a shortened DNA enzyme that cleaves the phosphodiester bond of a ribonucleotide in an intermolecular reaction, based on one of the selected sequences.

binding to the enzyme is ensured with two longer base-paired regions. These are interrupted by three unpaired bases immediately after the splicing site (Scheme 6b). It is planned, however, to achieve this in further experiments by in vitro evolution.[9, 16]

The development of the deoxyribozyme reported by Breaker and Joyce brings medical applications to mind. A deoxyribozyme that uses less toxic metal ions than Pb^{2+}, for example Mg^{2+} or Ca^{2+}, could cleave specific mRNA targets under physiological conditions, thereby constituting an alternative to antisense and ribozyme techniques.[17]

The man-made ribo- and (now also) dexyribozymes, which have been created, or at least given birth to, catalyze a remarkable spectrum of chemical reactions. They will certainly be applicable in some diagnostic, technical, or medical purposes, where it is advantageous that they are based not on proteins but on nucleic acids. We will not go so far as to maintain that nucleic acid enzymes could catalyze as broad a variety of reactions as protein enzymes can. The examples presented here show, however, that they have far greater potential than merely the storage of information. Prebiotic evolution may possibly have included a phase of the "RNA world", in which primitive organisms existed whose metabolism and replication were controlled by RNA enzymes, and which then led into the DNA–RNA–protein world. It is unclear whether we will ever know how an RNA world may have looked, or how it began. Experiments of the type described may soon, however, allow us to develop a plausible scenario.

The Structure of the *D. gigas* [NiFe] Hydrogenase and the Nature of the Hydrogenase Nickel Complex

Malcolm A. Halcrow*

The enzyme hydrogenase is central to the metabolisms of many classes of bacteria and archaebacteria, acting as an energy transducer to allow the controllable generation and disposal of electrons and protons by reversible catalysis of the oxidation of H_2 [Eq. (a)].[1, 2] The protons produced by H_2 oxidation can be

$$H_2 \rightleftharpoons H^+ + 2e^- \qquad (a)$$

used for the maintenance of proton gradients for ATP synthesis, for example, while the electrons may be channeled to the reduction of electron transport co-factors such as flavins, cytochromes, and NAD^+, and thus fed into one of several respiratory chains. The mode of action of this enzyme is therefore of interest to chemical engineers as well as to biochemists and microbiologists, because it allows the organism to utilize H_2 as a fuel source in aqueous conditions using cheap metals, namely iron and nickel, as catalysts.

By far the most common hydrogenases are the [NiFe] enzymes which contain one equivalent of Ni and varying amounts of Fe and S^{2-} per active site. A subset of these also contain one equivalent of Se per Ni, in the form of selenocysteine which is ligated to the Ni ion, and are therefore termed the [NiFeSe] hydrogenases. A small class of Fe-only hydrogenases is also known, which show very different properties from those of the [NiFe] enzymes. Despite wide variations in metal content and subunit and cofactor inventories between enzymes,[1a] it is thought that the structure of the Ni-containing site is similar in all [NiFe] hydrogenases and that this Ni center forms the H_2 oxidation site of the enzyme.

The Ni site of [NiFe] hydrogenases exhibits a complex chemistry, which may be summarized as follows.[1, 2] The enzymes are generally isolated in one of two, or as a mixture of both inactive states (termed "Ni-A" and "Ni-B"), which show EPR spectra typical of a Ni^{III} ion with a $d_{z^2}^1$ ground state. Incubation of this enzyme with H_2 or other reductants leads to the disappearance of the Ni-A and Ni-B spectra and the successive formation of an EPR-silent "silent intermediate" form, a form ("Ni-C") showing an EPR spectrum ascribable to either a Ni^{III} or Ni^{I} species with a $d_{z^2}^1$ ground state, and a fully reduced form ("Ni-R") again showing no EPR signals attributable to Ni. The silent intermediate and the Ni-C and Ni-R forms are active toward H_2 oxidation and proton reduction; the EPR spectrum of the Ni-C form has been observed in intact bacteria. Low-temperature photolysis of the Ni-C form and its incubation with CO both lead to the reversible formation of new EPR-active species which can be interconverted. The Ni-A, Ni-B, and Ni-C EPR spectra show splittings at very low temperatures consistent with coupling to a nearby paramagnetic center; all the above EPR signals are observed in addition to those arising from the iron–sulfur clusters that form an electron-transport chain to and from the active site.

The structure of the Ni hydrogenase complex and the assignment of the different redox states shown by this unusual biologically active metal center have been debated for over a decade. A plethora of EPR and XAS (X-ray absorption spectroscopy) data have generally favored two structural models for the hydrogenase Ni site: isolated Ni ions with square-planar or square-pyramidal coordination as in $[Ni(cys)_4L]^{2-}$, cysH = cysteine, L = vacant coordination site or N/O donor (Fig. 1, A), or (pseudo-) trigonal-bipyramidal coordination as in $[Ni(cys)_2(N/O)_3L]$ and $[Ni(Secys)(cys)(N,O)_3L]$, SecysH = selenocysteine (Fig. 1, B).[1, 2] Some authors have also suggested the presence of a $[Fe_4S_4]$ cluster covalently bound to the Ni ion through a cysteinyl or S^{2-} bridging ligand (Fig. 1, C).[3a]

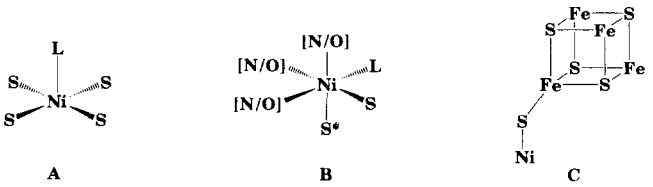

Fig. 1. Previously proposed structural models for the Ni complexes in hydrogenase. The starred S donor corresponds to that proposed to be replaced by Se in [NiFeSe] hydrogenases. L = N/O donor or vacant coordination site.

The assignment of the Ni-C EPR signal to a Ni^{III} or Ni^{I} center, which has an important bearing on the mechanism of enzyme catalysis, has been similarly controversial.[1, 2] Indeed, a thorough XAS study of one hydrogenase questioned the involvement of Ni in any of these redox processes.[3] Now, Volbeda et al. have shed some light on the matter with the first reported single-crystal X-ray structural characterization of a hydrogenase, namely the [NiFe] hydrogenase from *D. gigas* in the (probably Ni^{III}-containing) Ni-A state.[4] Hydrogenase thus has the distinction of being the first of the four known Ni-containing enzymes to be crystallized.

In view of the aforementioned hypotheses regarding the active site of hydrogenase (Fig. 1) the structure described by Volbeda et al.[4] is both surprising and tantalizing (Fig. 2). The Ni ion in the hydrogenase is clearly in a binuclear metal site. It is ligated by four cysteine S atoms in a distorted geometry that may be described as a square pyramid lacking one basal ligand, or as an octahedron with two *cis* coordination vacancies. Two of the basal thiolato ligands form a bridge to a second metal ion M 2.7 Å from the Ni ion; M is further ligated by three non-proteinaceous donors modeled as water, in a geometry approximating octahedral with one missing vertex. The vacant coordination sites at Ni and M correspond to a third bridging position

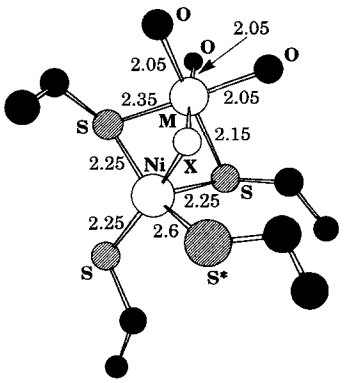

Fig. 2. The NiM site in the *D. gigas* hydrogenase as described by Volbeda et.al. X is the vacant coordination site common to Ni and M, and the starred S donor corresponds to that replaced by Se in [NiFeSe] hydrogenases. Bond lengths are in Å.

between the two ions (X in Fig. 2). Although the identity of M is unclear, the strong anomalous scattering properties of this atom in the Fourier difference map rule out Ni, Cu, Zn, Ca, and Mg. According to ICP analyses Co, Mn, V, and Mo also seem unlikely because of the zero or near-zero content of these metals in the enzyme samples. The most likely metal ion M is therefore an Fe ion, an assignment consistent with the previously reported Fe analysis for this enzyme and apparently supported by very recent EXAFS results.[4] Unfortunately, large temperature factors for the atoms in the active site may indicate some disorder in the structure, which could be related to the fact that the sample employed, while predominantly in the Ni-A form, contained approximately 15% of the Ni-B form. Hence, despite the reasonable resolution of the reported structure (2.85 Å, $R = 0.18$), structural parameters derived from the refinement must be interpreted with care.

Only two thiolato-bridged Ni–Fe complexes have appeared in the literature, namely the tetranuclear species $[\{Ni(BME\text{-}DACO)FeCl\}_2(\mu\text{-}Cl)_2]$, (BME-DACO)$H_2$ = *N*,*N*′-bis(2-mercaptoethyl)-1,5-diazacyclooctane (Fig. 3, A) and $[\{Ni(dmpn)\}_3Fe]^{2+}$, (dmpn)H_2 = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-mercaptoethyl)-1,3-diaminopropane (Fig. 3, B).[5, 6] While it is tempting to compare the Ni–S and Fe–S bond lengths in these and other Ni and Fe complexes with those of the NiM cluster in the hydrogenase structure, the caveats regarding the structural refinement, the ambiguity about the identity of M, and the lack of structural data on relevant Ni^{III} model complexes[2] prevent firm conclusions about the electronic character of the NiM site from being drawn. The Ni···M distance of 2.7 Å is at the low end of the 2.6–3.9 Å range of Ni···Ni distances observed for synthetic $[Ni_2(\mu\text{-}SR)_2]^{2+}$ complexes[2] and suggests pre-organization of the NiM center for the inclusion of a third bridging ligand.

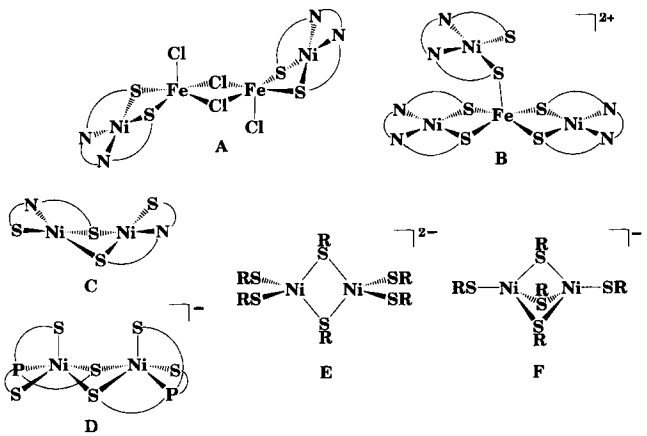

Fig. 3. Schematic structures of the model complexes referred to in the text. A: $[\{Ni(BME\text{-}DACO)FeCl\}_2(\mu\text{-}Cl)_2]$; B: $[\{Ni(dmpn)\}_3Fe]^{2+}$; C: $[Ni_2(memta)_2]$ and $[Ni_2(pdmt)_2]$; D: $[Ni_2\{P(2\text{-}SC_6H_4)_3\}_2]^-$; E: $[Ni_2(SC_4H_9)_6]^{2-}$; F: $[Ni_2(S\text{-}2,4,5\text{-}i\text{Pr}_3C_6H_2)_5]^-$.

A large number of dimers with two thiolato bridges and Ni^{II} ions with square-planar coordination have been reported, some of which are redox active.[2] In particular, Maroney and co-workers have reported that $[Ni_2(memta)_2]$, (memta)H_2 = $(HSC_2H_4)_2NC_2H_4SMe$ (Fig. 3, C), exhibits a chemically reversible one-electron oxidation at $E_{1/2} = -0.35$ V versus the ferrocene/ferrocenium couple (+ 0.05 V vs SCE) to form a mixed-valence species $[Ni_2(memta)_2]^+$.[7] The EPR spectrum of this oxidized species is comparable to the spectra of the Ni-A and Ni-B forms, unlike the EPR spectra of mononuclear Ni^{III} thiolates,[8] while experiments with ^{61}Ni-enriched samples of a closely related oxidized product indicate a valence-delocalized $[Ni_2^{2.5}]^+$ electronic structure.[9] By contrast, however, Krüger and Holm have reported that the structurally related $[Ni_2(pdmt)_2]$, (pdmt)H_2 = 2,6-bis(mercaptomethyl)pyridine (Fig. 3, C), shows a chemically reversible one-electron *reduction* at $E_{1/2} = -1.21$ V versus SCE to form a valence-delocalized species $[Ni_2^{1.5}(pdmt)_2]^-$.[10] The reason for the difference in behavior between these two complexes is unclear, and it is therefore impossible to predict the redox chemistry expected for the $[Ni(\mu\text{-}SR)_2Fe]$ complex proposed by Volbeda et al.

Perhaps the most relevant model compound for the NiM center is the valence-delocalized complex $[Ni_2\{P(2\text{-}SC_6H_4)_3\}_2]^-$, described by Millar and co-workers as containing a doubly thiolato-bridged core, $[Ni_2^{2.5}(\mu\text{-}SR)_2]^{3+}$, with Ni–($\mu$-S) = 2.251(2)–2.260(2) Å and Ni···Ni = 2.501(2) Å.[11] The square-pyramidal Ni ions and are also coordinated by one basal and one apical thiolato ligand ($Ni\text{-}S_{ba} = 2.115(2)$, $Ni\text{-}S_{ap} = 2.373(2)$ Å) and one basal phosphano ligand (Fig. 3, D). While this compound demonstrates the viability of a binuclear $[Ni^{III}(\mu\text{-}S)_2M]$ cluster, it is a poor model for the reductive activation of the NiM site of Volbeda et al., since the parent complex $[Ni_2\{P(2\text{-}SC_6H_4)_3\}_2]^{2-}$ is a dimer of square-planar Ni^{II} ions spanned by arms of the tris(2-mercaptophenyl)phosphano ligands. Finally, it should be stressed that several other structural models also exist for low-nuclearity Ni^{II} thiolate complexes. Of particular relevance to the NiM structure are the complexes $[Ni_2(SC_4H_9)_6]^{2-}$ (Fig. 3, E) and $[Ni_2(S\text{-}2,4,5\text{-}i\text{Pr}_3C_6H_2)_5]^-$ (Fig. 3, F), which are dimers of Ni^{II} ions with distorted tetrahedral coordination bridged by two and three thiolato ligands, respectively.[12] All redox studies performed on these and other tetrahedral Ni^{II} thiolates have shown only irreversible behavior, however.

The structure determination of the binuclear NiM center raises as many questions as it answers. Firstly, the relationship between this structure in the *inactive* form of the enzyme and that in the reduced, active species is unclear. An obvious possibility for the activation reaction would be insertion of a ligand into the vacant site common to Ni and M. But the nature of this putative ligand, which is unlikely to be proteinaceous but could be derived from H_2O or S^{2-}, and the site of the reductive transition are not known. Secondly, the interpretation of the Ni-A, Ni-B, and Ni-C EPR spectra, for which the Ni center has been treated as an isolated Ni^{III} or Ni^{I} paramagnet and which is fundamental to previous discussions of the Ni site, must now be reassessed. In particular, given the probable assignment

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1194 $ 10.00+.25/0

of M (Fig. 2) as Fe, it is interesting that the EPR spectrum of the Ni-A form does not show hyperfine coupling to ^{57}Fe even in ^{57}Fe-enriched enzyme.[13] Thirdly, it is unclear whether a heterobinuclear site can account for the Ni XAS data of Maroney and co-workers, which are inconsistent with large changes in electron density at Ni between the different redox states of hydrogenase.[3] The structure of the NiM site has evidently presented inorganic coordination chemists and spectroscopists with a new series of challenges!

While the reported structure clearly shows potential electron and proton transport pathways to and from the NiM center (Fig. 4),[4] little light has been shed on the mechanism of H_2 oxidation by this complex. It is known that H_2 oxidation by

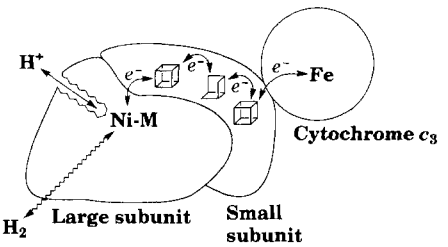

Fig. 4. Schematic diagram showing the relationship of the hydrogenase subunits and the proposed docking site of cytochrome c_3, the arrangement of the NiM and Fe–S clusters within the polypeptide, and the proposed electron and proton transfer pathways to and from the NiM center [4].

hydrogenase involves heterolytic rather than homolytic H–H cleavage, although the nature of the proton and hydride acceptors at the active site is unclear. In proposed mechanisms a Ni hydride is formed in either the + 3 or +1 oxidation states from a Ni^{II} precursor, with concomitant electron transfer and protonation of a neighboring base.[1, 2] In addition to the Ni-bound thiolates, there are several groups in the active site pocket of the *D. gigas* hydrogenase that may act as external bases for the H–H cleavage step; these include nearby arginine and histidine residues and the putative third bridging ligand if this were OH^-. Alternatively, if the third bridging ligand were S^{2-}, this could act as hydride acceptor, as has been shown in several synthetic metal sulfide clusters.[14]

It is noteworthy, however, that Ni-substituted rubredoxin, which contains a well-defined tetrahedral $[Ni(cys)_4]^{2-}$ unit, also catalyzes H_2 oxidation through a reaction that shows some kinetic similarities to that exhibited by hydrogenase.[15] A small number of mononuclear Ni thiolate complexes have also been reported to interact directly with H_2 or to reduce protons.[16] Hence, it seems that in principle the activation of H_2 by Ni thiolate complexes does not require a second metal ion or a S^{2-} bridging ligand, and it is interesting to speculate what the role of M in the NiM site might be.

$^3_\infty[(CoCp_2) \subset Fe(\mu\text{-}CNSnMe_3NC)_3]$: A Purely Organometallic Channel Inclusion Compound**

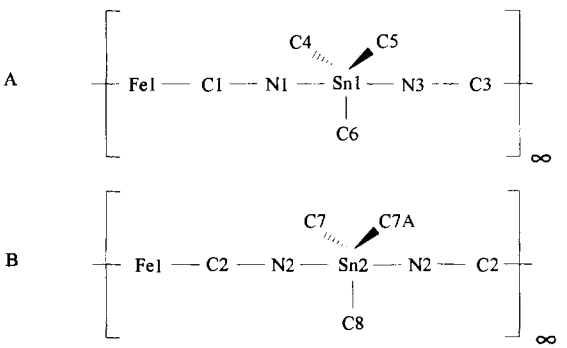
Peter Schwarz, Eric Siebel, R. Dieter Fischer,*
David C. Apperley, Nicola A. Davies,
and Robin K. Harris*

Inclusion compounds with metallocene guest components are of interest not only in fundamental research, but also increasingly in materials science.[1, 2] So far, metal dichalcogenide intercalates[1] and zeolite–metallocene host–guest compounds[3] have been of particular interest.[3] Yet to our knowledge, no crystals of such a zeolite derivative suitable for X-ray structural analysis have been obtained.[3f] As early as 1988 we postulated that merely by grinding the supramolecular organotin(IV) polymer **1** (which may, alternatively, be formulated as $[(Me_3Sn)_3Fe(CN)_6]$

$^3_\infty[Fe^{III}(\mu\text{-}CNSn^{IV}Me_3NC)_3]$ **1**

$^3_\infty[(Fe^{III}Cp_2) \subset Fe^{II}(\mu\text{-}CNSn^{IV}Me_3NC)_3]$ **2**

$^3_\infty[(Co^{III}Cp_2) \subset Fe^{II}(\mu\text{-}CNSn^{IV}Me_3NC)_3]$ **3**



or $Fe(CN_3)\cdot 3Me_3SnNC$[4]) with ferrocene would produce the zeolite-like host–guest compound **2** in the form of an X-ray amorphous powder.[5] Here we present the first insights into the static and dynamic structure of the homologous cobaltocenium compound **3**,[6] which readily crystallizes, as we have found recently, when prepared by spontaneous self-assembly in H_2O [Eq. (a)].

$$[CoCp_2]ClO_4 + K_4[Fe(CN)_6] \xrightarrow[(H_2O)]{3\,Me_3SnCl} \mathbf{3}\downarrow + 4K^+ + 3Cl^- + ClO_4^- \quad (a)$$

A crystal structure analysis[8] shows that **3** strongly resembles **4**, the Co^{III} homologue of **1**,[4] in that it contains an extensively

$^3_\infty[Co^{III}(\mu\text{-}CNSnMe_3NC)_3]$ **4**

porous, three-dimensional (3D) host framework, built up of corner-sharing octahedral $[Fe(\mu\text{-}CN)_6]$ and trigonal-bipyramidal $[SnMe_3(\mu\text{-}NC)_2]$ constituents (with equatorial Me ligands). In an alternative view, two unique, infinite chains **A** (nonlinear, I_{rel}: 2) and **B** (quasi linear, I_{rel}:1) turn out to span the 3D network found in **3** (Scheme 1).

Scheme 1. Topology of the chains **A** and **B** (H atoms have been omitted). Atomic distances [pm] and angles [°], **A**: Sn1-N1 230.4(6), Sn1-N3 236.2(6); C1-N1-Sn1 148.4(5), C3-N3-Sn1 134.5(5), C1-Fe1-C3 91.8(3), C4-Sn1-C5 119.5(4), C5-Sn1-C6 114.8(4), C6-Sn1-C4 125.6(4), **B**: Sn2-N2 230.2(6); C2-N2-Sn2 173.2(5), C2-Fe1-C2A 180.0(1), C7-Sn2-C8 121.1(3), C7-Sn2-C7A 117.7(5).

The average Sn–N distance in **3** (232.3 pm) lies between the corresponding values for $[Me_3SnNCS]$ (215 pm[9]) and polymeric $[Me_3SnCN]$ (249 pm[10]). The formation of unusually large channels in **3** and **4** argues against the presence of a real ionic lattice, which would be expected to be more compact. Stacks of $[CoCp_2^+]$ guest ions extend in the direction of the *c* axis in **3** (the shortest intermolecular ring–plane distance: 240–245 pm). Surprisingly, the channels in **3** contain two $(CoCp_2^+)_n$ stacks alternating with solely Me ligands from the Sn atoms (Fig. 1). The Cent-Co-Cent′ axes (Cent: Cp center) do not lie

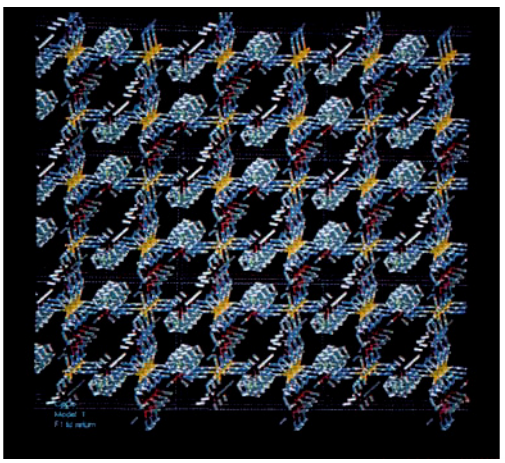


Fig. 1. View of the 3D network in **3** along the *c* axis in the direction of the main channels. The type **B** chains run horizontally (seen in projection!) (red Sn, yellow Fe, green Co, gray C).

strictly parallel to the *c* axis (Fig. 2). The average Co–C(Cp) distance (199.0 pm)[11] is slightly shorter than that in conventional cobaltocenium salts (about 202.9 pm).[12] However, the formula volume $V_f = 0.602 \times V/Z = M_r/\rho_{calcd}$ of **3** (520 $cm^3\,mol^{-1}$), as determined from the X-ray data, exceeds

that of **4** by approximately half the V_f value of crystalline $FeCp_2$ (123 $cm^3 mol^{-1}$).[13] At room temperature neither the $[CoCp_2^+]$ ion (Fig. 3) nor the methyl C atoms of the two nonequivalent Me_3Sn components are disordered. The calculated[14] X-ray powder diagram of **3** corresponds excellently with the experimental diffraction pattern.[15]

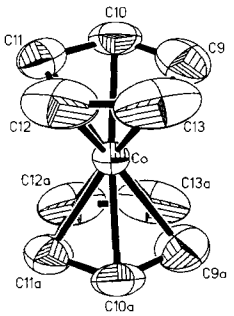

Fig. 3. SHELXTL PLUS drawing of the $[CoCp_2^+]$ guest ion in **3** (ellipsoids represent 30% probability).

The unambiguous X-ray diffraction data make the diamagnetic compound **3**, preferably when enriched with the ^{15}N isotope, a promising candidate for a detailed comparison with cross polarization magic angle spinning (CP/MAS) solid-state NMR data. The ^{13}C, ^{15}N, and ^{119}Sn nuclei of the $[Fe(CNSn_{0.5})_6]$ framework show (already at about 25 °C) exactly as many resonance signals as would be expected for the asymmetric unit deduced from the X-ray structure (see Scheme 1; three singlets each for the ^{13}C and ^{15}N nuclei and two singlets for the ^{119}Sn nucleus).[16] The chemical shifts δ for **3** correspond to those of the homologous host–guest compound **5** with Et_4N^+ instead of the $[CoCp_2^+]$ guest ions.[6]

$^3_\infty[(Et_4N) \subset Fe(\mu\text{-}CNSnMe_3NC)_3]$ **5**

$[(Me_3Sn)_4Fe(CN)_6]$ **6**

However, in the structurally different polymers **4**[4] and **6**, certain framework nuclei exhibit significantly shifted δ values (Table 1). The extremely low frequencies of the ^{119}Sn resonance signals for **3** and **5** are also noteworthy.[17]

The ^{13}C NMR spectra of all the Me and Cp ligands suggest a dynamic behavior. The sharp methyl ^{13}C singlet[18] (only one line at 25 °C) splits into the pair of signals expected for the two nonequivalent, but still freely rotating, Me_3Sn groups at about −60 °C (Fig. 4). The appearance of five lines in the spectrum measured at −140 °C corresponds to the number of signals predicted by the asymmetric unit.[20] Interestingly, also in the case of **4** three methyl ^{13}C singlets, instead of nine, indicating three crystallographically nonequivalent but labile Me_3Sn groups, were seen at −60 °C. At −20 °C only two signals occurred.[4] Occupation of the cavities in **3** by guest ions

Table 1. Solid-state NMR data (^{13}C, ^{15}N, ^{119}Sn; room temperature) of the framework atoms in **3**–**6** [16].

	3	**5**	**6**	**4** [b]
$^{13}C(CN)$ [a]	166.4	171.0	169.6	
	175.0		175.2	ca. 132
	179.5	175.5	178.9	
$^{15}N(CN)$ [a]	−112.0	−116	−109	−116
	−121.5	−123	−124	−119
	−123.2	−125	−166	−123
^{119}Sn [a]	−189 [c]	−181 [c]	−108	−118 [c]
	−139	−159	46	−88

[a] δ values are referenced to $SiMe_4$ (^{13}C), NH_4NO_3 (NO_3 signal, ^{15}N), $SnMe_4$ (^{119}Sn); for further experimental details see Ref. [4,16]. [b] Without ^{15}N enrichment. [c] ^{119}Sn NMR signals of lower intensity.

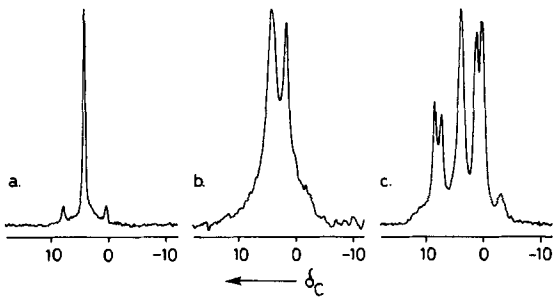

Fig. 4. CP/MAS ^{13}C NMR spectra (75.4 MHz) of the methyl C atoms in **3**: a) 25 °C, b) −60 °C, c) −140 °C (nominal temperature). Contact time: 1 ms; recycle delay: 10 s; number of acquisitions: 120 (a,b), 180 (c); rotation frequency: 3.23, 3.33, 3.00 kHz.

should lead, as in the case of **6**,[16, 19] to increased restriction of rotation. Conversely, from the considerably expanded lattice of **3** (for example, when compared with that of **4**), a substantial opposite effect may be expected. At 25 °C the Cp ligands display rotation about their C_5 axes (only one singlet at $\delta = 85.9$ is seen).[21] This rotation would probably be "frozen out" at about −140 °C; however, instead of the five expected signals, only three are resolved ($\delta = 81.8, 84.4, 88.2$).[20] A resonance signal for the quadrupolar ^{59}Co nucleus was not observed. A possible reason for this could be the strongly anisotropic surroundings of the $[CoCp_2^+]$ ion (see Figs. 1 and 2).

Experimental Procedure

3: An aqueous solution of Me_3SnCl (234.4 mg, 1.176 mmol) and $[CoCp_2]ClO_4$ (135.8 mg, 0.047 mmol) was added dropwise to a stirred, saturated aqueous solution of $K_4[Fe(CN)_6]\cdot 3H_2O$ (165.6 mg, 0.392 mmol) (total volume 35 mL H_2O). After filtration and repeated washing with a little H_2O, the precipitate was dried in vacuo (oil pump vacuum at room temperature) to provide 135.8 mg (0.356 mmol = 91%) of analytically pure **3** (correct C, H, N, Co, Fe, Sn analyses). Orange color, m.p. = 280 °C (decomp.; blackening), ν(CN) frequencies in cm^{-1}: 2044, 2061, 2077 (IR); 2066, 2083, 2124 (Raman). Single crystals were grown as described above, but with the following amounts: 28.3 mg (0.067 mmol) $K_4[Fe(CN)_6]\cdot 3H_2O$, 46.1 mg (0.23 mmol) Me_3SnCl, and 22.5 mg (0.078 mmol) $[CoCp_2]ClO_4$ in a total of 75 mL H_2O. After 2–3 days suitably sized crystals were obtained (correct C, H, N analyses). The preparation of **3** with 50% ^{15}N enrichment was analogous to that of **3** with the use of $K_4[Fe(CN)_6]\cdot 3H_2O$ and $K_4[Fe(C^{15}N)_6]\cdot 3H_2O$ [16] in a 1:1 molar ratio (correct C, H, N analyses).

AlMepO-α: A Novel Open-Framework Aluminum Methylphosphonate with Organo-Lined Unidimensional Channels

Kazuyuki Maeda,* Junji Akimoto,
Yoshimichi Kiyozumi, and Fujio Mizukami

Microporous crystals such as zeolites are important materials for molecular sieves, shape-selective catalysts, ion-exchangers and many other applications.[1, 2] An ultimate goal in the syntheses of these compounds is the control of size, shape, and (hydrophilic or hydrophobic) character of micropores. Our aim was to design a pore system in which organic groups formed parts of the framework. Most organic phosphonates of various metals have layered structures[3, 4] with few exceptions, and such molecularly engineered layered structures are promising as optical and intercalation materials, and solid catalysts, etc.[5, 6] They are closely related to purely inorganic layered phosphates.[3, 4] We expected to be able to substitute phosphate groups in the microporous aluminophosphates[7–9] (ALPOs) by methylphosphonate groups to produce novel open frameworks. Recently, we reported on a microporous aluminum methylphosphonate (AlMepO-β) synthesized under hydrothermal conditions.[10] AlMepO-β has a framework composition of $Al_2(CH_3PO_3)_3$ and unidimensional channels formed from intertwined fused four-ring chains.[11] Here we report the synthesis and structural analysis of another microporous aluminum methylphosphonate (AlMepO-α), which has the same composition as AlMepO-β.

AlMepO-α crystallizes in the trigonal space group $P31c$ with $a = 13.9949(13)$ and $c = 8.5311(16)$ Å. The structure is based on a three-dimensional net in which aluminates and methylphoshonates alternate like in ALPOs (Fig. 1). ALPOs are generally composed of only 4-connected nets, while AlMepO-α includes four-coordinate but also topologically 3-connected phos-

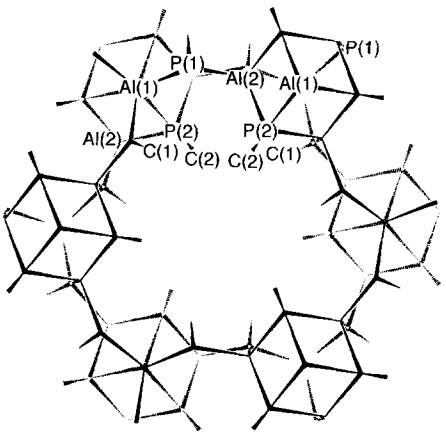

Fig. 1. Schematic drawing of the framework of AlMepO-α projected along the c axis. Oxygen and hydrogen atoms are omitted. Wedged lines locate structural features above the plane of the paper and wedged hashed lines locate those below the plane of the paper. The thicker end of the wedged lines denotes the upper side. Threefold rotation axes parallel to the c axis both along the center of the channel and through the position where every Al(1) atom locates.

phorus owing to terminal methyl groups. To compensate the framework charge, one of the three oxygen atoms in each CH_3PO_3 group is bound to a six-coordinate aluminum atom [Al(1)], the other two oxygen atoms are bound to four-coordinate aluminum atoms [Al(2)]. This mode of connectivity is the same as that predicted from MAS-NMR results for AlMepO-β.[10] The three-dimensional framework is based on aluminate and methylphosphonate layers, which alternate along the c axis (Fig. 2). This suggests that the initial layered structure of boehmite is essentially retained throughout the hydrothermal reaction.

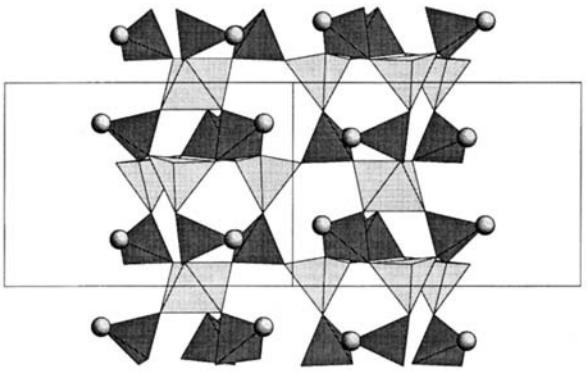

Fig. 2. Polyhedra model of the channel wall of AlMepO-α viewed along the [110] axis. Dark gray tetrahedra with spheres (methyl group) denote $[CH_3PO_3]$, the other pale gray tetrahedra denote $[AlO_4]$, and the octahedra denote $[AlO_6]$. Methylphosphonate and aluminate layers alternate along the c axis.

The most remarkable feature of AlMepO-α is the existence of unidimensional channels running parallel to the c axis. All of the methyl groups point toward the centers of the channels. Figure 3 shows that the channels are almost completely lined by the methyl groups, and that the cross section of a channel is close to an equilateral triangle (side length ca. 7.0 Å). The inorganic framework forming the basis of a channel is made up of 18-rings composed of a sequence of [P(1)-Al(1)-P(1)-Al(2)-P(2)-Al(2)]$_3$. Similar 18-rings were found also in AlMepO-β, whose framework is composed of ladderlike polymeric chains.[11] Besides AlMepO-β, only β-Cu(CH_3PO_3)[13] reported recently, as far as we know, has unidimensional channels lined with organic groups among reported metal organophosphonates. Similar unidimensional channels lined with hydrogen atoms bound to phosphorus atoms are reported in several metal phosphites, $M_2(HPO_3)_3$ (M = Fe,[14] Al,[15] Ga[15]) and $M_{11}(HPO_3)_8(OH)_6$ (M = Zn,[16] Mn,[17] Fe[17]). Unidimensional channels lined with both hydrogen (P–H) and terminal OH groups are reported in $Zn(H_2PO_3)_2 \cdot 3H_2O$.[18] Since the largest rings that make up the inorganic frameworks of these compounds are 12-rings, however, there is not sufficient space in the channels to allow small molecules to enter. Although there are also 6-rings between the channels in AlMepO-α, no small molecule probably can pass through the holes because they are partly covered by methyl groups (Fig. 2). The structure of AlMepO-α is related to that of the AFI framework[19] such as that in ALPO-5. Replacement of the three aluminum atoms of every other 6-ring in the framework of ALPO-5 by a six-coordinate aluminum atom located in the center of the triangle formed by the replaced aluminum atoms can generate a framework of the same topology as AlMepO-α.

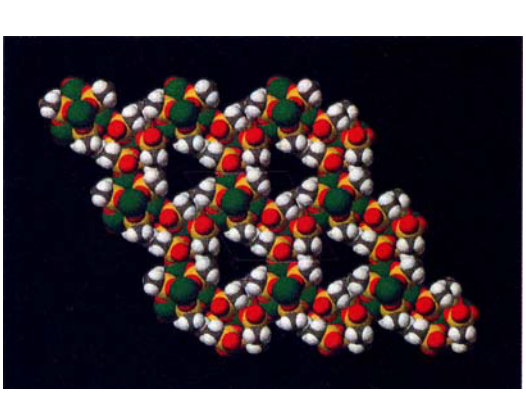

Fig. 3. The structure of AlMepO-α viewed along the c axis. Green: aluminum; yellow: phosphorus; red: oxygen; gray: carbon; white: hydrogen. The central rhombus denotes a unit cell ($a = b = 13.995$ Å). van der Waals radii of 1.7 Å for C and 1.2 Å for H were used to draw the figure [12].

According to X-ray diffraction, ^{13}C, and ^{31}P NMR studies, thermal treatment at 500 °C under vacuum causes no substantial change of the AlMepO-α framework structure and its methyl groups. AlMepO-α degassed at 400 °C adsorbed 2,2-dimethylpropane, for which a kinetic diameter of 6.2 Å was reported.[20] This result shows that the molecules fit well into the triangular-shaped channels and demonstrates the flexibility of the methyl groups forming the channel wall.

Experimental Procedure

Single crystals of AlMepO-α suitable for an X-ray structural analysis were obtained from an unstirred aqueous mixture (Al:P:H_2O = 1:1:40) of methylphosphonic acid (Aldrich, 98 wt.%) and pseudo-boehmite powder (PURAL SCF from Condea Chemie, 74.4 wt.% Al_2O_3, 25.6 wt.% water). The mixture was hydrothermally treated at 220 °C for 48 h without stirring under an autogeneous pressure using an autoclave with a Teflon sleeve. Subsequently, crystals floating on the liquid phase were separated from boehmite-derived solid at the bottom of the vessel. The air-dried product gave an approximate composition of $Al_2(CH_3PO_3)_3 \cdot nH_2O$ ($n = 0$–1.5) from elemental analyses.

Single-crystal X-ray diffraction data were collected on $0.1 \times 0.1 \times 0.6$ mm crystal with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å) using a Rigaku AFC-5 four-circle diffractometer. A total of 5272 reflections were collected; of the 1795 unique reflections, 1712 had $F_o^2 > 2\sigma(F_o^2)$. Although initial survey suggested a hexagonal cell with the lattice parameters described above, attempts to derive crystallographically meaningful structural models based on several possible space groups expected from the systematic extinction ($l = 2n$ for hhl) were unsuccessful. The adoption of the space group $P31c$ in trigonal system with the same cell parameters led to a plausible framework structure by using direct methods [21]. The isotropic refinement based on F_o^2 using SHELXL-93 [22] on the assumption of the twinning [23] of the reciprocal lattice by a rotation operation along the [110] axis [24] resulted in a drop of $R_w(F^2)$ to 0.205, otherwise $R_w(F^2)$ was 0.537. The final refinement included anisotropic thermal displacement parameters for all non-hydrogen atoms and a rotating rigid group model for hydrogen atoms (104 parameters). The structure was refined by full-matrix least squares to $R_w(F^2) = 0.108$ (for all 1795 reflections) and $R_w(F) = 0.046$ ($F > 4.0\sigma$). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58862.

Galloxane and Alumoxane Hydroxides: $[Ga_{12}tBu_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$ and $[Al_6tBu_6(\mu_3\text{-}O)_4(\mu\text{-}OH)_4]$**

Christopher C. Landry, C. Jeff Harlan, Simon G. Bott, and Andrew R. Barron*

In contrast to the extensive oxide and oxide-hydroxide chemistry observed for aluminum and indium,[1] there are relatively few studies of the analogous chemistry of gallium. A recent ^{71}Ga NMR spectral study has indicated the formation of the unstable cationic cluster, $[Ga_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$, whose structure is proposed to be identical to that of the aluminum analog.[2] Similarly, the first organogallium-oxo compound reported, $[t\text{BuGa}(\mu_3\text{-O})]_9$, was determined by mass spectrometry and NMR spectroscopy to also be isostructural to its aluminum analog.[3] The first reported examples of apparent diversification between the chemistry of aluminum and gallium oxide and oxide-hydroxide clusters was for the hexagallium compounds $[Ga_6Mes_6O_4X_4]$, Mes = mesityl, X = F,[4] OH[5] for which the equivalent aluminum compounds did not exist. We now report the structural characterization of the largest galloxane hydroxide isolated thus far, as well as the aluminum analog of $[Ga_6R_6O_4(OH)_4]$.

Oxidation of $[t\text{Bu}_2\text{Ga(Spy)}]$ (H-Spy = 2-mercaptopyridine),[6] followed by atmospheric hydrolysis yields colorless crystals with a composition corresponding to $[Ga_{12}tBu_{12}O_{10}(OH)_4]$ (**1**). Single crystals of **1** suitable for X-ray structure analysis[7] were obtained from Et_2O and four molecules of solvent are present in the formula unit. While the Et_2O molecules of solvation are disordered, the O···O distances are within the range expected for weak hydrogen bonding interaction. The molecular structure of **1** is shown in Figure 1. Each of the gallium atoms and bridging O atoms (Ga-O-Ga) lie on a mirror plane. The cage structure consists of twelve fused six-membered rings. Each gallium atom is coordinated to one carbon and three oxygens, while there are two types of oxygen atom sites; six oxygens bridging two galliums [O(1)], and eight oxygens capping three galliums [O(2)]. However, the structure may also be considered to consist of an oxo-cube [O(2)], with each face capped by a [tBuGa(μ-X)GatBu] unit, X = O or OH.

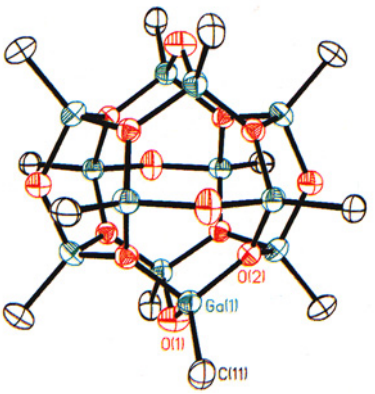

Fig. 1. Molecular structure of **1**. The methyl groups have been omitted for clarity. The bridging oxygen atom, O(1), exists as a 40:60 disorder of an oxo and a hydroxo ligand. Selected bond lengths [Å] and angles [°]: Ga(1)–O(1) 1.911(5), Ga(1)–O(2) 1.878(1), Ga(1)–C(11) 1.98(1); O(1)-Ga(1)-O(2) 98.4(2), O(2)-Ga(1)-O(2a) 106.7(2), O(1)-Ga(1)-C(11) 114.6(5), O(2)-Ga(1)-C(11) 117.6(2), Ga(1)-O(1)-Ga(1a) 129.1(1), Ga(1)-O(2)-Ga(1a) 119.6(1).

Based upon charge balance and ^{1}H NMR spectroscopy the actual formula of **1** is $[Ga_{12}tBu_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$. Thus, the oxygen atoms bridging two galliums are a disorder of two oxo and four hydroxo ligands. In line with this, the Ga–O(1) distances [1.911(5) Å] are a weighted average of the values expected for a gallium-oxide (1.87–1.89 Å) and a gallium-hydroxide (2.21–2.45 Å). The Ga–O(2) distance [1.878(1) Å] is exactly as expected for a gallium-oxide interaction. The higher esd's in the Ga–O(1) bond lengths and the thermal parameters for O(1), as compared to O(2), is consistent with the presence of a disorder, however, the high symmetry of the molecule precluded refinement of this disorder.

A similar disorder between oxo and hydroxo ligands is observed in the structure of $[Al_6tBu_6(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4]$ (**2**), (Fig. 2).[7] Compound **2**, prepared from the hydrolysis of $[t\text{BuAl}(\mu_3\text{-O})]_6$,[8] is isostructural to $[Ga_6Mes_6O_4X_4]$ (X = F, OH). As with the gallium compounds, **2** can be described as an octahedron of aluminum atoms, with each face capped by either a μ_3-O or μ_3-OH moiety.[9] An alternative description is that compound **2** is a cube of oxygen atoms face-capped by six AltBu units, and as such a structural relationship between **1** and **2** may be drawn. Like the gallium compounds, the oxide and hydroxide sites in **2** are disordered. The Al(1)–O(1) distance [1.900(8) Å] is within the range of values we have previously reported for Al–OH [1.84–1.90 Å] interactions, while the Al(1)–O(2) distances [1.87(1)–1.95(1) Å] cover the range for both Al–O [1.78–1.88 Å] and Al–OH distances.[10] This is obviously a result of the high symmetry of the $[Al$$t$$Bu]_6$ core.

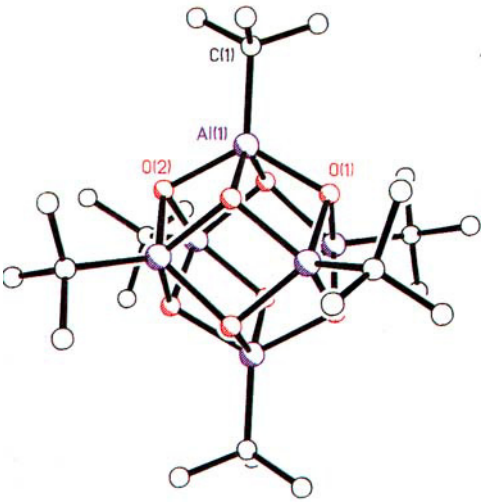

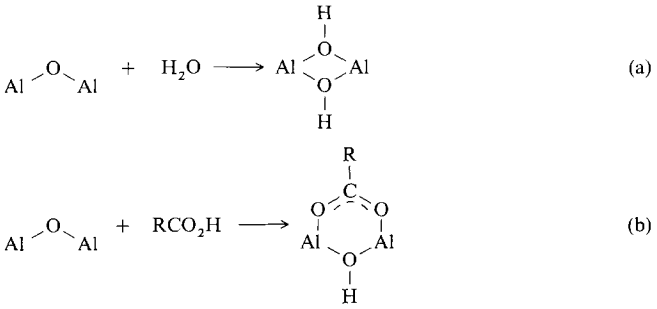

Fig. 2. Molecular structure of **2**. The hydrogen atoms have been omitted for clarity. Both O(1) and O(2) exist as a 50:50 disorder of an oxo and a hydroxo ligand. Selected bond lengths [Å] and angles [°]: Al(1)–O(1) 1.900(8), Al(1)–O(2) 1.95(1), Al(1)–O(2a) 1.88(1), Al(1)–O(2b) 1.87(1), Al(1)–C(1) 1.910(9); O(1)-Al(1)-O(2) 74.8(3), O(1)-Al(1)-O(2a) 76.4(3), O(1)-Al(1)-O(2b) 122.1(3), O(1)-Al(1)-C(1) 116.6(6), O(2)-Al(1)-O(2a) 125.3(3), O(2)-Al(1)-O(2b) 77.9(3), Al(1)-O(1)-Al(1a) 103.7(9), Al(1)-O(2)-Al(1a) 102.5(9).

A rational for the formation of **2** from $[t\mathrm{BuAl}(\mu_3\text{-O})]_6$ is the addition of H_2O to an Al–O bond [Eq. (a)]. We have observed a similar reaction during the formation of alumoxane carboxylates from the aluminum oxides [Eq. (b)].[11]

Given that several workers have postulated the existence of five-coordinate aluminum in alumoxanes,[12] it is important to note that compound **2** represents the first structural characterization of an alkylalumoxane in which the aluminum centers are five-coordinate.

Finally, we note that **1** is unusual when compared to previous group 13–16 cluster compounds or solid-state phases, in that while several chalcogenide cages are made entirely of six-membered cycles, this represents the first example of an oxygen derivative with such a structure.[1] Thus, **1** consists of twelve vertex-sharing tetrahedra (Fig. 3), while other alumoxanes, galloxanes, and indoxanes consist of edge- as well as vertex-sharing tetrahedra. Furthermore, **1** has a cavity of about 2.4 Å in diameter in which the shortest centroid-cage distance is to O(2) (1.3 Å); sufficiently large to accommodate a variety of different cations. In this regard **1** represents the first example of a group 13–16 cage in which inclusion may occur in a manner analogous to that observed for vanadium phosphates.[13]

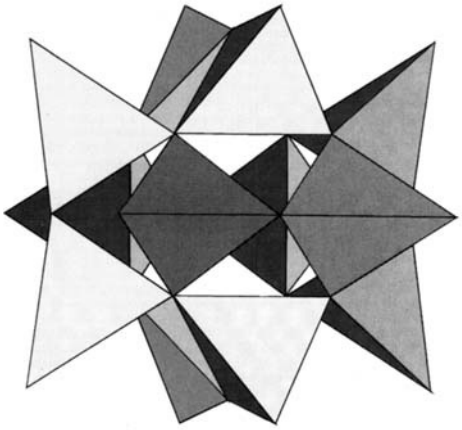

Fig. 3. Polyhedral structure of **1**. The methyl groups have been omitted for clarity.

Experimental Procedure

1: A solution of $[t\mathrm{Bu_2Ga(Spy)}]$ (0.501 g, 1.71 mmol) in toluene (30 mL) was exposed to an atmosphere of dry oxygen, upon which a white precipitate formed from the yellow solution. Filtration, followed by crystallization from Et_2O in air allowed the isolation of **1**. Isolated yield: about 70%. ^{1}H NMR (C_6D_6): $\delta = 1.10$ (4 H, br, s; OH), 1.06 [36 H, s; $C(CH_3)_3$], 1.02 [72 H, s; $C(CH_3)_3$]; IR (cm^{-1}): $\tilde{\nu} = 3600$ (OH).

2: To a solution of $[t\mathrm{BuAl}(\mu_3\text{-O})]_6$ (0.415 g, 0.691 mmol) in hexane (20 mL) was added wet β-lactone (0.056 g, 0.65 mmol). The reaction was stirred overnight at room temperature. An insoluble white precipitate formed. Filtration and cooling of the supernatant resulted in the crystallization of compound **2**. Isolated yield: about 9%. ^{1}H NMR (C_6D_6): $\delta = 2.48$ (4 H, s; OH), 1.02 [54 H, s; $C(CH_3)_3$]. IR (cm^{-1}): $\tilde{\nu} = 3424$ (OH).

Six Interpenetrating Quartz-Like Nets in the Structure of $ZnAu_2(CN)_4$**

Bernard F. Hoskins, Richard Robson,* and Nicola V. Y. Scarlett

Infinite frameworks composed of tetrahedral centers linked together by 2-connecting units often adopt a topology related to that of diamond. In SiO_2 where silicon is tetrahedral and oxygen is 2-connecting, the diamond-related topology, β-cristobalite, is thermodynamically less stable than the alternative 4-connected topology of quartz. It is therefore perhaps a little surprising how few classes of substances are known with the quartz topology. Examples generally involve a single atom bridge between two tetrahedral centers as in $GaPO_4$,[1] BeF_2,[2] and stuffed structures such as eukryptite, $LiAlSiO_4$.[3] We report here an example in which tetrahedral centers linked together by polyatomic connectors adopt a quartz-like topology.[4] The range of structural types for infinite cyano-bridged networks, especially those involving cadmium(II), is remarkable and continuously expanding.[5] We[6] and others[7] have started to explore the possibility that this structural diversity may be further enriched by using $[M(CN)_2]^-$ (M = Au, Ag, and possibly Cu) as an extended, approximately linear 2-connector in place of CN^-.

Aqueous solutions containing zinc nitrate and potassium dicyanoaurate deposit crystals of composition $ZnAu_2(CN)_4$, whose structure we have determined by single-crystal X-ray diffraction. The hexagonal unit cell is shown in Figure 1. All zinc centers are equivalent as are all gold centers. Two types of cyano units occur in slightly different environments. The zinc atoms are in an approximately tetrahedral environment of four nitrogen atoms (∢ N-Zn-N, 106.3, 107.3, 109.6, and 112.1°) from $[Au(CN)_2]^-$ units, which act as approximately linear zinc-to-zinc connectors (∢ Zn-N-C: 166 and 172°; ∢ N-C-Au 178 and 173°; ∢ C-Au-C, 174.6°). The 3D net generated thereby has a topology identical to that of quartz, in which each tetrahedral Si atom is replaced by a Zn atom and each Si-O-Si connection by Zn-CN-Au-CN-Zn (Zn ··· Zn, 10.041 Å). A consequence of this lengthening of the connections is that there is room for the interpenetration of six identical but independent nets. Fragments of these six independent nets can be seen in the unit cell in Figure 1.

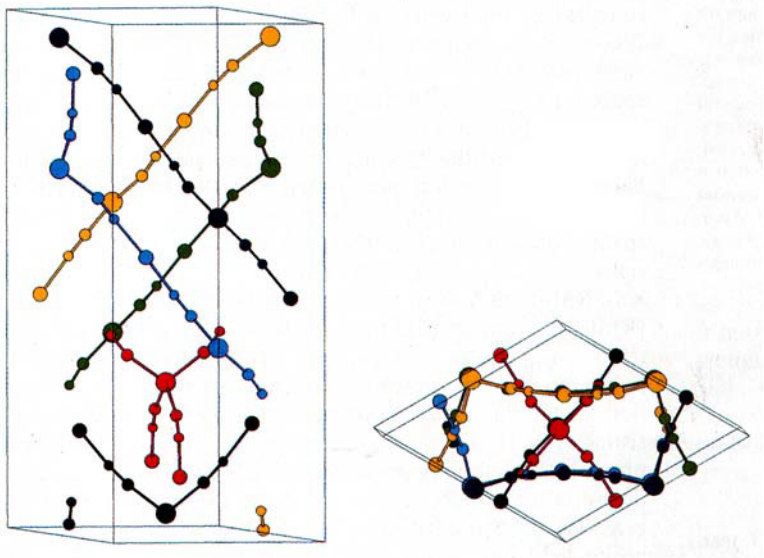

Fig. 1. The hexagonal unit cell of $ZnAu_2(CN)_4$ viewed perpendicular to the c axis (left) which here is vertical and from an angle slightly displaced from the c direction (right). Circles in order of decreasing size represent Zn, Au, N, and C. Fragments of six independent infinite networks are represented by different colours.

A single extended net is represented in Figure 2. The quartz-like connectivity is immediately evident. The six independent nets consist of three pairs, the members of any particular pair being related to each other by a translation along the sixfold c axis of approximately $c/4$ or 5.20 Å. The pairs are color-coded for easy identification in Figure 1: yellow/green, red/black, and dark blue/pale blue. Figure 3 shows how the three pairs interpenetrate (paired colors as in Figure 1).

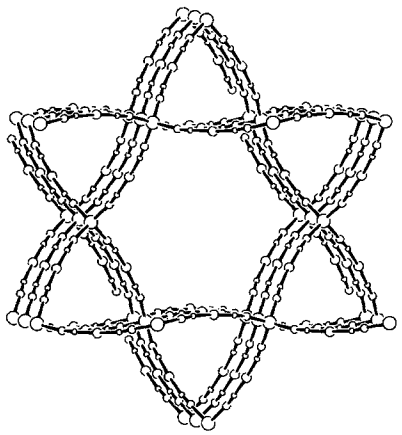

Fig. 2. A view from an angle slightly displaced from the c direction, of a single quartz-like net in the structure of $ZnAu_2(CN)_4$ which contains six such independent nets.

Like the quartz prototype, $ZnAu_2(CN)_4$ is enantiomorphic. All six nets have the same handedness; in the particular crystal studied, the absolute configuration of the threefold helices within each net is that of a righthanded screw.

The closest approach between nets is a Au ··· Au contact of 3.11 Å, examples of which can be seen in Figure 1 between yellow and dark blue frameworks and between green and light blue frameworks; these and other analogous Au ··· Au contacts can also be seen in Figure 3. The bowing in the Zn-NC-Au-CN-Zn links apparent in Figures 1b and 3 is suggestive of an attractive Au–Au interaction. Schmidbaur has previously presented convincing evidence for the reality of such Au^I–Au^I bonding interactions, which he notes are comparable in strength with hydrogen bonds and, like hydrogen bonds, may be "conformation determining";[8a] homoatomic d^{10}–d^{10} interactions, in general, have been reviewed by Jansen.[8b]

The basic structural type reported here would appear to lend itself to considerable variation in composition, and it remains to be seen how many related $[M(CN)_2]^-$-derived materials with this topology can be generated. It may also be possible to incorporate chiral guest molecules of appropriate size and shape in order to generate materials with fewer than six individual quartz-like nets.

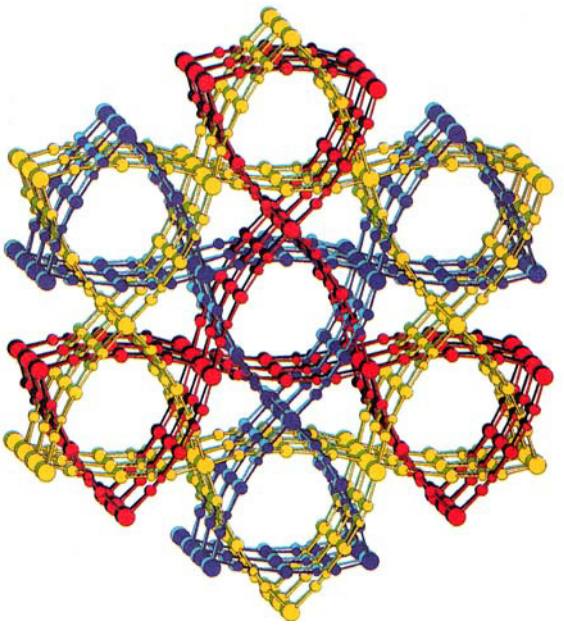

Fig. 3. Extended structure of $ZnAu_2(CN)_4$ showing the six independent, interpenetrating quartz-like nets.

Experimental Procedure

To a solution of $K[Au(CN)_2]$ (8.6 mg, 0.029 mmol) in H_2O (2 mL) was added a solution of $Zn(NO)_3 \cdot 6H_2O$ (25.0 mg, 0.087 mmol) in H_2O (2 mL). A small amount of very fine, cloudy white precipitate was formed immediately and settled on standing. Within 24 h, large, colorless, air-stable crystals of $ZnAu_2(CN)_4$ grew, many in the form of brilliant hexagonal bipyramids.

Crystal data: $ZnAu_2(CN)_4$, $M = 563.4$, hexagonal, space group $P6_422$ (No. 181), $a = 8.4520(10)$, $c = 20.622(11)$ Å, $V = 1275.8(7)$ Å^3, $Z = 6$, approximate crystal dimensions $0.21 \times 0.21 \times 0.29$ mm, $\rho_{calcd} = 4.400$ g cm^{-1}, $F(000) = 1440$, 2959 reflections measured, 757 unique reflections, $2\theta_{max} = 50°$. Intensity data were measured at 293(2) K with $Mo_{K\alpha}$ radiation (graphite crystal monochromator) on an Enraf-Nonious CAD-4MachS diffractometer with the $\omega/2\theta$-scan method; corrections for Lorentz, polarization, and absorption effects were applied ($\mu(Mo_{K\alpha}) = 37.146$ mm^{-1}, min/max transmission = 0.0221 and 0.0463). The structure was solved with a combination of Patterson map, direct methods, and difference synthesis (SHELX-76 [9] and SHELXS-86 [10]). A full-matrix least-squares refinement method based on F^2 (SHELXL-93 [11]) was employed, and anisotropic thermal parameters assigned to all atoms. For the space group $P6_422$ (No. 180), $R_1 = 0.0551$ and $wR_2 = 0.0858$. The absolute structure (Flack) parameter indicated that the true space group was $P6_422$ (No. 181). This was confirmed by refinement in this space group which yielded $R_1 = 0.0459$ and $wR_2 = 0.0616$ (for all data). $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$ and $wR_2 = [\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]]^{0.5}$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58823.

Hyperbolic Lone Pair Structure in $RhBi_4$

Yuri Grin, Ulrich Wedig, and
Hans Georg von Schnering*

With studies of the electronic structure of several low valence tin compounds, SnSe, SnP_3, and SrSnP Wagner[1] shows that even SrSnP, with formal Sn^I, exhibits a strong tendency to form lone pairs. Thus, the Sn–Sn bonds in this compound are considerably weaker than the Ga–Ga bonds in the isostructural compound CaGaN. Compounds such as $PdGa_5$,[2,3] $PtPb_4$,[2] $PdSn_3$,[2] and $RhBi_4$ have been found to be suitable for the investigation of similar phenomena in classic intermetallic phases. The electronic structure of $RhBi_4$, presented here, is remarkable because of its extraordinary topology.

The crystal structure of $RhBi_4$ has been known for a long time.[4] Cubic $RhBi_4$ is built of two independent crystallographic sites, one occupied by Rh and the other by Bi, and is described as a packing of tetragonal antiprisms.[5] A special peculiarity of this structure is the arrangement of the Rh atoms and subsequently, the condensed ($RhBi_{8/2}$) polyhedra, which form the so-called V* framework as described by Hellner et al. (Fig. 1). It consists of two interpenetrating chiral $3^2.10^4$ nets, which are enantiomorphic.[6] From our experience, the separation of space into regions of different interaction types is particularly evident in chemical structures that have interpenetrating atomic nets.[8] In the $RhBi_4$ structure, these regions are defined, on one hand, by the two interpenetrating chiral $3^2.10^4$ nets of condensed ($RhBi_{8/2}$) antiprisms and, on the other hand, by the spaces between the nets. Therefore this separation should be reflected in the electronic structure.

In $RhBi_4$, each three slightly distorted tetragonal antiprisms, ($RhBi_{8/2}$), are condensed through the square faces of a common (empty) trigonal Bi_6 prism (Fig. 1). Thus, both frameworks of polyhedra not only show the characteristics of a V* framework, but also the characteristics of the so-called Y** framework consisting of the three-connected nodes in the centers of the trigonal prisms.[6] The periodic nodal surface (PNS) I_2-Y**[9] perfectly describes the hyperbolic organization of the entire $RhBi_4$ structure. The PNS is defined only by the symmetry of the space group $Ia\bar{3}d$ and can be easily calculated.[10] It envelops both interpenetrating polyhedral frameworks and separates them from the embedding empty space (Fig. 1). This space has the topology of the hyperbolic PNS Y**[9] and of Schoen's[11] minimal surface "gyroid", representing a non-Euclidean mirror.

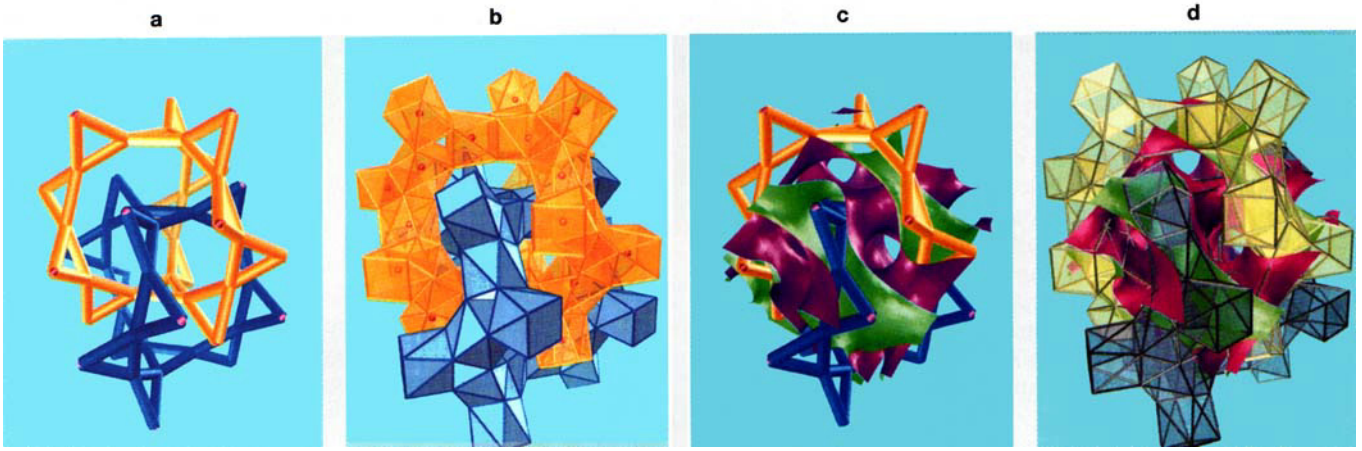

Fig. 1. a) Two enantiomorphic chiral ($3^2.10^4$) nets [7] form the V* framework according to Hellner et al. [6]. Each four-connected node (here Rh) belongs to two three-membered and four ten-membered rings. b) The two chiral nets of condensed ($RhBi_{8/2}$) polyhedra with Rh (red/pink) situated in the centers and Bi on the vertices of the tetragonal antiprisms. c) and d): The periodic nodal surface I_2-Y** envelops both parts (V* framework (c), framework of polyhedra (d)) and separates them. There are two separated interpenetrating labyrinths (green) and one common hyperbolic space (violet).

The electronic structure of $RhBi_4$ was determined with the tight-binding-LMTO program[12] using the local density functional approach (LDA) with the exchange correlation potential taken from reference [13]. The partial waves were derived from the solutions of the radial scalar-relativistic Dirac equation. Interstitial spheres (E1–E5) had to be added to reduce the overlap of the atomic spheres when using the atomic spheres approximation (ASA, corrections according to [14]). The volume of the empty spheres amounts to 27.8% of the unit cell volume, indicating an open structure. The radii of the atomic spheres are: Rh 1.533 Å, Bi 1.714 Å, E1 1.223 Å, E2 1.208 Å, E3 1.110 Å, E4 0.947 Å, E5 0.867 Å.

Within the density functional theory, the electron localization function (ELF)[15] was calculated from the Pauli local kinetic energy density $t_p(r)$,[16] where $t_p(r)$ is that part of the local kinetic energy density $t(r)$, which is due to the Pauli principle. At each point r, the ELF is related to the value $t_{p,h}(\rho(r))$ for the homogeneous electron gas with the density $\rho(r)$. The ELF falls between values of 0 to 1;[15] the higher ELF values indicating regions of high localization such as bonds or lone pairs.

The results are shown in Figure 2. The isosurface of $\rho(r) = 0.035\ e a_0^{-3}$ (in blue) was selected to represent the electron density, and the isosurface of ELF(r) = 0.7 (in red) was taken for the electron localization function. Since only the valence electron bands were used for the calculation, the density minima were obtained at the position of the atomic nuclei. The difference between the distribution of electron density and ELF is remarkable:

- The isosurface of $\rho(r)$ around the Bi atoms is spherical and possesses tubelike connections to the Rh atoms in the centers of the ($RhBi_{8/2}$) polyhedra. This gives the impression of continuous electronic nets that link the Rh and Bi atoms.
- The ELF of the valence electrons, however, indicates maxima exclusively at the Bi atoms but situated outside the polyhedra and directed into the space between the polyhedral nets. No appreciable localization has been found between Rh and Bi atoms, nor in the peripheral regions of possible Bi–Bi interactions (two- or three-center bonds).

Therefore, the ELF maxima cannot be attributed to covalent bonds, but obviously show the lone pairs of the Bi atoms. All electrons in the regions of Rh–Bi bonds are strongly delocalized

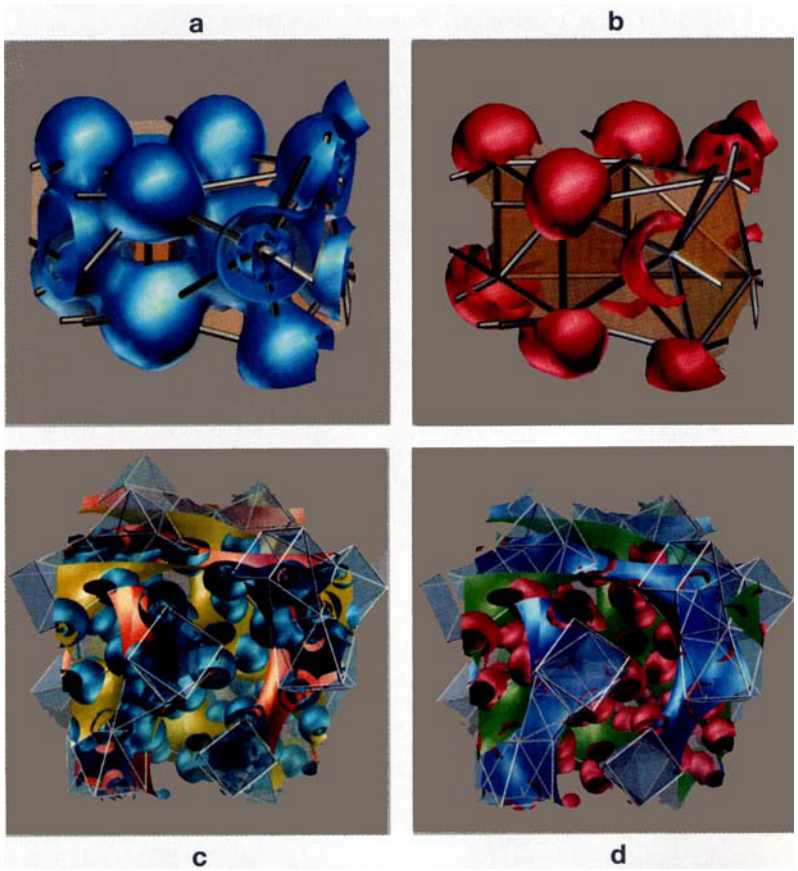

Fig. 2. a) Valence electron density $\rho(r)$ (isosurface of $r = 0.035\ e a_0^{-3}$; blue) shows a spherical form at the Bi atoms and pronounced tubes around Rh–Bi bonds. b) In contrast, ELF exclusively shows the localization of the lone pairs of Bi atoms on the periphery of the polyhedral nets (isosurface of ELF = 0.7: red). c) Polyhedral nets and $\rho(r)$ together with the PNS I_2-Y**. d) Polyhedral nets and ELF together with the PNS I_2-Y**. The common space between the nets (green) represents a hyperolic layer of lone pairs.

indicating metallic character. The hyperbolic PNS I_2-Y** bounds regions with very different degrees of valence electron localization, that is of different bonding character. One has the impression that the metallically conducting $3^2.10^4$ nets are separated by insulating hyperbolic layers.

The cubic phase $RhBi_4$ as a whole is isotropic. Nevertheless, the atomic distribution and electronic structure show intrinsically a strongly anisotropic, layerlike structure. However, due to the hyperbolic (non-Euclidean[8]) form of these layers, all anisotropic components are compensated in the crystal.

The formation of regions with very different localization of the valence electrons and the resulting microscopic anisotropy should influence the electro-kinetical properties and may correlate to the superconductivity of the compound (T_c = 2.9–3.4 K[17]).

[10] The PNS I_2-Y** represents the zero points of the Fourier series built using geometrical structure factors $|S(112)| = |S(220)| = 1$ and their phases $\alpha(112) = \alpha(220) = 0$ as coefficients under the consideration of the permutations of the space group $Ia\bar{3}d$. The reduced form is (c = cos, s = sin, $X = 2\pi x$, $Y = 2\pi y$, $Z = 2\pi z$): $0 = -2[s2X\,cY\,sZ + sX\,s2Y\,cZ + cX\,sY\,s2Z] + c2X\,c2Y + c2Y\,c2Z + c2X\,c2Z$. The description I_2-Y** uses the symbols according to [6] and shows that the point configurations I_2 and Y** were separated by this PNS [8]. All 16 points of the twofold body-centred lattice I are placed in one labyrinth, which separates two other enantiomorph labyrinths. The 2 × 8 points of the nets $^{+}$Y* + $^{-}$Y* = Y** are located in the last two labyrinths.

Optical Activity of Chiral Dendritic Surfaces**

Johan F. G. A. Jansen, H. W. I. Peerlings, Ellen M. M. de Brabander-Van den Berg, and E. W. Meijer*

Macroscopic, nanoscopic, and mesoscopic chirality are among the intriguing new key words in the studies of chiral clusters, associated complexes, homo- and heterogeneous catalysts, and of many polymers.[1] Major drawbacks for these studies are, generally, the complexity of the materials under investigation and their lack of long-range order. Therefore, comprehensive studies of macroscopic chirality are primarily performed on single crystals and synthetic bilayers.[2] However, for a better understanding of the chiroptical features of non-ordered structures, well-defined materials are required. Dendrimers are promising candidates for the preparation of well-defined chiral materials with nanoscopic dimensions.[3] To the best of our knowledge only chiral dendrimers of lower generations have been prepared and no irregularities in the chiroptical properties of these enantiomerically pure dendrimers are reported.[4–9] Newkome et al.[4] modified an amine-terminated dendrimer with enantiomerically pure tryptophane, whereas Seebach et al.[5] prepared some dendrimers with a chiral core and Chow et al.[6] prepared dendrimers with a chiral spacer. Hudson and Damha[7] synthesized a nucleic acid based chiral dendrimer, Mitchell[8] a glutamic acid based dendrimer, while Denkewalter disclosed a number of dendrimeric structures based on amino acids.[9]

Larger chiral dendrimers with a more dense packing of functional groups in the shell have not been studied so far. Recently, we successfully prepared chiral structures of nanometer dimensions based on poly(propylene imine) dendrimers (DAB-*dendr*-$(NH_2)_{64}$)[10] that are terminated with amino acid derivatives and we presented evidence that these compounds are useful as dendritic "boxes" (DAB-*dendr*-(NH-*t*-BOC-L-Phe)$_{64}$; Fig. 1).[11] Due to the dense packing of the shell and the presence of internal cavities, we are able to encapsulate a variety of guests into these dendritic boxes; guests that are physically locked. The synthesis of this and other amino acid modified dendrimers is summarized in Scheme 1. Here we report on the peculiar chiroptical properties of these dendritic boxes and discuss the structure of highly curved chiral dendritic surfaces.

The investigation presented here was triggered by the observation that the specific optical rotation of the DAB-*dendr*-(NH-*t*-BOC-L-Phe)$_x$ decreases to almost zero on going from dendrimers of the first generation ($[\alpha]_D = -11$; $c = 1$, $CHCl_3$) with four end groups to dendrimers of the fifth generation ($[\alpha]_D = -0.1$; $c = 1$, $CHCl_3$) with 64 end groups. A more thorough investigation employing a variety of different amino acid derivatives reveals that this decrease of optical rotation with increasing generation is a general phenomenon for all the amino acids studied (Table 1). The most striking results are found for the DAB-*dendr*-(NH-*t*-BOC-ε-*Z*-L-Lys)$_x$, in which the $[\alpha]_D$ value decreases from −28 ($c = 1$, $CHCl_3$) for the first generation dendrimer ($x = 4$) to 0 ($c = 1$, $CHCl_3$) for the fifth generation den-

drimer ($x = 64$). Dramatic changes are also observed for L-(*S*)-benzylcysteine and the L-tyrosine derivatives. For the smaller amino acids (Ala, Val and Leu) the decrease in optical rotation is less pronounced. As the number of chiral end groups per weight unit is roughly independent of the generation (in each new generation both the number of end groups and the molecular weight double), the decrease in the $[\alpha]_D$ values with increasing generation is not due to the reduction of chiral chromophores.[1,2] Furthermore neither concentration nor temperature effects are responsible for this decrease in optical activity, as nearly identical rotations are observed for $c = 0.1$, 1, and 4 in chloroform at temperatures of 20 and 55 °C in the L-Phe dendrimer series. However, a significant solvent dependency of the specific rotations was noticed for the lower generations and was investigated in detail for the model compound *N*-*t*-BOC-L-Phe-propylamide. Specific optical rotations were dependent on the dielectric constant of the solvent, varying from $[\alpha]_D = 7.3$ ($c = 1$, toluene) to $[\alpha]_D = -6.4$ ($c = 1$, acetonitrile) for the model compound. The behavior of the corresponding dimeric model compound from diaminobutane and two L-Phe residues deviated remarkably from all other ones. The dimer is only slightly soluble, indicative of intermolecular hydrogen bonding, and the optical rotation is large ($[\alpha]_D = 22$, $c = 1$, $CHCl_3$; see Fig. 4). The peculiar behavior of symmetric dipeptides is the subject of many recent studies.[13] Finally, we have demonstrated that the protected amino acids do not undergo racemization in the coupling method employed; analysis of the amino acids after acid-catalyzed hydrolysis of the modified dendrimers by HPLC using chiral stationary phases revealed an enantiomeric excess of greater than 96%.

Scheme 1. Synthesis of the dendritic "box", DAB-*dendr*-(NH-*t*-BOC-L-Phe)$_{64}$ and other amino acid derivatives.

Circular dichroism (CD) and optical rotatory dispersion (ORD) studies in conjunction with UV/Vis absorption spectroscopy have been performed to gain a better insight into the peculiar chiroptical effects observed. The restricted solubility of the dendritic boxes hampers the use of the entire spectral range. Most of the Cotton effects (CEs) present in the CD spectra of the lower generations decrease with generation; the results of the L- and D-Phe series are given in Figure 2. Both the CE of the car-

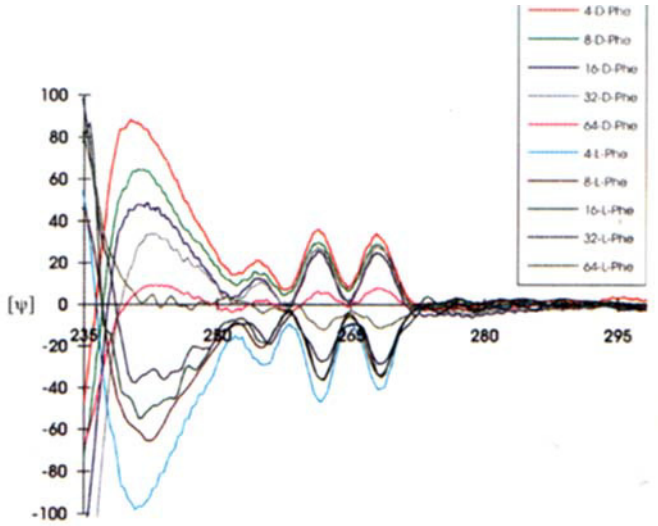

Fig. 2. Dependence of the specific ellipticity ψ [deg cm^2 g^{-1}] on the wavelength for D- and L-Phe modified dendrimers in $CHCl_3$.

bamate chromophore at $\lambda_{max} = 240$ nm and the CEs of the phenyl chromophore at $\lambda = 250-270$ nm are influenced strongly by the generation, while some (diminished) residual optical activity remains for the amide chromophore.[14] The decrease in the CEs is accompanied by some small changes in the UV/Vis spectra, indicative of changes in conformation. Similar chiroptical effects are observed for dendrimers modified with other amino acids. Since the L-Tyr series has limited solubility, ORD spectra are taken in dimethylsulfoxide (DMSO) and compared with those of the 4- and 64-L-Phe derived dendrimer (Fig. 3: note the change of sign in the rotation of the L-Phe series; negative in $CHCl_3$ and positive in DMSO)

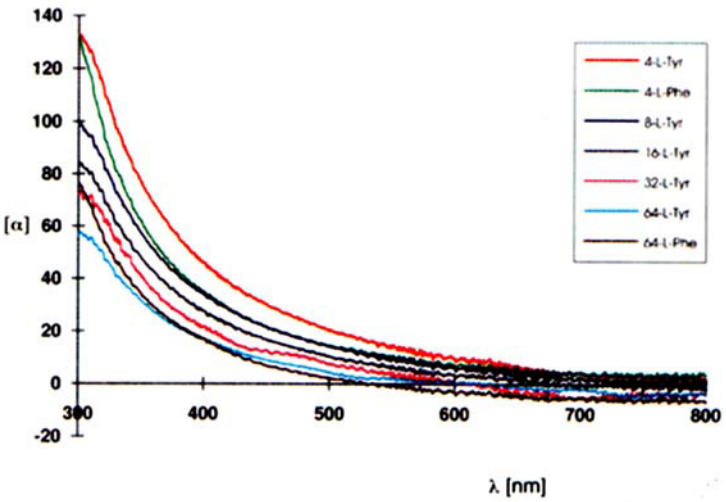

Fig. 3. Dependence of the specific rotation [α] [deg cm^2 g^{-1}] on the wavelength for the L-Tyr modified dendrimers in DMSO.

The optical behavior of the amino acid modified dendrimers is in sharp contrast with the optical rotations found for chiral dendrimers with more rigid end groups. The rigid dendritic camphor sulfonamides (Fig. 4) and camphanic amides have almost identical rotations ($[\alpha]_D \approx 23$; $c = 1$, $CHCl_3$ and $[\alpha]_D \approx -18$;

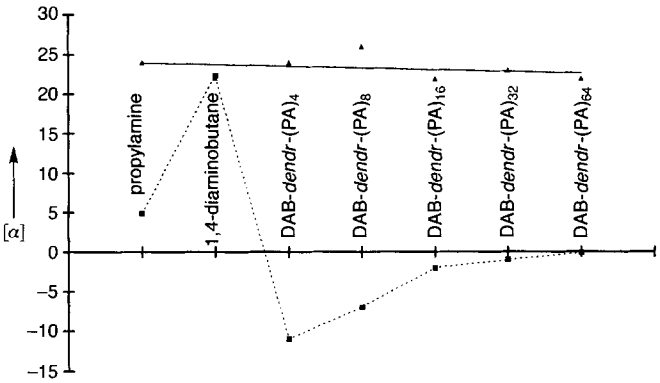

Fig. 4. Specific optical rotation of camphor sulfonic acid modified dendrimers (▲) and L-Phe modified dendrimers (■), both measured in $CHCl_3$ ($c = 1$).

$c = 1$, $CHCl_3$, respectively) for all generations. Furthermore, the corresponding *N*-propyl camphor sulfonamide model compound showed a specific rotation independent of solvent ($[\alpha]_D \approx 25$; $c = 1$, $CHCl_3$).

A number of phenomena other than trivial ones, like racemization or concentration effects, can explain the remarkable observations presented above for the amino acid modified dendrimers. A decreasing/vanishing optical activity of dendrimers is observed for dendrimers with chiral end groups; whose optical activity is susceptible to changes in the local environment. We are prompted to propose an explanation based on the fact that the outer surface (shell) of these dendrimers exhibit a highly dense solidlike packing in solution, as has been demonstrated by ^{13}C NMR relaxation measurements.[11] The rigidity of the shell is probably enhanced by multiple hydrogen bonding of the amide and carbamate groups in the shell. This rigid, close packing will lead to a number of conformations that are frozen. Due to the sensitivity of the chiroptical properties of the amino acid derivatives to the molecular environment and, hence, to conformational disorder, it is hypothesized that an internal compensation effect of different chiral conformers in the dendritic surface causes the vanishing or decreasing optical activity of the dendrimers. Chiral conformers with a non-equilibrium conformation are formed, forced by the dense packing in the shell. This explanation is related to the discussions by Green and Garetz on how the configurational stereochemistry of polymers can lead to vanishing optical activities by compensation among diastereomeric states.[15]

As these dendritic structures are highly organized, it is tempting to suggest that the conformational disorder in the shell is limited to the presence of only two frozen conformations with a kind of pseudo-enantiomeric relationship and almost opposite CD and ORD for both pseudo-enantiomers. It is well documented that the density of racemic crystals is higher than that of conglomerates[16] and the most dramatic differences are found for amino acid derivatives.[17] A pseudo mirror-image relation of conformers of enantiomerically pure compounds has been observed in X-ray studies of a number of crystals.[18] We have performed a variety of preliminary studies using scalemic mixtures to evaluate this pseudo-enantiomer hypothesis, but a detailed interpretation is lacking.[19] However, it is apparent from our results that the highly curved surface does not allow the packing of all amino acid derivatives into their preferred lowest energy conformations. This effect is probably strengthened by multiple hydrogen bonding.[20]

The constant optical rotation of the camphor sulfonamide and camphanic amide dendrimers of different generations is in

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1208 $ 10.00+.25/0

full agreement with the insensitivity of its rotation with respect to changes in the molecular environment. The constant $[\alpha]_D$ value does not imply that the camphor sulfonamide and camphanic amide shells are not densely packed nor that they do not possess frozen-in conformations. However, in these densely packed surfaces the frozen-in conformations all have the same optical activity and no internal compensation effects are operative here. Also the number and strength of the hydrogen bonds in these cases will be lower than in the case of the amino acid derived dendrimers. Further research to elucidate the reasons for the observations presented here are in progress. It is foreseen that research on chiral dendrimers with highly packed shells will yield important information for this type of curved structures; structures that are so prominently present in nature.

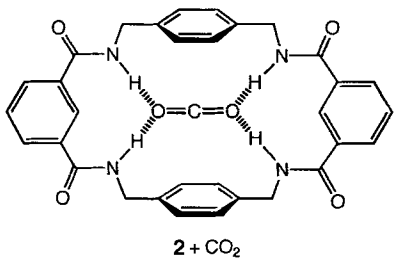
[19] In order to discriminate between disorder and pseudo-centrosymmetry, we performed experiments using scalemic mixtures of D-Phe and L-Tyr in the formation of the fifth-generation box. In sharp contrast to the $[\alpha]_D$ values of 0 for the pure D-Phe or L-Tyr, we found $[\alpha]_D = +16$ ($c = 1$, DMSO) for the 50:50 scalemic mixture of D-Phe and L-Tyr, and optical rotations between +16 and 0 for the other mixtures studied. The trend observed is indicative for some kind of pseudo-centrosymmetric ordering in the shell, in which in the case of the 50:50 scalemic mixture both units can adopt their preferred conformation and still the most dense packing is formed.

[20] This conclusion seems at first glance to be in contrast with "la coupe du roi" in which both chiral halves are of the same handedness, however a chiral dendritic surface possesses molecular chirality while "la coupe du roi" has only macroscopic chirality, see K. Mislow, *Bull. Soc. Chim. Fr.* **1994**, *131*, 534-538.

Facile Synthesis and Solid-State Structure of a Benzylic Amide [2]Catenane**

Andrew G. Johnston, David A. Leigh,* Robin J. Pritchard, and Michael D. Deegan



The synthesis of interlocked molecular rings, *catenanes*, is one of the greatest challenges in preparative chemistry.[1–3] Large macromolecular catenane structures (10^5 D) are found in DNA, where they appear to act as intermediates during the replication, transcription, and recombination processes,[4, 5] and are probably formed in small quantities in some polymerization reactions by the chance threading of growing molecular chains through large rings.[6] Recently the structural characteristics of smaller catenanes (10^3 D) have earmarked them, together with their relatives the rotaxanes, as key elements in the development of components for nanoscale electronic devices and molecular machines such as molecular shuttles, switches, and information storage systems.[3, 7] Here we report the serendipitous formation of a new amide-based [2]catenane (**1**) prepared in one step from two commercially available starting materials (see Scheme 2). The catenane is obtained in 20% yield (remarkable for an eight-molecule condensation) following a chromatography-free purification procedure simple enough to be performed in a well-equipped high school or undergraduate laboratory. The structure of **1** has been confirmed by NMR spectroscopy, mass spectrometry, and, in particular, by X-ray crystallography, which reveals a beautiful self-assembled system held together by networks of inter- and intramolecular hydrogen bonds and perfectly tessellating π-stacking interactions between four aromatic rings. Each catenane consists of two identical, interlocked, 26-membered rings with an internal cavity of 4×6 Å, making **1** the smallest interlocked ring system yet isolated.

[**] We thank Dr. J. P. Smart for useful discussions and advice, and S. Davey, M. Bolgar, and Prof. S. Gaskell for mass spectral data. This work was carried out through the support of a British Gas Scholarship award (to A. G. J).

As part of a program to prepare chemical sensors for small gas molecules we identified the simple amide macrocycle **2** as a potential molecular receptor for carbon dioxide. Molecular modeling indicated a favorable mode and enthalpy of interaction of **2** with CO_2 (Scheme 1),[8] and the synthesis was attempted by means of a direct [2 + 2] condensation (Scheme 2). Upon addition of equimolar quantities of isophthaloyl dichloride (**3**) and *para*-xylylenediamine (**4**) to a solution of triethylamine in chloroform, a precipitate began to form almost immediately. After 24 h the precipitate was removed by filtration, and the filtrate was washed with acid, base, and water, and concentrated to dryness to give a white solid which proved to be a single compound. ^1H and ^{13}C NMR spectra in [D_6]dimethylsulfoxide (Figs. 1a and 1b) and the low molecular weight mass spectrum (< 1000 Da, Fig. 1c) were consistent with the anticipated macrocyclic structure. However, in complexation experiments the material showed no signs of binding CO_2.

2 + CO_2

Scheme 1. Structure of an amide macrocycle designed to bind to CO_2.

Scheme 2. One step, eight-molecule condensation to give the [2]catenane **1**. 1) Et_3N, anhydrous $CHCl_3$.

Single crystals were obtained (by slow diffusion of acetone vapor into a methanolic solution of the material) which proved suitable for structural investigation by X-ray crystallography (Figs. 2–4). The crystal study revealed why CO_2 binding did not occur; the [2 + 2] macrocycle formed was not in fact a discrete molecule but rather the [2]catenane **1** with a second macrocycle threaded tightly through the cavity of the first!

Octaamide [2]catenanes derived from a hindered aniline have been independently reported by Hunter et al.[9–11] and Vögtle et al.,[12] and characterized by extremely elegant NMR experiments and mass spectrometry. However, **1** is the first amide-based catenane for which the structure has been determined by X-ray crystallography. The solid-state ensemble is dominated by inter- and intramolecular hydrogen bonding interactions together with π-stacks composed of four aromatic rings.

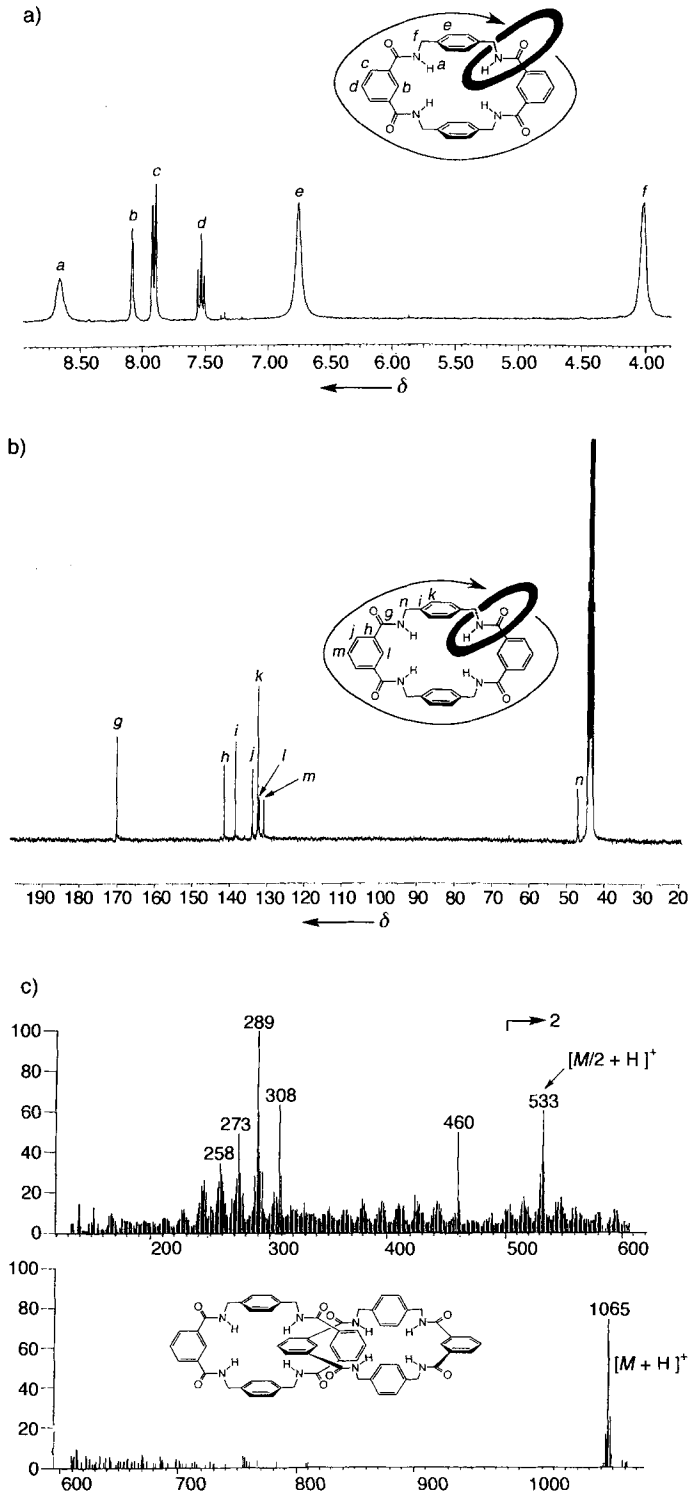

Fig. 1. Selected spectroscopic data for **1**: a) ^1H NMR and b) ^{13}C NMR spectra in [D_6]DMSO at room temperature (298 K). The second macrocycle is represented by the heavy ring. The simple NMR spectra indicate that the macrocyclic rings of **1** rotate rapidly on the NMR timescale at room temperature in DMSO, but the signals for protons *e* and *f* are still broad. c) Fast atom bombardment mass spectrum using *meta*-nitrobenzyl alcohol as matrix.

Selected dihedral angles [°]: C11-C10-C9-N5 −27.081, C11-C10-C9-O1 152.343, C10-C9-N5-C30 173.748, C9-N5-C30-C29 109.880, N5-C30-C29-C28 63.120, C11-C12-C13-N6 −150.140, C11-C12-C13-O2 22.751, C12-C13-N6-C14 179.816, C13-N6-C14-C15 −77.409, N6-C14-C15-C34 −85.918, C22-C21-C20-N7 −18.619, C22-C21-C20-O3 160.175, C21-C20-N7-C19 178.022, C20-N7-C19-C18 139.509, N7-C19-C18-C17 −30.022, C22-C23-C24-N8 25.692, C22-C23-C24-O4 −151.932, C23-C24-N8-C25 178.325, C24-N8-C25-C26 −152.766, N8-C25-C26-C39 91.121. b) Representation of **1** with 100% van der Waals radii.

The macrocyclic rings of each catenane are structurally and, in the solid state, conformationally identical (Fig. 2a), bearing close resemblance to the conformation determined for the Hunter catenane in $CDCl_3/CD_3OD$ solution.[9] Each macrocycle adopts a chairlike conformation with a single carbonyl group pointing into the macrocyclic cavity (i.e. each macrocyclic ring contains one *endo*- and three *exo*-carbonyl groups). The two isophthaloyl rings of each macrocycle are parallel to each other and form roughly an 80° angle with the mutually parallel xylylene units of the same macrocycle (Figs. 2a and b).

The two macrocyclic rings of each catenane are held in a fixed orientation in the solid state by a total of six hydrogen bonds, including two sets of bifurcated hydrogen bonds between the amide hydrogens of the cisoid isophthaloyldiamide unit of each macrocycle and the *exo*-carbonyl group of the transoid isophthaloyldiamide unit of the other macrocycle (i.e. N7···O1′···N8 and N7′···O1···N8′, Fig. 3). The fixed orientation of the macrocyclic rings within a catenane confers chirality upon the individual catenanes (adjacent molecules in the crystal structure form enantiomeric pairs, Fig. 3).

The crystal lattice has a fascinating layered structure. In both directions within each layer the catenanes assemble to maximize both inter- and intramolecular π-stacking interactions. Each stack consists of four units in three different catenanes in an ABCD sequence (Fig. 4). The four aromatic rings in each stack are close to parallel and offset from each other in the classic manner which maximizes favorable electrostatic interactions within the stack.[13] Every aromatic ring in every catenane is involved in one of these π-stacks, which pack perfectly to form a single layer.

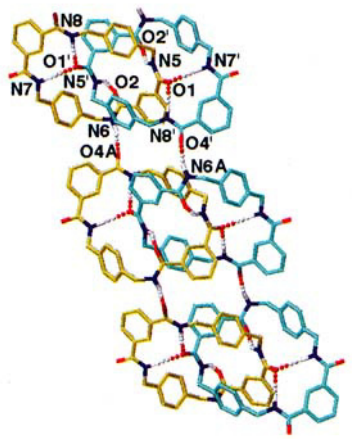

Fig. 3. Interlayer packing in the crystal structure of **1** in which all three modes of hydrogen bonding (two intra- and one intermolecular) are clearly shown. The layers are held together by an exquisite hydrogen bonding array in which four intramolecular hydrogen bonds per catenane hold the macrocyclic rings of an individual molecule in a fixed orientation and two intermolecular hydrogen bonds per catenane pair hold adjacent layers in place. Note that only the protons of the "inverted" amide groups are available for intermolecular hydrogen bonding. Distances for these intracatenane hydrogen bonds [Å]: O1-N7′ (= O1′-N7) 3.264, O1-N8′ (= O1′-N8) 3.119, O2-N5′ (= O2′-N5) 3.052; distance for the hydrogen bond between the catenanes: O4A-N6 (= N6′A-O4′) 2.913.

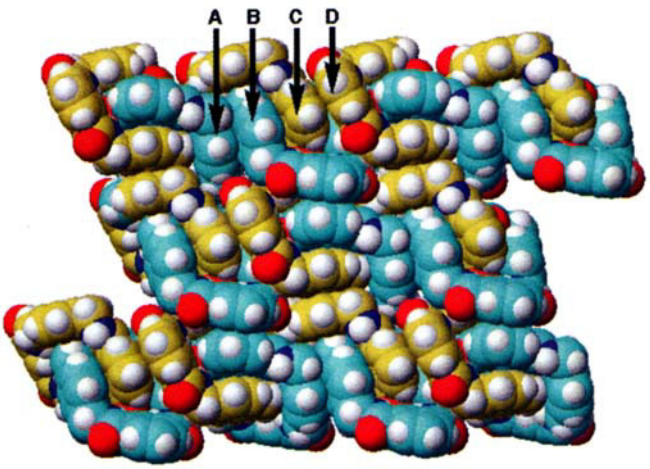

Fig. 4. Intralayer packing in the crystal structure showing tessellation of the π-stacks of four aromatic units to form discrete layers within the crystal. A is a xylylene group bearing one *exo*- and one *endo*-carbonyl group; B is a xylylene group bonded to two *exo*-carbonyl groups of a second, adjacent catenane; C is the transoid isophthaloyldiamide unit of the other macrocycle of the second catenane; and D is the cisoid isophthaloyldiamide unit of a third catenane, adjacent to the second and one-removed from the first. Distances between the centroids of the rings forming a π-stack [Å]: A···B 3.874, B···C 4.033, C···D 4.239.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1211 $ 10.00+.25/0

The catenane layers, in turn, are held together by van der Waals interactions and two intermolecular hydrogen bonds between each catenane and its nearest neighbors in the layers above and below (Fig. 3). The interlayer hydrogen bonds are formed between the amide hydrogen atoms of the inverted amide groups and the carbonyl groups of the cisoid isophthaloyldiamide units. The remaining amide hydrogen atoms and carbonyl groups (N5′ and O2; N5 and O2′) appear, by the positioning of the heavy atoms, to be connected through an unusual hydrogen bonding architecture in which the amide proton either binds to the π-cloud of the O=C bond or binds in a nonlinear arrangement to the oxygen atom. Since the H atoms are not resolved in the structure, these two possibilities cannot currently be distinguished.

The X-ray crystal structure supports the proposal that the driving force for catenane formation is hydrogen bonding between the newly formed 1,3-diamide units and carbonyl groups on the acid chloride or other intermediates. The stacking of the electron-rich xylylene and electron-poor isophthaloyl rings may also play a supporting role. *In the manner first introduced with the Stoddart catenanes, the formation of new functional groups in this reaction controls the self-assembly of a topologically complex product.*[3]

The following communication[17] shows that **1** is not an isolated example of a [2]catenane, but rather the simplest of a diverse family of catenanes derived in one step from aromatic 1,3-dicarbonyl compounds and benzylic diamines. Self-assembly processes currently provide the only viable route to these kinds of topologically complex molecules which exhibit, in both solution and the solid state, a range of structural and dynamic properties not available to topologically trivial molecules.

Experimental Procedure[18]

To a stirred solution of triethylamine (1.19 g, 18.9 mmol) in anhydrous chloroform (130 mL, stabilized with amylenes not ethanol) [19] under argon were added **3** (0.87 g, 4.3 mmol) in anhydrous chloroform (130 mL) and **4** (0.58 g, 4.3 mmol) in anhydrous chloroform (130 mL) simultaneously, over 30 min by means of motor-driven syringe pumps. The mixture was allowed to stir for about 12 h and then filtered. The filtrate was washed with 1 M aqueous hydrochloric acid (3 × 200 mL), then 5% aqueous sodium hydroxide (3 × 200 mL), and finally water (3 × 200 mL). The organic layer was then dried over anhydrous magnesium sulfate and concentrated under reduced pressure to afford 0.23 g (20.1%) of [2]catenane **1**. M.p. 315 °C (decomp); ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 4.01 (br. s, 16H, CH$_2$), 6.75 (br. s, 16H, *p*-xylyl H), 7.50 (t, $J_{4,5} = J_{5,6} = 8$ Hz, 4H, isophthaloyl 5-H), 7.88 (dd, $J_{4,5} = 8$ Hz, $J_{2,4} = 1$ Hz, 8H, isophthaloyl 4-H and 6-H), 8.05 (d, $J_{2,4} = 1$ Hz, 4H, isophthaloyl 2-H), 8.62 (s, 8H, CONH); ^{13}C NMR (75 MHz, [D$_6$]DMSO): δ = 46.98, 130.03, 130.81, 132.40, 133.78, 138.40, 141.35, 168.94; FAB-MS (*m*NBA matrix): m/z 1065 [$(M + H)^+$], 533 [$(M/2 + H)^+$]. The precipitate from the reaction contains polymers, larger macrocycles, and catenanes (as indicated by FAB-MS and NMR analysis) which have not yet been completely characterized.

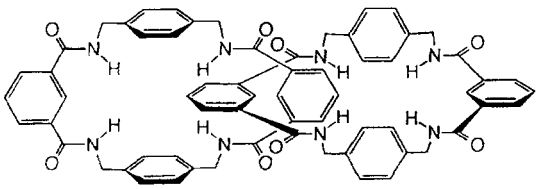
[18] Few examples of self-assembly processes are straightforward enough to be introduced into undergraduate laboratories. The synthesis of **1** is an exception and has been successfully incorporated into the first-year organic chemistry course at the University of Manchester Institute of Science and Technology.
[19] The use of chloroform that has not been rigorously dried or contains ethanol gives lower yields of the [2]catenane and, more problematically, produces byproducts arising from the partial hydrolysis of the starting acid chloride. These are not removed in the above workup procedure. However, in this case the [2]catenane can be obtained pure by carefully washing the end product with cold chloroform.

Structurally Diverse and Dynamically Versatile Benzylic Amide [2]Catenanes Assembled Directly from Commercially Available Precursors**



Andrew G. Johnston, David A. Leigh,* Lida Nezhat, John P. Smart, and Michael D. Deegan

The unique architectures and structural characteristics of catenanes and rotaxanes have identified them as attractive targets in the search for nanoscale devices and molecular electronic applications.[1] Accordingly, following the pioneering work of Stoddart et al.[2] and Sauvage et al.,[3] there is great interest in the development of new catenane systems that can be obtained in high yield[4–10] and especially syntheses that are tolerant towards structural variations which can be used to control the dynamic properties of the catenanes. In 1992 Hunter and Vögtle et al. reported the first amide-based catenanes,[4, 5]

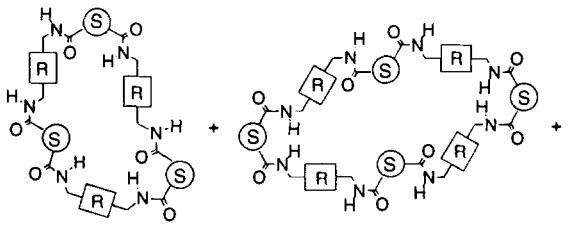
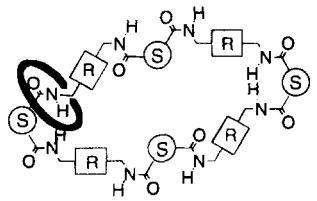
which relied on a hindered anilide structure. However, both groups found that the catenane assembly process was not tolerant to some simple modifications in the aromatic 1,3-dicarbonyl unit (5-nitrobenzene 1,3-dicarboxylic acid dichloride (Vögtle) and pyridine 2,5-diamidyl precursors (Hunter)). Furthermore, the steric demand of the spacer prevents the macrocyclic components of these catenanes from rotating. The preceeding communication describes the serendipitous formation of the first benzylic amide [2]catenane (**1**).[11] Here we report that benzylic





1

amide catenanes form a readily accessible and functionally diverse [2]catenane system, allowing the self-assembly of catenanes with differing conformational and dynamic properties in good yields. Commercially available and other readily accessible dicarboxylic acid dichlorides and benzylic diamines serve as starting materials.

The generality of the catenane-forming reaction described in ref. [11] was examined in detail (Scheme 1, Table 1). Variations in both the aromatic 1,3-dicarbonyl compound (five-membered rings (**11**), six-membered rings (**1**–**10**, **12**–**15**), thiophenes (**11**), pyridines (**12**, **13**), with nitro groups (**9**), alkyl groups (**2**, **3**), alkenes (**4**, **14**, **15**), ethers (**4**–**7**, **14**, **15**), halogens (**8**, **10**)) and the

+ higher cyclic oligomers, catenanes and polymers

Scheme 1. Possible products from the reaction of aromatic 1,3-dicarboxylic acid dichlorides with benzylic amides. The benzylic amide [2]catenanes ((2+2+2+2) catenanes) **1**–**15** (Table 1) are formed by eight-molecule condensations.

Table 1. Products and yields (either of isolated material or, in the case of very insoluble or difficult-to-purify products, by HPLC) from the condensation of equimolar quantities of various aromatic 1,3-dicarboxylic acid dichlorides and benzylic diamines in dry chloroform in the presence of triethylamine according to Scheme 1.

[a] The very poor solubility of these products made their analysis impossible, even by HPLC.
[b] Mixtures of diastereomers and, in the case of the [2]catenane, topological enantiomers.

benzylic spacer (1,4-phenylene (**1**–**13**), 2,6-naphthalenediyl (**14**), 4,4′-biphenylene (**15**)) were well tolerated, in all cases but one, giving rise to [2]catenanes in yields of 15–27%. The exception was 2,4,5,6-tetrafluorobenzene 1,3-dicarboxylic acid dichloride, which failed to produce detectable amounts of catenane with any of the benzylic diamines.

Also formed in each reaction were the topologically trivial macrocycles arising from (2+2), (4+4), and higher condensations (the macrocycle from the (3+3) condensation was usually formed only in trace amounts); however, these could not always be isolated as pure compounds due to their poor solubilities. The (2+2+2+2) catenane and (2+2) macrocycle were invariably the most abundant reaction products. With the exception of catenane **1**, whose trivial isolation is reported in ref. [11], all of the products required purification by careful column chromatography (silica gel, 1–15% methanol in dichloromethane as eluent); in each case the (2+2+2+2) catenane was the first compound eluted.

The macrocycles and catenanes were distinguished by FAB mass spectrometry and ^1H and ^{13}C NMR spectroscopy (Figs. 1–3). FAB mass spectra of the catenanes show features characteristic of interlocked molecules such as the lack of fragmenta-

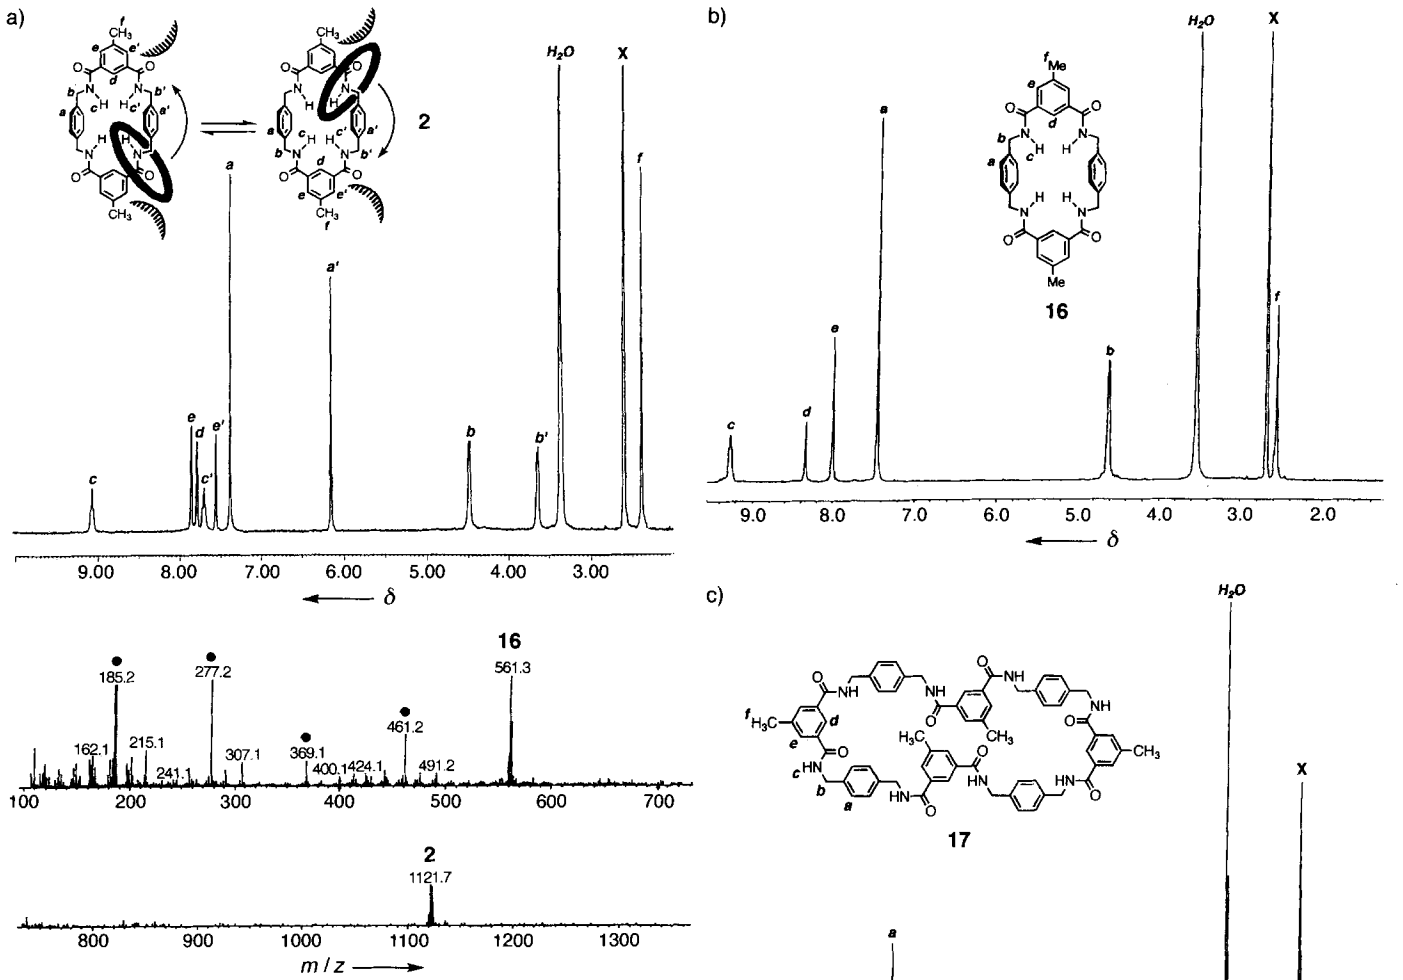

Fig. 1. Room-temperature ^{1}H NMR spectra (300 MHz, [D$_6$]DMSO, X = residual solvent peak) of a) the catenane **2** (along with its FAB mass spectrum; • = peaks arising from the matrix), b) the (2+2) macrocycle **16**, and c) the (4+4) macrocycle **17**. In the formula of **2** the unringed side of the catenane is on the left. The two xylylene, rather than the (5-methylisophthaloyl) units, of the constituent macrocycles of **2** are in different chemical environments on the NMR timescale. Inspection of CPK models reveals that the methyl groups prevent rotation of either macrocycle around the other giving rise to this phenomenon. Heating the sample does not bring about coalescence of these signals. As a catenane that cannot spin, this molecule may be considered a kind of "cyclic rotaxane" [12]. Somewhat suprisingly, however, the mass spectrum still shows no fragmentation peaks between M and $M/2$.

tion between M + H and $M/2$ + H (upon cleavage of a macrocyclic bond in the spectrometer the catenane unthreads to two components of $m/z \leq M/2$ + H).

The self-assembly process is clearly very tolerant to structural and functional variations in the reactants (indeed even the yields of the catenanes are remarkably similar). However, NMR spectroscopy reveals that the functional and structural changes impart varied dynamic and conformational properties to the different catenanes in solution.

The substituents on the isophthaloyl units of catenanes **2**–**10**, **14**, and **15** prevent complete circumvolution (also termed "circumrotation"; the spinning of one macrocyclic ring through the other), thereby locking the two sides (i.e. the two *para*-xylylene units) of each macrocycle in different chemical environments. This reduction in symmetry is evident in the ^{1}H NMR spectra of catenane **2** (Fig. 1a), which has two signals for most protons. The exceptions are protons *d* and *f* which lie on the axis separating the "ringed" and "unringed" halves of each macrocycle. The signals arising from the "ringed" half of the macrocycle (labeled with primed letters) are shifted to higher field, owing to the shielding effects of the aromatic rings of the "ringing" macrocycle. In contrast to the catenane **2**, both the (2+2) and (4+4) macrocycles (**16** and **17**, respectively) give simple NMR spectra with no doubling of resonances, and which remain simple even upon cooling in [D$_4$]methanol. Indeed, the ^{1}H NMR spectra of the (2+2) and (4+4) macrocycles are very similar (Fig. 1b and c). The largest chemical shift difference is that of H-2 (*d*) of the isophthaloyl rings, which is attributable to the greater flexibility (open and closed conformations) of the (4+4) macrocycle.[10]

Catenanes **1**, **11**, and **13**, which bear unsubstituted aromatic rings in the dicarbonyl unit, rotate rapidly on the NMR timescale at room temperature in [D$_6$]DMSO, giving rise to simple time-averaged ^{1}H NMR spectra. Catenane **11**, for example, yields only four signals for its 48 hydrogen atoms (Fig. 2a). In these cases the ^{1}H NMR spectra of the catenanes resemble those of the (2+2) and (4+4) macrocycles in terms of the number of signals. However, comparison of the ^{1}H NMR spectrum of catenane **11** with that of the corresponding (2+2) macrocycle **18** (Fig. 2b) shows that the catenane signals are all shifted considerably further upfield from the signals of the macrocycle, again due to the shielding effect of the aromatic

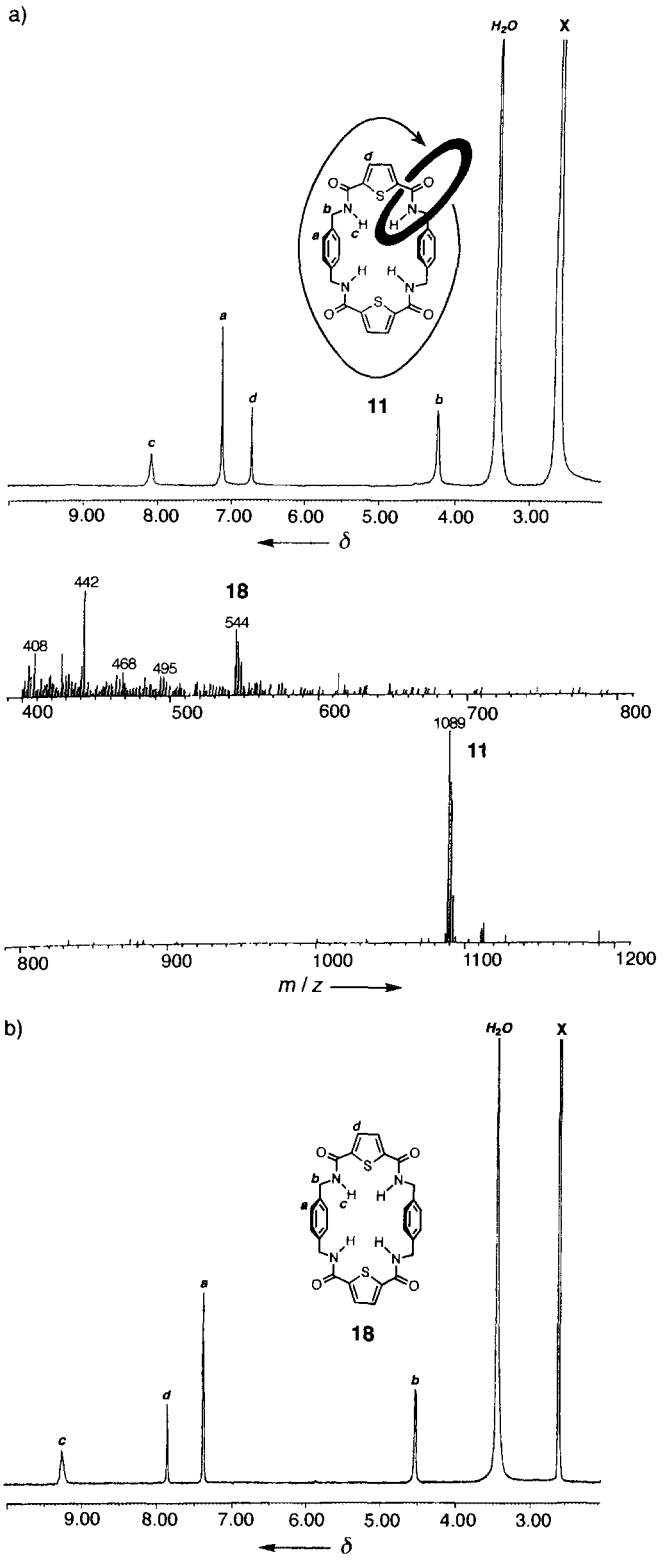

Fig. 2. Room-temperature ^{1}H NMR spectra (300 MHz, [D$_6$]DMSO) recorded of a) the catenane **11** (along with its FAB mass spectrum) and b) the (2+2) macrocycle **18**.

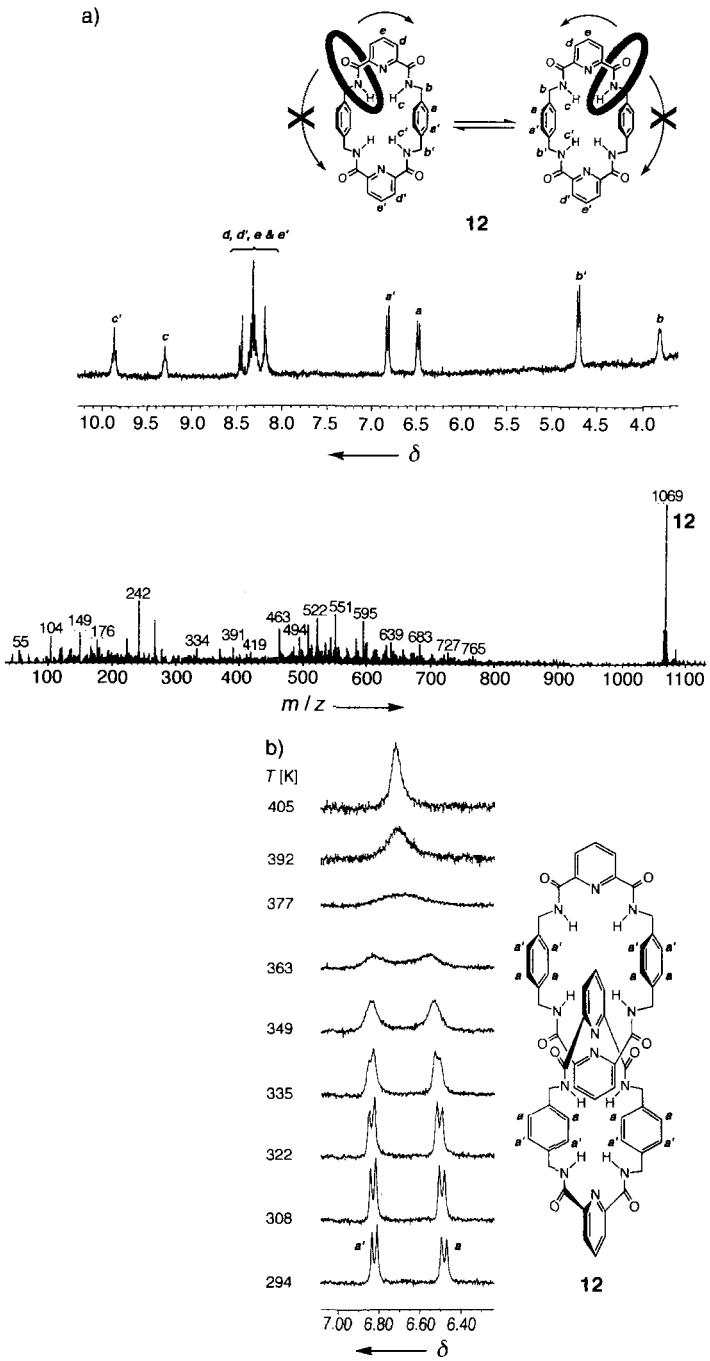

Fig 3. ^{1}H NMR spectra (300 MHz, [D$_6$]DMSO) of the catenane **12** at a) room temperature (along with its FAB mass spectrum) and b) of the phenylene units of **12** at elevated temperatures. The unprimed signals (especially *a*, *b*, *c*) in the ^{1}H NMR spectrum are broad at room temperature because the passage of the macrocyclic ring over the pyridine unit also has an appreciable energy barrier. In the formulas of **12** in a) the ringed part is on the top, and the unringed part is on the bottom.

rings of the rapidly spinning macrocycles. In this way, in particular, the (4+4) macrocycles and their isomeric, fast rotating (2+2+2+2) catenanes can be readily distinguished.

Catenane **12** is extraordinary in that the circumvolution of its macrocyclic ring is slow on the NMR timescale (giving rise to a symmetry-reduced spectrum, Fig. 3), although **12** does not have any substituents on the 1,3-dicarbonyl unit! Furthermore, the ^{1}H NMR spectrum shows that it is the two pyridine units (top and bottom halves) of each macrocycle that are in different environments, whereas the single set of signals for the two *para*-xylylene sides of the macrocycles (an AA'BB' system) indicate that the two sides of each macrocycle are chemically equivalent. Clearly, in this catenane the macrocyclic rings do not pass over the xylylene spacers rapidly on the NMR timescale and are effectively isolated on individual pyridine units. Upon heating, the primed and unprimed phenylene signals coalesce (Fig. 3b) as

the rate of macrocyclic ring circumvolution increases and the process becomes rapid on the NMR timescale.

Comparison with the [D_6]DMSO ^{1}H NMR spectra of both **1** and **13** recorded at room temperature indicates that this hindrance to circumvolution is peculiar to **12** and therefore must be governed wholly by the electronic nature of the pyridine unit rather than by the steric requirements of the catenane components. The X-ray crystal structure of **1** suggests that circumvolution of benzylic amide catenanes is restricted primarily by the two sets of intramolecular, intermacrocyclic hydrogen bonds between the cisoid 1,3-diamide hydrogen atoms and the amide carbonyl groups (Fig. 4). Remarkably, even in a solvent that

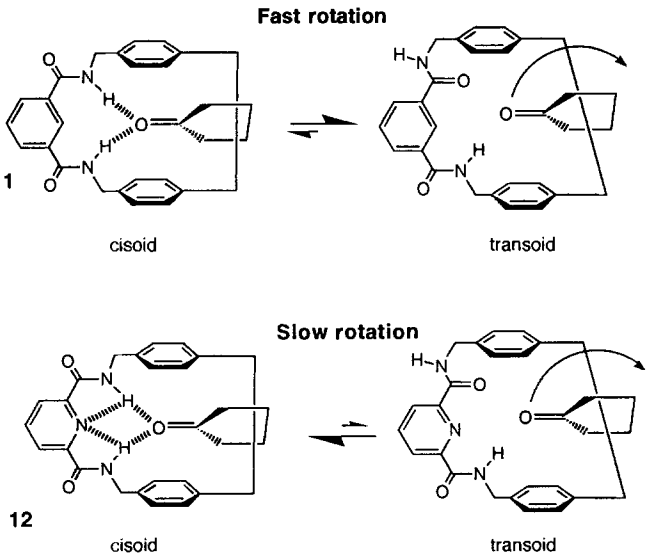

Fig. 4. Circumvolution of the catenanes involves the breaking and subsequent reforming of the intramolecular hydrogen-bonding networks between the two macrocyclic components. Rotation is achieved more easily when the 1,3-dicarbonyl moiety is attached to a benzene ring (e.g. **1**, top) rather than a pyridine unit (e.g. **12**, bottom), since the lowest energy conformation of the isophthaloyl group has the diamide in a transoid orientation, which releases the hydrogen-bonded carbonyl of the other macrocyclic ring. In the minimum energy conformation of the pyridine unit of **12** the diamide is in a cisoid orientation. This can be explained by the hydrogen bonding of the amide hydrogens to the pyridine nitrogen and/or electrostatic repulsions between the pyridine lone pair and the carbonyl group in the pyridine-2,6-dicarbonyl system. This leads to strong bifurcated hydrogen bonds between the two rings, fixing them in position and preventing macrocyclic ring rotation.

can form hydrogen bonds such as DMSO the circumvolution of catenane **12** is slow on the NMR timescale at temperatures below 100 °C! Since catenanes **13**, **1**, and **11** do not display this slow rotation behavior in DMSO, the phenomenon can be attributed to the greater propensity for pyridine-2,6-dicarbamido units to adopt the cisoid conformation necessary for strong binding to a carbonyl group.[10] Conversely, in macrocyclic components of catenanes **1**, **11**, and **13** the lack of binding sites for strong bonds with carbonyl groups allows unhindered, and consequently rapid, circumvolution to occur.

The synthesis of benzylic amide based catenanes is remarkably tolerant to significant variations in both the diamine and the dicarboxylic acid dichloride starting materials. The resulting catenanes display rotational properties associated with an intricate intramolecular network of hydrogen bonding interactions, which can be controlled both electronically and sterically. These fascinating molecules are clearly well suited for the construction of *revolutionary* nanoscale molecular devices.

Experimental Procedure

The optimum conditions for the catenane-forming reaction described in ref. [11] were worked out by systematic variations in reactant concentration, solvent, and temperature. The ideal concentration for catenane formation is ca. 0.02 M; more dilute solutions decrease the yield of [2]catenane in favor of the (2+2) macrocycle, more concentrated solutions lead preferentially to polymeric products. Nonaromatic, unpolar, ethereal, and halogenated solvents (in particular, chloroform) are amongst the best solvents for catenane formation. Reactions in toluene and chlorobenzene generally have lower yields, possibly due to inhibition of π-stacking interactions which may play a supporting role in catenane formation. Polar solvents such as acetone, dimethylformamide, and methanol inhibited the catenane self-assembly process almost completely, probably because of competitive hydrogen bonding between key intermediates and solvent molecules. Lowering the reaction temperature increases the yield of [2]catenane only at very dilute concentrations where solubility of the intermediates and products is not an important factor. At a concentration of 0.02 M, 298 K appears to be close to the optimal temperature for [2]catenane formation.

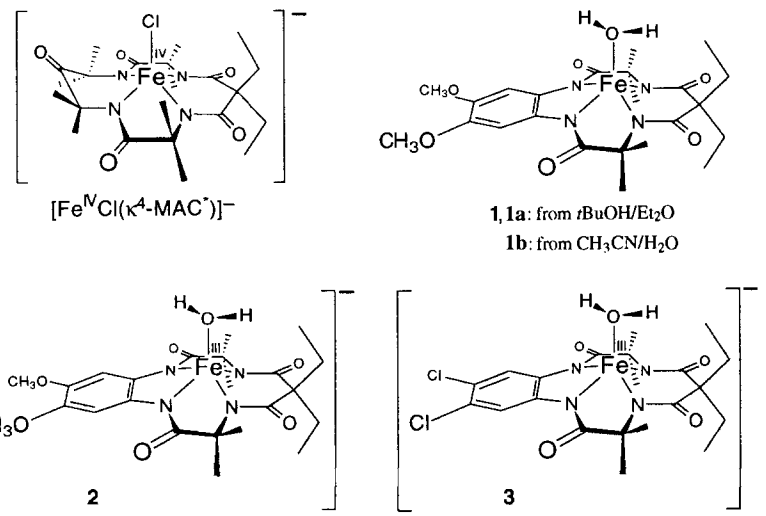
A Stable Aquairon(III) Complex with $S = 1$: Structure and Spectroscopic Properties**

Michael J. Bartos, Christopher Kidwell, Karl E. Kauffmann, Scott W. Gordon-Wylie, Terrence J. Collins,* George C. Clark, Eckard Münck,* and Susan T. Weintraub



The importance of iron in biological oxidations continues to attract widespread attention to the chemistry of high-valent iron complexes. We have developed macrocyclic tetraamides that stabilize iron compounds in high oxidation states; resistance to oxidative degradation and strong donor capacities are the essen-

[**] This work was supported by the U. S. National Institutes of Health (Grant GM44867 to T. J. C. and GM22701 to E. M.).

tial criteria in ligand design.[1] One such ligand, $(\kappa^4\text{-MAC*})^{4-}$, has been used to make two novel Fe^{IV} compounds, a five-coordinate, high-spin ($S = 2$) complex with an axial chloro ligand[2] and a six-coordinate complex ($S = 1$) with two axial isocyanide ligands.[3] In these studies, we have aimed at producing oxidized iron complexes with biologically significant oxygen ligands. Here we report on an oxidized iron complex with the biologically important aqua ligand. The five-coordinate complex **1** is derived by oxidation of the identically ligated, intermediate-spin ($S = 3/2$) iron complex **2**. We show that the oxidation is ligand-centered in a manner that is both reminiscent of heme redox chemistry[4] and indicative[5] of a further source of stable non-porphyrinic iron compounds in high oxidation states.

Compound **2** was prepared by employing metal-insertion procedures developed for the macrocyclic tetraamides.[1] While **2** has not been structurally characterized, its Mössbauer and EPR data are very similar to those of **3**, a structurally characterized analogue with chlorine substituents on the aromatic ring in place of the methoxy groups (unpublished results). Compound **1** can be prepared by oxidation of **2** with Ag^I salts or with $Ce(NH_4)_2(NO_3)_6$. The complex is slightly soluble in water (< 0.5 mM), in which it shows a one-electron reduction with well-defined isosbestic points giving **2** (Fig. 1); complex **2** can be reoxidized to **1** with $Ce(NH_4)_2(NO_3)_6$. The cyclic voltammogram of **2** in water shows a reversible oxidation wave (+ 0.46 vs. SSCE, glassy carbon electrode, 0.1 M KPF_6). Depending upon the isolation conditions, **1** is produced in different crystal forms. Form **1a**, isolated from tBuOH/Et_2O, has been characterized by X-ray crystallography (Fig. 2). The average Fe–N distance in **1a** is 1.871 Å. The four N atoms are nearly planar (maximum displacement from mean plane 0.025 Å) with the Fe atom 0.362 Å above the N_4 plane. The Fe–O(H_2O) distance is 2.068(3) Å. The coordination of the O7 atom of the aqua ligand appears to deviate from ideal sp^3 hybridization. While experimental uncertainties in the O–H distances are large, one O–H distance is long (O7–HO7B, 0.92(6) Å); the H atom forms a strong hydrogen bond with an amide oxygen atom of a neighboring anion (HO7B···O2, 1.86 Å). The second more isolated O–H bond is short (O7–HO7A, 0.72(6) Å) with long distances to the O atoms of the methoxy substituents in the other macrocyle of the complex dimer (HO7A···O5′ 2.47 Å; HO7A···O6′, 2.57 Å). Short O–H bonds (< 0.8 Å) with similar experimental uncertainties have been found for other aquairon complexes.[9–11]

The zero-field Mössbauer spectrum of crystalline **2** (Fig. 3A) consists of a doublet with $\Delta E_Q = 4.19(4)\ mm\,s^{-1}$ and $\delta_{Fe} = 0.14(2)\ mm\,s^{-1}$ at 4.2 K. These parameters are similar to those observed for the $S = 3/2$ complex **3** ($\Delta E_Q = 4.01\ mm\,s^{-1}$, $\delta_{Fe} = 0.12\ mm\,s^{-1}$). Aqueous solutions of **2** (0.1–0.5 mM) at 2 K exhibit broad EPR spectra ($S = 3/2$) with resonances at $g = 4.5$ and 3.3; the region near $g = 2$ was obscured partially by signals of a contaminant. The zero-field Mössbauer spectrum of polycrystalline **1a**, recorded at 4.2 K (Fig. 4A), exhibits a sharp doublet with $\Delta E_Q = 3.97(2)\ mm\,s^{-1}$ and $\delta_{Fe} = 0.14(1)\ mm\,s^{-1}$. Remarkably, the isomer shifts of **1a** and **2** are the same. Since δ values are generally quite sensitive to the oxidation state of the metal atom, this observation suggests that the oxidation of **2** is essentially ligand-based rather than metal-centered. In the following we will pursue this suggestion.

Figure 3B shows a Mössbauer spectrum of crystalline **2** recorded in an 8.0 T applied field. We have analyzed spectra recorded at 4.2 K and 1.5 K in fields of 2.0, 4.0, 6.0, and 8.0 T with the Hamiltonian given in Equation (a) ($S = 3/2$), allowing

$$\mathcal{H} = \boldsymbol{D}[\boldsymbol{S}_z^2 - S(S+1)/3] + \boldsymbol{E}(\boldsymbol{S}_x^2 - \boldsymbol{S}_y^2) + \boldsymbol{S}\cdot\boldsymbol{g}\cdot\boldsymbol{H} + \boldsymbol{S}\cdot\boldsymbol{A}\cdot\boldsymbol{I} + \boldsymbol{I}\cdot\boldsymbol{P}\cdot\boldsymbol{I} - g_n\beta_n\boldsymbol{H}\cdot\boldsymbol{I} \quad \text{(a)}$$

that the magnetic hyperfine tensor, **A**, and the quadrupole tensor, **P**, are rotated relative to the zero-field splitting (ZFS) tensor by Euler angles $(\alpha_A,\beta_A,\gamma_A)$ and $(\alpha_P,\beta_P,\gamma_P)$, respectively. Figure 3B shows a representative simulated spectrum obtained with the parameters listed in Table 1. Figure 4 shows 8.0 T spectra of **1a** obtained from crystalline powder (Fig. 4B) and frozen aqueous solution (Fig. 4C). The spectra are typical of those obtained for complexes with integer electronic spin. We have analyzed a series of spectra of the solution sample in applied fields by applying Equation (a) for $S = 1$; a representative fit is shown in Figure 4C (solid line). The choice of spin state $S = 1$ is based on magnetization data of **1b** (crystallized from MeCN/H_2O), which has the same δ_{Fe} and ΔE_Q as the solution sample that yielded the spectrum shown in Figure 4C.[12] Data recorded at 2 to 300 K in fields up to 5.0 T show that μ_{eff} is nearly

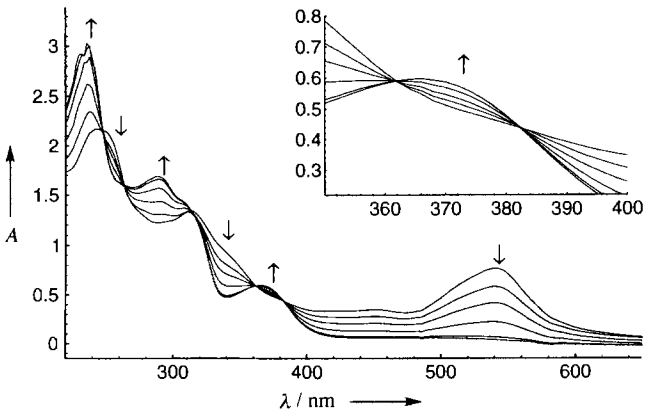

Fig. 1. UV/Vis spectra showing one-electron reduction of **1** with $[Ru^{II}(NH_3)_6]Cl_2$ in water. The concentration of **1** [λ_{max} (ε): 539 (9240)] decreases upon addition of five aliquots of $[Ru^{II}(NH_3)_6]Cl_2$ (0.2 equiv per aliquot) to give the spectrum of the pure **2** [366 (6740)].

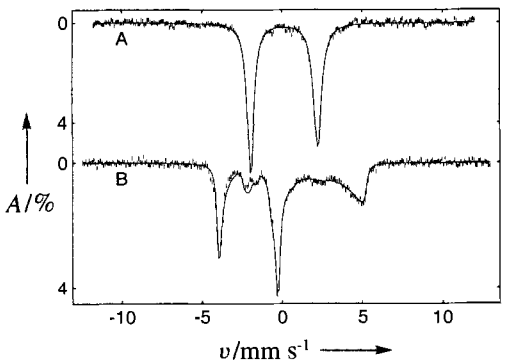

Fig. 3. Mössbauer spectra of the Fe^{III} complex **2** with $S = 3/2$ recorded at 4.2 K in zero field (A) and in an 8.0 T parallel applied field (B). The solid line in B is a simulation based on Eq. (a) using the parameters in Table 1.

constant above 50 K and $\approx 3.0\ \mu_B$, which is close to the spin-only value of 2.83 for an $S = 1$ system.

Crystalline **1a** behaves at 4.2 K like a diamagnet even in a field of 8.0 T (Fig. 4B). However, 8.0 T spectra taken at temperatures greater than 15 K reveal paramagnetic hyperfine structure, suggesting that molecules in the crystal interact in pairs by intermolecular exchange. We have fitted the solution parameters of **1a** (Fig. 4B) with a model that considers intermolecular antiferromagnetic exchange of two monomers with $S_1 = S_2 = 1$,

Table 1. Mössbauer parameters of **1** and **2**.

	D [cm^{-1}]	E/D	A_x, A_y, A_z [MHz]	β_A [°]	ΔE_Q [$mm\,s^{-1}$]	η	β_P[a] [°]	δ[b] [$mm\,s^{-1}$]
1	+9.2	0.10	−32, −28, +11	55	+3.72	0.23	65	0.14
2	+2–3	0.04	−31, −22, +11	90	+4.29	0.20	90	0.14

[a] Because the ZFS-, ***P***-, and ***A***-tensors are nearly axial, the spectra are quite insensitive to Euler angles α and γ. [b] Isomer shift is given relative to Fe metal at 298 K.

$\boldsymbol{H} = j\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$, with $j \approx 20\ cm^{-1}$.[13] Similar intermolecular couplings have been reported, for instance, for porphyrins.[4] Inspection of the structure of the dimers (Fig. 2, bottom) suggests a likely exchange pathway through the aromatic rings of the ligands. Thus, within isolated pairs, segments of the aromatic rings of the ligands touch at van der Waals distances (C16–O5′ 3.34, C16–C19′ 3.49, C20–C18′ 3.40, C21–C18′ 3.50 Å).

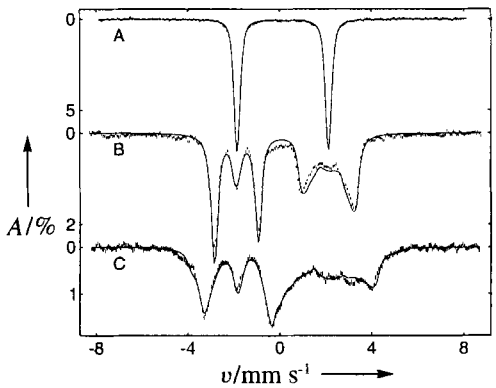

Fig. 4. Mössbauer spectra of **1** recorded at 4.2 K in zero field (A) and in an 8.0 T parallel applied field (B and C). The spectra in A and B were obtained for **1a**. The solid line in A is a least-squares fit to a doublet with $\Delta E_Q = 3.97\ mm\,s^{-1}$ and $\delta_{Fe} = 0.14\ mm\,s^{-1}$. The solid line in B is a spectral simulation assuming that two monomers with $S_1 = S_2 = 1$ are coupled by $\boldsymbol{H} = j\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$ with the parameters listed in Table 1. The spectrum in C was obtained for an aqueous solution containing 0.4 mM ^{57}Fe-enriched (> 90%) **1**. The sample contained 10% of **2**; its contribution was simulated and is included in the theoretical curve. The solid line in C is the result of fitting a group of spectra to Eq. (a) for $S = 1$.

The similarity of the parameter sets (Table 1) obtained for **1** and **2** is remarkable. Thus, both compounds have nearly axial ZFS tensors. The ***A***- and ***P***-tensors are nearly collinear for each compound. The z-axes of both tensors are tilted by $\beta \approx 90°$ (for **2**) and $\beta \approx 60°$ (for **1**) away from the z-axis of the ZFS tensor. The striking similarity of the fine and hyperfine structure parameters of **1** and **2**, especially the identical δ-values, indicates that both complexes have Fe^{III} centers. This suggests a description of the $S = 1$ state of **1** by antiferromagnetic coupling ($\boldsymbol{H} = J\boldsymbol{S}_1 \cdot \boldsymbol{S}_R$, $J > 0$) of the spin of the Fe^{III} site with $S_1 = 3/2$ to a ligand-based radical with $S_R = 1/2$. In this coupling model, the ***A***- and ***D***-tensors of the $S = 1$ system are very similar to those of the $S = 3/2$ system and are related to those of the Fe^{III} site by $\boldsymbol{A} = (5/4)\boldsymbol{A}(Fe^{III})$ and $\boldsymbol{D} = (3/2)\boldsymbol{D}(Fe^{III})$.[14] The interpretation of **1** as an Fe^{III} complex containing a ligand-based radical[15] is supported by the X-ray structure of **1a**, which suggests that the locus of the oxidation is centered on the aromatic portion of the macrocycle. If **1** were an Fe^{IV} complex, the C_φ–N distances

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1218 $ 10.00+.25/0

should be those of single bonds, in this case close to 1.4 Å.[1] The observed C–N distances from the aromatic ring to N1 (1.356 Å) and N4 (1.374 Å) are noticeably shorter, consistent with a semiquinone-like ligand and an Fe^{III} formulation. Moreover, two of the C–C bonds in the aromatic ring (C17–C18, C19–C20) are significantly shorter than the other four. Finally, the methyl groups of the methoxy substituents lie in the plane of the aromatic diamide unit, suggesting that oxygen π-donor interactions are important, as would be expected for an oxidized aromatic ring. A Hückel treatment (assuming C_s symmetry) suggests that the pattern of bond length changes results from removing an electron from an A' molecular orbital of the ligand.

These high-field Mössbauer studies of **1** and **2** and the crystal structure of **1a** delineate the electronic structure of **1**. The values of ΔE_Q, δ, and μ_{eff} for **1**, taken alone, could easily mislead one to suggest an Fe^{IV} complex with $S = 1$. The oxidation of **2** to give **1** is fundamentally different from that reported for $[Fe^{III}Cl(\kappa^4\text{-}MAC^*)]^{2-}$, a tetraamide complex lacking the aromatic ring in the macrocycle.[2] As noted, oxidation of the latter is metal-centered and produces a high-spin Fe^{IV} complex. With two axial *tert*-butylisocyanides, the $(\kappa^4\text{-}MAC^*)^{4-}$ ligand stabilizes a complex with an $S = 1$ state and an Fe^{IV} ion ($\delta_{Fe} = -0.04$ mm s^{-1}).[3] Thus, the spin state depends on the axial ligation, and the location of the oxidation can be locked at the metal by ligand design or freed to range over ligand fragments with delocalized electrons that remain in intimate contact with the metal. We are particularly interested in understanding how these details of electronic structure can be exploited in reactivity and are currently exploring deprotonation procedures for **1** to obtain stable oxidized hydroxo- and oxoiron complexes.

Experimental Procedure

2: $[Et_4N]_2[Fe^{III}Cl(\kappa^4\text{-}L)]$ (L = tetramido ligand in **1** and **2**) (500 mg, 0.6 mmol), prepared by standard techniques [16], was dissolved in deionized H_2O (40 mL) and the mixture was filtered. A solution of $[PPh_4]Cl$ in H_2O (1.2 g, 3.2 mmol, 10 mL) was added and the solution was stirred (24 h). The burgundy precipitate was collected and washed with deionized water (2 × 10 mL). Yield: 255 mg (50%). IR (Nujol): 1610 (ν(CO)amide), 1562 (ν(CO)amide), 1546 cm^{-1} (ν(CO)amide). Separate analyses on three different samples gave satisfactory, reproducible data for $C_{47}H_{52}N_4FeO_7P_1 \cdot H_2O$. Anal. calcd: C 63.44, H 6.12, N 6.30; found: C 63.28, H 6.00, N 6.25. ESI-MS: $[Ph_4P]$**2** in CH_3CN: m/z 514 [**2** – H_2O] (base peak), 573 [**2** + CH_3CN].

1: $[Et_4N]_2[Fe^{III}Cl(\kappa^4\text{-}L)]$ (600 mg, 0.7 mmol) was dissolved in deionized water (20 mL). A solution of $AgBF_4$ (720 mg, 3.7 mmol) in H_2O (5 mL) was added and the mixture was stirred (3 h). The solid was collected and extracted into CH_3CN (20 mL). The mixture was filtered (celite), water was added (10 mL), and the CH_3CN was removed under reduced pressure. The resulting purple crystalline solid was collected (160 mg, 0.3 mmol, 43% yield). **1** was chromatographed (silica gel, Davison Chemical, CH_2Cl_2, 10 cm × 1.5 cm column, 7.5% MeOH in CH_2Cl_2, 200 mL) and the solvent removed under reduced pressure. The resulting purple solid was recrystallized from CH_3CN/H_2O giving **1b**. IR (Nujol): 3667 (sharp), 3332 (br.), 3175 (br.) ν(OH)H_2O, 1680, 1599, 1578, 1542 cm^{-1} ν(CO)amide. Anal. calcd for $C_{23}H_{32}N_4FeO_7 \cdot H_2O$: C 50.19, H 6.23, N 10.18; found: C 50.33, H 6.20, N 10.18.

1a · 0.4(C_2H_5)$_2$O: Crystals of **1b** · 0.4$(C_2H_5)_2O$ were recrystallized from *tert*-butyl alcohol/ether. IR (Nujol): 3525 (sharp), 3365 (br.) ν(OH)H_2O, 1688, 1673, 1599, 1582, 1580, 1540 cm^{-1} ν(CO)amide. Crystal structure: tetragonal, space group $I4_1/a$, $a = 35.697(8)$, $c = 10.052(3)$ Å, $V = 3775(3)$ Å^3, $T = -100$ °C, $Z = 16$, $\rho_{calcd} = 1.17$ g cm^{-3}, $\rho_{obs} = 1.20(1)$ g cm^{-3}, $\mu = 5.32$ cm^{-1}; 6144 unique reflections ($2° < 2\theta < 56°$) collected using $\omega/2\theta$ scans with graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). Hydrogen atoms were located in a difference map. Methyl hydrogen atoms were refined as rigid rotors; all other hydrogen atoms, including those on the coordinated water, were refined individually. The crystal studied contained a poorly resolved diethyl ether molecule of solvation which had a purely space-filling role. Its occupancy refined to 0.40. Refinement converged with R_1 (based on F) = 0.058 for 4434 observed reflections [$I > 3\sigma(I)$]. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[12] Since the axial water ligand is hydrogen-bonded to neighboring ions in **1a**, it is not surprising that ΔE_Q of the solution sample differs slightly from that of **1a**.
[13] Mössbauer studies of polycrystalline **1b** have also revealed dimer interactions. However, these interactions are much weaker ($j \approx 3$ cm^{-1}) than those of **1a**. Calculations show that for $j \approx 3$ cm^{-1} and $D \approx 10$ cm^{-1}, μ_{eff} is independent of D and j for $T \geq 50$ K. For this reason, we have chosen **1b** rather than **1a** for the magnetization studies.

[15] While exchange coupling seems plausible, more information is needed to decide on the most appropriate description of the electronic structure. Magnetization studies above 200 K will be sensitive to the population of the putative $S = 2$ manifold for $J < 300$ cm^{-1}. While our preliminary data indicate the presence of such a state, our samples do not yet have the desired purity for presenting a convincing case.

Diastereo- and Enantioselective Synthesis of 1,2-Amino Alcohols from Glycol Aldehyde Hydrazones; Asymmetric Synthesis of (*R*,*R*)-Statin**

Dieter Enders* and Ulrich Reinhold

Dedicated to Professor Franz Dallacker on the occasion of his 70th birthday

The 1,2-amino alcohol unit **A** is found in many important natural products and drugs.[1] In this context diastereo- and enantiomerically pure amino alcohols are becoming increasingly important in the development of enzyme inhibitors. γ-Amino-β-hydroxycarboxylic acids of type **B** such as statin (R = *i*Bu), 3-amino-2-hydroxy-5-phenylpentanoic acid AHPPA (R = CH_2Ph = Bn), and cyclohexylstatin (R = $CH_2C_6H_{11}$) are important examples of peptide mimetics.[2] Statin and AHPPA are essential components of pepstatin[3] and aphatinin,[4] respec-

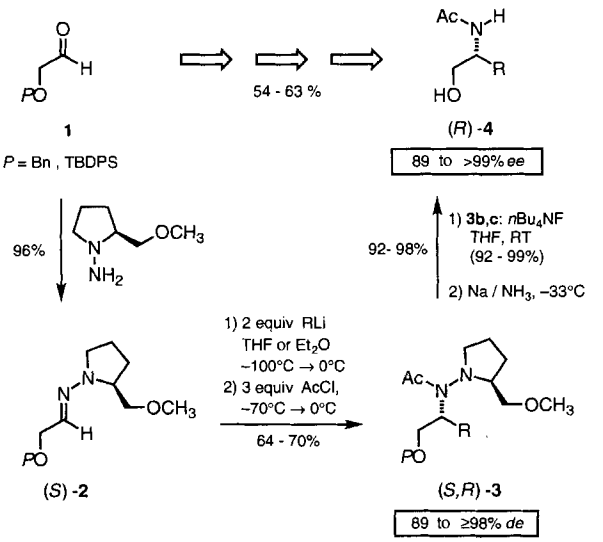
tively, both natural peptidic inhibitors of acidic proteases such as renin and HIV-1-protease.

Despite the previously known syntheses of optically active amino alcohols, in most cases from naturally occurring amino acids, there is still demand for new, efficient, flexible, and highly stereoselective methods; asymmetric synthesis, in particular, has become increasingly important recently.[1, 5, 6]

Our retrosynthetic analysis of the amino alcohol **A** leads to the 1,2-amino alcohol synthon **C**, which has a^1 reactivity with regard to the amino group and d^1 reactivity with regard to the hydroxyl function and to the corresponding nucleophile (Nu) und electrophile (El). An enantiomerically pure protected glycol aldehyde hydrazone **D** (P = protecting group) can serve as a



synthetic equivalent of **C**. In principle, aldehydes can be both electrophilically alkylated in the α-position and transformed into optically active amines by nucleophilic 1,2-addition to the C=N bond with high diastereo- and enantioselectivities by the SAMP/RAMP hydazone method.[7]

We now wish to report a C–C bond forming, flexible, *syn*-diastereo- and enantioselective synthesis of N-acetyl-protected amino alcohols **A** (R^1 = allyl, H; R^2 = alkyl, allyl, benzyl). Ozonolysis of a previously introduced alkenyl group and removal of the protecting groups opens up a new diastereo- and enantioselective approach to (*R,R*)-statin.

Starting from cheap and readily accessible benzyl- (Bn) or *tert*-butyldiphenylsilyl- (TBDPS) protected glycol aldehyde **1**, reaction with the chiral auxiliary (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP)[7a–e] yields the corresponding SAMP hydrazones (*S*)-**2** (Scheme 1). These are treated with two equivalents of an organolithium reagent at low temperature, and the lithium hydrazide formed was trapped with three equivalents of acetyl chloride.[8] After aqueous workup and purification by chromatography the N-acetyl-protected hydrazides (*S,R*)-**3** are obtained in good yields (64–70%) and with high to very high diastereomeric excesses (89–≥98% *de*; Table 1).[20] The silyl-protected acetyl hydrazides **3b** and **3c** are desilylated with tetra-*n*-butylammonium fluoride prior to cleavage of the N–N bond.[9] Reductive N–N bond cleavage with concomitant removal of the benzyl protecting group of (*S,R*)-**3a** is carried out with sodium in ammonia.[7h, 10] N-Acetyl-protected amino alcohols (*R*)-**4** are obtained without racemization after column chromatography in good yields (92–98%) and with high enantioselectivities (89 to >99% *ee*; Table 1).[20]

Enantiomeric excesses were determined by gas chromatography (GC) with chiral stationary phases (CSP) and by ^{1}H NMR shift experiments.[11] The chiral amine auxiliary (*S*)-2-methoxymethylpyrrolidine (SMP) can be recovered.[12] In a repre-

Scheme 1. Enantioselective synthesis of *N*-acetyl-1,2-amino alcohols (*R*)-**4**. RT = room temperature.

[a] THF was used as solvent for **2a,b**, diethyl ether for **2c**. [b] *de* Values were determined by gas chromatography for **3a** (SE-30, FID), and by ^{13}C NMR spectroscopy for **3b,c**. [c] Based on GC analysis with a chiral stationary phase and NMR shift experiments [11]. [d] Values in parentheses for yields after separation of the diastereomers of **3a** (SiO_2, diethyl ether/petroleum ether 1:1). [e] Optical rotation of the enantiomerically pure compound **4a**. [f] Determined by comparison of the optical rotation with the literature data [13].

sentative example, (*S,R*)-**3a** was obtained diastereomerically pure (>99% *de*) by column chromatography and converted to the enantiomerically pure protected 1,2-amino alcohols (*R*)-**4a** (>99% *ee*). The absolute configurations of **4a** and **4b** were determined by comparing their optical rotations to literature data.[10] The total yield (**1** → (*R*)-**4**) over three or four steps is 54–63%.

Scheme 2 shows the successive introduction of two vicinal stereogenic centers starting from benzyl-protected glycol aldehyde **1a** by α-alkylation and 1,2-addition to afford the amino alcohols (*R,R*)-**7**. The known α-alkylation of **1a** provides (*R,S*)-**5** in very good yield (81%, two steps) and with high asymmetric inductions (86–88% *de*) with (*S*)-1-amino-2-(1-methyl-1-methoxyethyl)pyrrolidine (SADP)[14] as chiral auxiliary.[7e] The SADP hydrazone (*S,R*)-**5** is subsequently treated with five equivalents of Grignard reagent in toluene[15] and then acetyl chloride to give the *syn*-configurated *N*-acetyl hydrazides (*S,R,R*)-**6** in 78–87% yield (Table 2)[20]. The diastereoselectivities achieved with regard to the newly generated stereogenic center are greater than 98%. In addition to the directing effect of the chiral hydrazone function, this very high induction can be explained by the influence of the α-stereogenic center, which should favor the same configuration according to the chelation model.[7g–i] Hydrazide **6b** (R = Bn) is obtained with ≥98% *de* after simple purification by column chromatography. After N–N bond cleavage and simultaneous removal of the benzyl protecting group with Na/NH_3, the functionalized N-protected

[a] Determined by ^{13}C NMR spectroscopy. [b] Contained 3–11% impurites (NMR, GC) after purification by column chromatography due to reduction of the allyic residue and Birch reduction of the aromatic ring. [c] Determined by ^1H NMR spectroscopy after esterification with (*S*)- or (*R*)-α-methoxy-α-trifluoromethylphenylacetic acid (MTPA) [16]. [d] Determined by comparison of the optical rotation of **9** with literature data [19] and on the basis of earlier α-alkylations and 1,2-additions with SAMP or SADP hydrazones [7e,f]. [e] After flash column chromatography (SiO_2, diethyl ether). [f] After purification by column chromatography (SiO_2, diethyl ether, petroleum ether 1:3).

The 1,2-amino alcohols (*R,R*)-**7**, accessible in four steps with yields of 46–56%, are precursors of (*R,R*)-statin (R = *i*Bu), AHPPA (R = Bn), and cyclohexylstatin (R = $CH_2C_6H_{11}$). The *N*-acetyl amino alcohol (*R,R*)-**7a** can be transformed to the methyl ester (*R,R*)-**8** by oxidative cleavage of the C=C bond with ozone in basic methanol/dichloromethane in good yield (71%) without racemization.[17] The acid hydrolysis of the methyl ester and the acetamide function proceeds at 100 °C in 6N aqueous hydrochloric acid within one hour quantitatively, yielding statin hydrochloride (*R,R*)-**9**·HCl. After ion exchange chromatography free (*R,R*)-statin (**9**) is obtained in a total yield of 38% over six steps[18] (Scheme 3).

Compounds **6**–**9** are assigned the (*R,R*) configuration by comparison of the optical rotation of the synthesized statin with literature data,[19] given the (*R*) configuration in the α-alkylation[7e] and assuming a uniform reaction course. The natural *syn*-(*S,S*)-statin is analogously accessible by the use of the auxiliary (*R*)-1-amino-2-(1-methoxy-1-methylethyl)pyrrolidine (RADP)[14] instead of SADP.

The method described here opens up a new *syn*-diastereo- and enantioselective route to N-acetyl-protected functionalized vicinal amino alcohols. The particular advantage is the high flexibility through variation of the nucleophilic and the electrophilic component. As was shown for statin and its analogues, this procedure should facilitate the asymmetric synthesis of a multitude of optically active 1,2-amino alcohols in the scope of natural product and drug synthesis.

Scheme 3. Diastereo- and enantioselective synthesis of (*R,R*)-statin (**9**).

Experimental Procedure

(*S,R*)-**3**: To a solution of 10 mmol of hydrazone (*S*)-**2** in 40 mL of THF (Et_2O for R = allyl) was added dropwise 20 mmol of the organolithium solution at −100 °C (for R = Me, −70 °C) with stirring. The solution was allowed to warm to 0 °C over 12 h. The solution was then cooled to −70 °C, 30 mmol of AcCl was added, and the mixture was stirred for 1 h at this temperature and for a further 0.5–2 h at 0 °C. It is advisable to monitor the reaction by thin-layer chromatography to avoid reduced yields. For hydrolysis 80 mL of saturated $NaHCO_3$ solution was added and the reaction mixture extracted three times with ether. The combined extracts were dried over $MgSO_4$ and the ether was removed in vacuo. After purification of the yellow-brown crude products by flash column chromatography (SiO_2, diethyl ether/petroleum ether 1:1 to 1:2), colorless or pale yellow liquids were obtained.

(*S,R,R*)-**6**: To a solution of 10 mmol of hydrazone (*S,R*)-**5** in 500 mL of toluene under argon was added dropwise at −40 °C with stirring 50 mmol of RMgBr (2N in diethyl ether). This solution was then allowed to warm to room temperature over 12 h. THF (100 mL) was added, the solution was cooled to −30 °C, and then 75 mmol of AcCl was added dropwise. The solution was warmed to room temperature over 2 h and then stirred for a further 2 h (tlc control). Finally workup was carried out as above to afford, after column chromatography (SiO_2, diethyl ether/petroleum ether 1:3 to 1:4), colorless to pale yellow liquids. **6b** precipitated as a colorless crystalline solid.

(*R*)-**4** and (*R,R*)-**7**: To 25 mL of liquid ammonia at −70 °C was added dropwise a solution of 1 mmol of acetyl hydrazide **3a** and **6** (**3b** and **3c** were previously desilylated with 1.5 equiv *n*-Bu_4NF in THF at room temperature) in 6 mL of THF, and then 10 mmol of Na was added. The solution was warmed to reflux (−33 °C). Upon complete consumption of starting material (tlc control) 1.5 g of NH_4Cl was added. The ammonia was evaporated, and the solid residue was extracted three times with 30 mL of dichloromethane. The combined extracts were filtered, and the solvent was removed in vacuo. Purification by flash column chromatography (SiO_2, diethyl ether or diethyl ether/MeOH 6:1 to 15:1) afforded either a colorless liquid or solid.

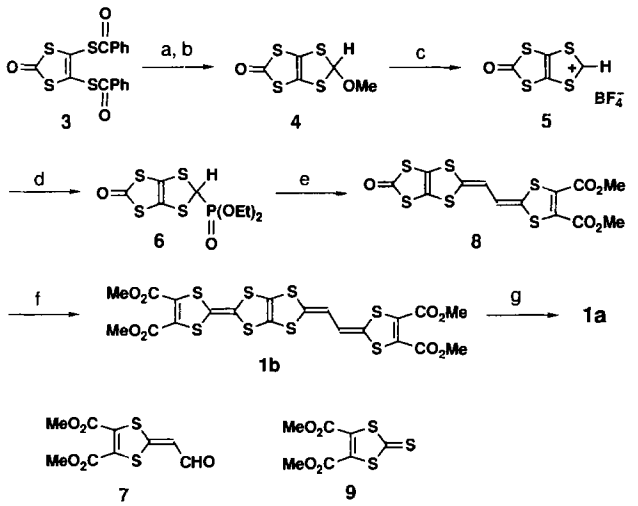
(DTEDT)[Au(CN)$_2$]$_{0.4}$: An Organic Superconductor Based on the Novel π-Electron Framework of Vinylogous Bis-Fused Tetrathiafulvalene**

Yohji Misaki,* Natsuko Higuchi, Hideki Fujiwara, Tokio Yamabe,* Takehiko Mori,* Hatsumi Mori,* and Shoji Tanaka

Highly conducting and superconducting organic solids have attracted much attention in the fields of organic chemistry, physical chemistry, and solid-state physics, amongst others.[1] The most appropriate strategy to stabilize the metallic state down to low temperature and to reach the superconducting transition has been thought to be the formation of a two-dimensional (2D) electronic structure, which is usually attained by use of TTF with "capped" dichalcogeno groups, such as bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF).[1, 2] We have now found that a bis-fused TTF, 2,5-bis(1,3-dithiol-2-ylidene)-1,3,4,6-tetrathiapentalene (BDT-TTP),[3] tends to produce 2D "metals" without such substituents.[4] The extended π-conjgation systems of BDT-TTP (bis-fused donors containing extended TTFs[5, 6]), which have received much attention recently, are of considerable interest in the search for new donors for organic superconductors. We report herein the synthesis of the first vinylogous BDT-TTP, DTEDT, **1a**, which contains one 2,2′-ethanediylidenebis(1,3-dithiole) (**2**).[6] Furthermore, we have found that the present donor produces a superconducting Au(CN)$_2$ salt, as well as many metallic cation radical salts stable to liquid helium temperature.

BDT-TTP

DTEDT **1a**



The synthesis of DTEDT was achieved as shown in Scheme 1. Treatment of 1,3-dithiol-2-one **3** with sodium methoxide, and then with α,α-dichloromethyl methyl ether afforded **4**. This one-pot reaction was carried out in acetone to avoid reaction of α,α-dichloromethyl methyl ether with usual solvent (methanol). The reaction of **4** with aqueous hydrofluoroboric acid gave the corresponding 1,3-dithiolium salt **5**, which was converted to a phosphonate **6** by treatment with triethylphosphite in the presence of sodium iodide. The compound **6** was allowed to react with lithium diisopropylamide in the presence of 2-formylmethylidene-4,5-bis(methoxycarbonyl)-1,3-dithiole (**7**)[6a] to give **8**. The cross-coupling reaction between **8** and 4,5-bis(methoxy-

[**] This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area "Molecular Conductors" (No. 06243215) from the Ministry of Education, Science, and Culture of Japan. DTEDT = 2-(1,3-dithiol-2-ylidene)-5-(2-ethanediylidene-1,3-dithiole)-1,3,4,6-tetrathiapentalene, TTF = tetrathiafulvene.

Scheme 1. a) NaOMe (2 equiv), acetone, room temperature, 30 min; b) Cl_2CHOMe (2 equiv), 30 min (59%), c) 42% aqueous HBF_4 (2 equiv), CH_2Cl_2/Ac_2O (4/1), 0 °C, 30 min (92%); d) $P(OEt)_3$ (2 equiv), NaI (2 equiv), acetone, room temperature, 12 h (83%); e) LDA (1 equiv), **7** (1 equiv), THF, −78 °C, 20 min (57%); f) **9** (2 equiv), $P(OMe)_3$ (100 equiv), toluene, 110 °C, 2 h (76%); g) $LiBr \cdot H_2O$ (20 equiv), HMPA, 90 °C, 1 h, 130 °C, 30 min (88%).

carbonyl)-1,3-dithiole-2-thione (**9**) with a large excess of trimethylphosphite afforded the tetrakis(methoxycarbonyl) derivative **1b**. The target molecule **1a** was obtained by heating **1b** with an excess of $LiBr \cdot H_2O$ in HMPA. DTEDT forms as yellow orange stable microcrystals,[7] which are less soluble in organic solvents than BEDT-TTF and BDT-TTP.

The cyclic voltammograms of **1a, b** exhibit four pairs of single-electron redox waves at +0.37, +0.50, +0.81, and +1.05 V (vs. SCE, in PhCN at 25 °C) for **1a**, and +0.56, +0.70, +1.07, and +1.30 V for **1b**. The E_1 value of **1a** is 0.07 V lower than that of BDT-TTP (+0.44 V)[3b] measured under the identical conditions. However, it is 0.08 V higher than that of **2** (+0.29 V) and is comparable to that of TTF (+0.35 V). The donor ability thus becomes weaker in spite of the apparent extension of the π-conjugation, as is also the case for BDT-TTP. On the other hand, $E_2 - E_1$ value (0.13 V) is smaller than those of BDT-TTP (0.18 V), TTF (0.42 V), and **2** (0.20 V), which suggests that the Coulomb repulsion has decreased in the dication.

The MNDO molecular orbital calculations of DTEDT revealed that in the highest occupied molecular orbital (HOMO) the phases of the sulfur atoms in the terminal vinylogous 1,3-dithiole ring are reversed with respect to the other sulfur atoms (Fig. 1).[8] This feature together with the crooked structure of DTEDT is anticipated to diminish the effectiveness of the transverse interaction both sterically and electronically in the charge transfer salts relative to the strip-like BDT-TTP in which all sulfur atoms have the same phase.[9]

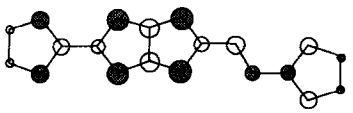

Fig. 1. The highest occupied molecular orbital (HOMO) of DTEDT (**1a**).

Cation radical salts of DTEDT were prepared by electrochemical oxidation in the presence of the corresponding tetra-*n*-butylammonium salts under a constant current of 0.3–1 $\mu A\,cm^{-2}$ in chlorobenzene or 1,1,2-trichloroethane at 50 °C. The I_3 salt was obtained by using the diffusion technique with n-Bu_4NI_3 in chlorobenzene at 50 °C. Table 1 shows their electrical properties measured by the four-probe technique on single crystals. Surprisingly, most of the salts obtained so far show metallic conducting behavior down to low temperature (1.4–4.2 K) regardless of the counteranion. Figure 2 shows conducting behavior of the $Au(CN)_2$ salt. It shows an abrupt drop of resistivity at 4 K, which is characteristic of the onset of the superconducting transition. However, the resistivity remained nonzero even at 2 K probably because of non-superconducting domains in the crystal. The superconductivity was also confirmed by magnetic susceptibility measurements with a SQUID susceptometer (Fig. 3). The diamagnetic shielding at 2 K amounts to 10% of the perfect diamagnetism, suggesting bulk superconductivity. Both zero-field cooled data (ZFC) and field cooled data (FC) start to decrease at 4 K, which agrees with the transition temperature obtained from the resistivity measurement.

Table 1. Composition and electrical conductivity of DTEDT salts (DTEDT · A_x).

Anion A	x[a]	σ[$S\,cm^{-1}$][b]	Behavior
ClO_4	0.67(Cl)	830	metallic[c]
BF_4	–[d]	540	metallic[c]
ReO_4	0.39(Re)	900	metallic ≥1.4 K
$GaCl_4$	0.48(Ga)	50	metallic ≥1.4 K
PF_6	0.39(P)	170	metallic ≥4.2 K
AsF_6	0.54(As)	90	metallic ≥1.4 K
SbF_6	0.57(Sb), 0.33[e]	80	metallic ≥1.4 K
I_3	0.34(I)	670	metallic ≥1.4 K
$Au(CN)_2$	0.39(Au), 0.4[e]	15	T_c = 4 K[f]

[a] Determined by the energy dispersion spectroscopy (EDS) from the ratio of sulfur and the elements designated in the parentheses. [b] Conductivity at room temperature measured by four-probe technique on a single crystal. [c] The resistivity increases a little at low temperatures, but the compound is essentially metallic down to 1.4 K. [d] The content of light elements such as B and F were not reliably determined by EDS. [e] Determined from X-ray structure analysis. [f] T_c designates critical temperature of superconducting transition.

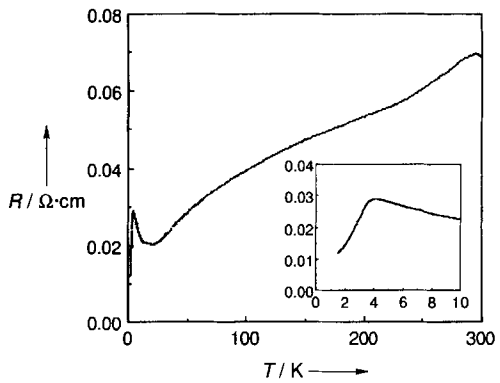

Fig. 2. Temperature dependence of resistivity of $(DTEDT)[Au(CN)_2]_{0.4}$. The inset shows the resistivity in the range of 1.4–10 K.

The crystal structure of this $Au(CN)_2$ salt was determined by X-ray structure analysis.[10] The donors form conducting sheets parallel to the *ac* plane (Fig. 4). They are stacked face-to-face, with ring-over-bond type overlap (Fig. 5). Because the present salt crystallizes in space group $P\bar{1}$ and there is only one DTEDT molecule in the unit cell, the donors are arranged in such a way that the stacking and transverse directions are parallel. Since DTEDT has a crooked structure and the phase of the sulfur atoms in the HOMO is reversed at the terminal vinylogous 1,3-dithiole, such a parallel arrangement results in the most

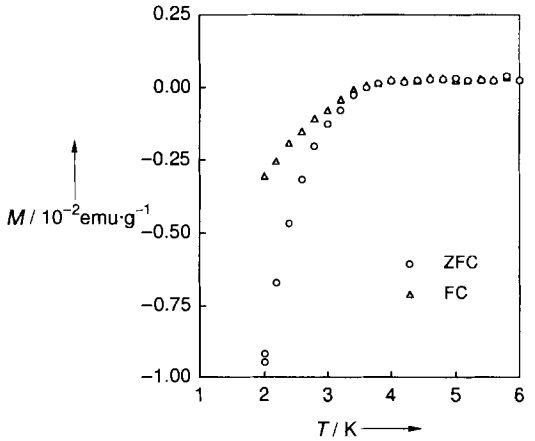

Fig. 3. Temperature dependence of magnetization at an applied magnetic field of 2 mT.

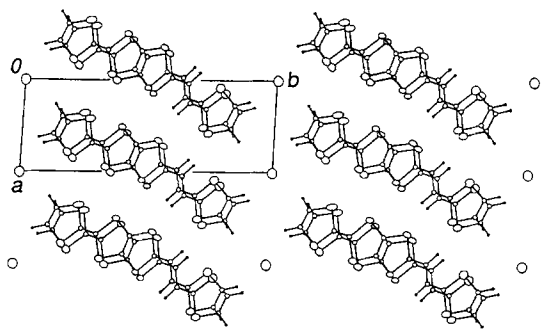

Fig. 4. Crystal structure of (DTEDT)$[Au(CN)_2]_{0.4}$. Projection onto the *ab* plane.

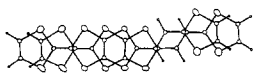

Fig. 5. Projection onto the plane of the molecule showing ring-over-bond type overlap of the donor molecules in (DTEDT)$[Au(CN)_2]_{0.4}$.

effective intermolecular interaction both sterically and electronically. Population analysis indicates that the ratio of DTEDT to $Au(CN)_2$ is 1:0.4. The linear anion, $Au(CN)_2$, is aligned along the *c* axis, and exists in every other unit cell with 80% population. This is in good agreement with the result of energy dispersion spectroscopy (D:A = 1:0.39). The arrangement of donors resembles that of β-(BEDT-TTF)$_2$X (X = I_3, IBr_2, AuI_2 etc.) (Fig. 6).[2] However, the donors form completely uniform stacks in (DTEDT)$[Au(CN)_2]_{0.4}$, whereas they exist as dimers in β-type BEDT-TTF salts. The interplanar distances is 3.51 Å. Such a uniform β-type arrangement of donors is also observed in (BDT-TTP)$_2$X (X = ClO_4, SbF_6)[4] and (DTEDT)$_3SbF_6$.[11]

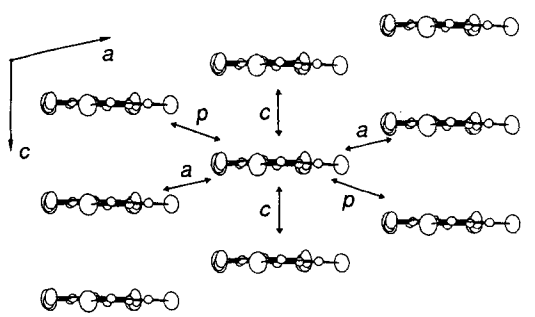

Fig. 6. Donor sheet structure of (DTEDT)$[Au(CN)_2]_{0.4}$.

The fact that both the SbF_6 and $Au(CN)_2$ salts have isostructural 2D arrays of donors regardless of the counteranions indicates that DTEDT has a strong tendency to form a 2D array in spite of its unsymmetrical and crooked structures.

The band structure calculated by the tight-binding method is shown in Figure 7. A fairly large overlap in the stack ($c = -18.3 \times 10^{-3}$) corresponds to a large bandwidth of 0.9 eV. On the other hand, the interstack overlap is about one third of the intrastack interaction. Such a comparatively large interstack interaction gives a closed Fermi surface, although one-dimensional character along the stacking direction is dominant.

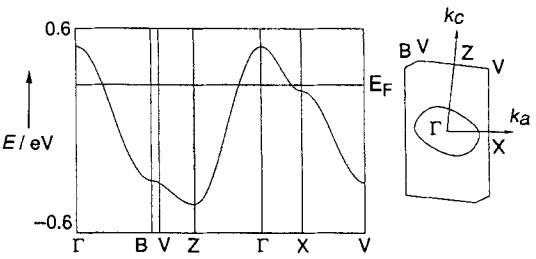

Fig. 7. Energy band structure and Fermi surface of (DTEDT)$[Au(CN)_2]_{0.4}$. The intermolecular overlap integrals are $a = -1.5$, $c = -18.3$, $p = -5.0 \times 10^{-3}$ (see also Fig. 6). E_F = Fermi energy.

In conclusion, we have synthesized an organic superconductor using a novel π-electron framework. DTEDT is the first vinylogous component for organic superconductors; however, the role of vinylogous TTF moiety is not clear at the present time. The further investigations on physical properties of the salt are in progress.

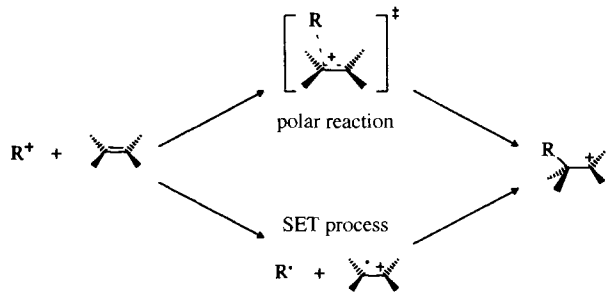
Reactions of Carbocations with π Nucleophiles: Polar Mechanism and No Outer Sphere Electron Transfer**

Matthias Patz, Herbert Mayr,* Junichi Maruta, and Shunichi Fukuzumi*



Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

The importance of electron transfer processes has been recognized in many areas of organic chemistry. Numerous reactions, previously described by "movements of electron pairs" by the familiar "curved-arrow" mechanisms are now understood as processes, in which an initial electron transfer step produces a pair of radical ions, which successively react with formation of a new bond.[1]

Consequently, for the reactions of cationic electrophiles R^+ with neutral π nucleophiles two different mechanisms have to be considered. In the polar mechanism depicted in the upper route of Scheme 1, the carbocation approaches the π system of the nucleophile, and the charge transfer is associated with the formation of the new carbon–carbon σ bond. In the alternative outer sphere electron transfer mechanism at the bottom of Scheme 1, rate-determining electron transfer (single electron transfer, SET) produces a radical and a radical cation which may combine to give the same cation produced by the polar reaction.

Scheme 1. Polar (top) and electron transfer mechanism (bottom) of the reaction of cationic electrophiles R^+ with neutral π nucleophiles.

Both mechanisms do not necessarily give identical products, however. As expected from their reactivity parameters,[2] isobutene and the *N*-methylacridinium ion **1** do not react by a polar mechanism at room temperature (estimated rate constant from Equation (1), $k_2 = 2 \times 10^{-7}$ L $mol^{-1} s^{-1}$). When the electron transfer was induced photochemically, the anti Markovnikov product **2** was produced exclusively, while the product expected from a polar mechanism (**3**) could not be detected.[3] The fact that only Markovnikov adducts have been observed in a manifold of reactions of carbenium ions with alkenes[4] thus provides a hint against the operation of electron transfer processes. We now confirm this suspicion on the basis of linear free energy relationships.

Two of us (H. M. and M. P.) recently demonstrated that the rates of reactions of cationic electrophiles with uncharged nucleophiles can be described by Equation 1 which relates the second-order rate constants with the nucleophile-specific constants *s* and *N* and with the electrophilicity parameter *E*.[2]

$$\lg k = s\,(E + N) \qquad (1)$$

There is a rough correlation between the one-electron oxidation potentials of a variety of π nucleophiles[5] and their nucleophilicity parameters *N*[2] (Table 1; Fig. 1), where the *N* value increases with a decrease in E_{ox} [Eq. (2); correlation coefficient r = 0.89; standard deviation of *N*, s_N = 1.6; number of data, n = 20].

$$N = -8.0\,E_{ox} + 14.2 \qquad (2)$$

As shown in Figure 2, the reduction potentials E_{red} (vs. saturated calomel electrode (SCE) in acetonitrile) of a variety of cations correlate fairly well with their electrophilicity parameters *E* [Eq. (3); correlation coefficient r = 0.98; standard deviation of *E*, s_E = 1.7; number of data, n = 7].

$$E = 12.1\,E_{red} - 0.6 \qquad (3)$$

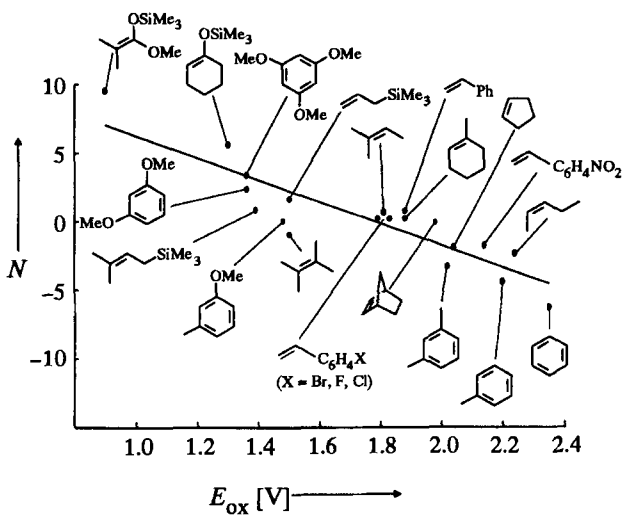

Fig. 1. Correlation between the one-electron oxidation potentials of π nucleophiles and the nucleophilicity parameter N.

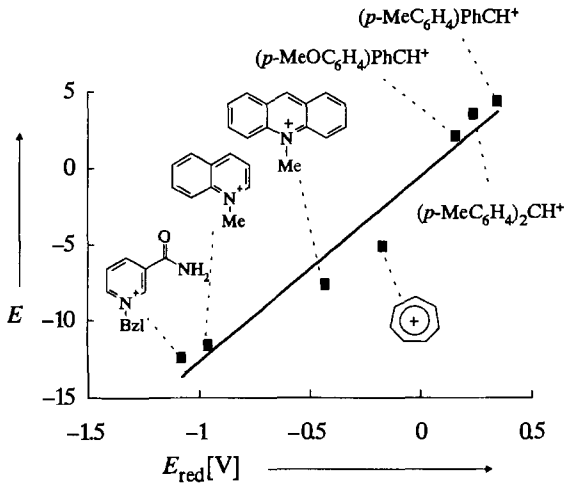

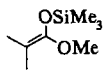

Fig. 2. Correlation between the reduction potentials [7] of electrophiles and the electrophilicity parameters E.

As a consequence of Equations 1 and 3, there is also a linear correlation between the activation-controlled electrophilic reactivities of carbocations and their reduction potentials as shown for the reactions with the silylketene acetal **4** in Figure 3 (left-curve ■).

One of us (S. F.) recently studied the kinetics of electron transfer processes from electron-rich π systems to one-electron oxidants.[6] The rate constants reported for the reactions of one-electron oxidants with the silylketene acetal **4** are considerably smaller (Fig. 3, right curve ▲) than the rate constants of the reactions of **4** with electron-pair acceptors of the same reduction potential (Fig. 3, left curve ■). The existence of two discrete correlations in Figure 3 thus provides an argument that two different mechanisms have to operate for the electron-pair acceptors on the left side and the one-electron oxidants on the right. Thus, an outer sphere electron transfer process cannot

4

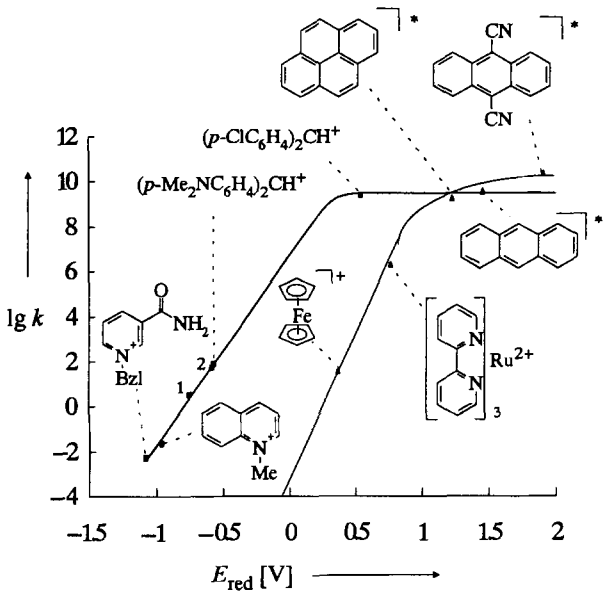

Fig. 3. Relationship between the rate constants of the reactions of various electron-pair acceptors (■) and one-electron oxidants (▲) with the silylketene acetal **4** (data from refs. [2, 6]). Points 1 and 2 correspond to pyronin G and the acridinium ion. E_{red} calculated from Equation 3 if not known experimentally.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1226 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 11

account for the rate constants observed for the reactions of the electron-pair acceptors, and the higher reactivity (10 orders of magnitude!) of the oxidants corresponding to the left graph is most readily explained by a mechanism in which electron transfer is accompanied by the formation of a new σ bond. It can alternatively be called an inner sphere electron transfer process or a polar mechanism.

A similar conclusion can be derived for the reactions with other π nucleophiles. The actual rate constant for the reaction of an electrophile with a nucleophile is given by Equation (4), which follows from Equations (1)–(3).

$$\lg k_{\text{polar}} = s\,(13.6 + 12.1E_{\text{red}} - 8.0\,E_{\text{ox}}) \quad (4)$$

Since ΔG^0 of the electron transfer step is given by Equation (5) and $\Delta G^{\neq} \geq \Delta G^0$, one can derive the maximum rate of the electron transfer processes from Equation 6,[8] which follows from Equation (5) and the Eyring equation.

$$\Delta G^0 = F\,(E_{\text{ox}} - E_{\text{red}}) \quad (5)$$

$$\lg k_{\text{ET}} \leq \lg(k_{\text{B}}T/h) - F(E_{\text{ox}} - E_{\text{red}})/(2.303\,RT) = 12.8 - 17.2\,E_{\text{ox}} + 17.2\,E_{\text{Red}} \quad \text{(at 20 °C)} \quad (6)$$

Subtraction of Equation 6 from Equation 4 yields $\lg k_{\text{polar}} - \lg k_{\text{ET}}$, that is, the ratio between the actual rate constant for the electrophile–nucleophile combinations and the maximum rate constant for the outer sphere electron transfer process under the condition that none of these reactions is diffusion controlled.

If we assume $s = 1.1$, the typical value for the nucleophiles shown in Figure 1, $\lg k_{\text{polar}} - \lg k_{\text{ET}}$ is given by Equation 7.

$$\lg k_{\text{polar}} - \lg k_{\text{ET}} \geq 2.2 + 8.4\,E_{\text{ox}} - 3.9\,E_{\text{red}} \quad (7)$$

According to Equation 7 the minimum value of $\lg k_{\text{polar}} - \lg k_{\text{ET}}$ is 8.2 for the electrophile–nucleophile combinations employed in this study ($E_{\text{ox}} \geq 0.9$ V, $E_{\text{red}} \leq 0.4$ V). Thus, the actual rates of the reactions of cationic carbon electrophiles with uncharged π nucleophiles are at least 10^8 times greater than the maximum rates calculated for the electron transfer processes.[9]

Apart from cases, where the rate of the polar reaction is reduced by steric effects, there are two situations in which an outer sphere electron transfer process may compete with the polar reaction. Such a case may be encountered with ethylenes substituted by strong donor groups in positions 1 *and* 2 or with arenes substituted by strong donors in *o*- or *p*-position. In these systems only one of the donors can stabilize the carbenium ion produced in the polar reaction and thus accelerate the polar reaction, while both donor groups will reduce the oxidation potential and thus increase the rate of the electron transfer process. The second case is indicated in Figure 3: Since the diffusion limit for electron transfer processes is found to be higher than for polar reactions, systems where $E_{\text{ox}} - E_{\text{red}}$ is smaller than -0.2 V can also be expected to proceed by SET processes.

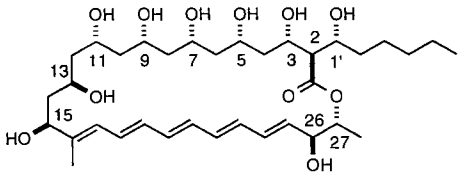
[8] Because of the small reorganization energies, the actual values of k_{ET} will only be slightly smaller than the maximal values used for our calculations.

[9] A similar method has been employed to differentiate electron transfer and classical S_N2 mechanisms for the reactions of anionic nucleophiles with alkyl halides by comparing observed rate constants and those expected for the electron transfer process: a) T. Lund, H. Lund, *Acta Chem. Scand. B* **1986**, *40*, 470–485; b) *Tetrahedron Lett.* **1986**, *27*, 95–98; c) *Acta Chem. Scand. B*, **1988**, *42*, 269–279.

Relative and Absolute Configuration of Filipin III**



Scott D. Rychnovsky* and Timothy I. Richardson

Filipin belongs to a class of natural products known as the polyene macrolide antibiotics. There are over 200 known representatives of this class, most of which are produced by soil actinomycetes belonging to the genus *Streptomyces*.[1] Although structural formulas for many polyene macrolides are known, the complete stereochemical assignments have been made in only a handful of cases.[2] In cell biology, filipin has become a popular probe for cholesterol and has even been used to quantitate cholesterol in cell membranes.[3] Filipin complex is also used in the study and clinical diagnosis of Type C Niemann-Pick disease.[4] More recently, the use of filipin as a probe for cholesterol has been questioned.[5] The development of detailed models for the interaction of cholesterol with filipin has not been possible because, until now, the configuration of filipin III was unknown. We report herein the complete absolute stereochemical assignment of filipin III (**1**, Scheme 1).

1

Scheme 1. Configuration of natural filipin III (**1**).

Filipin was isolated in 1955 from *Streptomyces filipinensis* found in a sample of Philippine soil.[6] Much later filipin was shown to be a mixture of four components—filipin I (4%), II (25%), III (53%), and IV (18%).[7] The connectivity of filipin III, the major component of the filipin complex, was assigned in a series of degradation studies.[8] Filipin I, which has been difficult to characterize, is probably a mixture of several components having two hydroxyl groups fewer than filipin III.[9] Filipin II is 1′-deoxy-filipin III.[9-10] Filipin IV is isomeric to filipin III and is probably epimeric at C1′ or C3.[11]

We have shown that *syn* and *anti* 1,3-diols can be easily distinguished by ^{13}C NMR analysis of the corresponding acetonides: the *syn* isomers have methyl resonances at $\delta \approx 20$ and 30, whereas the *anti* isomers have methyl resonances at $\delta \approx 25$ ppm.[12] This analysis was used to determine the relative configuration of filipin III. Initial attempts to prepare an acetonide derivative of filipin III with *p*-toluenesulfonic acid showed that the molecule is acid sensitive. Treatment of filipin complex[13] (Sigma) with the mild acid catalyst, pyridinium *p*-toluenesulfonate (PPTS), in a 2:1 mixture of acetone and 2,2-dimethoxypropane (DMP), followed by silica gel chromatography gave tetraacetonide **2** in 6% yield and a mixture of triacetonides in 31% yield (Scheme 2, Table 1). A highly purified sample of filipin III gave the same mixture of products when subjected to the reaction conditions, confirming that these derivatives arise from the major component of the complex. The mixture of triacetonides was acetylated and separated to give triacetonide **3** in 64% yield and triacetonide **4** in 19% yield. The structures of triacetonides **3** and **4**, including the positions of the acetyl groups, were established with ^1H NMR and COSY data.[14] The acetylation of the hydroxyl groups was carried out with 50% enriched 1,3-$^{13}C_2$-acetone to simplify detection and identification of the acetonide methyl signals in the ^{13}C NMR spectra.

Scheme 2. Preparation of filipin III acetonide derivatives **2**–**4**. DMAP = 4-dimethylaminopyridine.

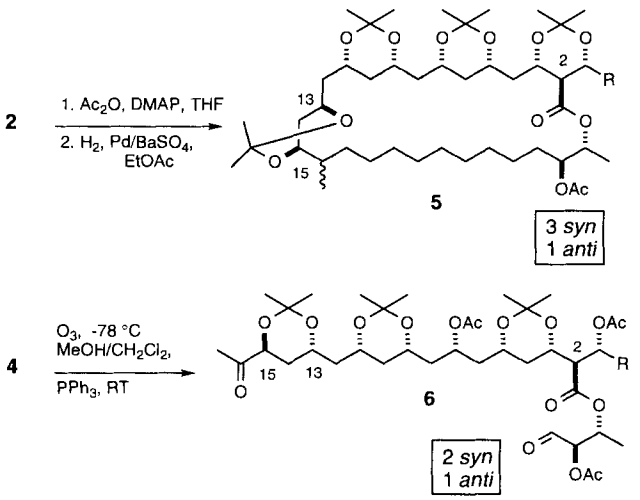
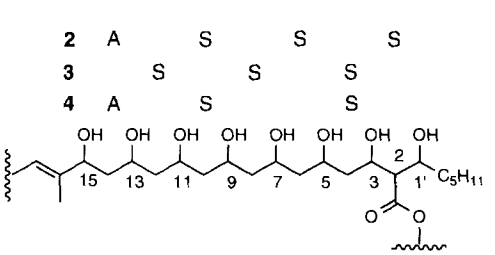
[a] The NMR and MS data are reported for samples with natural ^{13}C abundance.



The signals in the ^{13}C NMR spectrum of tetraacetonide **2** at $\delta = 31.00, 30.65, 30.50, 30.13, 24.82, 19.97$, and 19.54 (×2) were assigned to methyl groups of three *syn* acetonide groups and one further acetonide group with methyl peaks at $\delta \approx 30$ and 24.82. The ^{13}C NMR spectrum of triacetonide **3** showed methyl resonances at $\delta = 30.76, 30.70, 30.02, 19.93, 19.82$, and 19.41 that correspond to three *syn* acetonide groups. The methyl resonances in the ^{13}C NMR spectrum of triacetonide **4** at $\delta = 30.46, 30.15, 30.05, 24.74, 19.03$, and 18.97 belong to two *syn* acetonide groups and an additional acetonide group with methyl peaks at $\delta \approx 30$ and 24.74. The acetonide rings from the compounds **2**, **3**, and **4** span all the potential 1,3-diol relationships in the C1′ to C15 segment of filipin III.

Both compounds **2** and **4** show a very unusual set of methyl peaks for one of the acetonide rings. Over 200 acetonide rings were analyzed in a previous paper, and none of them showed a pair of methyl peaks at these positions.[12c] One compound that shows similar ^{13}C chemical shifts for the acetonide methyl groups is 2,2,4,4,6-pentamethyl-1,3-dioxane. This heterocycle is known to adopt a chair conformation because of the quaternary center at C4, and the chemical shift of the C2 axial methyl group is $\delta = 24.93$ and that of the C2 equatorial methyl group 32.04.[15] These are very close to the observed values in compounds **2** ($\delta \approx 30$ and 24.82) and **4** ($\delta \approx 30$ and 24.74). The signal at $\delta \approx 24$ is characteristic of an axial acetonide methyl group that has another axial substituent at the C4 or C6 atom, and can best be attributed to an *anti* acetonide that adopts a chair conformation. Apparently the macrocyclic ring of **2** and **4** biases the *anti* 1,3-diol acetonide group to adopt a chair conformation rather than the more stable twist-boat conformation. The chair conformation, although still energetically

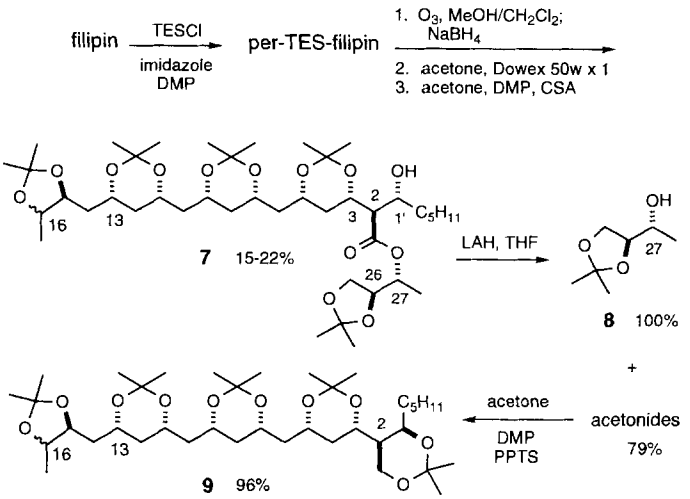
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1228 $ 10.00+.25/0



unfavorable, is more accessible for an alkene-substituted acetonide than for an alkyl-substituted acetonide,[16] and so the most likely position of the *anti* acetonide is at C13–C15.

To test this hypothesis we degraded compounds **2** and **4** as shown in Scheme 3. Acetylation, followed by hydrogenation of **2** gave the saturated macrocycle **5**, which showed methyl signals

Scheme 3. Preparation of compounds **5** and **6**. These compounds are instrumental in confirming the C13–C15 position of the *anti* acetonide ring in derivatives **2** and **4**. RT = room temperature.



at $\delta = 30.75$, 30.69, 30.14, 25.69, 24.78, 19.95 ($\times 2$), and 19.45 in the ^{13}C NMR spectrum. The new methyl peaks at $\delta = 25.69$ and 24.78 fall in the expected range for a saturated *anti* acetonide. Triacetonide **4** was ozonized and reduced with triphenylphosphane to give a 43% yield of triacetonide **6**, whose methyl groups resonate at $\delta = 30.50$, 30.30, 25.94, 24.32, 19.57 and 19.29. The new methyl peaks at $\delta = 25.94$ and 24.32 clearly represent an *anti* 1,3-diol acetonide. More significantly, the difference $\Delta\delta = 1.62$ between the two peaks is larger than one would expect for a saturated *anti* 1,3-diol acetonide but is in line with an acyl-substituted *anti* acetonide.[12c] Thus the *anti* acetonide ring in both **2** and **4** is located at C13–C15, and the relative configurations for the other alcohol stereogenic centers in the C1′ to C15 section are as shown in Scheme 4.

Scheme 4. The relative configuration of filipin III in the C1′–C15 section. The relative stereochemistry at each acetonide position is listed as either S (*syn*) or A (*anti*) for compounds **2**–**4**.

The acetonide ring at C1′–C3 adopts a chair conformation in tetraacetonide **2**. The signal of the C2 proton in the ^1H NMR spectrum of tetraacetonide **2** is a triplet with a coupling constant of 10.1 Hz. This coupling constant is only consistent with an equatorial ester; therefore the configuration at C2 is *anti* with respect to C1′ and C3.

The configuration of filipin III at the C26 and C27 stereogenic centers was determined by another degradation sequence (Scheme 5). Per-TES-filipin prepared from filipin complex (Upjohn or Sigma) was ozonized and then reduced with $NaBH_4$.

Scheme 5. Degradation of filipin to determine the absolute configuration of filipin III. Advanced Mosher analysis of **7** identified the absolute configuration at C1′ as *R*. Compound **8** was identified as the enantiomer of an authentic sample prepared from D-mannitol.

The triethylsilyl (TES) protecting groups were exchanged for acetonides to give 15–22% of pentaacetonide **7** as a mixture of diastereomers at C16. The position of the lone hydroxyl was identified by COSY analysis of acetylated **7**. Reduction of **7** with $LiAlH_4$ (LAH) gave a quantitative yield of *anti*-1,2-di-*O*-isopropylidene-1,2,3-butanetriol (**8**) that was identified by direct comparison (^1H NMR spectroscopy, GC) with an authentic sample.[17] The absolute configuration of **8** was identified as (2*S*,3*R*) by comparison of the *R* and *S* Mosher's esters of **8** with those prepared from an authentic sample of (2*R*,3*S*)-1,2-di-*O*-isopropylidene-1,2,3-butanetriol.[17] The reduction of **7** also gave a mixture of acetonides that was treated with acetone and acid to give pentaacetonide **9** in 76% yield. The ^{13}C NMR spectrum of **9** showed four *syn* 1,3-diol acetonide rings and a mixture of *syn* and *anti* 1,2-diol acetonide rings, which provides independent support for the relative configurations proposed in Scheme 5.[18]

The last question to be resolved is the absolute stereochemistry of the C1′ to C15 fragment. An advanced Mosher's ester analysis[19] of C1′ alcohol **7** led to $\Delta\delta_H$ ($= \delta_S - \delta_R$) values (reported as Hz at 500 MHz in $CHCl_3$) of −58 (H3), −8.5 (H2), −10 (H1′), +5 (H2′), and +25 (H3′). These values indicate an *R* configuration at C1′, and complete the structure assignment of filipin III. Thus the configurations of the stereogenic centers in filipin III are 1′*R*, 2*R*, 3*S*, 5*S*, 7*S*, 9*R*, 11*R*, 13*R*, 15*S*, 26*S*, and 27*R*. It must be emphasized that the relative configurations for the nine stereogenic centers in the top half of the structural formula **1** of filipin were initially identified from just three acetonide derivatives, **2**, **3**, and **4**, arising from a two-step protection sequence. Subsequent experiments confirmed the analysis. The stereochemical assignment of filipin III will facilitate rational modeling of filipin–cholesterol interactions.

[13] Filipin complex was obtained from Sigma (F-9765) as a crude mixture containing about 50% filipin III or from Upjohn (Lot 2923-DEV-39) containing about about 8% filipin III. It can be purified by reversed-phase preparative HPLC.

[14] The location of the C1′ acetates in **3** and **4** were determined by their cross-peak in the COSY spectra with the readily identifiable C2 proton. The C15 acetate in **3** was identified by the simplicity of its coupling pattern. The location of the C7 acetate in **4** is less secure, and was assigned from the COSY spectrum. The second acetate in **4** must be at either at C7 or C11, and its location does not affect the stereochemical analysis. The assignments for these protons are listed in Table 1.

Competing Pathways in the Reaction of Bis(pentafluorophenyl)borane with Bis(η^5-cyclopentadienyl)dimethylzirconium: Methane Elimination versus Methyl–Hydride Exchange and an Example of Pentacoordinate Carbon**

Rupert E. von H. Spence, Daniel J. Parks, Warren E. Piers,* Mary-Anne MacDonald, Michael J. Zaworotko, and Steven J. Rettig

The combination of group 4 bent metallocene compounds with group 13 Lewis acids often leads to catalysts capable of polymerizing olefinic substrates by ring opening metathesis[1] or Ziegler–Natta type mechanisms.[2] The activation in the latter systems commonly involves treatment of dichloro metal complexes $[Cp_2MCl_2]$ with an excess of methylaluminoxane (MAO) which leads to $[Cp_2MCH_3]^+[MAO]^-$, the cation of which is generally accepted to be the active species in these catalysts.[3] Alternatively, the reaction of $[Cp_2ZrR_2]$ derivatives (R = H, alkyl) with equimolar amounts of $B(C_6F_5)_3$[3b,4] has proven to be an effective means of producing active centers by alkyl abstraction, minimizing the need for excessive amounts of cocatalyst.

Spurred by these discoveries, we have developed synthetic routes to the electrophilic borane $HB(C_6F_5)_2$ (**1**)[5] as a reagent for incorporating the $B(C_6F_5)_2$ moiety into the structural framework of ancillary ligands which support soluble Ziegler–Natta catalysts. During these studies, we found borane **1** to be reactive towards simple alkylzirconium complexes as exemplified by its reaction with $[Cp_2Zr(CH_3)_2]$ (**2**). In addition to methyl-hydrogen exchange pathways,[6] **1** was found to induce methane elimination from **2**, ultimately leading to an intriguing compound containing a rare example of pentacoordinate carbon. The chemistry reported herein is summarized in Scheme 1.

The reaction of **1** with one equivalent of **2** in benzene, led to an intractable mixture of several zirconium- and/or $B(C_6F_5)_2$-containing products. Conversely, the same reaction in hexanes resulted in the evolution of methane (confirmed by ^{1}H NMR spectroscopy) and isolation of a single product, a brick red solid, **3**, in 86% yield.

The product **3** decomposed at room temperature in benzene over one to two hours to give several species but could be stabilized with PMe_3 with which it forms a 1:1 adduct **3**·PMe_3. Spectroscopic data indicated that **3** contained a four-coordinate boron[7] (^{11}B NMR, $\delta = -1.1$), a Zr-H-B arrangement (^{1}H NMR, $\delta = -0.75$, broad; IR, $\tilde{\nu} = 1602\ cm^{-1}$), and a deshielded methylene group bonded to boron as evidenced by quadrupolar broading of the ^{1}H NMR signal (^{1}H NMR, $\delta = 5.30$). These data are consistent with the structure shown

Scheme 1. Reactions of $HB(C_6F_5)_2$ (**1**) with $[Cp_2Zr(CH_3)_2]$ (**2**). a) **1**, hexane; $-CH_4$; b) PMe_3; c) **1**; d) 2 **1**, $-CH_2[B(C_6F_5)_2]_2$; e) 4 **1**, benzene; $-CH_4$, $-CH_3B(C_6F_5)_2$ and $-CH_2[B(C_6F_5)_2]_2$; **4**:**5** ≈ 1:2.

for **3** in Scheme 1, a species which may formally be described as a zirconocene methylidene unit in a state of arrested hydroboration, stabilized by $HB(C_6F_5)_2$ in a similar bonding arrangement to that found in $[Cp_2Ti(\mu\text{-}CH_2)(\mu\text{-}Cl)AlMe_2]$, Tebbe's reagent.[8]

This formulation was confirmed by an X-ray crystallographic analysis of **3**·PMe_3 (Fig. 1).[9, 10] The PMe_3 ligand occupies an *exo* coordination site, quenching the electron deficiency of the zirconium center in unligated **3**. The methylene unit resides in the central position and is shielded by the PMe_3 ligand as evidenced by the upfield shift of its signal in the ^1H NMR spectrum relative to the corresponding signal of **3** ($\delta = 0.93$). The Zr–C1 and C1–B distances of 2.300(7) and 1.586(12) Å, respectively, are typical of single bonds for these bonding partners. While the position of the μ-H ligand had to be calculated, the spectroscopic and structural evidence is clearly indicative of a four-membered Zr-C-B-H[11] unit in **3**·PMe_3 and presumably also in **3**.

When $[Cp_2Zr(CH_3)_2]$ was treated with an excess of borane **1** in benzene, two zirconium-containing products, **4** and **5**, were formed in a ratio of approximately 1:2. The minor product was identified as the bis(dihydroborate) complex $[Cp_2Zr\{H_2B(C_6F_5)_2\}_2]$ (**4**) by NMR spectroscopy, characteristic IR absorptions for the Zr-(μ-H)$_2$-B units[12] at 2184, 2110, and 2028 cm^{-1} (Zr-(μ-D)$_2$-B, $\tilde{\nu} = 1597\ cm^{-1}$), and its synthesis by a separate route from $[Cp_2ZrH_2]$[13] and two equivalents of **1**.

The major product in the reaction, **5**, apparently arises from complexation of **3** with a further equivalent of borane. The ^1H NMR spectrum of **5** consists of singlets at $\delta = 5.23$, 2.29 (broad), and -2.05 (very broad) in a 10:2:2 ratio, suggesting retention of the methylene unit to form a complex of stoichiometry $[Cp_2ZrH_2 \cdot CH_2\{B(C_6F_5)_2\}_2]$. Four-coordinate boron was implied by the ^{11}B chemical shift at about $\delta = 0.0$.[7] The signal for the methylene carbon was not detected with standard pulse sequences, but by using the HMQC experiment[14] a broad signal at $\delta = 0.5$ was identified ($^1J_{C-H} = 120$ Hz).

These spectral features of **5** were consistent with the general formulation given above but an X-ray analysis[15, 10] of the compound as a benzene solvate revealed a unique bonding arrangement in which the methylene carbon is five coordinate by virtue of a bonding contact with the zirconium center (Fig. 2).

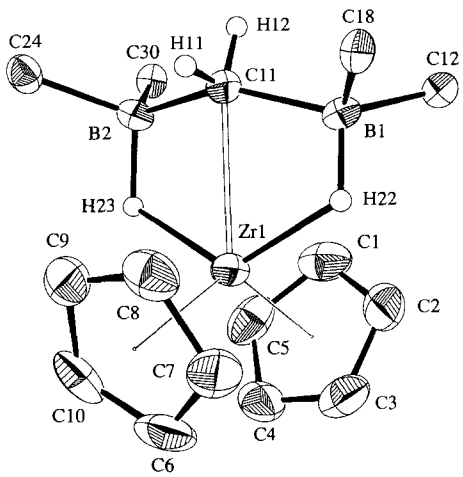

Fig. 2. Molecular structure of **5**; noncyclopentadienyl hydrogens were located and refined. The C_6F_5 groups have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Zr1–C11 2.419(4), Zr1–H22 1.97(3), Zr1–H23 1.94(3), C11–B1 1.697(7), C11–B2 1.693(7), B1–H22 1.13(3), B2–H23 1.27(3), Zr1–$Cp1_{cent}$ 2.19, Zr1–$Cp2_{cent}$ 2.19; H22-Zr1-H23 126(1), B1-C11-B2 149.3(4), B1-C11-Zr1 76.6(2), B2-Zr1-C11 78.0(2), Zr1-H22-B1 112(2), Zr1-H23-B2 110(2), C12-B1-C18 108.4(4), C24-B2-C30 106.0(4); $Cp1_{cent}$-Zr1-$Cp2_{cent}$ 128.6.

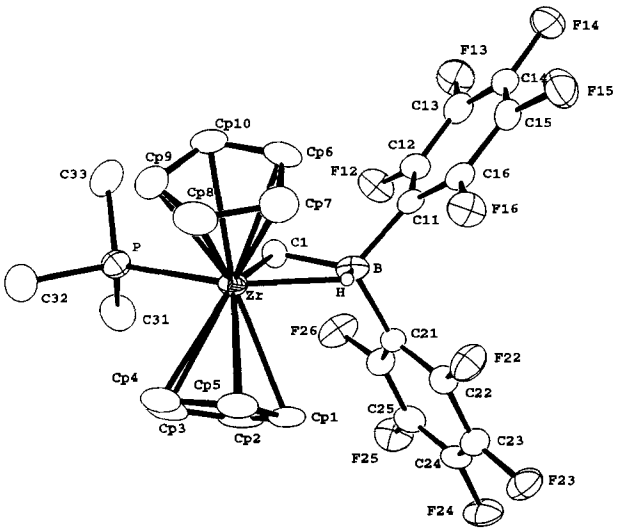

Fig. 1. Molecular structure of **3**·PMe_3. Selected bond lengths [Å] and angles [°]: Zr–P 2.726(3), Zr–C1 2.300(7), B–C1 1.586(12), B–H 1.51(5), Zr–H 1.99(5), Zr–$Cp1_{cent}$ 2.232, Zr–$Cp2_{cent}$ 2.225; P-Zr-C1 72.83(19), Zr-C1-B 85.0(4), C1-B-C11 116.7(7), C1-B-C21 116.4(7), C11-B-C21 108.5(7), Zr-H-B 98(3); $Cp1_{cent}$-Zr-$Cp2_{cent}$ 131.4.

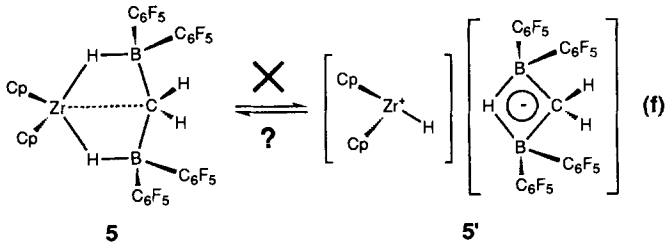

The Zr1–C11 distance is 2.419(4) Å, only slightly longer than the distances of about 2.27 Å for **2**[16] and Zr–C1 in **3**·PMe_3. Both the H22-Zr1-H23 (126(1)°) and B1-C11-B2 (149.3(4)°) angles are significantly greater than expected values,[17, 18] allowing for interaction between Zr1 and C11, which is approximately trigonal bipyramidal in geometry. The unusual coordination environment around C11 is reflected in its upfield chemical shift in the $^{13}C\{^1H\}$ NMR spectrum, compared to chemical shifts of $\delta > 30$ which we have observed for the B-C-B carbons in "free" chelating boranes of general formula $[RCH_2CH\{B(C_6F_5)_2\}_2]$.[5]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1231 $ 10.00+.25/0

The sum of the angles between C11 and the three atoms in the equatorial plane is 358° but the atoms are not in an ideal trigonal arrangement, that is the Zr1-C11-H11 angle of 107(2)° is decidely more acute than the Zr1-C11-H12 angle of 149(2)°. No evidence, however, was found for an agostic interaction in the solution NMR data. Previous examples of five-coordinate carbon involved either the three-center, two-electron bonding type of an alkyl ligand bridging two transition metals,[19] or "ate" complexes with lithium counterions.[20] If one views **5** formally as a complex of $[Cp_2Zr]^{2+}$ and the dianion $[CH_2\{HB(C_6F_5)_2\}_2]^{2-}$, one might expect negative charge localization on the methylene carbon which is donated to the electrophilic zirconium center; computational studies are required to define this interaction more precisely.

A plausible means of formation of **5** would involve complexation of **1** with the Tebbe-type complex **3** if the borane approaches from the μ-methylene side of the metallocene wedge. Interestingly, when **3** is treated with excess borane **1**, *both* **4** and **5** are formed, again in a ratio of approximately 1:2, suggesting that approach from the μ-hydride side is also occuring. This approach would produce the intermediate shown in square brackets in Scheme 1. We have not isolated this species, but signals in the ^{1}H NMR spectrum of the reaction of **3** plus one equivalent of **1** at $\delta = 4.95$ (Cp) and $\delta = 2.81$ (CH_2) are assignable to this compound. Further reaction with **1** resulted in the disappearance of these signals and growth of resonances for **4**.[21] Another pathway by which **4** may be formed from **1** and **2** involves methyl-hydride exchange[6] and complexation of further equivalents of **1** to Zr–H units. The identification of the compound $CH_3B(C_6F_5)_2$[4] in the product mixture of reaction (e) in Scheme 1 is consistent with this scenario.

Complex **5** is also significant because of its *inactivity* as an ethylene polymerization catalyst under ambient conditions. On the basis of recent disclosures by Marks et. al.[22] one might expect an isomer, **5'**, to be accessible and function as a highly active catalyst [Eq. (f)]. The implications of structure **5** for the

(f)

5 **5'**

use of counterions of general formula $[RCH_2CH\{B(C_6F_5)_2\}_2(\mu\text{-}H)]^-$ in homogenous Ziegler–Natta catalysts remain to be determined but if the isomers depicted in Equation f are interconvertible under realistic polymerization conditions, some attenuation of catalyst activity may be expected. We are currently exploring these issues further as well as the mechanistic details of the reactions of **1** with dialkylzirconium complexes.

Experimental Procedure

All NMR spectra were performed in C_6D_6 on a Varian Unity 400 instrument.

3: Hexane (15 mL) was condensed into a vessel containing **1** (115 mg, 0.33 mmol) and **2** (84 mg, 0.33 mmol) at −78 °C. The reaction was allowed to warm to room temperature. After stirring and sonicating for 1 hour a red precipitate was isolated by filtration. Yield 164 mg, 0.28 mmol, 86%. ^{1}H NMR: $\delta = 5.70$ (10H; C_5H_5), 5.30 (2H; CH_2), −0.75 (1H, br; Zr-H-B); ^{19}F NMR (referenced to $CFCl_3$ at $\delta = 0.0$): $\delta = -132.3$, −160.4, −165.2; ^{11}B NMR (referenced to $BF_3 \cdot Et_2O$ at $\delta = 0.0$): $\delta = -1.1$. IR (KBr, Nujol, cm^{-1}): $\tilde{\nu} = 1640$ m, 1602 w (B-H-Zr), 1509 m, 1305 w, 1282 w, 1374 w, 1094 s, 1017 s, 967 s, 810 s, 775 m.

3·PMe_3: To a frozen suspension of **3** (147 mg, 0.25 mmol) in benzene (3 mL) at −78 °C was condensed excess PMe_3 (1.5 equivalents). The reaction mixture was warmed to room temperature and filtered; hexane (15 mL) was added to precipitate the product as a lime green solid which was isolated by filtration. Yield, 113 mg, 0.17 mmol, 68%. Crystals were obtained by recrystallization from benzene ^{1}H NMR: $\delta = 5.07$ (d, 10H, J(P,H) = 2.4 Hz; C_5H_5), 0.93 (dd, 2H, ^3J(P,H) = 12.7 Hz, ^3J(H,H) = 3.9 Hz; CH_2), 0.54 (d, 9H, ^2J(P,H) = 6.4 Hz; PCH_3), −1.9 (br, 1H; Zr-*H*-B). ^{13}C{^{1}H} NMR (referenced to benzene at $\delta = 128.0$, HMQC [14]): $\delta = 105.1$ (C_5H_5), 33.0 (CH_2, ^1J(C,H) = 128 Hz), 15.6 (d, ^1J(P,C) = 24.4 Hz, PCH_3); ^{11}B NMR: $\delta = -30.3$; ^{19}F NMR: $\delta = -131.8$, −162.1, −165.9; ^{31}P{^{1}H} NMR (referenced to 85% H_3PO_4 at $\delta = 0.0$): δ −3.0.

4·C_6H_6: Benzene (25 mL) was condensed into a vessel containing $[Cp_2ZrH_2]$ (44.5 mg, 0.2 mmol) and **1** (138 mg, 0.4 mmol) at −78 °C. The reaction mixture was heated to reflux; on cooling, white crystalline needles of **4** appeared. The crystals were isolated by filtration and dried under vacuum. Yield: 122 mg, 0.13 mmol, 67%. Recrystallization from benzene gave clear cubes of the benzene solvate of **4**. ^{1}H NMR: $\delta = 5.42$ (s, C_5H_5); 0.38 (br, μ-H); ^{11}B NMR: $\delta = -12.9$ (t, ^1J(H,B) = 64 Hz); ^{19}F NMR: $\delta = -133.0$, −156.8, −163.4. Elemental analysis: calcd. for $C_{34}H_{14}F_{20}B_2Zr \cdot C_6H_6$: C 48.36, H 2.03; found (separate samples): C 47.61, 47.71; H 1.77, 1.81. IR (KBr, Nujol, cm^{-1}): $\tilde{\nu} = 2184$ w (br), 2110 w (br), 2028 w (br), 1645 m, 1514 s, 1288 m, 1260 m, 1114 m, 1094 m, 957 s, 826 m.

5·C_6H_6: Benzene (7 mL) was added to a flask containing **2** (126 mg, 0.5 mmol) and **1** (346 mg, 1 mmol). Upon stirring, the reaction mixture became dark red and gas evolution was observed. After 30 minutes, the reaction mixture was heated to reflux; on cooling, colorless crystals formed which were isolated by filtration, washed with benzene, and dried in vacuo. Yield 225 mg, 0.22 mmol, 45%. ^{1}H NMR: $\delta = 5.23$ (s, 10H; C_5H_5), 2.29 (s, 2H; CH_2), −2.05 (br, 2H; Zr-H-B); ^{13}C{^{1}H} (HMQC): $\delta = 111.1$ (C_5H_5), 0.5 (CH_2, ^1J(C,H) = 120 Hz); ^{19}F NMR: $\delta = -132.4$, −157.2, −163.4. ^{11}B NMR: 0.0 (fwhm, 135 Hz). IR (Nujol mull, KBr): $\tilde{\nu} = 1937$ w, 1902 w, 1857 m, 1822 w, 1779 w, 1644 m, 1516 s, 1284 m, 1128 w, 1098 s, 1025 m, 1015 w, 978 s, 895 w, 883 w, 855 w, 838 w, 824 m, 818 m, 793 w, 766 w, 754 w, 744 w, 702 w, 647 m. Elemental analysis: calcd for $C_{41}H_{20}B_2F_{20}Zr$: C 49.35, H 2.35; found: C 49.49, H, 2.14.

Crystal Structure of Dilithioacetylacetone: A Twenty-Four Vertex Li-O Cage Molecule with Limited Li–C(terminal) Bonding and Selective THF Solvation**

William Clegg, Lynne Horsburgh, Robert E. Mulvey,* and Michael J. Ross

Dienolate anions generated by double metallation of a β-diketone with alkali metals are important building blocks in organic chemistry.[1] In reality these are dimetallo intermediates, whose precise identities are normally concealed by the in situ manner of their utilization. Here we report the isolation and crystallographic characterization of the representative dilithium dienolate **1**. Though derived from the simplest 1,3-diketone,

1

2

acetylacetone (acac), **2**, its structure is surprisingly complicated, containing twelve Li^+ ions in an odd cage architecture, which is totally out of line with the regular dimeric, tetrameric, or hexameric aggregates generally adopted by lithium enolates.[2]

THF solvation proved to be the key to capturing the dilithioacetylacetone in a crystalline form suitable for X-ray diffraction study. However, despite the availability of excess THF in the reaction solution, solvation is incomplete with only eight of the twelve Li^+ ions carrying a THF ligand.

The implication of the THF-deficiency, that the doubly charged acac anions form a robust aggregate with the Li^+ ions, is confirmed by the crystal structure (Fig. 1a).[3] Possessing

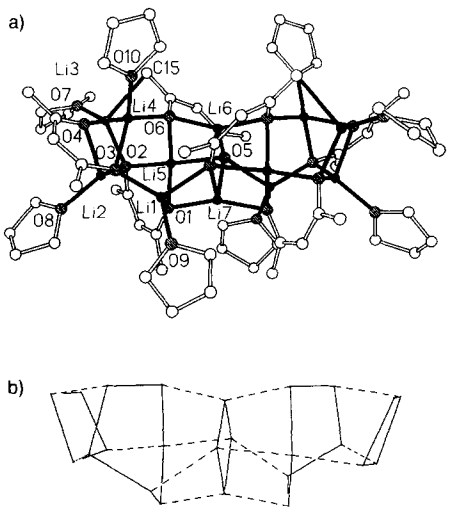

Fig. 1. a) Crystal structure of **1** (excluding hydrogen atoms). Principal distances [Å]: Li1–O1 1.947(7), Li1–O3 1.883(7), Li1–O5a 2.071(7), Li1–O9 2.009(7), Li2–O2 1.969(7), Li2–O3 1.961(7), Li2–O4 2.003(7), Li2–O8 2.037(7), Li3–O2 1.915(7), Li3–O4 1.853(7), Li3–O7 1.924(7), Li3–C15 2.429(8), Li4–O3 2.015(6), Li4–O4 1.984(7), Li4–O6 1.912(6), Li4–O10 1.945(7), Li5–O1 1.920(7), Li5–O2 1.906(6), Li5–O5 2.049(6), Li5–O6 1.980(7), Li6–O5 2.011(5), Li6–O6 1.912(3), Li7–O1 1.853(3), Li7–O5 2.165(9); angles at Li atoms in range 86.1(3)–159.7(8)°. b) Line drawing of the quintuple-decker sandwich core of **1** showing the Li–O rhomboid and six-membered boat layers with solid lines and connections between these layers as dashed lines; the view direction is as for a).

crystallographic C_2 symmetry about the Li6···Li7 axis, the molecule's irregular appearance can be made more intelligible if its Li–O(acac) core is viewed as a quintuple-decker sandwich (Fig. 1b): a central unique rhomboid Li6-O5-Li7-O5a sits between two identical, distorted boats Li4-O3-Li1-O1-Li5-O6 and its symmetry equivalent. Two identical, rhomboids Li2-O2-Li3-O4 and its symmetry equivalent form the outer layers. The unique "bridging" rhomboid forms η^4-contacts with the boats on either side, while the other rhomboids bind to them in a "terminal" η^3 manner. These latter rhomboids additionally interact with a terminal carbon atom of acac (C15/C15a).

Two of the three crystallographically distinct acac dianions **A** and **B** each participate in six Li–O contacts in total (three per O atom; Fig. 2). Such μ_3O–Li bonding is commonplace in higher aggregates, for example, the hexameric enolate derived from pinacolone.[4] In contrast, the third dianion **C** takes part in seven Li–O contacts, the odd number stemming from a novel μ_4-bonding stance assumed by O5. This extra coordination leads to long Li–O5 bonds (2.011–2.165 Å; mean 2.074 Å). In comparison, other Li–O(anionic) bonds have mean lengths below 2 Å (range of mean lengths, 1.907–1.953 Å). Figure 2 shows how the attached Li^+ centers are oriented with respect to

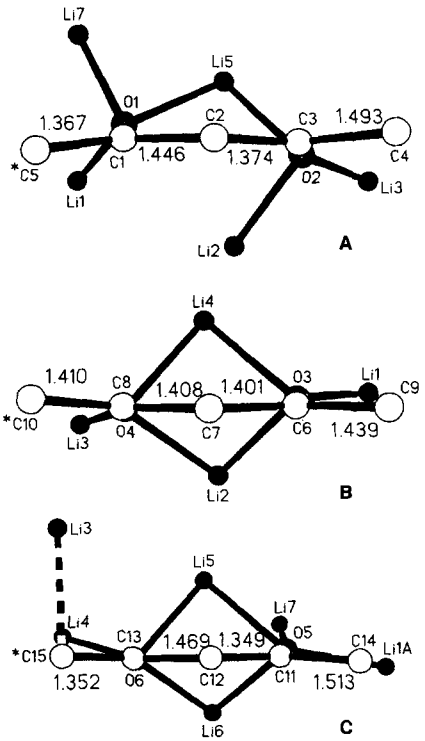

Fig. 2. The three distinct acac dianions **A** (top), **B** (middle), and **C** (bottom) edge on, with their connected lithium centers and C–C bond lengths; each terminal CH_2 group is marked with an asterisk. C–O bond lengths [Å]: C1–O1 1.352(5), C3–O2 1.318(5), C6–O3 1.338(4), C8–O4 1.335(4), C11–O5 1.342(4), C13–O6 1.341(4).

the mean acac ligand planes. Only in the case of dianion **A** do the O atoms (O1, O2) lie significantly out of the mean C-C(O)-C-C(O)-C plane (deviations 0.235 and −0.235 Å, respectively, cf., 0.079 and −0.093 in **B** and 0.080 and −0.080 Å in **C**).

Tetracoordination of Li^+ is usual in enolate structures.[2] In **1** it occurs in three distinct ways. Embedded close to the center of the cage, the group of Li5, Li6, and Li7 atoms attain it exclusively through coordination to acac O centers. Another trio of atoms, Li1, Li2, and Li4, positioned more towards the end of the cage, are only three-coordinate with respect to these centers, but have room to form a fourth bond with a THF solvent molecule. With the exception of the Li1–O(THF) bond, whose length (2.009(7) Å) implies that Li1 is the least sterically accessible of the ligated atoms, these terminal Li–O(neutral) bonds are comparable in length (1.937, 1.945 Å) to the bridging Li–O(anionic) type discussed above. Two acac O atoms, one THF O atom, and one terminal $C(H_2)$ atom make up the unique coordination of the Li3 atom. The bonds to these O atoms are comparatively short (1.853(7), 1.915(7) and 1.924(7) Å, respectively). Indicative of a modest degree of keto character, the Li3-C15 interaction (2.429(8) Å) is marginally shorter than that observed in the dimeric monolithium dienolate of 2,2,5,6,6-pentamethylhept-4-en-3-one[5] (2.50 Å). As shown both experimentally[6] and theoretically[7] by Schleyer et al., Li–C bonding makes a much more substantial contribution to "Y-conjugated" dilithium derivatives of α,α′-keto dianions.

The intricate nature of the Li–O/Li–C core bonding is communicated to the three coordinatively distinct acac dianions as evidenced by the profound variations in their dimensions (Fig. 2). Most significantly, dianion **B** is decidedly more symmetrical on account of its greater overall charge delocalization, for example, C–C bonds involving the terminal methyl and methylene groups differ in length by only 0.029 Å, in comparsion to 0.126 and 0.161 Å in **A** and **C**, respectively. This finding appears to be linked to the nature, solvated or unsolvated, of the attached Li^+ ions, as **B** interacts exclusively with the former, whereas **A** and **C** form contacts with both types. Although twofold disorder of dianion **B** could produce the apparent near-symmetry as an artefact, we do not believe this is the case here, since all six hydrogen atoms for each dianion were clearly located in difference syntheses, so that terminal CH_3 and CH_2 groups are distinguished. Also noteworthy is the insensitivity of the C–O bond lengths (C–O5 1.342 and C–O6 1.341 Å) to the electronic imbalance created by the Li–C(terminal) bonding found in **C**. Since these O atoms have different coordination numbers (five and four, respectively), this may be coincidental, given that the bond angles involved do vary significantly (C14-C11-O5, 115.1°; C15-C13-O6, 122.6°).

Herein we have demonstrated that dilithiation of a 1,3-dicarbonyl compound can lead to an extremely complicated contact ion pair aggregate. As an aid to establishing structure–reactivity correlations, our next targets are to ascertain the structure of the mixed Li–Na analogue, since it has been previously reported that it exhibits different chemical behavior,[8] and to investigate the solution structures of both building blocks.

Experimental Procedure

1: The preparation was performed in a Schlenk tube, under anaerobic and anhydrous conditions. Acetylacetone (20 mmol) was doubly deprotonated by action of LDA (40 mmol: prepared in situ in hexane/THF from *n*BuLi and diisopropylamine). The solution (initially chilled), was stirred for two hours at ambient temperature to ensure reaction completion. The best medium for crystallization of pale yellow **1** proved to be a 5/1, hexane/THF mixture, maintained at ambient temperature. Yield (without refinement), 41%. M.p. 106–108 °C. Satisfactory C, H, Li, N analyses. Single crystals suitable for X-ray crystallography were examined and mounted under an inert oil.

Phosphorane Iminato Complexes of Manganese and Cobalt with Heterocubane Structure**

Hans-Joachim Mai, Rolf Meyer zu Köcker, Sigrid Wocadlo, Werner Massa, and Kurt Dehnicke*

The phosphorane iminato ligand $[NPR_3]^-$, which is among others isoelectronic to the siloxy ligand $[OSiR_3]^-$, displays a diverse coordination chemistry. The mode of coordination realized depends on the transition metal fragment [M] as well as on the substituents bonded to the phosphorus atom. Electron-poor transition metals in high oxidation states prefer type **1** with M-N-P bond angles between 180 and 130°.[1] An example for this type is the ionic tantalum complex **4**.[2] In electron-rich metal complex fragments the μ_2-bridging type **2**, for example found in **5**,[3] and the μ_3-bridging type **3** found in the nickel complex **6**[4] have been observed. Phenyl groups bonded to the phosphorus atom stimulate the formation of **1**, alkyl groups promote the μ_3-N type **3**.

1a **1b** **2** **3**

Here we report the first phosphorane iminato complexes of manganese(II) (**10**) and cobalt(II) (**11**) with heterocubane structure, in which the bridging type **3** is found. Heterocubane complexes of manganese with μ_3-N atoms are unknown; however, manganese complexes with μ_3-OH, μ_3-OR groups, and μ_3-chalcogen atoms[5] have been reported. Cobalt preferably forms heterocubanes with phosphido and arsenido groups.[5] The only heterocubane of cobalt with a μ_3-N imido ligand is the nitrosyl complex **7**.[6]

$[Ta(NPPh_3)_4]^+[TaCl_6]^-$ **4** $[\{FeCl_2(\mu_2\text{-}NPPh_3)\}_2]$ **5**

$[(\mu_3\text{-}NH)(\mu_3\text{-}NPMe_3)(NiClPMe_3)_3]$ **6** $[\{Co(NO)(\mu_3\text{-}N\text{-}t\text{Bu})\}_4]$ **7**

We obtained the phosphorane iminato complexes of manganese(II) and cobalt(II) by reaction of the anhydrous metal halides MnI_2 and $CoCl_2$ with the silylated phosphorane imine $Me_3SiNPEt_3$. The reactions first yield the surprisingly stable monomeric donor–acceptor complexes **8** and **9**, in which according to the X-ray structure analysis[7] the N atoms of the phosphorane iminato ligands act as donor atoms. The Si–N interatomic distances in both complexes are 2–3 pm shorter than the comparable distances in the noncoordinating phosphorane imine $Me_3SiNPMe_3$.[8] This explains the thermal stability of **8** and **9**. Only heating to above 200 °C brings about the cleavage of trimethylsilyl halide and the formation of the heterocubanes **10** and **11** [Eqs. (a), (b)]. Considerable amounts of **10** could only be obtained after the addition of potassium fluoride.

$$4[MnI_2(Me_3SiNPEt_3)_2] + 4\,KF \quad (a)$$
8
$$\longrightarrow [\{MnI(NPEt_3)\}_4] + 4\,FSiMe_3 + 4\,KI + 4\,Me_3SiNPEt_3$$
10

$$4[CoCl_2(Me_3SiNPEt_3)_2] \quad (b)$$
9
$$\longrightarrow [\{CoCl(NPEt_3)\}_4] + 4\,ClSiMe_3 + 4\,Me_3SiNPEt_3$$
11

After the extraction of the solidified melt with dichloromethane the complexes are isolated as shiny red (**10**) and green (**11**) crystals, respectively. Intensive signals are observed for the molecular ions of the tetrameric units in the EI mass spectra (70 eV). The remarkably intense color of **9** is caused by three charge-transfer(CT) bands. Their maxima at 520, 462, and 365 nm (in dichloromethane) are located in the visible range of the spectrum and are missing in the starting material **8**. The measurement of the magnetic susceptibility of **10** at 20 °C gave a magnetic moment of $\mu_{eff} = 3.1$ B.M. per manganese atom. This value is considerably lower than the value of 5.92 B.M. which would be expected for a d^5 high-spin configuration and indicates the presence of spin-spin interactions between the manganese atoms in the heterocubane. In contrast to this, a magnetic moment of $\mu_{eff} = 3.2$ B.M. is found for the cobalt complex **11** at 20 °C, a value which is only slightly lower than the spin-only value for Co^{II} (3.87 B.M.).

The IR spectra of **10** and **11** show the characteristic stretching vibration of the phosphorane iminato ligand at 1035 and 1053 cm^{-1}, respectively. These frequencies are in agreement to the crystallographic findings of short P–N bonds.

According to the X-ray structure analyses[9] **10** and **11** are not isotypic; however, they form very similar heterocubanes (Figs. 1 and 2). Their inside bond angles differ only slightly from 90°, thus almost ideal cubane structures exist. The Co complex **11** exhibits C_2 symmetry, the Mn cubane **10** is without symmetry. The differences are caused mainly by the arrangements of the PEt_3 groups. The metal–nitrogen interatomic distances suggest single bonds.[10] In this respect it is remarkable that the Co–N interatomic distances in **11** (204.8 pm) are about 10 pm shorter

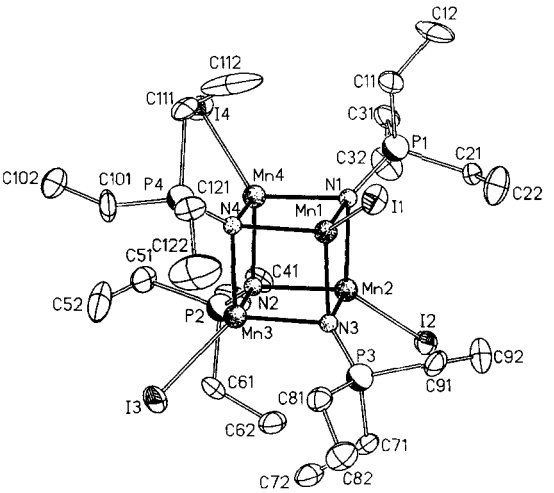

Fig. 1. Molecular structure of **10**. Selected interatomic distances [pm] and angles [°] (standard deviations in parentheses): Mn-I 265.83(9), Mn-N 213.7(5), P-N 159.2(5), Mn···Mn 296.1(1); Mn-N-Mn 88.5(2), N-Mn-N 92.2(2).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

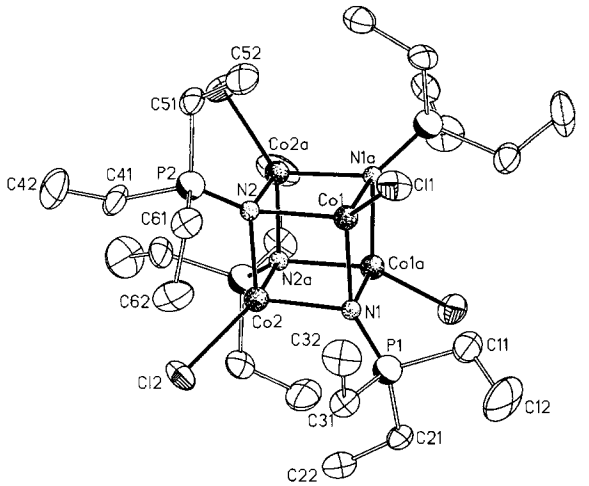

Fig. 2. Molecular structure of **11**. Selected interatomic distances [pm] and angles [°] (standard deviations in parentheses): Co-Cl 222.9(2), Co-N 204.8(5), P-N 159.6(6), Co···Co 280.5(1); Co-N-Co 86.5(2), N-Co-N 93.4(2).

than the Mn–N interatomic distances in **10**. This leads to relatively short Co···Co interactions (280.5 pm) in **11** compared to the value observed for the Mn···Mn interactions (296.1 pm) in **10**. This trend continues for phosphorane iminato complexes of 3d elements containing μ_3-N bridges; in the nickel complex **6** Ni–N interatomic distances of 195.3(6) pm[4] and in the hexameric copper cluster **12**[11] interatomic distances of 191.7(8) are

$[Cu_6Br_6(\mu_3\text{-}NPMe_3)_4]$ **12**

observed. These shortenings of interatomic distances are only partially caused by the contraction of the radii of the M^{2+} ions. The P–N interatomic distances in the heterocubanes **10** and **11** (159.2 pm and 159.6 pm) are equal within the standard deviation. They correspond to the expected values for double bonds (160–164 pm[10, 12]) which can be described as σ- and polar bonds according to type **3**.

The reactions of the heterocubanes **10** and **11** with organolithium compounds lead to hexane-soluble, highly reactive pyrophoric organometallic heterocubanes of the general formula $[\{M(R)(NPEt_3)\}_4]$, which are capable of undergoing various subsequent reactions.

Experimental Procedure

All reactions require the strict absence of oxygen and moisture.

10: A mixture of MnI_2 (2.05 g, 6.63 mmol), KF (1.05 g, 18.10 mmol), and $Me_3SiNPEt_3$ (2.93 mL, 13.25 mmol) [13] was heated to 230 °C for 4 h, then CH_2Cl_2 (40 mL) was added to the cooled mixture and KF/KI was removed by filtration. The solvent was removed under vacuum and the remaining solid was recrystallized with CH_3CN (20 mL). Yield: 2.83 g (34%). Single crystals were obtained by cooling the saturated solution to 4 °C. $C_{24}H_{60}Mn_4N_4P_4$ (1256.00 g mol^{-1}); elemental analysis: found C 21.71, H 4.20, N 4.20%; calc. C 23.41, H 4.87, N 4.54%.

11: A mixture of $CoCl_2$ (1.10 g, 8.5 mmol) and $Me_3SiNPEt_3$ (2.0 mL, 9.1 mmol) was heated to 150 °C for 2 h, then CH_2Cl_2 (10 mL) was added to the cool melt and insoluble material was removed by filtration. The solvent was removed under vacuum until about 4 mL of solution remained. The mixture was left to stand at 20 °C (Yield: 0.83 g single crystals (43%). $C_{24}H_{60}Cl_4Co_4N_4P_4$ (906.21 g mol^{-1}); elemental analysis: found C 31.84, H 6.47, N 5.99, Co 26.63, Cl 16.37%; calc. C 31.81, H 6.67, N 6.18, Co 26.04, Cl 15.65%.

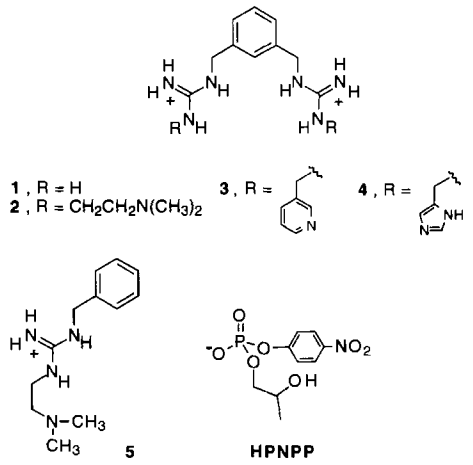
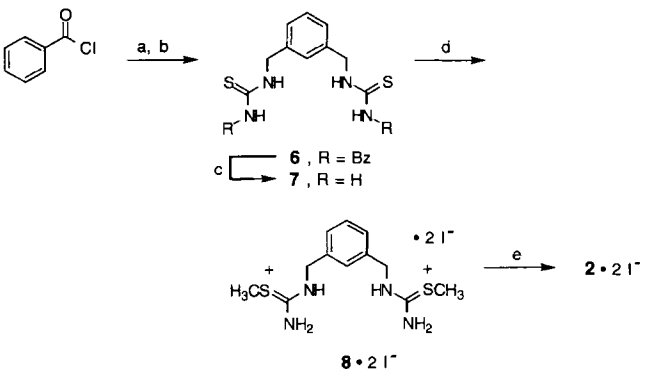
Acceleration of a Phosphate Diester Transesterification Reaction by Bis(alkylguanidinium) Receptors Containing an Appended General Base**



Vrej Jubian, Andrea Veronese, Robert P. Dixon, and Andrew D. Hamilton*

There is considerable interest in designing synthetic catalysts that can hydrolyze phosphate diesters[1-3] since such artificial nucleases have potential applications as novel antiviral and anticancer therapeutic agents.[4-6] An important strategy for developing artificial enzymes is to incorporate, into a synthetic framework, functional groups known to be present in the enzyme's active site and that are essential for maintaining catalytic activity. The DNA and RNA hydrolyzing enzyme, staphylococcal nuclease (SN), contains two key arginine residues, Arg35 and Arg87, in its active site.[7] Site directed mutagenesis studies have established[8-10] that only one arginine residue (Arg35) binds to the monoanionic substrate, but both residues are required for phosphate ester hydrolysis. In an attempt to exploit this important feature of SN, we[11] and others[12-18] have designed mono- and bis(guanidinium) derivatives that bind with phosphate diesters in organic solvents. We have shown that certain bis(guanidinium) receptors can mimic SN and accelerate the transesterification of phosphate diesters. A key requirement for these guanidinium receptors[19] and related systems[2, 20, 21] is the addition of a general base (e.g. lutidine, tetramethylguanidine, imidazole) to deprotonate the hydroxyl nucleophile (Scheme 1, A). In an attempt to design a receptor that contains



Scheme 1. Transesterification of HPNPP mediated by bis(guanidinium) receptors and an added base (A) and by a bis(guanidinium) receptor with an appended basic group (B).

all the necessary components for catalysis, we have linked general base groups to the bis(guanidinium) receptors. The receptor design is based on bis(alkylguanidinium) derivatives that remain protonated in the presence of a wide range of basic groups. These receptors can potentially accelerate phosphate ester cleavage by providing a hydrogen-bonding cleft to increase the electrophilicity and facilitate nucleophilic attack on phosphorus upon binding in the manner depicted in Scheme 1, B. In this paper we report a series of alkylguanidinium ions **1**–**5** containing appended nitrogen bases and compare their efficiencies in accelerating the transesterification reaction of the RNA model, 2-hydroxypropyl-*para*-nitrophenylphosphate (HPNPP).[22, 23]

All the *N,N'*-disubstituted guanidinium receptors were prepared from the reaction of a thiouronium salt with an appropriate diamine following the general method for the synthesis of substituted guanidines.[24, 25] The method involves in situ generation of benzoyl isothiocyanate (from ammonium thiocyanate and benzoyl chloride) and reaction with 1,3-bis(aminomethyl)-benzene to form the corresponding bis(benzoylthiourea) **6** (Scheme 2). Hydrolysis of **6** in 10% sodium hydroxide solution

Scheme 2. a) NH_4SCN, acetone, reflux; b) 1,3-$(H_2NCH_2)_2C_6H_4$, reflux; c) NaOH (10%), 80 °C; d) MeI, MeOH, reflux; e) $NH_2CH_2CH_2N(CH_3)_2$, *t*BuOH, reflux.

affords the bis(thiourea) **7**, which upon treatment with methyl iodide in methanol gives the desired thiouronium salt **8**. Treatment of **8** with various amines in refluxing *tert*-butyl alcohol affords the receptors **1**–**4**. Salts containing the bis(alkylguanidinium ion **1** were prepared in a single step from 1,3-bis(aminomethyl)benzene and pyrazole-1-carboxamidine hydrochloride.[26]

The phosphoryl transfer reaction of HPNPP gave, in the presence of the guanidinium receptors, the cyclic phosphate ester and *para*-nitrophenol as confirmed by ^{31}P NMR spectroscopy and HPLC, respectively. The rate of the transesterification reaction of HPNPP follows Michaelis–Menten kinetics showing saturation behavior as the concentration of receptor increases (Fig. 1). Eadie–Hofstee plots give values for k_{cat} and K_m (Table 1). When fully bound to receptor **1** with monosubstituted guanidinium groups, the phosphate ester undergoes cleavage ($k_{cat} = 5.5 \times 10^{-6}\ s^{-1}$) 14 times faster than the background reaction ($k_{uncat} = 3.8 \times 10^{-7}\ s^{-1}$). Receptors **2**–**4** with appended general base groups show increased efficiency for phosphate ester cleavage.

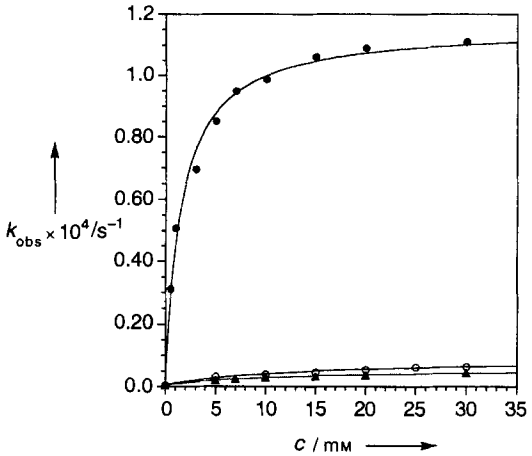

Fig. 1. Plot of the reaction rate versus the receptor concentration for **2** (●), **5** (○), and **1** (▲) for the accelerated transesterification of HPNPP.

The most efficient catalyst is the trialkylamine receptor **2**. At a concentration of 5 mM **2** ($k_{obs} = 8.5 \times 10^{-5}\ s^{-1}$) accelerates the cleavage of HPNPP by a factor of 45 relative to the rate with **1** ($k_{obs} = 1.9 \times 10^{-6}\ s^{-1}$) and displays an acceleration of 290-fold over the rate of the uncatalyzed reaction (Table 1). The efficiency of **2** stems in part from the increased basicity of its internal base relative to that in **3** and **4**. The basicity of the functional groups present in **3** (pyridine) and **4** (imidazole) are comparable with that of lutidine. At a concentration of 5 mM **3** ($k_{obs} = 7.3 \times 10^{-6}\ s^{-1}$) and **4** ($k_{obs} = 1.2 \times 10^{-5}\ s^{-1}$) display up to a sixfold increase in the rate of HPNPP transesterification compared to that of **1** with lutidine. The dimethylethylamine group in **2** is more basic than the nitrogen bases in **3** and **4** and hence **2** is the most efficient in accelerating the phosphoryl transfer reaction. However, the basicity of the amine in **2** is much weaker than simple trialkylamines due to the electron-withdrawing effect of the guanidinium groups and their tendency to form hydrogen bonds. As a consequence, compound **5** was used as a control because its basicity should be comparable to that in **2**.

Table 1. Rate constants for the transesterification of HPNPP accelerated by guanidinium receptors **1**, **2**, and **5** [a].

Receptor	K_m [mM]	k_{cat} [s^{-1}]	k_{cat}/k_{uncat}
2	1.6	1.1×10^{-4}	290
5	13.8	8.5×10^{-6}	22
1 [b]	12.6	5.5×10^{-6}	14

[a] In CH_3CN, HPNPP (1×10^{-4} M) at 25 °C. [b] With lutidine (1.25×10^{-2} M).

The first-order rate constant for HPNPP cleavage promoted by the "half receptor" **5** (10 mM) is $4.0 \times 10^{-6}\ s^{-1}$, whereas receptor **2**, at half the concentration (5 mM), increases the rate of the reaction by an additional 20-fold ($k_{obs} = 8.5 \times 10^{-5}\ s^{-1}$) (Fig. 1). Thus, the binding arrangement provided by both guanidiniums in **2** is crucial for obtaining large rate enhancements. The two guanidinium groups can work cooperatively to stabilize the dianionic trigonal-bipyramidal intermediate by means of four hydrogen bonds with concomitant charge neutralization.

The binding constant K_a of **2** ($625\ M^{-1}$) is higher than that of **1** in the presence of added lutidine ($K_a = 80\ M^{-1}$). Addition of excess lutidine lowers the binding affinity of the receptor, presumably reflecting the increased polarity of the medium. Binding studies were performed by ^{31}P NMR titrations of **2** and **5** with diethyl phosphate (Fig. 2). The binding isotherms for **2** and **5** are markedly different; the inflections are indicative of multiple binding equilibria.[13, 27, 28] The binding isotherm for **2** shows a downfield shift of the ^{31}P NMR signal ($\Delta\delta > 0$) for the 1:2 receptor/diethyl phosphate complex followed by a shift to higher field ($\Delta\delta < 0$) for the 1:1 complex, whereas for **5** a downfield shift for the 1:1 complex and a smaller downfield shift for the 2:1 complex are seen. The contrasting shapes of the two titration curves demonstrate the dramatically different microenvironments provided for the phosphate diester by **2** and **5**. At high host/guest ratios (2–4) the chemical shift of the bound phosphate differs by more than 2 ppm. This indicates that **2** forms a strong 1:1 complex with both guanidinium groups binding to the phosphate, while **5** forms a much weaker 2:1 complex of guanidinium and diethyl phosphate. These differences in complex structure are translated into the efficiency of the receptors in accelerating phosphoryl transfer reactions. Kinetic experiments were carried out with a large excess of receptor relative to the phosphate diester. Under these conditions, the bis(guanidinium) receptors will bind to only one phosphate ester substrate (Scheme 1, B).

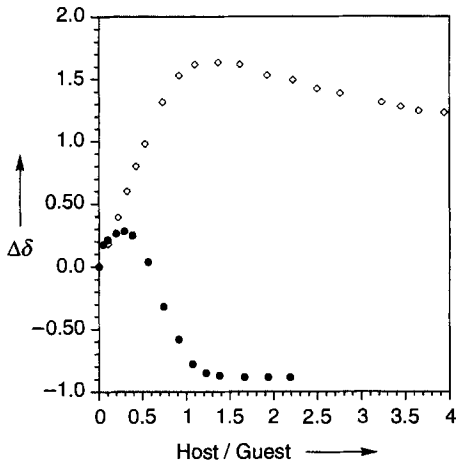

Fig. 2. Relative changes in the positions of the ^{31}P NMR resonances of diethyl phosphate (guest) at increasing concentrations of receptor (host) **2** (●) and **5** (○) in CD_3CN.

In summary we have taken an important step in the development of artificial nucleases by combining two key catalytic elements into a synthetic receptor. Substantial rate enhancements in a phosphoryl transfer reaction are shown by bis(guanidinium) receptors containing appended general base groups. The large accelerations are achieved by the provision of an intramolecular general base group and electrostatic complementarity of the binding site to the trigonal-bipyramidal intermediate in the phosphoryl transfer reaction.

Experimental Procedure

The intramolecular reactions of HPNPP were monitored by following the absorption of released 4-nitrophenol at 324 nm. The receptors were used as their tetraphenylborate salts. The reactions were carried out in acetonitrile under pseudo-first-order conditions with an initial concentration of HPNPP of 1×10^{-4} M and with the receptor (3–30 mM) and, if necessary, lutidine (1.25×10^{-2} M) in excess. In a typical kinetics experiment, 2 mL of a solution of the receptor (5 mM) in CH_3CN and 50 μL of a 0.5 M CH_3CN stock solution of lutidine (if necessary) were added to a cuvette. The reaction was initiated by adding 20 μL of a 0.01 M CH_3CN solution

of HPNPP [29]. The rate constants were obtained by fitting at least three half-lives of the reaction according to a first-order kinetics equation. For slower reactions, rate constants were calculated from the initial rates. First-order rate constants were calculated from the slopes of the linear plots of absorbance versus time by converting to concentration units of the phosphate ester ($\varepsilon = 4500\ M^{-1}cm^{-1}$) and dividing by the initial phosphate ester concentration. All kinetic experiments were run at least twice and were reproducible within 5% error.

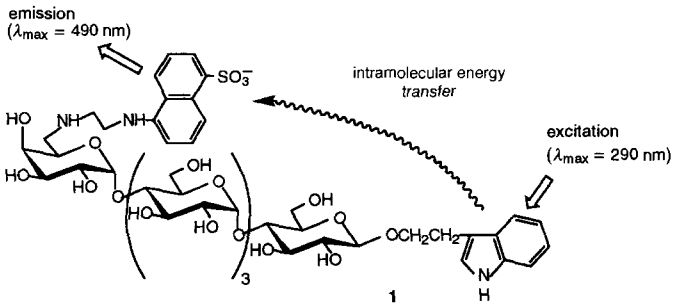
Chemoenzymatic Synthesis of a Modified Pentasaccharide as a Specific Substrate for a Sensitive Assay of α-Amylase by Fluorescence Quenching**

Nathalie Payre, Sylvain Cottaz, and Hugues Driguez*

Most living species such as microorganisms, higher plants, and animals generate energy by the metabolism of starch. The enzymes involved in the degradation of starch include α-amylase (1,4-α-D-glucan glucanohydrolase) [EC 3.2.1.1], an endoglycanase, and exoglucanases such as glucoamylase [EC 3.2.1.3] and β-amylase [EC 3.2.1.2].[1]

The detection and the determination of α-amylase activity are not only necessary for catalysis studies but also important for technological and medical applications, for example for monitoring fermentation processes and for diagnosing diseases like parotitis (mumps) and acute pancreatitis. The assay of amylases usually requires specific substrates to distinguish between the endo- and exoglucanases, which both act on the α-(1 → 4)-glycosidic bond in D-Glc-α-(1 → 4)-D-Glc units. A survey of the literature from the mid-1980s shows the considerable amount of work that has been directed toward this goal.[2]



The specific substrates can be divided into two groups: substrates with a single chromophore or fluorophore, which are used in most of the commercially available diagnostic kits, and substrates with an additional fluorescence-quenching group. The chromogenic substrates are usually nitrophenylmaltooligosaccharides bearing blocking groups at the nonreducing end to prevent action of exoenzymes. The nitrophenyl group and the blocking substituent are introduced by demanding multiple-step reactions and/or low-yielding procedures, either by chemical synthesis from maltodextrins with an appropriate degree of polymerization,[3] or by chemoenzymatic transformations of modified linear or cyclic dextrins.[4] Since the enzymatic hydrolysis of these substrates never occurs at the reducing unit, α-glucosidase or β-glucosidase and glucoamylase have to be added during the assay to liberate nitrophenol from the residual nitrophenylmaltooligosaccharides. Not only are these drawbacks costly but complications may also arise from the multitude of possible side reactions.

These problems may be overcome by the use of specific substrates that display intramolecular fluorescence quenching, in which the variation of fluorescence between a fluorophore/quencher pair on the same molecule can be monitored by using the intramolecular resonance energy transfer effect.[5] This strategy is analogous to that developed for the specific assay of proteases,[6] and for glycanases this was first achieved by Omishi and Ikenaka, who prepared a disubstituted maltopentaoside by a complex chemoenzymatic synthesis.[7] In a very recent paper, Bock et al. described the preparation of acylated maltotriosides which appeared to be pH sensitive and poor substrates for α-amylases.[8]

The merit of substrates that display intramolecular fluorescence quenching is confirmed here by the specific detection of α-amylase activities with micromolar concentrations of the sub-

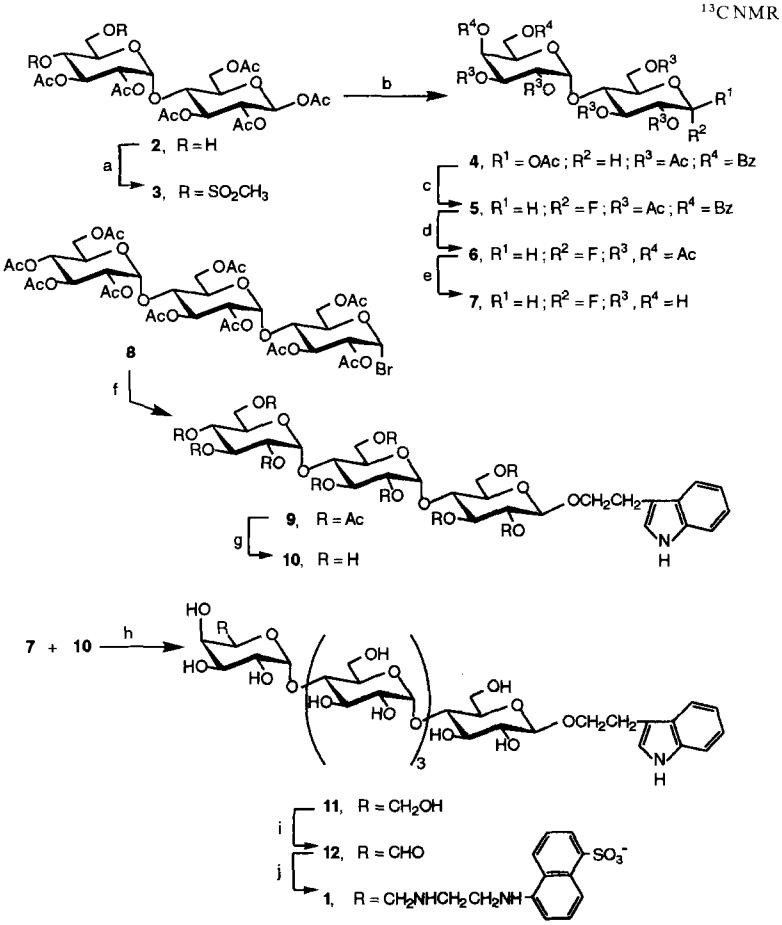

Scheme 1. Fluorescence quenching and intramolecular energy transfer in **1**. After irradiation of **1** at 290 nm, fluorescence at 490 nm was observed.

strate indolylethyl- and 5-(2-aminoethylamino)-1-naphthalenesulfonate-substituted maltopentaoside **1** (Scheme 1).

The design of **1** was based on several observations: maltopentaose is the best substrate for our model enzyme, porcine pancreatic α-amylase (PPA),[9] and the emission band of excited 3-(2-hydroxyethyl)indole (indolylethanol) (λ_{max} = 345 nm) and the absorption band of 5-(2-aminoethylamino)-1-naphthalenesulfonate (EDANS) (λ_{max} = 340 nm) show excellent overlap. Despite the relatively short lifetime of excited indolylethanol (2 ns), the efficiency of the fluorescence quenching is satisfactory.[5] The EDANS/indolylethanol pair was also chosen based on synthetic considerations. Our strategy requires one fluorophore with an amino function that can form an amino linkages with the oligosaccharide, and the other fluorophore with an aliphatic hydroxyl group that can form an ether linkage. These two linkages are much more stable than an ester bond during the enzymatic assay.[8]

Compound **1** was prepared chemoenzymatically (Scheme 2); this approach is very valuable for the synthesis of regiospecifically modified oligosaccharides.[10] The key steps of the synthesis of **1** are the α-amylase-catalyzed coupling of a modified α-maltosyl fluoride donor **7** with an indolylethylmaltotrioside **10**, and the oxidation of pentasaccharide **11** by galactose oxidase [EC 1.1.3.9], such that EDANS can be introduced regiospecifically at the nonreducing end of the oligosaccharide. α-D-Galactosyl-(1 → 4)-α-D-glucosyl fluoride **7** and indolylethylmaltotrioside **10** were obtained by conventional chemical modifications from known hexa-*O*-acetyl maltose **2**[11] and maltotriosyl bromide **8**[12] (Table 1).

The glycosylation of **10** with **7** was achieved by using conditions originally described by Kobayashi et al. for the enzymatic

polymerization of α-maltosyl fluoride with α-amylase as catalyst.[13] Under these conditions **11** was obtained in 78% yield (determined by HPLC, 59% isolated yield). The epimerization at the 4'-position in the formation of **4** is beneficial for two reasons. Firstly, **7** is accepted by the α-amylase as a donor, but neither **7** nor **11** are acceptors because of the axial 4-OH at the nonreducing end unit. Therefore only one disaccharide is added and **11** is obtained in good yield. Secondly, the nonreducing galactosyl residue at the C-6 position in **11** can be oxidized regiospecifically by the galactose oxidase/catalase system to give aldehyde **12**.[14] In the final step the EDANS group can be introduced by reductive amination, giving **1** in 54% isolated yield (Table 1).

The intramolecular fluorescence quenching in **1** was demonstrated in preliminary experiments at concentrations of 10 μM. When **1** was excited at 290 nm, the EDANS fluorescence emitted at 490 nm was 12 times more intense than that of free EDANS. We also detected a fivefold decrease in the intensity of the indolylethyl emission at 345 nm. At this concentration we can assume that variation of fluorescence intensity due to collisional quenching is negligible. In fact a 2% increase in fluorescence intensity at 490 nm was observed for solutions of free EDANS with indolylethylpentasaccharide **11** when the EDANS concentration was increased from 10 to 20 μM.

When a 5 μM solution of **1** was incubated with PPA, the intensity of the fluorescence at 490 nm decreased rapidly. After 6 min the substrate was completely hydrolyzed (Fig. 1). At this stage,

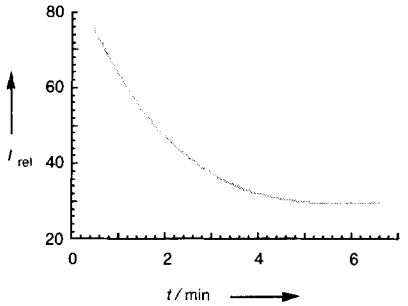

Fig. 1. Progress of the PPA-catalyzed hydrolysis of **1** monitored by steady-state fluorescence based on the relative fluorescence intensity I_{rel} at 490 nm. A 5 μM solution of **1** in phosphate buffer (0.02 M, pH 7) was incubated with PPA (Sigma, 100 U L^{-1}) at 30 °C [16].

HPLC analysis of the reaction mixture confirmed the complete conversion of **1** into two shorter oligosaccharides (EDANS-galactosyl-α-(1 → 4)-maltose and indolylethylmaltoside; the retention times were compared to those of authentic standards prepared independently).

When the same experiment was conducted with different concentrations of α-amylase, a linear relationship was found for the initial rate of hydrolysis of **1** and the concentration of the enzyme. In contrast, even under optimal conditions, α-galactosidase, β-amylase, α-glucosidase, and glucoamylase were inactive.[15]

Compound **1** is thus the first specific, sensitive, and readily available substrate for the in vitro assay of human salivary and pancreatic α-amylases (HSA and HPA). Further studies on **1** and the preparation of new substrates with improved performances are under way.

[15] For the glucoamylase used (Sigma) low hydrolytic activity was detected but attributed to contamination by α-amylase (sigma).
[16] α-amylase activity was previously determined with the Sigma Amylase Diagnostic Kit by using nitrophenyl 4,6-ethylidenemaltoheptaoside as substrate.

The Synthesis of Tris(perfluoroalkyl)-phosphanes**

Joel J. Kampa, John W. Nail, and Richard J. Lagow*

Many papers and review articles have dealt with the synthesis, characterization, and reactions of highly fluorinated phosphanes.[1, 2] Much attention has been drawn to the fact that fluorinated phosphanes form complexes with transition metals. Phosphorus trifluoride (PF_3), the first member of the fluorophosphane family, has been shown to be an analogue of carbon monoxide. In its reactions with transition metals, PF_3 closely resembles CO electronically. Other highly fluorinated phosphorus(III) compounds similar to PF_3 exhibited similar reaction chemistry. Recent work in our laboratory has shown that $P(CF_3)_3$ forms complexes with numerous transition metals.[3]

Tris(trifluoromethyl)phosphane, $P(CF_3)_3$,[4] has been known for years; however, its preparation from trifluoromethyl iodide

is not applicable to the larger perfluoroalkyl groups. Synthesis of phosphanes by this route has not produced trisubstituted products with larger alkyl groups. Only dialkylated products are produced, and in low yield.[5, 6] Occasionally, a perfluorinated trialkylphosphane such as $[(CF_3)_2PCF(CF_3)_2]$ does appear in the literature;[7–9] however, the methods described are, in general, unsuitable for a wide range of compounds.

The preparation of numerous difluorotris(perfluoroalkyl)-phosphoranes of various structural types has been achieved by direct elemental fluorination in solution. The development of methodologies for safely treating organic substrates with elemental fluorine has made it possible to prepare complex and unique new materials.[10] The most recent advance in this technology is the use of inert solvents to reduce fragmentation and side reactions and thus to enhance the selectivity of the reaction further.[11] Organophosphanes have been subjected to direct elemental fluorination in Freon to produce a series of difluorotris(perfluoroalkyl)phosphoranes (**1**–**7**) in good yield.

Results of ^{19}F NMR experiments are shown in Table 1. Peak locations, multiplicity, and intensities are all consistent with the structures indicated.[12] Spin–spin coupling between the ^{31}P and ^{19}F nuclei provides definitive structural information. The two fluorine atoms bound to the phosphorus center in **1**–**7** are equivalent, as are the three perfluoroalkyl groups. This indicates a trigonal bipyramidal configuration with the σ-bound fluorine atoms in the axial positions and the alkyl groups in the equatorial positions.[13] No fluxional behavior was observed on the NMR time scale. In the ^{31}P NMR spectra of **1**–**7** (Table 1) each signal appears as a triplet of septets (Fig. 1 shows the spectrum of **1**). The triplet is due to ^1J coupling of about 1000 Hz. Each of the peaks of the triplet is split into a septet by the ^2J coupling of about 125 Hz between the phosphorus and the six fluorine atoms bound to the α-carbon atoms of the three alkyl groups.

Mass spectral analysis of these perfluorophosphoranes provides additional evidence for the proposed formulas. The general

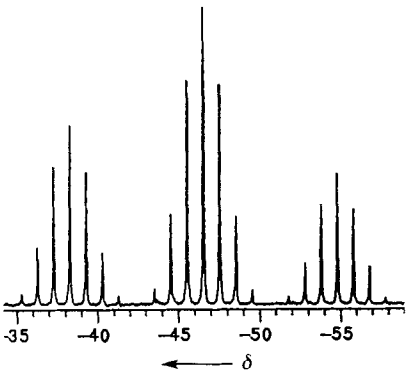

Fig. 1. ^{31}P NMR spectrum of difluorotris(pentafluoroethyl)phosphorane (**1**).

[a] The values are relative to the $[M^+ - F]$ fragment.

fragmentation pattern observed coincides with the thermaldecomposition pattern observed by Mahler for $F_2P(CF_3)_3$.[14] High resolution mass spectra (HR-MS) on the $[M^+ - F]$ fragments confirms their elemental composition (Table 1).

The careful reduction of these phosphorus(v) compounds **1**–**7** to the phosphorus(III) compounds **8**–**14** by selective removal of the two axial fluorine atoms directly bound to phosphorus yields the previously inaccessible (perfluoroalkyl)-phosphanes. Previous work has shown trimethylsilyldiphenylphosphane to be an effective reducing agent for the fluorophosphoranes.[15] Trimethylsilylfluoride is produced as an easily removable volatile by-product. Tris(trimethylsilyl)phosphane was used as the reducing agent for these studies. During the reaction a black, nonvolatile material of undetermined composition is produced; it is assumed to be a trimethylsilyl-substituted polyphosphane.

The identities of the tris(perfluoroalkyl)phosphanes **8**–**14** were determined by NMR spectroscopy and mass spectrometry (Table 2). The doublet of complex multiplets indicative of the axial fluorine atoms of the phosphorane starting materials **1**–**7** is no longer present. In addition, the resonance of the α-fluorine atoms of the perfluoroalkyl group is shifted downfield slightly. Table 2 shows the ^{19}F and ^{31}P chemical shifts for the compounds under investigation along with their coupling constants.

In the case of tris(pentafluoroethyl)phosphane (**8**), the ^{31}P NMR spectrum was simulated with the $^2J_{PCF}$ and $^3J_{PCCF}$ values (48 Hz and 16 Hz, respectively) obtained from the ^{19}F NMR spectrum. The overlapping resonances with the appropriate intensities would give a 28 peak pattern, each 16 Hz apart, with a relative intensity ratio of 1:9:36:90:180:342:603:927:1305:1785:2286:2664:2961:3195:3195:2961:2664:2286:1785:1305:927:603:342:180:90:36:9:1. Neglecting the four outside peaks on each side yields a 20 peak pattern with relative intensities of 1:1.9:3.3:5.2:7.2:10:12.8:15:16.7:17.8:17.8:16.7:15:12.8:10:7.2:5.2:3.3:1.9:1 (Fig. 2). The ^{31}P spectra of perfluorophosphanes **9**–**14** do not have the same serendipitous overlap of coupling constants.

In contrast to the phosphorane starting materials, each of **8**–**14** produce a positive parent ion under electron impact conditions with surprisingly little fragmentation. High resolution spectra of the parent ion of the (perfluoroalkyl)phosphanes under investigation confirms their elemental composition (Table 2).

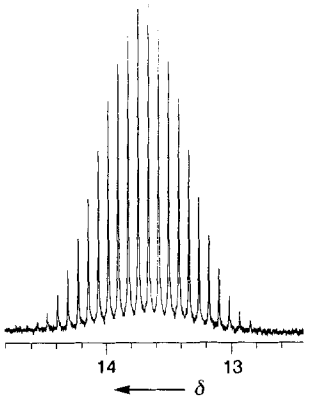

Fig. 2. ^{31}P NMR spectrum of tris(pentafluoroethyl)phosphane (**8**).

Experimental Procedure

The mass spectra were recorded on the following mass spectrometers: HR-MS: analytical ZAB2-E; CI-MS: Finnigan MAT TSQ-70; and EI-MS: Bell and Howell 21-491 (70 eV). ^{19}F NMR analysis was performed on a Nicolet NT-360 spectrometer. Samples were handled anaerobically and sealed in Teflon tubes for NMR experiments. All spectra are references to external $CFCl_3$ ($\delta = 0.0$); higher field was

designated as negative. ^{31}P NMR spectra were obtained on a General Electric (QE-300 spectrometer operating at 121.5 MHz, and are referenced to external 85% aqueous H_3PO_4 ($\delta = 0.0$). The spectral parameters were such that the digital resolution was at least one data point per Hz.

Alkylphosphanes: The trialkylphosphane precursors were synthesized by the action of three equivalents of the corresponding alkyl Grignard compound on PCl_3. PEt_2Bu was prepared from Et_2PCl (prepared by the method of Issleib et al. [16]) and subsequent reaction with BuLi (2.5 M in hexanes; Aldrich). This was followed by work-up in the usual manner and purification by distillation. 1,2-Bis(diethylphosphano)ethane (Strem) was used as received.

1–7: Fluorination of the alkylphosphanes was carried out in a solution phase reactor, which has been fully described elsewhere [17]. The reactor was charged with a mixture of Freon 11 and 113 (1:1), then cooled to −60 °C, and purged with 100 $cm^3 min^{-1}$ of helium overnight. After this period of deoxygenation, typically 5 g of the organophosphane was injected into the reactor and fluorinated under the conditions outlined in Table 3. The contents of the reactor were then filtered and excess Freon removed by passing dry argon over the surface of the solution.

Table 3. Conditions for the fluorination of the alkylphosphanes **1–7**.

t [h]	F_2 [$cm^3 min^{-1}$]	He [$cm^3 min^{-1}$]	T [°C]
12	0	100	−60
4	5	50	−60
8	10	50	−40
12	15	50	−20
12	15	15	0
12	15	15	+25
12	0	15	[a]

[a] Room temperature.

The reducing agent, $P(SiMe_3)_3$, was synthesized by slightly adapted literature methods [22] and purified by a single distillation.

8–14: Routinely difluorophosphorane (5 mmol) was treated with an excess (20%) of $P(SiMe_3)_3$. The reagents were stirred vigorously (by magnetic stirrer) in the absence of any solvents and heated to 100 °C in an oil bath. In the absence of agitation the two materials quickly separated, and the more dense fluorinated materials formed a clear lower phase. The by-product $(CH_3)_3SiF$ was occasionally vented from the reaction tube to avoid excessive pressure build-up. The formation of trimethyl-silyl fluoride was confirmed by ^1H and ^{19}F NMR, EI-MS, and IR analysis. Reaction times were increased as the length of the perfluoroalkyl chain increased. Compound **8** was completely reduced in about 3 days. One day was added for each additional carbon in the alkyl chain. Compound **12** was therefore heated for a full week. Upon completion of the reaction stirring was stopped, and the two immiscible phases allowed to separate. The lower perfluorophosphane phase, which was >90% pure (NMR), was then removed from the black, nonvolatile residue of the reducing agent.

C–C Coupling Reactions as a Novel Synthetic Route to π-Allyl- and π-Butadienylrhodium Complexes**

Ralf Wiedemann, Justin Wolf, and Helmut Werner*

Dedicated to Professor Manfred Hesse on the occasion of his 60th birthday

Transition-metal complexes containing vinylidene ligands have not only been discussed as important intermediates in homogeneous and heterogeneous catalytic reactions[1] but have also been considered as useful starting materials in organic and organometallic synthesis.[2] Our interest in the chemistry of the already thoroughly studied compounds of the type **A** (cf. **1–3**)[3, 4] has recently been focussed upon the question whether by

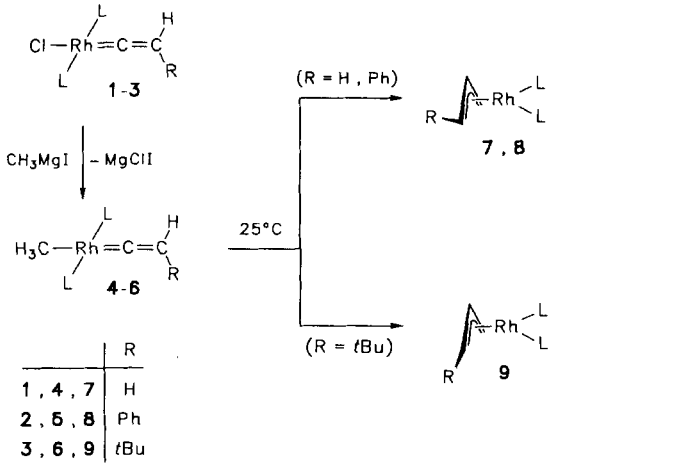
substitution of the chloro or acetato ligand corresponding organorhodium derivatives **D** (cf. **4–6**, and **10**, **11**) would be accessible and could be used for metal-assisted C–C coupling reactions. One of the first successes was achieved on reacting the compounds **D** with CO, which led, by migration of the group R′ to the α-carbon atom of the vinylidene ligand, to the formation of σ-vinylrhodium complexes **B** and **E** (see Scheme 1). Subsequent treatment of these isolated and structurally characterized products with acetic or trifluoroacetic acid yielded butatrienes **C** (or enynes, respectively) or the (*E*) isomers of disubstituted ethenes **F**.[5, 6] In continuation of this work we have now found that a coupling of the C-bonded ligands of the organo(vinylidene)rhodium compounds **D** is even possible *without* the presence of a supporting substrate and that this opens up a novel synthetic route to π-allyl and π-butadienyl metal complexes.[7]



The methyl(vinylidene) complexes **4**, **5**,[6] and **6** are obtained from the well-known precursors **1–3**[3] upon reaction with Grignard reagent (CH_3MgI) in benzene/ether at 10 °C (see Scheme 2). The deep-blue or dark violet compounds **4–6**, isolated in 80% yield, react slowly (12 h) in benzene at room temperature to give the π-allylrhodium complexes **7–9** (yellow or orange air-sensitive solids) of which the parent derivative **7** has also been prepared in a different way.[8] It is most noteworthy that from **5** the allylic ligand is formed in the *syn* (**8**) and from **6** in the *anti* configuration (**9**),[9] and that compound **9** even after

stirring for 24 h in benzene does not rearrange to the thermodynamically more stable *syn* isomer. With regard to earlier studies[10] we assume that initially a 14-electron species of the composition **G** (analogous to **H**)[8] is formed as an intermediate which by β-H shift reacts to give a four-coordinate (η^2-allene)hydrido metal derivative. This generates the final product by a hydride transfer from the metal to the central carbon atom of the allene ligand.

$[Rh(\eta^1\text{-}C(CH_3)=CHR)(PiPr_3)_2]$ **G**

$[Rh(\eta^1\text{-}CH_2Ph)(PiPr_3)_2]$ **H**

The vinyl(vinylidene)rhodium complexes **10**[6] and **11** (violet crystalline solids), which are prepared in a similar way to the compounds **4**–**6**, also undergo isomerization reactions. The most remarkable feature is that *in solution* and in the *solid state* different products are formed. Whereas the reaction of **10** and **11** in benzene (3 h, 45–50 °C) exclusively affords the η^3-2,3,4-*trans*-butadienyl complexes **12** and **13**, respectively, on storing the solid compounds under argon (10–14 days, 25 °C) the alkynyl(ethene) metal derivatives **14** and **15**, respectively, are obtained. The latter have previously been prepared from

$[Rh(\eta^3\text{-}CH_2Ph)(PiPr_3)_2]$ and HC≡CR (R = Ph, *t*Bu) under an atmosphere of ethene.[4c] The ^{13}C NMR data of **12** and **13**, in particular, which are in good agreement with those of other η^3-2,3,4-butadienyl metal compounds[11] support the structural proposal shown in Scheme 3.

Scheme 3. L = P*i*Pr$_3$.

As already mentioned,[6] the reaction of **5** with CO yields the η^1-vinylrhodium complex **E**, R = Ph, R′ = Me which reacts with acetic acid to give **16**.[6] This olefin is also formed almost quantitatively upon treatment of **8** with acetic acid (Scheme 4). The corresponding reaction of **13** with acetic acid affords regioselectively the butadiene derivative **18**.[12] The exclusive for-

Schema 4. L = $PiPr_3$.

mation of the (*Z*) isomer supports the assumption that in compound **13** (and probably also in **12**) the substituents at the non-coordinated C=C double bond are arranged *cis*. The rhodium-containing product of the reaction of **8** or **13** with acetic acid is the chelate complex **17**,[8] which can be reconverted in two steps [a) reaction with HC≡CR to give **I**;[4b] b) "chromatography" of **I** on chloride-containing Al_2O_3[13]] to the starting materials **2** and **3**. In this way a cyclic process can be established by which, from HC≡CR, R'MgX, and CH_3CO_2H and assisted by the metal, an olefin RCH=CHR' (R = Ph, *t*Bu; R' = Me, $CH=CH_2$) is *regio- and stereoselectively* formed.

trans-[RhH(C≡CR)(η^2-O_2CCH_3)($PiPr_3$)$_2$] **I**

Preliminary attempts indicate that the "metallabutatrienes" **J**[14] behave similarly towards Grignard reagents as the vinylidene complexes **1**–**3** and that the corresponding vinyl metal derivatives **K** undergo isomerization reactions as well. Therefore, the expectation is that even higher unsaturated hydrocarbons than **18** could be accessible by a rhodium-assisted C–C coupling procedure.

Synthesis of a 2*H*-Azirine by [1+2] Cycloaddition of a Phosphinocarbene with a Nitrile and Its Ring-Expansion to a 1,2λ^5-Azaphosphete**

Gilles Alcaraz, Ulrich Wecker, Antoine Baceiredo, Françoise Dahan, and Guy Bertrand*

Whether carbene, germylene, and silylene are justifiable terms for stabilized versions[1–4] of the reactive species is a very debatable question.[5] Calculations[6] and an X-ray diffraction study[1d] have clearly shown that phosphinocarbenes are best formulated as phosphorus-vinyl ylides. However, for synthetic chemists, the most important issue is to know whether these stable species show the reactivity of transient carbenes. The formation of azaphospholidines upon thermolysis (intramolecular carbene insertion into a carbon–hydrogen bond),[1a] cyclopropanations,[1b] and [1+1] addition to isocyanides giving keteneimines[1b,c] are nice examples of the carbene behavior of phosphinocarbenes. Here we report another carbene-type reaction, which has never been described with transient carbenes, namely the formation of a 2*H*-azirine by a [1+2] cycloaddition. We also report the first example of a ring expansion reaction of an azirine to a four-membered ring system with four π electrons.

The phosphinocarbene **1**[1e] reacts with a large excess of benzonitrile in toluene, at room temperature, to afford compound **2** (Scheme 1) in 85% isolated yield. According to ^{31}P NMR spec-

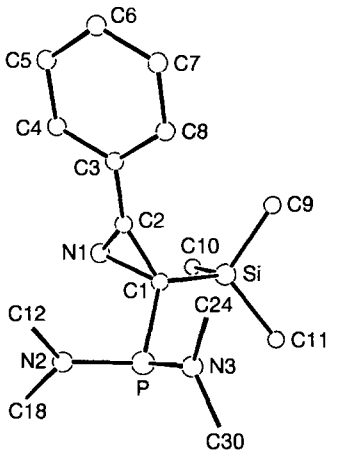
[**] This work was supported by the Alexander von Humboldt Foundation in the form of a Feodor-Lynen grant (U.W.), and by the Centre National de la Recherche Scientifique.

troscopy, the reaction was complete after 18 hours, and no intermediate was detected. Multinuclear NMR spectroscopy and mass spectrometry as well as elemental analysis showed that compound **2** was a 1,1-adduct of **1** with benzonitrile,[7] and an X-ray diffraction study[8] demonstrated that **2** was a 2*H*-azirine. The molecular structure of **2** is shown in Figure 1. Note, the typical[9] very long C1–N1 bond [1.629(4) Å]; for comparison, in diazirines the value of the C–N bond length is around 1.46 Å.[10]



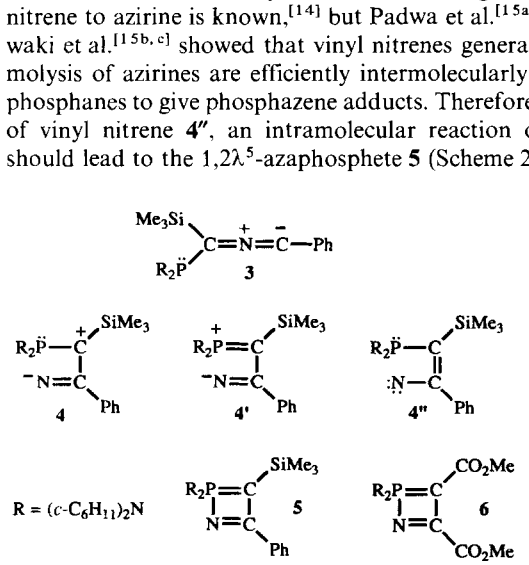


Fig. 1. Structure of **2** (ORTEP view). The cyclohexyl groups on N2 and N3 are omitted for clarity. Selected bond lengths [Å] and bond angles [°]: P-C1 1.870(3), P-N2 1.692(2), P-N3 1.705(2), C1-C2 1.468(3), C1-N1 1.630(3), C1-Si 1.899(2), C2-N1 1.254(4), C2-C3 1.452(4), P-C1-Si 118.1(1), P-C1-C2 125.9(2), P-C1-N1 111.5(2), N1-C1-C2 47.4(2), C1-N1-C2 59.5(2), N1-C2-C1 73.1(2), N1-C2-C3 137.6(3), C1-C2-C3 149.2(3).

Formally, azirine **2** results from a [1 + 2] cycloaddition of the carbene **1** to the nitrile. Electrophilic carbenes are known to react with nitriles giving transient[11] or even stable nitrile ylides.[12] Phosphinocarbenes have never shown any electrophilic character, and the ring closure of nitrile ylides into 2*H*-azirines is quite unlikely;[11–13] thus the nitrile ylide **3** cannot be the intermediate in the reaction leading to **2**. A stepwise mechanism, first involving the nucleophilic attack of the carbene at the carbon atom of the nitrile would lead to the 1,3-dipole **4**. However, it should be noted that **4** can also be regarded as azabetaine **4′**, or vinyl nitrene **4″**. The ring closure of vinyl nitrene to azirine is known,[14] but Padwa et al.[15a] and Nishiwaki et al.[15b,c] showed that vinyl nitrenes generated by thermolysis of azirines are efficiently intermolecularly trapped by phosphanes to give phosphazene adducts. Therefore, in the case of vinyl nitrene **4″**, an intramolecular reaction of this type should lead to the 1,2λ^5-azaphosphete **5** (Scheme 2).

Scheme 2.

Interestingly, addition of a catalytic amount of dichloro(*p*-cymene)ruthenium(II)[16] to a solution of **2** in dichloromethane at room temperature led to the 1,2λ^5-azaphosphete **5** in 95% yield! The four-π-electron four-membered heterocycle **5** has been fully characterized,[7] and the NMR data compared very well with those of the recently reported 1,2λ^5-azaphosphete **6**[17] ($\delta^{31}P = +52.3$ (**5**), +52.6 (**6**); $\delta^{13}C\alpha$ and $\beta = +84.9$ and +192.4 (**5**), +92.4 and 181.7 (**6**)).

These results as a whole suggest that either the formation of azirine **2** results from a concerted [1 + 2] cycloaddition, or that **2** is the kinetic product of the stepwise reaction of the stable carbene **1** with benzonitrile; the 1,2λ^5-azaphosphete **5** is the thermodynamic product. Whatever the mechanism, these findings should open a new route to the synthesis of a variety of 2*H*-azirines from transient nucleophilic carbenes.[18] More generally, after having used well-known reactions of transient species to demonstrate the existence of their stabilized versions, now, it is probably time to use the stabilized derivatives to discover new reactions applicable to the transient species.

Trends and Controversies

Redox Mechanisms in Inorganic Chemistry. (Ellis Horwood Series in Inorganic Chemistry.) By *A. G. Lappin*. Ellis Horwood, Chichester, 1994. 285 pp., hardcover £ 56.50.—ISBN 0-13-770751-7

This is a very timely and urgently needed book by an author who is well known for his contributions to the understanding of electron transfer reactions in inorganic chemistry. The author makes it clear in the preface that this is not a book on kinetics and mechanisms, nor on electron transfer or the theory of electron transfer reactions. The focus of the book is an examination of trends in mechanisms that are found in inorganic electron transfer reactions. And that is exactly what the book offers, a detailed account of available literature data and the trends that can be seen in these data.

As one would expect, the main topics covered, following a general introductory chapter, are the outer-sphere mechanism, the inner-sphere mechanism, intramolecular electron transfer, and multiple electron transfer. The author has devoted an impressive effort to compiling the available literature data and pointing out the trends observed. The individual chapters are excellent reviews on the topics, with the advantage that they are all written by the same author, resulting in a consistent style of presentation. At the end of each chapter a series of questions are given that enable the reader to check the insight gained into the topic treated. In addition, a detailed list of references to the original sources of the data is provided for each chapter.

The quality of production is good, except for the aspect referred to at the end of this review. Data are summarized in tables and correlations are summarized in figures. This method of presentation avoids excessive text and makes it easy for the reader to find the desired data. Reaction schemes and details of intermediate species are presented in a very clear manner, which all adds to the convenience and readability of the book.

The book will be of great help to anyone involved in the study of inorganic electron transfer reactions, since it is an up-to-date presentation of the available literature data. Furthermore, it identifies areas in which there is scope for further investigation and theoretical treatment of the data. All in all, it will be a standard text for students and researchers involved in the study of inorganic electron transfer processes.

It is rather unfortunate that there are quite a number of very obvious typing errors, especially in the first chapter of the book. It is the responsibility of the publisher, and to some extent the author, to eliminate such errors, which detract from the quality of the book and fail to do justice to the author's diligent efforts. Notwithstanding this, the book is highly recommended for everyone interested in inorganic electron transfer reactions.

Rudi van Eldik
University of Erlangen-Nürnberg (FRG)

The Organic Chemistry of Aliphatic Nitrogen Compounds. (International Series of Monographs on Chemistry, Vol. 28.) By *B. R. Brown*. Clarendon Press, Oxford, 1994. 767 pp., hardcover £ 145.00.—ISBN 0-19-855783-3

The author's aim in this well set out work was to provide a comprehensive survey of the organic chemistry of classical nitrogen compounds. The title is intended to indicate that heterocyclic systems are not in general covered, although aziridines and β-lactams are in fact included. The 22 chapters deal in varying degrees of detail with the following compound types: amines (Ch. 1), enamines and ynamines (Ch. 2), imines, iminium salts, ketenimines, and keteniminium salts (Ch. 3), nitriles, together with acyl nitriles and trimethylsilyl cyanide (Ch. 4), *N*-oxides, nitrones, and nitrile oxides (Ch. 5), isonitriles (Ch. 6), cyanates, isocyanates, and their sulfur analogs (Ch. 7), amides (especially dimethylformamide and its acetals), thioamides, carbamates, and sulfonamides (Ch. 8), urea derivatives and carbodiimides (Ch. 9), amidines (Ch. 10), nitro and nitroso compounds (Chs. 11 and 12, respectively), diazoalkanes (Ch. 13), hydroxylamines and oximes (Ch. 14), hydrazines (Ch. 15), azo and azoxy compounds (Ch. 16), azides (Ch. 17), nitrates, nitrites, and nitramines (Chs. 18 and 19), β-aminoalcohols (Ch. 20), aziridines (Ch. 21), and β-lactams (Ch. 22).

The main emphasis is on the synthesis of the various classes of compounds, including details of several reactions in each case, although these are not always the most important from a preparative standpoint. Each chapter begins with a very brief description of the structural properties of the compounds under discussion. Not all these introductions reflect the latest research results, and the selection of original papers that are cited is often idiosyncratic and sometimes incomplete. The frequent use of the abbreviation "F. & F." betrays the fact that the principal literature source used was the standard work by Fieser and Fieser. Altogether there are more than 1800 literature citations, mainly from the period 1960–1985. More recent citations (up to 1990) are found only occasionally. Some important original publications by well-known contributors to the field of nitrogen chemistry, such as Arnold, Böhme, and Viehe, are noticeably absent. By providing better coverage of recent reviews (including at least references to the *more recent* volumes in the Patai series), the author could have made it easier for the reader to gain access to the original literature. Moreover, the many typographical errors in authors' names, some of which are quite grotesque, are an annoying distraction.

The book is provided with a comprehensive subject index, but some random tests indicate that it does not always give the interested reader the required information. For example, the chapter on

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

enamines includes a section devoted to 1-chloro-*N*,*N*-2-trimethylpropenylamine, which is correctly described as having reactions typical of a keteniminium salt; however, this fact is not mentioned in the index, nor in the chapter on keteniminium salts. To give another example, the Vilsmeier reagent appears in the chapter on iminium salts, but its reactions are covered in the chapter on dimethylformamide, with no cross-reference. Inconsistencies of this kind make it rather difficult to use the book. Regrettably, the author (who died in September 1992) was unable to complete the manuscript himself.

I have some reservations about recommending that one should buy this book. It undoubtedly offers a clearly written and well illustrated guide to a wealth of interesting literature on nitrogen chemistry. However, as it is not very up-to-date and because of the shortcomings mentioned above, it can only serve as an introduction to the field and—with some reservations—as a reference source. As one would expect, it is not an alternative to the more comprehensive standard works such as "Houben-Weyl" and "Patai".

Talking Back to Prozac: What Doctors Aren't Telling You about Today's Most Controversial Drug. By *P. R. Breggin* and *G. R. Breggin*. St. Martin's Press, New York, 1994. XIV, 273 pp., hardcover $ 19.95.—ISBN 0-312-11486-9

Audiatur et altera pars! (Let the other side also be heard!) In many ways this book is the mirror image of Peter D. Kramer's controversial best-seller *Listening to Prozac* (Viking, 1993; for a review see G. B. Kauffman, *American Scientist* **1995**, *83*, 90–91). Both books were written by practicing psychiatrists; both deal with the mechanism of operation of antidepressants, particularly the class of selective serotonin reuptake inhibitors (SSRIs) to which Prozac, hailed by many as the antidepressant drug of choice of the 1990s, belongs; both recount the development and testing of Prozac and present detailed personal case studies and accounts of positive and negative effects of the drug; both consider the ethics of administering the drug as a "mood brightener", what Kramer himself called "cosmetic psychiatry"; and both, although replete with extensive documentation, were written for a popular audience. But here the similarity ends.

Peter R. Breggin, M.D., who wrote the first medical books on the brain-damaging effects of electroshock and psychiatric drug treatment, is a leading medical critic of biological psychiatry. His efforts at reform have included numerous articles and books, and U.S. media appearances on "Sixty Minutes," "20–20", and "Dan Rather Reports". His wife, Ginger Ross Breggin, is Director for Research and Education at her husband's non-profit Center for the Study of Psychiatry and is his coauthor of the forthcoming book, *The War Against Children*, a critical examination of the growing psychiatric movement to increase medication of pre-school children and minorities, with Prozac joining Ritalin as the drug of choice. Dr. Breggin, who has been called "the conscience of American psychiatry", states: "I wrote *Talking Back to Prozac* because of my compassion for the hundreds of thousands of people who suffer from depression, and for the many people who are being misled by the current emphasis on antidepressants as safe and effective treatments." He claims to be "one of the few psychiatric drug experts in the country without ties to the pharmaceutical companies, and can therefore speak openly about Prozac."

The Breggins' book is an urgently needed antidote to Kramer's book, which, they state: "has misled hundreds of thousands of readers and millions more who have heard its message of better living through chemistry." The Breggins argue that Kramer "bases his theory of Prozac-induced personality transformation on nothing more than a handful of his own cases, ... shows a naive reliance on the manufacturer of Prozac, Eli Lilly, in his discussion of the drug's impact on the brain, ... shows too little awareness of the pharmacological mechanisms that could cause the opposite of Prozac's intended effect, ... gives no credence to the Prozac survivor movement, ... [and] sprinkles his book with moral considerations, but does not seem to take them seriously."

In contrast to most books about psychiatric drugs, which provide the kind of information drug advocates and pharmaceutical companies want the public to have, the Breggins' book "provides information not readily available, even to most experts in the field, much of it ... systematically withheld from physicians and patients alike." Among other topics, they discuss in detail: the supposed selectivity of Prozac; the fact that Prozac was tested in trials of only four to six weeks before receiving U.S. Food and Drug Administration (FDA) approval; the difficulty that Eli Lilly had in proving its efficacy during these tests; the side effects that the FDA failed to include in its final labeling requirements; Prozac's short-term and long-term impacts on the brain; how Prozac acts as a stimulant similar to the addictive drugs cocaine and amphetamines; the economic and political forces ("the medical-industrial complex") backing promotion of the drug; the dangers of possible Prozac addiction, abuse, and withdrawal symptoms; the seriousness and frequency of Prozac's side effects; the growing evidence from case study after case study that Prozac can cause violence and suicide; the avalanche of lawsuits against Eli Lilly involving Prozac; and the social and workplace implications of using drugs, not to cure depression, but to change personality and enhance performance.

The authors also disclose the intricate web of cozy connections between the FDA, the drug companies, and the psychiatric community (what they call the "psycho-pharmaceutical complex"); the close ties that existed between Eli Lilly and both former U.S. President George Bush and former U.S. Vice-President Dan Quayle; and the FDA ban on the food supplement L-tryptophan, which forces people to use SSRIs instead. They decry the flooding of the country with propaganda in favor of taking drugs—"a technological shortcut for people who want to find their real personalities the fast-food way"—for conditions such as depression, which, in many cases, may be part of the human condition and a normal concomitant of an empathic life. They explore the positive side of depression and state: "To the degree that a human being is capable of suffering deeply, to that same degree the human being is capable of a full, rich, exciting, and creative life." They describe the resounding success achieved by more humane non-drug alternatives to the "National Prescription Drug" for the treatment of depression. In their copious notes the Breggins provide an extensive bibliography listing every author, article, or project mentioned in the book, and in the appendix they give useful information about the Psychiatric Reform Movement and the Prozac Survivors Support Group, including addresses and telephone numbers. They also provide a form and full directions for filing an adverse drug reaction report with the FDA.

This fact-packed book is a gold mine of valuable data for practicing scientists, science educators, pychiatrists, historians of science, policy makers, and those concerned with the relations between government regulatory agencies and pharmaceutical companies. On a more personal level,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1250 $ 10.00+.25/0

it is intended for anyone taking Prozac, considering taking it, or wanting to stop taking it, as well as for the families and physicians of anyone suffering from depression. It deserves to be as well known as or even better known than Kramer's book, which has received an incredible amount of publicity. Because the two books are complementary, they should be read together. Caveat aeger! (Let the patient beware!)

George B. Kauffman
Department of Chemistry
California State University
Fresno, CA (USA)

Synthesis of Sulphones, Sulphoxides and Cyclic Sulphides. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester, 1994. 720 pp., hardcover £ 175.00.—ISBN 0-471-93970-6

The book reviewed here belongs to the series *The Chemistry of Functional Groups*, which began over 30 years ago and is of great importance to synthetic chemists. As noted by the editors in the preface, this volume is the last in the current series of updated versions. It contains seven chapters by well-recognized authors, dealing mainly with synthetic aspects of open-chain and cyclic sulfones and sulfoxides, as well as cyclic sulfides. Three of the chapters (Ch. 1: "Synthesis of Open-Chain Sulfones", by K. Schank; Ch. 3: "Synthesis of Sulphoxides", by J. Drabowicz, P. Kielbasinski and M. Mikolajczyk); Ch. 5: "Cyclic Sulfones and Sulfoxides", by U. Zoller) are identical with Chapters 7–9 of the volume *The Chemistry of Sulphones and Sulphoxides*, published in the same series in 1988 (review: J. Voss, *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 1070). The latest developments in these areas (since 1986) are covered in the form of appendices (Chapters 2, 4, and 6). These follow the same structure as Chapters 1, 3, and 5, and the numbering system for the reaction equations, tables, and literature references continues directly on from the preceding chapters, so that one can easily compare the two and quickly find out about the latest research. The literature up to 1992 is covered thoroughly, extending in some cases up to early 1993. The lengths of these "appendix" chapters are clear evidence of the rapid developments in the last few years on many aspects of the chemistry of sulfones and sulfoxides. This is seen especially in Chapter 4, which is largely concerned with the use of chiral sulfoxides for asymmetric syntheses. All the authors have aimed at a concise but well-balanced treatment. Unavoidably, the monograph *Sulphones in Organic Synthesis*, by N. S. Simpkins, published in 1993 by Pergamon Press, appeared too late to be cited in the bibliography.

The last chapter, "Cyclic Sulfides", by G. Capozzi, S. Menichetti, and C. Nativi, seems to me to be of special importance and a very welcome part of this book for several reasons. Firstly, cyclic sulfides are in many cases indispensable precursors for the synthesis of cyclic sulfoxides and sulfones, reactions for which a wide variety of effective oxidizing agents for different situations are now available. Secondly, the most important characteristic properties of sulfur heterocycles with three- to eight-membered rings, mainly saturated, are here summarized in a single chapter. The authors have concentrated mainly on developments since 1980, while not neglecting earlier results of fundamental importance. In addition the comprehensive bibliography to this chapter (698 references) allows rapid access to earlier publications.

A minor point, but one that is unusual in a monograph, is that the authors have each been allowed to use their preferred spellings "sulphur" or "sulfur" in the names of the compounds discussed.

The volume contains a total of 3037 literature references and has carefully prepared author and subject indexes, which contribute to giving it the true quality of a handbook. It will be an extremely useful source of information, not exclusively for "sulfur chemists", and should therefore be available in every chemistry library.

Eberhard Wenschuh
Berlin (FRG)

Carbon-13 NMR Chemical Shifts in Structural and Stereochemical Analysis. (Series: Methods in Stereochemical Analysis. Series editor: *A. P. Marchand.*) By *K. Pihlaja* and *E. Kleinpeter*. VCH Publishers, New York, 1994. 379 pp., hardcover DM 150.00.—ISBN 0-89573-332-3

In the early 1970s, when ^{13}C NMR spectroscopy was approaching its full maturity, the effects of substituents on chemical shifts (substituent chemical shifts—SCSs) were important as an empirical aid in the interpretation of spectra, and thus in determining the structures of organic molecules. Since that time the importance of empirical correlations has declined as new one-dimensional and multi-dimensional experimental techniques have become available. These yield "hard" information (e.g., on scalar spin–spin couplings or on the nuclear Overhauser effect), making the "softer" information based on chemical shift considerations largely superfluous. This is a welcome development, as it puts structure determination onto a firmer basis and reduces the necessity for interpretations that rely on probabilities. Therefore, one might well ask whether it is still appropriate to bring out a book such as this one by the Finnish-German team of Pihlaja and Kleinpeter, which aims to stimulate an interest in ^{13}C NMR chemical shifts and to convince the reader of the usefulness of such data in structural analysis. The answer to the question is a definite yes, because the book is mainly concerned with the stereochemical aspects of ^{13}C chemical shifts, and the most recent major reviews on this subject appeared a considerable time ago, for example the articles in *Topics in Stereochemistry* by Wilson and Stothers in 1974 and by Duddeck in 1986.

The introductory chapter deals with practical considerations, including a discussion of the assignment of ^{13}C NMR spectra. The advice given to the reader seems somewhat arbitrarily chosen; the tips are occasionally trivial (e.g., "peak picking is strongly recommended"), and owing to the shortness of the chapter its value is rather limited. There is an error on page 2, where it is stated that the improvement in signal-to-noise ratio using quadrature detection compared with single-phase detection is a factor of $\sqrt{n}$ (where n is the number of accumulations); the correct factor is $\sqrt{2}$. In the section on "Referencing the Spectrum" it is of little help to give only the chemical shifts of undeuteriated solvents, and the information that deuterium isotope effects can be as large as 1 ppm does not improve matters. In the spectra shown in Figures 1.5 and 1.6 the numbering of the peaks does not entirely correspond to that in the structural formula. The list of literature references for Chapter 1 contains many errors, especially in the names of authors, which will immediately catch the reader's eye without even having to look up the references: "Breitmeier" for Breitmaier, "Hull" for Hill, "Schoolery" for Shoolery, "Bedall" for Bendall, "Submarian" for Subramanian, and so on. The references attached to the later chapters also show a lack of care.

The short second chapter deals in a general way with additivity relationships for SCSs (and deviations therefrom), and with the use of SCSs in structure determination and stereochemical assignments. Chapter 3 then discusses in greater detail

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1251 $ 10.00+.25/0

how SCSs (classified according to the effects of monosubstitution at α, β-, γ-, and δ-positions, vicinal disubstitution, polysubstitution, and buttressing effects) are related to molecular constitution and geometry. The arrangement of the subject matter in this chapter is not always ideal. In Chapters 4 (A–C) and 5, which form the major part of the book, the authors discuss in detail the ^{13}C chemical shifts for alicyclic compounds with four to seven atoms in the ring and for heterocyclic compounds with boron, nitrogen, oxygen, phosphorus, and sulfur as the heteroatom. An impressive amount of information is collected together in these chapters. The choice of material reflects the authors' research interests to some extent; for example, it contains a substantial collection of 54 methyl-substituted tetrahydro-1,3-oxazines (with up to five methyl groups) from Pihlaja's laboratory. The best part of the book in my opinion is Chapter 5, dealing with ^{13}C chemical shifts as probes for configurational and conformational analysis. Examples from a wide variety of compound types are discussed, showing how ^{13}C NMR spectroscopy is able to give answers to many different questions of stereochemistry. These include *endo/exo* isomerism in annelated norbornanes, configurations of diastereomeric pyranoses, conformations of hydroanthracenes and hydrophenanthrenes, configurations of olefins, conformational equilibria in cyclohexane derivatives and their hetero-analogs, steric perturbation of conjugated systems, stereochemically relevant deuterium isotope effects, relative configurations in compounds with several chiral centers, absolute configurations in chiral ketones and secondary alcohols, and conformations and tautomerism in the solid phase. The book is completed by three rather short chapters: one on dynamic ^{13}C NMR spectroscopy, one on configurational and conformational studies of natural products, organometallic compounds, and synthetic polymers, and a third on additional NMR parameters (δ_H, J_{HH}, J_{CH}, NOE, T_1) that can be combined with ^{13}C chemical shift data to yield information about configurations or conformations. Finally there is a fairly comprehensive subject index, but no author index.

This is in itself a very useful work, but as well as the defects already mentioned there is one more, which should not be exaggerated but nevertheless deserves to be mentioned. There were some long sections (probably written by only one of the two authors) in which I found the style very irritating. Typical faults were a lack of clarity, unnecessarily complicated sentence constructions, and occasionally modes of expression that might have been used in musty offices long ago. Moreover, the impression persists that in the translation (self-translation?) from this author's mother tongue into English there has been some sacrifice of clarity, which could put the reader into a state of "selective excitement" (quoted from p. 19). A more thorough language-polishing job by the publishers would have improved the book. When I read out some selected passages to an English colleague he found them incomprehensible. I will avoid prolonging this review by quoting examples. In fairness it must be added that the reader's irritation with these passages will quickly subside on reaching parts of the text that are clearly the work of the other author. I recommend that one should consider buying copies of this book by Pihlaja and Kleinpeter for the departmental library and/or for the NMR laboratory.

(FRG)

Free Atoms, Clusters, and Nanoscale Particles. By *K. J. Klabunde*. Academic Press, London, 1994. 311 pp., hardcover DM 177.00.—ISBN 0-12-410760-5

Fourteen years after the appearance of the monograph *Chemistry of Free Atoms and Particles* (Academic Press, 1980), in which the fundamentals of the generation and use of such species were presented for the first time, a second monograph on the subject has appeared from the same author, well known as one of the pioneers in this area. The current state of development in the chemistry of high temperature (HT) particles is presented in this volume.

After the initial rapid development phase of this chemistry in the 60s and 70s, in which the main emphasis was on matrix isolation studies and later increasingly on the molecular chemistry of such highly reactive particles, interest has now turned to new topics during the 80s and early 90s. In addition to the use of free atoms as synthetic building blocks in complex and organometallic chemistry, *Free Atoms, Clusters and Nanoscale Particles* also deals with studies of naked and ligand-stabilized (metal) clusters and particles. In addition to these main themes, the author, as hinted at in the title, devotes particular attention to the synthesis of new materials in the nano range by the use of free atoms and particles, as well as the study and characterization of the frequently unusual material properties of the nanoparticles thus prepared.

With regard to the organization of material, the author retains the trusted classification used in the earlier book mentioned above. After a brief introduction to the chemistry of highly reactive particles (first chapter), the second chapter (the only one that is completely new) deals with techniques and apparatus added since 1980 to the synthetic arsenal for the generation of free (metal) atoms, (metal) clusters, and also heterogeneous metal catalysts. In the whole section the reader is introduced, with the help of clear and precise diagrams, to the construction and mode of operation of the apparatus for the generation of these species. Thus, for example, the *S*olvated *M*etal *A*tom *D*ispersion (SMAD) technique for the preparation of supported heterogeneous catalysts is discussed in detail. Then, in 280 pages and eight chapters, subdivided according to the periodic system of the elements (Groups 1 and 2, 3–7, 8–10, 11, and 12, 13, 14, 15, and 16, together with lanthanides and actinides), the author discusses the chemistry of the individual HT species of the respective elements. Each chapter concludes with a summary of the relevant literature. Within the individual chapters there is a further subdivision into free atoms, free clusters, and molecular species of the elements in question. Each chapter closes with a generally brief report on the generation and properties of thin films of the elements in the group. In particular the first two subdivisions are further subdivided into a) preparation and occurrence, b) physical properties, and c) chemical reactions of these species.

The fact that the organization of the contents is almost identical to that in the earlier book—*Chemistry of Free Atoms and Particles*—might lead the reader to suspect that the work has only been superficially brought up to date. However, that is clearly not the case. The collection of almost 1300 references, mainly from the period 1980–1993, of which only a tiny portion appeared in the first work, refutes this impressively and, in addition, shows the amount of work that has gone into preparing the references. In particular, researchers active in the area of highly reactive particles will find a highly valuable source and reference for their own work in the detailed literature references in the individual chapters. The literature citations will provide those entering the field of HT

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1111-1252 $ 10.00+.25/0

particles as newcomers with a survey of almost the whole range of topics covered during the period 1980–1993.

In spite of the extensive literature references in the individual chapters, a few important investigations are unfortunately missing. Two examples from organometallic chemistry and heterogeneous catalysis will illustrate this. Thus, there is no reference in Chapter 3 to the preparation of sterically hindered Group II metallocenes by the use of atomic alkaline earth elements such as $Ca(^0)$, $Ba(^0)$, and $Sr(^0)$ (year of publication 1986). Similarly, in Chapter 10, there is no reference to investigations into ethene dimerization on heterogeneous $Sm(^0)$ and $Yb(^0)$ catalysts prepared according to the SMAD method (published 1989).

With regard to the content, in each of the eight chapters in the book the new developments within the individual areas of the main- and sub-groups of the Periodic Table are described concisely, but in sufficient detail where appropriate. The author avoids detailed repetition of topics that have already been adequately covered in the earlier work, referring the reader to that instead.

Chapter 8 (hydrocarbon groups) is the one that has been extended most in comparison with the earlier work. The reason for this is the newly added treatment of fullerenes, in which their preparation, bonding characteristics, and chemistry are discussed. The concise overviews on physical and spectroscopic studies of fullerenes, the preparation of fullerenes with encapsulated metal atoms (endohedral fullerenes), and the compilation of properties of thin films generated from C_{60} and C_{70} fullerenes, given in clearly arranged tabular form and again presented with a multitude of useful literature citations, are extremely useful. However, I feel that the reactions of fullerenes, in so far as they do not directly involve HT processes, could have been omitted without compromising the topicality of the book in this area. The reader who needs a more detailed account of the chemistry of the fullerenes can make use of the specialist monographs devoted to this topic.

The remaining criticisms are limited to a few formal matters. Thus, it is evident that the index is incomplete for efficient use of the book, because the organization is too brief to allow specific points to be found quickly or even at all. A little more detail in this respect would have helped the book a great deal. Also, although collecting the literature references together at the end of each chapter has some merits, it has the disadvantage that cross-references are difficult to follow up without tedious searching through the volume.

Regarding the visual presentation, it is a pity that most of the molecular structures, in particular those of the complex compounds presented, convey no spatial or perspective impression of the molecules. This is particularly evident in Chapters 4 ("Early Transition Metal Elements") and 5 ("Late Transition Metal Elements").

In spite of these rather formal criticisms, the reviewer has an overall positive impression of the book. It is a successful account of the developments in the chemistry of HT species, starting from 1980 up to the most recent past. In addition, it represents the sole currently available up-to-date summary of this topic. Using it in combination with the author's earlier monograph, one has an overview both of the basics and of the most recent developments and trends in the chemistry of HT species, which can be expressly recommended without hesitation to everyone interested in this area.

For the researcher already working on the chemistry of HT particles, *Free Atoms, Clusters and Nanoscale Particles* will, exactly as its predecessor—*Chemistry of Free Atoms and Particles*—quickly become an indispensable compendium on the chemistry of HT particles, despite of the rather high price. For the newcomer who wants a compact overview of this special area, the high price will discourage personal purchase, so that for this group of potential users the monograph may only be available by way of a well-stocked library.

Vibrational Spectroscopy in Supercritical Fluids: From Analysis and Hydrogen Bonding to Polymers and Synthesis**

Martyn Poliakoff,* Steven M. Howdle, and Sergei G. Kazarian

Supercritical fluids are beginning to be used widely in chemistry. Applications range from extraction and chromatography in analytical chemistry to solvents for reaction chemistry and preparation of new materials. Spectroscopic monitoring is important in much of supercritical chemistry, and vibrational spectroscopy is particularly useful in this context because the vibrational spectrum of a given molecule is usually quite sensitive to the environment of that molecule. Thus, vibrational spectra are excellent probes of conditions within the fluid. In this review, we describe a variety of techniques and cells for IR and Raman spectroscopy in supercritical fluids and illustrate the breadth of applications in supercritical fluids. The examples include: the use of supercritical Xe as a spectroscopically transparent solvent for chemistry and for supercritical fluid chromatography with FTIR detection of analytes; Raman spectroscopy as a monitor for gases dissolved in supercritical CO_2; the effect of solvent density on hydrogen bonding in supercritical fluids and the formation of reverse micelles; IR as a monitor for the supercritical impregnation/extraction of polymers and the reactions of organometallic compounds impregnated into polymers; reactions of organometallic compounds in supercritical fluids; and finally, the use of miniature flow reactors for laboratory-scale preparative chemistry. Overall, our aim is to provide a starting point from which individual readers can judge whether such measurements might usefully be applied to their own particular problems.

Keywords: analytical chemistry · IR spectroscopy · photochemistry · Raman spectroscopy · supercritical fluids

1. Introduction

Supercritical fluids are currently the subject of major research projects in both academic and industrial chemistry.[1] The fluids have already had a significant impact on traditional analytical chemistry[2] and may well transform wide areas of chemistry. The systematic study of supercritical fluids is therefore a matter of both urgency and interest.

In its broadest sense, the term supercritical fluid can be applied to any gas that is compressed to a pressure greater than its critical pressure, p_c, and heated to a temperature above its critical temperature, T_c (Table 1). In practice, the definition is generally restricted either to gases close to their critical temperatures or, if the temperature is far above T_c, to those gases compressed to densities close to their critical densities, ρ_c. The behavior of such gases is so far from ideal that supercritical fluids have been a source of continuing scientific interest since the middle of the nineteenth century. In recent years, this interest has been significantly increased by the possibility of using supercritical fluids for a wide range of extraction processes and chemical reactions, applications which exploit the almost counter-intuitive power of supercritical fluids to dissolve solid substances.[1] The result has been a general shift in focus of research

[a] For critical data of other substances, see the excellent compilation by Reid et al [112]. [b] **Safety warning**: N_2O has similar critical parameters and rather better solvent properties than $scCO_2$ but there have been reports [113] of potentially disastrous explosions when scN_2O has been used with even small amounts of organic compounds. Therefore, scN_2O should only be used with extreme caution.

from pure fluids to the behavior of more complex supercritical solutions. Traditionally, most investigations of supercritical fluids have involved macroscopic phenomena (phase changes, thermodynamics, etc) but the complexity of these mixtures has led to the need for more detailed information on a molecular level. It is the purpose of this review to show how vibrational spectroscopy, both infrared and Raman, is now providing molecular information relevant to a wide range of processes in supercritical fluids.

The application of vibrational spectroscopy to the investigation of supercritical fluids is relatively new. In this review, we outline the scope of the technique and highlight how it has been applied to problems of chemical interest. We also discuss the main technical problems and indicate how they have been overcome. Mostly, we consider fluids whose critical temperatures lie in the range close to room temperature (i.e. from scC_2H_4 with $T_c = 9\,^{\circ}C$ to $scSF_6$ with $T_c = 46\,^{\circ}C$) since these have had the widest impact on both synthetic and analytical chemistry.[1, 2] scH_2O is only briefly discussed, not because scH_2O is less interesting (it has considerable potential for the oxidation of toxic materials and environmental contaminants[3]) but because the high temperature and pressure ($T_c = 374\,^{\circ}C$ and $p_c = 218$ atm) render most of the technical problems quite different. Our review complements Buback's excellent summary of near-IR spectroscopy in supercritical fluids,[4] and the reader's attention is drawn to a number of recent multiauthored books[2, 5] which, together, constitute an excellent introduction to the current state of supercritical science and its applications to chemistry. In Section 2, we describe a number of designs of high-pressure cells for IR and Raman spectroscopy. Then, in Section 3, we describe the use of scXe as a solvent for both spectroscopy and chromatography and compare its properties with those of $scCO_2$. In Section 4, we outline the role of Raman spectroscopy and show how it can be applied to the study of supercritical fluid/gas mixtures. Sections 5–7 give an illustrative range of applications to hydrogen bonding (5), to polymers (6), and to organometallic chemistry (7). Finally, in Section 8, we show how IR spectroscopy is playing an important role in the development of laboratory-scale flow-reactors.

M. Poliakoff

S. M. Howdle

S. Kazarian

Martyn Poliakoff was born in 1947 in London (UK), studied chemistry at Cambridge University (BA, 1969) and received his Ph.D. for work on the matrix isolation of large molecules under the supervision of J. J. Turner, with whom he has subsequently had a long and productive scientific collaboration. In 1972 he moved to the University of Newcastle upon Tyne and in 1979 to the University of Nottingham, where he is currently Professor of Chemistry and holder of an EPSRC Fellowship in Clean Technology. For the past eight years his research has focussed increasingly on the chemical and analytical applications of supercritical fluids. He has been awarded the Meldola Medal (1976) and Tilden Medal (1990) of the Royal Society of Chemistry and has held a Nuffield Foundation University Fellowship (1988/9) and a Royal Society Leverhulme Trust Senior Fellowship (1993/4). He has longstanding scientific connections with Germany; Stipendiat of the Alexander von Humboldt Stiftung (Laserforschung in Garching), 1978 and 1979, and fruitful collaborations with the Max-Planck-Institut für Strahlenchemie, Mülheim, and the University of Würzburg.

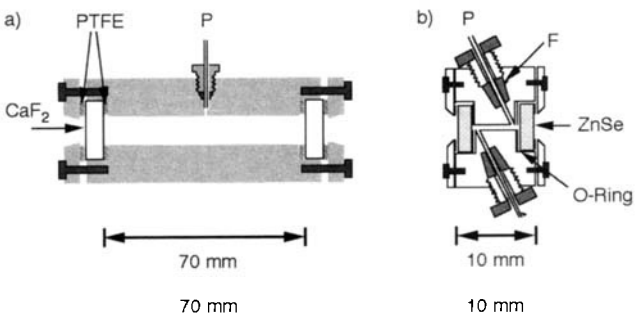
Steve Howdle was born in 1964 in Rotherham, Yorkshire. He studied chemistry at the University of Manchester (1986) and then moved to Nottingham to study for his Ph.D. (1989) under the supervision of M. Poliakoff. For the next two years, he extended his Ph.D. work on chemical reactions in supercritical fluids, as BP Venture Research Fellow at Nottingham. In 1991, he was awarded a Royal Society University Research Fellowship, which he has held at Nottingham. Over the past three years, he has investigated the supercritical impregnation of polymers porous solids and his interests have broadened to encompass the preparation and characterization of biocompatible coatings. Recently, he and M. Poliakoff have built up a strong and extremely fruitful collaboration with research groups in Russia.

Sergei Kazarian born in 1958 in East Kazakhstan (USSR), studied physics at the Novosibirsk State and Yerevan State Universities. After completing his diploma in physics (1980) he moved into physical chemistry and received his doctorate in 1987 under the supervision of B. V. Lokshin at the Nesmeyanov Institute of Organoelement Compounds (Moscow) for the work on the interactions of transition metal complexes with proton donors in liquefied noble gases. In 1988, he moved to the Institute of Spectroscopy in Troitzk, where he continued this work. He spent six months at the Max-Planck-Institut für Strahlenchemie, Mülheim and from 1991–1994 he worked as Visiting Researcher in M. Poliakoff's group at the University of Nottingham (UK). Currently, he is a Research Associate with C. A. Eckert at Georgia Institute of Technology, Atlanta (USA). His research interests include the spectroscopic study of intermolecular interactions in liquid xenon, supercritical fluids, and polymers.

2. The Design of High-Pressure Cells

2.1. General Considerations

The design of the high-pressure cell needed for a particular IR experiment clearly depends on the nature of that experiment. Important points include the maximum operating pressure and temperature, the optical pathlength required, the particular range of the IR spectrum, which will restrict the choice of window material and, finally, whether the contents of the cell need to be stirred. There is also a number of more subjective questions: Are the measurements to be strictly quantitative? Is it likely the cell will have to be dismantled frequently (for example, to remove reaction products)?



Although the pressures involved in experiments in supercritical fluids (usually less than 300 atm) are sometimes considered to be modest by those who specialize in "high-pressure" chemistry, the gaslike nature of the fluids impose quite severe constraints on the design of the cells. As far as we are aware, there are few, if any, cells which are commercially available. However, a considerable variety of designs for high-pressure cells for use with supercritical fluids have already been published[6] including some elegant designs in Buback's review.[4] All of these cells share a number of general features. Clearly, the cell has to be safe for high-pressure operation, there has to be at least one IR transparent window, although most designs accommodate two, and at least one port for filling/venting the fluid.

In general, the IR transparent windows are mechanically the weakest part of any cell and sealing these windows to the cell body is usually the most difficult engineering task. Sherman and Stadtmuller have provided a very detailed discussion of the design of high-pressure cells, although much of their book[7] is devoted to pressures greatly in excess of those required for supercritical fluids, and Whyman has reviewed the design of high-pressure IR cells for conventional solvents.[8] Both the book and the review discuss, in some detail, the safety margins needed for the IR windows. Three of the key parameters are the ratio of the total area of window to the unsupported area (i.e. the area through which the IR light passes), the thickness of the window, and the rupture modulus of the window material. By applying the appropriate formulae, one finds that surprisingly thin windows, only 2 or 3 mm thick, are required for miniature cells with very small unsupported areas, such as the chromatography cell shown in Figure 1b. All modern Fourier transform (FT) IR instruments have a circular IR beam profile so it is no longer necessary to use rectangular windows,[9] which improved the performance of high-pressure cells in older dispersive IR spectrometers. Even so, it should be borne in mind that most commercial suppliers have a range of standard diameters for IR windows and apparently minor changes in design can alter the cost of a cell disproportionately, depending on whether the windows are standard or non-standard sizes.

Sherman and Stadtmuller have described a number of approaches to the design of the pressure seal between optical windows and the cell body,[7] two of which are most appropriate for supercritical fluids. Both approaches work well but each has problems. The more straightforward approach, the "opposed force" method, involves sealing the cell body to the inner face of the window (i.e the face which is in contact with the fluid) with a gasket, O-ring, or similar. The main drawback is that windows often break during assembly; most window materials are brittle, and mechanical pressure must be applied to the window to make the seal. Supercritical fluids can cause swelling in some polymers and, in smaller cells, the swelling of polymer O-rings can be sufficient to shatter the windows. The alternative approach, the "Poulter" method, has been pioneered for liquefied gases by Bulanin in Russia.[10] This approach involves sealing a window on its planar outer surface; the internal pressure of the fluid then forces the window into the seal, and leaks are less frequent. However, it is often difficult with this design to avoid crevices and dead-volumes which can be more easily penetrated by supercritical fluids than by conventional liquids. Such crevices preclude quantitative measurements and, in evacuable cells, additional precautions are needed to prevent atmospheric pressure pushing the windows inwards away from their seals. We now describe a selection of cells that illustrate these general design principles.

2.2. Selected Cell Designs for IR Spectroscopy

The cell shown in Figure 1a was developed by Johnston and Kim for investigating solvatochromism and hydrogen bonding[11] (see Section 5). The pathlength is long (70 mm) because the cell is intended for use with dilute solutes in fluids (e.g. $scSF_6$ or $scCO_2$) which do not themselves absorb in the region of interest. Since the studies were to be quantitative, the overriding requirement was to eliminate dead volumes where undissolved solute might accumulate. Thus, the windows are sealed on their inside edges, and a mechanical stirrer is provided to ensure that the contents of the cell are homogeneous. An absence of dead volume is also a crucial requirement for the cell shown in Figure 1b. This cell, developed by Jenkins et al. is intended for FTIR identification of analytes separated by capillary supercritical fluid chromatography (cSFC,[12] see Section 3). The volumes of fluid involved in such a separation are very small, because the capillary is only 50–100 μm in diameter, so the internal volume of the cell has to be extremely small to preserve the separation of the analytes. At the same time, the optical

70 mm 10 mm

Fig. 1. Two high-pressure IR cells for use with supercritical fluids, both with windows sealed by the "opposed force" method. a) Schematic cross-section of a stainless steel cell designed by Johnston and Kim for studying solvatochromism and hydrogen bonding [11]. P = fill port; PTFE = polymer seals; CaF_2 = calcium fluoride windows. The cell has two electric cartridge heaters (not shown) embedded in the walls for raising the temperature of the cell. b) A brass cell for cSFC-FTIR measurements [12]. P = ports connected to a silica capillary tube (50 μm i.d.); F = graphite ferrule for sealing the capillary to the cell body; O-ring = Viton seals; ZnSe = zinc selenide windows. Note that the two parts of the Figure are drawn to different scales. The cell a) has an internal volume of about 5 mL, while cell b) has a volume of only 500 nL.

pathlength must be as long as possible to give increased sensitivity and good limits of detectability. The design is therefore a carefully engineered compromise between these conflicting requirements: Although the internal volume of the cSFC cell in Figure 1b is 500 nL, 10^{-4} times that of Johnston's cell,[11] the pathlength of the cell is 4.4 mm, that is only 1/16th of that of Johnston's. With appropriate beam condensing lenses on the cSFC cell,[12] the optical throughputs of the two cells are remarkably similar.

Figure 2 illustrates a completely different approach adopted by Smith and co-workers for the study of reverse micelles in supercritical and near-critical solution.[13] In this case, the optical pathlength needed to be short because the mixtures under

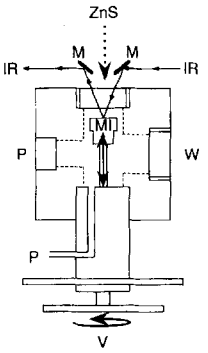


Fig. 2. Variable pathlength IR reflectance cell devised by Smith and co-workers. P = fill ports; IR = beam of FTIR interferometer; M = external mirrors; MI = internal mirror, which can be moved up and down to vary the pathlength by rotating the handle of the modified high-pressure valve V; ZnS = zinc sulfide window; W = observation window; from ref. [13].

study were highly IR absorbing but, at the same time, the vessel itself had to be relatively large so that the components could be properly mixed. The design satisfies these requirements in that the spectra are measured in reflectance rather than in transmission, with a single IR-transparent window and a highly polished steel mirror, which can be moved to adjust the optical pathlength. Although this design worked well for their particular experiments, quantitative measurements are quite difficult to make in such a cell because one has to correct for the effect of the light which is reflected from the outside face of the window without passing through the solution.

The three cells described so far were designed, at least initially, for very specific experiments. A much simpler and more general design is shown in Figure 3. This cell, developed at Nottingham, is specifically designed to be easy to dismantle and reassemble.[14] The windows are therefore sealed on their outer

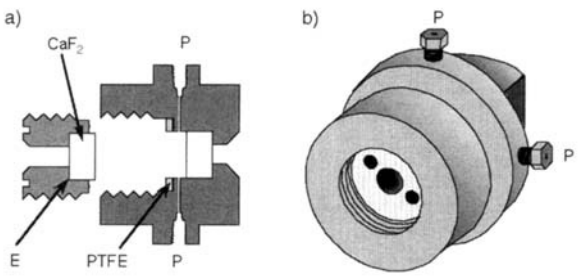

Fig. 3. Cross-section (a) and external view (b) of a stainless steel general purpose high-pressure IR cell. P = fill ports, threaded for standard 1/16th inch o.d. pipe fittings; E = epoxy resin, which is used to seal the CaF_2 windows (15 mm diameter, 10 mm thickness) by the "Poulter principle"; PTFE = principal seal between the two parts of the cell, which is made metal → metal. For further details, see ref. [14].

edges (one into the body of the cell and the other into the removable holder), and the main seal is made between metal surfaces and a PTFE spacer. Unlike the Smith cell (see Fig. 2), the pathlength cannot be varied during an experiment, but a selection of different pathlengths is available merely by using a number of different holders, each with the window held at a different depth. The simplicity of the cell means that it can easily be adapted for experiments as varied as impregnation of polymers (Section 6) or photochemistry of organometallic compounds (Section 7). The cell is however too small to allow effective stirring, although it can be used as a component of flow systems (see Section 8).

Any of these cells can be heated and varying the temperature of the fluid is frequently a key feature in supercritical experiments. It should, however, be remembered that even quite modest rises in temperature can cause substantial rises in pressure. In general, it is more difficult to cool IR cells than to heat them. The Russian cell designs, described in some detail by Bulanin[10] have usually included cooling, largely because the cells were primarily intended for spectroscopy in liquid solution at cryogenic temperatures. Figure 4 shows a relatively simple miniature

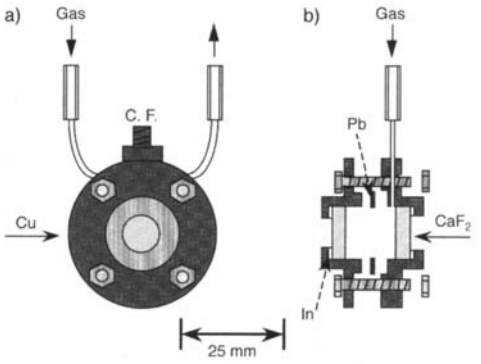

Fig. 4. External view (a) and cross-section (b) of a miniature high-pressure IR cell, made of copper and capable of being cooled to cryogenic temperatures. C. F. = mounting stud for cold finger of cryogenic cooler; In = indium metal which seals the CaF_2 window to the Cu cell body by the "Poulter Principle"; Pb = main lead seal between the two halves of the cell; ↑ and ↓ = gas fill ports.

high-pressure cell,[15] small enough to mount directly on a closed cycle-cryogenic cooler, and suitable for use in the temperature range 30–300 K. This design will allow fluids with a critical temperature T_c well below room temperature to be studied close to their critical points as well as at ambient temperatures.

2.3. Cells for Raman Spectroscopy

A number of IR cells have been based on high-pressure T- or X-pieces,[16] adapted so that the ports can take IR windows rather than pipes. This design approach has also been taken in the construction of cells for Raman spectroscopy, where the optical and geometric requirements are somewhat different from those of IR. Briefly, Raman experiments in supercritical fluids usually involve excitation of the sample by a focussed and relatively intense laser beam; the scattered light is then detected in a direction perpendicular to the laser beam. Raman scattering is a relatively weak effect and so this scattered light has to be

collected efficiently which is difficult to achieve in practice. Thus, the number of published Raman studies on supercritical systems is much smaller than that for the corresponding IR studies. Ben-Amotz and co-workers have designed an elegant cell with a single window;[17] the scattered light is collected at 180° to the incident laser beam. Although similar in concept to Smith's design for IR cells (see Fig. 2), the Raman cell does not require a mirror since Raman scattering occurs in all directions. A number of groups have used optic fibers to introduce the laser light and this considerably simplifies the Raman experiment. Figures 5a and b show two such designs; a) is a cell intended for

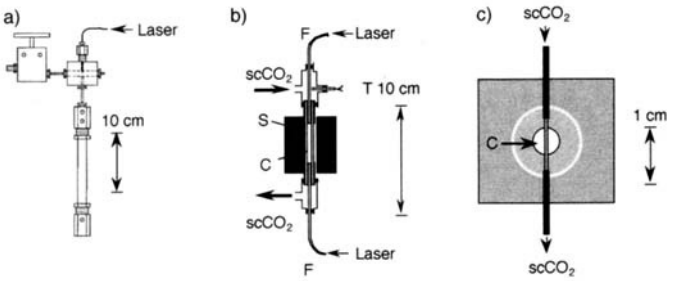

Fig. 5. Three high-pressure cells for Raman spectroscopy of supercritical fluids. a) Cell for studying reactions in scH_2O. The laser beam enters the cell through an optic fiber, and a parallel fiber is used to collect the scattered light; from ref. [18]. b) A cell, based on high-pressure capillary tubing, C, for Raman measurements with an Ar ion (visible wavelength) laser. The cell is mounted directly between the entrance slits S of the spectrometer. F = optic fibers for the input of laser light; T = thermocouple; $scCO_2$ = ports for the supercritical fluid (for more complete diagrams, see ref. [19]). c) Cell for FT Raman, based on a capillary, C, similar to that in Fig. 5b. The opaque polyimide coating of the capillary, (thick black bar) is removed at the point where the near-IR laser irradiates the cell (similarly, the coating is removed in cell b). The capillary is mounted directly in the holder supplied with the Perkin-Elmer System 2000 FT Raman instrument, which has a silvered reflector designed to optimize collection of the scattered light. (Note the different scales of the drawings of the three cells.)

experiments in scH_2O, fibers are used both for laser excitation and collection of the scattered light[18] and b) is a sub-miniature capillary cell,[19] devised by Howdle et al. for studying gases dissolved in $scCO_2$. Raman spectroscopy has distinct advantages over IR spectroscopy for experiments in scH_2O, largely because the fluid is highly absorbing over much of the range of the IR spectrum and so corrosive that most IR window materials are rapidly destroyed. The ultimate in simplicity is achieved by the cell for FT-Raman[20] shown in Figure 5c. This cell is made merely by removing the polyimide coating from standard silica capillary tubing of the type normally used for chromatography. The small diameter of these capillary cells ensures that the scattered light can be collected extremely efficiently and, furthermore, one does not need to worry about cleaning the cell since it is essentially disposable!

Safety Note: All of the illustrations in Figures 1 to 5 are purely schematic and should not be regarded as engineering drawings for the construction of safe high-pressure cells. Those wishing to build such equipment for themselves must carry out their own safety evaluation.

3. Supercritical Xenon

Ever since the classic work by Andrews on the critical point,[21] a huge proportion of the published research on super critical fluids has involved $scCO_2$, most recently because of its potential as an environmentally acceptable substitute for organic solvents in extraction and in synthetic chemistry.[1, 2] From the spectroscopic standpoint, $scCO_2$ has the distinct disadvantage that a number of key regions in the IR spectrum are completely obscured by absorptions of $scCO_2$ itself. This problem has led to considerable interest in liquefied and supercritical noble gases[10b] which constitute a unique set of solvents for spectroscopy, totally transparent throughout the spectrum from vacuum-UV to far-IR.

The first systematic IR studies in liquid noble gas solution were initiated in Leningrad by Bulanin and co-workers over 20 years ago.[10a] Their primary interests have centered on cryogenic noble gas solutions, an area which they have recently reviewed in some detail[10b, 22] but, as mentioned in Section 2, some of their cells had a sufficiently high-pressure rating (i.e. > 60 atm) to be used with supercritical xenon scXe. Maier et al. also developed the use of liquid noble gases in the USA but his equipment could not be used for supercritical fluids because it was not suitable for use at pressures above 20 atm.[9]

scXe is a fascinating material. Its critical temperature, 16.7 °C (see Table 1), is very close to ambient temperature, making scXe a convenient medium for investigations of the spectroscopic effects associated with the transition from the liquid to the supercritical state. The critical density ρ_c, $1.11\,g\,mL^{-1}$, is greater than the density not only of water but also of many common organic compounds, both liquid and solid. scXe is a moderately good solvent for nonpolar compounds and, although there have been few quantitative comparisons, the solubility in scXe is somewhat higher than in $scCO_2$, in at least some cases (e.g. polycyclic aromatic compounds).[23, 24] In general, the solvent properties of scXe are comparable to but not quite as good as those of hexane or other alkanes. scXe can therefore be used as a solvent for chemical reactions and for chromatographic separations. For a given compound, solubility is nearly always greater in scXe near room temperature than in liquid Xe (LXe) at cryogenic temperatures; this increase in solubility is probably due more to the higher temperature of the scXe rather than to some inherent solvent property of the fluid itself. Whatever its cause, the effect is substantial. For example, $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$ is virtually insoluble in LXe even at −30 °C, but usable concentrations can be obtained[25] in solution in scXe at 25 °C, even in the presence of "antisolvents" such as H_2 or N_2. As with other supercritical fluids, solubility of a compound in scXe at a particular temperature increases with increasing pressure and hence density. This property is a key factor in the use of scXe for chromatography[12, 23] but it can complicate some studies such as the investigation of hydrogen bonding (see Section 5).[16]

Liquid Xe (LXe) has been extremely successful as a solvent for studying weak intermolecular interactions,[10b] for example for proton donors,[22] or for stabilizing highly labile organometallic compounds.[26] This success largely derives from the cryogenic temperatures of LXe, a property which clearly cannot be matched by scXe, although scXe still retains the chemical inertness of LXe. Nevertheless, IR spectra of stable solutes reveal few differences between the properties of LXe and scXe. Some IR bands, for example, ν(C–O) vibrations of transition metal carbonyl compounds are significantly broader in

scXe than in cryogenic LXe, possibly a consequence of the lower viscosity of scXe. On the other hand, inherently broader bands,[27] for example the ν(H–H) band of $[W(CO)_5(\eta^2\text{-}H_2)]$, can have identical FWHM (full width half maximum) values in scXe at 25 °C and LXe at −90 °C. The transition through the critical point from LXe → scXe has almost no effect on some vibrational properties. For example, Moustakas and Weitz found[28] that the rate of vibrational relaxation of HCl ($v = 1 \rightarrow v = 0$) in Xe is unchanged on heating at constant density from 289 K (liquid phase) to 291 K (supercritical), possibly because bimolecular encounters HCl + HCl are not a major relaxation pathway.

In general, as shown in Figure 6, the IR bands of a particular solute in scXe are slightly narrower than the bands of the same

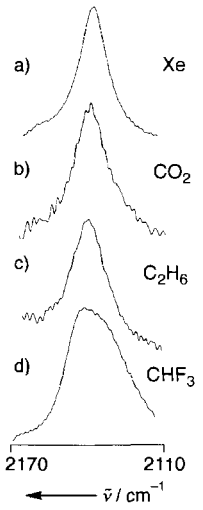

Fig. 6. Comparison of the IR bands of $[Cp^*Ir(CO)(H)_2]$ ($Cp^* = \eta^5\text{-}C_5Me_5$) dissolved in different supercritical fluids, all of which are doped with H_2: a) Xe, b) CO_2, c) C_2H_6, and d) CHF_3. In each case, $[Cp^*Ir(CO)(H)_2]$ was generated in situ by irradiation of $[Cp^*Ir(CO)_2]$ with UV light in the presence of H_2. The IR band illustrated is in the ν(Ir–H) region and corresponds to the unresolved a′ and a″ vibrations of the H-Ir-H moiety; from ref. [29].

solute dissolved in other supercritical fluids at the same temperature.[29] As might be expected the width of the bands is dependent on the polarity of the fluid; the broadest band in Figure 6 is observed in the most polar fluid CHF_3, although it is possible that some form of hydrogen bonding could be occurring in this case. The overriding advantages of scXe remain its inertness and its transparency (lack of absorption bands) which can transform IR spectroscopy into a surprisingly sensitive and versatile tool for structural chemistry. This transparency of scXe has also been a key factor in its use as a mobile phase for supercritical fluid chromatography (SFC).

SFC is a relatively specialized chromatographic technique that shares features of both gas and liquid chromatography (GC and LC). The techniques of SFC have been described in detail elsewhere[30] but in principle they are quite simple. In its capillary form (cSFC), separation occurs on a microbore silica column suitably coated on the inside surface with a stationary phase similar to that used for capillary GC. The supercritical fluid mobile phase flows down the column and then through an extremely narrow bore restrictor which throttles the flow of the fluid sufficiently to maintain a high pressure in the column. To carry out a separation, the fluid is made to flow through the column at a relatively low pressure and the mixture of analytes is injected onto the column so that the components partition between the mobile and stationary phases. The pressure of the fluid, and hence its density, is then gradually increased under computer control, and the various components of the mixture elute from the end of the column sequentially, with the most soluble compound eluting first. Thus, unlike GC, the whole separation is carried out isothermally and cSFC is particularly suited to separating thermally labile compounds of high molecular weight (e.g. polyglycerides).[31] One of the attractions of cSFC over LC is that one can use most of the detectors normally used for GC (i.e. FTIR, flame ionization, etc).[31a, 32] Such detectors are not easily used with LC because signals from the liquid mobile phase swamp those due to the analytes. cSFC-FTIR, therefore, offers excellent opportunities not only to separate but also to fingerprint the components of a complex mixture and Novotny and co-workers were the first to suggest that the IR transparency of scXe would make it preferable to $scCO_2$ as a mobile phase for cSFC-FTIR.[33]

The general requirements of a high-pressure IR cell for cSFC-FTIR were discussed in Section 2. The differences between the cell designs from different groups have lain in the volume and beam optics rather than in the overall concept but it is these differences which have determined the sensitivity and detection limits of the various cells.[12, 23, 34] The more sensitive cells can be used to record spectra "on the fly" so that spectra of all of the components in a mixture can be obtained in a single run.

Figure 7 shows a chromatogram for the separation of a mixture of polycyclic aromatic compounds (PAH) and the FTIR

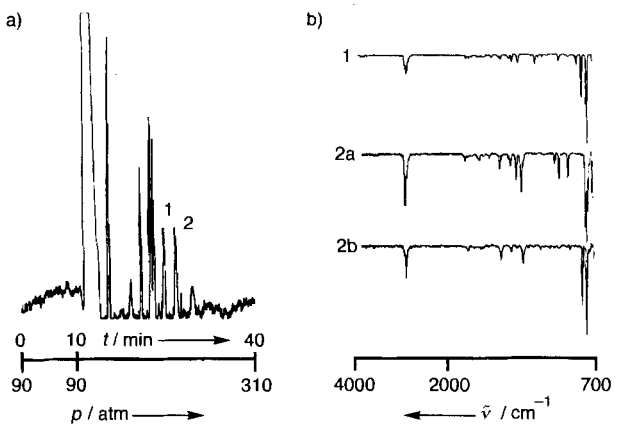

Fig. 7. cSFC-FTIR separation of a test mixture of eight polycyclic aromatic compounds (PAH) (10 mg mL^{-1} in CH_2Cl_2) using scXe as a mobile phase. a) Chromatogram, reconstructed from the total IR absorption spectrum; the first peak is due to the solvent CH_2Cl_2, and the other peaks are due to the different PAH compounds which elute from the column in order of increasing molecular weight. b) IR spectra corresponding respectively to peak 1 and to the leading (2a) and trailing edges (2b) of peak 2 of the chromatogram; the spectra are readily identifiable as those of chrysene (1), 9,10-diphenylanthracene (2a), and perylene (2b). Spectra were recorded in 15 s using the cell illustrated in Fig. 1b; from ref. [12].

spectra corresponding to some of the peaks.[12] In this case, the most characteristic bands of the different PAH compounds lie below 800 cm^{-1}, a region which is obscured in $scCO_2$ by absorptions of the CO_2 itself. On the other hand, the absorptions of CO_2 mask relatively limited regions of the spectrum (3800–3500, 2250–2100, and < 800 cm^{-1}, see Fig. 9a) and, for many compounds, spectra adequate for identification can be obtained with $scCO_2$ as eluent. A quite detailed comparison has been made between scXe and $scCO_2$ as mobile phases.[35] The conclu-

sion was that there are minor differences. Analytes do not necessarily elute in precisely the same order; the more polar analytes taking longer to elute in scXe than in $scCO_2$. There are modest shifts in the wavenumbers of IR bands of solutes as the density of the fluid is increased but the effect is similar in magnitude for both fluids. These shifts present problems when analytes are to be identified by matching the observed spectra against a library of spectra, which are unlikely to have been recorded under supercritical conditions.[36, 37] It seems, however, that particular classes of bands (e.g. ν(C–O) bands of ketones) all display comparable shifts and so it should be relatively simple to adapt the standard algorithms for library searching to allow for these supercritical shifts.

The sensitivity of the cSFC-FTIR method is surprisingly high and, outside the regions where $scCO_2$ absorbs, there is little difference between scXe and $scCO_2$. Using the cell illustrated in Figure 1b, the minimum detectable injected quantity of caffeine in $scCO_2$ is only 95 pg. and the cell gives a linear response over a wide range of concentrations[36] (Fig. 8). Over the past decade, the price of Xe has been highly volatile but, in recent years, the price has stabilized at a level which permits scXe to be used in the laboratory whenever cSFC-FTIR data are required over the entire region. cSFC columns have a very small volume and Cook and co-workers quote a usage of about 3 mL scXe per day[23] (although they did not define how many separations constituted a "day"). With larger scale usage, there is always the possibility of recycling the Xe, for example, as is done by Bulanin and co-workers.[10] Fortunately, cSFC-FTIR equipment can easily be switched between $scCO_2$ and scXe so that the chromatographer can choose the more appropriate mobile phase for a particular separation.

tection, there are some experiments where it is a distinct advantage, particularly those where the properties of pure fluids are to be probed. In such cases, the IR absorption bands associated with the fundamental vibrations of the molecules (CO_2, C_2H_6, etc) are so intense that extraordinarily short optical pathlengths would be needed for usable measurements. This difference can be seen clearly in Figure 9, where the Raman and FTIR spectra of $scCO_2$ are compared.

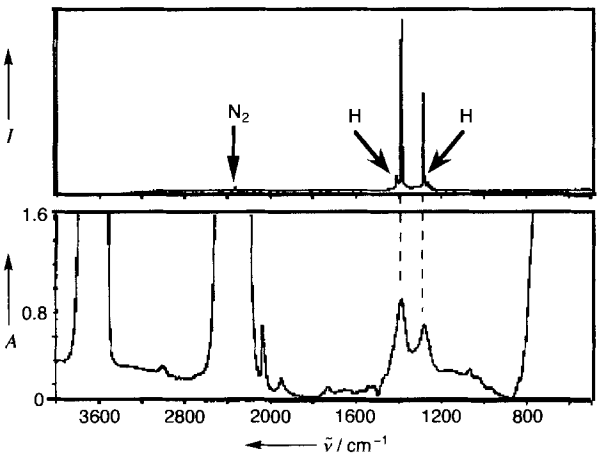

Fig. 9. Comparison of the FTIR spectrum (bottom) and the FT Raman (top) spectrum of $scCO_2$. The IR spectrum was recorded in the cSFC cell (Fig. 1b) at 250 bar pressure and ca. 32 °C with a 4.4 mm optical pathlength, while the Raman spectrum was recorded at ca. 100 bar pressure in the cell constructed from high-pressure capillary tubing (Fig. 5c). The dotted lines indicate the two Fermi resonance bands in the IR spectrum which coincide with the principal bands in the FT Raman spectrum. The two weak features, labeled H in the Raman spectrum, are due to hot bands, while the band labeled N_2 is due to atmospheric nitrogen in the light path of the FT Raman spectrometer.

4. Raman Spectroscopy in Supercritical Fluids

Raman scattering is a relatively weak effect compared to IR absorption. Although this weakness can create problems in detection, there are some experiments where it is a distinct advantage, particularly those where the properties of pure fluids are to be probed. In such cases, the IR absorption bands associated with the fundamental vibrations of the molecules (CO_2, C_2H_6, etc) are so intense that extraordinarily short optical pathlengths would be needed for usable measurements. This difference can be seen clearly in Figure 9, where the Raman and FTIR spectra of $scCO_2$ are compared.

There have been a number of Raman investigations where changes in either the contour or the position of Raman bands have been measured as a function of fluid density and these changes have then been related to the intermolecular interactions within fluids such as $scCO_2$,[38] scC_2H_6,[17] and recently, near-critical H_2S.[39] Figure 10 shows data obtained by Ben-Amotz et al. for C_2H_6 just below its critical point, a regime where the fluid compressibility is already anomalously high.[17] The data are striking because they show that the behavior of two vibrational modes of the same molecule can be substantially different under identical conditions. Nevertheless, their behavior can be modeled reasonably well by using a hard sphere model and the differences between the modes is ascribed to the fact that the ν(C–H) vibration is more polarizable than the ν(C–C). Ben-Amotz makes the interesting point that these differences might be reflected in a chemical reaction with two or more possible products. If branching in such a reaction were to involve sig-

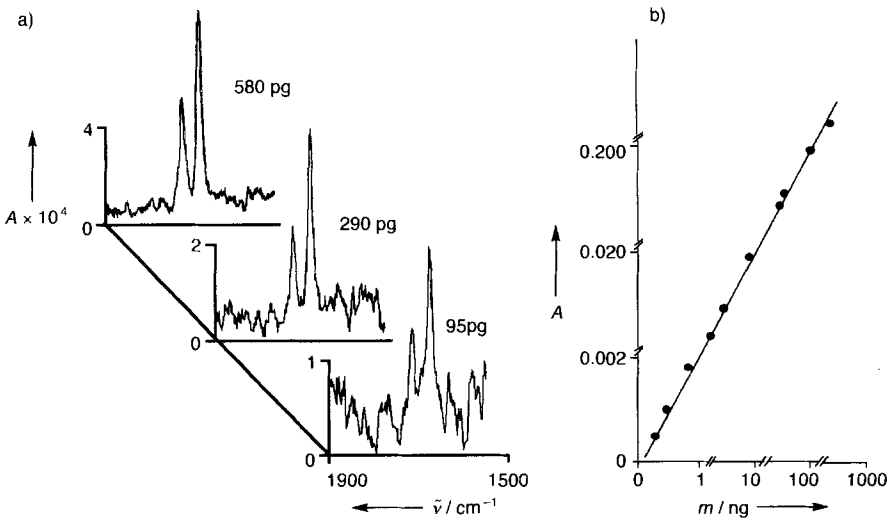

Fig. 8. a) Spectra illustrating the sensitivity of the cSFC-FTIR method with $scCO_2$ as the mobile phase and using the 500 nL IR cell illustrated in Fig. 1b. ν(C–O) region of the spectrum recorded for injections of solutions containing respectively 580, 290, and 95 pg of caffeine. b) Beer's Law plot (IR peak absorbance vs. injected concentration) for caffeine in $scCO_2$. Note that, somewhat unusually, both axes have been split so as to accommodate the very large range of concentration (95 pg–170 ng) on a single Figure; from ref. [36].

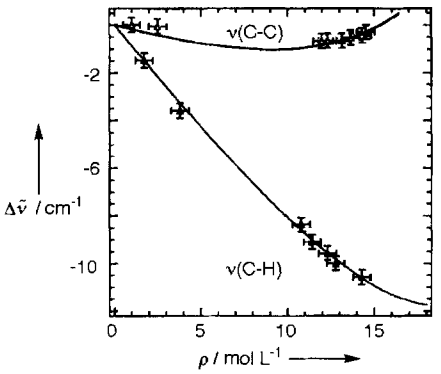

Fig. 10. The shifts in frequency $\Delta\tilde{\nu}$ of two vibrational modes with increasing density ρ of sub-critical C_2H_6 at 26 °C. The lines show the shifts computed with a hard fluid model; from ref. [17]

nificantly different vibrational coordinates, changes in fluid density might change the relative yields of the products. Density effects have been observed in a number of reactions, most dramatically for the photodimerization of isophorone,[40] but the changes in product distribution have been explained satisfactorily on the basis of solvation effects in bimolecular intermediates. Thus, Ben-Amotz's intriguing prediction remains to be verified experimentally.

An alternative approach to studying interactions is to use Raman spectroscopy to monitor bands of solute molecules dissolved within the fluid. The problem is one of sensitivity; relatively concentrated solutions must be used. Elegant Raman spectroscopic work has been carried out by Akimoto and Kajimoto in acetone and acetonitrile, both of which have quite high solubility in a variety of fluids ($scCO_2$, $scCF_3Cl$, etc).[41] They monitored the position of the $\nu(C{=}O)$ and $\nu(C{\equiv}N)$ bands as a function of fluid density and interpreted the shifts of these bands in terms of the solute–fluid interaction potential. In general, however, such studies are often easier to carry out by IR spectroscopy, as can be seen from the spectra in Figure 11, comparing the effects of scC_2H_6 and scC_2F_6 on the ν_2 (bending vibration) band of CO_2. These spectra were recorded by Yee et al. as part of an investigation[42] aimed at establishing whether the high solubility of fluorocarbons in $scCO_2$ (see Section 5) might be due to a strong $C{-}F\cdots CO_2$ interaction. However, the similarity of the spectra of CO_2 in scC_2H_6 and in scC_2F_6 shows that, in this case at least, there is no exceptional $C{-}F\cdots CO_2$ interaction.

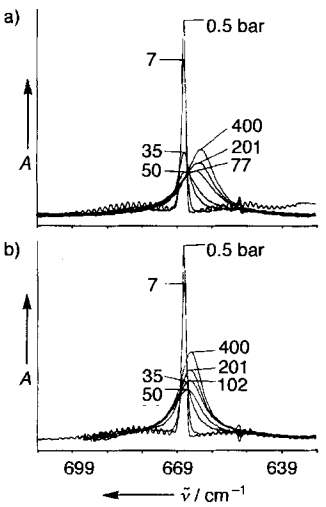

Fig. 11. IR spectra showing the effect of fluid pressure on the $\nu_2(O{=}C{=}O)$ bending vibration of CO_2 (0.02 M) in a) C_2H_6 and b) C_2F_6 from 0.5 bar (pure CO_2 gas) to 400 bar; from ref. [42].

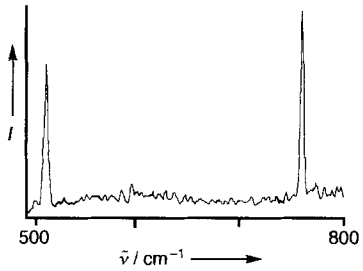
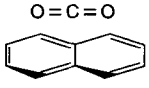
Even a cursory glance at Figure 9 reveals the consequences of the centrosymmetric structure of CO_2 and the mutual exclusion principle of IR- and Raman-active bands; regions of the spectrum which are obscured by IR absorptions of $scCO_2$ (Fig. 9 bottom) are essentially free of bands in the Raman spectrum (Fig. 9 top). The only exception is in the region, 1400–1200 cm^{-1}, where two bands, formally forbidden in IR spectroscopy, become allowed at high pressures and are observed as relatively weak, pressure-dependent absorptions. (The presence of these two bands can cause some difficulty in cSFC-FTIR with $scCO_2$ as the mobile phase but the bands can be removed from the spectra of the analytes by the appropriate computer subtraction of "blank" spectra of $scCO_2$ itself.[36]) A detailed FTIR study[43] of these bands has recently been published. The advantage of mutual exclusion can be seen in the Raman spectrum of naphthalene in $scCO_2$ (Fig. 12), which shows two bands in a region which would be obscured in the IR spectrum.[19] Unfortunately, the low sensitivity of most Raman experiments means that spectra of solutes can only be recorded in relatively concentrated solutions. A more detailed Raman study[44] of naphthalene/$scCO_2$ was carried out by Zerda et al. who deduced from the shifts in the wavenumbers of three different bands of naphthalene that there was a modest anisotropic interaction between naphthalene and CO_2. Their calculations suggested that this interaction might be due to the quadrupole–quadrupole $CO_2/C_{10}H_8$ interaction ($U^{QQ} = 19.1$ kJ mol^{-1}) shown in **1**. These conclusions have been supported by recent MINDO/3 calculations from Dean and co-workers.[45]





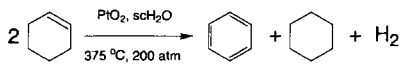


Fig. 12. Part of the Raman spectrum, ν_9 and ν_8 vibrations, of a saturated solution of naphthalene in $scCO_2$ (165 atm and 39 °C) recorded with 488 nm excitation (30 mW) and using the cell shown in Fig. 5b. Note that this region of the IR spectrum would be totally obscured by intense absorptions of $scCO_2$ itself; from ref. [19].

1

A more practical application of Raman spectroscopy is for monitoring reaction mixtures. Some Raman spectroscopic studies[18, 46] have been reported for scH_2O, where technical problems preclude the use of IR spectroscopy; apart from the absence of IR windows which are not corroded rapidly by scH_2O, high temperatures can cause problems in FTIR, and scH_2O itself has extremely intense absorptions over much of the mid-IR region. Masten et al. have followed the decomposition of N_2H_4 in near-critical and scH_2O,[46] while, using the cell shown in Figure 5a, Kolis and co-workers were able to monitor the catalytic dehydrogenation of cyclohexene given in Equation (a) (ca. 12% in scH_2O; Fig. 13).[18]

(a)

The complete miscibility of H_2 and N_2 with supercritical fluids can be exploited for a variety of new or more efficient reactions (see Section 7). Raman spectroscopy is proving to be the most convenient method of detecting these gases;[19, 20] the vi-

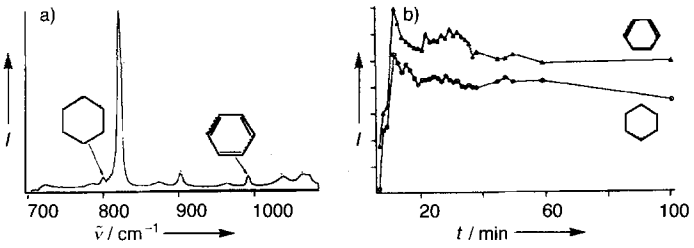

Fig. 13. a) Raman spectrum recorded during the catalytic reaction of cyclohexene in scH_2O, see Equation (a). The unlabeled bands are due to unconverted cyclohexene, those marked are due to cyclohexane and benzene. The intensity of the bands for cyclohexane and benzene are recorded as a function of time in Fig. 13 b; from ref. [18].

bration of an isolated homonuclear diatomic does not give rise to an IR absorption and, even though the vibrations may become IR active in solution or at high pressures, only very weak IR absorptions can be observed.[25] The vibrational Raman bands[19] of both N_2 and H_2 show modest shifts and broadening on going from the pure gas at high pressure to a mixture of the gas with $scCO_2$ at a similar pressure (Fig. 14a). The broadening, however, is considerably more dramatic and highly pressure-dependent for the rotational bands of H_2 in near- and supercritical CO_2 (see Fig. 14b); this broadening has been tentatively attributed to clustering of the solvent around the H_2 "solute".[47]

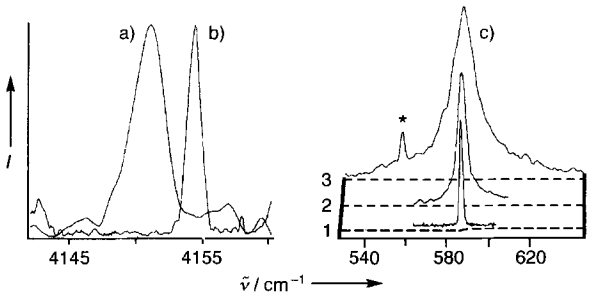

Fig. 14. Raman spectra showing how the $Q_1^{(1)}$ vibrational band of H_2 is broadened and shifted to lower frequency in $scCO_2$ (a) (23 °C and 175 atm; mole ratio H_2:CO_2, 1:4.8) compared to the same band (b) of H_2 gas at the same total pressure (175 atm). By contrast, there is almost no frequency shift in the $S_1^{(1)}$ rotational band (c) but there is a strong pressure dependence in width; 1: pure H_2 gas (87 atm); H_2 gas dissolved in $scCO_2$ at 60 atm (2) and 160 atm (3). The band marked with an * is a laser plasma line; from ref. [19].

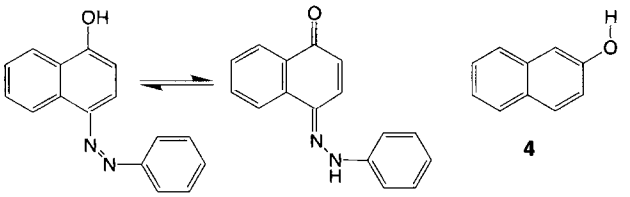
Solute/solvent clustering[48] (sometimes also referred to as "Charisma"[48]) in supercritical systems is still a subject of much debate.[49] Near the critical point, local fluctuations of density undoubtedly occur even in pure fluids and give rise to the well-known effect of "critical opalescence". This can cause such strong scattering of light that the fluid is rendered opaque even in the IR region. The scientific debate, however, centers on whether clustering can occur specifically around solute molecules. Evidence for clustering comes largely from UV/Vis fluorescence measurements where fluorescence lifetimes are extremely sensitive to the concentration of the fluorescer; unexpectedly short lifetimes close to the critical point are taken to indicate a local increase in the concentration of solute. In fluorescence studies, the behavior of solute molecules is monitored in dilute solution and, for precisely this reason, effects due to clustering are relatively easy to detect.[50, 51] By contrast, Raman studies generally involve observation of the spectrum of a pure fluid or very concentrated solution. Thus, the spectra will be dominated by features from the bulk of the fluid, and the effects of clustering may be difficult or impossible to observe. Thus, it is not surprising that Raman studies such as that by Ben-Amotz et al. do not show evidence for clustering.[17]

Solute/solvent clustering is discussed further in Section 5 in the context of hydrogen bonding, but first we highlight a promising application of Raman spectroscopy to the study of dissociation processes in supercritical fluids. One of the most fascinating features of supercritical fluids is that phenomena can be studied as a function of solvent density, from gaslike to liquidlike values. Homolytic dissociation of molecules and the subsequent recombination of radicals (or atoms) is a process which is likely to be heavily influenced by solvent density; at high densities, geminate recombination within the solvent cage should be significant but, at low densities, the process is highly improbable. Ravi et al. have modeled the effects of solvent density on the dissociation of Br_2 in noble gas solvents.[52]

Clearly, geminate recombination is an extremely rapid process. Recently, Knopf and co-workers have begun experiments[53a] aimed at detecting vibrationally excited I_2 formed by geminate recombination in $scCO_2$ on a picosecond timescale [Eq. (b).]

$$I_2(v = 0) \xrightarrow[scCO_2]{h\nu} 2I^{\bullet} \longrightarrow I_2(v \gg 1) \longrightarrow I_2(v = 0) \qquad \text{(b)}$$



In principle, the requisite sensitivity can be achieved because the dissociation is completely reversible and spectra can be accumulated over many shots at 200 Hz. Preliminary experiments in cyclohexane have been successful, revealing the generation of very highly excited I_2 ($v < 52$); work on $scCO_2$ solutions is in progress. The dynamics of the geminate recombination itself have been studied in scAr on much shorter (i.e. sub-picosecond) timescales by Zewail and co-workers[53b] using UV/Vis detection which has much higher inherent sensitivity than Raman spectroscopy but which cannot provide as detailed information as Raman spectroscopy on the vibrational distribution in condensed phases.

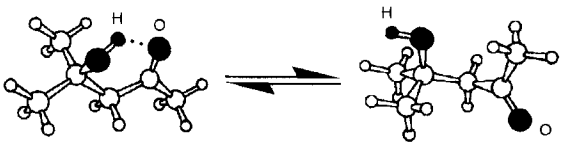
5. Hydrogen Bonding

5.1. The Need for IR Monitoring

The original impetus for studying hydrogen bonding in supercritical fluids was twofold; first, the possibility of establishing whether equilibria involving hydrogen bonding were sensitive to solvent density and, second, the fact that hydrogen bonding is frequently a key factor in the action of so-called "modifiers", compounds added to supercritical fluids to enhance the solubility of particular solutes.[54] It is occasionally possible to use UV/Vis spectroscopy for monitoring equilibria of compounds with hydrogen bonds. This has obvious advantages because UV spectrometers have high sensitivity and few, if any, of the common supercritical fluids absorb in the UV range. Thus, the absorption spectra of the two tautomers in equibrium, **2** and **3**, are significantly different.[55] In scC_2H_6 (and in liquid higher alkanes), the azo tautomer, **2**, predominates at all fluid densities

while, in $scCO_2$, increased fluid density increases the concentration of hydrazone **3** relative to that of **2**, to a point where the concentrations of the two tautomers are almost equal. This effect is attributed to a quadrupolar interaction of **3** with CO_2 (analogous to the interaction between naphthalene and CO_2 in **1**). By contrast, **3** is favored at all densities in the more polar fluid $scCHF_3$, presumably because a hydrogen bond between the solvent and solute ($F_3C-H\cdots O=C$), can stabilize **3** relative to **2**.

2 **3** **4**

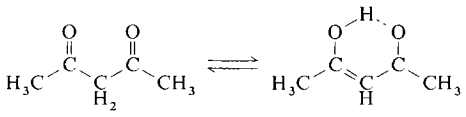


On the other hand, significant hydrogen bonding has been excluded by Tomasko et al. as a possible explanation of their fluorescence experiments[51] with **4** and related compounds in pure and modified $scCO_2$. In general, however, hydrogen bonding cannot be detected by UV spectroscopy and vibrational spectroscopy is needed.

5.2. Hydrogen Bonding and IR Spectroscopy

Unlike UV/vis spectroscopy, IR spectroscopy is widely applicable for studing hydrogen bonding. Thus, in compounds with O–H groups, hydrogen bonding causes the ν(O–H) band, typically at 3600 cm^{-1}, to broaden, increase in intensity, and to shift down in wavenumber;[56] both qualitatively and semiquantitatively, the stronger the interaction the greater the increase in intensity and the greater the wavenumber shift.[57] Most studies of hydrogen bonding in supercritical fluids have been carried out with alcohols and have involved measuring the change in equilibrium constant as a function of temperature, pressure, or density for a particular equilibrium [Eq. (c)].

$$RO-H + B \rightleftharpoons RO-H-B \qquad K_c = \frac{[RO-H-B]}{[RO-H][B]} \tag{c}$$



However, the variation in intensity of the ν(O–H) band of hydrogen-bonded O–H groups makes it difficult to measure the concentrations of both the alcohol [ROH] and that of the hydrogen-bonded complex [RO–H–B]. To circumvent this problem, quantitative studies have often been made with the total concentration of alcohol constant (i.e. [ROH] + [RO–H–B] = constant) whereupon it is only necessary to monitor the amount of free alcohol [ROH] by way of the ν(O–H) band. Unfortunately, $scCO_2$ has a strong IR combination band in precisely the region where this ν(O–H) band occurs (see Fig. 9 bottom), and ν(O–H) vibrations are poor Raman scatterers so that Raman spectroscopy is not a viable alternative in this case. A number of strategies have been tried to overcome this difficulty. One approach,[16] tried by Ikawa and Fujita, is to use scXe which has no IR absorptions there (see Section 3). They studied 4-hydroxy-4-methyl-pentan-2-one, one rotamer of which has intramolecular hydrogen bonding [Eq. (d)].

(d)

Although the ν(O–H) region of the spectrum contained no solvent absorptions in scXe, the bands of the free and hydrogen-bonded rotamers overlapped so that computer subtraction was still required to disentangle the spectra. Furthermore, the solubility of the compound increased dramatically with increasing density of scXe so that spectra required additional normalization. Nevertheless, their results reveal a striking change in partial molar volume associated with the rotamerization close to the critical point, changes which are over two orders of magnitude larger than those observed in conventional solvents. This anomaly was attributed to solvent/solute clustering.

Surprisingly, no such clustering effects were observed by Saito and co-workers,[58] who investigated the tautomerism of 2,4-pentanedione in $scCO_2$, which also involves intramolecular hydrogen bonding [Eq. (e)]. The ratio of tautomers was measured based on the ν(C=O) region of the spectrum, where $scCO_2$ does not absorb significantly. Increasing density was found to favor the keto (non-H-bonded) tautomer, although the enol form remained predominant at all densities. This decrease in hydrogen bonding (intra- or intermolecular) as the fluid density increases appears to occur in nearly all of the systems studied so far.

(e)

5.3. Hydrogen Bonding of Methanol

The most extensive work on hydrogen bonding in supercritical fluids has been carried out by the groups of Johnston and his collaborators and of Smith, using the cells illustrated in Figures 1a and 2, respectively. Much of their attention has been focussed on CH_3OH which is the most commonly used modifier for $scCO_2$; indeed, chromatographers often use commercial cylinders of CO_2 premixed with CH_3OH.[59] Smith and coworkers[60, 61] overcame the difficulty of observing ν(O–H) vibrations in $scCO_2$ by using deuterated CH_3OD which has its ν(O–D) band in the region, about 2600 cm^{-1}, unobscured by absorptions of $scCO_2$ (Fig. 15). They were helped by the design of their cell which allowed high concentrations of CH_3OD to be used, because the use of low concentrations of deuterated alcohols in metal apparatus is frequently plagued by D/H exchange with residual traces of H_2O. Some of their results are shown

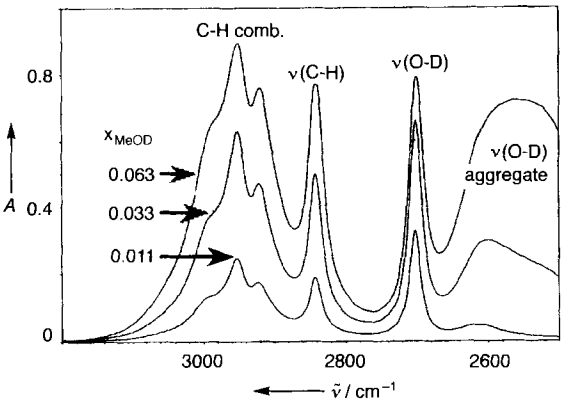


Fig. 15. The FTIR spectrum of CH_3OD in $scCO_2$, illustrating the strategy by Smith and co-workers of using deuterated alcohols to avoid the spectral regions obscured by absorptions of $scCO_2$. The spectrum was recorded in the cell shown in Fig. 2 at 40 °C and 400 bar. The band marked "C-H comb." is a composite absorption resultng from several ν(C-H) combinations; from ref. [61].

schematically in Figure 16. The phase diagram shown there indicates that it is possible for higher concentrations of CH_3OD to be dissolved in the single supercritical phase than in the gas phase at the same temperature.[61] Thus, supercritical mixtures of $scCO_2$ and CH_3OH can contain predominantly hydrogen-bonded alcohol. Surprisingly, their experiments showed that there was relatively little difference in aggregation between any of the $CH_3(CH_2)_nOH$ alcohols $0 < n < 9$. Figure 16 illustrates

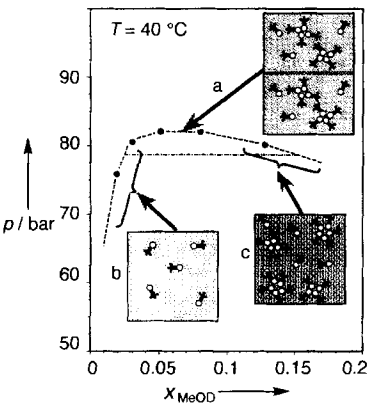

Fig. 16. Phase diagram (pressure p vs. mole fraction x) for CH_3OD in CO_2 at 40 °C, with schematic representations of the aggregation of CH_3OD in the vapor, liquid, and single phase regions of the diagram. a = critical point; b = vapor phase; c = liquid phase; from ref. [61].

two further points: First it is extremely important in such studies, indeed in any supercritical study, to know the precise phase behavior of the system in question. Second the self-association of CH_3OH and other alcohols consists of a series of coupled equilibria [Eq. (f)], which are complicated, if not impossible, to separate for quantitative study.

$$n\,ROH \rightleftharpoons (ROH)_2 + (n-2)ROH \rightleftharpoons (ROH)_3 + (n-3)ROH \ldots \rightleftharpoons (ROH)_n \quad (f)$$

Gupta et al. largely avoided this problem of self association of CH_3OH by using a considerable excess of the base Et_3N.[62] They then tried to use the equilibrium in Equation (g) for

$$CH_3OH + Et_3N \rightleftharpoons CH_3O\text{-}H\text{-}NEt_3 \quad (g)$$

investigating the effect of solvent density on hydrogen bonding in $scCO_2$. The results were encouraging; increased solvent density appeared to shift the equilibrium in favor of the unbonded species. This study was made with $scSF_6$ which, unlike $scCO_2$, has no IR bands in the ν(O–H) region so that undeuterated CH_3OH could be used. The ν(O–H) bands of both the free and the hydrogen-bonded alcohol could also be monitored, but the extinction coefficient of the band of hydrogen-bonded complex was difficult to calibrate. More importantly, the vapor pressures of CH_3OH and NEt_3 were sufficiently low that care was needed to keep the $CH_3OH/NEt_3/CO_2$ mixture as a single phase.

5.4. Hydrogen Bonding of Perfluorinated Alcohols

Smith and co-workers were the first to use perfluoroalcohols in the study of hydrogen bonding in supercritical systems.[42] These alcohols had been used in related studies in the non-supercritical range over a number of years prior to this,[22b] particularly because they are much more acidic than their nonfluorinated analogues[63] and therefore form stronger hydrogen bonds and can be used in greater dilution in the supercritical solution. In $scCO_2$, fluoroalcohols have the added attraction that they are considerably more soluble than the corresponding nonfluorinated compounds. Studies of the type illustrated in Figure 11, suggest that there is no enhanced interaction between CO_2 and C–F bonds. Smith and his co-workers therefore proposed that the reason for the high solubility lay in the formation of weaker hydrogen bonds by the fluoroalcohols than by the nonfluorinated alcohols.[42] However, this suggestion does not explain why other fluorocarbons that are not alcohols also show enhanced solubility in $scCO_2$. Whatever the reason, the phenomenon is quite widespread and has considerable promise, as shown by DeSimone et al., for the synthesis of fluoropolymers[64] and by Wai et al., for the extraction of metals with fluorinated chelating agents in supercritical fluids.[65]

Smith's experiments on hydrogen bonding were performed with unbranched perfluoroalcohols,[42] which retain the propensity to aggregate and therefore the equilibria are just as complicated as those of the unfluorinated compounds. By contrast, branched perfluoroalcohols such as perfluoro-*tert*-butyl alcohol (PFTB), $(CF_3)_3COH$, have a very small degree of self-aggregation,[22b] even at low temperature in cryogenic solvents. This means that PFTB has quite a low boiling point and vapor pressure (ca. 40 Torr at room temperature) relatively high in comparison to the unbranched alcohols. In collaboration with Gupta and Johnston, we have exploited the volatility of PFTB to study its hydrogen bonding to $(CH_3)_2O$, an even more volatile base (vapor pressure at room temperature ca. 4 atm).[66] With PFTB and $(CH_3)_2O$ in the cell shown in Figure 1a, it was possible to obtain the required concentrations of acid and base in the gas phase *without* any added fluid. We were therefore able to study the effect of fluid density on this equilibrium between the components without and with hydrogen bonds from zero up to liquidlike densities. Again $scSF_6$ was used as the fluid because it has no significant IR absorptions above 2500 cm^{-1} even with an optical pathlength of 7 cm. As pointed out by Inomata et al.,[67] the key problem in such studies is that IR extinction

coefficients of solutes can vary with fluid density and, furthermore, the effect is not necessarily linear[66] nor is it the same for different solutes. Thus, for the PFTB/$(CH_3)_2O$/SF_6 system, a considerable amount of calibration was required to allow for the nonlinear variation of IR extinction coefficients with fluid density and to avoid spectroscopic artefacts. Spectra, such as those in Figure 17, fully supported the results of earlier workers,

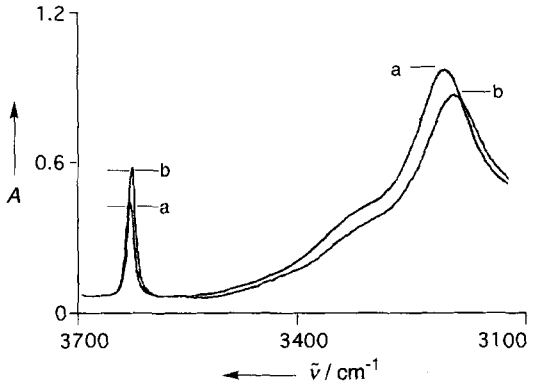

Fig. 17. IR absorption spectra in the ν(O–H) region showing the effect of adding SF_6 to a mixture of $(CF_3)_3COH$ and $(CH_3)_2O$ at 50 °C. Trace a was recorded after addition of 560 psi of SF_6 and trace b with 645 psi total pressure of SF_6. The increase in pressure causes a reduction in intensity of the broad band of the complex with hydrogen bonds with a concomitant increase in the sharp band of the free $(CF_3)_3COH$. The spectra were recorded in the cell shown in Fig. 1a; from ref. [66].

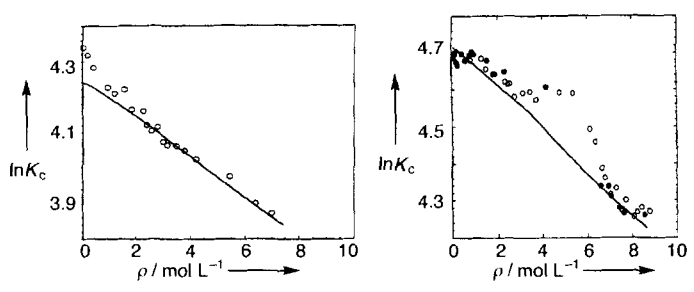
namely that increased solvent density shifts the equilibrium in favor of the free acid and base. It can be seen from these spectra that, close to the critical pressure, even quite modest changes in pressure can cause a significant shift in equilibrium. Gupta et al. have outlined the thermodynamics behind this shift.[62] Very tritely, their explanation can be summarised as stating that solvation energies become increasingly important as the density of the fluid increases, and that the solvation energy of the complex with hydrogen bonds is less than the sum of the solvation energies of the free alcohol and free base. This behavior has been successfully modeled and $\ln K_c$ decreases almost linearly with increasing fluid density (Fig. 18 left). Perhaps the most interesting finding was the observation of nonlinear behavior of $\ln K_c$ of the PFTB/$(CH_3)_2O$/SF_6 system at temperatures close to critical (Fig. 18 right). This deviation was attributed to enhanced solute/solute interaction, probably mediated by solute/solvent



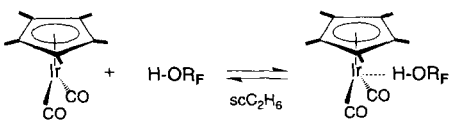


Fig. 18. Plots for the $(CF_3)_3COH/(CH_3)_2O$ system, showing the variation of $\ln K_c$ with density of SF_6 at *constant temperature*. See Equation (c) for definition of K_c. Left: 60 °C, [PFTB] 1.2 mM, $[(CH_3)_2O]$ 30 mM; right: 50 °C, points marked ○ [PFTB] 2.0 mM, $[(CH_3)_2O]$ 16 mM and those marked ●, [PFTB] 1.5 mM, $[(CH_3)_2O]$ 25 mM. In both parts of the Figure, the solid lines indicate the predictions of the modified lattice fluid hydrogen bonding model; from ref. [66].

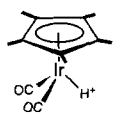
clustering.[66] As in other studies, it was important to establish whether the presence of PFTB and $(CH_3)_2O$ affected the critical point of SF_6. It was shown that T_c was unaffected within experimental error by PFTB (ca. 1 mM) and $(CH_3)_2O$ (ca. 30 mM) using the relatively uncommon method of measuring the velocity of sound in the fluid.[66] The acoustic properties of a fluid change very substantially in the region of the critical point and, hence, even small changes in T_c and p_c can be detected.[20a, 68] The method promises to have quite widespread applications.

Recently, Ochel and Schneider[69] have monitored the hydrogen bonding and solubility of polar organic acids and esters in $scCClF_3$. In an elegant application of near-IR spectroscopy, they used the 2 × ν(O–H) bands to quantify the amount of hydrogen bonding and the 2 × ν(C–H) bands, which are essentially unaffected by hydrogen bonding to measure the total amount of solute in the fluid. Their conclusion was that the more important factors for determining solubility were molecular size, polarity, and self-association.



5.5. Hydrogen Bonding and Protonation of Organometallic Compounds

Kazarian et al.[63] made a qualitative study in scC_2H_6 of the interaction between $(CF_3)_2CHOH$ and $[Cp^*Ir(CO)_2]$ ($Cp^* = C_5Me_5$) [Eq. (h)]. The effect of fluid density was similar to that for other systems; increased density disfavors hydrogen bonding. Equilibrium (h) is interesting, however, because it is one of the rare cases where such an equilibrium has been monitored by way of the base rather than the acid, using the extremely intense ν(C–O) bands of the metal compound.

(h)

A similar study[70] in scXe of the interaction of $[Cp^*Ir(CO)_2]$ with the stronger proton donor HCl produced an unexpected result; the IR spectra showed only the known bands of the protonated ion **5**.[70] No IR absorptions which could be assigned to a counter anion were observed but Cl^- does not absorb IR radiation, and the bands of $[HCl_2]^-$ would probably have been much weaker than the ν(C–O) bands of **5**, which themselves were very weak in this experiment. Although the observation of ionic species in a nonpolar fluid is unusual, Lokshin et al. reported some years ago that protonation of neutral organometallic compounds can lead to ionic species in LXe solution at cryogenic temperatures[22b, 71] and, presumably, such charged species are present as ion pairs or small aggregates in both LXe and scXe. Therefore, it is not entirely surprising that solutions of **5** in scXe proved to be unstable, with the ν(C–O) IR bands disappearing within a few minutes of the HCl being added, possibly because of precipitation or further reaction with HCl.

5

5.6. Reverse Micelles in Supercritical Fluids

Very recent, and as yet unpublished, work by Eckert and co-workers[72] has shown that phase transfer catalysts can transport ions into $scCO_2$. However, most of the research effort to solubilize ionic compounds in supercritical fluids has involved surfactants and reverse micelles. Indeed, much of the IR work of Smith's group has been aimed directly or indirectly at the study of reverse micelles in supercritical fluids.[73] Apart from $scCHF_3$, most fluids with a critical temperature T_c close to room temperature are nonpolar. This means that a vast range of hydrophilic and ionic compounds cannot be dissolved or processed in these fluids. Smith and co-workers have shown that some of these compounds (e.g. cytochrome c) can be solubilized by adding surfactants which allow reverse micelles to form in the supercritical fluid.[74] Such micelles have been observed in scC_2H_6, in near-critical and scC_3H_8, and in scXe[74, 75] but crucially no suitable surfactant has yet been found which can form reverse micelles in $scCO_2$. The search for such a surfactant has been intense because, once identified, it will open up whole new areas of chemistry in $scCO_2$. Unfortunately, as Smith and co-workers wryly remark,[73c] "the list of conventional (ionic) surfactants that are insoluble in CO_2 is indeed impressive but not surprising because these (surfactants) have been developed for 'oil' phases of much different character". Therefore, FTIR studies of hydrogen bonding have been an important tool in the search for non-ionic surfactants for $scCO_2$. The role of IR spectroscopy has been twofold, to estimate the degree of aggregation of the surfactants and to establish whether water has indeed been incorporated into the aggregates. Smith and co-workers[73c] have used the approach already outlined above, namely their variable path IR cell and deuterated alcohols, to compare hydrogen bonding of polyethylene glycol dodecyl ethers in scC_2H_6 (where reverse micelles have already been observed) and in $scCO_2$ (where they have not). Their results indicate that, in the absence of added water, the solubility of these surfactants is higher in $scCO_2$ than in scC_2H_6 but that there is less aggregation of the molecules in $scCO_2$ than in scC_2H_6. Clearly, a tendency to aggregate is an important factor in the formation of reverse micelles and so the difference between $scCO_2$ and scC_2H_6 is consistent with the lack of micelles in $scCO_2$.

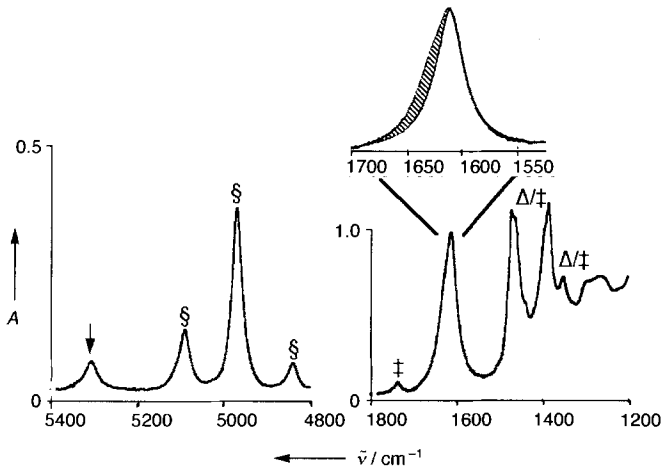


Fig. 19. FTIR spectra of a mixture containing 2.5% surfactant, 6.0% pentanol and H_2O in $scCO_2$ at 60 °C and 5000 psi pressure. The absorption bands of H_2O are the weak combination band (arrowed) and the stronger band, ca. 1600 cm^{-1}, shown separately with an expanded wavenumber scale. This band is broader in the presence of surfactant than in pure $scCO_2$, as indicated by the shading. Other bands are labeled as follows: §: $scCO_2$; Δ: pentanol; ‡, surfactant; from ref. [76].

In a similar study, McFann et al. investigated the non-ionic surfactant,[76] pentaethylene glycol *n*-octyl ether, dissolved in $scCO_2$/*n*-pentanol/H_2O. FTIR spectra recorded in the presence of the surfactant showed an unresolved broadening to high wavenumber of the band at approximately 1600 cm^{-1}, compared to spectra recorded in the absence of surfactant (Fig. 19). This broadening is attributed to water within surfactant aggregates but the level of water present in the surfactant/$scCO_2$ phase did not appear to be much higher than that found in the absence of the surfactant.

6. Impregnation and Extraction of Polymers

Supercritical fluid extraction (SFE) is one of the major uses of $scCO_2$ both on the industrial scale[1] and in the analytical laboratory,[31a] where it is rapidly replacing more traditional extraction (e.g. Soxhlet) in many "standard" methods. Analytical SFE not only eliminates the use of potentially toxic organic solvents but also it is usually faster than conventional extraction techniques. Equally important, SFE delivers the extracted analytes free of solvent for subsequent analysis, allowing measurement to be made from smaller samples than could be handled by conventional means.

One of the major problems with any analytical extraction method lies in knowing when an extraction is complete. Of course, one can deliberately "spike" a matrix with some material and then establish how well the spike is recovered. However, one cannot know, by definition, how much analyte is contained in an "unknown" sample; all that can be done is to compare the amounts of analyte extracted from the same sample by different methods. SFE appears to be efficient; there have even been occasions when SFE has extracted *more* analyte from a certified sample than that sample was supposed to contain. Nevertheless, Clifford and co-workers are attempting to develop models[77] that will allow analysts to use the accumulated results of several sequential extractions to estimate the probable total content of the sample.

There is clearly a need to test such models. Spectroscopic monitoring of extraction requires high sensitivity because the extracted analyte is usually present in the fluid at relatively low concentrations. The aim is to monitor the levels of both the extracted analyte in solution and of the residual analyte in the matrix. FTIR spectroscopy is probably a better method than UV/Vis spectroscopy for carrying out this monitoring because IR absorption bands are usually more sensitive to environment than are UV/Vis bands but the detection limits of IR spectroscopy are much worse. Although attempts are being made to couple FTIR detection to SFE,[32] the technique is less developed than the cSFC-FTIR method (see Section 3). Nevertheless, progress is being made. Hawthorne and co-workers have reported the use of IR optic fibers for monitoring SFE[32b] and recent work at Nottingham[54b, 78] has shown that FTIR spectroscopy can be used for monitoring the extraction of transition metal carbonyl compounds, for example $[CpMn(CO)_3]$

($Cp = \eta^5$-C_5H_5), with supercritical phases from and impregnation into polymers. The important feature of this work is that such compounds have unusually narrow and intense ν(C–O) IR bands, the precise wavenumbers of which are particularly sensitive to the environment. Thus, one can easily distinguish between the IR absorptions of $[CpMn(CO)_3]$ in $scCO_2$ solution and those of $[CpMn(CO)_3]$ isolated within a polymer matrix. Using a cell similar to that in Figure 3, Howdle and co-workers[78] have shown that FTIR spectroscopy can be used to follow the impregnation of $[CpMn(CO)_3]$ into polyethylene (PE) and its subsequent extraction (Fig. 20). So far, the technique has only been used with static extraction (i.e. in a closed cell without any flow of $scCO_2$) but even in these circumstances there is potential for accumulating useful data.

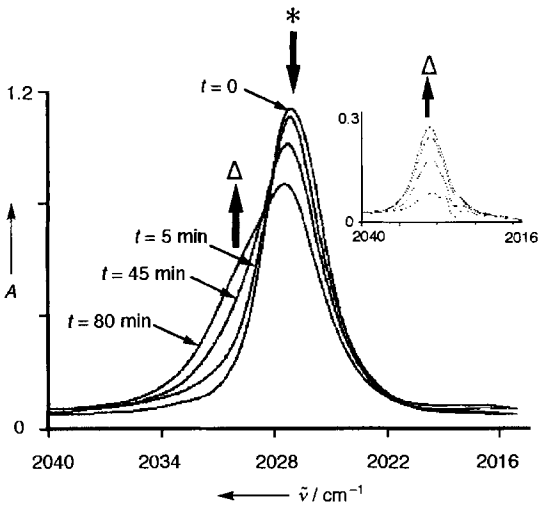

Fig. 20. "Real-time" FTIR monitoring of extraction of $[CpMn(CO)_3]$ from polyethylene (PE) with supercritical $scCO_2$. The extraction can be monitored because the ν(C–O) bands of $[CpMn(CO)_3]$ have slightly higher wavenumber when the compound is dissolved in $scCO_2$ solution than when it is in a PE matrix. The spectra were obtained by placing four pieces of PE film (total thickness 1 mm) in a cell and then pressurising with $scCO_2$ (200 atm 32 °C). The absorption due to $[CpMn(CO)_3]$ in $scCO_2$ grows as a shoulder, marked with a Δ, on the side of the band due to $[CpMn(CO)_3]$ within the PE, labeled with an *. The spectra in the inset were obtained by computer subtraction and show the growth of the band of "free" $[CpMn(CO)_3]$ dissolved in $scCO_2$; from ref. [78].

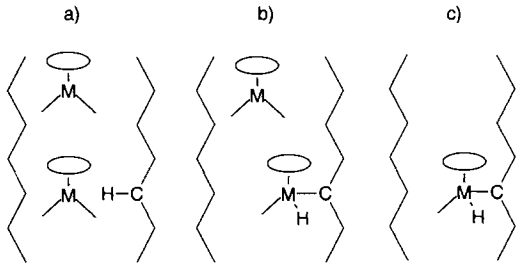
The impregnation of organometallic compounds into a polymer matrix with supercritical phases leaves no solvent residues within the polymer because the CO_2 for example can easily diffuse out. This diffusion process can also be monitored by FTIR spectroscopy but Briscoe and co-workers have devised ultrasonic methods that are considerably more sensitive.[79] Once impregnated into the polymer, the organometallic compounds can be induced to react with the polymer itself without any side reactions with solvent residues. One such reaction,[80] the C–H activation of PE by $[Cp^*Ir(CO)_2]$ is illustrated schematically in Figure 21. This photochemical reaction can be followed easily by FTIR spectroscopy because reactant and product have substantially different spectra in the ν(C–O) region, where PE itself does not absorb significantly. Furthermore, the fact that the product is bound to the polymer was established by showing that excess reactant can be extracted by $scCO_2$, while the product cannot. Unfortunately, this reaction



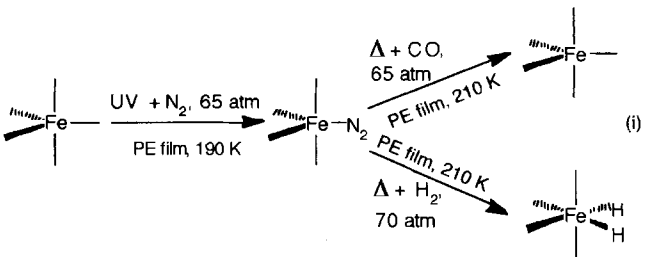


Fig. 21. Schematic representation of the three stages of the C–H activation of polyethylene (PE), the chains of which are represented by zigzag lines, by $[Cp^*Ir(CO)_2]$. a) Impregnation of $[Cp^*Ir(CO)_2]$ into PE using $scCO_2$; b) C–H activation by UV irradiation of the impregnated film, and c) extraction of unconverted $[Cp^*Ir(CO)_2]$ by $scCO_2$. The whole experiment was carried out in a cell similar to that shown in Fig. 3; from ref. [80].

suffers from the same limitation as the C–H activation of lighter hydrocarbons by $[Cp^*Ir(CO)_2]$; once $[Cp^*Ir(CO)H(R)]$ has been formed, it is extremely difficult to develop the chemistry by exploiting the activated C–H bond to make new organic compounds.[81] Interestingly, hydrogen bonding of the Ir center by $(CF_3)_3COH$ was found to reduce significantly the efficiency of the C–H activation.[82] It is not clear, however, whether this reduction in efficiency is due to the change in the electron density on the metal center or merely due to a reduction in the UV extinction of the complex with hydrogen bonds, leading to less UV light absorbed in a given irradiation time. Clearly, the impregnation of other organometallic compounds into polymers offers considerable possibilities for the modification or tailoring of both bulk and surface properties of the polymers.

Over the past decade, Rest and co-workers have pioneered the use of impregnated polymer films as a substitute for frozen noble gases in matrix isolation experiments,[83] to create what they rather self-depreciatively describe as "infra-dig" matrices. Impregnation using supercritical fluids extends the possibilities of Rest's technique because some of his original experiments were bedevilled by problems of solvent residues. Recently, the high-pressure/low-temperature cell, illustrated in Figure 4, has been used[15a] to synthesize the highly unstable molecule $[Fe(CO)_4N_2]$ from $[Fe(CO)_5]$ impregnated into PE and then to follow its subsequent thermal reaction with H_2. Both the photochemical and thermal steps were followed by FTIR spectroscopy [Eq. (i)].

(i)

The same high-pressure/low-temperature cell has also been used by Kazarian et al. to investigate the reaction of HCl with $[Cp^*Ir(CO)_2]$ in PE.[15b] This reaction led to the formation of $[Cp^*Ir(CO)_2H]^+$, again with no detectable counterion, but unlike scXe solution at room temperature (see Section 5),

$[Cp^*Ir(CO)_2H]^+$ was quite stable in PE at 250 K. More surprisingly, venting the HCl and warming the impregnated PE film back to room temperature caused up to 70% regeneration of the neutral $[Cp^*Ir(CO)_2]$ [Eq. (j)]. Under these conditions,

$$[Cp^*Ir(CO)_2] \underset{290\ K}{\overset{+HCl,\ 250\ K,\ PE\text{-}Film}{\rightleftharpoons}} [Cp^*Ir(CO)_2H]^+ \qquad (j)$$

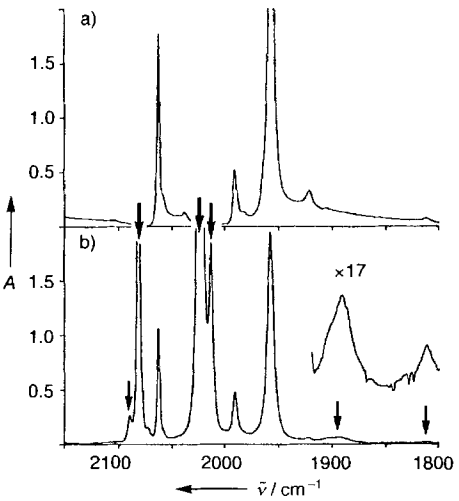
$[Cp^*Ir(CO)_2]$ appears to be isolated within PE and its ν(C–O) bands are only slightly broader than those observed in alkane solution. Thus, the fact that the protonation of $[Cp^*Ir(CO)_2]$ in PE is largely reversible strongly suggests that $[Cp^*Ir(CO)_2H]^+$ is present as ion pairs rather than as large aggregates.

A rather different non-spectroscopic study involving ions, polymers, and $scCO_2$ has just been reported by Sullenberger et al., who fabricated two platinum microelectrodes, embedded next to each other in the end of a glass rod.[84] The electrodes were then covered with a 50 μm film of polyethylene oxide (PEO) doped with an appropriate electrolyte (i.e. $LiCF_3SO_3$). The coated electrode assembly was then mounted in a high-pressure cell, filled with $scCO_2$ containing dissolved anthracene or benzoquinone. The aromatic compound was thus impregnated into the polymer where it be could be oxidized or reduced electrochemically. When the PEO film was additionally doped with $[Ru(bpy)_3]^{2+}$, there was evidence for the electrochemical activation of CO_2 and its reaction with benzoquinone.

7. Reactions of Organometallic Compounds

For over three decades, IR spectroscopy has played a central role in the mechanistic study of photochemical reactions of organometallic compounds, particularly of transition metal carbonyls.[85] Techniques such as frozen hydrocarbon glasses, matrix isolation, liquefied noble gases, and time-resolved IR spectroscopy, have been developed and optimized through such studies, sometimes exclusively so. The emphasis on metal carbonyls and the closely related dinitrogen and nitrosyl compounds derives partly from inherent chemical interest but equally importantly from the enormous amount of structural information that can be derived merely from recording IR spectra in the ν(C–O), ν(N–N), and ν(N–O) regions. Molecular geometries, bond angles and, on occasions, even estimates of bond lengths can be derived from these spectra. Improved instrumentation, particularly FTIR instruments, has allowed at least some of these techniques to be extended in recent years to non-carbonyl organometallic compounds.[86]

The original impetus for studying photochemical reactions of organometallic compounds in supercritical fluids arose from the very low solubility of some substituted metal carbonyl compounds in liquid xenon.[87] Thus, even though $[Ru(CO)_4(PPh_3)]$ is virtually insoluble in LXe, it has modest solubility in scXe at 25 °C. Figure 22 illustrates spectra recorded by Upmacis et al. during the reaction of $[Ru(CO)_4(PPh_3)]$ with H_2 in scXe, one of the first reactions of organometallic compounds to be carried out in supercritical fluid solution.[87] The reaction product, $[H_2Ru(CO)_3(PPh_3)]$ had previously only been observed by Whyman[88a] in a thermal reaction in heptane under very much harsher conditions, 100 °C and 300 atm H_2. Once generated[87]



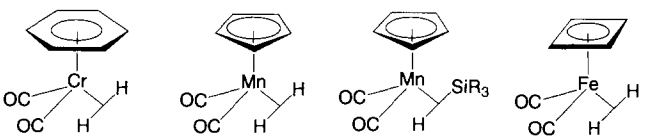


Fig. 22. FTIR spectra showing the photochemical synthesis of $[H_2Ru(CO)_3(PPh_3)]$ by irradiation of $[Ru(CO)_4(PPh_3)]$ and H_2 with UV light in scXe at 25 °C; a) spectrum before irradiation; b) spectrum after 9 min photolysis. Bands due to $[H_2Ru(CO)_3(PPh_3)]$ are marked with arrows. The ν(Ru–H) region of the spectrum is shown with a 17-fold expansion of the absorbance scale; from ref. [87].

in scXe, $[H_2Ru(CO)_3(PPh_3)]$ decayed over a period of about six hours even under a high pressure of H_2, possibly by reaction with the photoejected CO. This reactivity is considerably greater than that of $[H_2Ru(CO)_2(PPh_3)_2]$ which had been isolated many years earlier.[88b]

This reaction of $[Ru(CO)_4(PPh_3)]$ led to the realization that the irradiation of metal carbonyl compounds with UV light in supercritical solution in the presence of H_2 might be a relatively general route to either dihydrogen or dihydrido complexes, depending on the particular metal center[25] [Eq. (k)].

$$[L_nM(CO)_x] + H_2 \underset{-CO}{\overset{h\nu}{\longrightarrow}} [L_nM(CO)_{x-1}(\eta^2\text{-}H_2)] \quad \text{or} \quad [L_nM(CO)_{x-1}(H)_2] \qquad (k)$$

Using this route, Howdle et al. generated a series of compounds, including the half-sandwich dihydrogen complexes, **6**–**8**, formed from the corresponding $[(\eta^n\text{-}C_nH_n)M(CO)_3]$ compounds in scXe solution.[25] Such compounds should, in

6 **7** **7'** **8**

principle, have a weak IR band within the region 3400–2400 cm^{-1}, associated with the ν(H–H) vibration of the η^2-H_2 group.[89] Although the ν(H–H) band of $[W(CO)_5(\eta^2\text{-}H_2)]$ has been observed[27] in scXe using a cell similar to that in Figure 3, no band was found for any of the compounds, **6**–**8**, presumably because the bands were extremely weak. Nevertheless, there was sufficient circumstantial evidence to confirm that each of these compounds did indeed contain an η^2-H_2 group. The compounds **6**–**8** are of interest because **7** was the first nonclassical dihydrogen complex of manganese to be identified, and **8** was the first

dihydrogen compound of iron also to contain a coordinated olefin or diene ligand. Compound **7** appeared to be relatively stable even after the H_2 had been vented (see Section 8). The arrested oxidation of the Mn center is not unprecedented in view of the extensive series of known η^2-H–SiR_3 complexes of Mn (e.g **7'**).[90]

H_2 is significantly less soluble than other gases (e.g. N_2, CO, etc) in conventional organic solvents. However, H_2 is completely miscible with a supercritical solvent, such as scXe, since the fluid is merely a dense gas. Thus, if properly mixed with the fluid (see Section 8), a given pressure of H_2 will give an effective concentration of "dissolved" H_2 nearly an order of magnitude higher than in a conventional solvent under a similar pressure of H_2. The predominant reaction pathway for labile dihydrogen complexes appears to involve dissociative loss of the η^2-H_2 group and so this very high concentration of H_2 can increase the lifetime of such complexes in scXe solution.[25] Nevertheless, even under a such pressure of H_2, **8** reacted further within a few minutes, possibly through transfer of H_2 to the C_4H_4 ring, while **6** decayed only slowly under the same conditions.

The miscibility of H_2 and scXe has an additional benefit namely that, in a closed vessel, the concentration of dissolved H_2 is independent of temperature. By contrast, the solubility of H_2 in a conventional solvent will show a temperature dependence as dictated by Henry's Law. Howdle et al.[25] exploited this constant concentration of H_2 in scXe to investigate the kinetics of the reaction of CO with $[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2(\eta^2\text{-}H_2)]$ [Eq. (l)]. The reaction was monitored via the a″

$$[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2(\eta^2\text{-}H_2)] \underset{+H_2}{\overset{-H_2}{\rightleftharpoons}} [(\eta^6\text{-}C_6H_5Me)Cr(CO)_2] \xrightarrow{CO} [(\eta^6\text{-}C_6H_5Me)Cr(CO)_3] \quad (l)$$

ν(C–O) band of $[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2(\eta^2\text{-}H_2)]$; it showed pseudo-first order kinetics with an activation energy of 70 ± 5 kJ mol^{-1} over the temperature range 11 to 80 °C (Fig. 23). If loss of H_2 is assumed to be the rate-determining step, this activation energy can be taken as an estimate of the Cr–$(\eta^2$-$H_2)$ bond dissociation energy and, perhaps fortuitously, the value is almost identical to that estimated by photoacoustic and calorimetric techniques for related Cr–$(\eta^2$-$H_2)$ bonds.[91]

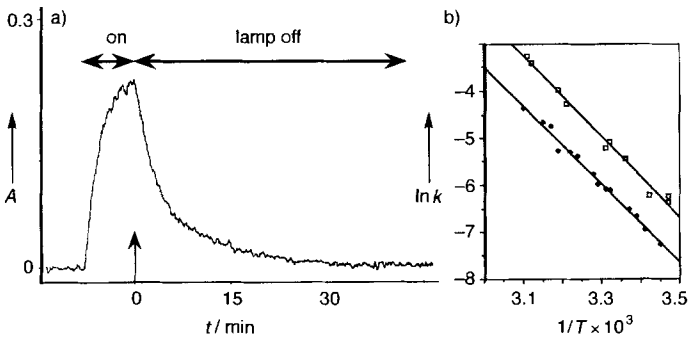

Fig. 23. a) An IR kinetic trace showing the photochemical generation and thermal decay of $[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2(\eta^2\text{-}H_2)]$ in scXe/H_2 at 70 °C, see Equation (l). The decay follows pseudo-first order kinetics. b) Arrhenius plot for the rate of decay of $[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2(\eta^2\text{-}H_2)]$ measured in the presence of two concentrations of added CO. Note that, within experimental error, the two curves have the same gradient, corresponding to an activation energy of 70 kJ mol^{-1}; from ref. [25].

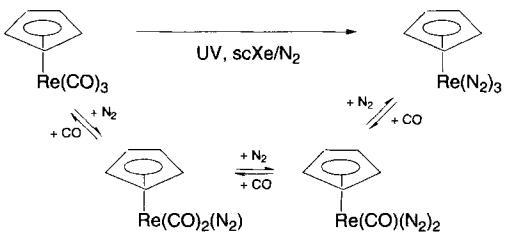


Equation (l) is, perhaps, slightly misleading because there is increasing evidence that reaction intermediates such as $[(\eta^6\text{-}C_6H_5Me)Cr(CO)_2]$ are not genuinely coordinatively unsaturated but are weakly solvated by a molecule of solvent acting as a "token" ligand in the otherwise vacant coordination site.[85] Even solvents, apparently as inert as Xe, can act as token ligands and the strength of the M–Xe interaction has been estimated for the group 6 metals in gaseous and liquid Xe.[92] In recent experiments we have begun using nanosecond time-resolved IR spectroscopy to monitor these interactions in scXe and $scCO_2$.[93]

The high concentrations of H_2 in supercritical solution have since been exploited by other groups. Rathke and co-workers[94] reported a series of elegant experiments where thermal hydroformylation reactions catalyzed by $[Co_2(CO)_8]$ in $scCO_2$ were monitored by NMR spectroscopy. The product distribution was rather different from that found in conventional solvents and a patent has been granted on the process.[94c] The very low viscosity of supercritical solvents is of considerable benefit for NMR spectroscopy and nuclei with spin ≥ 1 have shorter correlation times and correspondingly sharper resonances under supercritical conditions.

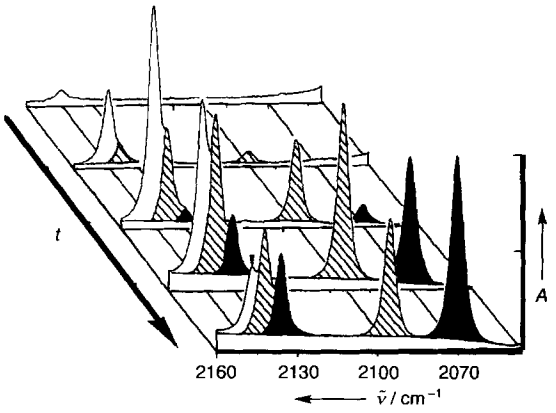
Very recently, Noyori and co-workers[95] have reported the catalytic hydrogenation of $scCO_2$ itself [Eq. (m)]. This experiment has aroused considerable excitement, not because the product (formic acid) is any way different from that in THF solution but because the reaction is over an order of magnitude faster in $scCO_2$. Presumably, this acceleration is the result of the greater concentration of H_2 in the supercritical fluid.

$$CO_2 + H_2\,(85\text{ atm}) \xrightarrow[scCO_2,\ p_{tot.} = 205\text{ atm},\ 50\,^\circ C]{[Ru(PMe_3)_4H_2] + NEt_3} HCOOH \quad (m)$$

N_2 is also miscible with supercritical fluids, and Howdle et al. have again exploited this for the generation of new compounds. Their most striking reaction[96a] was the total substitution of CO by N_2 in the molecule $[CpRe(CO)_3]$ to generate $[CpRe(N_2)_3]$ [Eq. (n)]. As with many of the reactions described previously,

(n)

this substitution reaction was followed by FTIR spectroscopy but this time in the ν(N–N) region (Fig. 24). The assignment of the bands was confirmed by comparison with earlier experiments in solid N_2 matrices doped with $^{15}N_2$ at 20 K. Neither $[CpRe(CO)(N_2)_2]$ nor $[CpRe(N_2)_3]$ had been observed previously at room temperature. However, once generated $[CpRe(N_2)_3]$ was remarkably stable, persisting for more than 24 h in scXe solution under a pressure of N_2, and then taking nearly 1 h to react with added CO at room temperature. $[CpRe(CO)(N_2)_2]$ was even more robust and, although only spectroscopic amounts were generated, the experiments suggested that $[CpRe(CO)(N_2)_2]$ might be air stable.[29]



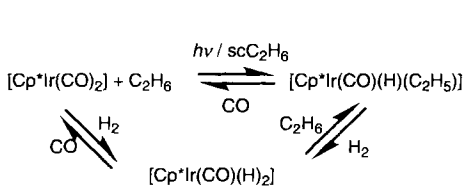


Fig. 24. FTIR spectra in the ν(N–N) region recorded during the UV photolysis of $[CpRe(CO)_3]$ in $scXe/N_2$ (total pressure 2600 psi). The spectra show the sequential formation of $[CpRe(CO)_2(N_2)]$ (white bands), $[CpRe(CO)(N_2)_2]$ (shaded bands) and, finally, $[CpRe(N_2)_3]$ (black bands). The total irradiation time was 2 h but subsequent experiments with more powerful lamps show that the reaction can be carried out far more rapidly; from ref. [96a].

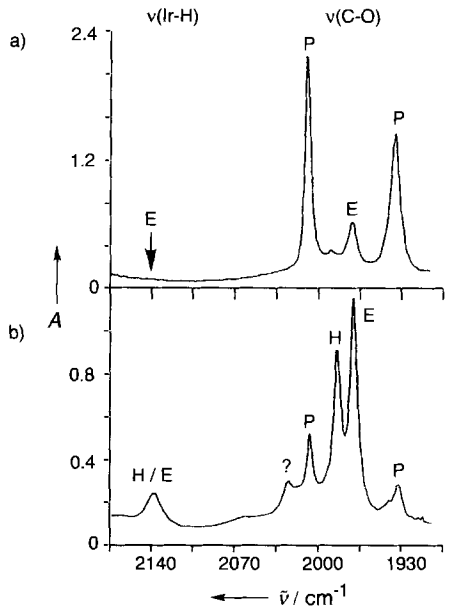
A number of other dinitrogen compounds have been generated by a similar route but there are limitations; UV photolysis of $[(C_5H_4Me)Mn(CO)_2(PR_3)]$ compounds with N_2 in supercritical solution leads to considerable loss of the PR_3 ligand and, only with PMe_3, were significant amounts of the $[(C_5H_4Me)Mn(CO)(N_2)(PR_3)]$ compound observed.[96b]

Apart from Noyori's hydrogenation experiment[95] with $scCO_2$, most attempts to activate $scCO_2$ have been disappointing.[97] In fact, $scCO_2$ is a remarkably inert solvent and Jobling et al. have taken advantage of this inertness[98] to use $scCO_2$ for photochemical activation of C–H bonds by $[Cp^*Ir(CO)_2]$. C–H activation of alkanes is an area of considerable research activity but one continuing problem has been to find suitably inert solvents in which to carry out activation of light alkanes such as CH_4 or C_2H_6. Graham and co-workers were successful in using fluorocarbon solvents[81] and Bergman and co-workers used LXe[99] but neither solvent was ideal. Jobling et al.[98] showed that photochemical C–H activation of scC_2H_6 could be carried out satisfactorily in $scCO_2$. It quickly became apparent, however, that the $scCO_2$ was superfluous because the critical temperature of C_2H_6 is so close to that of CO_2 (see Table 1). Thus, scC_2H_6 could be used as both solvent and reactant but the C–H activation did not proceed far because a photostationary state was established rapidly (Fig. 25a). Surprisingly, addition of high pressures of H_2 to the mixture not only promoted formation of $[Cp^*Ir(CO)(H)_2]$ but led to greatly increased amounts of C–H activation [Fig. 25b and Eq. (o)].

(o)

Since the critical pressure of C_2H_6 is considerably lower than that of CO_2 (see Table 1), it was possible to use much higher pressures of H_2 with C_2H_6 without exceeding the pressure rating of the cell shown in Figure 3, and even to reach approximately



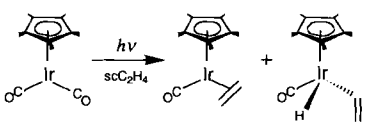


Fig. 25. FTIR spectra illustrating the dramatic effect of H_2 on the C–H activation of scC_2H_6 by $[Cp^*Ir(CO)_2]$. a) IR spectrum recorded after 3 minutes UV irradiation of $[Cp^*Ir(CO)_2]$ in scC_2H_6 (68 atm); b) IR spectrum showing the strikingly different result of 10 minutes UV photolysis of $[Cp^*Ir(CO)_2]$ in scC_2H_6 (50 atm) with added H_2 to give a total pressure of 179 atm. The bands are labeled as follows: E = $[Cp^*Ir(CO)(H)(C_2H_5)]$; H = $[Cp^*Ir(CO)(H)_2]$; P = residual $[Cp^*Ir(CO)_2]$; ? = an unidentified labile photoproduct; from ref. [98].

equimolar concentrations of H_2 and C_2H_6 in the solution. The effect of H_2 on C-H activation is chemical rather than physical because high pressures of He are ineffective; experiments with D_2 indicated that no deuterium was incorporated into $[Cp^*Ir(CO)H(Et)]$. Sequential experiments in $scCO_2$ (addition of H_2 to generate $[Cp^*Ir(CO)(H)_2]$ followed by addition C_2H_6) showed that C–H activation by $[Cp^*Ir(CO)(H)_2]$ is more efficient than by $[Cp^*Ir(CO)_2]$ itself. The reason for this still remains unclear but the overall effect is dramatic.

CH_4 has its critical temperature at 190.5 K well below that of C_2H_6. Nevertheless, it is possible to dissolve small amounts of $[Cp^*Ir(CO)_2]$ in $scCH_4$ at temperatures close to ambient, provided that the pressure is sufficiently high to give a fluid density close to ρ_c, 0.162 g mL^{-1}. This density can be achieved at a pressure of about 3750 psi at 297 K. Under these conditions,[100] UV irradiation of $[Cp^*Ir(CO)_2]$ leads to activation of CH_4 and formation of $[Cp^*Ir(CO)H(CH_3)]$, identifiable by comparison with IR data from low temperature matrices.

Irradiation of $[Cp^*Ir(CO)_2]$ in scC_2H_4 leads to two processes,[29] substitution of CO by C_2H_4 and C–H activation to generate a hydrido(vinyl) complex [Eq. (p)]. As in the other C–H activation experiments, both compounds were identified by FTIR spectroscopy; scC_2H_4 has strong IR bands which obscure considerable regions of the spectrum but, fortuitously, it has a series of "windows" in each of the regions, ν(Ir–H), ν(C–O), ν(C=C), and δ(C–H), needed to characterize $[Cp^*Ir(CO)H(\eta^1\text{-}C_2H_3)]$.

(p)

These experiments are interesting not only because C_2H_6 or C_2H_4 can be activated but also because the reaction products can be recovered. Product recovery has been a substantial problem in C–H activation experiments in conventional solvents; attempts to remove the solvent frequently lead to decomposition of the compound. By contrast, a reduction in applied pressure will result in precipitation of solid compounds from supercritical solution. Figure 26 shows how such precipitation can be

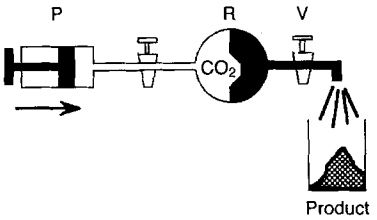

Fig. 26. Schematic illustration of how small quantities of reaction product can be recovered from a cell, R (such as that shown in Fig. 3). A syringe pump P forces $scCO_2$ through the system to flush the reaction mixture (shown black) through an expansion valve V. The reduction in pressure across the expansion valve causes the dissolved solids to precipitate from solution allowing collection.

achieved in a controlled manner by pumping $scCO_2$ to flush the contents of the reaction cell through an expansion valve.[93a] In this way, it was possible to recover sufficient [Cp*Ir(CO)H(R)] (R = Et or η^1-C_2H_3) for ^{1}H NMR confirmation of the structures, already identified by IR spectroscopy. Alternatively, the compounds can be redissolved in scXe to obtain IR spectra free from interfering IR absorptions of the solvent.[29] This method of precipitating a product from supercritical solution is a key feature of the miniature flow reactors under development for continuous reactions in supercritical fluids.

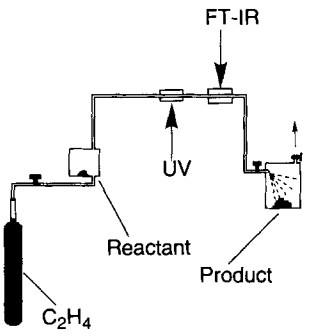
IR spectroscopy can be used, of course, to monitor a much wider range of processes than just reactions of organometallic compounds. Buback describes a number of applications of IR and near-IR spectroscopy for following polymerization reactions.[4] Saito and co-workers[101] have recently reported the use of IR spectroscopy for monitoring Diels–Alder reactions between isoprene and methyl acrylate, which has relatively intense ν(C=O) bands. In fact, most reactant/product combinations are likely to have absorption bands somewhere within the mid-IR region, suitable for spectroscopic monitoring. However, the particular advantage of IR spectroscopy in reactions of organometallic compounds is both the high sensitivity provided by the ν(C–O) bands and the possibility of identifying previously unknown compounds with a considerable degree of certainty merely from their IR spectra.

8. Reactions with Supercritical Fluids on a Preparative Scale

The ultimate objective of many chemists is to harness new techniques to make new compounds on a preparative scale. However, most of the reactions and processes described in the previous sections of this review have been carried out in dilute solutions and on a relatively small scale. These reactions, therefore, need to be scaled up. Vibrational spectroscopy is playing a key role in the scale-up of reactions of organometallic compounds in supercritical fluids.

Apart from any safety considerations, the scale-up of reactions in supercritical fluids presents a number of unusual problems. Most substrates have critical temperatures far higher than that of CO_2 and so to maintain supercritical conditions reactions must either be run in very dilute solution or at high temperatures. However, dilute solutions prevent the processing of large quantities of material unless the reaction vessel is extremely large. High temperatures are often undesirable because reaction products, if labile, may degrade. Furthermore, many of the more interesting phenomena associated with supercritical fluids occur relatively close to the critical point (see for example, Fig. 18). In addition, the composition of a reaction mixture changes as the reaction proceeds and so the critical point will also change, making it difficult to maintain the desired near-critical reaction conditions.

These problems can be minimized, if not removed completely, by use of a continuous flow reactor because at any particular point in such a reactor the composition remains constant throughout the reaction. Equally, the gaslike nature of supercritical fluids (low viscosity, good heat transfer, etc) readily lends itself to flow reactors. Pickel and Steiner[102] have pioneered the use of flow reactors for industrial-scale processes in the pharmaceutical industry, particularly catalytic hydrogenation. Their use of such reactors in one process has resulted in a 1/250 reduction in reactor volume compared to the batch process in conventional solvents.



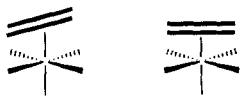


Fig. 27. A schematic diagram of the flow reactor used for the synthesis [103] of $[Cr(CO)_5(C_2H_4)]$. scC_2H_4 is pumped through a reservoir containing solid $[Cr(CO)_6]$, which dissolves in the scC_2H_4. The supercritical solution then passes through a UV irradiation cell (a modified version of that in Fig. 3) where reactant is converted into product, through an IR cell for FTIR monitoring and finally through an expansion valve (analogous to Fig. 26) to precipitate the product as a dry solid.

At Nottingham, we are developing miniature flow reactors for laboratory-scale preparative reactions. Our prototype reactor was designed for reactions in scC_2H_4, where the fluid acted both as solvent and as one of the reactants.[103] Figure 27 shows a schematic view of the reactor; a solid organometallic compound is dissolved in scC_2H_4, converted into product by UV irradiation, monitored by IR spectroscopy, and finally precipitated as a fine powder, all as a single continuous process. Once the fluid pump is running, reactant is converted into product automatically, while the operator uses IR monitoring to optimize the reaction conditions. Using this reactor, it was possible to isolate $[Cr(CO)_5(C_2H_4)]$ (>80% purity) directly from the reaction of $[Cr(CO)_6]$ and scC_2H_4 at a rate of approximately 40 mg h^{-1} [Eq. (q)].

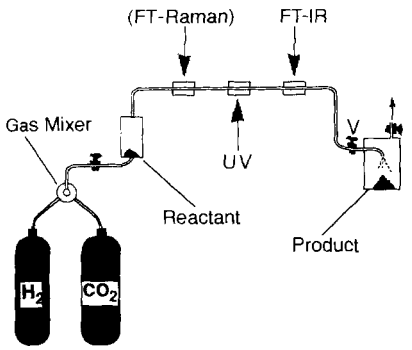
$$[Cr(CO)_6] \xrightarrow[scC_2H_4]{UV} [Cr(CO)_5(C_2H_4)] \quad (q)$$

Although $[Cr(CO)_5(C_2H_4)]$ was already known in solution,[104] previous attempts to isolate it had been thwarted by

the lability of the C_2H_4; removal of the solvent also removed the ligand. Expansion of scC_2H_4 is more rapid than conventional solvent evaporation; thus the solution does not need to be heated and a high concentration of the free ligand C_2H_4 is maintained right up to the moment at which the solid is formed. Once precipitated, $[Cr(CO)_5(C_2H_4)]$ appears to be moderately stable in the solid state.[103] The relative intensities of the ν(C–O) IR bands of $[Cr(CO)_5(C_2H_4)]$ suggest that the C_2H_4 group is aligned parallel to a *trans* pair of CO groups (as in **9** not **10**) as found by Grevels and co-workers in the crystal structure of the related compound $[Cr(CO)_4(C_2H_4)_2]$.[104b]

9 **10**

Success with $[Cr(CO)_5(C_2H_4)]$, encouraged us to build a more complex reactor using H_2 mixed with $scCO_2$ (Fig. 28) for the isolation on a larger scale of the dihydrogen compounds which we had previously made only on a spectroscopic scale (see Section 7).[105] In this case, the mixing of the



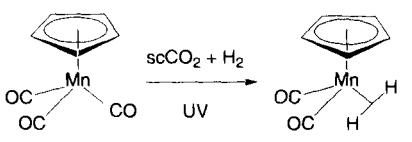


Fig. 28. A simplified schematic diagram of the flow reactor used for photochemical reactions of organometallic compounds in $scCO_2/H_2$ mixtures. Initially, high-pressure H_2 and $scCO_2$ are mixed. The organometallic compound (e.g. $[CpMn(CO)_3]$) is then dissolved in the mixture and the H_2 content can be verified, as necessary, by FT Raman spectroscopy using the cell shown in Fig. 5c. After UV irradiation, the fluid is monitored by FTIR spectroscopy and finally the product is precipitated, as in Figs. 26 and 27, by expansion through a high-pressure valve.

H_2 and $scCO_2$ is monitored in-line by FT-Raman spectroscopy using the cell shown in Figure 5c, and the photochemistry is followed by FTIR spectroscopy, as before. This reactor has been used successfully to prepare **7**[106] [Eq. (r)]. This com-

(r)

7

pound has never been isolated before and transpires to be remarkably robust; it is a pale yellow solid that melts to a brownish liquid at room temperature. The thermal stability contrasts with the relative lability of many other dihydrogen complexes.[89]

9. Conclusions

Supercritical fluids have a range of properties that are qualitatively different from those found in conventional solvents, including "tunable" density, high solubility of gases, low viscosity, etc. High-pressure conditions make chemistry in supercritical fluids necessarily more complicated than in conventional solvents, although the technology for microscale reactions is rapidly becoming simpler. We remind readers, however, that false expectations have sometimes been aroused in the past by over-optimistic articles and patents. There are many things which supercritical fluids cannot do. They are not magic solvents that will dissolve materials which have defied all other attempts to dissolve them. Of course, there are unexpected surprises such as the ability of $scCO_2$ to dissolve fluoropolymers but such cases are exceptions. Similarly, the behavior of supercritical fluids cannot contravene fundamental laws of thermodynamics, although the different solvation properties may alter the precise energetics of a process. Nevertheless, it is clearly important to identify those areas of chemistry where the special properties of supercritical fluids bring real benefits. Fortunately, diagnostic tools and laboratory techniques have now developed to the point where chemists can place their investigations on a systematic basis.

This review has shown that vibrational spectroscopy already plays a significant role in a very varied range of chemistry in supercritical fluids and clearly the range will become still broader in the future. In some areas the role of spectroscopy is central to the whole investigation while, in others, the role is to provide diagnostics for optimizing a process. In selecting our examples, we have not tried to be encyclopaedic but rather we hope to have described a sufficient number of applications for individual readers to judge whether such measurements might usefully be applied to their own particular problems. It is important, however, to repeat the fact that we have largely ignored those areas already covered in Buback's review.[4] Neither have we had the space to discuss the applications of UV/Vis spectroscopy and also some important areas of chemistry in supercritical fluids where vibrational spectroscopy has not yet been exploited fully. For example, supercritical fluids permit the use of enzymes in an essentially non-aqueous environment for reactions such as esterification.[107] Sievers and co-workers have shown that supercritical fluids have considerable promise for the deposition of thin films and coatings because their use eliminates the need for solvents which might leave residues and contaminate the resulting film.[108] Furthermore, the solvent power of supercritical fluids increases the range of possible precursor molecules for MOCVD (metal organic chemical vapor deposition because molecules can be induced into the gas phase at relatively low temperatures.[109] Lynch and co-workers have found that $scCO_2$ can be used for removal of solvent from thin films, originally deposited by wet chemistry, without destroying the integrity of the film.[110] Finally, we have not described the chemical possibilities of fluids with critical points at rather higher temperatures. For example, recent work by Wood et al. has shown that previously unknown metal sulfide complexes can be synthesized relatively simply from K_2S_4 and $[W(CO)_6]$ in supercritical ethylene diamine ($T_c = 320\,^{\circ}C$).[111]

We hope that our review has shown how many of the boundaries in traditional chemistry, analytical/spectroscopy/polymer/synthetic become blurred in supercritical chemistry or, like the liquid/gas boundary, may even disappear completely. The study of supercritical fluids should not be considered as the exclusive preserve of physical chemists and chemical engineers. When chemists have collaborated with scientists working with supercritical fluids, for example, Fox and Johnston, the outcome has been extremely successful.[140] There are now many laboratories throughout the world with expertise in handling supercritical fluids and we urge synthetic chemists to begin collaborating with them. Exciting new science will emerge.

We thank our co-workers, colleagues, and technical staff at Nottingham and our UK and overseas collaborators for their contribution to our work described within this review. We gratefully acknowledge financial support for this work from EPSRC Chemistry and Clean Technology (Grant nos. GR/H95464 and GR/J95065), from EC Human Capital and Mobility and COST programs, the Volkswagen Stiftung, Perkin-Elmer, BP International, BP Chemicals, Zeneca, NATO Laboratory Linkage Program and particularly to the Royal Society for providing a Leverhulme Senior Research Fellowship to M. P., a University Research Fellowship to S. M. H., and a Visiting Fellowship to S. G. K.

Recent Trends in Photoaffinity Labeling

Florence Kotzyba-Hibert, Isabelle Kapfer, and Maurice Goeldner*

Dedicated to the memory of Christian Hirth

Investigation of receptor–ligand interactions remains an inexhaustible challenge for chemists and biologists. Structural exploration of biological receptors is the starting point for a better understanding of how they function. Photoaffinity labeling is a biochemical approach to identify and characterize receptors targeting further structural investigations. The primary structure of a receptor protein was typically obtained by reverse genetics after exhaustive purification and sequencing of the N-terminal peptide, which allowed the design of the corresponding oligonucleotide probes. Synthesis of these oligonucleotide probes then led to identification of cDNA clones by hybridization. Following this strategy, several membrane neurotransmitter receptors and constituent polypeptides, present in very small quantities in the central nervous system, were identified and their sequence deduced from the cDNA sequence. Since photoaffinity labeling implies the formation of a covalent bond between a radiolabeled ligand analogue and a receptor binding site, it becomes theoretically possible to isolate and sequence radiolabeled peptides and then synthesize the corresponding oligonucleotide probes. Photoaffinity labeling might avoid the critical solubilization and purification steps of the classical approach. To our knowledge, no such example of primary structure determination based on photoaffinity labeling experiments has been reported. However, the extraordinary developments in gene cloning technologies, in particular homology cloning and expression cloning, have made this approach obsolete and raised the question of new perspectives for photoaffinity labeling technology. In this article we present an update on selected original developments, as well as new challenges for this method. Photoaffinity labeling not only gives access to structural elements but is also a potential tool for the investigation of functional aspects of biological receptors, for example their role in signal transduction mechanisms.

Keywords: amino acids · photoaffinity labeling · proteins · reactive intermediates · structure elucidation

1. Introduction

Discovered over thirty years ago by Westheimer et al.,[1] photoaffinity labeling has evolved considerably, although the basic principle remains unchanged. Photoaffinity labeling requires the use of a photoactivatable but chemically inert ligand analogue, which by the action of light produces a highly reactive species that binds irreversibly to the biological receptor at the site of interaction. Figure 1 illustrates the different levels of structural information that can be expected from such labeling studies. Photoaffinity labeling has been thoroughly reviewed,[2–4] and a complete study of the photochemical reagents as well as an analysis of the photolabeling experiments can be found in Bayley's monograph.[5a]

Several hundred recent articles refer to photoaffinity labeling as a tool for labeling polypeptides with photoactivatable ligand analogues. In many cases these radiolabeled ligands allowed the characterization of functional proteins on sodium dodecylsulfate (SDS) gels. However, only a few of these experiments led to the identification of the amino acid residues labeled by the photosensitive probes (Fig. 1). This ultimate step gives important structural information, the position of the binding site on the primary structure of a receptor and precise data on the ligand–receptor interaction. Other, more chemically oriented articles describe new photosensitive functional groups for potential application in photoaffinity labeling. In some cases, efforts have been made to understand the photochemical reaction by studying the reactivity of the photogenerated species.

The present article concentrates on a few types of photoaffinity reagents: fluoroaryl azides, because of their promising photolabeling potential, and aryldiazonium salts and trifluoromethylaryldiazirines, because of their efficient photocoupling properties to proteins. With respect to the biochemical aspects of photoaffinity labeling, this article also highlights the contribution of the target protein in photoaffinity labeling reactions.

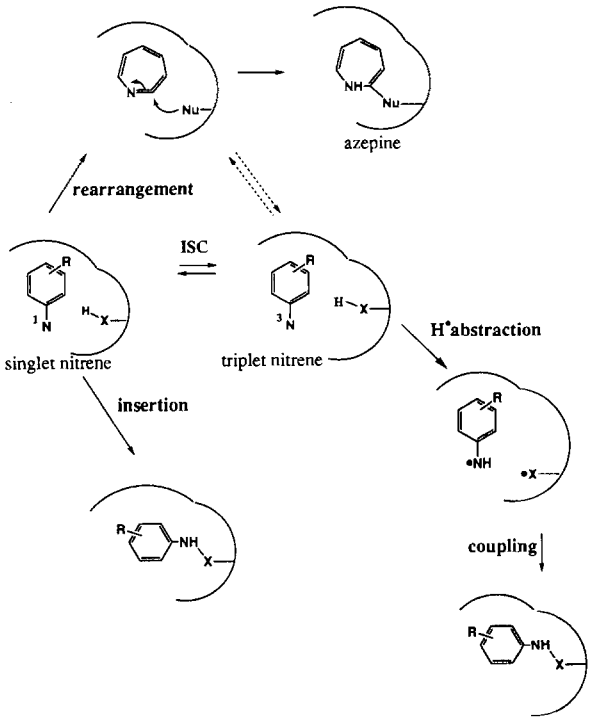
2. The Search for Ideal Photoaffinity Probes

Much time has been devoted to elaborating new chemical functions that could be used in photoaffinity labeling experiments. This search was mainly directed towards analogues of previously described photosensitive chemicals rather than towards finding truly new chemical functions. This is not surprising when one considers that the photochemical generation of a highly reactive species is generally accompanied by the production of a stabilized counterpart, ideally a gaseous compound. This is the criterion that has restricted the area of investigation. Photochemical fragmentations that induce the release of nitrogen make up the majority of documented examples, since nitrogen is an inert gas and several chemical functions can serve as precursors, for example azido, diazo, and azo groups, diazirines, and diazonium ions. These functional groups serve as precursors of reactive species such as nitrenes, carbenes, radicals, and carbocations (Scheme 1). Among these probes, aryl azides are by far the most frequently used photoaffinity labels. This popularity is more related to their chemical stability in the dark and their ready synthesis rather than to their intrinsic photochemical properties.

Scheme 1. Typical compounds used as precursors of reactive species in photoaffinity labeling.



2.1. The Aryl Azide Series

2.1.1. Towards a Better Understanding of the Photochemical Reaction

The photochemistry of aryl azides has often been considered confusing essentially because of the contradictory results obtained with different aryl azides in photoaffinity labeling experiments. Since their discovery in 1969 by Knowles et al.,[6] many substituted aryl azides have been developed such as nitro-substituted derivatives,[7] which can be activated at wavelengths beyond the protein absorption region. It has now been shown that the nature of the substituent on the aromatic ring influences the photochemical reaction and thus the chemical reactivity of the photogenerated intermediate.[8] Recent photochemical studies, mainly from the groups of Schuster and Platz, have elucitated these photochemical reactions.[9] Upon irradiation, an azide is promoted to a singlet excited state which either loses nitrogen to form singlet nitrene or undergoes intersystem crossing (ISC) to triplet azide, which in turn can lose nitrogen to form triplet nitrene. A simplified picture (Scheme 2) starts with singlet nitrene, which can either insert into a carbon–hydrogen or

Maurice Goeldner was born in 1945 in Strasbourg, France, where he studied chemistry at the Université Louis Pasteur. He received his doctorate in 1972 under the direction of Dr. J. F. Biellmann, and during this time he conducted research at the Centre National de la Recherche Scientifique in Strasbourg. After postdoctoral studies with Prof. S. Wolfe (Kingston, Canada) and Prof. A. Eschenmoser (ETH, Zürich, Switzerland), he returned to Strasbourg to codirect, with his friend Christian Hirth, the Laboratoire de Chimie Bio-organique. In 1983 Goeldner was appointed Professor of Organic Chemistry at the Faculté de Pharmacie. His research interests focus on bioorganic chemistry, in particular, the structural determinants of membrane receptors investigated by site-directed labeling methods.

Scheme 2. Possible mechanisms for the coupling of arylnitrenes to biological receptors. ISC = intersystem crossing.

heteroatom–hydrogen bond, rearrange to the corresponding didehydroazepine, or undergo intersystem crossing to triplet nitrene. These intermediates lead to different reactions in photoaffinity labeling experiments:

a) A quasi-nondiscriminative insertion reaction with any amino acid residue or with the solvent is expected in the case of singlet nitrene.

b) A reaction with an appropriate nucleophile may follow formation of the didehydroazepine; possible nucleophiles are cysteinyl and histidinyl residues, while side chains with hydroxyl groups and the protonated lysine side chain are probably not sufficiently nucleophilic. For example, it has been shown that methanol does not react with didehydroazepines.[10]

c) Triplet nitrene leads to less predictable radical chemistry (see Section 2.3).

With few exceptions, such as the fluorinated aryl azide and the azidonucleotides (see Sections 2.1.2 and 2.1.3), aryl azides either rearrange to the corresponding didehydroazepines or convert to the triplet nitrene; insertion reactions of singlet nitrene are not observed.[8] Schuster et al. have clearly demonstrated the influence of the substituent on the aromatic ring on the photochemical reaction (Table 1). The complexity of the reaction is demonstrated by the completely opposite reactivity of the *para*-chloro- and the *para*-dimethylaminophenyl azides. Irradiation of *para*-chlorophenyl azide in cyclohexane in the presence of diethylamine as nucleophile gave the azepine in 100% yield, whereas *para*-dimethylaminophenyl azide led to compounds arising from radical chemistry. Thus, for photoaffinity labeling experiments using aryl azides, the course of the labeling reaction depends not only on the nature of the substituents on the aromatic ring but also on the presence of a nucleophilic residue in the binding site. Therefore, predictions

Table 1. Yields of the products formed by irradiation of aryl azides $XC_6H_4N_3$ in cyclohexane alone and in the presence of diethylamine [8]. The azo compounds and the anilines arise from triplet nitrene coupling, the azepines from singlet nitrene coupling.

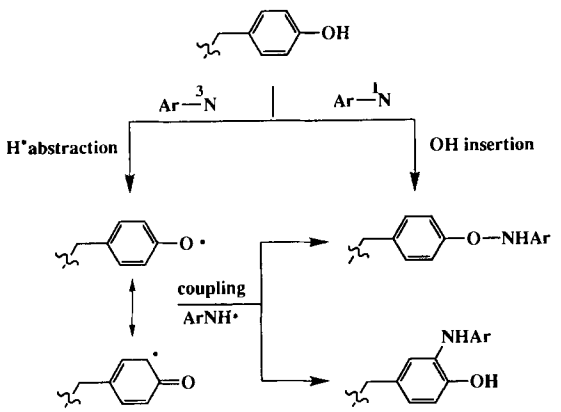
concerning the course of photoaffinity labeling experiments using aryl azides are practically impossible.



For the photochemical coupling of aryl azides to receptors, nucleophilic addition to the didehydroazepine might be of limited use since the azepines obtained are not always stable to the proteolytic conditions typically used for peptide and amino acid identification. On the other hand, many successful labeling reactions with aryl azides reacting as triplet nitrenes have been observed. Radical chemistry involves a multistep process for the coupling reaction between the ligand and the receptor. The abstraction of a hydrogen radical from the protein by the triplet nitrene and combination of the newly formed radicals to give the covalent bond are shown in Scheme 2. In the context of the receptor, this reaction raises the question of which amino acid residues are likely to form stabilized radicals (see Section 2.3).

An interesting observation made by Platz et al.[11] is that low-temperature photochemistry (77 K) favors the formation of triplet nitrene by preventing the rearrangement of singlet nitrene into didehydroazepine. This could be applied to *meta*-azidophenyl-substituted acylchymotrypsin; irradiation at 77 K led to increased irreversible photolytic inactivation of the enzyme. This phenomenon, however, could not be applied successfully to the inactivation of the estrogen receptor.[12]

2.1.2. *Azidonucleotides*

Azidonucleotides are an interesting category of aryl azides. They are very often excellent nucleotide analogues with a minimum of chemical modification since the azido group is incorporated on the heterocyclic ring. They have been used successfully in many photoaffinity labeling studies. In particular, radiolabeled 2-azido-ATP,[13, 14] 2-azido-ADP,[15–17] 8-azido-ATP,[18, 19] 8-azido-GTP,[20] and 8-azido-cAMP[21] allowed the characterization of the labeled amino acid residues on the target receptor's binding site. By considering the different amino acid residues that have been labeled by these purinergic azido probes (Tyr, Trp, Lys, Thr, Leu, Ile, and Pro; see Section 4, Table 7), it is not possible to associate clearly singlet or triplet reactivity with the corresponding photogenerated nitrene. The reactivity of either singlet or triplet nitrene could account for the observed

results. Nucleophilic addition on the nucleotide-derived didehydroazepine seems unlikely, unless tyrosinate ions are involved. Scheme 3 illustrates the possible insertion mechanisms on the tyrosine side chain by both nitrene species; tyrosine is the amino acid most frequently labeled with these purinergic azido probes (15 examples of tyrosine labeling are listed in Table 7). A structural analogy with carbonyl azide, known to generate highly

Scheme 3. Possible reaction mechanisms for the insertion of singlet or triplet nitrenes in the tyrosine side chain.

reactive nitrenes,[22] has been proposed for the nucleotide azides.[5b] It is certain that precise kinetic data and in particular the determination of the lifetime of the corresponding singlet nitrene, as well as the rates of rearrangement to didehydroazepine and to triplet nitrene, would be very valuable for a clearer understanding of the photochemical reactions involving these azidonucleotides.

2.1.3. *Fluorinated Aryl Azides*

The fluorinated aryl azides constitute by far the most promising development in the aryl azide series for photoaffinity labeling. In early findings, Banks et al.[23] described the thermolysis of fluorinated aryl azides and demonstrated C–H insertion in mesitylene and trimethoxybenzene. A detailed study of the photochemical reaction reported by Platz et al.[10, 24–27] led to the conclusion that singlet fluorinated arylnitrene rearranges more slowly to the corresponding didehydroazepine than the unsubstituted species, thus allowing this intermediate to react with most chemical bonds, including C–H bonds, by formal insertion (Table 2). New functionalized fluorinated aryl azides have been synthesized as potential photoaffinity probes.[28, 29] Few examples of photochemical cross-linking[30] and photoaffinity labeling[12, 31–33] using such derivatives have been published. Comparative photoaffinity labeling studies between fluorinated and non-fluorinated arylazido photoaffinity probes led to contradictory results. In one case labeling results were comparable with the two probes,[12] while in the second case the fluorinated probe was more effective.[34] Care should be taken in analyzing these results, especially in the absence of data demonstrating analogous positioning of these probes within the target binding site. A recent study on fluorinated aryl azides substituted in different positions on the aromatic ring established a precise correlation between the reactivity and the substitution pattern.[35] The 4-substituted 2,6-difluorophenyl azides demonstrate maximum reactivity with minimum fluorine substitution. It is suggested that these derivatives are able to react as singlet nitrene in an hydrophobic environment, while hydroxylated solvents catalyze intersystem crossing to triplet nitrene. Considering the implications for photoaffinity labeling, the authors claimed these reagents to be effective only in a hydrophobic environment through efficient insertion reactions in single bonds by means of the corresponding singlet nitrenes. They suggested that triplet nitrene reactivity in a hydrophilic environment leads to cleavage of the polypeptide rather than coupling to the biological receptor. However, this latter proposal can be questioned, when one considers the numerous successful examples of photoaffinity labeling experiments involving triplet nitrenes (see Section 2.3 and Table 7 for typical radical-issued photoaffinity labeling examples).

Table 2. Yield of singlet and triplet nitrene adducts formed on photolysis of pentafluorophenyl azide in various solvents RH (as trapping agent) [27].

Solvent	C_6F_5NHR [%]	$C_6F_5NH_2$ [%][a]	*trans*-$(C_6F_5)_2N_2$ [%][a]

diethylamine	58	22	0

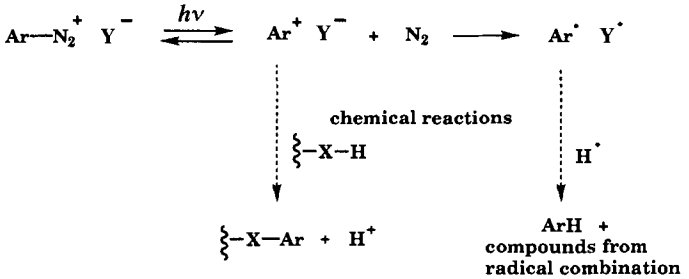
[a] Triplet nitrene adduct. [b] Triplet sensitized. [c] The yield was not determined, but the product was formed in only minor amounts.

Although fluorinated aryl azides can be activated only by light with wavelengths less than 300 nm, which might be harmful for sensitive proteins, these compounds fulfill most of the criteria of effective photoaffinity labeling reagents and should gradually replace the other commonly used aryl azides. In particular, phospholipidic probes incorporating fluorinated aryl azides are promising tools for the structural investigation of membrane receptors. The predicted singlet nitrene reactivity[35] should lead to insertion into C–H bonds, which is a prerequisite for efficient labeling of the hydrophobic amino acid residues of membrane proteins. Finally, the elaboration of synthetic strategies allowing the incorporation of radiolabeled isotopes in fluorinated aryl azide reagents[36, 37] should guarantee enormous success for these probes.

2.2. Efficient Photoaffinity Probes

In addition to the aryl azides, a great variety of other photosensitive compounds have been described as potential probes for photoaffinity labeling.[5a] We will describe two classes of very powerful probes, aryldiazonium salts and trifluoromethylaryldiazirines. Their remarkable ability to couple to proteins will be discussed in Section 5. We briefly summarize here their chemical and photochemical properties.

2.2.1. *Aryldiazonium Salts*



Aryldiazonium salts are often considered to be difficult to isolate and handle. This is certainly true for diazonium salts with electron-withdrawing substituents, which are unstable species under nonacidic conditions. On the other hand, electron-donating substituents in *ortho* and *para* position confer sufficient stability and also interesting photochemical properties to these species such as high quantum yields[38] and absorption at wavelengths greater than 300 nm (Table 3). Thus these derivatives are good candidates for photoaffinity probes.

Table 3. Absorption maxima λ_{max}, molar extinction coefficients ε, and quantum yields ϱ for several *para*- and *meta*-substituted diazonium ions $XC_6H_4N_2^+$.

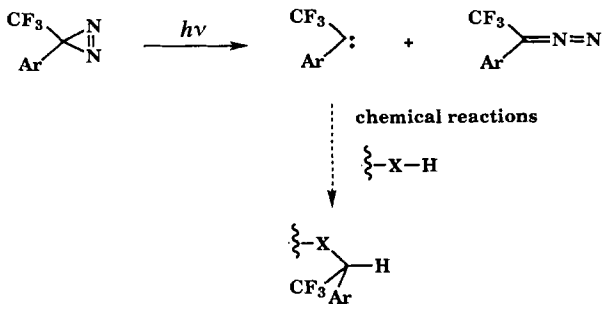
The primary process in the photochemical decomposition is the formation of the corresponding aryl cation, which can undergo further photochemical reduction to give the corresponding aryl radical (Scheme 4). These transient species lead to different chemical reactions. Put simply, the presence of electron-withdrawing groups on the aromatic ring favors the electronic photoreduction process, whereas electron-donating substituents stabilize the cationic species by resonance. For instance, the photochemical reaction of *para*-nitrophenyldiazonium salts in alcohol gives nitrobenzene as the major product, while the *para*-dimethylamino derivative gives almost exclusively the corresponding ether derivative.[38]

Scheme 4. Photochemical reactivity of aryldiazonium salts $ArN_2^+Y^-$ and subsequent reactions. X = heteroatom, CR_2.

Aryl cations are highly reactive species,[39] whose lifetime has not yet been determined accurately. The lifetime of the phenyl cation in water has been determined indirectly by laser flash techniques to be less than 500 ps.[40] A direct study of the photochemical decomposition of aryl cations in hydrocarbon solvents, in which the C–H bond serves as a reference bond, is difficult due to the insolubility of these cations in such media. Nevertheless, a few examples of intramolecular reactions with C–H bonds have been described.[41, 42] In an original approach Speranza et al. generated an unsolvated aryl cation by radiolysis of tritiated benzene.[43] Several interesting aspects of the reactivity of the free aryl cation could be observed, including several efficient reactions with C–H bonds. The photochemical reaction of the *para*-dimethylaminophenyldiazonium ion (DDF) with the amide bond in *N*-ethylacetamide, as a model of a peptide bond, was tested.[44] Over 90% of the reaction led to an O- or N-alkylation process which was expected from the solvation of the charged moiety of the diazonium salt by the oxygen and nitrogen atoms (Scheme 5).



Scheme 5. Analysis of the photochemical reaction of the *p*-(*N*,*N*-dimethylamino)-phenyldiazonium ion with *N*-ethylacetamide [44].

Aryldiazonium salts with electron-donating substituents meet all the criteria of potential photoaffinity probes,[45] and we have used them extensively in our group for the labeling of cholinergic proteins; the binding site for the quaternary ammonium group could be efficiently probed by the charged diazonium species. Several examples will be described in detail in Sections 4 and 5.

2.2.2. *Trifluoromethylaryldiazirines*

Aryldiazirine derivatives were initially described by Smith and Knowles[46] as potential photoaffinity probes. The search in this series for powerful reagents led to the discovery of trifluoromethylaryldiazirines,[47] which show favorable photochemical properties in addition to excellent chemical stability. On irradiation the diazirine either undergoes fragmentation to the corresponding carbene or isomerizes to a linear diazo compound (Scheme 6). The rearrangement products are long-lived species under the diazirine irradiation conditions and have led to undesired alkylation reactions in the dark.[48] This problem was overcome with trifluoromethylaryldiazirines. Photolysis in cyclohexane gives C–H insertion products in satisfactory yields,[49] whereas in alcohols O–H insertion reactions are the main reactions; both reactions are attributed to the singlet reactivity of the carbene. Other reactions involving triplet carbenes have been observed during the photolysis in alcohols[50] (Table 4).

Scheme 6. Photochemical reactivity of diazirines and subsequent reactions. X = heteroatom, CR_2.

Table 4. Distribution of products obtained on photolysis of two 3-trifluoromethyl-3-aryl-3*H*-diazirines in organic solvents [49a].

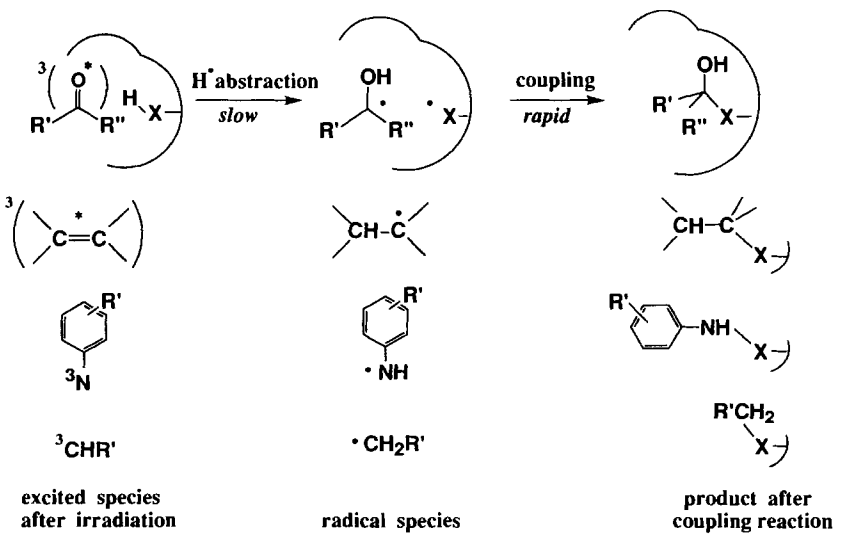
			$ArCH_2CF_3$	5



3-Trifluoromethyl-3-*meta*-iodophenyl-3*H*-diazirine (TID) synthesized by incorporation of [^{125}I] is an outstanding photoactivatable probe.[51] This reagent has been used successfully for hydrophobic labeling of membrane proteins,[49a] illustrating in particular the ability of the photogenerated carbene to react with nonactivated amino acid side chains. More recently,[52] TID has been used as a true photoaffinity probe by interaction with the noncompetitive blocker binding site of the nicotinic acetylcholine receptor. The observed outstanding photochemical labeling results will be described in Section 5.

2.3. Radical Reactions in Photoaffinity Labeling

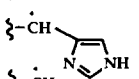
Photochemically generated free radicals may couple with receptors in two different ways, either to the peptide backbone or to the amino acid side chains. Diradicals (triplet states from nitrenes, carbenes, excited ketones and alkenes) probably abstract a hydrogen radical from the receptor, and the two newly created radicals combine rapidly[5c] (Scheme 7). In the case of monoradical species, photogenerated for instance from aromatic halides, the coupling process is less obvious, since the hydrogen abstraction reaction results in the disappearance of the initially formed radical. Nevertheless, a delayed coupling between two radical species can always be postulated. Finally, a last type of radical mechanism might occur during the cleavage of disulfide bonds leading to the formation of stabilized thiol radicals, which ultimately combine with another radical species.

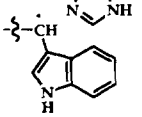
Acetophenones and benzophenones have been used extensively for photoaffinity labeling experiments and are typical examples of precursors of photogenerated radicals. The properties of the excited-state radicals generated from these aromatic ketones are well understood.[58] The physicochemical requirements for photoaffinity labeling using such aromatic ketones are fulfilled: the reactive triplet state does not rearrange, is easily generated at long wavelengths ($\lambda \geq 320$ nm), avoiding significant damage to aromatic amino acids of proteins,[53] and is able to insert into C–H bonds. Abstraction–addition reactions of the triplet radicals of aromatic ketones were first used for the selective introduction of functional groups at methylene positions in steroids and long-chain alcohols[55–57] and for photoaffinity labeling of the binding sites of peptide hormones.[58] Triplet radicals of aromatic ketones do not react efficiently with water,[59] a property claimed to be useful for photoaffinity labeling experiments.[54] However, reactive species not quenched by the solvent may lead to nonspecific labeling (Section 3).

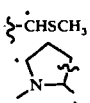
At which sites do free radicals react with the protein, and which amino acid residues are involved in these reactions? The α-carbon radicals generated on the peptide backbone are stabilized through the synergistic effect of captodative substituents with opposite polarity.[60] However, this effect could not be experimentally determined in measurements of the thermodynamic reaction and activation parameters for the formation of α-cyano-α-methoxyalkyl radicals.[61] Preferential reactivity of glycine residues in free radical reactions with peptide model compounds has been observed and attributed to selective hydrogen atom abstraction from the α-carbon of the glycine moiety. This preference was unexpected, as glycine affords secondary radicals by homolysis of the C_α–H bond, whereas the analogous reaction on other amino acid derivatives produces thermodynamically favored tertiary radicals. This peculiar stability of the glycyl radical has been studied by Easton et al.[62–64] using the reactivity of NBS towards *N*-acylglycine derivatives. The stability has been attributed to a favorable conformation of the radical, which is planar and relatively free of nonbonding interactions, thus allowing maximum delocalization of the unpaired electron. In the presence of C_α-substituents unfavorable nonbonding interactions arise (Table 5). The preferential reactivity of glycine residues has also been demonstrated with a model

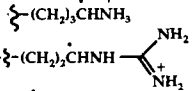
Scheme 7. Radical coupling of photogenerated triplet species to biological receptors through H' abstraction.

Table 5. Relative rate k_{rel} of the reaction of *N*-bromosuccinimide (NBS) with three amino acid derivatives $PhCONHCHRCO_2CH_3$ [62, 63].









R	Corresponding amino acid	k_{rel}[a]

reaction, the oxidative cleavage of a C-terminal peptide with nickel oxide,[64] and with photoalkylation reactions of some synthetic glycine-containing polypeptides with 1-butene or toluene.[65] Yet, a protein is a complex polypeptide and the degree of selectivity depends on the location of the glycine residue in the peptide (i.e its accessibility) as well as on the conformation of the peptide.[66]

Table 6 contains bond dissociation energies[67, 68] for a series of compounds, which can be correlated to the relative energies required for hydrogen abstraction (or disulfide dissociation) from amino acid side chains. Clearly the disulfide dissociation reaction is by far the least energetic process and should lead to the efficient radical-induced cleavage of disulfide bridges in the protein. For the other amino acid side chains, hypotheses can be forwarded concerning the stabilization of derived radicals. The functional groups that are presumed targets for photogenerated radicals, based on the bond dissociation energies listed in Table 6, are shown in Scheme 8. Stabilized radicals such as phenoxyl radical for Tyr, benzylic radicals for Trp, Phe, and His, and thiolate radical for Cys are likely candidates. Also radicals α to heteroatoms (O in Ser and Thr, N in Arg, Lys, Pro) and α to carbonyl groups (Asp, Glu, Asn, Gln) are stabilized and could be formed by hydrogen abstraction. Finally, even some tertiary alkyl radicals (Val, Leu, Ile) can be envisaged as arising from hydrogen abstraction. As a consequence, practically all the amino acid side chains could be involved in radical chemistry through hydrogen abstraction reactions.

Table 6. Bond dissociation energies E_{diss} determined with model compounds for amino acid side chains [67, 68].

Scheme 8. Radical reactivity of peptides: radicals in the peptide backbone (I) and stabilized radicals in the side chains (II).

The existence of other radical species has been demonstrated recently by γ-irradiation of protein and protein–DNA complexes.[69] The major radical species formed under these conditions by electron loss have been identified by ESR as N radicals in the peptide backbone and not carbon-centered radicals as proposed in previous work; side-chain radical cations such as $Trp^{\bullet+}$ and $Tyr^{\bullet+}$ have been found in relatively low yields.[70] Nevertheless, such a process does not occur under classical irradiation conditions. Finally, photodestruction of proteins most probably proceeds through formation of radicals and involves several amino acid residues, especially those sensitive to light such as Cys–Cys, Trp, Phe, and Tyr.[71]

3. Nonspecific Labeling: A Major Problem in Photoaffinity Labeling

Probes directed at the active site are generally used to study the interactions between ligands and biological macromolecules. This strategy requires the replacement of a weak and reversible ligand–receptor interaction, as indicated by the transient character of the complex, by formation of a stable covalent bond. To be valuable, this chemical reaction must be site specific, that is, it must occur exclusively at the binding site of the target molecule and not at any other protein domain or on any other material in the incubation mixture. This problem of nonspecific labeling occurs often in photoinduced labeling studies, since highly reactive species are generated in the vicinity of the proteins. The higher the ligand excess during the labeling

reaction (low-affinity probe), the greater the extent of nonspecific labeling. Another case of nonspecific labeling was demonstrated for photogenerated species having a longer lifetime, for which pseudophotoaffinity labeling can occur.[72] The use of radical scavengers has been recommended and used successfully to trap reactive intermediates in the outer medium, restricting the chemical reaction to the binding site.[5d] Obviously, most successful photoaffinity labeling experiments (Table 7) were performed with purified proteins available in large quantities. This permitted the photochemical reaction to be conducted at high receptor concentrations, thereby reducing the ligand excess and the resulting nonspecific labeling. How can nonspecific labeling be minimized when the labeling receptors are present in very small quantities within a preparation?

3.1. The Historical Example

The labeling of α-chymotrypsin by diazoacetylchymotrypsin[1] was indeed a clever example of site-directed labeling in which the photoreactive species was generated exclusively at the active site. The chemical stability of the acylated enzyme was sufficient for the removal of the unreacted photosensitive substrate, *p*-nitrophenyl diazoacetate, thus allowing an efficient photolabeling reaction on a stoichiometrically modified enzyme.[73, 74] Beyond the problems encountered due to the rearrangement of the diazoacetyl probe, this experiment was a remarkable example of selective photoactivation within the active site which thus avoided nonspecific labeling.

3.2. Photochemical Cross-Linking of Long-Lived Complexes

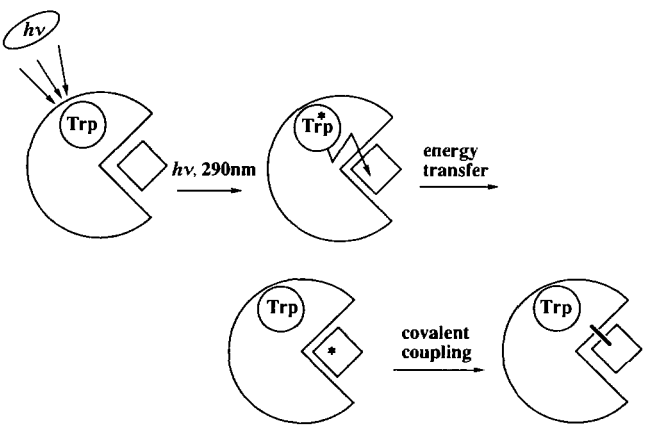
The use of ligand analogues having very high affinity for a binding site is the simplest way to avoid the use of an excess of ligand in the labeling reaction and thus reduce nonspecific labeling. High affinity corresponds generally to a very slow dissociation rate of the ligand–receptor complex and generally allows excellent labeling conditions. When highly dilute ligand solutions are used, for example, quasi-stoichiometric receptor–ligand complexes are formed after an appropriate incubation time. The success of the photolabeling reaction becomes exclusively dependent on the intrinsic reactivity of the photogenerated species.

Neurotoxins are an extraordinary group of very specific ligands showing extremely high affinities for a number of neuroreceptors (affinity constants of up to 10^{-12} M)[75] and giving rise to typical examples of long-lived complexes. Because neurotoxins form an almost irreversible interaction with the receptor in the absence of light, radiolabeled toxin derivatives are required for further analyses under denaturating conditions. Generally, the toxins are modified specifically (i.e. at cysteine or lysine residues) by using photochemical cross-linking reagents.[5e] Snake venom neurotoxins acting on the nicotinic acetylcholine receptor have been modified by bifunctional reagents and have been used extensively to probe this receptor.[76–81] The relatively large surface of these neuropeptide probes (M_w from 70 to 80 kDa) offers many possible sites for probe–receptor interactions. Thus, several derivatives modified at different positions can be designed to study different areas of the receptor. These photoaffinity labeling probes limit the nonspecific labeling and provide powerful tools for structural investigations. The determination of the three-dimensional structure of membrane receptors is at an early stage, especially for heterooligomeric polypeptide assemblies for which only low-resolution (9 Å), low-temperature, electronic microscopy data are available.[82] Therefore, labeling results obtained with these toxin derivatives might be a sophisticated method for characterizing the quaternary organization of the receptor polypeptides.[76–81]

3.3. Photosuicide Labeling

It is clear that modified neurotoxins are highly elaborate tools that are not always available to the scientist. Therefore, the development of a method that minimizes nonspecific labeling and is applicable to more commonly used derivatives is of general interest. Photosuicide inhibitors are ligand analogues whose selective photodecomposition is triggered by the intrinsic properties of the target protein.[83] This method, which is an extrapolation of the more conventional suicide or k_{cat} enzyme inactivation,[84] combines the high reactivity of photogenerated probes with a selective mode of activation within a binding site.

Three methods have been described for the preferential photoactivation of a ligand when it is bound to a receptor site. In the first, nitrosamine derivatives in the hydrophobic environment of the binding site are photoactivated preferentially.[85] The second method consists of an enzymatic-induced shift of the absorption band of the chromophore, allowing the selective photoactivation of the enzyme-bound reaction product.[86] The third approach relies on the photoactivation of a ligand having an appropriate chromophore by tryptophan-mediated energy transfer (Fig. 2).[87] This type of photoactivation requires the presence of a tryptophan residue in the binding site or its vicinity, as well as a probe with appropriate spectroscopic properties. In particular, these probes should have minimal absorption at the Trp excitation wavelength ($\lambda \approx 290$ nm) and maximum absorption at the Trp emission wavelength (λ_{max}(probe) $\approx$ 320–340 nm). Three types of molecules having the appropriate photosensitive chromophores are shown in Scheme 9. The improvement of the labeling reaction by energy transfer photoactiva-



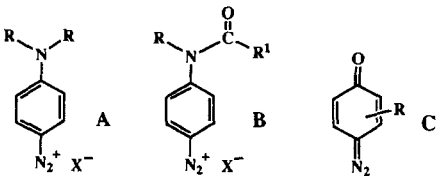


Fig. 2. Photolabeling by tryptophan-mediated energy transfer.

tion ($\lambda_{exc} \approx 290$ nm) over the usual photolabeling reaction ($\lambda_{exc} \approx \lambda_{max}$(probe)) was first demonstrated with the inactivation of acetylcholinesterase by an aryldiazonium derivative (compound **A**, Scheme 9).[87] This method should be applicable in many cases, and several other successful examples of receptor labeling by tryptophan-mediated photoactivation have already been described.[88-92]

4. Identification of Labeled Amino Acid Residues

Numerous amino acid residues labeled in photoaffinity labeling experiments have been identified recently. This success can be related to a) the increasing number of known protein sequences deduced from the corresponding cloned genes,[93,94] which obviously facilitates the sequencing of peptides and the identification of amino acids; and b) recent progress in microsequencing technology, which facilitates the sequencing of very small quantities of peptides.[95]

These identification studies have several consequences. First they allow the location of a ligand binding site along the protein sequence and the eventual deduction of important information on the receptor–ligand interaction. In addition, if the three-dimensional structure of the target receptor is known, it is extremely important for crystallographers to have access to additional structural data not accessible in the solid state. Secondly, the identified amino acid residues are suitable targets for site-directed mutagenesis experiments. Clearly, the greater the number of residues identified, the more information obtained on the structure in solution.

Table 7 summarizes successful photoaffinity labeling experiments that identified labeled amino acid residues and lists the probes and target receptors used. Several comments can be made:

a) In most of the examples proteins available in purified form and in appreciable quantities were used. Remarkable exceptions are the β-adrenergic,[96] GABA,[97] and vasopressin[98] receptors.

b) Many different photosensitive probes have been used, ranging from the classical aryl azides to diazirines, diazoketones, aryldiazonium salts, and aromatic halides. The fact that aryl azides are the most frequently listed reflects frequent usage rather than better labeling properties of the generated species. The list includes also nonphotoactivatable probes such as unmodified nucleotides,[99-102] nicotine,[103] physostigmine,[104] and d-tubocurarine.[105] The use of such probes as site-directed photochemical inactivators is indeed a convenient alternative to photoaffinity labeling, but the actual mechanism by which the coupling reaction to the protein occurs remains undefined.

c) Of the different probes, only a few could be used to label several amino acid residues within the binding site. *para*-Dimethylaminobenzenediazonium tetrafluoroborate (DDF; **A**, R = CH_3, X = BF_4; Scheme 9)[89-92] showed exceptional reactivity, in particular for the nicotinic acetylcholine receptor;[106,107] eight different amino acid residues could be identified on the receptor α-subunit: Cys 192, Cys 193, Tyr 93, Tyr 151, Tyr 190, Tyr 198, Trp 86, and Trp 149. Also the monochlorophenothiazine derivative chlorpromazine[108-110] could be photoincorporated, although very weakly, on seven different amino acids belonging to putative channel-forming M2 segments of the nicotinic acetylcholine receptor (αSer 248, βSer 254, βLeu 257, γThr 253, γSer 257, γLeu 260, δSer 262). A remarkable diversity of labeling was observed with the reagent [^{125}I]TID,[49b] which allowed extensive labeling of the nicotinic acetylcholine receptor. Eight different residues (βLeu 257, δLeu 265, βVal 261, δVal 269, βSer 250, βSer 254, δSer 258, δSer 262) on the channel-forming M2 segments from the β- and δ-subunits[52] could be identified. Considering the lipid–protein interface of *Torpedo*, the labeling results are even more impressive: five residues (Cys 412, Cys 418, Met 415, Thr 422, Val 425) from the hydrophobic M4 segment of the α-subunit[111] and sixteen residues (3 Phe, 3 Met, 3 Ile, 2 Ser, 2 Asn, Gly, Val, Leu) from the M_3 segment of the β-, γ-, and δ-subunits.[112] A few other probes listed in Table 7 showed a similar trend but to a much lesser extent.

d) Each of the twenty amino acids has been labeled at least once. Tyr and Cys are most frequently labeled. These residues can be labeled by different types of probes generating nitrenes, carbenes, aryl cations, or even undefined reactive species. Surprisingly, the nucleophilic His residue, which is often labeled by specific protein modification reagents[113] and by affinity reagents,[114] has been identified only twice in photoaffinity labeling experiments. Other amino acids with functionalized side chains are frequently encountered (Met, Trp, Lys, Glu, Ser, Thr), while a few hydrophobic residues could be labeled occasionally (Leu, Ile, Pro, Phe, Ala, Val). It is noteworthy that the labeling of the hydrophobic residues is mainly achieved with probes that generate particularly reactive species such as carbenes and aromatic cations (Section 2.2).

The survey in Table 7 shows firstly that most of these residue identifications result from recently published photoaffinity labeling experiments, which reflects technical progress in this research area. Secondly, it seems that no evident connection can be made between the nature of the labeled residues and the reactivity of the photoprobes; such a relationship is even more difficult to evaluate because of the lack of quantitative results for irreversible labeling in many publications. Finally, the molecules that can be used for the efficient labeling of several amino acid residues are potentially powerful probes for the investigation of the topology of membrane receptors, a topic of growing interest. This point will be discussed in detail in the following section.

Table 7. Amino acids in biological receptors that have been identified by photolabeling; the amino acids are listed in order of decreasing frequency.

Amino acid	Radioactive probe	Target receptor	Ref.
Tyr	2-azido-[α-^{32}P]ADP	beef heart mitochondrial F_1 ATPase (β-subunit)	[15]
	[^{3}H]SAM, [*methyl*-^{3}H]AdoMet	guanidinoacetate methyltransferase	[101]
	2-azido-[β,γ-^{32}P]ATP	chloroplast F_1 ATPase (β-subunit)	[14]
	2-azido-[β,γ-^{32}P]ADP		
	2-azido-[β,γ-^{32}P]ATP	beef heart F_1 ATPase (β-subunit)	[16]
	8-azido-[α-^{32}P]ATP	recA protein from *E.coli*	[18]
	8-azido-[α-^{32}P]cAMP	cAMP-dependent protein kinase	[21, 127]
	[^{14}C]Gly-Pro-Arg-*N*-(4-azido-2-nitrophenyl)-Lys-NH_2	fibrin (γ-chain)	[117]
	[^{32}P]azidonitrophenylphosphate	mitochondrial F_1 ATPase	[118]
	[^{3}H]DDF[a]	*Torpedo* nicotinic acetylcholine receptor	[106, 107]
	[^{3}H]nicotine	*Torpedo* nicotinic acetylcholine receptor	[103]

His	*N*-2,4-dinitrophenyl-*p*-aminobenzoate	anti dinitrophenyl antibody	[135,136]
	[α-^{32}P]dTPP	*E.coli* DNA polymerase I (Pol I)	[149]
Asn	[^{125}I]TID[b]	*Torpedo* nicotinic acetylcholine receptor	[112]
Gln	[^{32}P]azidonitrophenylphosphate	mitochondrial F_1 ATPase	[118]
Val	[^{125}I]TID[b]	*Torpedo* nicotinic acetylcholine receptor	[52,111,112]

[a] DDF = *p*-(*N*,*N*-dimethylamino)phenyldiazonium tetrafluoroborate. [b] TID = 3-trifluoromethyl-3-*meta*-iodophenyl-3*H*-diazirine. [c] NANDP = 2-[(4-azido-2-nitrophenyl)amino]ethyl diphosphate. [d] A cross-linker.

5. Topographical Mapping

5.1. Definition

Topographical mapping can be defined as a labeling pattern that involves the full environment of a ligand within a binding site. This mapping can be established either on a macromolecular level by labeling different subunits defining the receptor binding site or can be defined on a molecular level by labeling and identifying amino acids that surround the binding site (Fig. 3). It is clear that topographical mapping is necessarily related to the intrinsic chemical reactivity of the photogenerated species. Probes with the highest possible reactivity ("universal reactivity") are required, since they should be able to map the entire surroundings of the ligand by reacting with all amino acid residues, including those with chemically inert alkyl side chains. Consequently, these probes should react not only with nucleophilic residues, which would lead to a partial mapping of the binding site. The best way to estimate the reactivity of the probe is to measure the lifetime of the photogenerated species in different media, from water to hydrocarbons. The probe should be able to react efficiently with a C–H bond (for instance from the solvent), since the C–H bond can be considered to represent any particular bond in the ligand binding site of a receptor.

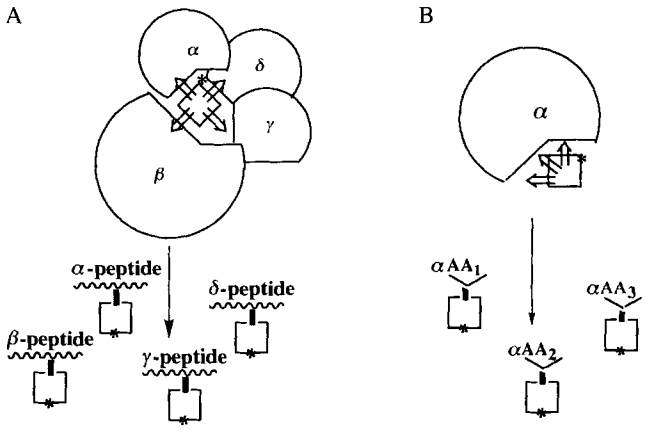

Fig. 3. Definitions in topographic mapping A) at the macromolecular level: labeling of all peptide subunits α–δ defining the binding site; b) at the molecular level: labeling of all amino acid residues that compose the binding site.

5.2. Limitations

The use of highly reactive probes is not enough to ensure topographical mapping. Different situations that might occur during photoaffinity labeling experiments are represented in Figure 4. For instance the photoactivated probe might be rapidly quenched by surrounding water molecules if the environment of the bound probe is hydrophilic (Fig. 4A). We described the example of labeling on one receptor binding site existing in two different conformations by using a highly reactive photoactivatable probe. We observed that very efficient labeling occurred in one conformation, while labeling was nonexistent in the other conformation, possibly because the reactive moiety was oriented towards the aqueous medium.[89] Another possible limitation to full topographical mapping is the use of a probe showing very high affinity for a binding site. These probes generally (although

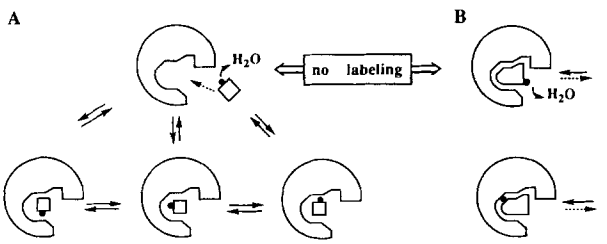

Fig. 4. Differences in receptor mapping with highly reactive photoaffinity probes having moderate (A) and high (B) binding affinity. A) Topographical mapping through dynamic interaction (fast dissociation) of the probe and the binding site. B) Specific but partial mapping through "static" interaction (slow dissociation) of the probe and the binding site.

not necessarily) dissociate very slowly from the binding site. This is likely to correspond to a static interaction between the photoactivated ligand and a limited area of the binding site (Fig. 4B). This situation is typically encountered during the slow photochemical coupling of modified neurotoxins or hormone peptides (Section 3.2). In contrast, topographical mapping requires dynamic interaction, allowing the probe to adopt different positions in the binding site. The extreme reactivity of the excited species guarantees efficient labeling of all the areas of the binding site. Hence, by definition, the best topographical probes show a rather moderate binding affinity for their recognition site, leading to an efficient dynamic labeling process. Theoretically, the use of probes showing moderate binding affinities should lead to increased nonspecific labeling (Section 3). However, in this case, nonspecific labeling is usually limited, due to efficient quenching of the photogenerated species by the solvent.

5.3. Expected Consequences

Oligomeric protein complexes are frequently encountered in biology and raise the question of the precise localization of a binding site within the multisubunit protein complex. Recent descriptions of highly organized quaternary structures of several membrane receptors such as neurotransmitter-gated receptors[152] require appropriate tools to identify the ligand binding sites. As an example, the five constituent subunits of the ion channel on the nicotinic acetylcholine receptor were labeled by using photosensitive channel blocker derivatives.[109, 110, 131, 153] Topographical probes are best adapted to labeling receptor sites located on different receptor subunits. Many publications describe the labeling of one subunit in a multisubunit complex, but interpretations that tend to localize the binding site on the singly labeled subunit may be misleading. A more reactive topographical probe might extend the labeling to residues belonging to other subunits.

Of the probes listed in Table 7 (see also Sections 2.2 and 4), only two molecules might be considered as topographical probes: the aryldiazonium salt DDF[90, 106, 107] and the diazirine derivative TID.[49b, 52, 111] Both compounds generate highly reactive species and lead to high yields of irreversible labeling on the nicotinic acetylcholine receptor, which allowed the identification of several binding site residues. Their binding affinities are rather low (K_i = 200 μM for DDF on the acetylcholine binding site[90] and 6.5 μM for TID on the noncompetitive binding site[52]). The remarkable labeling pattern obtained with DDF on the α-subunit of the nicotinic acetylcholine receptor can be explained by the combination of the high reactivity of the photogenerated aryl cation (lifetime in water ≤ 0.5 ns[40]) and the ideal replacement of the quaternary ammonium group of acetylcholine with the charged diazonium group of the photoreactive moiety. Figure 5 shows an overview of the labeling results obtained with different probes tested on the acetylcholine binding site of the nicotinic receptor. The efficiency of DDF as a topographical probe is apparent.

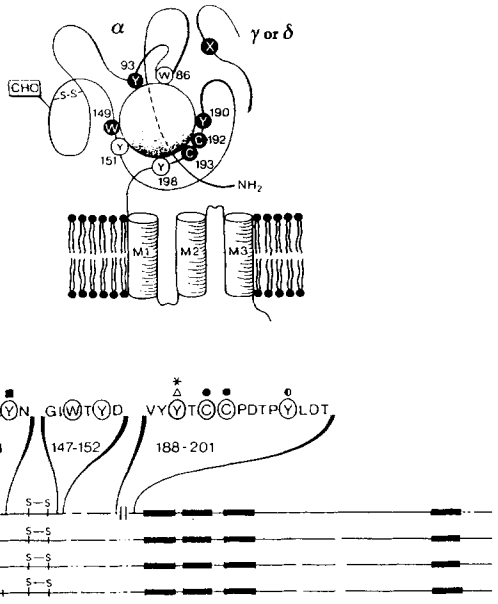

Fig. 5. Amino acids in the cholinergic binding area of the nicotinic acetylcholine receptor from *Torpedo* [157] localized by: chemical affinity labeling with 4-(*N*-maleimido)benzyltrimethylammonium (iodide; MBTA) [154] (●), lophotoxin [155] (△), and acetylcholine isothiocyanate [156] (■); photoaffinity labeling with DDF [90, 106, 107] (○), d-tubocurarine [105] (*), and nicotine [103] (◐).

Extensive labeling of membrane protein domains with hydrophobic probes can be considered an extension of the topographical mapping of a binding site to the lipid–protein interface. Again, an outstanding result was obtained with [^{125}I]TID:[112] 16 different amino acid residues were identified from the M_3 transmembrane segments of the nicotinic acetylcholine receptor, which led to interesting topographical analyses of the membrane components.

6. Site-Directed Labeling and Site-Directed Mutagenesis

Both site-directed labeling and site-directed mutagenesis are designed to investigate functional proteins but in different ways. The first objective in site-directed labeling experiments is to gain as much structural information on ligand binding sites as possible by identifying amino acid residues belonging to these sites. As emphasized in this article, topographical mapping is the most efficient method in this respect. Site-directed mutagenesis addresses the same problem by identifying amino acid residues for which mutations alter the functional properties of the

biological receptor. The evaluation of this change in function is used to interpret the structure–function relationship. In contrast, the functional properties are totally lost during site-directed labeling experiments. Mutational analyses of the amino acid residues identified by labeling experiments represent an evident link between the two methods. It is clear that site-directed mutagenesis requires structural information. Ideally, X-ray data, in particular for protein–ligand complexes, are available. Another way to identify sites that might determine functional properties is to find sequence alignments within protein families.[158] The aim of the search for sequence alignments, apart from implications on evolution, is to locate the conserved regions that might be essential for function and to identify more precisely the highly conserved amino acid residues. This method has become particularly attractive for recently cloned and sequenced membrane receptors,[159] for which structural determinations of sufficient resolution are still lacking. An enormous amount of information has been and will be generated by site-directed mutagenesis on these receptors.[160] However, it is clear that many of the mutations that induce functional alterations do not result from direct changes in interactions within the binding site. Many examples in the literature refer to somatic mutations which induce long-range effects on ligand binding properties as proven by X-ray data.[161–164] Finally, the lipid–protein interface, which might play an important role in the regulation of allosteric transitions of membrane receptors,[165, 166] cannot be probed by classical mutation and requires adapted photochemical labeling experiments.[49a] In summary, both methods have their own advantages and drawbacks; ideally one would like to support data obtained from mutagenesis studies with biochemical techniques and vice versa.

7. Future Trends in Photoaffinity Labeling

7.1. Photoaffinity Labeling of Recombinant Receptors

Photoaffinity labeling of recombinant receptors is the ideal answer to a series of issues raised recently by molecular biologists. In particular, molecular heterogeneity of a series of receptors has been demonstrated by the isolation of genes coding for many isoforms, especially in the neurobiological field.[167] This heterogeneity leads to the presence of several receptor subtypes having a high degree of homology within an organ; the complexity correspondingly increases when heterooligomeric receptors are considered.[168, 169] Recombinant receptors, which are expressed in cell lines not normally expressing this receptor following transfection with the cDNAs encoding the chosen receptor subunits, overcome the heterogeneity problem. The legitimate question of the physiological relevance of such expressed receptors is not a major drawback for photoaffinity labeling experiments as long as the functional properties, in particular the ligand binding properties, are retained. Photoaffinity labeling studies on such recombinant receptors[170, 171] were first achieved to establish molecular identity with the native receptors, emphasizing the relevance of such biological material. A photoaffinity labeling study on several recombinant *N*-methyl-D-aspartic acid (NMDA) receptors was described recently by using a highly specific [^{125}I]iodoarylazido-NMDA antagonist.[172] Different labeling patterns revealed by autoradiography on sodium dodecylsulfate gels were obtained according to the subunit composition, underscoring the value of such an approach in analyzing structural heterogeneity. The successful photoaffinity labeling of a cloned purinergic receptor was also reported[173] and raised the question of the existence of specific binding sites for ATP and UTP on this receptor.

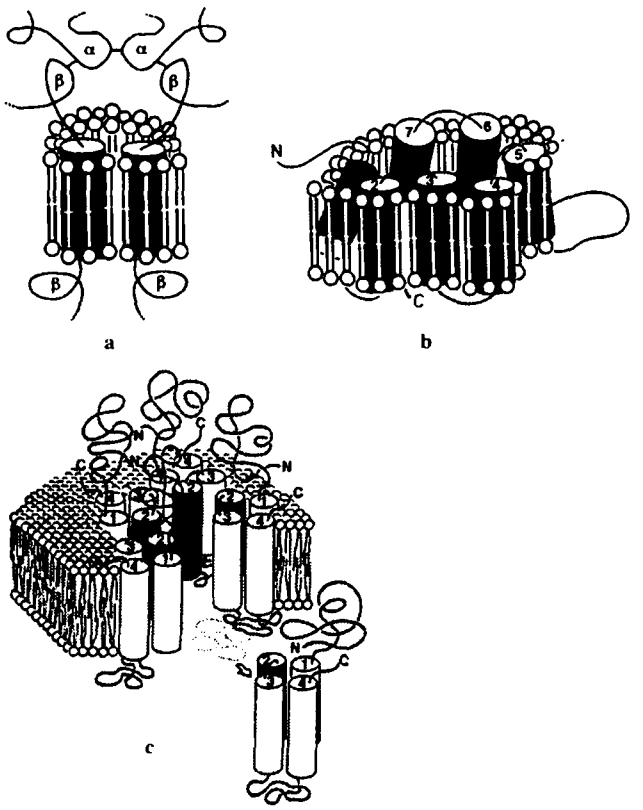
The step following photoaffinity labeling on recombinant receptors is the identification of the binding sites on the polypeptides. As mentioned in Sections 4 and 5, amino acid identification is best achieved when efficient probes (topographical probes) are used on purified material available in appreciable quantities. This in turn requires an efficient system of expression for the recombinant receptors of interest. The use of insect cells infected with baculovirus proved to be very efficient for the overexpression of a number of receptors,[174] and it is certain that this and/or other efficient expression systems will be used frequently in the future.

7.2. Photoaffinity Labeling and Signal Transduction Mechanisms

There are two basic types of receptor transducing systems: intracellular receptors which upon activation by their effector interact directly with DNA and alter the genetic program of a cell, and membrane-bound receptors which are generally activated at the cell surface by the appropriate hormone or neurotransmitter and transmit their signal inside the cell. These membrane-bound receptors have been divided into three main classes, each having several subtypes.[152] Typical structural features of selected receptors in these three classes are shown in Figure 6: a) the ligand-stimulated tyrosine kinases or guanylate cyclases which are monomers or dimers of polypeptides having a single hydrophobic domain, b) the G-protein linked receptors formed by a polypeptide which typically has seven hydrophobic transmembrane domains, and c) the transmitter-gated ion channels, which form (hetero)oligomeric complexes and for which four postulated transmembrane helices on each polypeptide are predicted to span the membrane.

How can photoaffinity labeling be used to investigate the function of such biological receptors? As already mentioned, a direct link can be made by site-directed mutagenesis of the amino acid residues that were previously identified by photoaffinity labeling and that are directly involved in ligand recognition. Such mutations should induce changes in the ligand binding properties, depending on the nature of the mutation. Another way to relate structural elements and functions is to use photoaffinity probes to visualize receptor sites in different conformations. As mentioned earlier, topographical probes are appropriate tools for such studies. The cholinergic antagonist DDF was used to probe the structural changes that occur upon desensitization of the acetycholine receptor; the labeled amino acid residues were identified in both resting and desensitized states of the receptor.[175] Similarly, TID[52] has been used to probe channel-forming regions of the nicotinic receptor of *Torpedo* in resting and desensitized conformations.

The interconversion of the resting state to the desensitized state proceeds via a transitory active state, in which the ionic



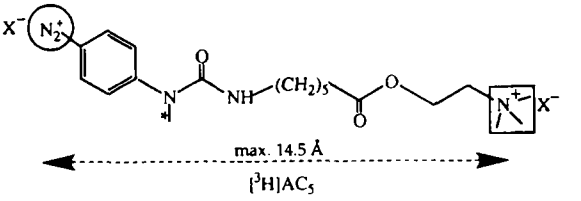


Fig. 6. Three classes of membrane-bound receptors: a) polypeptides having a single hydrophobic transmembrane domain (ligand-stimulated tyrosine kinases and guanylate cyclases); b) peptides with seven hydrophobic transmembrane domains (G-protein linked receptors); c) peptides with four hydrophobic transmembrane domains (transmitter-gated ion channels).

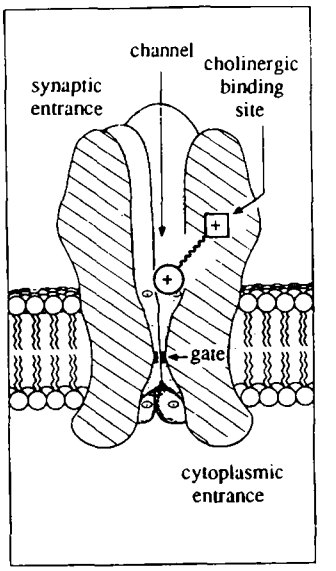

Fig. 7. The photoactivatable agonist AC_5 and its hypothetical position in the cholinergic binding side of the nicotinic acetylcholine receptor.

channel remains open for a short (≈ 10 ms) period of time. This rapid transduction signaling process,[176, 177] triggered by the binding of an agonist, was analyzed by trapping the transient conformation and requires adapted analytical methods. In particular, it requires rapid mixing techniques (stopped-flow equipment) and appropriate photochemical procedures (time-resolved flash photolysis).[178] Such experiments require the design and the synthesis of photoactivatable agonists having the photochemical properties of a topographical probe to ensure that the light-induced coupling reactions are faster than the conformational transitions of the receptor. The analysis of these time-dependent labeling reactions on the receptor should allow characterization of the structural transitions that occur during a physiological process. For the nicotinic acetylcholine receptor, we have developed different photosensitive agonists to probe the conformational transitions of this heterooligomeric receptor upon agonist binding.[179, 180] The analysis can be conducted at a macroscopic level by probing the entire protein complex with an agonist bearing a remote photoactivatable moiety. In the photosensitive compound AC_5 (Fig. 7), for example, the ammonium group of the choline moiety is separated from the photosensitive diazonium by up to 14.5 Å in an extended conformation. The flexible spacer confers sufficient mobility on this ligand such that all the subunits of the pentameric nicotinic acetylcholine receptor complex can be proved. Successive transitions of the receptor complex from the resting state to the desensitized state could be visualized by use of the radiolabeled probe $[^3H]AC_5$. The radioactivity incorporated into the different subunits of the receptor under two different sets of experimental conditions (with flash photolysis after 30 ms preincubation and at equilibrium) were determined[180] (Fig. 8). In similar analysis at a molecular level a photoactivatable agonist of appropriate size would be used to probe the agonist binding site directly. In this investigation the labeled amino acid residues would be identified after photolytic experiments, again after appropriate time-controlled agonist mixing and subsequent flash photolysis. To our knowledge, such a study has not yet been conducted. It should allow the identification of amino acid residues specifically involved in conformational transitions of receptors and might provide key structural information for the understanding of receptor functioning.

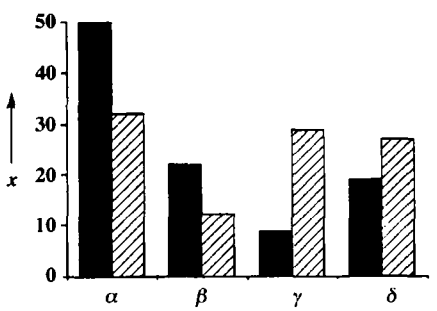

Fig. 8. Labeling pattern obtained by photoaffinity labeling with $[^3H]AC_5$ on all four subunits α-δ of the nicotinic acetylcholine receptor in two conformational states, the mainly resting state (preincubation time 30 ms) (■) and the desensitized state) (▨) [180]. x = relative amount of specific incorporated radioactivity.

8. Summary and Outlook

Although over thirty years old, photoaffinity labeling is a useful and reliable method for the structural investigation of receptor binding sites. It remains a classical research area for chemists who design and synthesize new photoactivatable reagents; biochemists and biologists then use these reagents to identify and characterize the target receptors. In the present article we did not try to review or update these aspects; Bayley's monograph[5a] is still the best reference work. Instead, we emphasized the importance of the identification of amino acid residues belonging to the target binding sites which might lead to further insight into ligand–receptor interactions. We presented an update on the different amino acid residues that have been identified on the different biological receptors by means of photoaffinity labeling, and emphasized mainly the photochemical probes that permitted extensive labeling of a binding site. Finally, we discussed new perspectives for photoaffinity labeling. The possibility of studying ligand–receptor interactions in a dynamic fashion, in particular, makes this method even more attractive and opens up a new field of investigation, the study of rapid physiological events.

Photoaffinity labeling remains, however, a labor-intensive method, from the radiosynthesis of the probes to the sequencing of the receptor peptides. In contrast, site-directed mutagenesis can usually be carried out more rapidly. In this last case, much information can be obtained on the subsequent functional alterations of these mutations. However, in the absence of appropriate structural information, great care should be taken to avoid hasty interpretation of such results in a direct structure–function relationship. Photoaffinity labeling therefore remains a reliable method which should be considered complementary to rather than in competition with site-directed mutagenesis.

Many of the results reported here were obtained during the last decade by collaborators from our laboratory; we are very grateful to all of them. The authors thank Drs. M. Hibert and B. Winsor for critical reading of the manuscript.

Sulfuric Acid from Sulfur Trioxide and Water—A Surprisingly Complex Reaction**

Ralf Steudel*

Sulfuric acid is not only one of the longest known and utilized chemicals but also one of the most important compounds of all; the annual worldwide production varied in the last four years between 135 and 152 million tons depending on the economic situation.[1] Under these circumstances it is surprising that the structure of the free H_2SO_4 molecule was experimentally determined only in 1981: microwave spectroscopy of gaseous H_2SO_4[2] showed that the molecule has C_2 symmetry; the two hydrogen atoms are situated *anti* to one another (Fig. 1). Previously, a somewhat more symmetric conformation with the hydrogens in *trans* positions (symmetry C_{2v}) had been assumed since the vibrational spectra of H_2SO_4 vapor had been assigned in this point group. In the meantime the C_2 conformation of H_2SO_4 has been confirmed as the most stable structure by various ab initio MO calculations.[3–6] These findings demonstrate once more that the structure of highest symmetry is not always the most stable one, as is often claimed.

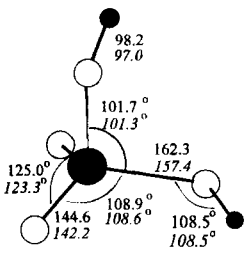

Fig. 1. Structure of the H_2SO_4 molecule in the vapor phase (bond lengths in pm). The geometrical parameters were obtained by ab initio MO calculations [4]; values in italics from microwave spectroscopy [2].

Industrially, sulfuric acid is produced from sulfur trioxide and water. However, the direct reaction of these reagents is not practical for several reasons. First, reaction (a) is highly exothermic, which results in high temperatures and thereby leads to problems with corrosion. Second, the very hygroscopic sulfuric acid molecules formed would react with water vapor to give a mist of $H_2SO_4 \cdot n H_2O$ droplets which are difficult to precipitate. Therefore, the gas prepared by the contact process and containing SO_3 as well as S_3O_9 is washed with concentrated sulfuric acid (98%) resulting in polysulfuric acids; these are then hydrolyzed by water[7] [Eqs. (b)–(e)].

$$SO_3(g) + H_2O(g) \longrightarrow H_2SO_4(g) \quad \Delta H_6^\circ = -92\ kJ\,mol^{-1} \qquad (a)$$

$$3\,SO_3 \rightleftharpoons S_3O_9 \qquad (b)$$

$$SO_3 + H_2SO_4 \rightleftharpoons H_2S_2O_7 \qquad (c)$$

$$S_3O_9 + H_2SO_4 \rightleftharpoons H_2S_4O_{13} \qquad (d)$$

$$H_2O + H_2S_2O_7 \rightleftharpoons 2\,H_2SO_4 \qquad (e)$$

Nevertheless, the simple reaction according to Equation (a) is also of considerable interest, for example, in context with the formation of sulfuric acid in the earth's atmosphere, where H_2SO_4 mainly results from SO_2. To a large extent the latter is of anthropogenic origin, resulting in the phenomenon of acid rain in certain regions of the northern hemisphere. However, as recent results show, the pathway from SO_2 to H_2SO_4 is rather complex, although very interesting. In the atmosphere SO_2 is mainly oxidized by $OH^\bullet$ radicals which are generated photochemically from electronically excited oxygen atoms and water[8] [Eqs. (f)–(h)]. The resulting $HOSO_2^\bullet$ radicals react rapidly and exothermically with dioxygen to give SO_3[9] [Eq. (i)]

$$O_3 \xrightarrow{h\nu} O_2 + O(^1D) \qquad (f)$$

$$O(^1D) + H_2O \longrightarrow 2\,OH^\bullet \qquad (g)$$

$$OH^\bullet + SO_2\,(+\,M) \longrightarrow HOSO_2^\bullet\,(+\,M) \qquad (h)$$

$$HOSO_2^\bullet + O_2 \longrightarrow HO_2^\bullet + SO_3 \qquad (i)$$

(M = collision partner). Since reaction (h) is slower than reaction (i), it is rate determining. The $HO_2^\bullet$ radicals react with NO to give NO_2 and $OH^\bullet$ thus regenerating the latter.

Because of the low SO_3 partial pressure in the atmosphere the equilibrium (b) is of no importance. It therefore may seem that SO_3 and H_2O can simply combine according to Equation (a) to give H_2SO_4. However, this reaction occurs in several steps and only under certain conditions. Initially, the Lewis acid SO_3 and the Lewis base H_2O react, analogously to other reactions of SO_3 with bases, to give an adduct $SO_3 \cdot H_2O$ [Eq. (j)]. This adduct

$$H_2O + SO_3 \rightleftharpoons \overset{(+)}{H_2O}\text{–}\overset{(-)}{SO_3} \qquad (j)$$

was first detected in matrix isolation experiments by vibrational spectroscopy.[10, 11] The spectra showed that the product has a H_2O-SO_3 bond rather than a hydrogen-bonded structure, $HOH\cdots OSO_2$. A precise structural characterization was achieved by high-level ab initio MO calculations (Fig. 2).[3-5] The most accurate of these calculations showed the SO_3 group slightly pyramidalized; the "intermolecular" S–O bond length

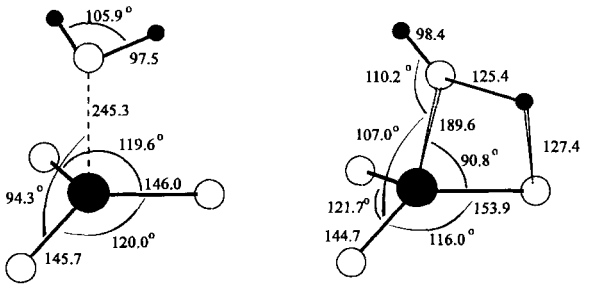

Fig. 2. Left: Structure of the adduct $H_2O\cdot SO_3$ according to ab initio MO calculations (distances in pm). The two hydrogen atoms are almost eclipsed by two oxygen atoms of SO_3 (overall symmetry C_s). The intermolecular H···O distance is larger than the intermolecular S···O distance. Therefore, the proton migration requires a considerable activation energy [4]. Right: Transition state of the reaction $H_2O\cdot SO_3 \rightarrow H_2SO_4$ according to ab initio MO calculations [4].

between the two components is 254 pm.[4] Surprisingly, the hydrogen atoms have no close contacts to the oxygen atoms of the SO_3 group but point slightly in the oposite direction; the angle between the two molecular planes is 22°.[4] Very recently the rotational spectrum of $H_2O\cdot SO_3$ was measured by FT microwave spectroscopy[12] but only a few molecular parameters could be determined. Assuming that d_{OH} and α_{HOH} have the same values as in free H_2O molecules, the "intermolecular" S–O bond length was determined as 243.2(3) pm. The SO_3 fragment is in fact slightly pyramidal; the angle between the two molecular planes is 13°. The torsional angle around the "intermolecular" S–O bond could not be determined.[12]

Previously it had been assumed that $H_2O\cdot SO_3$ can isomerize to H_2SO_4 by a simple proton migration; however, in 1985 it was already demonstrated by MO calculations that this isomerization requires a rather large activation energy.[3] Very recent ab initio MO calculations,[4] performed at the very high level MP4SDQ/6-311+G(2df,p)//RMP2(fu)/6-31+G* (taking the zero point energy calculated at level RMP2(fu)/6-31G* into account) yielded an activation energy of 114 kJ mol^{-1} for the reaction $H_2O\cdot SO_3 \rightarrow H_2SO_4$ at 0 K. This energy has to be compared with the reaction enthalpy of reaction (j) which is only -33 kJ mol^{-1}. Therefore, it has to be concluded that any activation of $H_2O\cdot SO_3$ would result in dissociation rather than isomerization. In other words, the formation of H_2SO_4 by this route is impossible! If the thermal energy at 25 °C is taken into account the free reaction enthalpy for reaction (j) is found to be $\Delta G^0_{298} = 0$ kJ mol^{-1} (because of the negative reaction entropy), from which the equilibrium constant $K = \exp(-\Delta G^0_{298}/RT) = 1$ is obtained. The free activation enthalpy $\Delta G^{\neq}_{298}$ of the isomerization $H_2O\cdot SO_3 \rightarrow H_2SO_4$ is 119.6 kJ mol^{-1}.[4]

This picture changes dramatically if a second water molecule is added. In the vapor phase H_2O is in equilibrium with its dimer, the structure of which is well known [Eq. (k)]. There are now two possibilities: either H_2O can react with $H_2O\cdot SO_3$ or

$$2H_2O \rightleftharpoons (H_2O)_2 \qquad (k)$$

$(H_2O)_2$ attacks SO_3 directly. In both cases this results in the formation of the adduct $(H_2O)_2\cdot SO_3$, the structure of which has been determined by ab initio methods (Fig. 3 left).[5] This structure indicates that a proton migration should be much easier since the $HOH\cdots OSO_2$ distance of 210.8 pm is considerably smaller than in the case of $H_2O\cdot SO_3$ (> 250 pm). However, the formation of H_2SO_4 from $(H_2O)_2\cdot SO_3$ requires the synchronized migration of *two* protons in the corresponding hydrogen bonds. The transition state structure (Fig. 3 right) is character-

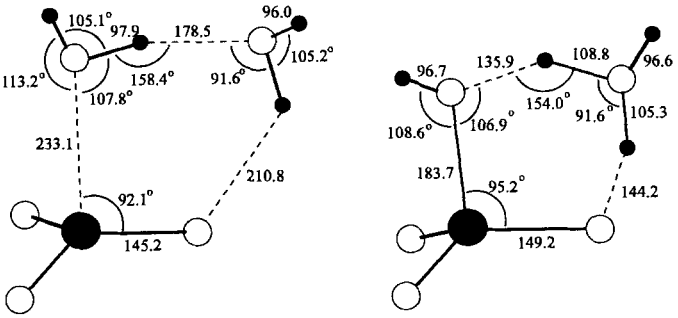

Fig. 3. Left: Structure of the adduct from SO_3 and $(H_2O)_2$ according to ab initio MO calculations (distances in pm) [5]. The intermolecular S···O distance (233.1 pm) is smaller than that in $SO_3\cdot H_2O$ (245.3 pm). Right: Transition state of the isomerization $(H_2O)_2\cdot SO_3 \rightarrow H_2SO_4\cdot H_2O$. The two protons in the almost linear hydrogen bonds move synchroneously and clockwise towards their new bonding partners [5]. The structure may be interpreted as a cyclic ion pair, $H_3O^+HSO_4^-$. The final product $H_2O\cdot H_2SO_4$ is not an ion pair.

ized by a six-membered ring; this lies about 96 kJ mol^{-1} higher in energy than the adduct $(H_2O)_2\cdot SO_3$, the formation of which from $2H_2O$ and SO_3 is exothermic by 110 kJ mol^{-1}. In other words, in this case the activation energy is *smaller* than the dissociation energy, and the isomerization $H_2O\cdot SO_3 \rightarrow (H_2O)\cdot H_2SO_4$ may proceed without problems. The energy profiles of reactions (a) and (l) are shown in Figure 4.

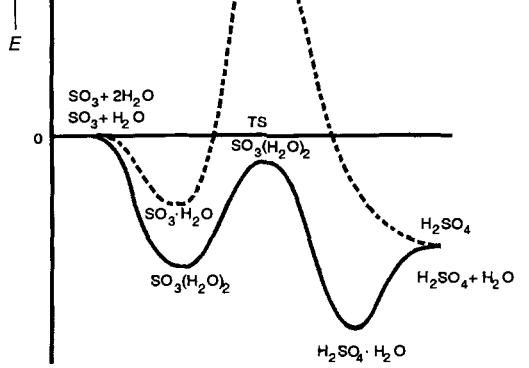

Fig. 4. Energy profiles for the reactions of SO_3 with H_2O via $H_2O\cdot SO_3$ to H_2SO_4 and of SO_3 with $(H_2O)_2$ via $(H_2O)_2SO_3$ to $H_2O\cdot H_2SO_4$. The x axis is the reaction coordinate; TS = transition state.

Recent kinetic measurements[13] support the idea of a second-order reaction with respect to H_2O [Eq. (l)]. Such measurements are all but trivial, since wall reactions have to be suppressed.

$$2H_2O + SO_3 \longrightarrow H_2SO_4 + H_2O \quad (l)$$

Using a reactor with turbulent flow, designed to minimize wall reactions, it could be demonstrated that SO_3 on mixing with water vapor at 22 °C disappears in a reaction of order 2.04 with respect to the H_2O concentration. Reaction (l) proceeds in two steps: dimerization of H_2O according to Equation (k) and reaction of the dimer with SO_3 to give H_2SO_4 and H_2O. Because of the slightly exothermic pre-equilibrium (k), the rate of reaction (l) increases with decreasing temperature.[13] The concentration of $(H_2O)_2$ in the atmosphere has been estimated to be approximately 10^{14} cm^{-3} at ground level and approximately $10^4 cm^{-3}$ at an altitude of 40 km. These concentrations are sufficient to allow the formation of significant amounts of H_2SO_4 by reaction (l).[13] It should however be pointed out that about 50% of the atmospheric SO_2 is oxidized as an aqueous solution, that is dissolved in the droplets of clouds, rather than in a homogeneous gas phase reaction. Suitable oxidants for the dissolved SO_2 are ozone and hydrogen peroxide, but in addition peroxoacetic acid, methyl hydroperoxide, and peroxoacetylnitrate are discussed. The relative importance of these reagents depends on pH and temperature.[8]

Besides SO_2 tremendous amounts of carbonylsulfide (COS) and dimethylsulfide (DMS) are released into the atmosphere. DMS is of biological origin, produced mainly by marine phytoplankton, and together with its oxidation products and COS it yields the "background" of sulfur compounds in the atmosphere. The oxidative degradation of DMS is complex but among its products also yields SO_2 as in the case of COS.[14]

Finally, it should be mentioned that the sulfuric acid formed in the atmosphere causes a variety of effects. H_2SO_4 molecules attract water molecules and form droplets of less than 1 μm diameter (the size depends on the humidity). These droplets absorb atmospheric ammonia and form what is called a liquid "sulfate aerosol". This aerosol not only reduces the visibility but also increases the earth's albedo. As a consequence, the reflection of sunlight is enhanced and it is most probably this effect that partly compensates the global warming resulting from the greenhouse effect in industrialized areas.[15, 16] Approximately 90% of the anthropogenic SO_2 emissions occur in the northern hemisphere. The half-lifes of SO_2 and H_2SO_4 in the atmosphere are only a few days. Therefore, these compounds are not transported to the southern hemisphere, in contrast to CO_2, COS, CH_4, N_2O, and fluorochloro hydrocarbons. These facts possibly explain why most of the global warming has been observed in the southern hemisphere although most of the air pollution is generated in the northern hemisphere.[15]

As acid rain, H_2SO_4 causes well-known damage, but at the same time serves as a nutrient for plants which depend on the availability of sulfate ions for the synthesis of sulfur-containing amino acids. There are good reasons to demand a rigorous reduction of SO_2 emissions; however, this will result in an increased need for sulfur-containing fertilizers for sulfur-deficient farm land.

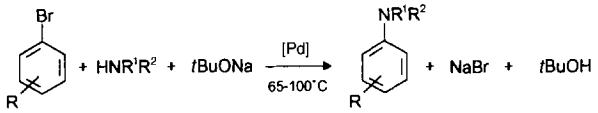
Palladium-Catalyzed Amination of Aryl Halides—Catalysts on New Routes to Known Targets

Matthias Beller*

"The discovery of truely *new* reactions is likely to be limited to the realm of transition-metal organic chemistry, which will almost certainly provide us with additional "miracle reagents" in the years to come", was predicted by D. Seebach in 1990.[1] No other area of classic synthetic chemistry today still offers such innovative possibilities as metal-catalyzed processes. Transition metal catalyzed reactions are becoming increasingly more significant not only for the synthesis of complex building blocks, but also for structurally simpler, industrially important intermediates. Since the inception of the Wacker–Hoechst oxidation[2] and the Heck reaction,[3] palladium-catalyzed processes, in particular, have aroused the interests both of the synthetic chemist in the laboratory and also of the industrial chemist. Based on the almost unique range of catalytic activity of palladium complexes, whose use however is often limited by low selectivities and deactivations during the reactions, a multitude of palladium-supported syntheses were discovered or developed further in the the last few years.[4] So far, the research has focussed on methods for C–C coupling. Because of the significance of unsymmetrically substituted ethers and amines in organic synthesis, the transferability of catalysis by palladium complexes of C–C couplings to the equally important C–O and C–N couplings are of general interest.

Against this background new methodic developments for hetero-Heck-reactions by Hartwig et al. and Buchwald et al. are noteworthy,[5] the simple, palladium-catalyzed aminations of aryl bromides to give arylamines with aminostannanes[6] described in 1994 (Scheme 1).

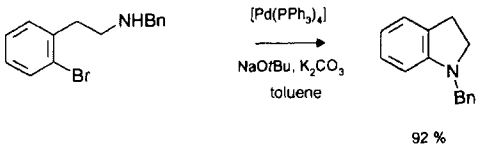


Scheme 1. [Pd] = $[PdCl_2(P(o\text{-tolyl})_3)_2]$. Selected substituents: R = 4-$CO_2C_2H_5$, 4-$(CH_3)_2N$, 3-OCH_3, 3-CH_3; R^1 = $C_6H_5CH_2$, $C_{18}H_{37}$, C_6H_5; R^2 = H, CH_3, $CH_2CH_2C_6H_5$.

Palladium(0) or palladium(II) compounds are used as catalyst precursors in the presence of tri-*o*-tolylphosphane as ligand. According to investigations by Hartwig et al. the actual active species seems to be a palladium(0)bis(tri-*o*-tolylphosphane) complex, which in the catalytic cycle initially inserts oxidatively into the aryl–halogen bond. The resulting arylpalladium(II) complex then reacts with the tin amide under transmetalation; this step is postulated to be rate determining. The subsequent reductive elimination leads back to the palladium(0) catalyst. Very recent investigations show that in addition to tri-*o*-tolylphosphane complexes, simpler arylpalladium(II)-bis(triphenylphosphane) complexes can also react with alkali metal amides to form amido complexes, which can be converted by reductive elimination to give arylamines.[7]

By clever coupling of a transamination reaction of tributyl-*N*,*N*-diethylaminostannane with higher boiling amines with Pd catalysis, Buchwald and Guram succeeded in extending the method.[5b] It was shown that secondary aliphatic and aromatic amines react with substituted aryl bromides to afford the corresponding arylamines in good yields. As in the classic Heck reaction, depending on the substitution pattern of the arene, electron acceptor substituents promote the reactivity of the aryl bromide.

The use of stoichiometric amounts of organo tin compounds is the main disadvantage of this method both for ecological reasons and with regard to practicability. Thus, from an industrial point of view the aim was to replace the tin amides by simpler amino sources, ideally the amines themselves.[8] Independently, Buchwald et al.[9] and Hartwig et al.[10] reported the first catalytic aminations of aryl bromides with free amines. The palladium-catalyzed reactions occur in the presence of stoichiometric amounts of a sterically hindered base such as NaO*t*Bu in toluene or tetrahydrofuran at temperatures of 65–100 °C (Scheme 2).



Scheme 2. [Pd] = $[PdCl_2(P(o\text{-tolyl})_3)_2]$. Selected substituents: R = 4-C_4H_9, 4-CF_3, 4-C_6H_5, 4-$(CH_3)_2N$; R^1 = C_6H_5, C_6H_{13}; R^2 = H, CH_3; R^1–R^2 = $H_2C(CH_2)_3CH_2$, $H_2CCH_2N(CH_3)CH_2CH_2$.

The arylamines are generally formed in good yields (67–89%). Dehalogenation products are the only by-products that occur, which probably arise from base-induced β-hydride elimination of the amido arylpalladium complex and subsequent reduction. The base employed has a decisive influence on the course of the reaction. In the amination of 1-bromo-4-*n*-butylbenzene with free amines in the presence of silyl amides as base—in contrast to the coupling with tin amides—the rate-determining step in the catalytic cycle is the oxidative addition of bis(tri-*o*-tolylphosphane)palladium(0) to the aryl halide. However, when LiO*t*Bu is used as base, the formation and reductive elimination of the amido arylpalladium complex is decisive for the rate of the reaction. In the presence of NaO*t*Bu both reaction steps seem to take place at similar rates.[10]

Extending the intermolecular coupling, dihydroindoles (Scheme 3), dihydroquinolines, and other N-heterocycles were successfully synthesized by simple intramolecular trapping reactions, starting from alkylamino substituted aryl bromides.[9] Intramolecular amination can be achieved in the presence of tetrakis(triphenylphosphane)palladium as catalyst and stoi-

Scheme 3. Intramolecular variant of the palladium-catalyzed amination of aryl halides.

chiometric amounts of base in toluene. The best results are obtained with mixtures of NaO*t*Bu and potassium carbonate.

The quality of the catalysts applied with turnover numbers of up to 200 and turnover frequencies of up to 100 h^{-1} does not yet satisfy industrial demands. Nevertheless the publications by Buchwald and Hartwig are noteworthy in that they demonstrate the general applicability of the Heck reaction and its Stille and Suzuki variants to C–N couplings and open up new possibilites for Tandem processes. Thus, they show the way to further catalytic carbon–heteroatom couplings.[11] Furthermore, it becomes evident that there is a need for alternative synthetic methods also for apparently structurally trivial molecules such as arylamines. The future will show that in this respect organometallic chemistry and catalysis offers manifold possibilities.

First-Ever Per(onio) Substitution of Benzene: The Role of the Counterion

Robert Weiss,* Bernd Pomrehn, Frank Hampel, and Walter Bauer

In earlier studies we have shown that the transition from neutral to cationic sets of substituents by poly(onio) substitution (POS) with main group element derivatives and nonaromatic organic π systems generally leads to a marked increase in Lewis acidity and electron affinity.[1–6] At the same time, novel reaction pathways are observed for redox and substitution reactions with appropriate reagents.[5, 6] This is attributed primarily to the electrostatic field effect (pole effect)[7] of the cationic substituents. Since electrostatic effects are not, in principle, subject to any saturation effect, but are instead additive in nature, it is of particular interest to introduce the maximum number of onio substituents structurally possible at a basic core unit. In this context, we have now turned our attention to the example of an aromatic π system and report herein on the synthesis, structure, and some properties of the first hexakis(onio)-substituted benzene derivative.[8]

In 1993 Streitwieser et al. reported on an unsuccessful attempt at synthesizing one such hexacationic substituted benzene derivative.[9] Upon reaction of hexafluorobenzene (**1**) with 4-dimethylaminopyridine (DMAP, **2**), an S_NAr sequence gave the corresponding 1,4-bis(onio)-substituted benzene derivative, which was obtained in 20% yield and structurally characterized. An attempt at synthesizing the corresponding per(onio)-substituted salt starting from **1** and DMAP led, after a reaction time of three and a half months, to a higher substituted product in extremely low yield. This was identified on the basis of spectroscopic data as the corresponding pentakis(onio)-substituted benzene. The last fluorine substituent could not, however, be displaced, even under elevated pressure.

The low reactivity of this bis(onio)-substituted and particularly the pentakis(onio)-substituted benzene is at variance with the expectation that the electrophilicity of π systems should be enhanced with an increase in the number of onio substituents. To explain the results of Streitwieser et al., we assume that contacts between the electrophilic countercation and the liberated fluoride ions lead to inhibition of any further nucleophilic substitution. A number of possibilities may be discussed regarding the nature of these contacts, for example the formation of kinetically stable ion clusters or even the formation of stable Meisenheimer complexes (more likely with higher levels of onio substitution). Exchange of fluoride ion for a more strongly nucleofugic anion should then hold the key to successful per(onio) substitution in the benzene system. This simple approach met with complete success and led to the thermodynamically particularly favorable variant of poly(onio) substitution depicted in Scheme 1.

Scheme 1. Synthesis and hydrolysis of **4**.

The desired per(onio) substitution product **4**, the sole reaction product, was obtained in virtually analytically pure form in 92% yield as a sparingly soluble salt. It is clear that the reaction is greatly facilitated by the combination of the S_NAr substitution sequence with the formation of the extremely stable Si–F bond. We do not rule out an assisting intervention by **3** at a relatively early stage of the substitution sequence. The exclusive formation of **4**, even upon addition of **2** and **3** in a molar ratio of 1:1:1, underlines most explicitly the electrophilic autoactivation of the π system through increasing onio substitution and confirms our interpretation of the results of Streitwieser et al.[9]

Remarkably, **4** can be recrystallized from hot water without decomposition. This allowed us to obtain colorless needles suitable for X-ray structure analysis,[10] the results of which are depicted in Figure 1 (for clarity four of the triflate ions located at a greater distance from the hexacation are omitted).

The following structural features are noteworthy:

- With a torsion angle of 80.0°, the pyridine rings are almost orthogonal to the benzene ring, whereas the corresponding angle in hexaphenylbenzene amounts to about only 65°.[11] MNDO calculations give an average torsion angle of 83° for

the cation in **4**. The bond lengths in the onio substituents attest to a considerable contribution from resonance structure **B** (Scheme 1)—a charge-stabilizing effect generally found for onio systems derived from **2**.[1, 4, 9, 12]

- Whereas four of the six triflate ions occupy peripheral positions relative to the polycation (in the outer region of the pyridinio substituents), the remaining two triflate ions are located directly above and below the plane of the benzene π system. Thus, the two planes through the oxygen atoms in the triflate groups are almost parallel to that of the benzene ring. Clearly, the hexacation is partially neutralized—in the primary sphere, so to speak—by two electrostatically strongly bound counterions, whereas the remaining four counterions form a distinctly more weakly bound secondary anion sphere. The resulting central triple-decker ion cluster is a completely novel structural element. To the best of our knowledge, this positioning of anions relative to an aromatic π system seen here has not been observed previously. The interplanar distance of 3.2 Å here points to purely ionic interactions. Weak bonding contacts between the oxygen centers and the α-hydrogen atoms of the pyridinio substituents are also evident (mean O–H distance 2.2–2.5 Å).

Cyclic voltammetric investigations of **4** yielded one quasi-reversible reduction at -0.80 V and a second, irreversible one at -1.14 V.[13] This corresponds to an increase in redox potential of 2.55 V relative to that of benzene,[14] which, because of the extensive out-of-plane torsion of the pyridinio substituents, must be essentially electrostatic in origin. The poly(onio)-substituted salts 1,3,5-tris(4-dimethylamino-1-pyridinio)benzene tris(trifluoromethanesulfonate) (**6**) and 1,2,3,4,5-pentakis(4-dimethylamino-1-pyridinio)benzene pentakis(trifluoromethanesulfonate) (**7**), which we synthesized in analogy to **4**, exhibit (irreversible) $E_{1/2}$ values of -1.34 and -0.88 V, respectively.[13] Figure 2 shows a plot of the redox potentials of the compounds investigated versus the number of pyridinio substituents.

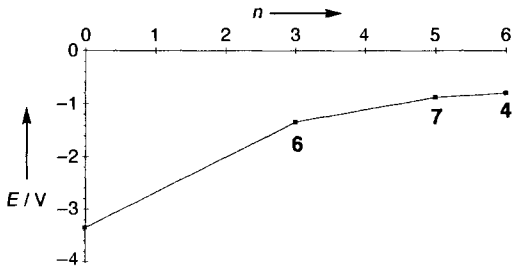

Fig. 2. Dependence of the redox potentials of substituted benzenes on the number n of 4-dimethylaminopyridinio substituents.

It can be seen that the first three onio substituents, arranged alternately, increase the electron affinity of the benzene system much more efficiently than those following. This deviation from the additivity of the substituent effect may be a consequence of the $-$M effect of the pyridinio substituents, which, due to the conformationally restricted conjugation in **4** and **7**, can only be realized for **6**. That the redox potential of **4** lies only slightly above that of **7** can be attributed to an increasingly nonlinear contribution from the dimethylamino groups. The importance of the iminium structure **B** (Scheme 1) increases with increasing electrophilicity of the template such that the positive charge is increasingly shifted to the periphery of the molecule. This hypothesis is supported by the observation that this effect is found only with dimethylaminopyridinio substituents and not with pyridinio substituents.[15, 16]

The ^{13}C NMR spectrum of **4** in solution (CD_3NO_2/CF_3COOD) shows, as expected, only one signal for the benzene ring and one set of signals for the onio substituents. Thus, in solution, (averaged) D_{6h} symmetry can be inferred for the poly(onio) system. In the crystal, on the other hand, **4** is present with a lower degree of symmetry. The asymmetric unit consists of a "half" molecule of **4**, with three carbon atoms of the benzene ring, three onio substituents, and three counterions. Consequently, the ^{13}C CP/MAS solid-state NMR spectrum[17] contains three sets of signals for the cation in **4**. The smallest differences in the δ values are shown by the signals for C2/C6 of the substituents ($\Delta\delta \approx 0.6$). For the carbon atoms of the benzene ring and carbon atoms C3/C5 of the substituents, the difference is larger ($\Delta\delta \approx 2.7$ and 2.5, respectively).

The electrostatic activation of **4** is likewise illustrated by its hydrolysis. Whereas hexafluorobenzene is stable at normal pressure to aqueous sodium hydroxide solution,[18] **4** undergoes hydrolysis within 30 min in refluxing 0.1 N $NaHCO_3$ solution to give the corresponding pentakis-substituted phenolate **5** virtually quantitatively. The analogous introduction of a hydroxyl group under comparably mild conditions is also observed with hexacyanobenzene.[19] Apparently the almost purely electrostatic activation of this reaction through the set of cationic substituents in **4** is as effective as the $-$M activation of the cyano groups in hexacyanobenzene.

The reactions of **4** with reducing agents and nucleophiles are being investigated currently.

Experimental Procedure

4: To a solution of **1** (0.20 mL, 1.73 mmol) in anhydrous CH_3CN (30 mL) under N_2 was added **3** (2.50 mL, 13.8 mmol) and **2** (2.00 g, 16.4 mmol), and the solution was then stirred at reflux. After 7 d the resulting white precipitate was filtered off, washed first with CH_3CN (2 × 5 mL) and then CH_2Cl_2 (3 × 5 mL), and dried under high vacuum for 12 h. Yield: 2.71 g (92.1%). The use of stoichiometric quantities of **2** and **3** afforded significantly lower yields, even after longer reaction times. Single crystals of **4** were obtained by boiling briefly in water followed by slow cooling. Correct C,H,N-analysis; ^{1}H NMR (399.65 MHz, CD_3NO_2/CF_3COOD, 20 °C, TMS): $\delta = 8.21$ (d, ^3J(H,H) = 8.0 Hz, 12H; H-2/H-6), 7.02 (d, ^3J(H,H) = 8.0 Hz, 12H; H-3/H-5), 3.31 (s, 36H; CH_3); ^{13}C NMR (100.4 MHz, CD_3NO_2/CF_3COOD, 20 °C, TMS): $\delta = 157.79$ (s; C4, DMAP), 141.12 (s; C2/C6, DMAP), 140.99 (s, benzene), 121.48 (q, ^1J(C,F) = $-$ 317.0 Hz; CF_3), 111.07 (s; C3/C5, DMAP), 41.66 (s; CH_3); ^{19}F NMR (470.4 MHz, D_2O/HCl, 20 °C, C_6F_6): $\delta = -79.6$ (s; CF_3); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3060w, 3050w, 1650s, 1600m, 1480w, 1440m, 1410w, 1350vw, 1330vw, 1260vs, 1230s, 1150s, 1060vw, 1030s, 810m, 790w, 750vw, 630s.

5: A suspension of **4** (1.00 g, 0.59 mmol) in aqueous $NaHCO_3$ solution (0.1 N, 30 mL) was heated for 30 min at reflux. The solution was then cooled to 5 °C and the resulting pale yellow precipitate filtered off, washed with cold water (1 × 5 mL) followed by CH_2Cl_2 (2 × 5 mL), and then dried under high vacuum for 12 h. Yield: 0.72 g (94.2%). Correct C,H,N-analysis; ^{1}H NMR (400.05 MHz, CD_3CN, 20 °C, TMS): $\delta = 8.25$ (d, ^3J(H,H) = 7.57 Hz, 2H; H-2/H-6), 8.19 (d, ^3J(H,H) = 7.33 Hz, 4H; H-2/H-6), 8.03 (d, ^3J(H,H) = 7.57 Hz, 4H; H-2/H-6), 6.87 (d, ^3J(H,H) = 7.57 Hz, 4H; H-3(H-5), 6.78 (d, ^3J(H,H) = 7.33 Hz, 4H; H-3/H-5), 6.72 (d, ^3J(H,H) = 7.57 Hz, 2H; H-3/H-5), 3.17 s (12H; CH_3), 3.13 s (12H; CH_3), 3.12 s (6H; CH_3); ^{13}C NMR (100.50 MHz, CD_3CN, 20 °C, TMS): $\delta = 164.56$ (s; C1, phenol), 157.51 (s; C4, DMAP), 157.34 (s; C4, DMAP), 157.25 (s; C4, *p*-DMAP), 144.23 (s; C2/C6, *p*-DMAP), 143.86 (s; C2/C6, DMAP), 141.96 (s; C2/C6, DMAP), 137.50 (s; C3/C5, phenol), 132.31 (s; C2/C6, phenol), 121.93 (q, ^1J(C,F) = $-$ 321.4 Hz; CF_3), 113.70 (s; C4, phenol), 109.51 (s; C3/C5, DMAP), 109.48 (s; C3/C5, *p*-DMAP), 108.95 (s; C3/C5, DMAP), 41.09 (s; CH_3), 41.04 (s; *p*-CH_3), 40.87 (s; CH_3); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3050w, 1650vs, 1580m, 1540m, 1440w, 1405m, 1270s, 1220s, 1150s, 1030s, 820w, 750vw, 720vw, 630s.

Compound **5** may be protonated with trifluoromethanesulfonic acid in CH_2Cl_2 to give pentakis(4-dimethylamino-1-pyridinio)phenol pentakis(trifluoromethanesulfonate).

6: To a solution of 1,3,5-trifluorobenzene (0.30 mL, 2.90 mmol) in anhydrous chlorobenzene (20 mL) under N_2 was added **3** (2.00 mL, 11.1 mmol) and **2** (1.60 g, 13.1 mmol), and the solution was then stirred at reflux. After 9 d the resulting white precipitate was filtered off, washed with Et_2O (2 × 5 mL), and then dried under high vacuum for 12 h. Yield 1.06 g (41.1%, unoptimized). Correct C,H,N-analysis; ^{1}H NMR (400.05 MHz, CD_3CN, 20 °C, TMS): $\delta = 8.44$ (d, ^3J(H,H) = 7.93 Hz, 6H; H-2/H-6), 8.01 (s, 3H; C-H, benzene), 7.10 (d, ^3J(H,H) = 7.93 Hz, 6H; H-3/H-5), 3.30 (s, 18H; CH_3); ^{13}C NMR (100.50 MHz, CD_3CN, 20 °C, TMS):

δ = 157.93 (s; C4, DMAP), 144.74 (s; C1/C3/C5, benzene), 141.85 (s; C2/C6, DMAP), 122.05 (q, ^1J(C,F) = − 319.5 Hz; CF_3), 121.17 (s, C2/C4/C6, benzene), 109.18 (s; C3/C5, DMAP), 41.22 (s; CH_3); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3060w, 1650vs, 1640vs, 1605s, 1570s, 1530w, 1450m, 1400m, 1350w, 1260s, 1160s, 1090w, 1030s, 830m, 820m, 730w, 630s.

7: To a solution of pentafluorobenzene (0.10 mL, 0.91 mmol) in anhydrous CH_3CN (20 mL) under N_2 was added **3** (0.95 mL, 5.26 mmol) and **2** (0.800 g, 6.55 mmol), and the solution was then stirred at reflux. After 8 d the reaction mixture was concentrated to dryness and the resulting white solid suspended in CH_2Cl_2 (20 mL), filtered off, washed with CH_2Cl_2 (3 × 5 mL), and then dried under high vacuum for 12 h. Yield 0.808 g (62.1%, unoptimized). Correct C,H,N-analysis; ^{1}H NMR (400.05 MHz, CD_3CN, 20 °C, TMS): δ = 8.65 (s, 1H; benzenel), 8.13 (d, ^3J(H,H) = 7.94 Hz, 4H; H-2/H-6), 8.07 (d, ^3J(H,H) = 8.67 Hz, 2H, H-2/H-6), 8.02 (d, ^3J(H,H) = 8.06 Hz, 4H; H-2/H-6), 7.01 (d, ^3J(H,H) = 7.94 Hz, 4H; H-3/H-5), 6.91 (d, ^3J(H,H) = 8.06 Hz, 4H; H-3/H-5), 6.88 (d, ^3J(H,H) = 8.67 Hz, 2H; H-3/H-5); 3.25 (s, 12H; CH_3), 3.21 (s, 12H; CH_3), 3.20 (s, 6H; CH_3); ^{13}C NMR (100.50 MHz, CD_3CN, 20 °C, TMS): δ = 158.00 (s; C4, DMAP), 157.67 (s; C4, DMAP), 157.63 (s; C4, DMAP), 142.40 (s; C1/C5, benzene), 141.43 (s; C2/C6, DMAP), 140.97 (s; C2/C6, DMAP), 138.31 (s; C3, benzene), 137.96 (s; C2/C4, benzene), 132.88 (s; C6, benzene), 121.83 (q, ^1J(C,F) = − 319.8 Hz; CF_3), 110.65 (s; C3/C5, DMAP), 110.55 (s; C3/C5, DMAP), 109.81 (s; C3/C5, DMAP), 41.44 (s; CH_3), 41.37 (s; CH_3); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3100s, 2980w, 1660s, 1580s, 1510s, 1450s, 1350m, 1270vs, 1170s, 1060m, 1030s, 940m, 830s, 790m, 750m, 740w, 730w, 710w, 630s.

[8] The first hexacationically substituted benzene derivative was reported by R. Breslow et al. (R. Breslow, G. A. Crispino, *Tetrahedron Lett.* **1991**, *32*, 601). The sixfold alkylated hexakis(4-pyridyl)benzene described therein has onio centers in the periphery of the ligands, and therefore cannot be generated, as in our case, by a substitution sequence at the central benzene ring but only by a multistep synthesis. Reduction potentials for this compound have not yet been published.

η^5:η^2 Coordination of a *cyclo*-E_5 Ligand, E = P, As**

Michaela Detzel, Gabriele Friedrich, Otto J. Scherer,* and Gotthelf Wolmershäuser

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

In the extensive literature[1] on ferrocene and its derivatives there is to our knowledge no example in which in addition to η^5 coordination, the η^2-side-on coordination to one of the two parallel five-membered rings has been achieved. In lanthanoid complexes with bent sandwich structures, a (μ-η^5:η^2-C_5H_5) structural unit is found in $[(C_5H_5)_3La]_n$,[2a] a type of coordination which is also discussed in $[Cp^*_2Sm(\mu\text{-}C_5H_5)SmCp^*_2]$.[2b] We have now been able to show that the sandwich complexes **1** (**1a**: E = P;[3] **1b**: E = As[4]), which are iso(valence)electronic and isolobal to ferrocene $FeCp_2$, can be converted to the complexes **4** in which the unusual μ-η^5:η^2-*cyclo*-E_5 coordination (**4a**: E = P; **4b**: E = As) is realized. So far only terminal η^1 coordination of 16 VE complex fragments could be verified both in sandwich complexes with five-membered rings consisting of P(As) and CR building blocks[5a] as well as in **1**.[5b]

Compound **4a** forms brown crystals that can be manipulated in air for short periods, **4b** dark brown crystals that are air and moisture sensitive. They are sparingly soluble in pentane and dissolve well in toluene and dichloromethane. The five P atoms of the *cyclo*-P_5 ligand give rise in the ^{31}P NMR spectrum to an

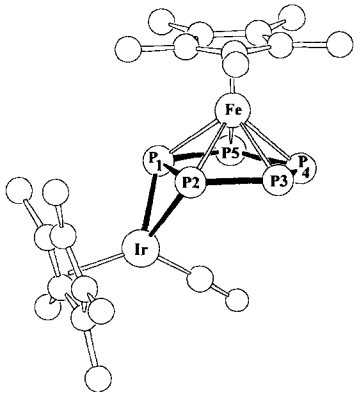

Fig. 1. Crystal structure of **4a**. Selected bond lengths [Å] and angles [°]: P1-P2 2.359(2), P2-P3 2.134(3), P1-P5 2.132(3), P3-P4 2.117(3), P4-P5 2.112(3), Ir-P1 2.375(2), Ir-P2 2.378(2), Fe-P1 2.381(2), Fe-P2 2.399(2), Fe-P3 2.320(2), Fe-P5 2.317(2), Fe-P4 2.380(2), Ir-$Cp^*_{(centroid)}$ 1.94, Fe-$Cp^*_{(centroid)}$ 1.72; P1-Ir-P2 59.50(6), P2-P1-P5 104.97 (10), P1-P2-P3 105.25(10), P2-P3-P4 109.15(12), P3-P4-P5 110.31(11), P1-P5-P4 109.54(11).

ABB′XX′ spin system,[6] whose ^1J(P,P) coupling constants for the four short P–P bonds (−391 to −433 Hz) lie in the expected range.[7] In contrast, a ^1J(P,P) coupling constant of −211 Hz is found for the significantly longer P1–P2 bond (Fig. 1); however, this value is considerably larger than the ^2J(P,P) value of −41 Hz in the IrP_5 six-membered ring (P···P 2.64 Å)[8] of the complex **5**.

$[\{Cp^*Fe\}\{Cp^*_2(CO)_2\overline{Ir_2}\}\{\overline{P_5}Ir(CO)Cp^*\}\{Ir(CO)Cp^*\}]$ **5**

Among the selected MS data[6] the fragments $[Cp^*FeE_5MCp^*]^+$ and $[Cp^*FeE_3MCp^*]^+$ (E = P, M = Ir; E = As, M = Rh), which give rise to intense signals, are particularly noteworthy, since they could possibly be assigned to 31VE and 29VE triple-decker cations, respectively.

The crystal structure analyses[9] reveal **4a** (Fig. 1) and **4b** (Fig. 2) to be sandwich complexes with μ-η^5:η^2 coordination of

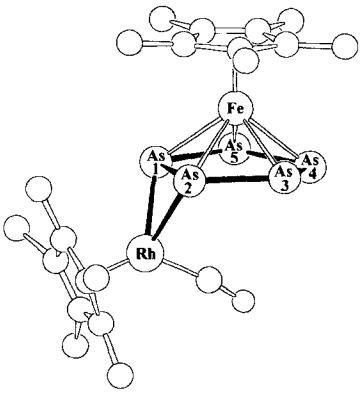

Fig. 2. Crystal structure of **4b**. Selected bond lengths [Å] and angles [°]: As1-As2 2.502(2), As2-As3 2.356(2), As1-As5 2.345(2), As3-As4 2.317(2), As4-As5 2.315(2), Rh-As1 2.486(2), Rh-As2 2.486(2), Fe-As1 2.550(2), Fe-As2 2.558(2), Fe-As3 2.447(2), Fe-As5 2.463(2), Fe-As4 2.528(2), Rh-$Cp^*_{(centroid)}$ 1.91, Fe-$Cp^*_{(centroid)}$ 1.71; As1-Rh-As2 60.44(5), As2-As1-As5 106.57(7), As1-As2-As3 105.04(6), As2-As3-As4 109.30(7), As3-As4-As5 109-54(8), As1-As5-As4 108.63 (7).

the *cyclo*-E_5 ligand (E = P, As). As expected, the additional η^2-side-on coordination of a 16VE Cp*(CO)M fragment (M = Ir, Rh) to the starting materials **1a** and **1b** leads to a significant lengthening of the respective E–E bonds. However, the P1–P2 distance (2.36 Å) is considerably shorter than the 2.46 Å found for the side-on coordinated intact P_4 edge in the $[RhCl(\eta^2\text{-}P_4)(PPh_3)_2]$ complex.[10] P–P bonds of comparable length are present in $P_2(BR)_2$ (2.35 Å)[11a] and $P_2(SiR_2)_2$ (2.34 Å),[11b] molecules with butterfly skeletons (R = 2,2,6,6-tetramethylpiperidino, mesityl); a structural subunit, which is also formed by the atoms Fe,P1,P2,Ir in **4a**. In **4b** the As1–As2 distance (2.50 Å) is likewise longer than the other As–As bonds; however, for example, in realgar, As_4S_4 (2.59 Å)[12a] and in $As_2(SiMestBu)_2$ (2.60 Å)[12b] the As–As bonds are even longer. The average values of 2.12 and 2.33 Å found for the remaining four P–P and As–As distances of the respective five-membered rings can be divided into two pairs (Figs. 1 and 2). These values do not differ or scarcely differ from those in the starting material **1a** (2.12 Å)[13] and $[(C_5Me_4Et)Fe(As_5)]$ (2.32 Å).[4] In **4a** and **4b** Ir,P1,P2 and Rh,As1,As2, respectively, form an almost equilateral triangle. P4 and As4 are tilted below the plane of the ring by 8.6 and 6°, respectively, which, as expected, leads to a slight reduction in the sum of the angles in the *cyclo*-P_5 (539.2°) and the *cyclo*-As_5 (539.0°) unit. The plane of the four remaining P and As atoms is arranged almost parallel (deviation: **4a** 0.7°, **4b** 2.1°) to the plane of five-membered ring of the Fe-Cp* ligand. The dihedral angles of the Fe,P1,P2,Ir and Fe,As1,As2,Rh "butterfly" structural subunits are 158.5 and 152°, respectively.

In the synthesis of **4a** the isomer **6a** is formed as a by-product. Unlike **4a**, **4b** can isomerize to give **6b** (see Experimental Procedure). The M(CO)Cp* ligand is not η^2 (as in **4**) but η^1 bound in the complexes **6**.

$[Cp^*Fe(\mu\text{-}\eta^{5:1}\text{-}E_5)\{M(CO)Cp^*\}]$ **6**

6a: E = P, M = Ir; **6b**: E = As, M = Rh

Experimental Procedure

Improved synthetic method for **1a** [3]: $[Cp^*Fe(CO)_2]_2$ (1.0 g, 2.02 mmol), P_4 (1.0 g, 8.07 mmol), decalin (250 mL), were heated to reflux for 3h. After the decalin had been removed under vacuum, the brown residue was transferred to a column (25 × 3 cm) packed with SiO_2 (2% H_2O)/petroleum ether. Elution with petroleum ether gave a green fraction of **1a** (840 mg, 60%).

4a: **1a** (132 mg, 0.38 mmol) and **2** (364 mg, 0.95 mmol) [14] (excess used for yield optimization) were dissolved in toluene (80 mL) and irradiated for approximately 4 h (150 W-Hg lamp, water cooled, Ar stream) and monitored by IR spectroscopy. The red-brown solution was evaporated to dryness under vacuum, the residue dissolved in dichloromethane (ca. 5 mL), and dried with basic Al_2O_3 (1 g, 2% H_2O). Column chromatographic workup (column: 20 × 1.5 cm, Al_2O_3, petroleum ether), initially gave excess **2** (160 mg, 44%) with petroleum ether as a pale yellow fraction. A pale brown fraction of **4a** (122 mg, 45% based on **1a**) was obtained with petroleum ether/toluene. Red-brown **6a** (95 mg; 36% based on **1a**) was eluted with pure toluene. The product contained small amounts of phosphorus-containing impurities.

4b: **1b** (150 mg, 0.26 mmol) [4] and **3** [70 mg, 0.13 mmol) [15] were each dissolved in toluene (15 mL) and mixed at room temperature. A reaction took place (color change to brown) immediately, which, according to IR spectroscopy, was completely finished after 5 min. Workup as for **4a**. A sand-colored fraction of **4b** was obtained with petroleum ether/toluene (3:1). Yield 55 mg (25%), pale brown powder, which was recrystallized (0 °C) from a toluene/hexane mixture (1:10). Small amounts of a mixture of products that could not be characterized were eluted with CH_2Cl_2.

6b: **4b** (100 mg, 0.12 mmol) was warmed to 110 °C in toluene (ca. 20 mL) for 150 min (^{1}H NMR control indicates quantitative isomerization). After recrystallization (0 °C) **6b** (70 mg; 70%) was obtained as a brown-black microcrystalline powder from toluene/hexane (ca. 1:5).

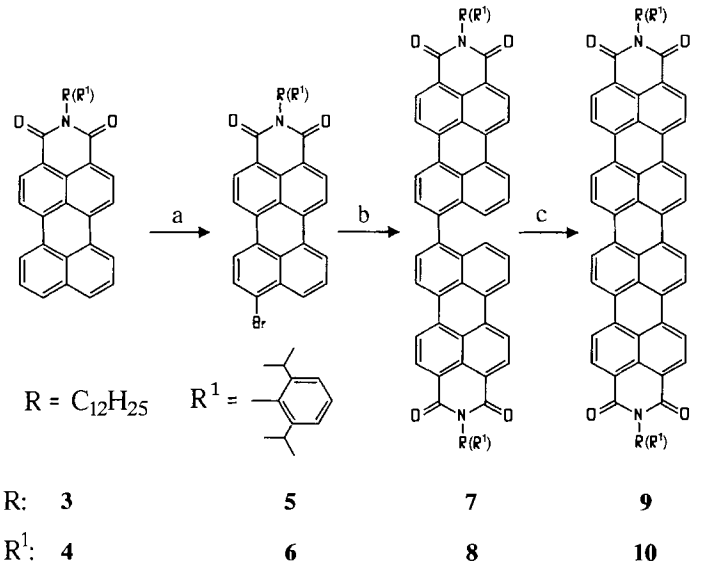
Quaterrylenebis(dicarboximides)**

Heribert Quante and Klaus Müllen*

Perylene-3,4:9,10-bis(dicarboximides) **1** are important chromophores in dye chemistry.[1] They are characterized, above all, by their chemical, thermal, and photochemical inertness.[2, 3] Because of their absorption between 530 and 590 nm and their high fluorescence quantum yield,[3] compounds like **1** have wide technical applications both as pigments and as soluble dyes. In recent years the electrooptical properties of **1** have received more attention, and the use of **1** in reprographic processes,[4] fluorescence solar collectors,[5] photovoltaic processes,[6] and molecular switches[7] has been reported.

1 **2**



A particular challenge in current, in particular nontextile, dye chemistry is the generation of stable dyes that absorb at the limits of the visible spectrum or even in the near-infrared region.[8] In view of the advantages shown by **1**, it is reasonable to make use of this structural type in the search for "highly colored" chromophores.[8]

We describe here the synthesis and attractive optical properties of quaterrylenebis(dicarboximides) **2**. Depending on its structure, the new chromophore **2** may be a pigment or a soluble dye, which leads to a wide range of applications as well as the development of even larger chromophoric systems.

The key units in our synthetic approach (Scheme 1) are the perylene derivatives **3** and **4** functionalized on one side only. The preparation of these intermediates in the case of the N-alkylated species **3** was achieved by the known procedure of decarboxylating perylenetetracarboxylic monoimide monoanhydride.[9, 10] Subsequent bromination gave the monobromo derivatives **5** and **6** in yields of over 90%. Coupling to form the biperylenyl compounds **7** and **8** was a considerable challenge. Coupling by means of an Ullmann reaction, as suggested by Misono and Nagao,[11] is limited to N-alkylated derivatives with a maximum chain length of four C atoms and, in addition, gives only low yields. Because of the moderate solubility of the resulting biperylenyls, their isolation and characterization can be accomplished only with great difficulty. Yamamoto coupling[12] with [Ni(cod)$_2$] (cod = 1,5-cyclooctadiene) proved to be the method of choice for the preparation of N-alkyl- and N-arylbiperylenyls in yields of 83–89%. The subsequent cyclization to provide the target compounds **9** and **10** was achieved in the conventional manner by heating in molten KOH with an added oxidizing agent.[13] Compound **9** synthesized in this manner (see Table 1 for spectroscopic data for this and other compounds) is regarded as a pigment since it is insoluble in all organic solvents. Compound **10**, on the other hand, is moderately soluble in chlo-

Scheme 1. Synthesis of quaterrylenebis(dicarboximides) **9** and **10**. Reagents, conditions, and yields: a) **3**: Br_2/CH_2Cl_2, reflux, 94%, **4**: Br_2/C_6H_5Cl, 50 °C, 98%; b) $[Ni(cod)_2]$/DMF, 60 °C, 2 d, **7**: 89%, **8**: 83%; c) KOH/EtOH/ox., **9**: 37%, **10**: 83%.

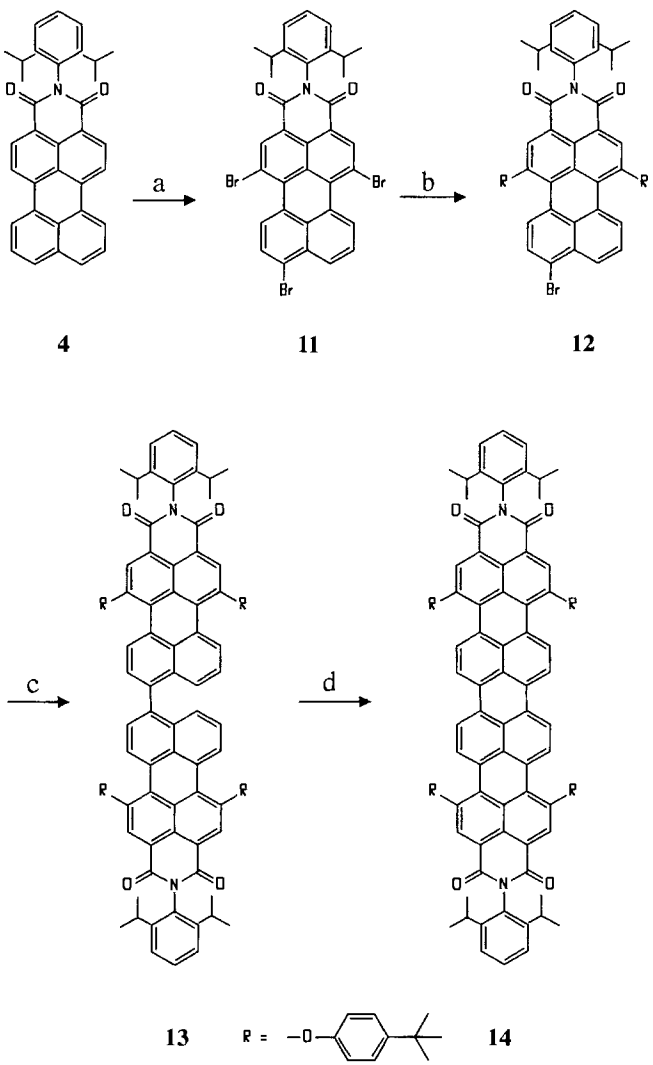

Table 1. Selected spectroscopic data for compounds **9**, **10**, and **14** [a].

9: m.p. >300 °C; IR: $\tilde{\nu}$[cm^{-1}] = 1690 (C=O), 1650 (C=O); UV/VIS [H_2SO_4/oleum (57%) (4:1)]: $\lambda_{max}(\varepsilon)$ = 281 (524288), 323 (57659), 784 (34367), 876 (337000) nm.

10: m.p. >300 °C; ^{1}H NMR (300 MHz, $C_2D_2Cl_4$, 135 °C): δ = 8.68 (d, 4H), 8.68 (d, 4H), 8.63 (d, 4H), 8.56 (d, 4H), 7.42 (dd, 2H), 7.29 (d, 4H), 2.80 (m, 4H), 1.19 (d, 24H). IR: $\tilde{\nu}$[cm^{-1}] = 1702 (C=O), 1659 (C=O); UV/VIS (CH_2Cl_2): $\lambda_{max}(\varepsilon)$ = 264 (97377), 274 (100124), 317 (9195), 375 (14689), 764 (162024) nm; UV/VIS [H_2SO_4/oleum (57%) (4:1)]: $\lambda_{max}(\varepsilon)$ = 281 (698994), 326 (58801), 783 (83173), 876 (654705) nm.

14: m.p. >300 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 9.09 (d, 4H), 8.32 (s, 4H), 7.76 (d, 4H), 7.41 (t, 2H), 7.34 (d, 8H), 7.28 (d, 4H), 7.00 (d, 8H), 2.76 (m, 4H), 1.26 (s, 36H), 1.13 (d, 24H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 162.99, 153.55, 152.93, 147.00, 145.75, 131.24, 130.85, 130.80, 129.40, 129.19, 128.87, 127.73, 127.47, 127.17, 126.42, 125.24, 124.32, 123.94, 122.53, 121.63, 117.39, 34.37, 31.44, 29.23, 24.10; IR: $\tilde{\nu}$[cm^{-1}] = 1707 (C=O), 1669 (C=O); UV/VIS (CH_2Cl_2): $\lambda_{max}(\varepsilon)$ = 262 (95819), 271 (97645), 382 (12895), 709 (71931), 781 (166571) nm.

[a] The FD mass spectra of all compounds contain the correct M^+ peaks. IR: KBr pellet.

Scheme 2. Synthesis of (tetraphenoxy)quaterrylenebis(dicarboximide) **14**. Reagents, conditions, and yields: a) $Br_2/CHCl_3$, reflux, 91%; b): *p-tert*-butylphenol/K_2CO_3/*N*-methyl-2-pyrrolidinone, 33%; c) $[Ni(cod)_2]$/DMF, 60 °C, 2 d, 88%; d) KOH/EtOH/ox., 87%.

rinated hydrocarbons but very soluble in boiling tetrachlorethane, nitrobenzene, and pyridine. Since each step in the synthesis of **10** is high yielding and chromatographic procedures are not required, technical production should be possible.

Quaterrylenebis(dicarboximides) with very good solubility (15–25 gL^{-1}, $CHCl_3$) may be prepared by introducing phenoxy substituents into the bay reaction (Scheme 2). This is achieved by brominating **4** under drastic conditions to afford tribromide **11**, which is converted to **12** with *p-tert*-butylphenol/K_2CO_3. Coupling and cyclization as in Scheme 1 leads to the (tetraphenoxy)quaterrylenebis(dicarboximide) **14**.

All the quaterrylene derivatives synthesized were characterized by FD mass spectrometry, and IR and UV/VIS spectroscopy. ^{1}H NMR spectra were obtained for **10** and **14**, but a ^{13}C NMR spectrum was obtained only for **14**.

In the electronic absorption spectra (Fig. 1) of **10** (λ_{max} (ε) = 762 (162024) nm) and **14** ($\lambda_{max}(\varepsilon)$ = 781 (166571) nm) the wavelength of the end absorption increases considerably owing to the greater size of the chromophore. Compared to the UV/VIS spectrum of perylenebis(dicarboximide) **1**, **10** shows a bathochromic shift of 250 nm and a considerable increase in the absorption coefficient. The distinct bathochromic shift of **14** can be ascribed to the introduction of the phenoxy groups and corresponds to the related bands in the equivalent phenoxy-substituted perylenebis(dicarboximides).[5] All the quaterrylenebis-

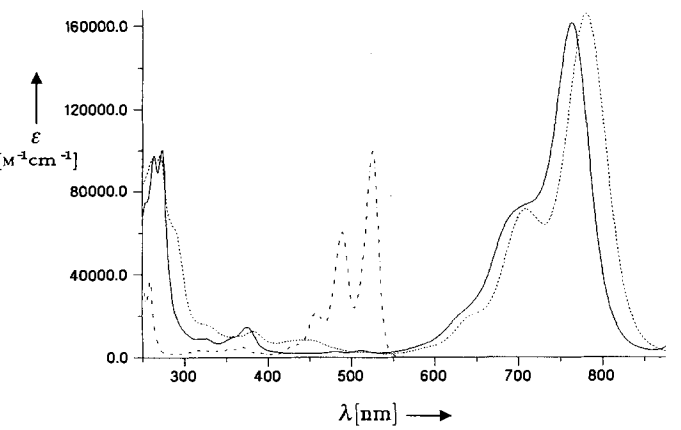

Fig. 1. Electronic absorption spectra of **1**, R = 2,6-diisopropylphenyl (– · · · –), **10** (—), and **14** (– – –) in CH_2Cl_2.

(dicarboximides) are green both in the solid state and in concentrated solutions. At the concentrations required for UV spectroscopy, $c = 10^{-5}$ M, the solutions are largely colorless. Similarly, films of **14** spin-coated onto quartz are also colorless. To compare the aryl- and alkyl-substituted quaterrylenes **9** and **10**, their spectra were measured in sulfuric acid/oleum. Both compounds have unusual but identical UV spectra in the NIR region with only a single very sharp peak (*J*-band[14]). Particularly remarkable is the extremely high extinction ($\varepsilon = 654705$) of the band at 876 nm (**10**, Fig. 2). The identical behavior of **9** and **10** may be used as supporting evidence for the structure of the alkyl derivatives which are not soluble in organic solvents.

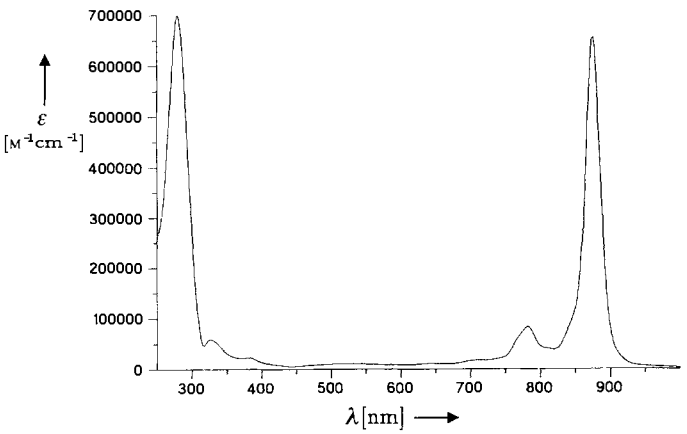

Fig. 2. Electronic absorption spectrum of **10** in H_2SO_4/oleum (57%) (4:1).

According to thermogravimetric investigations, the stabilities of **9**, **10**, and **14** (no decomposition up to 480 °C) correspond to those of the known perylenebis(dicarboximides). The important contributor to the thermal stability of the perylenebis(dicarboximides) is only, therefore, the type of N-substitution; the mass loss determined corresponds exactly to the loss of the substituent on the N atom.

The marked absorption in the region 764 to 782 nm in this system has particular advantages since it can be used in many optical applications in conjunction with commercially available GaAlAs lasers which emit at 780 nm. This is a necessary prerequisite, for example, for applications in optical data storage systems. Future investigations will aim at extending applications to semiconductors and thermal liquid crystal displays.

The First Clusters with a Y-Shaped Arrangement of Ligands at Three-Coordinate Rh^I Atoms in the Solid State: $[M^1M^2\{\mu\text{-}P(C_6H_{11})_2\}(CO)_8Rh(PPh_3)]$ (M^1, M^2 = Mn, Re)**

Hans-Günther Beckers, Ulrich Flörke, and Hans-Jürgen Haupt*

According to kinetic studies by Halpern et al.,[1] during the homogeneously catalyzed hydrogenation of alkenes, complex fragments are formed from the Wilkinson catalyst [RhCl(P$Ph_3)_3$] by dissociation that contain three-coordinate Rh^I atoms. Corresponding species should also be produced in solution during the thermal decomposition (−70 °C) of [RhH(N_2)($PR_3)_2$] complexes with sterically demanding phosphane ligands (R = Bu, cyclohexyl (Cy)) by the release of $N_{2(g)}$.[2] In the solid state, however, a coordination number of 3 for a central d^8 rhodium(I) atom is unusual and has only been described for the diamagnetic, red complex cation $[Rh(PPh_3)_3]^+$ in salts with various anions (ClO_4^-, [*nido*-7-(1-*closo*-1,2-$C_2B_{10}H_{11}$)-7,8-$C_2B_9H_{11}]^-$).[3, 4] According to the X-ray structure analysis, the three covalent Rh–P bonds are arranged in a T formation. For the perchlorate salt, this ground state geometry is stabilized by the attractive Rh···H interactions with a concomitant weakening of the Lewis acid strength of the central atom.[3, 5] Futhermore, the rigidity of the cation in non-coordinating solvents was verified by ^{31}P DNMR spectroscopy.[6] Spin coupling data between ^{103}Rh and ^{31}P from temperature-dependent experiments indicate that an intramolecular exchange of the phosphane ligands takes place. This would occur, in agreement with MO calculations, via a Y-shaped intermediate (C_{3v}).[7, 8] Instead of using sterically demanding ligands we attempted to produce threefold coordination by the inclusion of a ligand-stabilized Rh^I center into a bond system capable of mesomerism. In the light of our work on π-bonding properties of *cyclo*-M_3 and *tetrahedro*-M_4 clusters, we decided to join suitable anionic phosphido-bridged binuclear complexes with rhodium(I) complex cations using a so-called redox condensation.[5, 7, 8]

The title compounds **3** and **4** were obtained from hydridophosphido-bridged binuclear complexes of metals from group nine [9, 10, 12] in a three-step synthesis as summarized in Scheme 1: 1) deprotonation by a non-nucleophilic base, 2) "redox condensation", and 3) selective oxidative removal of a Rh-bound CO ligand. The analogous Mn_2Rh cluster **5** was obtained

$[M^1M^2(\mu\text{-PCy}_2)(CO)_8Rh(PPh_3)]$ $M^1 = Mn$, $M^2 = Re$, **3**; $M^1 = M^2 = Re$, **4**

Scheme 1.

by a somewhat modified synthesis.[12] On swapping Rh^I for Ir^I, reaction step 3 did not produce any corresponding clusters of the title compounds. The molecular structures of the two precursors $[M^1M^2(\mu\text{-PCy}_2)(CO)_8Rh(CO)_2(PPh_3)]$, namely the *cyclo*-$Re_2Rh$ cluster ($M^1 = M^2 = Re$) and **2** ($M^1 = Mn$, $M^2 = Re$), have been established by single-crystal X-ray diffraction.[8, 12] They differ in that one of the terminal CO groups on the Rh^I atom in the Re_2Rh cluster is in a semi-bridging position towards the manganese atom in compound **2**.

The molecular structures of **3**–**5** were solved by single-crystal X-ray analysis[13] (Fig. 1). The central molecular fragment is a three-membered ring consisting of MnReRh in **3**, Re_2Rh in **4**, and Mn_2Rh in **5**. The Rh^I atom coordinates with both metal atoms of group nine to give an acute bond angle (69.59(2)° in **3**, 68.93(3)° in **4**, and 68.80(3)° in **5**) and with the phosphorus atom in the PPh_3 ligands to give differing obtuse bond angles (P(2)-Rh-M(1) 135.4(1), P(2)-Rh-M(2) 153.7(1)° in **3**; 136.2(1), 151.7(1)° in **4**; 135.9(1), 154.0(1)° in **5**). Such varying bond angles are also found in precursors with five-coordinate Rh^I atoms[8, 12] and are therefore independent of the coordination number. Consequently, the Rh^I atom in the three structurally analogous *cyclo*-M_3 clusters is, in each case, coordinated in a distorted Y-shaped, almost planar manner; the smaller of the two exocyclic bond angles always occurs on the longer Rh–transition metal bond. This differentiation leads to a quasi *trans* positioning of the Rh–P bond towards the shorter Rh–M bond in **4** and **5** (a thermodynamic *trans* effect). The resulting significant shortening of the Rh–M bond is 0.025(1) Å in **3**, 0.015(1) Å in **4**, and 0.038(1) Å in **5**. Because compounds **3**–**5** do not show any unusual distances between neighboring ligands along the two Rh–M bonds, and they crystallize in different crystal systems, the Y-shaped coordination geometry at the Rh^I atom is not influenced by either repulsive interactions of neighboring ligands or by packing effects. In contrast to the ideal D_{3h} geometry of a $[Rh^IL_3]$ complex, both this new Y-shaped as well as the previously described T-shaped coordination geometry (ideally C_{2v}) at the Rh^I atom allows the removal of the degeneracy of the e' orbital set that is occupied by two valence electrons. This explains the diamagnetism of compounds **3**–**5**. Not only the P atom of the bridging dicyclohexylphosphido group but also the Y-coordinated Rh^I atom is a component of an edge-sharing coordination dioctahedron of the two transition metal atoms. There are no distortions of the coordination geometry when compared to the structures of similar heteronuclear *cyclo*-M_3 clusters.[7, 8, 10] From this, it follows that in the molecular fragment $[M^1M^2(\mu\text{-PCy}_2)(CO)_8]$ (M^1–M^2, d^7–d^7) of the *cyclo*-M_3 cluster the covalent bonds to the Rh^I atom are formed over centered as well as over edge-sharing frontier orbitals, as was already postulated by MO calculations on related complexes.[14] If the fragment is considered to be an anionic two-electron donor ligand, the Rh^I atom (d^8) with the PPh_3 ligand has the same number of donor electrons, that is formally only 12 valence electrons as opposed to the usual 14 and 16 valence electrons in the compounds known to date. This obvious electron deficiency on the Rh atom is compensated by π-electron delocalization along the two Rh–M bonds. Therefore these are shorter than the corresponding covalent single bonds. This is demonstrated by the following comparisons which, on the one hand, show a shortening of the Rh–M bonds in **3**–**5** compared to σ bonds, and on the other hand, a lengthening compared to π bonds in other similar compounds. Thus, in **4** the Rh–Rh distance is 2.827(1) Å (average value), whilst for $[(PCy_2)_2ReH(\mu\text{-PCy}_2)_2Rh(1,5\text{-cod})][BF_4]$ (cod = cyclooctadiene) with diphosphido-bridged metal centers, a Re–Rh distance of 2.9361(8) Å[15] for a σ bond is observed. In the hydridosulfido-bridged compound $[RhRe(CO)_3(\mu\text{-H})(\mu\text{-SEt})(dppm)_2]$ (dppm = bis(diphenylphosphano)methane) the Re–Rh σ bond length is 2.9697(8) Å.[16] In comparison, the Re–Rh π bond in $[Re_2Rh(\mu\text{-CO})_2(\mu\text{-PCy}_2)(CO)_6(PPh_3)_2]$ is 2.681(1) Å.[8] Likewise, the Mn–Rh bond in **5** (mean 2.708(1) Å) is shorter than the Mn–Rh σ bond in $[MnRh(CO)_4(dppm)_2]$ (2.843(1) Å)[17] and longer than the Mn–Rh π bond in $[ReMnRh(\mu\text{-CO})_2(\mu\text{-PCy}_2)(CO)_6(PPh_3)_2]$ (2.585(2) Å).[12] Therefore, the Rh–M bond lengths found for the title compounds lie in the range of a bond order of 1.5, which corresponds to a π-electron delocalization in the M^1-Rh-M^2 ring. This effect undoubtedly reduces the strength of the M^1–M^2 bond, so that the M^1–M^2 bonds in **3**,

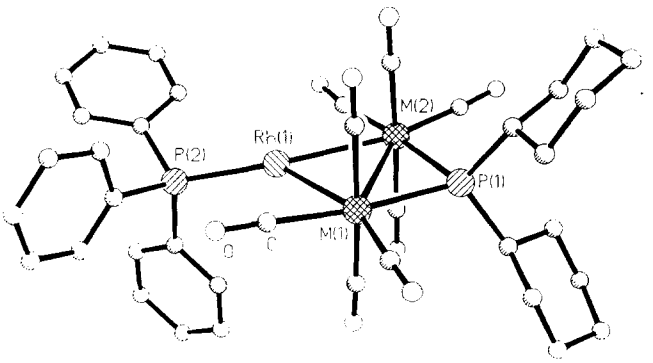

Fig. 1. Molecular structure of **3** ($M^1 = M^2 = Mn,Re$), **4** ($M^1 = M^2 = Re$) and **5** ($M^1 = M^2 = Mn$). Important bond lengths [Å] and angles [°]: for **3**: M1-M2 3.164(1), M1-Rh 2.785(1), M2-Rh 2.760(1), M1-P1 2.375(2), M2-P1 2.391(2); M1-Rh-M2 69.59(2), M1-Rh-P2 135.42(5), M2-Rh-P2 153.65(5), Rh-M1-M2 54.83(2), Rh-M2-M1 55.58(2), M1-P1-M2 83.20(6); for **4**: Re1-Re2 3.199(1), Re1-Rh 2.834(1), Re2-Rh 2.819(1), Re1-P1 2.435(2), Re2-P1 2.443(2); Re1-Rh-Re2 68.93(3), Re1-Rh-P2 151.65(5), Re2-Rh-P2 136.20(5), Rh-Re1-Re2 55.32(2), Rh-Re2-Re1 55.75(2), Re1-P1-Re2 81.96(6); for **5**: Mn1-Mn2 3.060(2), Mn1-Rh 2.727(1), Mn2-Rh 2.689(1), Mn1-P1 2.301(2), Mn2-P1 2.310(2); Mn1-Rh-Mn2 68.80(3), Mn1-Rh-P2 135.88(5), Mn2-Rh-P2 153.96(5), Rh-Mn1-Mn2 55.02(3), Rh-Mn2-Mn1 56.17(3), Mn1-P1-Mn2 83.17(6).

4, and **5** are longer than the corresponding bonds in compounds of the type $[M^1M^2(\mu\text{-H})(\mu\text{-PCy}_2)(CO)_8]$.[9] Similar results have been found for the mercury atom in the *cyclo*-M_3 compound $[ReMo(\eta\text{-}C_5H_5)(\mu\text{-PCy}_2)(CO)_6HgW(CO)_3(\eta\text{-}C_5H_5)]$.[10]

Because the rhodium(I) atom in **3**–**5** has one or two free coordination sites for two-electron donors, we were also interested in the homogeneous catalytic properties of these compounds. However, attempts at homogeneous catalytic hydrogenation with **4** or **5** as the catalyst in dioxane were unsucessful (10 bar H_2, 1-hexene, 100 °C, 12 h); only metal deposition was observed in each case. Consequently, the transitions between 16 and 18 valence electrons, which are typical for a catalytic hydrogenation cycle with Rh^I complexes, cannot be obtained with the title compounds because the activation barrier is too high. Therefore, the three-coordinate Rh^I atom only appears to be an active homogeneous catalyst if it is not a particularly strong Lewis acid. This argumentation is supported by our observations that the similar *cyclo*-M_3 cluster $[M^1M^2(\mu\text{-PCy}_2)Rh(\mu\text{-CO})_2(PPh_3)(CO)_8]$ (M^1, M^2 = Mn, Re) with (4 + 2)-fold coordination of the Rh^I atom is catalytically active under analogous reaction conditions (THF, 3 bar H_2, 3 bar CO, 60 °C, 1-hexene).[12] For example, TON values of approximately 100 h^{-1} were obtained with an Mn_2Rh compound in an oxo reaction.[12] To date, this could not be even nearly achieved with a soluble heteronuclear Rh cluster as the catalyst.[18, 19] The Rh^I atom shows in the cited *cyclo*-M_3 clusters a rarely observed (4 + 2) coordination.[8] Therefore, in the Rh^I complex fragments bound in the clusters the decisive factor for the interplay between 16 and 18 valence electron species in the catalytic cycle and for the catalytic efficiency is not the threefold coordination of the Rh^I atom, but the type of ligands and the symmetry of their spatial arrangement. Such considerations are important for the development of new Rh^I catalysts.

Experimental Procedure

FT-IR spectra (Nicolet P510) of the new compounds were recorded, unless otherwise stated, in CH_2Cl_2 in the range 2200 to 1600 cm^{-1} for ν(CO) absorption bands. ^{31}P NMR spectra (Bruker AMX 300) were recorded in $CDCl_3$ with 85% H_3PO_4 as the external standard. Solvents used were distilled twice, dried, and stored under argon. All reactions were carried out under argon.

1: $[MnRe(\mu\text{-H})(\mu\text{-PCy}_2)(CO)_8]$ (663 mg, 1 mmol) [9] in THF (20 mL) was deprotonated with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (300 mL, 2 mmol) at 20 °C in 4 h. To isolate the product, the solvent was evaporated, the residue dissolved in C_2H_5OH (10 mL), and PPh_4Br (545 mg, 1.3 mmol) added. Compound **1** was precipitated by addition of oxygen-free water (50 mL), filtered off, and washed with water (3 × 15 mL) followed by *n*-hexane (3 × 15 mL). Yield: 940 mg (94%) of air-stable, yellow complex salt.

2: Equimolar amounts of **1** (100 mg, 0.1 mmol) and $[RhCO(PPh_3)_2]Cl$ (69 mg, 0.1 mmol) were dissolved in CO-saturated THF at 0 °C and $TlPF_6$ (419 mg, 1.2 mmol) was added as a halogen trap. The reaction solution immediately turned deep red and was allowed to warm to 20 °C over 2 h in a weak flow of $CO_{(g)}$. To isolate the product, the THF was removed and the solid residue dissolved in CH_2Cl_2, the solution was filtered through Celite and the components separated by thick layer chromatography using CH_2Cl_2/*n*-hexane (1/3) as the eluent. Yield: 74 mg (69%) of red solid.

3: **2** (108 mg, 0.1 mmol) in THF (15 mL) was treated with Me_3NO (8.3 mg, 0.11 mmol) at 0 °C and the reaction mixture was allowed to warm to 20 °C over 2 h, during which time the color of the solution changed from red to yellow. To isolate the product the THF was removed, the solid residue dissolved in a small amount of acetone, the solution filtered through basic Al_2O_3 and the product separated chromatographically and crystallized with CH_2Cl_2/hexane (1/5). Yield: 83 mg (80%) of yellow product.

4: In an analogous procedure to that used for **1** from $[Re_2(\mu\text{-H})(\mu\text{-PCy}_2)(CO)_8]$ (794 mg, 1 mmol) [10], DBU (450 mL, 3 mmol), and PPh_4Br (545 mg, 1.3 mmol) produced $PPh_4[Re_2(\mu\text{-PCy}_2)(CO)_8]$ (1008 mg, 95%). The reaction of this salt (113 mg, 0.1 mmol) with $[Rh(CO)(PPh_3)_2]Cl$ (69 mg, 0.1 mmol)[11] under the same conditions applied for complex **2**, gave $[Re(\mu\text{-PCy}_2)(CO)_8Rh(CO)_2(PPh_3)]$ [8]. Treatment of the latter (118 mg, 0.1 mmol) with Me_3NO (8.3 mg, 0.1 mmol) in an analogous way to that used for **3** gave the pale yellow product **4** (99 mg, 85%).

Compounds **1**–**4** and $PPh_4[Re_2(\mu\text{-PCy}_2)(CO)_8]$ gave correct C,H analysis (Automat PE 240). IR (CH_3COCH_3): **1**: $\tilde{\nu}$(CO) = 2039 m, 1971 s, 1936 vs, 1905 s, 1888 s; 1871 s cm^{-1}; **2**: $\tilde{\nu}$(CO) = 2079 w, 2035 m, 2015 s, 1998 vs, 1946 s, 1898 m (br.) cm^{-1}; **3**: $\tilde{\nu}$(CO) = 2013 s, 1973 vs, 1944 s, 1921 s cm^{-1}; $PPh_4[Re_2(\mu\text{-PCy}_2)(CO)_8]$: $\tilde{\nu}$(CO) = 2042 m, 1988 m, 1936 vs, 1911 m, 1888 s, 1873 s cm^{-1}; **4**: $\tilde{\nu}$(CO) = 2033 s, 1977 vs, 1950 s, 1921 s cm^{-1}; UV-Vis (Perkin-Elmer-Lambda-15, CH_2Cl_2): **3**: $\lambda_{max}(\varepsilon)$ = 338 (817), 392 nm (359 m^2mol^{-1}); **4**: $\lambda_{max}(\varepsilon)$ = 323 (773), 359 (522 m^2mol^{-1}); ^{31}P-NMR ($CDCl_3$): **1**: δ = 156.7 (s, μ-P), 23.7 (s, PPh_4); **2**: δ = 215.1 (s, μ-P), 35.1 (d, ^1J(P,Rh) = 147 Hz); **3**: δ = 177.9 (s, μ-P), 18.5 (d, ^1J(P,Rh) = 322 Hz); $PPh_4[Re_2(\mu\text{-PCy}_2)(CO)_8]$: δ = 101.4 (s, μ-P), 23.7 (s, PPh_4); **4**: δ = 124.5 (s, μ-P), 21.1 (d, ^1J(P,Rh) = 352 Hz).

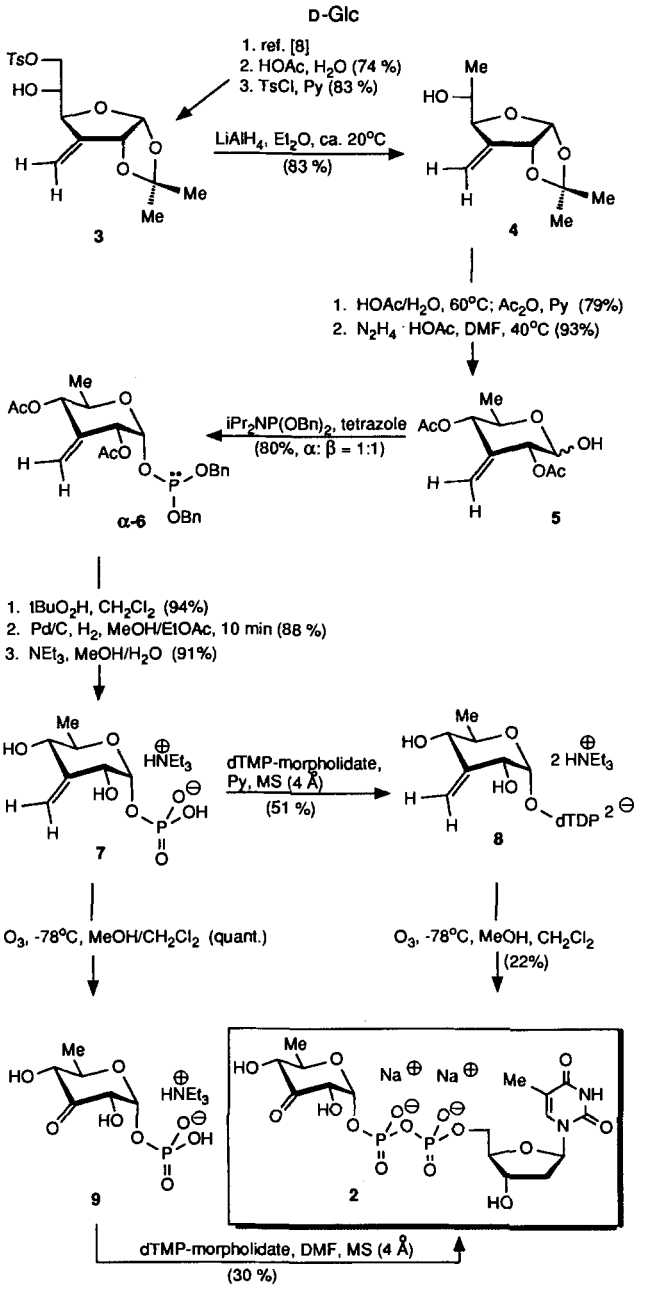
Thymidine Diphospho-6-deoxy-α-D-*ribo*-3-hexulose—Synthesis of a Central Intermediate in the Biosynthesis of Di- and Trideoxysugars**

Thomas Müller and Richard R. Schmidt*



Many antibiotics contain deoxy-, aminodeoxy-, and C-branched deoxysugar units. Elucidation of their biosynthesis is far from complete.[1, 2] An important initial intermediate in this biosynthetic pathway is dTDP-6-deoxy-D-*xylo*-4-hexulose (**1**), made from dTDP-glucose (Scheme 1) by NAD-dependent

Scheme 1.

dTDP-glucose-4,6-dehydratase (e.g. from *E. coli*); **1** is a precursor for, amongst other rare sugars, the commonly occurring 6-deoxysugars.[1-3] An isomerase apparently converts **1** into the corresponding 3-hexulose **2**,[2] the compound mentioned in the title, which serves as the next key intermediate (with pyridoxamine phosphate as cofactor) for preparation of the important dideoxy-, aminodeoxy-, and C-branched sugars.[2, 4] Since the 6-deoxy-3-hexulose intermediate **2** has not yet been isolated,[2] its synthesis is very important for elucidation of the biosynthesis of di- and trideoxysugars (e.g. with 4,6-dehydratase- or isomerase-deficient mutants).[2] The synthesis of **2** is particularly difficult due to the hydrolytic instability of nucleoside diphosphates of deoxysugars[5] and the tendency of 3-ulosides to undergo β-elimination of the nucleoside diphosphate group.[6] We report here on a first efficient synthesis of **2**,[7] which is based on removal of all protecting groups (in the penultimate or last reaction step) and introduction of the 3-oxo function by ozonolysis of the corresponding methylene group.

Firstly, D-glucose was converted to the 1,2:5,6-di-*O*-isopropylidene-3-methylene derivative by published methods;[8] selective cleavage of the 5,6-*O*-isopropylidene group with 50% acetic acid, and subsequent regioselective 6-*O*-tosylation resulted in compound **3** (Scheme 2). The 6-deoxy compound **4** was produced in 83% yield by reaction with $LiAlH_4$ in ether at room temperature. Treatment with 80% acetic acid at 60 °C resulted

Scheme 2.

in cleavage of the isopropylidene group; subsequent acetylation with acetic anhydride in pyridine, and selective cleavage of the 1-*O*-acetyl group with hydrazine acetate[9] in DMF at 40 °C produced the pyranose derivative **5** in high overall yield. Phosphite **6** was obtained as a 1:1 α/β mixture[11] by reaction with the monofunctional phosphitylation reagent bis(benzyloxy)-diisopropylaminophosphane[10] in the presence of tetrazole. Compound **6** proved to be sufficiently stable for separation by flash chromatography on silica gel (petroleum ether/

EtOAc = 10:1 + 1% NEt_3). The compound **α-6** thus obtained (Table 1) was converted almost quantitatively by oxidation with *tert*-butylhydroperoxide to the corresponding phosphate, which was much less stable than the phosphite **α-6**. The phosphate was chemoselectively debenzylated by brief hydrogenation with palladium on carbon as catalyst without removal of the methylene group. Deacetylation was performed with NEt_3 in methanol/water, and thus the important intermediate **7** was obtained in high overall yield as the completely unprotected triethylammonium salt.

Table 1. Selected physical data for **2**, **α-6**, and **7**–**9**. Coupling constants in Hz.

2: ^{1}H NMR (250 MHz, D_2O): $\delta = 1.05$ (d, $J_{5'',6''} = 5.8$, 3H, 6″-H), 1.73 (s, 3H, CH_3), 2.14–2.18 (m, 2H, $2'_a$-H, $2'_c$-H), 3.93–4.07 (m, 5H, 4′-H, $5'_a$-H, $5'_c$-H, 4″-H, 5″-H), 4.41–4.56 (m, 2H, 3′-H, 2″-H), 5.67 (dd, $J_{1'',P} = 7.1$, $J_{1'',2''} = 4.3$, 1H, 1″-H), 6.13 (dd, $J_{1',2'a} = 6.6$, $J_{1',2'c} = 6.9$, 1H, 1′-H), 7.55 (s, 1H, 6-H); ^{31}P NMR (161.7 MHz, D_2O): $\delta = -10.64$ (d, $J_{P,P'} = 22.5$, 1P), -6.02 (d, $J_{P,P} = 22.5$, 1P); FAB-MS (70 eV, negative-ion mode): *m/z* (%): 545 (27) $[M-H^+]^-$

α-6: ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 1.16$ (d, $J_{5,6} = 6.2$, 3H, 6-H), 1.97, 2.17 (2 s, 6H, 2 × OAc), 3.99 (dq, $J_{4,5} = 9.8$, $J_{5,6} = 6.2$, 1H, 5-H), 4.86–4.94 (m, 4H, 2 × CH_2Ph), 4.95–5.11 (m, 3H, 4-H, methylene-H), 5.41 (dd, $J_{1,2} = 3.5$, $J_{2,4} = 1.1$, 1H, 2-H), 5.68 (dd, $J_{1,P} = 8.3$, $J_{1,2} = 3.5$, 1H, 1-H), 7.24–7.38 (m, 10H, 2 × Ph); ^{31}P NMR (161.7 MHz, $CDCl_3$): $\delta = 138.85$ (s, P)

8: ^{1}H NMR (250 MHz, D_2O): $\delta = 1.05$ (d, $J_{5'',6''} = 5.8$, 3H, 6″-H), 1.07 (t, $J = 7.3$, 18H, 2 × $N(CH_2CH_3)_3$), 1.73 (s, 3H, CH_3), 2.13–2.18 (m, 2H, 2′a-H, 2′e-H), 2.97 (q, $J = 7.3$ Hz, 12H, 2 × $N(CH_2CH_3)_3$), 3.61–3.63 (m, 2H, 4″-H, 5″-H), 3.95–3.97 (m, 3H, 4′-H, 5′-H, 5″-H), 4.08 (m, 1H, 2″-H), 4.42 (m, 1H, 3′-H), 4.97–5.04 (m, 2H, methylene-H), 5.37(dd, $J_{1'',P} = 7.0$, $J_{1'',2''} = 3.7$, 1H, 1″-H), 6.16 (dd, $J_{1',2'a} = 6.8$, $J_{1',2'c} = 7.1$, 1H, 1′-H), 7.52 (d, $J = 0.9$, 1H, 6-H); ^{13}C NMR (62.9 MHz, D_2O), $\delta = 9.17$ (s, 6C, 2 × $N(CH_2CH_3)_3$), 12.59 (s, 1C, CH_3), 18.20 (s, 1C, 6″-C), 39.56 (s, 1C, 2′-C), 47.63 (s, 6C, 2 × $N(CH_2CH_3)_3$), 66.32 (d, $J_{5',P} = 5.2$, 1C, 5′-C), 71.07 (d, $J_{2'',P} = 9.1$, 1C, 2″-C), 71.82–73.44 (m, 3C, 3′-C, 4″-C, 5″-C), 85.92 (s, 1C, 1′-C), 86.35 (d, $J_{4',P} = 9.1$, 1C, 4′-C), 96.25 (d, $J_{1'',P} = 6.4$, 1C, 6″-C), 105.62 (s, 1C, 3″-C), 112.62 (s, 1C, 5-C), 138.33 (s, 1C, 6-C), 164.54 (s, 1C, methylene-C), 152.60 (s, 1C, 2-C), 167.40 (s, 1C, 4-C); ^{31}P NMR (161.7 MHz, D_2O): $\delta = -12.35$ (d, $J_{P,P'} = 22.5$, 1P), -10.81 (d, $J_{P,P'} = 22.5$, 1P); FAB-MS (70 eV, negative-ion mode): *m/z* (%): 543 (31) $[M-H^+]^-$

9: ^{1}H NMR (250 MHz, D_2O): $\delta = 1.09$ (t, $J = 7.3$, 9H, $N(CH_2CH_3)_3$), 1.23 (d, $J_{5,6} = 5.8$, 3H, 6-H), 3.00 (q, $J = 7.3$, 6H, $N(CH_2CH_3)_3$), 3.86–3.99 (m, 2H, 4-H, 5-H), 4.44 (m, 1H, 2-H), 5.58 (dd, $J_{1,P} = 6.7$, $J_{1,2} = 4.3$, 1H, 1-H); ^{13}C NMR (62.9 MHz, D_2O): $\delta = 13.82$ (s, 3C, $N(CH_2CH_3)_3$), 23.98 (s, 1C, 6-C), 51.16 (s, 3C, $N(CH_2CH_3)_3$), 77.70–83.52 (2 s, 2C, 4-C, 5-C), 81.71 (d, $J_{2,P} = 5.2$, 1C, 2-C), 103.06 (d, $J_{1,P} = 4.3$, 1C, 1-C), 199.54 (s, 1C, 3-C); ^{31}P NMR (161.7 MHz, D_2O): $\delta = -1.44$ (s, P); FAB-MS (70 eV, negative-ion mode): *m/z* (%): 241 (100) $[M-H^+]^-$

Two routes were used to synthesize the target molecule **2** from **7**. First, the thymidine diphospho derivative **8** was produced using thymidine phosphomorpholidate[12] in pyridine and 4 Å molecular sieves. Compound **8** was obtained with 51% yield by preparative HPLC (5% CH_3CN in 0.5 M $HNEt_3^+$ HCO_3^-) as the bis(triethylammonium) salt; as expected, it was stable at pH 7. It is also of interest for biological investigations as the methylene analogue of **2**. To obtain the 3-ulose structure, a methanolic solution of **8** at $-78\,^\circ C$ was mixed with a dichloromethane solution saturated with ozone at $-78\,^\circ C$, and the reaction mixture was separated by subsequent reversed-phase HPLC on RP-18 (3% CH_3CN in 0.5 M $HNEt_3^+$ HCO_3^-); following lyophilization the target molecule **2** was obtained in 22% yield as the bis(triethylammonium) salt along with recovered starting material. Due to low hydrolytic stability of this salt (half-life ca. 1 h at pH 7), the disodium salt of **2** was obtained by ion exchange (Amberlite IR-120, Na^+ form), which, as expected,[13] was much more stable. Surprisingly, a higher overall yield was obtained for the synthesis of **2** from **7** by changing the order of the reaction steps. The 3-ulose phosphate **9** was obtained in almost quantitative yield by direct ozonolysis of **7** at $-78\,^\circ C$. In spite of the greater instability of **9**, the target molecule **2** was obtained in 30% yield by the morpholidate method,[12] when the procedure described above was used for purification.[14] The target molecule **2** was thus obtained in a pure form (30 mg), and its structure was confirmed by NMR (^{1}H, ^{13}C, ^{31}P) and FAB-MS data, as were the structures of the intermediate compounds **3**–**9** (for **2**, **α-6**, **7**–**9**, see Table 1). The synthetic strategy presented here is apparently variable and suitable for production of further interesting nucleoside derivatives of deoxysugars;[7] it should make an important contribution to the elucidation of their biosynthesis.

S_7NH and S_7NCH_3 as Novel Chelating Ligands in $[(\eta^5\text{-}C_5H_5)_2Ti]$ Complexes: Synthesis of Medium-Sized Sulfur–Nitrogen Rings by Ligand Transfer**

Klaus Bergemann, Monika Kustos, Per Krüger, and Ralf Steudel*

A vast number of sulfur–nitrogen compounds is known.[1] These may be classified as saturated or unsaturated depending on whether the nitrogen is two- or three-coordinate. The remarkable properties of the linear polymer $(SN)_x$, a superconductor at temperatures below 0.26 K, have considerably stimulated the interest in this class of compounds.[1] Most of the cyclic species contain small rings and only very few compounds with rings containing more than eight atoms are known. Examples are the unsaturated cation $S_5N_5^+$[1b] and the saturated twelve-membered S_8N_4 ring in $S_8(NSO_2CF_3)_4$.[2] For quite some time we have been investigating the sulfur homocycles S_6–S_{20}, most of which have been prepared as pure materials.[3] The results of the studies on these rings suggest that cyclic sulfur imides of the type S_nNR (R = H, organic group; $n > 7$) should also be stable. However, so far only derivatives with $n = 7$ have been prepared, which is explained by the lack of synthetic routes for the planned preparation of saturated SN rings with more than eight ring atoms. Since the preparation of sulfur homocycles has profited enormously from the application of $[(\eta^5\text{-}C_5H_5)_2TiS_5]$ as a ligand transfer reagent,[3] we have tried to find a similar access to SN heterocycles by preparing a titanocene complex containing a sulfur–nitrogen ligand.

Here we report on the syntheses and structures of two titanocene complexes with sulfur–nitrogen ligands and on the preliminary results on the application of these compounds in ligand transfer reactions to synthesize S_8NCH_3 and S_9NCH_3. Titanocene dicarbonyl reacts with elemental sulfur[4] as well as with organic di- and trisulfanes [4b, 5] at 20 °C with insertion of the Cp_2Ti unit in a sulfur–sulfur bond and liberation of carbon monoxide. In an analogous way, we have obtained the complexes **1** and **2** by reaction of $[Cp_2Ti(CO)_2]$ (Cp = η^5-C_5H_5) with S_7NH and S_7NCH_3, respectively, in *n*-hexane at 20 °C [Eq. (a)].

$$[Cp_2Ti(CO)_2] + S_7NR \longrightarrow [Cp_2Ti(S_7NR)] + 2\,CO \qquad \text{(a)}$$

1: R = H
2: R = CH_3

$[Cp_2TiS_5]$ and $[Cp_4Ti_2S_4]$ are observed as minor products in these reactions.

Compounds **1** and **2** are the first titanocene complexes with exclusively sulfur-bound SN ligands.[6] Both compounds form black crystals stable at 20 °C in air. Solutions of the complexes for example in CH_2Cl_2 or CS_2 are intense violet (**1**) or green (**2**), respectively. In solution complexes **1** and **2** slowly decompose. On heating the solid compounds to 115–120 °C $[Cp_2TiS_5]$ is formed. The complexes **1** and **2** were characterized by single-crystal X-ray structural analyses,[7] which surprisingly showed that **1** contains a disulfide and a pentasulfide bridging ligand (Fig. 1), while **2** exhibits a trisulfide and a tetrasulfide bridge (Fig. 2). In principle, insertion of a Cp_2Ti unit in one of the S–S bonds of S_7NH or S_7NCH_3 can result in *three* isomeric products in both cases. At present, we cannot explain why only *one* isomer is formed in each case and why the coordination in **1** is $[Cp_2Ti(\mu\text{-}S_2)(\mu\text{-}S_5)NH]$, while that in **2** is $[Cp_2Ti(\mu\text{-}S_3)(\mu\text{-}S_4)NCH_3]$. This differing behavior is not attributed to either recognizable steric or electronic reasons. We confirmed that both samples are homogeneous by high-resolution HPLC (one peak only);[8] in addition, the ^1H NMR spectrum of **2** shows only one signal for the methyl protons, and X-ray powder diffraction measurements on a representative sample of **2** showed lines at positions in accordance with those calculated from the single-crystal diffraction data.[9]

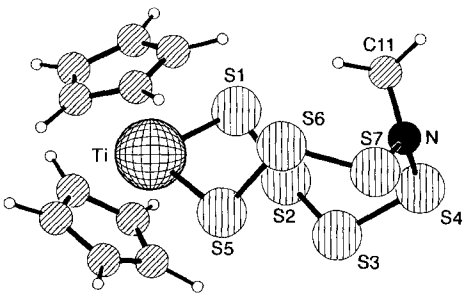

Fig. 2. Structure of **2** in the crystal. Selected distances [pm] and angles [°]: Ti–S1 242.6(2), S1–S2 204.2(2), S2–S3 204.9(3), S3–S4 204.1(3), S4–N 170.3(7), Ti–S5 241.4(2), S5–S6 207.6(2), S6–S7 202.3(3), S7–N 171.6(7), N–C 144(1); S1-Ti-S5 95.44(6), S4-N-S7 117.7(4), S4-N-C 117.8(5), S7-N-C 117.7(5); S5-Ti-S1-S2 65.5(1), Ti-S1-S2-S3 −67.7(1), S1-S2-S3-S4 −80.5(1), S2-S3-S4-N 86.6(3), S3-S4-N-S7 60.4(4), S1-Ti-S5-S6 61.73(9), Ti-S5-S6-S7 −126.4(1), S5-S6-S7-N 88.6(3), S6-S7-N-S4 −110.0(4), S3-S4-N-C −90.0(6), S6-S7-N-C 40.4(6).

Despite the differing connectivities of **1** and **2** the conformations of the nine-membered rings[11] are comparable. The motifs (the signs of the torsional angles) are in both cases the same:

+ − + − + + − − + (starting from the Ti atom). The values of the torsional angles at the S–S bonds range from 67 to 126°; consequently, the S–S internuclear distances are in the range 201.2–207.6 pm. These conformations may be compared to that of *cyclo*-S_9 for which an experimental structure determination is not available yet. However, density functional calculations have shown that the most stable form of S_9 has C_2 symmetry[12] with exactly the same motif as the nine-membered rings in **1** and **2**.

In solution the metallacycle of **1** seems to undergo pseudorotation (ring inversion) at 20 °C, since only one Cp signal is observed in the ^{1}H NMR spectrum in CS_2/[D_6]acetone or in [D_8]THF. However, at −57 °C two Cp signals (at $\delta = 6.49$, 6.47) are observed. In contrast, **2** yields two well-separated Cp signals already at 25 °C (in CS_2/[D_6]acetone). Evidently, either the methyl group hinders the pseudorotation or the presence of four neighboring S–S bonds as in **1** is a prerequisite for pseudorotation (assuming that the torsional barriers at the Ti–S and S–N bonds are considerably higher than those at S–S bonds[13]); **2** has only three neighboring S–S bonds.

To check whether the novel complexes are suitable reagents for ligand transfer reactions, we treated **2** with SCl_2 and S_2Cl_2.[14] The new imides S_8NCH_3 (**3**) and $S_9N(CH_3)$ (**4**) were isolated as yellow oils [Eq. (b)]. Compounds **3** and **4** were detect-

$$\underset{\mathbf{2}}{[Cp_2Ti(S_7NCH_3)]} + S_nCl_2 \longrightarrow [Cp_2TiCl_2] + \underset{\begin{array}{l}\mathbf{3}\ (n=1)\\ \mathbf{4}\ (n=2)\end{array}}{S_{7+n}NCH_3} \qquad (b)$$

ed as molecular ions in the EI mass spectra. The retention times of **3** and **4** in HPLC analysis[15] together with that of S_7NCH_3 yield a linear regression of the type $\ln k' = a + bn$ (k' = capacity factor) as is typical for homologous series of compounds. Heterocycles of this kind should make it possible to study the conformation of sulfur-rich rings in solution by temperature-dependent NMR spectroscopy (^{1}H, ^{15}N). We expect that pseudorotation will be frozen in at low temperatures making it possible to indirectly detect the nonequivalent ring atom positions present in homocycles like S_9 and S_{10} by spectroscopy. In addition, the large and ever increasing number of inorganic and organic sulfur compounds prepared by ligand transfer from $[Cp_2TiS_5]$[16] makes it likely that **1** and **2** will also become precursors for numerous novel compounds not accessible by other routes.

Experimental Procedure

1: Under an inert atmosphere $[Cp_2Ti(CO)_2]$ (85 mg, 0.36 mmol) in *n*-hexane (15 mL) was added dropwise within 30 min to S_7NH (87 mg, 0.36 mmol) in *n*-hexane (70 mL) at 20 °C and stirred for an additional 2.5 h. The black precipitate formed was isolated and extracted with CS_2 in a Soxhlet apparatus. The extracts were reduced in volume resulting in black crystals which were recrystallized from CH_2Cl_2. Yield 65 mg (41%). Correct C,H,N analysis. ^{1}H NMR (200 MHz, CS_2/[D_6]acetone, 25 °C): $\delta = 6.44$, 6.45 (Cp). UV/VIS (methanol): $\lambda_{max} = 209$, 230, 313, 575 nm (diode array detector).

2: As in the case of **1**, $[Cp_2Ti(CO)_2]$ (234 mg, 1 mmol) in *n*-hexane (30 mL) was added to S_7NCH_3 (235 mg, 1 mmol) in *n*-hexane (150 mL) at 20 °C and stirred for 24 h. Workup as for **1**. Yield: 215 mg (50%). Correct C,H,N analysis. ^{1}H NMR (200 MHz, CS_2/[D_6]acetone, 25 °C): $\delta = 6.47$ (s, 5H), 6.37 (s, 5H), 3.27 (s, 3H); UV/VIS (methanol): $\lambda_{max} = 206$, 231, 290, 390, 578 nm (diode array detector).

A Camouflaged Icosahedral Carborane: Dodecamethyl-1,12-dicarba-*closo*-dodecaborane(12) and Related Compounds**

Wei Jiang, Carolyn B. Knobler, Mark D. Mortimer, and M. Frederick Hawthorne*

The selective placement of substituents on the boron vertices of the three isomeric icosahedral $C_2B_{10}H_{12}$ carboranes remains as a major target of synthetic strategies.[1] At the same time, the attachment of functional groups to the carbon vertices and their subsequent conversion is relatively well developed[2, 3] since the CH vertices of the parent carboranes may be deprotonated with strong bases and the resulting carbanions employed as nucleophilic reagents. The principal mode of reaction of the BH vertices has been attack by electrophilic reagents leading to halogenation, metalation, or alkylation.[1, 2] The nature of the products that result from these electrophilic substitution reactions are very dependent upon the identity of the carborane isomer employed as the substrate.

The three isomeric icosahedral $C_2B_{10}H_{12}$ carboranes are frequently suggested as structural components for molecular scaffolding[4] and supramolecular constructs.[5] These applications of carboranes might be better served if the BH and CH vertices were converted to their chemically stable and hydrophobically enhanced BCH_3 and CCH_3 counterparts. Completely sheathing an icosahedral carborane with methyl groups would provide a form of camouflage for the underlying polyhedral borane framework and produce a molecule whose exterior resembles a hydrocarbon, but whose superstructure is that of a polyhedral borane. Consequently, one might expect the external $(CH_3)_{12}$ sheath to reduce the reactivity characteristic of the carborane skeleton[1, 2] while at the same time presenting opportunities for typical hydrocarbon reactions in an unusual environment. Such compounds would also be expected to exhibit the excellent thermal stability characteristic of carboranes and unsurpassed hydrophobicity. Until now, no successful syntheses have been reported leading to fully alkylated icosahedral carboranes, although a few low-yielding routes are known for the smaller carboranes,[6] and partial substitution of icosahedral carboranes leads to mixtures of isomers which can be difficult or impossible to separate. We here report high-yielding syntheses of 1,12-dicarba-*closo*-dodecaborane(12) derivatives in which all boron vertices are methylated and one or both carbon vertices are either methylated or remain as CH vertices available for lithiation and further reactions.

Permethylated 1,12-dicarba-*closo*-dodecaborane(12) (**1**) was obtained in 91% isolated yield by reaction of 1,12-dimethyl-1,12-dicarba-*closo*-dodecaborane(12)[7a] with neat methyl trifluoromethanelsulfonate (methyl triflate) and small quantities of trifluoromethanesulfonic acid (triflic acid) acting as a catalyst at reflux for 20 h (Scheme 1). The identity of **1** was clearly indicated by the presence of a single signal in the ^{11}B NMR spectrum with no coupling to hydrogen. The crude reaction products when subjected to GC/MS analysis revealed that the reaction had gone to completion; no species having less than twelve methyl groups was present. Similarly, reaction of 1,12-dicarba-*closo*-dodecaborane(12) with methyl triflate and triflic acid as described above gave deca-*B*-methyl-carborane **2** in 89% yield. As with compound **1**, the presence of only one singlet peak in the ^{11}B NMR spectrum unequivocally demonstrated full methylation of all the boron vertices. Analysis of the crude reaction mixture by GC/MS revealed small amounts (ca. 5%) of a compound with a mass suggesting the presence of eleven methyl groups, which was assumed to be undecamethylcarborane **3** (vide infra), formed by attack of the methylating agent on a carbon vertex. Thus the reaction is essentially chemoselective towards the boron vertices.

Scheme 1. Methylation reactions of 1,12-dicarba-*closo*-dodecaboranes(12): a) CF_3SO_3Me, CF_3SO_3H, reflux 10–24 h; b) PhLi (10 equiv.), C_6H_6, reflux 10 h; D_2O.

In order to provide a single free carbon vertex as a potential site for further reactions, 1-methyl-1,12-dicarba-*closo*-dodecaborane(12)[7b] was reacted with methyl triflate under the usual conditions to afford undecamethylcarborane **3** in 60% yield. Compound **3** exhibited two signals in the ^{11}B NMR spectrum, one arising from the boron atoms adjacent to the CH vertex, and the other from those adjacent to the CCH_3 vertex. Two BCH_3 signals were also distinguishable in the ^1H NMR spectrum, in addition to CH and CCH_3 peaks. A derivative with a single CBr vertex was also prepared, giving the molecule another potential functionality; 1-bromo-deca-*B*-methyl-carborane **4** was formed in 55% yield by reaction of 1-bromo-1,12-dicarba-*closo*-dodecaborane(12)[7b,c] with methyl triflate and triflic acid. Like compound **3**, **4** showed two singlets in its ^{11}B NMR spectrum, and signals for two sets of BCH_3 groups and a CH moiety in the ^1H NMR spectrum.

In previous work by Plešek et al. with 1,2-dicarba-*closo*-dodecaborane(12) derivatives,[8] it was proposed that initial alkylation of carboranes under electrophilic conditions activates the cluster to further substitution in a manner analogous to that seen with aromatic hydrocarbons. However, these reactions did not proceed to completion, presumably due to increasing steric hindrance and the lack of reactivity of the BH vertices closest to the two adjacent CH vertices. The use of a very reactive methylating agent and catalyst combined with a substrate in which no vertex is strongly deactivated has overcome this problem.

Compounds **2**, **3**, and **4** have CH cage vertices still available for further reaction, but due to the electron-donating effect of the methyl groups, it was expected that the acidity of these positions would be reduced compared to the corresponding vertices of 1,12-dicarbaborane. While the 1,12 isomer is significantly less acidic than the 1,2 and 1,7 isomers,[9] it is possible to completely deprotonate the CH vertices by reaction with two molar equivalents of butyllithium in diethyl ether at room temperature for two hours. However, a similar reaction with **2** which was quenched with D_2O revealed only 25–30% C-deuteration, as estimated from ^1H NMR spectroscopy. Under more forcing conditions (ca. 10 mol equiv PhLi in benzene heat-

[**] This work was supported by the National Science Foundation (Grant CHE 9314037).

ed at reflux for 24 h followed by treatment with D_2O), [D_2]-**2** could be formed in 95% yield.

Our ability to fully deprotonate the CH vertices of **2** suggested that derivatives should be accessible. However, attempts to convert **2** into **1** by deprotonation of the CH vertices of **2** followed by reaction with methyl triflate met with only limited success. Analysis of the reaction products by mass spectrometry proved them to be a mixture of **1**, **2**, and **3** in a ratio of roughly 1:1:3. While distinguishable by GC/MS, these mixtures were not easily separated on a large scale. The difficulty in forcing this reaction to completion must be due to the relative lack of reactivity of the CH vertices present in **2**, which is exacerbated by the steric protection afforded to each CH vertex by the methyl groups of the five surrounding BCH_3 vertices.

The results of the structural studies carried out on **1** and **2**[10] are shown in Figures 1 and 2, respectively. Compound **1** showed

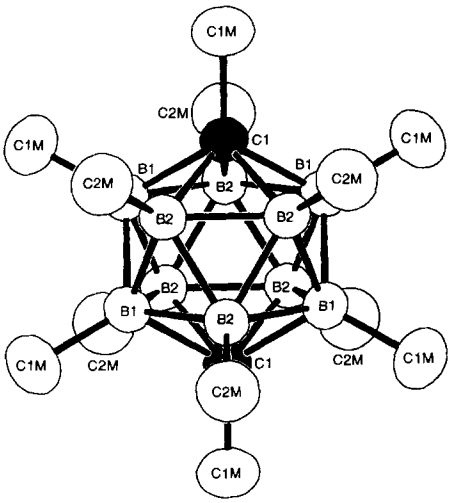

Fig. 1. Crystal structure of **1** (ORTEP representation) along the S_6 axis, showing the crystallographic numbering scheme. Hydrogen atoms are omitted. The molecule has crystallographically imposed S_6 symmetry. One of the two unique icosahedral atoms is described as carbon with one-third occupancy and boron with two-thirds occupancy. Two arbitrarily chosen vertices of the six are shaded and labeled C1, whilst the other four positions are labeled B1. The other unique icosahedral atom, B2, is refined as a boron atom. Selected bond lengths: C1–B1 1.735(6), C1–B2 1.757(6), B2–B2 1.763(6), C1–C1M 1.575(6), B2–C2M 1.583(6) Å.

no unusual features, although the structure exhibits crystallographically imposed symmetry which prohibited assignment of the carbon atoms within the cage. The icosahedral structure of **2** was found to have an interesting distortion in which the methyl groups are displaced slightly towards the C1–C1 axis. This was measured by comparing the angle between a line drawn from a boron vertex to the center of the molecule and the C1–C1 axis with the angle between a line drawn from the carbon of the respective methyl group to the center and the same axis (average C1-midpoint-B 64.0°, average C1-midpoint-C_{Me} 61.6°). The displacement of the methyl groups is accompanied by a compression of the cage at the CH poles, shown by a markedly short C1–C1 distance of 3.014(5) Å as compared with that of other structurally characterized 1,12-dicarbaboranes (3.065(5)–3.219(14) Å).[4a, 11] Both observations are attributed to a "roll-over" effect on the sp-hybridized boron orbitals in the cage due to steric repulsions between the methyl groups accompanied by a corresponding displacement of tangential p orbitals in the icosahedral surface. Similar distortions have been noted in the recent structural characterization[11] of deca-*B*-iodo-1,12-

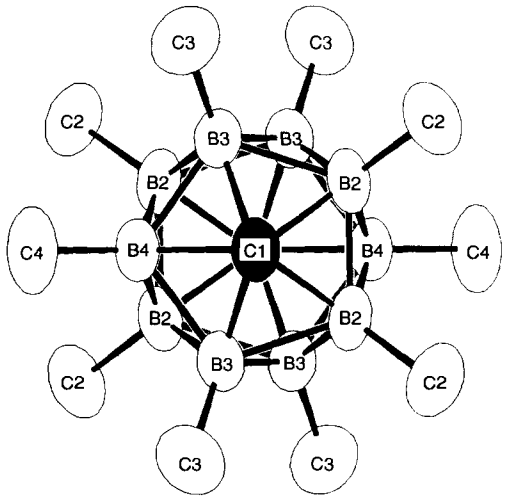

Fig. 2. Crystal structure of **2** (ORTEP representation) along the C1–C1 axis, showing the crystallographic numbering scheme. Hydrogen atoms are omitted. Compound **2** has crystallographically imposed C_{2h} symmetry. Selected bond lengths: B–C range 1.701(5)–1.712(7) average 1.707(4), B–B range 1.767(6)–1.798(5) average 1.785(7), B–C_{Me} range 1.577(5)–1.588(6) average 1.583(5). C1–C1 cross cage distance 3.014(5) Å.

dicarba-*closo*-dodecaborane(12),[12] whose structure resembles that of **2**.

Despite the diminished accessibility of the carbon vertices of the derivatives of deca-*B*-methyl-1,12-dicarba-*closo*-dodecaborane(12) described here, preliminary studies suggest that some further reactions are possible at these positions. Alternatively, the introduction of suitable groups to the carbon vertices prior to methylation of the boron vertices provides synthetic possibilities. Radical halogenation of the methyl groups might form the foundation of a fascinating chemistry formulated around a reactive "sphere" of organic functional groups. We are currently exploring these and other approaches directed towards a new class of carborane-based multifunctionalized compounds.

Experimental Procedure

General laboratory procedures were as described previously [11]. All reactions were carried out under N_2. It was generally found that yields were maximized when the smallest possible volume of experimental apparatus was used.

1: A solution of 1,12-dimethyl-1,12-dicarba-*closo*-dodecaborane(12) (50 mg, 0.35 mmol) in neat methyl triflate (0.4 mL, 3.5 mmol) and triflic acid (0.1 mL, 0.06 mmol) was heated at reflux for 20 h. After cooling, a saturated solution of sodium chloride in water was added (10 mL) and the product was extracted with diethyl ether (3 × 10 mL). The ethereal solution was dried over anhydrous magnesium sulfate and then solvent was removed in vacuo. The crude product was taken up in 5 mL of pentane and passed through a bed of silica gel. Removal of solvent under reduced pressure yielded **1** as a white solid (83 mg, 91%). M.p. 347–348 °C (sealed capillary); ^1H NMR (360 MHz, $CDCl_3$): $\delta = 0.79$ (s, 6H, CCH_3), −0.09 (br s, 30H, BCH_3); $^{13}C\{^1H\}$ NMR (90.5 MHz, $CDCl_3$): $\delta = 76.4$ (CCH_3), 13.1 (CCH_3), −4.0 (vbr, BCH_3); ^{11}B NMR (160.5 MHz, Et_2O): $\delta = -7.4$ (BCH_3); HRMS (EI) (*m/z*), calcd. 312.3820, found 312.3822 (M^+).

2: In a similar fashion, a solution of 1,12-dicarba-*closo*-dodecaborane(12) (100 mg, 0.7 mmol) in methyl triflate (0.8 mL, 7.0 mmol) and triflic acid (0.1 mL, 0.06 mmol) was heated at reflux for 10 h. Workup as for **1** afforded **2** as a white solid (176 mg, 89%). M.p. 232–233 °C (sealed capillary); ^1H NMR (360 MHz, $CDCl_3$): $\delta = 2.01$ (br s, 2H, CH), 0.05 (br s, 30H, BCH_3); $^{13}C\{^1H\}$ NMR (90.5 MHz, $CDCl_3$): $\delta = 74.5$ (CH), −3.7 (vbr, BCH_3); ^{11}B NMR (160.5 MHz, Et_2O): $\delta = -8.8$ (BCH_3); HRMS (EI) (*m/z*), calcd. 284.3507, found 284.3508 (M^+).

3: In a similar fashion, a solution of 1-methyl-1,12-dicarba-*closo*-dodecaborane(12) (43 mg, 0.27 mmol) in methyl triflate (0.3 mL, 2.7 mmol) and triflic acid (0.1 mL, 0.06 mmol) was heated at reflux for 10 h. Workup as for **1** afforded **3** as a white solid (49 mg, 60%). M.p. 308–309 °C (sealed capillary); ^1H NMR (360 MHz, $CDCl_3$): $\delta = 1.98$ (br s, 1H, CH), 0.77 (s, 3H, CCH_3), 0.04, −0.09 (br s, 2 × 15H, BCH_3); $^{13}C\{^1H\}$ NMR (90.5 MHz, $CDCl_3$): $\delta = 76.2$ (CCH_3), 73.7 (CH), 13.1 (CCH_3), −3.0, −3.8 (vbr, BCH_3); ^{11}B NMR (160.5 MHz, Et_2O): $\delta = -7.6$, −9.0 (5B, BCH_3); HRMS (EI) (*m/z*), calcd. 298.3663, found 298.3660 (M^+).

4: In a similar fashion, a solution of 1-bromo-1,12-dicarba-*closo*-dodecaborane(12) (100 mg, 0.45 mmol) in methyl triflate (0.5 mL, 4.5 mmol) and triflic acid (0.1 mL, 0.06 mmol) was heated under reflux for 10 h. Workup as for **1** afforded **4** as a white solid (145 mg, 89%). M.p. 251 °C (decomp) (sealed capillary); ^{1}H NMR (360 MHz, $CDCl_3$): δ = 2.11 (br s, 1H, CH), 0.04, 0.09 (br s, 2 × 15H, BCH_3); $^{13}C\{^1H\}$ NMR (90.5 MHz, $CDCl_3$): δ = 76.2 (CH), 72.7 (CBr), −2.3, −3.6 (vbr, BCH_3); ^{11}B NMR (160.5 MHz, Et_2O): δ = −7.2, −9.7 (5B, BCH_3); HRMS (EI) (*m/z*), calcd. 364.2591, found 364.2602 (M^+).

[10] Crystallographic data for **1**: $C_{14}H_{36}B_{10}$, M = 312.60, cubic, space group $Pa3$, a = 12.859(1) Å, V = 2126 Å^3, Z = 4 (1/6 molecule per asymmetric unit), ρ_{calcd} = 0.98 g cm^{-3}, T = 25 °C, μ = 3.0 cm^{-1}. Data were collected on a Syntex P$\bar{1}$ diffractometer using $Cu_{K\alpha}$ radiation (λ = 1.5418 Å) to a maximum 2θ = 115°, giving 484 unique reflections, of which 370 reflections with $I > 3\sigma(I)$ were retained for structure analysis. The data were corrected for Lorentz and polarization effects and for secondary extinction but not for absorption. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions. The final discrepancy index was R = 0.085, R_w = 0.110. Because of the high symmetry required by this space group for the molecule, there is disorder, and one of the two unique icosahedral atoms has been described as carbon with 1/3 occupancy and boron with 2/3 occupancy and with both carbon and boron constrained to the same values of x, y, z, and displacement parameters. The largest peak on a final difference electron density map was 0.9 e Å^{-3}. Crystallographic data for **2**: $C_{12}H_{32}B_{10}$, M = 284.54, orthorhombic, space group $Ccmb$ (No. 64, standard setting $Ccma$), a = 13.930(3), b = 15.440(3), c = 9.089(3) Å, V = 1954.9(8) Å^3, Z = 4, ρ_{calcd} = 0.97 g cm^{-3}, T = 25 °C, μ = 2.90 cm^{-1}. Data were collected on a Rigaku AFC5 diffractometer using $Cu_{K\alpha}$ radiation (λ = 1.5418 Å) to a maximum 2θ = 110°, giving 650 unique reflections, of which 488 reflections with $I > 3\sigma(I)$ were retained for structure analysis. The data were corrected for Lorentz and polarization effects and for secondary extinction but not for absorption. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically. Methyl hydrogen atoms were included in calculated positions, and the carboranyl hydrogen atom was included in the located position. The final discrepancy index was R = 0.077, R_w = 0.119. The largest peak on a final difference electron density map was 0.11 e Å^{-3}. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

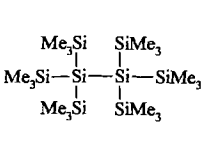
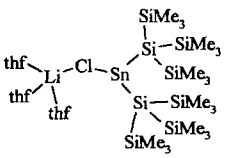
Bis(hypersilyl)tin and Bis(hypersilyl)lead, Two Electron-Rich Carbene Homologs**

Karl Wilhelm Klinkhammer* and Wolfgang Schwarz



Dedicated to Professor Peter I. Paetzold on the occasion of his 60th birthday

Molecular compounds of divalent tin and lead (stannylenes and plumbylenes, respectively) with solely electropositive σ-bonded substituents tend to oligomerize or to disproportionate, respectively. It has previously been possible to stabilize such systems by introduction of sterically demanding groups or additional coordinative saturation of the central atom. Typical examples are bis(trimethylsilyl)methyl and bis(trimethylsilyl)-amino derivatives,[1, 2] stannylenes and plumbylenes bearing aryl substituents,[3, 4] or intermolecularly donor-stabilized compounds such as $Sn[P(CMe_3)_2]_2$[5a] or $Sn[E(SiMe_3)_2]_2$ (E = P, As).[5b, c] Furthermore, several heteroleptic plumbylenes and stannylenes are known.[6] In the solid state the homoleptic stannylenes are either dimeric or monomeric, in the gas phase those studied to date have only been monomeric. The corresponding lead compounds were observed as monomers in all aggregate states.[7] Stannylenes and plumbylenes with stronger electropositive substituents were to date unknown. The synthesis and the structural characterization of two such derivatives, namely bis(hypersilyl)tin (**1**), and bis(hypersilyl)lead (**2**), is the subject of this communication.



$Sn[Si(SiMe_3)_3]_2$ **1**

$Pb[Si(SiMe_3)_3]_2$ **2**

Geanangel et al. reported in 1992 on the attempt to synthesize **2** from lead(II) chloride and the thf solvate of hypersilyllithium. However, in the course of a redox process they obtained 1,1,1,4,4,4-hexamethyl-2,2,3,3-tetrakis(trimethylsilyl)tetrasilane (**3**) and lead only.[8] It also proved not possible to synthesize the corresponding stannylene **1** by this process;[9a] however, a product that could be described as an LiCl adduct of **1** was isolated, namely the heteroleptic lithium stannanide **4**.[9b]

3

4

Recently, during the synthesis of a hypersilylthallium compound we avoided similiar problems by replacing thallium chloride with thallium bis(trimethylsilyl)amide.[10] Thus, we tried to apply the same method to synthesizing the desired tin(II) and lead(II) compounds.

If lead bis[bis(trimethylsilyl)amide] is treated with the hypersilyl derivative of a heavy alkali metal[11] in *n*-pentane at −60 °C, a clear blue solution is produced together with an al-

[**] We thank Prof. Dr. G. Becker for his splendid support. – For the term "hypersilyl" see citation 5 in ref. [10].

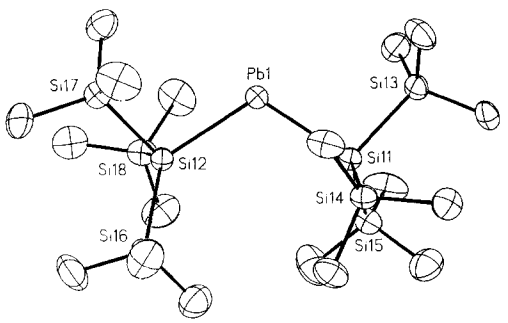
most colorless crystal paste. From this solution black, coffin-lid shaped crystals precipitate on concentration and cooling to $-60\,^{\circ}C$.

The correct elemental analysis and the molecular ion identified as the heaviest ion by mass spectrometry confirm the identity of the compound as **2**. ^{1}H, and ^{13}C NMR spectra of freshly prepared solutions of the diamagnetic compound show the expected singlets. After a short while, however, one observes the appearance of further resonances, which according to reference samples originate mostly from silane **3**. An absorption measurement in the UV/Vis range showed in addition to some intensive bands which are also found in other hypersilyl derivatives in the areas below 350 nm, two further, less intensive absorptions at 578 ($\varepsilon = 620$) and 1056 nm ($\varepsilon = 370$).

A reaction carried out in an analogous way with tin bis[bis(trimethylsilyl)amide] gave initially a green, and then later a violet-brown solution[12] from which, small black quadratic crystal platelets crystallized at $-60\,^{\circ}C$. Here too the elemental analysis gave correct results and the molecular ion could be identified by mass spectrometry as that for **1**. While as expected a singlet appears in the ^{1}H and ^{13}C NMR spectra of the diamagnetic[13] compound, it was not possible to obtain any satisfying ^{29}Si or ^{119}Sn NMR spectra in the temperature range between -60 and $+30\,^{\circ}C$. Therefore, at present it is not possible to make any statements concerning aggregation in solution by NMR spectroscopy. The UV/Vis spectrum is similiar to that of **2**. However, the absorption maxima (559 nm ($\varepsilon = 580$) and 838 nm ($\varepsilon = 120$)) are shifted to shorter wavelengths as could be expected. As no further absorptions occur even with more concentrated samples, the tin compound **1** is assumed to be largely monomeric in solution as is the lead compound **2**. A cryoscopic molar mass determination confirmed these presumptions.

The crystal structure analyses carried out to elucidate the constitution of the compounds show them to be the expected bis(hypersilyl)lead (**2**) and bis(hypersilyl)tin (**1**). While the lead compound is monomeric,[7a] bis(hypersilyl)tin dimerizes in the solid state to the distannene, tetrakis(hypersilyl)ditin (*Sn–Sn*) $(\mathbf{1})_2$.

The molecules of compound **2** (Fig. 1), like the other structurally characterized molecular lead(II) compounds, are bent



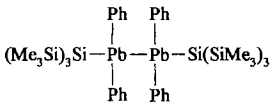


Fig. 1. Molecular structure of **2** in the crystal (thermal ellipsoids at 50% probability level). Selected bond lengths [pm] and angles [°] of one of four symmetry-independent molecules: Pb1–Si11 270.0(3), Pb1–Si12 270.4(3), Si11-Pb1-Si12 113.56(10), Pb1-Si11-Si13 99.6(2), Pb1-Si11-Si14 104.8(2), Pb1-Si11-Si15 125.0(2), Pb1-Si12-Si16 129.2(2), Pb1-Si12-Si17 98.3(2), Pb1-Si12-Si18 101.62(2).

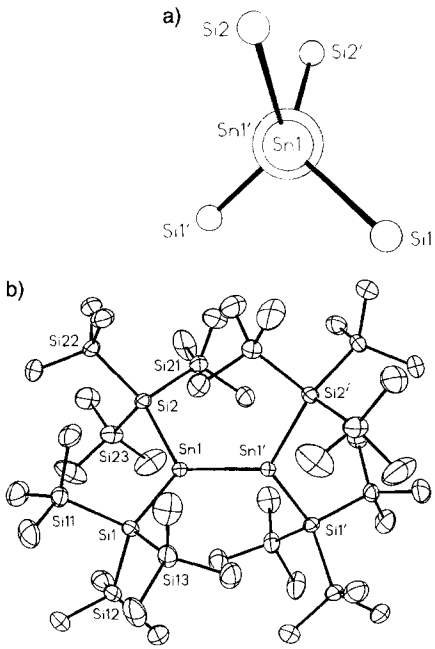
monomers. The Si-Pb-Si angles determined lie between 113.6 and 115.7° and are therefore considerably more obtuse than in other plumbylenes[8] studied so far. The Pb–Si bond lengths vary only slightly between 268 and 271 pm and are about 5 pm longer than those in bis[(hypersilyl)diphenyllead](*Pb–Pb*) (**5**),[15] the only structurally characterized silyl-substituted lead compound to date.

5

That overloading of the central atom in **2** with the very voluminous hypersilyl substituents has a distinct influence on the geometry of the molecule can be recognized by a considerable tilting of this substituent towards the Pb–Si bond axis. Thus, in addition to two Pb-Si-Si angles compressed to nearly 90°, one angle is widened up to 130°. A similiar although less pronounced variance is observed for the Si-Si-Si angles.

The $Si_2Sn–SnSi_2$ backbone (Fig. 2a) of the bis(hypersilyl)tin dimer $(\mathbf{1})_2$ (Fig. 2b) shows a unique strongly distorted *trans*-



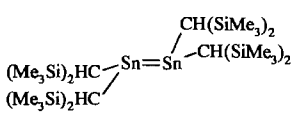


Fig. 2. a) Newman projection of the Sn_2Si_4-framework of $(\mathbf{1})_2$. b) Molecular structure of $(\mathbf{1})_2$ in the crystal (thermal ellipsoids at 50% probability level). Selected bond lengths [pm] and angles [°]: Sn1–Sn1' 282.47(6), Sn1–Si1 266.67(11), Sn1–Si2 267.81(11), Si1-Sn1-Sn1' 108.25(3), Si2-Sn1-Sn1' 123.25(3), Si1-Sn1-Si2 120.46(4), Sn1-Si2-Si21 106.19(5), Sn1-Si2-Si22 131.88(6), Sn1-Si2-Si23 99.78(5), Sn1-Si1-Si11 112.06(5), Sn1-Si1-Si12 115.51(5), Sn1-Si1-Si13 112.35(5).

bent conformation (crystallographic *C*2 symmetry). The dihedral angle (τ) between the planes defined by a tin atom and the central silicon atoms of the bound hypersilyl group is 63.2°, the angle (κ) between these planes and the Sn–Sn bond 28.6°. In the only structurally characterized stannylene dimer to date, the bis(trimethylsilyl)methyl derivative **6**,[1] Lappert et al observed the theoretically expected[7b] undistorted *trans*-bent arrangement ($\tau = 0°$; $\kappa = 41°$). Torsions about the central element–element bond, although considerably less pronounced, have so far only been detected in related sterically strongly loaded alkenes, disilenes, and digermenes.[16] As expected, the Sn–Sn distance in $(\mathbf{1})_2$[7b] is longer than in **6** and lies with 282 pm in the range of "normal" Sn–Sn single bonds in distannanes.[17] The Sn–Si bond lengths and the Si-Sn-Si angle in $(\mathbf{1})_2$ do not differ much from the values of the lithium stannanide **3** synthesized by Cowley et al.[9b]

6

Experimental Procedure

1: A solution of $Sn[N(SiMe_3)_2]_2$ (1.53 g, 3.49 mmol) in *n*-pentane at $-60\,^{\circ}C$ was quickly added to a thoroughly stirred suspension of $KSi(SiMe_3)_3$ (2.00 g, 6.97 mmol) [11] in *n*-pentane (20 mL). The resulting lime green mixture was stirred for 1 h at this temperature and then for 30 min at $0\,^{\circ}C$. The resulting violet-brown solution was pipetted off from the colorless crystal paste and concentrated to 10 mL by removal of the solvent under vacuum. After 15 h at $-60\,^{\circ}C$ black crystal platelets of $(\mathbf{1})_2$ precipitated from the solution (1.22 g, 1.99 mmol, yield 57%). Decomp. $130\,^{\circ}C$; correct elemental analysis; ^1H NMR (250.133 MHz, [D$_6$]benzene, $27\,^{\circ}C$, TMS): $\delta = 0.60$, $^2J(Si,H) = 6.1$ Hz; ^{13}C NMR (62.896 MHz, [D$_6$]benzene, $27\,^{\circ}C$, TMS): $\delta = 5.5$; EI-MS (70 eV; sample 360 K; source 510 K): *m/z* (%): 73 (100) $[Me_3Si^+]$, 247 (7) $[(Me_3Si)_3Si^+]$, 541 (2.7) $[M^+ - 73]$, 614 (1.3) $[M^+]$.

2: The reaction was carried out in a way similar to that for $(\mathbf{1})_2$ [$KSi(SiMe_3)_3$ (2.00 g, 6.97 mmol) and $Pb[N(SiMe_3)_2]_2$ (1.84 g, 3.49 mmol], however, because of the better solubility of the product the solution should be concentrated to 5 mL. After 15 h at $-60\,^{\circ}C$, black, coffin-lid shaped crystals of **2** (1.83 g, 2.60 mmol, 75%) were isolated. Decomp. $152\,^{\circ}C$; correct elemental analysis; ^1H NMR (250.133 MHz, [D$_6$]benzene, $27\,^{\circ}C$, TMS): $\delta = 0.54$, $^2J(Si,H) = 6.6$ Hz; ^{13}C NMR (62.896 MHz, [D$_6$]benzene, $27\,^{\circ}C$, TMS): $\delta = 8.5$, $^1J(Si,C) = 44.5$; EI-MS (70 eV; sample 350 K; source 400 K): *m/z* (%): 73 (100), 247 (19), 455 (4) $[(Me_3Si)_3SiPb^+]$, 702.2 (1.7) $[M^+]$.

[12] The reaction of bis[bis(trimethylsilyl)amides] with hypersilanides is strongly dependent on the temperature and the solvent. Larger quantities of unknown paramagnetic compounds are formed in pentane above $-30\,^{\circ}C$. In the presence of toluene additional interesting products are found: At temperatures below $-30\,^{\circ}C$ mainly solvated alkali metal tris[tris(trimethylsilyl)silyl]stannanides or -plumbanides are obtained in addition to **1** and **2**, respectively. At higher temperatures the main products are alkali metal derivatives of benzylbis[tris(trimethylsilyl)silyl]stannane or -plumbane.

[13] a) How much distannene $(\mathbf{1})_2$ is already present in the triplet state at room temperature remains an unclarified question. In the EPR spectrum of the solid, no triplet resonances were observed in the temperature range between 4 and 300 K. However, ab initio calculations performed on the model system $(H_3Si)_2Sn-Sn(SiH_3)_2$ reveal only a small energy difference of about 25 kJ mol^{-1} in favor of the singlet state [13b] in the observed $Si_2Sn-SnSi_2$ backbone conformation in the solid, so that a measurable population of the triplet state at room temperature cannot be excluded. b) MP2; quasi-relativistic pseudopotentials on Sn(46e core) and Si(10e core) and appropriate basis sets from G. Igel-Mann, H. Stoll, H. Preuss, *Mol. Phys.* **1988**, *65*, 1321; basis sets for H from T. H. Dunning, *J. Chem. Phys.* **1970**, *19*, 553.

[14] Crystal structure analyses: $(\mathbf{1})_2$: $a = 27.884(3)$ $b = 13.106(1)$, $c = 23.173(2)$ Å, $\beta = 126.203(6)^{\circ}$, $V = 6833.5(1)$ Å^3, $Z = 4$, monoclinic, space group $C2/c$ (no. 15), $F(000) = 2592$, $\rho_{calcd} = 1.194$ g cm^{-3}, $\mu = 1.03$ mm^{-1}, four-circle diffractometer $P2_1$ (Syntex), $3^{\circ} < 2\theta < 56^{\circ}$, $Mo_{K\alpha}$, Wyckoff scan, $T = -100\,^{\circ}C$, $N(hkl) = 8519$, from which $7364 > -1\sigma(I)$, Lorenz- and polarization correction, no absorption correction. The structure was solved by direct methods (SHELXS-86) refined with full-matrix least squares based on F_o^2 values (SHELXL93) ($(\mathbf{1})_2$ surprisingly crystallizes isotypically to tetrakis(hypersilyl)dithallium(*Tl–Tl*) which comprises two valence electrons less [10]). Sn, Si, and C atoms were refined anisotropically; the hydrogen atoms, except those which belong to a disordered trimethylsilyl group were found und their positional parameters were freely refined. The tin atom is slightly disordered; the occupation factor for the major position refined to 0.9812(9). 433 parameters, 57 restraints, residual electron density: 0.776/−0.621 e Å^{-3}, $R1[F_o > 4\sigma(F_o)] = 0.044$, $wR2 = 0.091$, GOF = 1.10. **2**: $a = 16.222(3)$, $b = 22.130(3)$, $c = 22.380(4)$ Å, $\alpha = 110.61(3)$, $\beta = 100.57(3)$, $\gamma = 100.35(3)^{\circ}$, $V = 7127(1)$ Å^3, $Z = 8$, triclinic, space group $P\bar{1}$ (no. 2), $F(000) = 2848$, $\rho_{calcd} = 1.309$ g cm^{-3}, $\mu = 5.04$ mm^{-1}, four-circle diffractometer $P2_1$ (Syntex), $6.5^{\circ} < 2\theta < 45^{\circ}$, $Mo_{K\alpha}$, Wyckoff scan, $T = -100\,^{\circ}C$, $N(hkl) = 18628$, from which $18406 > -3\sigma(I)$, Lorenz and polarization correction, empirical absorption correction (ψ scan, min./max. transmission: 0.63/0.99). All the examined crystals were twinned about (1 0 $\bar{1}$) by pseudomeroedry. In the individual used for the final structure solution, the refined volume proportion of the minority component was however very small [0.0131(5)]. The structure was solved by direct methods (SHELXS-86) refined with full-matrix least squares based on F_o^2 values (SHELXL93). Pb, Si, and C atoms were refined anisotropically; the hydrogen atoms were calculated at ideal positions and included in the refinement according to a riding model (AFIX 137) with fixed isotopic displacement parameters. In two out of four symmetry independent molecules the lead atom shows a positional disorder which was carried by a split model calculation. 1068 parameters, 64 restraints, residual electron density: 1.874/−1.074 e Å^{-3}, $R1[F_o > 4\sigma(F_o)] = 0.067$, $wR2 = 0.141$, GOF = 1.10. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-141531 $(\mathbf{1})_2$ and CSD-141530 (**2**).

Transition Metal Catalyzed Diboration of Vinylarenes**

R. Thomas Baker,* Paul Nguyen, Todd B. Marder,* and Stephen A. Westcott*

Dedicated to Dr. George W. Parshall on the occasion of his 65th birthday

Following the discovery of rhodium-catalyzed hydroboration of alkenes and alkynes,[1] subsequent studies have investigated analogous metal-mediated additions of boron–heteroatom bonds.[2] Although tetraalkoxydiboranes cannot be added to C–C multiple bonds by conventional reactions,[3] a report published by Suzuki et al. in 1993 described a platinum-catalyzed variant using a bis(pinacolate) derivative.[2d] Unfortunately,

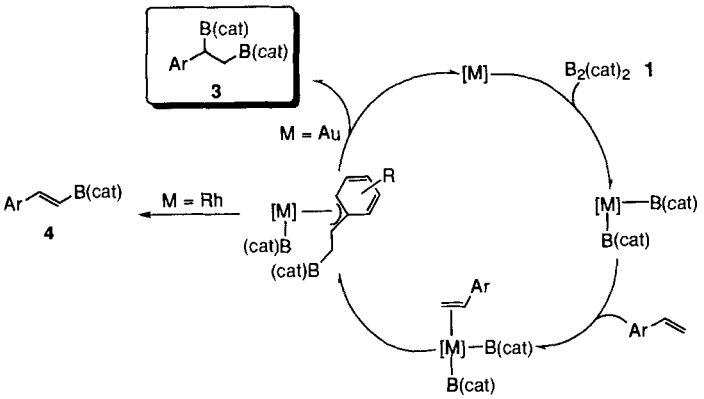
this catalyst system was limited to the diboration of alkynes; alkenes failed to react. The catalyzed diboration of alkenes to 1,2-bis(boronate) esters could provide a new route to a wide variety of 1,2-bifunctional organic compounds.[4] Reactivity studies of bis(boryl)rhodium complexes[5a] and the observation of B–B oxidative addition to Rh^I centers[5b] prompted us to investigate the Rh-catalyzed diboration of vinylarenes using $B_2(cat)_2$ (**1**) (cat = 1,2-$O_2C_6H_4$).[6] We report herein the first examples of metal-catalyzed addition of B–B bonds to C=C bonds.

Metal-catalyzed addition of **1** to 4-vinylanisole (**2**) was monitored by ^1H and ^{13}C NMR spectroscopy.[7] With typical rhodium hydroboration catalysts such as [$RhCl(PPh_3)_3$], the products consisted mostly of alkenyl- and alkylboronate esters (**4** and **5**) resulting from β-H elimination [Eq. (a)];[8] only 10% of the

1 **2**



3 (10%) **4** (32%) **5** (49%) (a)

desired 1,2-bis(boronate) ester (**3**) was observed.[9] Previous studies indicated that competing β-H elimination pathways could be avoided by use of a rhodium complex with a chelating bis(phosphane) ligand.[10, 11] Indeed, the more active zwitterionic catalyst precursor [Rh(dppb){η^6-(cat)B(cat)}][11] (dppb = butane-1,4-diylbis(diphenylphosphane)) gave the highest yield of **3** observed for any rhodium catalyst (44%). Unfortunately, even this catalyst system suffered from competing β-H elimination (23% **5**, 22% $ArCH_2C[B(cat)]_3$ **6**[7]).[12]

One approach to prevent β-H elimination is to find a catalyst system in which the alkylmetal intermediate is stabilized relative to the alkene metal hydride. As alkenegold complexes are known to be labile and there are no known mononuclear gold hydrides,[13] we examined diborations catalyzed by phosphanegold complexes. In initial studies the complexes [$AuCl(PR_3)_n$] (R = Et, Ph and n = 2, 3) showed little activity, even at 80 °C. We recently reported the preparation of new gold(I) complexes containing bulky, electron-rich bis(phosphane) ligands.[14] Addition of two equivalents of dcpe (ethane-1,2-diylbis(dicyclohexylphosphane)) to commercially available [$AuCl(PEt_3)$] generates a catalyst system that gives *exclusive* formation of the 1,2-bis(boronate) ester.[15]

This new catalyst system reacts selectively with vinylarenes, including electron-poor (4-$CF_3C_6H_4$)CH=CH_2 and some activated alkenes such as allylbenzene.[7] While polar solvents such as *N*,*N*-dimethylformamide increased diboration rates, competing degradation of **1** was also observed. Although we have not yet conducted mechanistic studies, we presume that the electron-rich phosphane is needed for reversible B–B bond activation[2d, 5b, 16] by the monovalent gold center (Scheme 1). Further studies are in progress to elucidate this mechanism and to increase the activity of these phosphanegold catalyst precursors for this new selective route to 1,2-bis(boronate) esters.

Scheme 1. Proposed cycle for metal-catalyzed diborations and the competing β-H elimination when M = Rh.

Experimental Procedure

In a typical Rh-catalyzed diboration reaction, a solution of **2** (34 mg, 0.25 mmol) in 0.5 mL of [D_8]THF was added to a suspension of **1** (60 mg, 0.25 mmol) and 0.01 mmol of catalyst in 0.5 mL of [D_8]THF. The mixture was stirred for 20 h, at which time the ^1H, ^{13}C, and ^{11}B NMR spectra were recorded. In several instances the ^1H NMR spectrum was rerecorded 4–6 weeks later. No significant changes in product distributions were observed. Product distributions were verified by comparison of the intensities of the OMe resonances in the ^1H and ^{13}C NMR spectra. The 2,2,2-tris(boronate) ester **6** was prepared independently by catalyzed diboration of vinylboronate ester **4**; full details will be published elsewhere.

Diborations using gold complex catalysts were conducted at 80 °C in [D_8]THF for 48 h with 8 mol% catalyst, 1.5 equiv **1**, and 1 equiv vinylarene.

[15] Catalyst lifetime was limited for less bulky bis(phosphane) ligands $(R_2PCH_2)_2$ (R = Et, *i*Pr).
[16] Oxidative addition of $B_2(cat)_2$ to organoplatinum compounds has been reported recently: C. N. Iverson, M. R. Smith, III, *J. Am. Chem. Soc.* **1995**, *117*, 4403.

1,5-Anhydrohexitol Nucleic Acids, a New Promising Antisense Construct**

Arthur Van Aerschot,* Ilse Verheggen, Chris Hendrix, and Piet Herdewijn

Antisense oligodeoxyribonucleotides (ODNs) can be considered a new class of potential therapeutic agents that function by preventing the synthesis of specific proteins by either physical blockage of the translation process or by inducing RNase H mediated cleavage of the mRNA. The major obstacles to the use of these constructs are their low metabolic stability and problems in cellular uptake.[1] It is clear this therapeutic approach could benefit from the availability of modified oligonucleotides that efficiently block translation by formation of very stable complexes with their target.

Of the many modifications in the ODN structure,[2] only few give an increase in duplex stability.[3] Among these, the most stable (albeit triple helix forming) are polyamide linked acyclic nucleic acids or PNAs; however, these also suffer from low solubility in water and limited uptake.[4] A more recent finding are the N3′ → P5′ phosphoramidates, which increase the melting temperature T_m of the duplexes by an average of 2 °C per base pair versus RNA.[5]

Because pyranose ODNs are energetically favored over furanose ODNs (smaller change in entropy during duplex formation), various pyranoses have already been studied.[6] In view of the structural similarity of 1,5-anhydrohexitol nucleoside analogues **1** (Fig. 1) with natural 2′-deoxynucleosides,[7] we have investigated ODNs made of monomers of type **1**. An extra methylene group is inserted between the base moiety and the ring oxygen atom, affording a much less flexible tetrahydropyran skeleton.

The synthesis of 1,5-anhydro-2-(adenin-9-yl)-2,3-dideoxy-D-*arabino*-hexitol (**2**, hA), and its congeners **3** (hT) and **4** (hG) has been described previously.[7] These monomeric units were incorporated into oligomers using phosphoramidite chemistry and standard protecting groups (A: benzoyl, G: isobutyryl); long-chain alkylamine controlled pore glass (CPG) was used as the support.[8, 9]

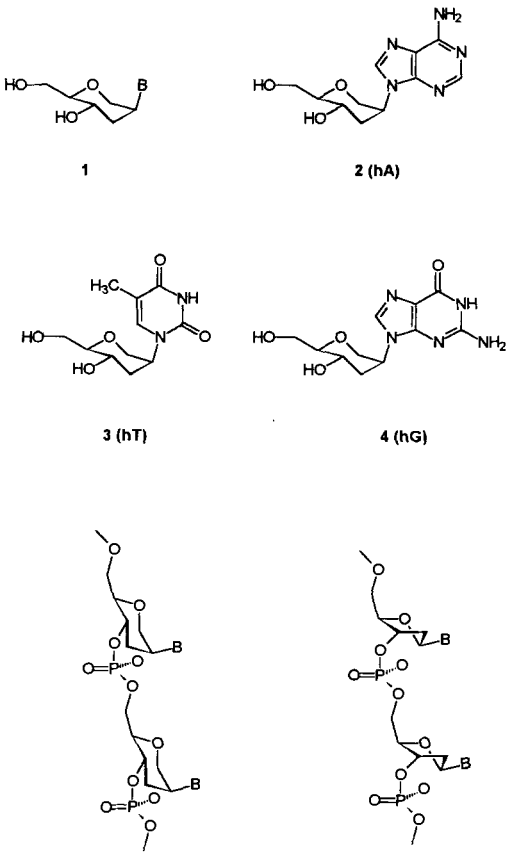

Fig. 1. Structural formulas of the anhydrohexitol monomers, and comparison of the structure of natural DNA (right) and 1,5-anhydrohexitol oligomers (left).

From Table 1 it is clear that incorporation of hA into an oligo(dA) gives nearly the same helix–coil transitions as insertion of a natural dA. Substitution of thymidine by hT into the oligo(dT) gives a substantial decrease in melting temperature, but there is no alteration in base pairing specificity with the 1,5-anhydrohexitol nucleosides.

Table 1. Melting temperatures T_m [°C] for the duplexes formed by oligonucleotides **5**, **6** and **7**, **8** and their respective complementary sequences $(dA)_6N(dA)_6$ and $(dT)_6N(dT)_6$, in which the internal A or T residue Ts scrambled to evaluate base pairing specificity; N = G, C, A, or T (0.1 M NaCl, 20 mM KH_2PO_4, pH 7.5, 0.1 mM EDTA, strand concentration 4 μM of each).

Sequence	T_m			
	G	C	A	T
5	20.0	17.9	18.5	34.0
6	20.2	17.1	17.7	31.9
	G	C	T	A
7	21.0	20.7	21.3	34.0
8	15.1	15.2	18.3	28.6

While adenine–adenine pairing has been described in homo-DNA,[10] we could not observe helix–coil transitions below 90 °C for either **10** or **12** under the physiological conditions studied here (Fig. 2). By measuring the thermal stability of homopolymer mixtures **12**·**7** and **10**·**5** (Table 2), we observed the

Fig. 2. Formulas of the oligonucleotides discussed in the text.

Table 2. T_m values [°C] (hyperchromicity H [%]) of melting curves (260 nm) of modified ODNs ($c = 4\,\mu M$) in 0.1 M NaCl buffer and their enzymatic stability ($t_{\frac{1}{2}}$[min]).

Sequence	Complement	T_m (H)	$t_{1/2}$ [a]
9	**5**	27.6 (32)	>120
10	**5**	45.4 (49) [b]	S [c]
11	**7**	30.3 (33)	>120
12	**7**	21.0 (49)	S [c]
10	**12**	76.3 (ND) [d]	
7	**5**	34.0 (35)	4

[a] Determined by hyperchromicity (260 nm) at 37 °C in 1 mL of 200 mM Tris · HCl, pH 8.6, 200 mM NaCl, 28 mM $MgCl_2$ with 0.04 U of SV PDE (*Crotalus Adamanteus* venom, Pharmacia) for 0.4 OD_{260}. [b] Measured at 284 nm. [c] Completely stable under the reaction conditions for 24 h. [d] Could not be determined due to the high melting temperature.

formation of complexes between a completely modified hexitol nucleic acid (HNA) and natural DNA. Respective melting temperatures of 21 and 45 °C were observed for the two homopolymer mixtures, in comparison with a T_m of 34 °C for the control duplex **7**·**5**. The T_m of **10** was determined at 284 nm, because the thermal behavior of the complex at 260 nm indicated that the oligo(hT)·oligo(dA) association does not have a classical helix structure. The UV absorption first decreases at 260 nm, shows a minimum at 46 °C, and then increases (Fig. 3).

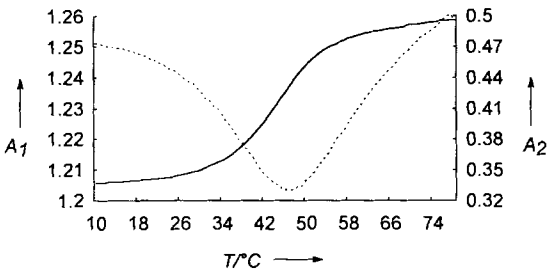

Fig. 3. T_m values of the duplex **10**·**5** in 0.1 M NaCl as determined at 260 nm (solid curve) (A_1) and at 284 nm (dashed line) (A_2). Both curves show an inflection point at 45–46 °C. A = absorption with 4 μM **10** and 4 μM **5**.

The modified oligonucleotides **10** and **12** are completely stable against snake venom phosphodiesterase (SV PDE), while the natural oligonucleotides **5** and **7** are degraded within minutes (Table 2). Substitution with two hA monomers at either end as in **11**, likewise afforded very stable ODNs. SV PDE is a 3′-exonuclease, and 3′-exonuclease activity is the major cause of degradation of ODNs in serum.[11]

A hexamer and a dodecamer (Table 3) consisting of a mixed purine sequence containing hA and hG clearly provide more stable duplexes with both DNA and RNA than their natural counterparts do. The observed T_m values are not the result of

Table 3. T_m values [°C] (hyperchromicity [%]) of fully modified oligonucleotides ($c = 4\,\mu M$) in 0.1 M NaCl, 20 mM KH_2PO_4 pH 7.5, 0.1 mM EDTA. Duplexes were formed with either DNA or RNA complementary sequences.

Sequence	DNA complement	RNA complement
13	31.2 (9.5) [a]	44.8 (13)
14	10.0 [a, b]	10.5 [b]
15	64.8 (14)	84.0 (>15 [b])
16	49.0 (19)	47.6 (15)

[a] Determined in 1 M NaCl. [b] Could not be determined due to the either low or high melting temperature.

self-association of the HNAs, since they do not display any hyperchromicity alone under these conditions. For the HNA–DNA duplex an increase in the T_m value of 16 °C for dodecamer **15** and 21 °C for hexamer **13** was noticed. The ΔT_m value per base pair is clearly dependent on the sequence. For HNA–RNA duplex formation, the increase relative to the DNA–RNA control duplex is even more pronounced: 36 °C for the dodecamer and 34 °C for the hexamer. An HNA–RNA duplex is thus more stable than an HNA–DNA duplex, which further underlines the potential of HNAs as antisense ODNs. The increase in the T_m value of 3 °C to 5.5 °C per base pair indicates the very strong interaction of these HNAs with complementary oligoribonucleotides.

These results indicate that ODNs containing 1,5-anhydrohexitol building blocks form very stable complexes with DNA and RNA and are enzymatically stable. Therefore these new constructs fulfill at least two requirements of an ideal antisense construct.

Diborylcarbenes as Reactive Intermediates in Double 1,2-Rearrangements with Low Activation Enthalpies**

Matthias Menzel, Heinz Jürgen Winkler, Tesfay Ablelom, Dirk Steiner, Stefan Fau, Gernot Frenking, Werner Massa, and Armin Berndt*

Dedicated to Professor Karl Dimroth on the occasion of his 85th birthday

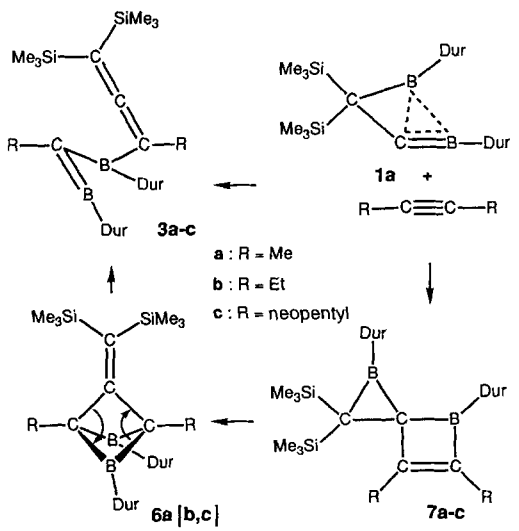
The topomerization of boriranylideneboranes **1**,[1] according to calculations by Schleyer et al.,[2] occurs via cyclic diborylcarbenes **2** as reactive intermediates. A C–C and a C–B bond of the skeleton (Scheme 1, see arrows, double 1,2-rearrangement) are broken under very mild conditions ($\Delta G^{\neq}$ = 11–13 kcal mol^{-1}).

R^1 = tBu, Mes = 2,4,6-trimethylphenyl, Dur = 2,3,5,6-tetramethylphenyl

R^2 = Me (**a**), Et (**b**), neopentyl (**c**) All = 1-alkyl-3,3-bis(trimethylsilyl)allenyl

Scheme 1. For clarity π and σ delocalizations in **1**–**5** are not shown in the diagram; bonds newly formed by 1,2 rearrangement are drawn in boldface.

Here we report on facile isomerizations of borylmethyleneboranes **3a–c** via open-chain diborylcarbenes **4a–c** to **5a–c**. The 1,2-migration of substituents (Scheme 1, see bent arrows) here replaces the breaking of bonds in the skeleton as in **1** and **2**. This interpretation is supported by the results of MP2/6-31G* calculations for tetramethylborylmethyleneborane **3d** and tetramethyldiborylcarbene **4d**.



The formation of allenylborylmethyleneboranes[1b,3] **3a–c** in the reaction of **1a** with alkynes can be easily explained by cycloreversion (Scheme 2, see arrows) of a four-membered ring in the intermediates **6a–c**. These are formed readily from **7a–c**, the primary products[4] of the reaction of **1a–c** and alkynes, as shown recently for the rearrangement of **7a** into **6a**.[5]

The primary rearrangement product of **6a** at 25 °C is **3a** as shown by trapping with acetone to yield **9**. The probable intermediate **8** undergoes a hydride shift to form **9** (Scheme 3),[6] which has been characterized by NMR spectroscopy (Table 1).

In the absence of a trapping reagent, the rearrangement product of **6a** is not **3a** but the isomer **5a**. The ^{13}C NMR spectra of **5a** show a boron-bound methyl group (broad signal at δ = 2.2) and a carbon-bound duryl group (sharp signal of the *ipso*-carbon atom at δ = 142.9). This indicates that a methyl group has migrated from a carbon to a boron atom, and a duryl group from a boron to a carbon atom. During the isomerization **6a** → **3a** → **5a**, at 25 °C, **3a** can not be detected by NMR spectroscopy. Therefore, the second step (**3a** → **5a**) of the reaction must be faster than the first (**6a** → **3a**), but slower than the trapping reaction (**3a** → **9**, see above). Compound **3b** is formed at −10 °C from **7b** and can be characterized by NMR spectroscopy; signals for **6b** can not be detected. Compound **3b** isomerizes to form **5b** at 30 °C in one hour. X-ray structural analysis of **5b** shows an ethyl group at the boron atom B1, and a duryl group at the carbon atom C1 between the two boron atoms (see Fig. 2 bottom). The isomerization of **3c** into **5c** is so slow that **3c** can be isolated by working quickly at low temperatures. The structure of **3c** has been confirmed by X-ray structural analysis (see Fig. 2 top). The free activation enthalpies of the isomerizations **3** → **5** are determined to be 23.0 for **3c** → **5c**, and 22.0 kcal mol^{-1} for **3b** → **5b**. Thus, $\Delta G^{\neq}$ for the isomerization **3a** → **5a** is concluded to be less than 22.0 kcal mol^{-1}.

MP2/6-31G* calculations[7,8] indicate that the diborylcarbene **4d** is 23.1 kcal mol^{-1} higher in energy than the borylmethyleneborane **3d** (Fig. 1).[9]

We conclude that the rearrangements of **3a–c** → **5a–c** proceed via diborylcarbenes, assuming that the barriers to rearrangement for the diborylcarbenes **4a–c** into the reactants **3a–c** or into the products **5a–c** are low. For the prototype diborylcarbene and for **4d** this assumption has been con-

Scheme 2.

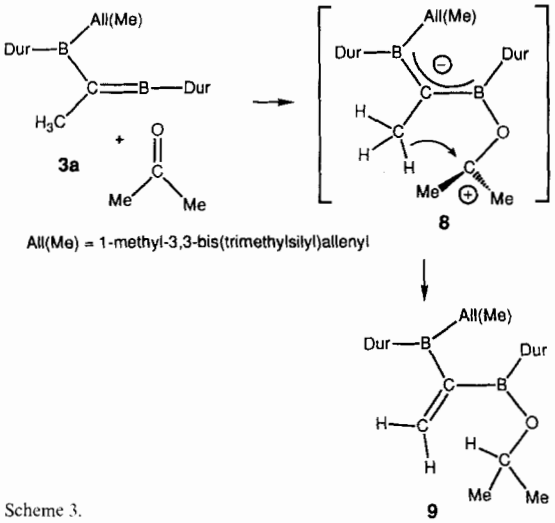
Table 1. Some physical properties of compounds **3b,c**, **5a–c**, **7b**, and **9**.

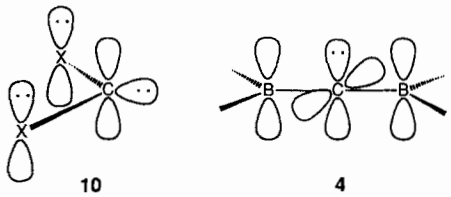
3b: Yield: quantitative by NMR spectroscopy. ^{1}H NMR (400 MHz, $CDCl_3$, 30 °C): δ = 0.14 (s, 18H, $SiMe_3$), 1.04 (br. 6H, CH_2-CH_3), 2.08, 2.28 (each s, each 12H, *o*- and *m*-CH_3), 6.92 (s, 2H, *p*-H). No signal was observed for the CH_2 groups. The equivalence of the duryl groups indicates the rapid shift of the allenyl group from the tricoordinate- to the dicoordinate-boron atom. ^{13}C NMR (100 MHz, $CDCl_3$, −40 °C): δ = 0.3 (q, 6C, $SiMe_3$), 13.4, 16.0, 19.7, 20.6, 21.3, 22.3, 23.7 (some are br., 12C, *o*- and *m*-CH_3 and CH_2-CH_3), 79.9 (s, 1C, CSi_2), 89.9 (br. s, 1C, CB of allene), 103.0 (br. s, 1C, CB_2), 127.6, 137.7 (each br. s, each 1C, *i*-C)), 129.5, 136.3 (each d, each 1C, *p*-C), 131.7, 132.9, 135.6, 143.5 (each s, each 2C, *o*- and *m*-C), ca. 214.0 (1C, middle allene-C). Additionally, at −40 °C the following signals are detected, which we attribute to a rotation isomer of **3b**: 0.5 ($SiMe_3$), 79.4 (CSi_2), 96.1 (br., CB).

3c: colorless crystals, m.p. 58 °C, yield: 55%. ^{1}H NMR (500 MHz, $CDCl_3$, −30 °C): δ = 0.17 (s, 18H, $SiMe_3$), 0.83, 0.93 (each s, each 9H, $C(CH_3)_3$), 1.72, 2.56 (each s, each 2 H, CH_2), 1.85, 2.02, 2.19, (each s, 24H, *o*- and *m*-CH_3), 6.43, 6.89 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): δ = 0.7 (q, 6C, $SiMe_3$), 19.7, 20.7, 21.1, (each q, 8C, *o*- and *m*-CH_3), 29.8, 30.1 (each q, each 3C, $C(CH_3)_3$), 32.5, 32.8 (each s, each 1C, $C(CH_3)_3$), 43.5, 44.1 (each t, each 1C, CH_2), 77.6 (s, 1C, CSi_2), 86.5 (br.s, 1C, CB of allene), 98.4 (br.s, 1C, CB_2), 128.3, 144.3 (each br.s, each 1C, *i*-C), 129.8, 135.6 (each d, each 1C, *p*-C), 131.9, 132.8, 136.7, 142.8 (each s, each 2C, *o*- and *m*-C), 213.7 (s, 1C, middle allene-C). ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 60.



5a: white solid, m.p. 93 °C, yield: 55%. ^{1}H NMR (500 MHz, $CDCl_3$, −40 °C): δ = 0.25, 0.28 (each s, each 9H, $SiMe_3$), 0.72, 1.67 (each s, each 3H, CH_3), 1.98, 2.00, 2.11, 2.16, 2.25 (each s, 24H, *o*- and *m*-CH_3), 6.68, 6.83 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = 1.0, 1.3 (each q, each 3C, $SiMe_3$), 2.2 (br.q, 1C, CH_3(B)), 16.1 (q, 1C, CH_3(C)), 17.2, 20.2, 20.3, 20.6, 21.2, 21.3 (each q, 8C, *o*- and *m*-CH_3), 63.6 (s, 1C, CSi_2), 71.9 (s, 1C, CB of allene), 126.4, 129.9 (each d, each 1C, *p*-C), 128.7, 132.4, 132.9, 134.2, 136.7 (each s, 8C, *o*- and *m*-C), 139.0 (br.s, 1C, *i*-C(B)), 142.9 (s, 1C, *i*-C(C)), 166.4 (br.s, 1C, CB_2), 214.1 (s, 1C, middle allene-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 27.

5b: white solid, m.p. 95 °C, yield: 50%. ^{1}H NMR (500 MHz, $CDCl_3$, −40 °C): δ = 0.21, 0.29 (each s, each 9H, $SiMe_3$), 0.99, 1.06 (each t, each 3H, CH_3(Et)), 1.11–1.16, 1.21–1.24 (each m, each 1H, CH_2(Et)), 1.81–1.85, ca. 2.10 (each m, each 1H, CH_2(Et)), 1.96, 2.03, 2.07, 2.14, 2.17, 2.21 (each s, 24H, *o*- and *m*-CH_3), 6.65, 6.08 (each s, each 1H, each *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = 0.9, 1.0 (each q, each 3C, $SiMe_3$), 10.8 (q, 1C, CH_3(Et)), 11.9 (br.t, 1C, CH_2(B)), 13.2 (q, 1C, CH_3(Et)), 17.2, 20.1, 20.5, 21.1, 21.2 (each q, 8C, *o*- and *m*-CH_3), 21.6 (t, 1C, CH_2(C)), 66.2 (s, 1C, CSi_2), 77.6 (s, 1C, CB of allene), 125.9, 129.7 (each d, each 1C, *p*-C), 128.4, 131.9, 132.7, 133.9, 136.6 (each s, 8C, *o*- and *m*-C), 139.7 (br.s, 1C, *i*-C(B)), 142.8 (s, 1C, *i*-C(C)), 164.3 (br. s, 1C, CB_2), 212.8 (s, 1C, middle allene-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 28.



5c: Oil, after crystallization the product contains decomposition products, yield: quantitative by NMR spectroscopy. ^{1}H NMR (500 MHz, $CDCl_3$, −40 °C): δ = −0.07 (s, 18H, $SiMe_3$), 0.62, 0.69 (each s, each 9H, $C(CH_3)_3$), 0.28, 1.61 (each s, each 2H, CH_2), 1.99, 2.20, 2.22, 2.43 (each s, each 6H, *o*- and *m*-CH_3), 6.70, 6.05 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = 0.7 (q, 6C, $SiMe_3$), 18.4, 20.1, 20.6, 21.2, (each q, 8C, *o*- and *m*-CH_3), 29.4, 30.7 (each q, each 3C, $C(CH_3)_3$), 31.2, 32.4 (each s, each 1C, $C(CH_3)_3$), 40.8 (br.t, 1C, CH_2(B), 41.8 (t, 1C, CH_2), 79.9 (s, 1C, CSi_2), 85.8 (br. s, 1C, CB of allen), 123.9 (br. s, 1C, *i*-C(B)), 126.0, 137.5 (each d, each 1C, *p*-C), 128.6, 131.9, 133.6 (each s, 6C, *o*- and *m*-C), 141.2 (s, 1C, *i*-C(C)), 151.1 (s, 2C, *o*-C), 211.9 (s, 1C, middle allene-C), the signal of the carbon atom that is bound to both boron atoms could not be observed; ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 43.

7b: yellow solid, yield: quantitative by NMR spectroscopy. ^{13}C NMR (100 MHz, $CDCl_3$, −30 °C): δ = 2.7, 3.6 (each q, each 3C, $SiMe_3$), 12.3, 14.2 (each q, each 1C, CH_3(Et)), 19.3, 20.0, 21.1, 22.5 (each q, 8C, *o*- and *m*-CH_3), 20.4, 20.7 (each t, each 1C, CH_2(Et)), 24.8 (s, 1C, CSi_2), 47.9 (br.s, 1C, CB_2), 130.2, 133.4 (each d, each 1C, *p*-C), 132.5, 132.6, 132.7, 135.4, 136.5, 139.5 (each s, 6C, *o*- and *m*-C), 144.5 (br.s, 2C, *o*-C at the three-membered ring), 149.5 (br.s, 1C, *i*-C), 162.7 (s, 1C, =C), 166.2 (br.s, 1C, =CB).

9: pale pink solid, m.p. 106 °C, yield: 59%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.23 (s, 18H, $SiMe_3$), 1.17 (d, 6H, CH_3-*i*Pr), 1.91 (s, 3H, CH_3), 2.16, 2.30 (each s, total 24H, *o*- and *m*-CH_3), 4.14 (m, 1H, C-H-*i*Pr), 5.99, 6.29 (each d, ^2J(H,H) = 5.8 Hz, each 1H, =CH_2), 6.91, 6.97 (each s, each 1H, *p*-H); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 0.5 (q, 6C, $SiMe_3$), 16.4 (q, 1C, CH_3), 19.4 (q, 2C, CH_3-*i*Pr), 20.0, 24.1 (each q, 8C, *o*- and *m*-CH_3), 70.1 (d, ^1J(C,H) = 143 Hz, 1C, C-H-*i*Pr), 77.7 (s, 1C, CSi_2), 87.9 (br. s, 1C, CB of allene), 129.5, 130.6 (each d, each 1C, *p*-C), 132.1, 132.2, 132.7, 134.1 (each s, 8C, *o*- and *m*-C), 140.3, 147.6 (each br. s, each 1C, *i*-C), 143.7 (t, ^1J(C,H) = 154 Hz, =CH_2), 159.6 (br. s, 1C, =CB), 215.2 (s, 1C, middle allene-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 49, 70.

Scheme 3.

Scheme 4.

firmed by calculations: the barriers for rearrangement of H_2B-$\dot{C}$-BH_2 and **4d** are 0.4[10] and > 0.1 kcal mol^{-1}, respectively.

The energy difference between **3d** and **4d** shows that diborylcarbenes **4** are not as high in energy as one may expect, given the three neighboring electron-deficient centers. In contrast to familiar carbenes **10**[11] with π-donor/σ-acceptor substituents (Goddard et al.[12]) diborylcarbenes **4** have π-acceptor/σ-donor substituents (Scheme 4). Following Bent's rule,[13] the σ-acceptor substituents in **10** form a small angle with the carbene-carbon atom, and the lone pair is localized in a low-energy σ orbital with high s character.

The σ-donor substituents in **4** lead to high s character in the bonds to the boron atoms. The lone pair at the carbene-carbon atom in the p orbital parallel to the p orbitals at the boron atoms is stabilized by π delocalization. This is reflected in the short (143.9 pm) B–C(B) bonds of **4d**. The empty p orbital at the carbene-carbon atom lying in the plane of the molecule strongly

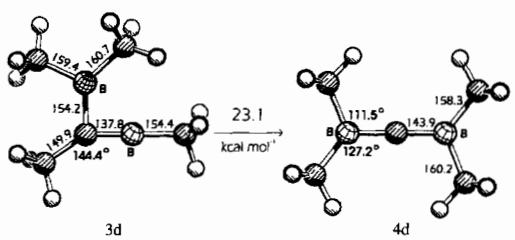


Fig. 1. Calculated geometries (distances in pm) and energy difference of **3d** and **4d**.

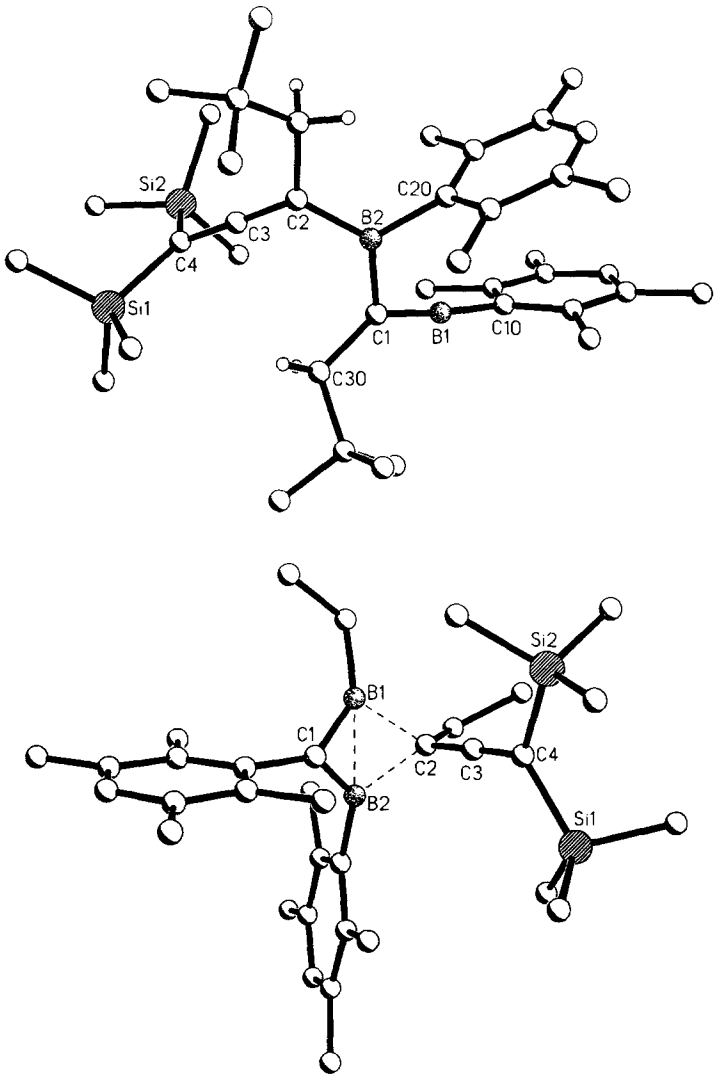
interacts with only one of the two B–CH_3 σ bonds of each of the two dimethylboryl substituents. This is reflected in small and large C-B-CH_3 angles (111.5° and 127.2°) and the elongated B–CH_3 distances (160.2 pm)[14] of the bonds which belong to the small angles. Preference for one of two equivalent σ bonds is characteristic[1b] of electron-deficient centers that interact strongly with neighboring σ bonds.

Figure 2 shows the X-ray crystal structures[15] of **3c** and **5b**. The structure of **5a** corresponds to that of **5b**, be-



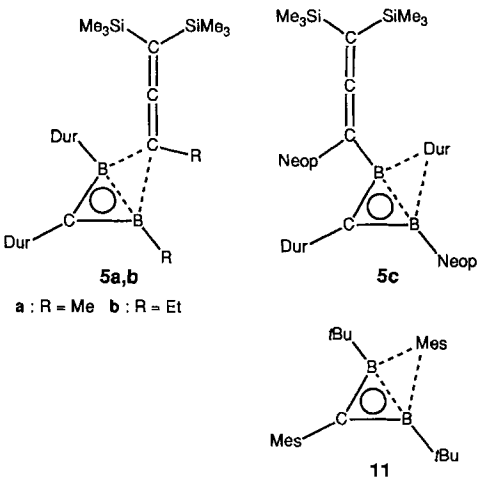


Fig. 2. Crystal structures of **3c** (top) and **5b** (bottom). Selected distances [pm] and angles [°]: **3c**: B1-C1 139.1(3), C1-B2 152.9(3), B2-C2 157.3(3), C2-C3 131.7(3), C3-C4 130.9(3); B1-C1-B2 104.3(2), B1-C1-C30 128.0(2), C30-C1-B2 127.3(2); B1-C1-B2-C2 156.3(2); **5b**: B1-C1 145.0(3), C1-B2 146.1(3), B2-C2 167.5(3), C2-B1 173.1(3), B1-B2 185.1(3), C2-C3 134.5(3), C3-C4 127.3(3); B1-C1-B2 79.0(2), B1-C2-B2 65.8(1), C1-B1-B2-C2, -148.5(2).

cause the chemical shifts of the skeleton atoms of **5a** and **5b** are similar ($\delta^{11}B = 27$ and 28, respectively; $\delta^{13}C = 166.4$ and 164.3, respectively). In contrast to the α-agostically distorted boryl-methyleneborane **3c** (with a B-C-B angle of 104.3°, cf. 91.0° in **3d**), **5a** and **5b** are bridged β-agostically[1b] by allenyl groups (Scheme 5).

The NMR data of the isomerization product of **3c** indicate the presence of the duryl-bridged structure **5c**:

Scheme 5.

the ^{11}B NMR signal at $\delta = 43$ corresponds to that ($\delta = 42$) in mesityl-bridged **11**.[16]

[6] The product of the trapping reaction of **3a** with 2-butyne and the subsequent reaction will be described elsewhere together with related reactions.

[7] The calculations have been carried out using GAUSSIAN 92 [8]. The geometries are fully optimized at the MP2/6-31G* level. The structures have been characterized as minima or transition states by calculation of the harmonic frequencies. The zero point energy (ZPE) corrections have been scaled by a factor of 0.90. The relative energies include the scaled ZPEs.

[8] GAUSSIAN 92, Revision A, M. J. Frisch, G. W. Trucks, M. Head-Gordon, P. M. W. Gill, M. W. Wong, J. B. Foresman, H. B. Schlegel, K. Raghavachari, M. A. Robb, J. S. Binkley, C. Gonzalez, R. Martin, D. J. Fox, D. J. DeFrees, J. Baker, J. J. P. Stewart, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1992**.

[9] The (orthogonal) triplet state of **4d** is a minimum on the potential energy hypersurface; it lies 16.6 kcal mol^{-1} higher in energy than the (planar) singlet state (MP2/6-31G* + 0.90 × ZPE).

[14] In **2** the corresponding interaction of the formally empty orbital at the carbene center, with the strained B–CH_2 σ bonds, leads to their elongation to 168.8 pm [2]. This stronger interaction explains—at least partially—the smaller energy difference between **2** and **1** (10–12 kcal mol^{-1}) compared to that between **4** and **3** (21–23 kcal mol^{-1}).

[15] Crystal structure determinations: yellow crystals of **3c** and colorless crystals of **5b** have been studied on a four-circle diffractometer (CAD4, Enraf-Nonius) at −60 °C (**3c**) and −80 °C (**5b**) with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). **3c**: $C_{40}H_{66}B_2Si_2$, crystal dimensions 0.6 × 0.5 × 0.5 mm^3, monoclinic, space group

$P2_1/n$, $Z = 4$, $a = 1712.0(3)$, $b = 1520.2(3)$, $c = 1776.3(4)$ pm, $\beta = 115.22(3)°$, $V = 4182 \times 10^{-30}$ m^3, $\rho_{calcd} = 0.992$ g cm^{-3}; in the range to $2\theta = 110°$ 5463 reflections have been measured by ω scans; 5244 of the 5251 independent reflections were used after LP corrections; no absorption correction ($\mu = 9.2$ cm^{-1}). The structure was solved by using direct methods and refined against the F_o^2 data using the full matrix. Some H atoms could be localized by difference Fourier synthesis, the others were calculated; they were included riding on their bond partners with groupwise commonly refined temperature factors. For all other atoms anisotropic temperature factors were used. This gave $wR_2 = 0.160$, corresponding to $R = 0.058$ for 4679 reflections with $I > 2\sigma(I)$; the residual electron density was max. 0.32 e Å^{-1}. **5b**: $C_{34}H_{54}B_2Si_2$, crystal dimensions $0.5 \times 0.5 \times 0.3$ mm^3, triclinic, space group $P\bar{1}$, $Z = 2$, $a = 931.1(2)$, $b = 1285.5(3)$, $c = 1636.4(3)$ pm, $\alpha = 70.37(3)$, $\beta = 89.26(3)$, $\gamma = 71.71(3)$, $V = 1742.2 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.030$ g cm^{-3}; in the range to $2\theta = 149°$ 7454 reflections have been measured by $\omega/2\theta$ scans; 7112 of the 7123 independent reflections were used after LP corrections; no absorption correction ($\mu = 10.4$ cm^{-1}). Treatment analogous to **3c** gave $wR_2 = 0.2375$, corresponding to $R = 0.071$ for 5686 reflections with $I > 2\sigma(I)$; the residual electrou density was max. 0.58 e Å^{-1}. Further details of the crystal structure investigations can be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58927.

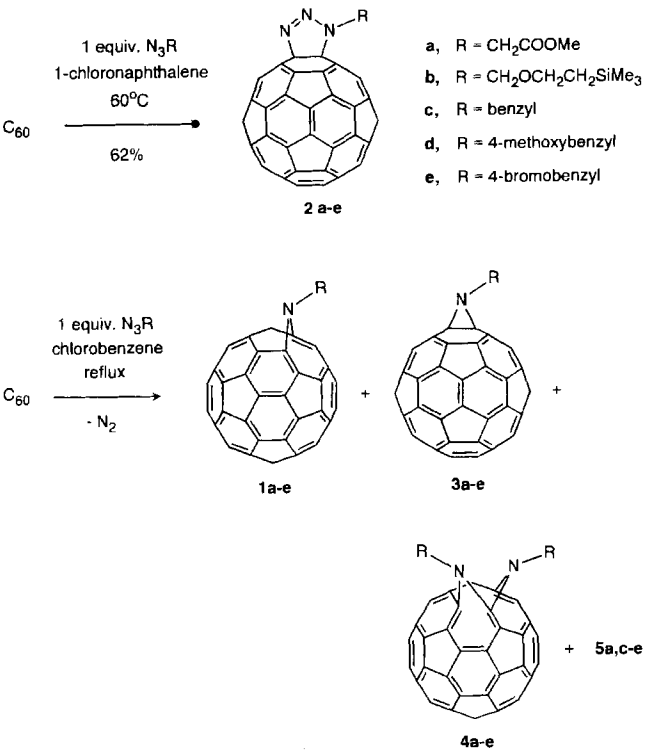
Ring Expansion of the Fullerene Core by Highly Regioselective Formation of Diazafulleroids**



Thomas Grösser, Maurizio Prato,* Vittorio Lucchini,* Andreas Hirsch,* and Fred Wudl*

Investigations on the regioselectivity of multiple additions to C_{60} are currently at the forefront of organic fullerene chemistry.[1] The first step in cycloadditions is always the attack of a double bond common to two six-membered rings (6-6 bonds) of the fullerene framework.[2] Multiple additions to 6-6 bonds show some degree of regioselectivity.[1] Subsequent additions to *e*-positions (octahedral sites), for example, allow the synthesis of highly symmetric hexaadducts.[1d–f] Addition of diazo compounds or azides[4] to C_{60} followed by extrusion of N_2 of the initially formed 6-6-bridged pyrazolines or triazolines leads also to ring-opened 5-6 adducts (fulleroids). In fulleroids $C_{61}R_2$ and $C_{60}NR$ the π-electron system of C_{60} remains intact and the fullerene core contains a bridged nine-membered ring.[3, 4] The expansion or opening of a ring in the C_{60} framework could be a key step for the systematic synthesis of endohedral C_{60} compounds. In this paper we report for the first time on the regiochemistry of additions to fulleroids. We show that diazafulleroids with a further ring expansion (three seven-membered and one eleven-membered ring in the fullerene core) are formed in an extraordinary regioselective pathway. In addition, intermediate triazoline adducts leading to azafulleroids have been isolated.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG), the Bundesministerium für Forschung und Technologie (BMFT), and Hoechst AG. M. P. thanks the Consiglio Nazionale delle Richerche for a travel grant. F. W. wishes to thank National Science Foundation for support (grant DMR91-22536).

We had first synthesized azafulleroids by allowing C_{60} to react with an equimolar amount of azide in chlorobenzene at reflux.[4] As major products we obtained the azafulleroids **1** together with more polar compounds, which were not further characterized. The intermediate triazolines **2** cannot be obtained by this procedure since they readily lose N_2 at elevated temperatures. We have now found that treatment of a concentrated solution of C_{60} in 1-chloronaphthalene with an equimolar amount of methyl azidoacetate at 60 °C yields triazoline **2a** in 62% yield (Table 1). When **2a** is heated in *o*-dichlorobenzene at 100 °C, **1a** is obtained as the major product (24%) together with C_{60} (22%), compound **3a** with an intact 6-6 bond (4%), and bisadduct **4a** (13%). In **4a** two neighboring, open 5-6 bonds are imino bridged. Besides **4a** we obtained only a small amount of another bisadduct **5a**, whose exact structure is not yet known. Bisadducts **4** and **5** are also accessible by the direct synthesis of azafulleroids from C_{60}; these compounds are the more polar side products, which we mentioned earlier.[4] The black microcrystalline compounds **1**–**4** were isolated by flash chromatography. Both **4a** and **5a** are stable in *o*-dichlorobenzene at 100 °C.

The addition of azide to C_{60} seems to be general, as analogous compounds were formed when other azides, for instance substituted benzyl azides RN_3 (R = benzyl, 4-methoxybenzyl, 4-bromobenzyl), were used. The addition of trimethylsilylethoxy methyl azide ($SEMN_3$) to C_{60} is a special case: **4b** is the exclusive bisaddition product. When a dilute solution of C_{60} and excess $SEMN_3$ in chlorobenzene was heated to reflux for approximately 12 h, **4b** formed as the main product (60% based on reacted C_{60}) along with **2b** (30%) and **3b** (10%). The presence of exclusively these three compounds was proved by the ^{1}H NMR spectrum of the crude mixture and by chromatographic separation of the three adducts in the same ratios.

Table 1. Selected spectroscopic data of the new compounds **1a**, **2a**, **3a**, **4a,b**, and **6a**.

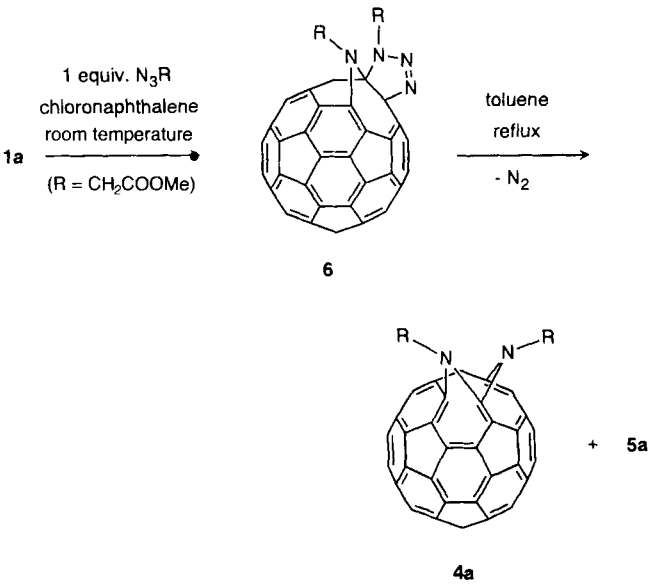
4a: ^{1}H NMR (CS_2/C_6D_6 4/1, 250 MHz): δ = 5.20 (AB-q, *J* = 17 Hz, 1H), 4.32 (AB-q, *J* = 17 Hz, 1H), 3.69 (s, 3H); ^{13}C NMR (CS_2/C_6D_6 4/1, 62.9 MHz): δ = 169.81, 161.00, 147.83, 147.20, 145.82, 145.59, 145.29, 145.25, 144.95, 144.92, 144.58, 144.51, 144.39, 144.30, 144.11, 143.85, 143.70, 142.85, 142.60, 142.02, 141.89, 140.04, 139.93, 139.33, 137.60, 135.61, 134.93, 132.71, 132.53, 131.35, 52.30 (CH_2), 51.83 (CH_3); UV/Vis (cyclohexane): λ_{max} [nm] = 702 (br), 538 (br), 456 (sh), 435 (sh), 327, 259, 212; FD-MS: *m/z*: 894 (M^+).

4b: ^{1}H NMR ($CDCl_3$, 600 MHz): δ = 5.56 (AB-q, 1H, *J* = 9.4 Hz), 5.41 (AB-q, 1H, *J* = 9.4 Hz), 4.14 (td, 1H, *J* = 9.5, 7.1), 3.98 (td, 1H, *J* = 9.5, 7.1), 1.67 (m, 2H), 0.15 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 160.19 (1C), 147.45 (2C), 147.09 (2C), 145.54 (1C), 145.36 (2C), 144.96 (2C), 144.86 (2C), 144.62 (2C), 144.59 (2C), 144.21 (6C), 144.10 (1C), 144.00 (2C), 143.77 (2C), 143.59 (2C), 143.45 (2C), 142.83 (2C), 142.33 (2C), 141.81 (2C), 141.74 (2C), 140.28 (2C), 139.59 (2C), 139.42 (2C), 139.15 (2C), 138.71 (2C), 136.74 (2C), 135.36 (2C), 134.66 (2C), 132.12 (2C), 132.93 (1C), 130.54 (2C), 82.89 (NCH_2O), 66.56 (OCH_2), 18.21 (CH_2Si), −1.24 ($Si(CH_3)_3$); UV/Vis (CH_2Cl_2): λ_{max} [nm] = 545, 430, 331, 261; FAB-MS: *m/z*: 1011 (M^+).



6a: ^{1}H NMR (CS_2/C_6D_6 4/1, 250 MHz): δ = 5.19 (AB-q, *J* = 17 Hz, 1H), 5.08 (AB-q, *J* = 17.4 Hz, 1H), 4.88 (AB-q, *J* = 17.4 Hz, 1H), 4.53 (AB-q, *J* = 17 Hz, 1H), 3.77 (s, 3H), 3.71 (s, 3H); UV/Vis (cyclohexane): λ_{max} [nm] = 694, 558 (sh), 497 (sh), 320, 253, 214; FAB-MS (NBA): *m/z*: 924 (M^+ + 2H).

Bisadduct **4b** is not stable in refluxing chlorobenzene. Heating **4b** for about 12 h resulted in quantitative conversion to a 7:1 mixture of **1b** and **3b**.

The unique structure of **4** was established by means of ^{1}H, ^{13}C, ^{15}N, and HMQC NMR techniques (Fig. 1, Table 1). The ^{1}H and ^{13}C spectra of bisadducts **4** exhibit some striking features: 1) The signal pattern is highly symmetrical; the two R groups are magnetically equivalent and the methylene hydrogens α to nitrogen are diasterotopic and give rise to well-resolved AB quartets. 2) In the ^{13}C spectra only 32 signals are observed for the fullerene core; the integrations of 28 signals (2C each) are twice that of the other four (1C each). This suggests C_s symmetry for compounds **4**, with the mirror plane crossing the four carbon atoms of two 6-6 junctions. 3) The presence of a ^{13}C signal at δ = 160 (1C) is common to all compounds **4**. The correct assignment of this peak and the definitive structural determination is based on the analysis of the multiplets at about δ = 160 in [^{15}N]**4b**, which was obtained from $SEMN_3$ labeled with ^{15}N (50%) at each terminal nitrogen atom; three isotopomers resulted with no, one, and two ^{15}N atoms. Three signals can be detected for these compounds: a singlet at δ = 160.19, a doublet at δ = 160.17 (J_{CN} = 6.9 Hz), and a triplet at δ = 160.14 (J_{CN} = 6.9 Hz) in an approximate 1:2:1 ratio. The signals can be assigned readily to the carbon atom bonded directly to both nitrogen atoms in [^{15}N]**4b**, which is labeled with none, one, amd two ^{15}N atoms, respectively, in statistical isotopomeric ratios. This assignment, which also explains the strong downfield shift of these peaks, is further substantiated by the coupling of this C atom with the α-methylene protons over three bonds (by multiple HMQC spectroscopy). In [^{15}N]**4b** the signal at δ = 138.71 (2C) is split into a singlet at δ = 138.71 and a doublet at δ = 138.69 (J_{CN} = 7.3 Hz) in a 1:1 ratio; these signals are assigned to the equivalent C_{60} carbon atoms bound to a single nitrogen atom. In compounds **4** the R groups are equivalent, but the α-methylene protons are diastereotopic. The two imino bridges are on adjacent 5-6 junctions and the nitrogen atoms would remain chiral, even if rapid pyramidal inversion would take place.

The ^{1}H NMR spectrum of **5** shows one quartet for the diastereotopic α-methylene protons, which indicates C_s symmetry. A possible structure could be the isomer in which two opened 5-6 bonds within the same six-membered are bridged by the imino groups. This is supported by the shift of the center of gravity of the methylene proton resonances by 0.7 ppm to lower field. In this structure, due to hindered inversion, the most favorable location of the R groups is above the five-membered rings, which leads to deshielding.[3d, e]

To obtain further information on the very regioselective formation of these bisadducts starting from **1**, we treated a concentrated solution of **1a** with methyl azidoacetate at room temperature. Under these conditions, in addition to a small amount of **4a** and **5a**, only one mixed triazoline/azafulleroid isomer **6** was

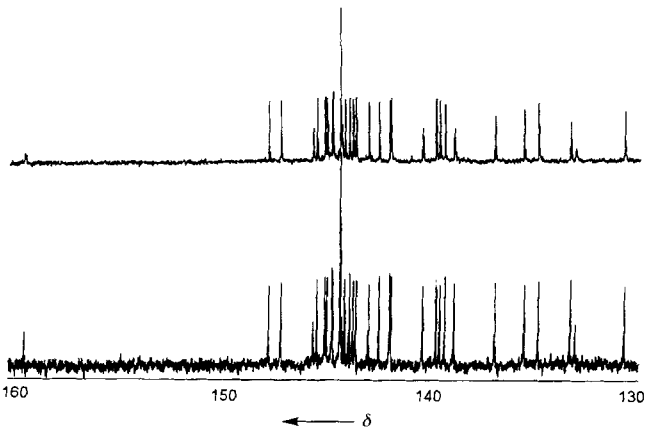


Fig. 1. ^{13}C NMR spectra (125 MHz, $CDCl_3$) of [^{15}N]**4b** (top) and **4b** (bottom).

formed (HPLC, NMR), which was isolated by flash chromatography. The ^{1}H NMR spectrum for **6a** shows two quartets for two sets of diastereotopic methylene protons and two singlets for the methyl groups (Table 1). The exclusive formation of **6a** is explained by the fact that **1** behaves as a strained electron-poor enamine. The significantly highest positive Mulliken charge of 0.06 (AM1) is at C-1 and C-6, and the lowest of -0.07 at C-2 and C-5 (Fig. 2). Enhanced Mulliken charges are also located at C-8 (0.03) and C-10 (-0.02). All other carbon atoms of the fullerene core exhibit Mulliken charges of 0.00 ± 0.01. The most negatively polarized N atom of the azide (AM1) is that bearing R (Fig. 2). A kinetically controlled attack of the azide, therefore, leads predominantly to **6**. Already at room temperature **6** rearranges slowly to give **4a** and **5a** in a 6:1 ratio.

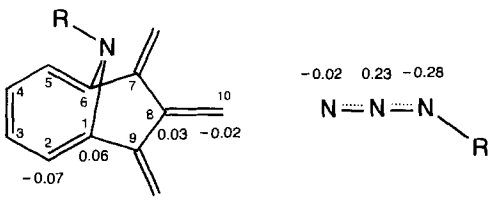

Fig. 2. Mulliken charges (AM1) near the imino bridge in **1a** and in N_3R ($R = CH_2COOMe$).

We are currently investigating the possibility of further ring expansions of fullerenes by the regioselective synthesis of tri- and tetraazafulleroids. Larger holes in the C_{60} framework could provide windows for the penetration of noble gases without the need for destructive reaction conditions at high temperatures.[5]

Experimental Procedure

2a: A solution of C_{60} (500 mg, 0.694 mmol) and methyl azidoacetate (80 mg, 0.695 mmol) in 1-chloronaphthalene (15 mL) was stirred overnight at 60 °C. The reaction mixture was then separated by flash chromatography (SiO_2, toluene) to give C_{60} (270 mg, 0.375 mmol), traces of **1a** and **3a**, and **2a** (165 mg, 0.198 mmol, 62% based on consumed C_{60}).

Thermolysis of **2a**: A solution of **2a** (200 mg, 0.239 mmol) in *o*-dichlorobenzene (15 mL) was stirred at 100 °C for 25 min. The reaction mixture was then separated by flash chromatography (SiO_2, toluene) to give C_{60} (38 mg, 22%), **1a** (53 mg, 24%), **3a** (8 mg, 4%), **4a** + **5a** (32 mg, 15%), and higher adducts (12 mg).

1a: A solution of C_{60} (516 mg, 0.7166 mmol) and 1.5 equiv of methyl azidoacetate (123.6 mg, 1.075 mmol) in 1-chloronaphthalene (15 mL) was stirred at 60 °C for ca. 12 h. The reaction mixture was then diluted with toluene to 400 mL and refluxed for 25 min. Separation by flash chromatography (SiO_2, toluene) yielded C_{60} (378.2 mg), **3a**, **1a** (92.2 mg, 59.7% based on consumed C_{60}), and **4a** + **5a**.

6a: A solution of **1a** (100 mg, 0.124 mmol) and methyl azidoacetate (14.5 mg, 0.126 mmol) in 1-chloronaphthalene (6 mL) was stirred for 3 d at room temperature. The reaction mixture was separated by flash chromatography (SiO_2, toluene) to give **1a** and traces of **4a** and **5a**. **6a** (17.2 mg, 15%) was then eluted with toluene/ethyl acetate (9:1).

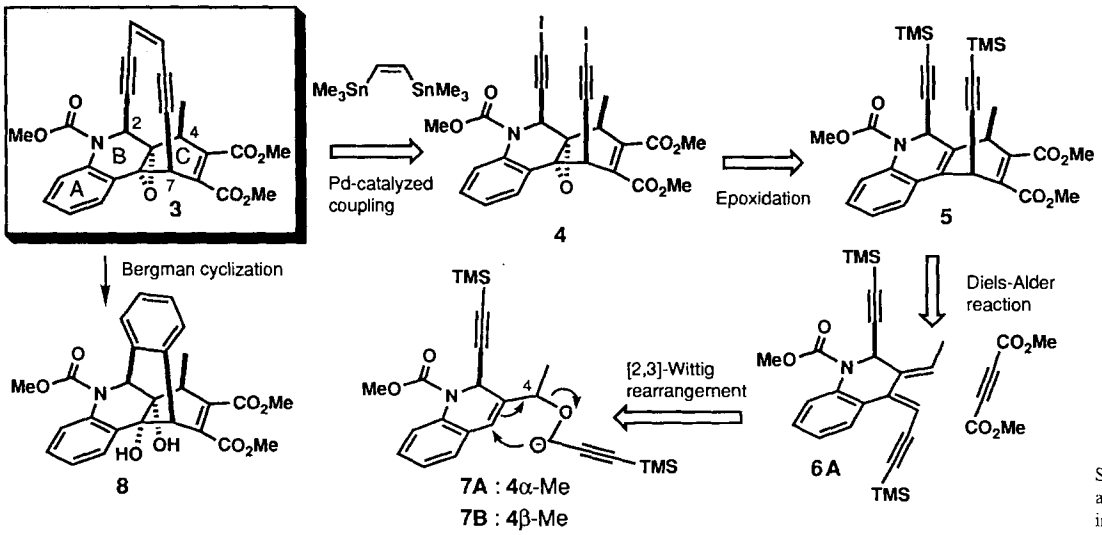
Synthesis of a Dynemicin A Analogue and Its Bergman-Type Cycloaromatization**

Takashi Takahashi,* Yasuharu Sakamoto, Haruo Yamada, Shuji Usui, and Yoshimasa Fukazawa

Dynemicin A (**1**) is a potent antibacterial and anticancer agent of the enediyne class[1] isolated from the fermentation broth of *Micromonospora chersina*.[2] The biological activity of **1** is attributed to its ability to undergo cycloaromatization to give the highly reactive benzenoid diradical **2**, which initiates



1 **2**

DNA cleavage through hydrogen abstraction from the deoxyribose backbone of DNA.[3a] It is presumed[3b–g] that the cycloaromatization of dynemicin A is induced by bioreduction of its anthraquinone moiety, opening of the epoxide, and Bergman cyclization. Its unique molecular structure and potent antitumor activity have stimulated extensive research on both the mechanism of action[4] and synthesis of model systems[5, 6] to mimic the action of dynemicin A. In this communication, we report the synthesis of dynemicin A model **3** and its Bergman-type cycloaromatization giving **8**.

Our retrosynthetic analysis is summarized in Scheme 1.[7] One key reaction is the palladium-catalyzed coupling reaction of bis(iodoalkyne) **4** with (*Z*)-bis(trimethylstannyl)ethylene,[6] which provides the highly strained enediyne unit in **3** directly. A second key reaction is the Diels–Alder reaction of diene **6A** with

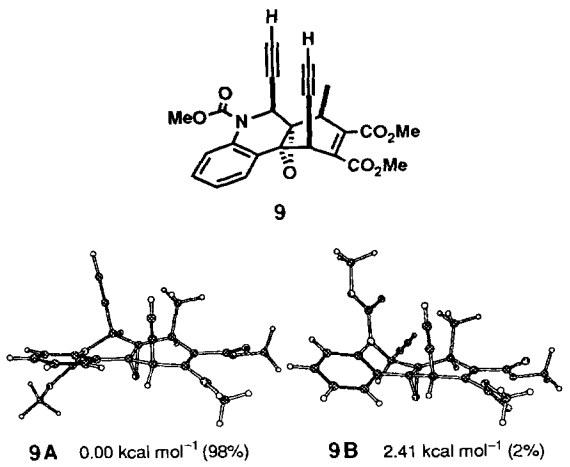
Scheme 1. Retrosynthesis of **3** and its Bergman cyclization giving **8**. TMS = trimethylsilyl.

dimethyl acetylenedicarboxylate. In this way, we are able to introduce the required all-*cis* relative configuration for the diethynyl side chains at C(2), C(7) (dynemicin numbering) and the C(4) methyl group in **5**. Simultaneously, the 1,4-hexadiene moiety is formed, in which the [3(8)] double bond can be used to introduce the α-epoxy function that serves as the "trigger". The (*Z*,*Z*) diene system in **6A** is constructed by the [2,3]-Wittig rearrangement[8] of allyl ether **7** and subsequent β-elimination of the resulting propargyl hydroxyl group. By this route the 10-membered ring enediyne system including the epoxide "trigger" can be prepared in four steps from the (*Z*,*Z*) diene **6A**.

The diaxial orientation of the diethynyl side chains at C(2) and C(7) in **4** is essential for the success of the palladium-catalyzed cyclization (**4** → **3**). Molecular modeling based on MM2 calculations has proved to be useful in the design of the key intermediates.[9] Thus, conformational analysis of bis(alkyne) **9**, a model of bis(iodoalkyne) **4**, was conducted by using the Monte Carlo conformational search[10] and the MM2* force field in MacroModel.[11] Sixteen unique lower energy conformations of **9** were found within 3.0 kcal mol^{-1} of the global minimum. Figure 1 shows the lowest energy conformations **9A** and **9B**, which have a diaxial and an axial–equatorial orientation of the diethynyl side chains, respectively. These calculations and a Boltzmann distribution based on the energy differences of the 16 conformations predict that the palladium-catalyzed coupling reaction of the bis(iodoalkyne) **4** should proceed through its diaxial conformation to give the double coupling product **3** preferentially.



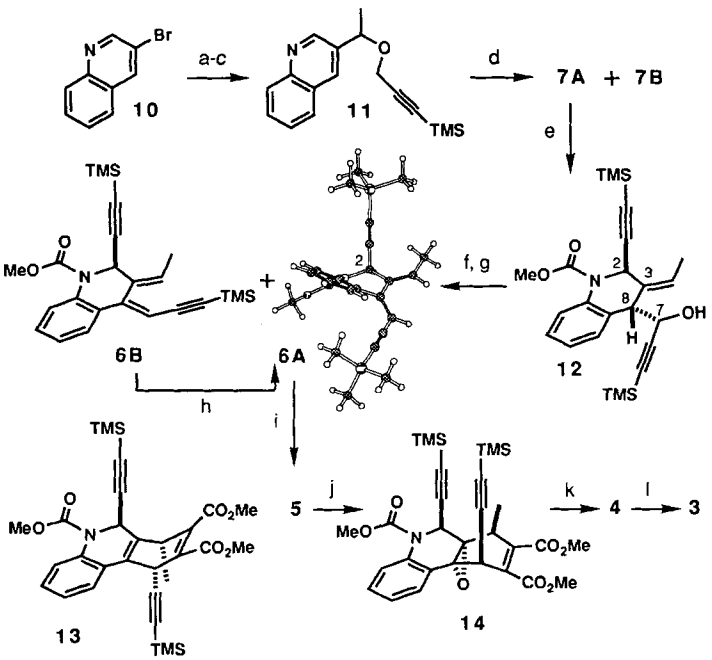


Fig. 1. Results of the conformational analysis of **9** based on MM2* calculations.

Synthesis of the precursor of **4**, bis(trimethylsilylalkyne) **14**, was carried out as follows (Scheme 2): Addition of the lithium derivative of **10**[12] to acetaldehyde, O-alkylation of the resulting secondary alcohol with propargyl bromide, and protection of the terminal alkyne with trimethylsilyl chloride gave the propargyl ether **11** in 78% overall yield. Addition of methyl chloroformate[13] to a mixture of (trimethylsilyl)ethynylmag-

nesium bromide and **11** afforded a 78:22 mixture of ether **7A** having 4α-methyl group and its β-isomer **7B**. Ether **7A** was subjected to the [2,3]-Wittig rearrangement to give alcohol **12** as a single isomer. The configuration of the [3(4)] double bond (*Z*) and the *trans* configurational relationship between alkynyl groups at C(2) and C(8) in **12** were established by NMR spectra and nOe studies; however, we have not yet assigned the stereochemistry at C(7). Mesylation of alcohol **12** followed by treatment with DBU gave a 45:55 mixture[14] of the (*Z*,*Z*) diene **6A** and the (*Z*,*E*) diene **6B**, which was converted to the desired **6A** by treatment with I_2. The configurations of dienes **6A** and **6B** were confirmed by NMR spectra and nOe studies (Table 1). The

Table 1. Selected physical data for compound **3**, **4**, **6A**, and **8**.

4: IR (neat): $\tilde{\nu}$ = 2944, 2184, 1717, 1437, 1261, 1043, 758 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$): δ = 7.76 (br. d, J = 7.6 Hz, 1H), 7.23–7.43 (m, 3H), 5.72 (br. s, 1H), 4.69 (s, 1H), 3.82 (s, 3H), 3.81 (s, 3H), 3.72 (br. s, 3H), 3.34 (br. q, J = 7.3 Hz, 1H), 1.64 (d, J = 7.3 Hz, 3H); ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 167.9, 165.1, 155.3, 142.9, 136.0, 128.7, 127.3, 127.1, 125.6, 125.5, 89.8, 89.1, 70.0, 59.5, 53.7, 52.8, 52.6, 47.4, 38.2, 30.8, 16.6, 4.4, 2.2; FAB-MS: m/z 710 [M + Na^+], 688 [M + H^+]; High-resolution FAB-MS: found: 709.9147 (calc.: 709.9149, $C_{24}H_{19}NO_7I_2Na$).

6A: IR (neat): $\tilde{\nu}$ = 2954, 2170, 2118, 1711, 1484, 1442, 1372, 1321, 1283, 1249, 1027, 907, 847, 760, 734 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$): δ = 8.27 (dd, J = 7.9, 1.7 Hz, 1H), 7.45 (br. d, J = 7.9 Hz, 1H), 7.30 (ddd, J = 7.9, 7.9, 1.7 Hz, 1H), 7.15 (ddd, J = 7.9, 7.9, 1.3 Hz, 1H), 6.09 (br. s, 1H), 6.03 (dq, J = 1.3, 7.3 Hz, 1H), 5.95 (s, 1H), 3.79 (s, 3H), 1.88 (d, J = 7.3 Hz, 3H), 0.20 (s, 9H), −0.05 (s, 9H); ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 153.9, 141.9, 138.1, 135.9, 129.0, 128.4, 127.7, 125.2, 124.5, 121.2, 104.4, 102.5, 102.1, 102.0, 87.6, 53.2, 46.3, 14.4, −0.30, −0.34; FAB-MS: m/z 444 [M + Na^+], 422 [M + H^+]; High-resolution FAB-MS: found: 444.1786 (calc.: 444.1791, $C_{24}H_{31}NO_2Si_2Na$).

8: IR (neat): $\tilde{\nu}$ = 3428, 2920, 1712, 1438, 1328, 1264, 1076, 765 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$): δ = 7.73 (m, 1H), 7.52 (br. d, J = 7.2 Hz, 1H), 7.42 (br. d, J = 7.4 Hz, 1H), 7.05–7.23 (m, 5H), 5.97 (s, 1H), 4.22 (s, 1H), 3.93 (s, 3H), 3.81 (s, 3H), 3.76 (s, 3H), 3.31 (q, J = 7.6 Hz, 1H), 1.21 (d, J = 7.6 Hz, 3H).

Diels–Alder reaction of **6A** with dimethyl acetylenedicarboxylate gave a 60:40 mixture[15] of **5** (from β-side attack) and **13** (from α-side attack). The epoxy function was introduced stereoselectively to the major product **5** giving the α-epoxide **14** in 88% yield. The configuration of **14** was established by X-ray crystallography (Fig. 2).[16] The ethynyl side chains were found to be diaxial, as expected based on MM2* calculations of the bis(alkyne) **9**.

In the next step the bis(trimethylsilylalkyne) **14** was converted to the bis(iodoalkyne) **4** (Table 1).[17] Then, the crucial palladium(0)-catalyzed coupling reaction[18] of **4** with (*Z*)-bis(trimethylstannyl)ethylene[19] gave the dynemicin model **3** (Table 1). In this reaction neither the corresponding homo coupling product of **4** nor the bis(vinyl) compound were obtained. Enediyne **3** was sufficiently stable under the reaction conditions and during purification on silica gel.

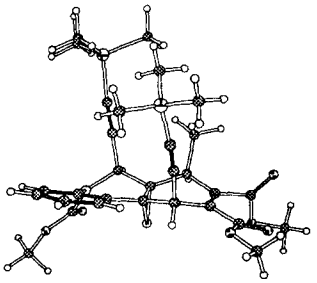

Fig. 2. Chem 3D representation of the X-ray crystal structure of **14**.

Acid-induced Bergman cyclization[5a,c] of enediyne **3** was achieved (Scheme 1) with *p*-TsOH·H_2O in THF in the presence of 1,4-cyclohexadiene at 25 °C to give the aromatized product **8** in 32% yield (Table 1). The formation of **8** can be explained by initial opening of the epoxide to give the corresponding diol, followed by Bergman cyclization and hydrogen abstraction.

In summary, the synthesis of the dynemicin model **3**, which has a 10-membered ring enediyne system and an epoxide "trigger", has been achieved by [2,3]-Wittig rearrangement, Diels–Alder reaction, and palladium-catalyzed coupling reaction. MM2 calculations were useful in the design of the key synthetic intermediate with the desired conformational property. Finally, compound **3** has been shown to undergo acid-induced Bergman cyclization, which suggests its potential as a novel DNA-cleaving molecule.

[14] Although it was expected that this elimination should provide a single isomer from the pure diastereomer **12**, a partial E_1 elimination through a benzyl anion intermediate resulted in the formation of the mixture of two dienes.
[15] The conformational analysis of **6A** based on MM2* calculations (see Scheme 2) predicts that the dominant conformation (>95%) has a twisted diene moiety and an axial orientation of the alkyne side chain at C(2). Attack of the dienophile from the less hindered convex β-face of the diene can explain the slightly preferential formation of **5**. These calculations also suggest "remote control" of the Diels–Alder reaction of **6A**, in which intermediate binding of the dienophile (acetylenedicarboxylate) to the alkynyl group attached to the diene moiety in **6a**, would help produce compound **5** as the sole product.

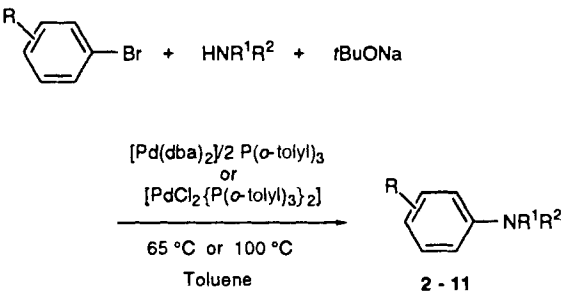
A Simple Catalytic Method for the Conversion of Aryl Bromides to Arylamines**

Anil S. Guram, Roger A. Rennels, and Stephen L. Buchwald*

Arylamines are of considerable importance in a variety of industries. As such, the development of new and more general methods for their preparation is of significant interest.[1, 2] We recently reported that the palladium-catalyzed reactions of aryl bromides with in situ generated aminostannanes provide a general route to a variety of arylamines.[1, 3, 4] While these tin-mediated reactions were efficient, they suffered from relatively long reaction times, non-trivial workup procedures (to remove tin by-products), and were inapplicable to primary aliphatic amines. Furthermore, the use of tin reagents was a concern, particularly for the large-scale preparation of arylamines of pharmaceutical significance. Herein, we describe an improved palladium-catalyzed reaction protocol which ameliorates, to a significant extent, the problems described above.



Our initial strategy, based on the well-established boron-mediated C–C bond-forming reactions,[5] focused on the investigation of analogous palladium-catalyzed reactions of aryl halides and aminoboranes. We discovered that tris(dimethylamino)borane ($B(NMe_2)_3$,[6] commercially available from Aldrich) reacts efficiently with 4-bromobiphenyl in the presence of $[Pd(dba)_2]/2\ P(o\text{-tolyl})_3$ (2 mol%; dba = dibenzylideneacetone) and sodium *tert*-butoxide in toluene at 100 °C to afford the arylamine **1** in 85% isolated yield [Eq. (a)]. Moreover,

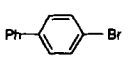
(a)

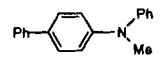
$B(NMe_2)_3$ also serves as a precursor for the transfer of other amines.[7] For example, the transamination reaction of $B(NMe_2)_3$ (1.0 equiv) with *N*-methylaniline (3.3 equiv) (in toluene under argon purge), followed by reaction of the in situ generated $B(N(Me)Ph)_3$ with 4-bromobiphenyl under similar conditions afforded 4-(*N*-methylanilino)biphenyl (**2**) in 83% isolated yield.

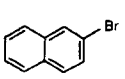
After some experimentation, we have found that aryl bromides react efficiently with amines in the presence of sodium *tert*-butoxide and a catalytic amount of $[PdCl_2(P(o\text{-tolyl})_3)_2]$ or $[Pd(dba)_2]/2\ P(o\text{-tolyl})_3$ to afford arylamines in good yields [Eq. (b), Table 1]. The experimental procedure simply involves heat-

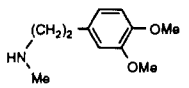
(b)

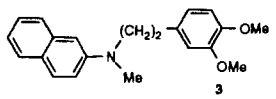
ing a mixture of aryl bromide (1 equiv), amine (1.2 equiv), sodium-*tert*-butoxide (1.4 equiv), and the Pd catalyst (≈2 mol%) in toluene at 65–100 °C. An aqueous workup and chromatography on silica gel afford the analytically pure arylamines.

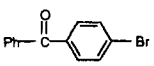


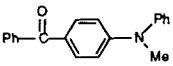


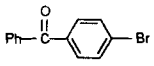


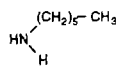


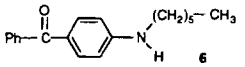


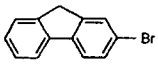


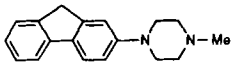


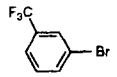


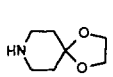


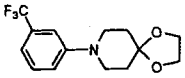


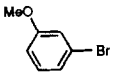


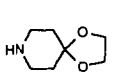


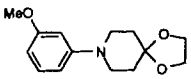


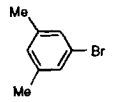


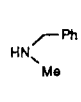


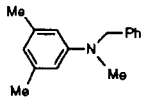












As illustrated in Table 1, the Pd-catalyzed aryl amination reactions provide a general route to a variety of arylamines. Aryl bromides with both electron-withdrawing and electron-donating substituents react efficiently with both primary and secondary amines. Substrates with acid-sensitive functional groups are well tolerated (entries 8 and 9), while those containing base-sensitive functional groups, as anticipated, are not (e.g., attempted amination of 4-bromoacetophenone was unsuccessful).

A side-product, resulting from reduction of the starting aryl bromide, is formed in variable amounts in these reactions. This side-product is readily separated from the arylamine products by flash chromatography. The amount of this side-product is dependent on the steric and electronic properties of both the aryl bromide and amine. In general, reactions involving simple secondary amines and simple aryl bromides with *para* electron-withdrawing substituents resulted in the formation of the least amount of reduced product (entries 1, 3, and 4), whereas reactions involving primary aliphatic amines resulted in the production of larger quantities of reduced product (entry 5).

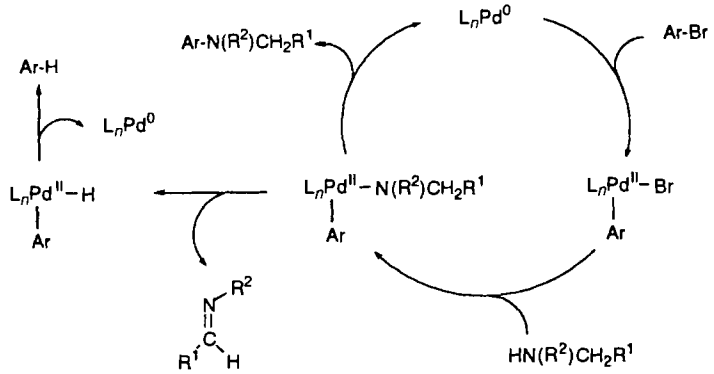
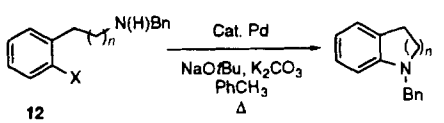
Table 1. Palladium-catalyzed reactions of aryl bromides and amines [a,b].

Entry	Aryl bromide	Amine	Arylamine	Yield [%][c]
1			 2	88
2			 3	78
3			 4	86
4			 5	89
5			 6	72
6			 7	71
7			 8	79
8			 9	67
9			 10	81
10			 11	84



[a] For entries 1 and 10, the catalyst [Pd(dba)$_2$]/2 P(*o*-tolyl)$_3$ and reaction temperature of 65 °C were employed, and for entries 2–9, the catalyst [PdCl$_2$(P(*o*-tolyl)$_3$)$_2$] and reaction temperature of 100 °C were employed. [b] By GC analysis using an internal standard, approximately 8, 12, 5, 6, 27, 24, 8, not determined, 12, 10% of reduced side-product was formed in entries 1–10, respectively. [c] Yields reported correspond to analytically pure, isolated compounds.

The Pd-catalyzed aryl amination reactions most likely proceed by the oxidative addition of the aryl bromide to a Pd^0 species, followed by the formation of an intermediate "Ar–Pd^{II} NCH$_2$R^1(R^2)" species which undergoes reductive elimination to afford the desired arylamine and regenerates the Pd^0 catalyst (Scheme 1).[8, 9] We believe that formation of the reduced side-product occurs, at least in part, as shown in Scheme 1. The "Ar-Pd^{II}-NCH$_2$R^1(R^2)" intermediate can undergo a β-hydride elimination reaction to produce a "Ar-Pd^{II}-H" species which can reductively eliminate to afford the arene side-product and regenerate the Pd^0 catalyst (Scheme 1).[10] Consistent with this notion, when *N*-methylbenzylamine is employed as the amine coupling partner, *N*-methylbenzylidene was detected by GC/MS.



Preliminary studies of the reaction of 1-bromo-3,5-dimethylbenzene with *N*-methylbenzylamine in the presence of a base and a catalytic amount of [Pd(dba)$_2$]/2 phosphanes (100 °C, toluene) indicate that the P(*o*-tolyl)$_3$ ligand is critical to the success of these intermolecular aromatic amination reactions. Related ligands such as PPh$_3$, 1,1′-bis(diphenylphosphano)ferrocene (dppf), and 1,3-bis(diphenylphosphano)propane (dppp) were found to be inefficient. With PPh$_3$ and dppf as ligands, the aryl bromide was completely consumed (< 1 h) with the formation of *m*-xylene as the major product. With dppp as the ligand, the aryl bromide remains mostly unreacted and only a trace of desired arylamine is formed. The Pd-catalyzed aromatic amination reaction is also very sensitive to the nature of base. With NaOMe, the aryl bromide slowly decomposes to *m*-xylene with no formation of the desired arylamine, while with K$_2$CO$_3$, no conversion to product is observed (100 °C, toluene, 3 h).

An obvious application of this methodology was to the intramolecular reaction of an amine with an aryl halide due to the importance of nitrogen heterocycles.[4, 11] We note that a transformation of this type which utilized a stoichiometric quantity of [Pd(PPh$_3$)$_4$] was reported by Boger and co-workers several years ago.[4]

Applying the NaO*t*Bu-mediated palladium-catalyzed procedure to the cyclization of **12** provides good yields of nitrogen heterocycles of ring size 5–7 [Eq. (c)] as shown in Table 2. Although the use of K$_2$CO$_3$ was not found to be essential in these transformations, cleaner reactions were generally observed when it was employed. At 100 °C all reactions proceeded quickly (0.5–6 h) and in excellent yields (entries 1, 3, 4, and 6).

3	Br	2	$[Pd(PPh_3)_4]$	1	100	6	87
4	Br	3	$[Pd(PPh_3)_4]$	1	100	6	89
5	Br	2	$[PdCl_2\{P(o\text{-tolyl})_3\}_2]$	10	65	21	75
6	I	1	$[Pd(PPh_3)_4]$	1	100	0.5	93
7	I	1	$[Pd(PPh_3)_4]$	1	65	2	96

[a] Yield of isolated product.

When the temperature was lowered to 65 °C, the reactions of the aryl bromides tend to slow greatly as they approach completion,[12] although good yields are still realized (entries 2 and 5). In contrast to the intermolecular process, aryl iodides proved to be superior substrates. Under the conditions described, aryl iodide **12** (X = I, $n = 1$) reacts rapidly and produces *N*-benzylindoline in excellent yields (entries 6 and 7). In general, the use of $Pd(PPh_3)_4$ proved superior to the procedures employing $P(o\text{-tolyl})_3$ for the intramolecular reactions, in contrast to the results seen for the intermolecular reactions.

The intramolecular aryl amination reaction of aryl iodide **12** (X = I, $n = 1$) has also been accomplished at room temperature using 5 mol% $[Pd(PPh_3)_4]$ and excess triethylamine (20 equiv) in toluene for 40 h, which afforded *N*-benzylindoline in 87% isolated yield [Eq. (d)]. When triethylamine was employed as the

(d)

solvent with 5 mol% $[Pd(PPh_3)_4]$, aryl iodide **12** (X = I, $n = 1$) was consumed in 15 h at room temperature and provided *N*-benzylindoline in 83% isolated yield.

In summary, we have developed a facile and general catalytic method for the conversion of aryl bromides to arylamines, which works well for inter- and intramolecular processes. Particularly noteworthy features of this method include the experimental simplicity, the tin/boron-free conditions, and the broad substrate scope. Efforts to discover improved catalyst systems which operate under milder reaction conditions as well as to employ these methods in synthetic organic chemistry are in progress.[13, 14]

Experimental Procedure

3: A mixture of 2-bromonaphthalene (205 mg, 0.99 mmol), *N*-methylhomoveratrylamine (234 mg, 1.20 mmol), sodium *tert*-butoxide (134 mg, 1.39 mmol) and $[PdCl_2(P(o\text{-tolyl})_3)_2]$ (14 mg, 0.02 mmol) in toluene (8–9 mL) was heated under argon at 100 °C for 3 h. After cooling to room temperature, the reaction mixture was taken up in Et_2O (30–40 mL) and washed with brine (15–20 mL). The organic fraction was dried with $MgSO_4$, and concentrated using a rotary evaporator. The crude material was purified by flash chromatography on silica gel using hexane (100 mL), hexane:EtOAc (10/1, 100 mL), and then hexane:EtOAC (4/1) to afford **1** (249 mg, 78%) as a pale yellow solid. Formation of ca. 12% of naphthalene (reduced side-product) was detected by GC analysis of the crude reaction mixture. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 7.69$ (overlapping d's, $J = 8$ Hz, 2H, ArH), 7.64 (d, $J = 8$ Hz, 1H, ArH), 7.36 (t, $J = 7$ Hz, 1H, ArH), 7.19 (t, $J = 7$ Hz, 1H, ArH), 7.14 (dd, $J = 7$, 2 Hz, 1H, ArH), 6.90 (dd, $J = 2$ Hz, 1H, ArH), 6.80 (d, $J = 7$ Hz, 1H, ArH), 6.77 (dd, $J = 7$ Hz, 1H, ArH), 6.70 (d, $J = 2$ Hz, 1H ArH), 3.86 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 3.67 (t, $J = 8$ Hz, CH_2N), 2.97 (s, 3H, NCH_3), 2.84 (t, $J = 8$ Hz, 2H, NCH_2CH_2). ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 148.9$, 147.5, 146.8, 135.1, 132.3, 128.8, 127.4, 126.6, 126.2, 126.0, 121.8, 120.7, 115.9, 112.1, 111.3, 106.0, 55.9, 55.8, 55.0, 38.9, 32.7. **M. P.**: 84–85 °C. Anal. Calcd. for $C_{21}H_{23}NO_2$: C 78.47, H 7.21. Found: C 78.41, H 7.29.

***N*-benzylindoline:** To a suspension of NaO*t*-Bu (154 mg, 1.60 mmol), K_2CO_3 (221 mg, 1.60 mmol), and tetrakis(triphenylphosphane)palladium(0) (12 mg, 0.01 mmol) in toluene (3 mL, 0.33 M) under argon was added by syringe *N*-benzyl-*o*-bromophenethylamine (**12**) (290 mg, 1.0 mmol). The reaction mixture was then heated in an oil bath for 2.5 h under argon until GC showed no starting material [12]. After cooling to room temperature, water and ether (5 mL each) were added. After stirring until all the solids were dissolved, the layers were separated and the aqueous layer was extracted with ether (2 × 5 mL). The combined organic fractions were then stirred with 30% hydrogen peroxide (5 mL) for 10 to 20 minutes to oxidize the triphenylphosphane. The hydrogen peroxide was removed and the organic layer was washed with water (10 mL). The combined hydrogen peroxide and water layers were extracted with ether (2 × 20 mL). The combined ether layers were then washed with saturated aqueous ferrous sulfate (10 mL) followed by water (10 mL). The combined ferrous sulfate and water layers were extracted with ether (2 × 20 mL). The combined ether layers were then washed with saturated aqueous sodium chloride and dried ($MgSO_4$). Concentration using a rotary evaporator and flash chromatography on silica gel using 40/1 hexane/ether afforded *N*-benzylindoline as a yellow oil. The product was essentially pure at this point. A small quantity of aliphatic impurity, however, which appeared at $\delta = 1.25$ in the ^1H NMR was removed by Kugelrohr distillation at 100 °C and 0.01 mm Hg to afford 197 mg of *N*-benzylindoline [15] as a clear colorless oil (94%).

Enantiomerically Pure Palladacycles Derived from β-Ketosulfoxides**

José L. García-Ruano,* Ana M. González, Isabel López-Solera, José R. Masaguer, Carmen Navarro-Ranninger,* Paul R. Raithby, and Jesús H. Rodríguez

The coordination of the sulfinyl group to transition metal atoms has been extensively investigated with particular reference to whether the ligand bonds through the sulfur or the oxygen atoms.[1] We are currently interested in *ortho*-metalation reactions[2] and the use of optically pure β-ketosulfoxides in asymmetric synthesis.[3] As part of these studies we therefore decided to investigate the behavior of sulfinyls ($RC(O)-CH_2-SO-p$-Tol) toward palladium(II) salts. These compounds contain several possible coordination sites, for example the carbonyl and the sulfinyl oxygen atoms, and one chiral center (sulfinyl sulfur atom). They may be obtained in high optical purity, and the inherent chirality may be transferred to the metal complexes derived from them. In addition, β-ketosulfoxides offer the possibility of forming diastereoisomeric *ortho*-metalated species by the initial insertion of the electrophilic Pd^{II} salts into the strongly acidic H–C bonds flanked by the SO and CO groups,[4] followed by the *ortho*-metalation of the *para*-tolyl ring. Despite the interest in chiral compounds containing a stereogenic sp^3 hybridized C atom directly bonded to the palladium atom, very few are known.[5] In this paper we describe the synthesis and structure of the enantiomerically pure trimer **2**, which exhibits an unprecedented structure of a C-metalated enolate ("palladium C-enolate"), unequivocally demonstrated by X-ray diffraction.

The reaction of $Pd(OAc)_2$ with (*R*)-3-*para*-tolylsulfinyl-2-propanone (**1**)[6] under nitrogen for 48–72 hours, afforded, after chromatographic purification, the complex **2** as a solid in 42% yield. The microanalytical data are consistent with the empirical formula $C_{10}H_{10}O_2SPd$, which indicates the structure $[LPd]_n$, and suggests that acetato ligands are not present. This was confirmed by the IR spectra, which revealed the absence of the two bands (1580 and 1420 cm^{-1}) typical of η^2-acetato ligands.[7] The S=O stretch is tentatively assigned to the strong band at 1127 cm^{-1}, which suggests that the coordination is through sulfur.[8] The C=O stretching absorption appears at 1570 cm^{-1} (139 cm^{-1} lower than in the ligand **1**), which indicates that the carbonyl oxygen must be involved in the coordination; however, the high value observed for $\Delta\tilde{\nu}$ is difficult to explain.[9]

1 **2**

The *ortho*-metalation of the *para*-tolyl ring is evident from the ^1H NMR data (only three aromatic protons), and instead of the methylene proton signal of **1** (δ = 3.83 (m, 2H)), a singlet with an integral corresponding to only one proton appears for the complex **2** (δ = 5.26 (s, 1H)). Both facts suggest the formation of a five-membered palladacycle with two Pd–C σ bonds.

The ^{13}C NMR parameters of **2** reveal the expected deshielding for the carbon atoms bonded to palladium, as well as of those carbon atoms directly connected to the ligand coordination sites. In comparison with previously reported compounds,[10] the observed deshielding effect is larger for the aliphatic carbon atom ($\Delta\delta$(C2) = 13–15) but smaller for the aromatic one ($\Delta\delta$(C11) = 12). These differences are difficult to explain unless we assume significant structural differences with respect to both Pd–C bonds. Finally, the strong deshielding observed for C1 ($\Delta\delta$ = 15.6) is consistent with the structural element Pd–O=C deduced from the IR data.

The structure of **2**, which crystallizes as yellow prisms from ethyl acetate/hexane (1/1), was confirmed by an X-ray structure determination.[11] Views of the molecular structure are shown in Figure 1. The complex is a trimer with crystallographic threefold symmetry. The core of the trimer is a nine-membered ring of alternating S, Pd, and C(H) atoms. The plane defined by the

palladium atoms is sandwiched between two planes, one of them defined by the sulfur atoms and the other by the methyne carbon atoms.

Each ligand is bonded to two palladium atoms. One palladium atom is joined through two dative bonds by using the lone pairs of electrons at the sulfur and carbonyl oxygen, while the other palladium atom is bonded to the ligand through two covalent bonds to the methyne carbon and the *ortho*-carbon of the *para*-tolyl unit. The two five-membered rings supported by each palladium atom (Fig. 2), adopt an envelope shape, in which C2 (− 0.97 Å) and S1 (− 0.84 Å) lie out of the planes defined by the Pd1a, C11, C12, and S1 atoms and the Pd1, O2, C1, and C2 atoms, respectively. The angle between the coordination planes of two adjacent Pd atoms is 62.3°. Figure 1 bottom shows that the trimer forms a cavity, 4.04 Å in diameter. The sulfur atom and the chiral carbon atom are both *R*-configurated. As expected, the two Pd–C bonds are different. The Pd1–C12a bond length is 1.95(2) Å, similar to M–C bonds in other cyclometalated aryl complexes[2] where there is some multiple-bond character because of metal-to-ligand back bonding.[12] The Pd1–C2a bond length is longer (2.10(2) Å) than that for Pd1–C12a, but also similar to other Pd–C(sp^3) σ bonds supporting a sulfur atom in the *trans* position (2.05–2.10 Å).[13] The value of the C1-C2-S1 angle (109(2)°) supports the palladium C-enolate structure of the compound **2**. The Pd1–O2 distance of 2.16(1) Å is indicative of a carbon atom of an aryl group lying in a *trans* position.[14] The Pd1–S1 distance of 2.32(6) Å is slightly longer than those observed for other complexes containing a Pd–S bond (2.19–2.25 Å).[15] The palladacycle containing the two Pd–C σ bonds is almost coplanar with the aromatic ring (angle between them is 3.2°). The sulfinyl oxygen atoms are located outside the central framework of S, Pd, and C(H) atoms, and they form a network of intermolecular hydrogen bonds with the methyl groups joined to the carbonyl groups [H3c···O1 = 2.50(4) Å, C3···O1 = 3.47(4) Å, C3-H3c···O1 = 173(8)°; symmetry: 0.6667 − *x* + *y*, 1.3333 − *x*, 0.3333 + *z*].

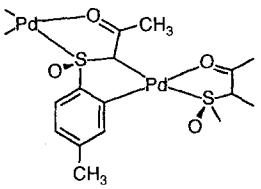

Fig. 2. Section of the structure of **2**, showing the coordination sphere of the palladium atoms.

Compound **2** exhibits a very high specific rotation ($[\alpha]_D^{20}$ = − 486.5; *c* = 0.2 in chloroform). Its absolute configuration was unequivocally established as (*R*,*R*) by X-ray diffraction studies (see above). Taking into account that compound **2** is the only diastereoisomer obtained in the reaction (the NMR spectra of the crude product reveals the presence of only one set of signals corresponding to this kind of diastereoisomer), we can conclude that the sequence involving the insertion of the palladium into the C–H bond (resulting in the formation of the Pd^{II} C-enolate) followed by the *ortho*-metalation is highly stereoselective. This behavior and the fact that the formation of the Pd–$C^*_{sp^3}$ σ bond does not require special activation, suggests that the formation of the palladacycle involving the two σ-Pd–C bonds must take place after the formation of the chelate containing the S–Pd and O–Pd bonds, since this chelation is responsible for the activation of the C–H methylene bonds.

The reactions of other β-ketosulfoxides with Pd^{II} acetate under conditions identical to those for compound **1**, yield complexes with structures similar to that of **2**.

In conclusion we have reported on the synthesis of a new type of enantiomerically pure complex composed of three molecules of ligand and three palladium atoms. The ligand supplies the two lone pairs of electrons to coordinate with Pd^{II} by formation of a stable five-membered ring and the two carbon atoms to form the covalent Pd–C bonds of a five-membered palladacycle. This is the first stable palladium C-enolate unequivocally characterized. The usefulness of this kind of compound as ferroelectric materials is currently under investigation.

[4] One immediate precedent of these insertion processes is the reactions of $PtCl_2$ with $(PhCOCH_2)_2SO$, which afforded a complex which contained a puckered four-membered ring with two C–Pt bonds (W. Henderson, R. D. W. Kemmitt, J. Fawcett, L. J. S. Prouse, D. R. Russell, *J. Chem. Soc. Chem. Commun.* **1986**, 1791–1793; W. Henderson, R. D. W. Kemmitt, L. J. S. Prouse, D. R. Russell, *J. Chem. Soc. Dalton Trans.* **1990**, 1853–1859). Similar insertion reactions have been observed starting from β-ketoesters (D. A. Clarke, R. D. W. Kemmitt, M. A. Mazid, P. Mckenna, D. R. Russell, M. D. Schilling, L. J. S. Sherry, *ibid.* **1984**, 1993–2002) and β-ketosulfones (W. Henderson, R. D. W. Kemmitt, L. J. S. Prouse, D. R. Russell, *ibid.* **1989**, 259–266). With some of these ligands (but not for sulfoxides), palladium complexes have also been obtained.

[11] Crystal data for **2**: $C_{30}H_{30}O_6Pd_3S_3 \cdot H_2O$, rhombohedral, space group *R*3, *a* = 13.935(2), *b* = 13.935(2), *c* = 17.114(2) Å, *V* = 2878.0(8) Å^3, *Z* = 3, ρ_{calcd} = 1.589 g cm^{-3}; *F*(000) = 1356; $\mu(Mo_{K\alpha})$ = 1.591 mm^{-1}, *T* = 153(2) K; 3271 reflections with $5° < 2\theta < 45°$, of which 1660 are independent were collected on a Stoe four-circle diffractometer using graphite monochromated $Mo_{K\alpha}$ (λ = 0.71073 Å) radiation. Three standard reflections were measured every 60 minutes. There was no evidence of crystal decomposition. The data were corrected for absorption. The structure was solved by a combination of Patterson and Fourier difference techniques [SHELXTL PLUS, Program version 4.0, Siemens Analytical X-Ray Instruments, Madison, WI, **1990**] and refined by a full-matrix least-square methodology based on F^2 to *R* = 0.079 with all non-H atoms anisotropic [SHELX 93, Program for Crystal Structure Refinement, G. M. Sheldrick, University of Göttingen, **1993**]; H atoms were placed in idealized positions and allowed to ride on the relevant C atom. Largest peak and hole in the final difference map 0.784 and − 1.658 e Å^{-3}, respectively. A H_2O solvate was located in three disordered positions, and an occupancy factor of 0.33 was assigned according to the height of the Fourier synthesis. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

The Lipophilically Wrapped Polyion Aggregate $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$, a Face-Sharing (Octahedron + Prismane) $Ba_6Li_3O_2$ Polyhedron in a Hydrocarbon Ellipsoid: Preparation, Single Crystal Structure Analysis, and Density Functional Calculations**

Hans Bock,* Tim Hauck, Christian Näther,

and Oliver D. Häberlen

Dedicated to Professor Gerhard Ertl

When barium metal is treated with *tert*-butyl alcohol, *n*-butyllithium in *n*-hexane added, the precipitate filtered off, dissolved in tetrahydrofuran, and the resulting solution layered with *n*-hexane, colorless monoclinic prisms of a novel type of cluster crystallize [Eq. (a)]. According to the single crystal structure determination (Fig. 1 center), its nucleus $[Ba_6Li_3O_2]^{11+}$ consists of a Ba_6^{2+} octahedron surrounding an O^{2-} ion and of an analogously O^{2-} centered prismate $Ba_3^{2+}Li_3^+$, formed by connecting three Li^+ centers to one of the triangular faces Ba_3^{2+}. The polyion aggregate with eleven positive charges is lipophilically wrapped by eleven *tert*-butyl alcoholate ions and three tetrahydrofuran solvent molecules. The surface of the distorted ellipsoid is covered by a total $9\times11 + 8\times3 = 123$ hydrogen substituents (Fig. 1 top).

(a)

Crystals of the title compound and other related compounds were first produced serendipitously,[1, 2a] and then also deliberately under well-designed[2b–d] conditions. They will be called "lipophilically wrapped polyion aggregates", which are defined as follows:[3] A cluster nucleus of cations and anions provides the essential contributions to the thermodynamic stability, whereas predominantly the largely impenetrable hydrocarbon skin lends kinetic stability. Other specimens of a different type,[2] prepared shortly thereafter, provided evidence of a wide-spread, generalizable crystallization (self-organization) principle.[3]

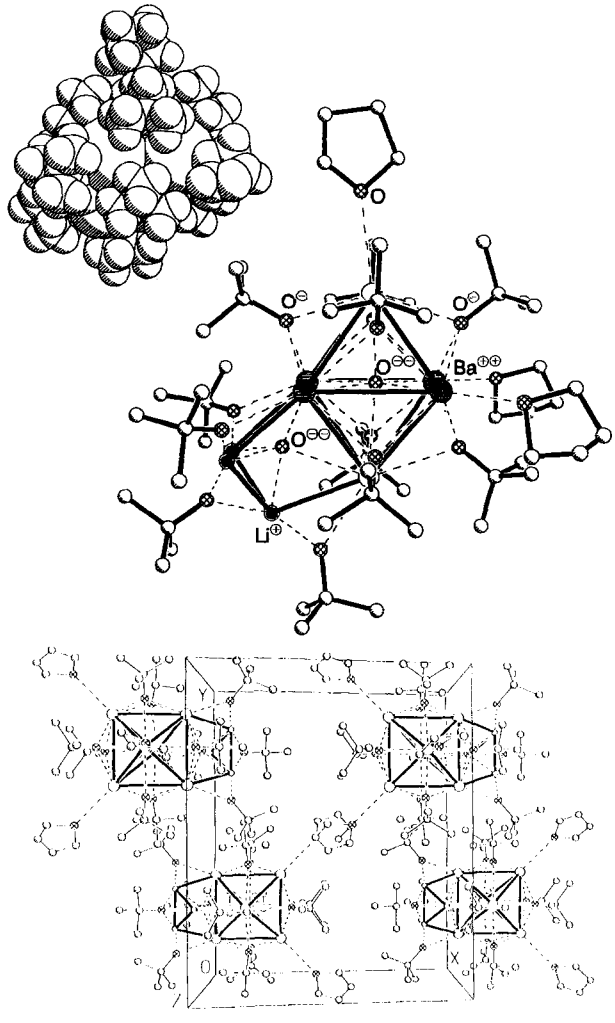

Fig. 1. Single-crystal structure of $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$ at 150 K. Top: Space-filling representation; center: side view; bottom: unit cell (monoclinic, $P2_1/m$, $Z = 2$) viewed along the *z* axis. Selected bond lengths [pm] and angles [°]: BaBa(Ba) 381, BaBa(Li) 373, BaLi 307, LiLi 238; BaBaBa 90 and 60, BaLiLi 103, LiLiLi 60; BaO(Ba) 260, 276, 277, BaO(Li) 266, LiO(Ba) 195, 199, BaO(R) 264 to 278, $BaO(R_2)$ 295, LiO(R) 178 to 191, $OC(R_3)$ 140. An additional THF molecule is disordered in the crystal cavities.

The following structural details are emphasized: The Ba octahedron is slightly distorted, since the interbarium distances are 8 pm shorter on its lithium side [BaBa(Li)]. The O^{2-} center is shifted by about 15 pm out of the center of the octahedron towards the outer Ba_3 triangle and that of the prismane by about 8 pm towards the Li_3 triangular face. Of the eleven *tert*-butyl alcoholate anions, seven are above Ba_3 octahedral faces,
