Organometallic Compounds for Nonlinear Optics—The Search for En-light-enment!

Nicholas J. Long*

The importance of nonlinear optical phenomena has been known for some time, however, since the mid-1980s, there has been an explosion of interest in the search for and development of nonlinear optical materials that possess commercial device applications. To date, the systems have been utilized in information processing, optical switching, optical frequency conversion, and telecommunications, and with the advancing development of optotechnology, burgeoning demands for suitable materials are becoming apparent. Of the many systems studied for example inorganic crystals and semiconductors, organic crystalline monomers, and long-chain polymers with delocalized π electrons, no one species has proved to be all-encompassing, with advantages for one application being negated by disadvantages for another. This is likely to remain the case for the foreseeable future with the criteria of the application governing the type of material used. However, chemists are gradually elucidating what actually governs second- and third-order nonlinear activity and thereby, tailoring species to show greater effects. In recent years, organometallic compounds, through their unique characteristics such as diversity of metals, oxidation states, ligands, and geometries, have found success and brought a new dimension to the area. This review attempts, with critical appraisal, to bring the discussion of organometallic nonlinear optical systems up to date, as well as giving a brief but general introduction to the field of nonlinear optics.

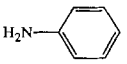
Keywords: NLO materials · polyacetylenes · sandwich complexes

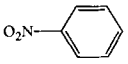
1. Introduction

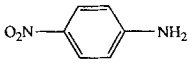
The interaction of the electromagnetic field of light (normally high intensity laser light) with a nonlinear optical (NLO) material can result in the generation of new electromagnetic fields. As light passes through a species, its electric field interacts with inherent charges in the material causing the original beam to be altered in phase, frequency, amplitude or polarization. The study of such interactions is the field of *"nonlinear optics"*, and describes deviations from linear behavior as defined by the laws of classical optics.[1]

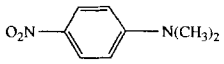
Such media are now creating intense interest not only due to their NLO properties, but also due to attempts to control other characteristics such as solubility, processability, optical clarity, absorption, and thermal stability, as these will obviously determine technological utility. Initial developments have already given rise to NLO devices, such as frequency doubling crystals useful in laser experimentation. However, there remain enormous possibilities in the field of telecommunications, computer and optical signal processing devices[2, 3] through a) optical phase conjugation and image processing, b) optical switching (i.e. transmission of light depending on the refractive index of the material), c) optical data processing (for computers, where incredibly rapid movements are needed), and d) new frequency generation.

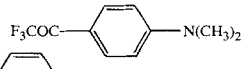
1.1. Inorganic and Organic Materials

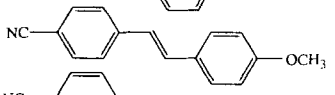


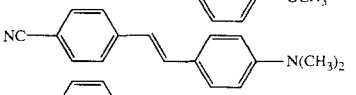


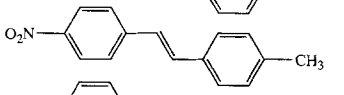


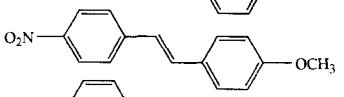


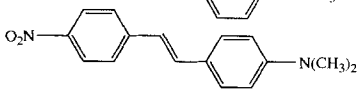












Investigations were initially focused on purely inorganic and organic systems, and the first solids to demonstrate second-order NLO properties were inorganic crystals (e.g. quartz, $LiNbO_3$, and KH_2PO_4),[4] where a photoinduced change in refractive index and later, a photorefractive effect were observed. Inorganic semiconductors followed, such as gallium arsenide (GaAs) and indium antimonide (InSb), which displayed large optical nonlinearities. Multilayer semiconductor materials, which were synthesized by using new crystal growth techniques,[5] exhibited special optical properties not apparent in the bulk material.[6] Both types of NLO materials are used in commercial applications (modulators, optical switches etc.)[7, 8] but they also have drawbacks: the crystals face a "trade-off" problem between response time and magnitude of optical nonlinearity, and the semiconductors are costly and difficult to produce; furthermore, they absorb strongly in the visible region and are of poor optical quality, thereby discounting many possible applications.

Several years later, organic systems were investigated as an alternative to inorganic species because of their low cost, fast and large nonlinear response over a broad frequency range, inherent synthetic flexibility, high optical damage thresholds, and intrinsic tailorability.[9-12] It was proposed[13] that the presence of electron-donating and electron-accepting groups on benzene and stilbene systems would result in strong second harmonic generation (SHG). Table 1 gives a list of highly polar

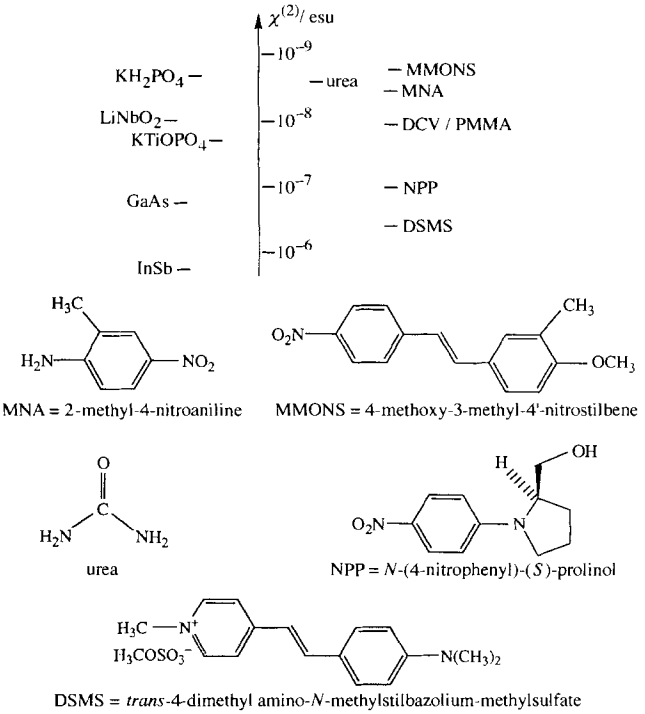
aromatic compounds of benzene and stilbene.[14,15] For example, 2-methyl-4-nitroaniline (MNA, see Fig. 1) produced large values of $\chi^{(2)}$ due to the presence of the methyl substituent on the aromatic ring, inducing non-centrosymmetric crystal packing.[16] This was followed by *trans*-4-dimethylamino-*N*-methyl stilbazolium methyl sulfate which showed a $\chi^{(2)}$ value three hundred times greater than that of MNA.[17] Further investigations have been carried out in an attempt to produce thin film systems, since the crystalline state imposes limitations on the applications. The two main methods for producing such films are polymer poling[18] and Langmuir–Blodgett film formation.[19]



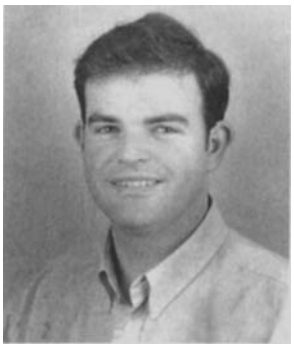


Fig. 1. Top: $\chi^{(2)}$ values for some industrially important inorganic and organic NLO systems. Bottom: Chemical formulas of the systems. For the definition of $\chi^{(2)}$ see Equation (d) (Section 2).

Conjugated organic polymer systems have been of interest in third-order nonlinearity studies; polydiacetylene is the most important.[20] The delocalized π-electron backbone is responsible for the NLO activity, and through a wide range of substitutional side groups, there is structural control and material processability. Poly(2,4-hexadiyne-1,6-diyl-*p*-toluenesulfonate) was synthesized in the solid state by irradiation of crystals of the

Nick Long, born in 1965, in Bristol, studied chemistry at the University of Durham from 1983–1986, and then obtained his Ph.D. from the University of Exeter in 1989 under the supervision of Eddie Abel and Tony Osborne. After staying in Exeter to take up a two-year appointment as "Demonstrator in Inorganic Chemistry", he then moved to the University of Cambridge to become the "Adrian Research Fellow" with Darwin College. In 1993, he was appointed as "Temporary Lecturer in Inorganic Chemistry" at the University of Cambridge. In January 1995 he took up his current position as "Lecturer in Inorganic Chemistry" at Imperial College, London. His interests include transition metal- and/or chalcogen-bridged metallocenophanes, the coordination chemistry of multidentate chalcogeno ligands and novel metallocenyl-acetylide metal complexes. Through close collaboration with Jack Lewis and Paul Raithby, he has become excited by organometallic nonlinear optics, the subject of this review.

monomer with UV, X-, or γ-rays. Formation of many other polydiacetylenes can be completed by this method, and soluble species, such as poly(*N*-*tert*-butoxycarbonyl-*N*-methyl urethane) have improved optical third-order nonlinearity.[21] Other conjugated polymers investigated include polythiophenes, polybenzothiophenes, polyphenylenes, and polyanilines.[2, 22] However, organic systems can suffer from problems, such as volatility, low thermal stability, and mechanical weakness.

Several inorganic and organic materials have found success in NLO (Fig. 1); more information is available in review articles concerned with inorganic,[23, 24] organic,[3, 25–30] polymeric,[31] and general[32] NLO systems. However, recent interest has been engendered by studying organometallic and coordination compounds. There has been scant in-depth discussion of the rapidly expanding area of organometallic NLO materials, with the notable exception of articles by Nalwa[33] and Marder.[34] Therefore, this review attempts to bring the field up to date and discuss the salient points arising from the exciting studies in this area.

1.2. Why Organometallic Compounds?

As data and understanding of inorganic and organic NLO materials have accumulated, corresponding information regarding the behavior of organometallic compounds has not developed. Nevertheless, in the last six years, investigations of organometallic systems have been greatly intensified. Incorporation of metals into NLO systems gives a new dimension of study and introduces many new variables. The metals can have a large diversity of oxidation states and ligand environments, and due to the polarizable d electrons, a number of interesting effects and greater nonlinear activity are likely to be observed. Reasons for this have been postulated:[34–36]

a) Organometallic systems can possess metal → ligand or ligand → metal charge transfer bands in the visible region of the spectrum. These optical absorption bands are usually associated with large second-order activity (although, they can also lead to "transparency" problems—see later).

b) The compounds have great possibilities for redox changes, a property largely associated with the metal center, which can be electron-poor or electron-rich depending on the oxidation state and ligand environment. Facile redox ability can be envisaged as leading to large hyperpolarizability, with the metal center being an extremely strong donor or acceptor in comparison to conventional organic systems.

c) Chromophores, such as phthalocyanines, containing metal ions are amongst the most intensely colored materials known. The strength of the optical absorption band (related to its transition dipole moment) is also associated with large optical nonlinearities.[37]

d) Many organometallic compounds have low-energy excited states with excited-state dipole moments significantly different from their respective ground-state dipole moments (Fig. 2). Most of these excited states involve transfer of electron density between the central metal and one or more of the associated ligands and have large oscillator strength. This charge transfer will provide a substantial contribution to β (defined in Equation (c); Section 2).

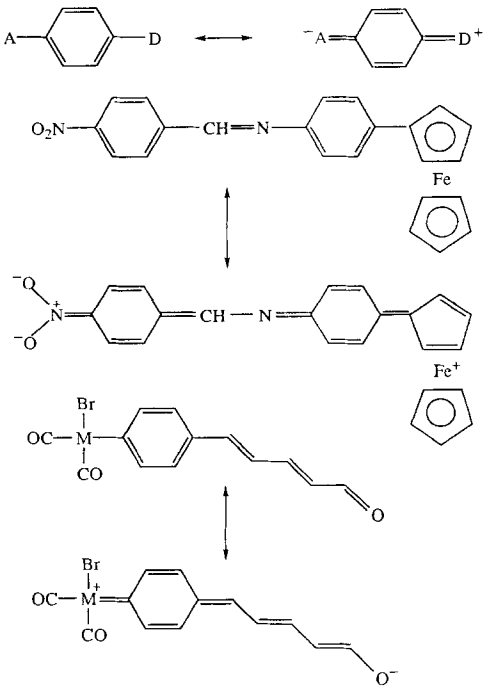

Fig. 2. Ground state and lowest energy excited state structures for some conjugated aromatic systems.

e) Organometallics compounds also have important advantages in the range and mix of non-aromatic ligands that can be attached to the metals. These ligands can shift the occupied and unoccupied metal d orbitals that interact with the π-electron orbitals of the conjugated ligand system. This provides a mechanism for fine-tuning and optimizing β or the crystallographic factors that control the bulk susceptibility.

f) Additionally, the metal centers in these molecules can constitute chiral species[38] so that if resolved, they must form materials that crystallize in non-centrosymmetric space groups, essential for non-zero β values.

g) Incorporation of transition metal ions can also be expected in some cases to increase the solubility of a material in common organic solvents, thereby enhancing its processability.

The only foreseeable problem is the low energy d-d transitions present in nearly all organometallic compounds, normally observed in the visible light region. This gives rise to what is termed a "nonlinearity/transparency trade-off". If a material is to be used in a frequency-doubling or -tripling capacity, then obviously, an aborption of the harmonic light that is produced will limit the usefulness of these materials. Depending upon the location of these bands, the "transparency window" can be large or small, but clearly, the larger a material's transparency range the greater the number of potential applications.

Overall, it is clear that there is plenty of scope for investigation of organometallic NLO compounds and a justified amount of great expectation.

2. The Theory of Nonlinear Optics

The interaction of an electromagnetic field with matter induces a polarization in that matter. In linear optics there is an

instantaneous displacement (polarization) of the electron density of an atom by the electric field E of the light wave. The displacement of the electron density away from the nucleus results in a charge separation (an induced dipole), with moment, μ. With small fields, the strength of the applied field is proportional to the displacement of charge from the equilibrium position, and leads to the relation (a), in which α is the linear polar-

$$\text{Polarization} = \mu = \alpha E \quad \text{(a)}$$

izability of the molecule or atom. If the field oscillates with a frequency, then the induced polarization will have the same frequency and phase, if the response is instantaneous.

Most applications of experiments with NLO are carried out on bulk or macroscopic materials and, in this case, the linear polarization is shown in Equation (b), where χ is the linear

$$P = \chi E \quad \text{(b)}$$

susceptibility of a collection of molecules (on which the parameters of the dielectric constant and refractive index have a bearing).

When a molecule is subjected to laser light (i.e. a very high intensity electric field), the molecule's polarizability can change and be driven beyond the linear regime. Therefore, the now nonlinear molecular polarization P_M (which is a function of the applied field and leads to nonlinear effects) can be expressed by Equation (c), where β = first molecular hyperpolarizability

$$P_M = \alpha E + \beta E^2 + \gamma E^3 + \ldots. \quad \text{(c)}$$

(second order effect) and γ = second molecular hyperpolarizability (third order effect). With increasing field strength, nonlinear effects become more important due to the higher powers of the field E [Eq. (c)]. Since α is much greater than β and γ NLO was not commonly observed before the introduction of the laser and its associated large electric fields.

The polarization of a material is again given by an analogous expression [Eq. (d)], where P_0 is the static dipole of the sample.

$$P = P_0 + \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \ldots. \quad \text{(d)}$$

$\chi^{(n)}$ is the nth order NLO suspectibility and is analogous to the molecular coefficients in Equation (c) (except that with the χ terms, local field effects, which are consequences of the surrounding medium, are taken into account).

An important point to note is that for β (or $\chi^{(2)}$) to be non-zero, the molecules (or material) need to be non-centrosymmetric. This can be explained by the fact that if a field $+E$ is applied to a molecule, then from Equation (c), the first nonlinear term will induce a polarization of $+\beta E^2$. If a field $-E$ is applied, the predicted polarization would still be $+\beta E^2$, but this should be $-\beta E^2$ if the molecules are centrosymmetric. This contradiction can only be rationalized if $\beta = 0$ in centrosymmetric media. Conversely, γ can be shown to be the first non-zero nonlinear term in centrosymmetric and, indeed, all media, as $+E$ gives $+\gamma E^3$ whilst $-E$ produces $-\gamma E^3$.

Although γ has the properties of a scalar quantity,[39] β cannot also be assumed to be a scalar quantity and in fact, β behaves as a vector.[40] This is important in experiments where the applied field points along a molecular axis and therefore, the hyperpolarizability in that direction will be the dominant component (i.e. the EFISH experiment, see Section 3).

The principle of second harmonic generation (SHG) is that if an intense light beam passes through a second-order NLO species, then light at twice the input frequency will be produced. This can be shown mathematically be expressing the electric field of a plane light wave according to Equation (e), and then introducing this into Equation (d) to give the Equation (f) for the polarization since $\cos^2(\omega t)$ is also $1/2 + 1/2\cos(2\omega t)$ then Equation (f) becomes Equation (g).

$$E = E_0\cos(\omega t) \quad \text{(e)}$$

$$P = P_0 + \chi^{(1)}E_0\cos(\omega t) + \chi^{(2)}E_0^2\cos^2(\omega t) + \chi^{(3)}\cos^3(\omega t)\ldots. \quad \text{(f)}$$

$$P = (P_0 + 1/2\chi^{(2)}E_0^2) + \chi^{(1)}E_0\cos(\omega t) + 1/2\chi^{(2)}E_0^2\cos(2\omega t) + \ldots.. \quad \text{(g)}$$

So, now the polarization consists of a new *"frequency doubled"* component, 2ω. This is called a "three-wave mixing" process, since two photons with frequency ω have combined to generate a single photon with frequency 2ω. This analysis can be extended to third and higher order terms, thus, third-order processes involve "four-wave mixing".

Generally, second-order NLO effects involve the interaction of two distinct waves of electric fields E_1 and E_2 with the electrons of the NLO material. Therefore, with two beams of different frequencies, the second-order term of Equation (g) becomes the left hand side of Equation (h). The right-hand side can be deduced from further mathematics or trigonometry.

$$\chi^{(2)}E_1\cos(\omega_1 t)E_2\cos(\omega_2 t) = 1/2\chi^{(2)}E_1E_2\cos[(\omega_1 + \omega_2)t] + 1/2\chi^{(2)}E_1E_2\cos[(\omega_1 - \omega_2)t] \quad \text{(h)}$$

This indicates that when two beams of light of frequencies ω_1 and ω_2 interact with an NLO material, polarization occurs at sum $(\omega_1 + \omega_2)$ and difference $(\omega_1 - \omega_2)$ frequencies. SHG is the case where the two frequencies are equal. Terms with frequencies that are the sum or difference of two input frequencies or twice the frequency of the input radiation are generated by second-order nonlinear susceptibility.

Third-order optical nonlinearities result from the introduction of a quartic term. By returning to Equation (g) and considering the polarization of a *molecule* [Eq. (c)] (and assuming that the even order terms are zero i.e. the molecule is centrosymmetric), this gives Equation (i) and with trigonometry $(\gamma/6)E_0^3\cos^3(\omega t) = (\gamma/6)E_0^3[3/4\cos(\omega t) + 1/4\cos(3\omega t)]$ this leads to Equation (j).

$$\mu = \mu_0 + \alpha E_0\cos(\omega t) + (\gamma/6)E_0^3\cos^3(\omega t) + \ldots \quad \text{(i)}$$

$$\mu = \mu_0 + \alpha E_0\cos(\omega t) + (\gamma/8)E_0^3\cos(\omega t) + (\gamma/24)E_0^3\cos(3\omega t) + \ldots \quad \text{(j)}$$

Therefore, the interaction of an intense beam of light with a third-order NLO material creates a polarization component at

the third harmonic. Similarly, for a bulk material, the third harmonic generation is represented by $\chi^{(3)}$, the material susceptibility. It should be noted that whilst negative and positive β values give rise to the same potential and physical effects, a positive γ leads to a different electron potential than a negative one would. The application of an intense voltage to a third-order NLO material will induce a refractive index change in that material, and the sign of γ determines whether the third-order contribution to the refractive index is positive or negative. For more in-depth discussion, please consult references[2b, 26, 32, 34].

3. Experiments for Nonlinear Optics

A crucial aspect in the progression of NLO studies has been the development of experimental techniques available for investigating and measuring a material's NLO activity. Over the years, several methods have been widely employed and are briefly discussed here:

1. *Kurtz Powder Technique*:[41-44] This technique was the first used in the study of organometallic materials. A laser is directed onto a powdered sample and, assuming that the material is SHG active, the emitted light at the second harmonic frequency is collected and compared to that of a reference sample, such as quartz or urea, to obtain a measure of the SHG efficiency. It is an excellent method for testing large numbers of powdered materials, but is recognized as semi-quantitative, and minor variations in relative efficiencies are probably not significant.[45] Results are dependent on the particle size, and recrystallization from a range of solvents can lead to different SHG efficiencies. The efficiency measured depends upon both the molecular (β) and bulk (or macroscopic) ($\chi^{(2)}$) polarizabilities, and powder testing is not a reliable probe of structure–property relationships.[34]

2. *Electric Field Induced Second Harmonic Generation (EFISH)*: The EFISH experiment[46-49] allows for a structure–property understanding and gives a projection of the β vector along the molecule dipole (μ) direction. A strong direct current electric field is applied to the gas, liquid, or solution of interest in order to remove the orientational averaging caused by statistical alignment of molecular dipoles in the medium.[40] The components of the experiment are shown in Figure 3.[46, 50, 51] Most materials are dissolved in an appropriate solvent, and methods have been developed[46] to distinguish between the contributions from the solvent and solute. Interpretation of EFISH results can also be difficult if the molecule lacks a clear charge transfer axis along the dipole direction.[35, 52] The experiment generates a harmonic field from three waves, so the induced nonlinear polarization arises from a third-order process and, as such, the second molecular hyperpolarizability (γ) is a component.[26, 35, 45] However, γ is normally determined from third harmonic generation (THG) experiments and then subtracted from the EFISH response to determine β. Yet, in compounds exhibiting significant charge transfer, $\mu\beta$ is much greater than γ and the third-order contribution is often ignored.

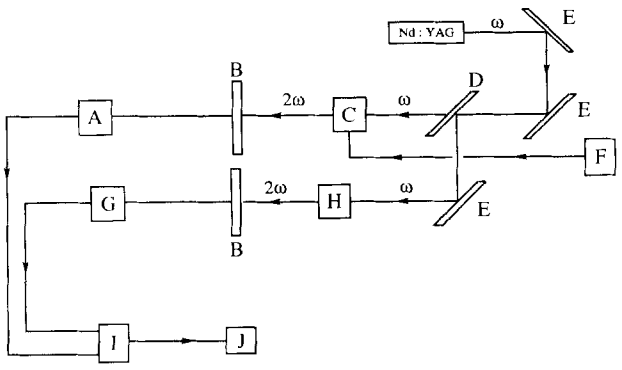

Fig. 3. Schematic diagram of the setup for an EFISH experiment. A = reference photomultiplier tube, B = filter, C = cell, D = beam splitter, E = mirror, F = high-voltage pulse generator, G = signal photomultiplier tube and monochromator, H = reference crystal, I = box car integrator, J = recorder.

3. *Hyper-Rayleigh Scattering (HRS)*: This newly developed technique[53, 54] is used for the determination of the first molecular hyperpolarizability β (second-order NLO polarizability) of NLO molecules. Values of β can be obtained without having to independently determine the dipole moment μ and the second hyperpolarizability γ, and thus this method has an advantage over the EFISH technique.

Intense infrared light pulses of a Nd-doped YAG laser are focused in a thermostated cylindrical cell. A small fraction of the incident light beam is directed on a fast photodiode for monitoring pulse shape and stability, and incident light intensity. The scattered light is collected by an efficient condenser system and gated integrators are used to retrieve actual values for the intensities of the incident and second-order scattered light pulses. HRS is the only method available for determining the β values of salts in solution (as EFISH cannot be applied to conducting solutions), and remarkable results for some mixed-valency metal complexes have been recently reported[55] (see Section 4.3).

4. *Third Harmonic Generation* (THG):[45, 56] This describes the process in which a fundamental laser field of frequency (ω) generates, through nonlinear polarization in the material, a coherent optical field at 3ω. It allows for the determination of the purely third-order electronic nonlinearity of molecules, without complications due to orientational or other motional contributions,[22, 57, 58] and is acknowledged as a rapid, reliable method for determination of γ for molecules in liquids and solutions. However, it should be borne in mind that many third-order NLO materials absorb in the visible and near IR regions, thus hampering assessment of their electronic hyperpolarizabilities.[45]

5. *Degenerate Four-Wave Mixing (DFWM)*[14, 15, 59, 60] is the other most commonly used technique to study third-order NLO materials. Here, three laser beams of the same frequency interact in a material. The nonlinear interaction produces a fourth beam and its intensity is proportional to the product of the input intensities and the square of the bulk susceptibility, $\chi^{(3)}$. If required, the second molecular hyperpolarizability, γ, can be obtained from the relation where N is the density of molecules and L is the local field factor. The capability to obtain measurements with ultra-short pulses is crucial in separating the various contributions to the DFWM signals. Vibrational and orientational mechanisms can contribute to the observed nonlinearity and this creates a problem when developing structure–property relationships of the purely electronic part of γ.[45]

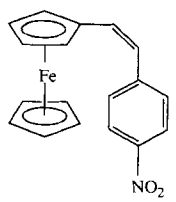
Methods such as optical Kerr gate,[61] linear electro-optic (LEO) modulation,[62] and Maker fringe and wedge techniques[63-65] have also been used for the measurement of opti-

cal nonlinearity. Commonly, a combination of techniques is necessary for complete investigation of a material's NLO behavior, though care should be taken in automatic comparison of NLO values resulting from different techniques due to the various conditions and mechanisms used. For complete and detailed discussion of all the methods, consultation of the listed references is encouraged.

4. Materials for Second-Order Nonlinear Optics

Design of second-order NLO materials is now quite advanced, as over the years, criteria have been discovered that are essential for exhibition of large hyperpolarizabilities. Whilst there is discussion on the importance and variation of these points, the basic tenets are universally accepted and are as follows:

1. polarizable material (the electrons need to be greatly perturbed from their equilibrium positions)
2. asymmetric charge distribution (incorporation of donor–acceptor molecules)
3. a pathway of π-conjugated electrons
4. acentric crystal packing (introduction of a chiral center should guarantee this).

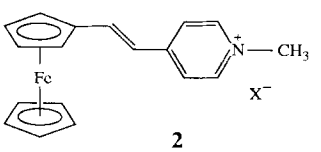


A two-step model concerned with electronic properties[14, 15] has been important in predicting the usefulness of new materials. This suggests that molecules must possess a) excited states close in energy to the ground state, b) large oscillator strengths for electronic transitions from ground to excited states, and c) a large difference between ground and excited state dipole moments.[15a, 66, 67] Such requirements are thus, best met by dipolar, highly polarizable, donor-π-acceptor systems, showing charge transfer between electron-donating and electron-withdrawing groups. Much effort[22, 49, 68] has been exerted into finding the optimum combinations of acceptor and donor groups, especially with organic compounds that are easily substituted. The general conclusion is that the first molecular hyperpolarizability (β) increases with increasing conjugation length. However, using the two-step model, it was shown that there is an optimal combination of donor and acceptor species that maximizes β[69] and, indeed, the strongest acceptor does not necessarily lead to the largest nonlinearity.[68a] Theoretical work[69–71] has also predicted this β maximum and then a decrease, and suggests that for any donor–acceptor pair, there is a certain bridge of a given length that maximizes β. Over the years, research has mainly concentrated on development of stronger acceptors and donors, and the structure of the molecular bridge connecting the two end groups has been rather neglected. Latest results suggest that this is unwise, and an optimal degree of bond length alternation in a polyene-type bridge[52, 72] and the importance of the donor and acceptor orbitals to those of the bridge[73] have been discovered.

A significant enhancement of polarizability has been demonstrated on extending the conjugation length between the donor and acceptor. This generally results from decreasing the energy gap and increasing the transition dipole moment between the relevant states. The effectiveness of various conjugated backbones has been well-studied.[74–76] From reports on some polyene, stilbene, and phenylhexatriene derivatives, it has become clear that phenyl ring-based conjugated linkers should be avoided when designing materials with high β values for NLO.[52]

However, even if a molecule has a large β value, it might fail to exhibit SHG activity. Crystallization in a non-centrosymmetric fashion is also required, and since about 70% of all achiral molecules crystallize in centrosymmetric space groups it is a major problem. To counter this, many strategies for forming acentric crystals capable of showing SHG activity have been employed: 1) incorporation of chiral molecules,[77, 78] 2) hydrogen bonding,[77, 79–81] 3) ionic chromophores,[82, 83] 4) steric hindrance,[16] 5) inclusion phenomena,[84–87] 6) Langmuir–Blodgett techniques,[19] 7) cocrystallization,[88] and 8) dipole–dipole interaction reduction,[89] and these methods have met with varying degrees of success in ensuring a dipolar alignment favorable for SHG.

4.1. Metallocenes

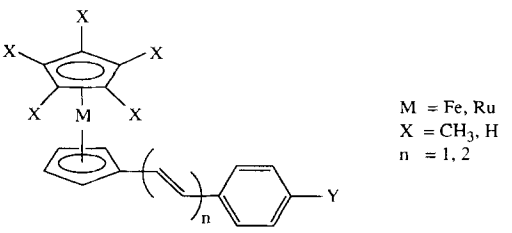


The report in 1987 by Green et al.[90] that a ferrocene derivative had an excellent SHG efficiency, first demonstrated that organometallic compounds could have great potential in the field of second-order NLO. This has led to metallocenes being the most thoroughly studied compounds to date with regard to this field of study. The *cis*-ferrocene derivative **1** was analyzed, since it crystallizes in a non-centrosymmetric space group (in contrast the *trans* isomer shows no SHG signal, because of its center of symmetry). Solvatochromatic behavior was observed in the UV/Vis spectra of **1**; two absorptions (at 340 and 492 nm) are observed in *N,N'*-dimethyl formamide, as opposed to the three (at 320, 406, and 462 nm) in heptane. It should be noted that marked differences in the UV/Vis spectrum of a compound on varying the solvent (i.e. solvatochromatic behavior) is a good initial indicator of potential NLO activity. Kurtz powder measurements at 1.064 μm for the compound gave an SHG efficiency 62 times that of the urea reference sample.[90] It is thought that the facile redox ability exhibited by the metallocene derivatives leads to large values of β by charge transfer through the π-electron conjugation system. The donating strengths of the metallocenes are attributed to the low binding energy of metal electrons, and their effectiveness is responsive to structural modifications which also influence their redox potentials. However, on the basis of binding energies and redox potentials, it was expected that the molecular hyperpolarizabilities would be larger than the observed values.[35] The authors state that poor coupling between the metal center and the substituents due to the π geometry lowers the donating ability of the metal center. Improved coupling and a direct bonding of the metal to the organic acceptor system was effected in a series of alkenylidyne diiron complexes.[91] Compounds such as $[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)_2(\mu\text{-}CO)(\mu\text{-}(E)\text{-}C\text{-}CH{=}CH\text{-}C_6H_4\text{-}p\text{-}N(CH_3)_2)]\,CF_3SO_3$ exhibit large molecular second-order hyperpolarizabilities but lower than expected SHG efficiencies (Kurtz), due to unfavorable alignment of the chromophores in the crystal lattice.

1

This led to reports on similar ferrocenyl compounds by Bandy et al.[92] and Marder et al.[93,94] Species of the formula $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_3(CH_3)CH{=}CHR)]$, where R = *p*-$NO_2C_6H_4$, *p*-$CNC_6H_4$, *p*-$CHOC_6H_4$, -(*E*)-CH=CH-*p*-$NO_2C_6H_4$ and $-\overline{C{=}CH{-}CH{=}C(NO_2)O}$ exhibited powder SHG efficiencies ranging from 1.2 to 17.0 times that of urea.[92] Substitution of a methyl group onto the cyclopentadienyl (Cp) ring containing the acceptor moiety resulted in asymmetry and optical activity and was instrumental in a larger SHG value being observed than for the analogous $(\eta^5\text{-}C_5H_4CH{=}CHR)$ compounds.

The largest SHG value to date for an organometallic compound came from a series of salts of the form **2**, where the counterion is I^-, Br^-, Cl^-, $CF_3SO_3^-$, BF_4^-, PF_6^-, *p*-$CH_3C_6H_4SO_3^-$, NO_3^-, $B(C_6H_5)_4^-$.[93,94] The value of the powder SHG signals depends on the counterion (as was found for organic salts[82,83]), with I^- giving a value 220 times that of the urea standard (Table 2). It is interesting to note that substitution of ruthenium for iron leads to smaller powder efficiencies. This is rationalized as being due to the less electron-rich and, therefore, less effective donor ruthenium, and that the ruthenium compounds examined tend to crystallize in centrosymmetric orientations.[94]



2

Table 2. The powder SHG efficiencies of a series of salts of type **2** [94].

X	SHG efficiency [a]
I	220
Br	165

[a] Intensity measured with 1907 nm fundamental radiation. SHG efficiency measured relative to urea.

A systematic study of the molecular hyperpolarizabilities of some ferrocene and ruthenocene derivatives has been recently carried out.[35,95,96] The compounds were of the form $[(\eta^5\text{-}C_5X_5)M(\eta^5\text{-}C_5H_4{-}(CH{=}CH)_n{-}C_6H_4Y)]$ and are depicted in Figure 4. Variations incorporating different metal centers M and acceptor groups Y, (NO_2, $COCH_3$, CN, CHO), *cis* and *trans* isomers, exten-sion of conjugation and electron-donating substituents on the Cp rings were studied to obtain a detailed understanding of the structural factors that affect molecular hyperpolarizabilities. It was shown that 1) substitution of pentamethyl groups (X = Me) leads to an increase in dipole moment and nonlinearity, 2) the β value of ferrocenes is greater than that for ruthenocenes and 3) the effect of the conjugation length is great, with a compound featuring two double bonds having a much higher β value ($\beta = 66.0 \times 10^{-30}$ esu) than the analogous species with one alkenene bond ($\beta = 31.0 \times 10^{-30}$ esu).

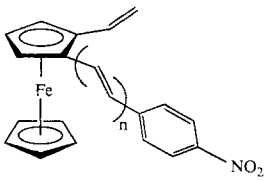
Fig. 4. Metallocenes with conjugated alkenic substituents.

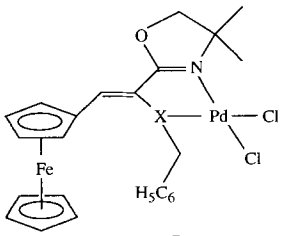
From ferrocenecarbaldehyde, a series of ferrocenyl Schiff bases of the form $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CH{=}NR)]$ (e.g. R = $NCH(C_6H_4\text{-}p\text{-}NO_2)$ and C_6H_4-*p*-CN) were prepared.[97,98] Although, considerable solvatochromism was observed, crystallization was in a centrosymmetric space group. The ferrocenyl imine, $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)CH{=}N(C_6H_4\text{-}p\text{-}NO_2)]$, did show some nonlinear activity, however, it was not large, being a third times that of the urea reference. The compound has a non-centrosymmetric crystal arrangement but, the $P2_12_12_1$ space group ensures a cancelling of the dipolar nature of the molecule.

Marder et al.[99-101] have utilized the ferrocenyl group as an electron donor in some "push-pull" organoboranes, [(*E*)-D-CH=CH-$B(Mes)_2$] and [D-C≡C-$B(Mes)_2$] (D = $P(C_6H_5)_2$, $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$, and Mes = mesityl). Three-coordinate boron has an empty p orbital making it a powerful π acceptor, and some π-conjugated organoboranes were known to exhibit large β coefficients. As a result of the low-lying charge transfer from electron-rich iron to electron-deficient boron, a β value of 24×10^{-30} esu was observed for $[(E)\text{-}(\eta^5\text{-}C_5H_5)Fe\{\eta^5\text{-}C_5H_4{-}CH{=}CH\text{-}B(Mes)_2\}]$.



Several other donor (ferrocene)-acceptor compounds have been investigated recently. 1) 4-Ferrocenyl-2′-methyl-4′-nitroazobenzene[102] is a polarizable dipolar molecule; however, the crystal packing involves a centrosymmetric head-to-tail pairing of molecules resulting in no NLO behavior. 2) A SHG signal for the 1,3-diazolidine **3** was detected by powder techniques but it had a low efficiency.[103] 3) Similar results have been reported for donor-acceptor substituted acetylenes.[104,105] For example, the SHG efficiency of ferrocenyl(phenyl)acetylene is 3.7 times that of urea at 1907 nm. However, it is about 15 times lower than the previously described analogous ferrocenyl *ethylenic* compound (**1**).[90]

3

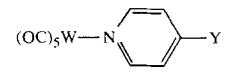


In order to ensure crystallization of a material in a non-centrosymmetric space group, Green et al.[106] have incorporated the chiral ligand (+)-DIOP (DIOP = 2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane) into a sequence of compounds of general formula $[(\eta^5\text{-}C_5H_5)Fe\{(+)\text{-}$

diop}(*p*-NCC_6H_4R')]PF_6 (R' = donor or acceptor group). When R = NO_2, the ferrocenyl fragment acts as a π donor through d-π* (NC) orbitals towards the NO_2 acceptor group, and leads to an SHG efficiency 38 times that of urea. After considering that the absence of inversion symmetry is a property of chiral, enantiomerically pure compounds, Togni and Rihs[107] have synthesized some enantiomerically pure ferrocene derivatives **4** for NLO. By also possessing conjugated donor–acceptor systems, large SHG values were expected, unfortunately, the species show a pairwise antiparallel arrangement of the molecules in the solid state, leading to poor SHG efficiencies.

4

Some bimetallic complexes featuring iron (ferrocenyl) and palladium have been formed,[108] where the ferrocenyl group is attached to an electron-attracting oxazoline group through an ethylene linkage (**5**). EFISH measurements of the ferrocenyl ligands gave reasonable values of β, yet the NLO properties were enhanced upon coordination with Pd^{II} by a factor of 2. It is thought that the metal ion withdraws electrons from the lone pairs of the heteroatoms. Other studies on metallocenes such as polymeric materials with pendant ferrocenyl-acceptor moieties[109] and novel arene-Cp-ruthenium complexes(arene = thiophene, nitrobenzene, *N*,*N*-dimethyl-4-nitroaniline, 2-methyl-4-nitroaniline)[110] have recently been communicated. Whilst the ferrocenyl methylmethacrylate[111] polymer has been found to display an SHG efficiency four times that of the quartz standard, NLO activity has yet to be demonstrated for the other species.



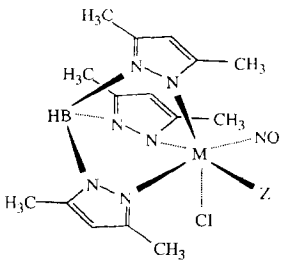
5, X = S, SO

Elegant and thorough theoretical investigations of organometallic structures as second-order NLO chromophores have recently been communicated by Marks, Ratner, and Kanis.[112] Using accurate, chemically orientated, computationally efficient ZINDO-SOS quantum chemical formalism, ferrocenyl molecules such as **2**,[113] (arene)chromium tricarbonyl complexes,[113] and Group VI stilbazole and pyridine pentacarbonyl derivatives[114] have been examined. By comparing computed quadratic hyperpolarizabilities with recent organometallic solution phase EFISH data, the authors were able to demonstrate the reliability of this theoretical approach, rationalize known molecular responses, and suggest chemical modifications in order to optimize hyperpolarizabilities in metal-containing chromophoric species.

One of the conclusions was that organometallic chromophores must possess a highly polarized, strongly coupled ligation sphere around a given metal for effective second-order NLO behavior. More importantly, it was shown that efficient quantum chemical methods can be used to understand hyperpolarizabilities and thus, be utilized in designing new chromophoric units possessing optimal NLO characteristics.

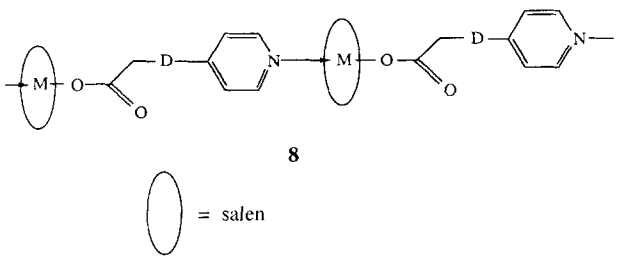
4.2. Metal Carbonyl and Metal Carbonyl Pyridine Complexes

In 1986, a large number of transition metal organometallic complexes of Group VI metal carbonyl arenes, pyridines, and chiral phosphanes were studied by powder techniques for SHG activity.[36] The metal carbonyl arene complexes have the formula $[M(CO)_n(\eta\text{-arene})L_{3-n}]$ (where M = Cr, Mo, W; L = phosphane; $n = 0-3$) but generally crystallize in centrosymmetric space groups, giving vanishing $\chi^{(2)}$ values. This was also the problem with the metal carbonyl pyridine species, the SHG efficiencies ranging between 0.04 and 1.0 (relative to urea). There are several reasons why metal carbonyl arene complexes were expected to show significant NLO response. Intense metal → ligand charge transfer absorptions are observed in the low-energy absorption spectra increasing the dipole moment, and the arenes introduce a number of delocalized electrons and, therefore, conjugation. With this in mind, Cheng et al.[95] examined a series of (η^6-arene) tricarbonylchromium complexes $[Cr(\eta^6\text{-}C_6H_5X)(CO)_3]$ (X = H, OCH_3, $COOCH_3$, NH_2, and $N(CH_3)_2$). However, β values were again small, with little effect on changing the substituents due to poor linking conjugation through the system. Some metal bipyridine complexes $[M(bpy)(CO)_4]$ (M = Mo, Cr, W) and $[M(bpy)Cl_4]$ (M = Pt, Pd) also showed SHG values similar to that of urea. In contrast, a series of pentacarbonyl(pyridine)tungsten σ-complexes **6** gave some interesting EFISH results.[95, 115] These compounds possess a σ linkage as the nitrogen lone pair donates to the empty d-orbital of tungsten. Efficient overlap of the pyridine π orbitals with the d_{xz} and d_{yz} orbitals also allows π donation toward the metal center which acts as a ground state π-acceptor due to the pentacarbonyl ligands. Compared to the (π-arene)tricarbonylchromium species, there was a good degree of nonlinearity shown here (values are comparable to well-known organic systems such as *p*-nitroaniline[15b]) and the β values were sensitive to substitution at the 4-position.



6, Y = H, NH_2, C_6H_5, CHO, $COCH_3$

Metal carbonyl complexes have been utilized in "guest–host" inclusion chemistry. Zero SHG results from the strong tendency of dipoles to dimerize in an antiparallel (centrosymmetric) orientation. If channel dimensions can be controlled and maintained small, relative to guest dimensions, then head-to-tail dipolar orientation becomes electrostatically preferred, leading to SHG active materials. Inclusion hosts such as thiourea, tris-*o*-thymotide and clathrates form polar inclusion complexes with organometallic compounds, and over 60% were found to be SHG active.[116, 117] Depending on the ratio of the host–guest, crystallization of the materials in non-centrosymmetric space groups can be observed. For example, a thiourea: $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$ inclusion complex (3:1) has an SHG efficiency 2.3 times that of urea, whereas the uncomplexed material is inactive. Inclusion of [(η^4-trimethylenemethane)$Fe(CO)_3$] and [(cyclohexadienyl)$Mn(CO)_3$] has also met with some success.[84]

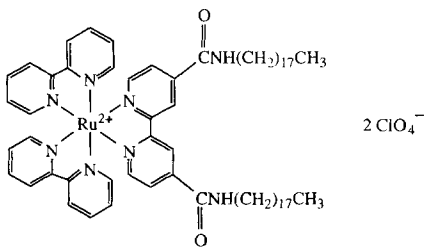


4.3. Octahedral Metal Complexes

In recent years, complexes of the form [M(NO)LXZ] (M = Mo, W; L = tris(3,5-dimethylpyrazolyl)borate; X = I, Cl; Z = O, NH, OPh, NC_4H_4, NHPh, SPh) have been shown to exhibit excellent SHG properties. The redox activities of these species are crucial with the 16e$^-$ [M(NO)LClZ] (Z = O or NH) and the 17e$^-$ [M(NO)LClZ]$^-$ moieties acting as electron-withdrawing and -donating substituents, respectively.[118, 119] With metal centers and ligands that are chiral,[38] it was perhaps surprising that only small SHG efficiencies were observed, until it was discovered that one molecule in the unit cell is orientated so that it opposes the other. Introduction of the bulky and electron-donating ferrocenyl group was more effective and complexes of the type **7** with M = Mo, Z = 4-NHC_6H_4-N=N-C_6H_4-4'-Fc as well as M = W, Mo, Z = 4-NHC_6H_3-(3-Me)-N=N-C_6H_4-4'-Fc (Fc = $(\eta^5$-$C_5H_5)Fe(\eta^5$-$C_5H_4)$), gave respective SHG efficiencies of 59, 53, and 123 times that of urea. Modification of various parts of the complexes indicated that without the [M(NO)LCl]$^-$ and, in particular, the [Fc-$C_6H_4N_2C_6H_4$] fragments, little or no SHG activity would be observed.[38]

7

Thompson et al.[120, 121] have investigated monomeric, dimeric, and oligomeric metal (primarily manganese) complexes **8** of the tetradentate salen ligand (*N*,*N*'-bis(salicylideneaminato)ethylene). The ligand was chosen due to its low optical absorption and propensity for planar



8

= salen

coordination geometries. Additionally, a bifunctional ligand is incorporated in these complexes which is capable of bonding to the metal in both a dative and covalent fashion. Initial results were not encouraging due to structural factors, but introduction of chirality into the organic bridging ligand should solve such problems.

Sakaguchi et al.[122] have demonstrated that metal → ligand charge transfer transitions are important for SHG by forming a ruthenium(II) tris(2,2'-bipyridine) complex **9**. The β value for this compound is around 70×10^{-30} esu which is comparable to the previously tested organic system, 2-methyl-4-nitroaniline.[123] Ruthenium has also been incorporated in complexes of the form $[(\eta^5$-$C_5H_5)Ru(PPh_3)_2L]PF_6$, where L can be various ligands including substituted nitriles.[124] EFISH measurements at 1.064 μm of second-order hyperpolarizabilities revealed a significant effect of type and length of conjugation. For example,

9

the biphenyl system (-C_6H_4-C_6H_4-$OC_{12}H_{25}$) gives a β value of 20×10^{-30} esu, whilst the single phenyl ring system shows one of 3.5×10^{-30} esu.

Recent measurements on mixed-valence metal complexes using the hyper-Rayleigh scattering technique have proved very interesting.[55] It was postulated that mixed-valence compounds characterized by an intervalence charge transfer transition, in which the donor and acceptor centers are both metal atoms, may well provide a large second-order response. Measurements of β of a bimetallic complex ion, $[(CN)_5Ru(\mu$-$CN)Ru(NH_3)_5]^-$ and an organometallic analogue, $[(\eta^5$-$C_5H_5)Ru(PPh_3)_2(\mu$-$CN)Ru(NH_3)_5]^{3+}$, gave values greater than 10^{-27} esu., which are among the largest recorded for solution species. The energy of the charge transfer transition is easily modified, suggesting that there is considerable NLO potential for this type of chromophore.

Independent studies have also investigated unsymmetrical ruthenium[125, 126] and osmium[126] acetylide complexes with donating and accepting groups (Fig. 5). Initial powder SHG

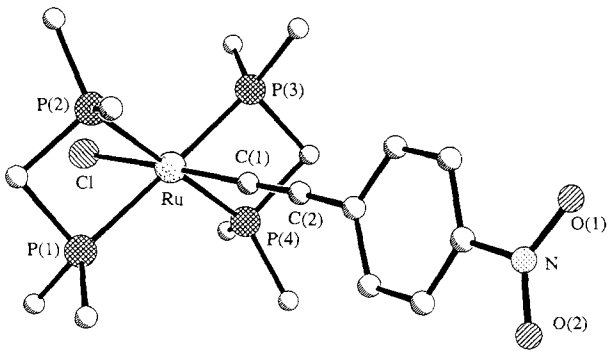


Fig. 5. Crystal structure of the donor-acceptor compound [ClRu(dppm)$_2$-(C≡C-C_6H_4-*p*-NO_2)]. (Hydrogen atoms and phenyl groups on the phosphane ligands are omitted for clarity).

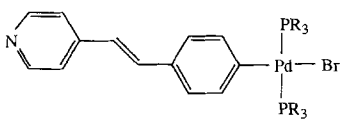
measurements[126] have proved disappointing due to the materials crystallizing in centrosymmetric space groups.

4.4. Square-Planar Metal Complexes

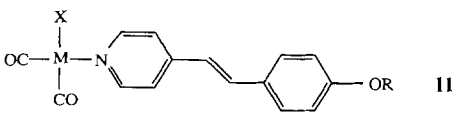
Due to the excellent electron-donating ability of square-planar metal fragments, such as $[M(PEt_3)_2X]$ (M = Ni, Pd, Pt; X = Cl, Br, I), in donor-acceptor aromatic complexes, materials suitable for SHG have been yielded.[127] A list of the powder SHG efficiencies for these compounds featuring a substituted aromatic electron-accepting species is shown in Table 3. The

Table 3. Second harmonic generation efficiencies of complexes of the form *trans*-$[M(PEt_3)_2X(2\text{-}Y\text{-}4\text{-}Z\text{-}C_6H_3)]$.



M	X	Y	Z	SHG efficiency β [a]
Pt	Br	H	NO_2	4.2
Pt	I	H	NO_2	5.0–8.0 [b]
Pt	Br	H	CHO	1.5–3.4 [b]
Pt	Br	CH_3	NO_2	2.0–14.0 [b]
Pt	Br	NO_2	H	0.8
Pd	I	H	NO_2	2.3
Pd	Br	CH_3	NO_2	5.0–10.0 [b]
Pd	Br	H	CHO	2.3

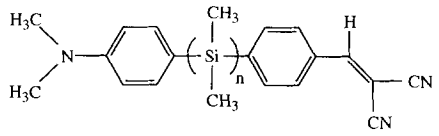
[a] Relative to urea. [b] Range due to values obtained from several preparations and probably dependent upon particle size.



para-orientated nitro-compounds showed the largest SHG signals, in one case up to 14 times that of urea. The values are also influenced by the nature of the metal atom, the halogen, and the substituent on the phenyl ring. EFISH measurements on related palladium and platinum derivatives of the formula $[ML_2XY]$ (where L = PEt_3; X = Br, I; Y = σ-$C_6H_4NO_2$ and σ-C_6H_4CHO) have reinforced these trends.[95] Here, the *para*-substituent is in conjugation with the metal center, and, as is expected, it has a significant effect on the hyperpolarizability, with $\beta(NO)_2 > \beta(CHO)$ due to greater electron acceptance of the former substituent. To a lesser extent, the metal, halide, and phosphane again influence the magnitude of β.

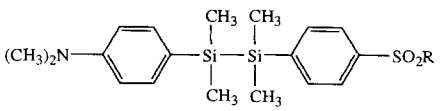
Some linear donor–acceptor substituted platinum bis(acetylides) of the form *trans*-$[Pt(PMe_2Ph)(C{\equiv}CX)(C{\equiv}CY)]$ (X = π donor e.g. MeO, MeS, Me_2N and Y = π acceptor e.g. CN, NO_2)[128, 129] crystallize in a non-centrosymmetric mode and exhibit reasonable SHG efficiencies. It was of interest to study the effect of the metal centers as a linker between the organic-donors and -acceptors. Similar donor–acceptor metal acetylides of the form $[(CO)_5Mn{-}C{\equiv}C{-}C_6H_4{-}C{\equiv}C{-}Pd(PBu_3)_2Cl]$ have been synthesized[130] and, although these species are expected to show interesting second-order NLO behavior, this has yet to be demonstrated.

Stilbazole-based square-planar metal complexes have been of recent interest. Addition of *trans*-4′-bromo-4-stilbazole to $[Pd(PR_3)_4]$ yields the corresponding Pd^{II} complexes **10**.[131] Although the compounds feature conjugated systems with an asymmetric charge distribution, powder SHG values, lower or comparable with that of urea, were obtained due to centrosymmetric crystallization. The situation is more positive when a *cis*-$[MX(CO)_2]$ group (M = Ir^I, Rh^I; X = Cl, Br) is bound to the N atom of the stilbazole-pyridine ring and R is a chiral, long-chain alkyl group (**11**).[132, 133] The β value of the free stilbazole increases on coordination of the *cis*-$[MX(CO)_2]$ species indicating that this metal fragment is a better acceptor than the heteroatom of the pyridine ring. It is advantageous that the compounds are not strongly colored but still possess reasonably large hyperpolarizabilities (species where a charge transfer term is the main component of the β value are normally highly colored), since this gives the material a wider transparency range and hence, more varied potential device applications. The SHG values are small but non-zero, showing that the chiral alkyl group R has little influence on the molecular packing.



10, R = CH_3, C_2H_5, C_3H_7

11

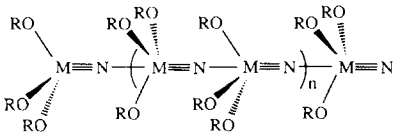


4.5. Silicon Complexes

In 1990, a series of substituted silanes (**12**) were formed, where the electron-donor and electron-acceptor groups were separated by silicon atoms.[134, 135] EFISH studies showed that the hyperpolarizability increases with increasing number of Si atoms due to the σ delocalization along the Si–Si backbone and, in addition, there was increased polarizability of the silicon backbone compared to that of carbon. Another important characteristic of these compounds is their optical transparency. For example, addition of silicon atoms to the chain lowers absorption maxima to 276 nm which is significantly lower than a standard donor–acceptor polyene like *p*-nitroaniline (λ_{max} = 365 nm).

12, n = 1, 2, 6

Polycarbosilanes[136] with main chain arylene and acetylene groups, $[-C{\equiv}C{-}SiPh_2{-}C{\equiv}C{-}Z{-}]_n$, have been prepared with a wide variety of arene groups, Z, for example fluorene-2,7-bipyridine-2,2′, anthracene-9,10, thiophene-2,5, and 5-cyano-2-hydroxybenzene-1,3-diyl. The NLO-active donor–acceptor groups are contained in a segment in the main polymer chain and although detailed results are awaited, promising NLO activity has been observed. Finally, a series of *p*-substituted diphenylsilanes have been formed with dimethylamino (donor) and sulfonyl (acceptor) groups (**13**),[137] and the β values obtained were close to those found for the compounds **12**.[134]



13, R = C_6H_5, C_4F_9

4.6. Metal Nitrido Compounds

Nitrido compounds of the type $[(RO)_3M{\equiv}N]$ have been known for some time.[138, 139] They crystallize in non-centrosymmetric space groups and exist as long chains of alternating short (triple) and long (single) bonds. Hopkins et al.[140] have since formed one-dimensional polymers of the

form $[(RO)_3M{\equiv}N]_n$ (M = Mo, W; R = CMe_3, CMe_2CF_3, CMe_2Et) **14** and studied their powder SHG efficiencies. Surprisingly, only small values were obtained, but they have been shown to be influenced by the nature of the alkoxido ligands and the length of the conjugated $[MN]_n$ backbone.

14

Finally, pentaamine ruthenium complexes, $[(NH_3)_5RuN{\equiv}C\text{-}R\text{-}C{\equiv}NRu(NH_3)_5](PF_6)_5$ (R = C_6H_4, $C_6H_2(CH_3)_2$ are thought to be potential NLO species, but this has not been proved due to decomposition upon irradiation of laser light.[141]

5. Materials for Third-Order Nonlinear Optics

The structure–property relationships that govern third-order NLO polarization are a little vague. Unlike the design of second-order NLO materials, which follow some well-defined guidelines, models for the synthesis of third-order species are much less well-developed. However, polymeric materials with extended π conjugation are known to be important, and an increased effective conjugation and hence, large π delocalization length has been recognized as a way of achieving large third-order nonlinearities.[10, 142, 143] Extended π-electron delocalization creates a large anharmonic component in the nonresonant electron oscillations.[144] In 1973, it was reported that $\chi^{(3)}$ increases with the number of atoms in long-chain molecules.[145] This was followed later by the suggestion that long π-electron conjugated structures are ideal for $\chi^{(3)}$.[146] The discovery of π-electron delocalized conducting polymers in the 1980s created further interest in third-order NLO properties and, to date, much of the research has focused on conjugated polymers such as polyacetylenes, polythiophenes, and various semiconductors.[2a] These organic enyne systems reach a saturation in material nonlinearity, so consideration needs to be given to ways of modifying the electronic and lattice configurations. Organometallic polymers have extended π-electron delocalization plus extra features which could enhance $\chi^{(3)}$. Transition metals are incorporated in such a way that some of their d orbitals interact with the conjugated π-electron orbitals of the organic repeating unit. Therefore, an extended, delocalized electronic system within the polymer chain is formed. Electronic features can be manipulated by varying the ligands attached to the metal center. Also, many organometallic polymers have low-lying charge transfer transitions not present in organic systems.

For third-order effects, there is no inherent symmetry restriction, and it is hoped that judicious use of metal moieties will further the design of radically different third-order species that perhaps do not involve large delocalized electronic systems.

5.1. Metallocenes

As was discussed in Section 4.1, metallocene derivatives are known to be important NLO materials. Less work has been completed featuring third-order materials than second-order ones, but metallocenes allow direct comparisons to be made between organic and organometallic compounds. The third-order optical nonlinearity of metallocenes such as ferrocene, hafnocene, ruthenocene, zirconocene, and bis(trimethylsilyl)ferrocene has been initially investigated by optical power limiting measurements.[147, 148] The values of γ obtained by using this technique were quite high and possibly electronic in origin. Similar experiments have focused on some lanthanide tris(cyclopentadienyl)metallocenes $(\eta^5\text{-}C_5H_5)_3M$ (M = Yb, Nd, Dy, Er, Pr).[149] Although the species did exhibit third-order NLO behavior, two-photon absorption takes place, thus limiting the suitability of the material for device applications.[150, 151]

Some symmetric end-capped acetylenes have undergone THG analysis.[104] One of the compounds, 1,4-bis(ferrocenyl)butadiyne, showed a $\chi^{(3)}$ value of 225×10^{-14} esu, which is more than double that of the organic species 1,4-diphenylbutadiyne.

To help elucidate the NLO properties of organometallic structures, a series of aryl and vinyl derivatives of ferrocene have been synthesized (Fig. 6).[152] The second molecular hyperpolarizabilities γ, determined by degenerate four-wave mixing at 602 nm, were overall fairly low. Nevertheless, some important points could be gleaned from the data: 1) The γ value increases strongly with the length of the conjugated π-electron system (a feature also found in organic polyenes) until a large limiting value is reached, where additional conjugation is ineffective with

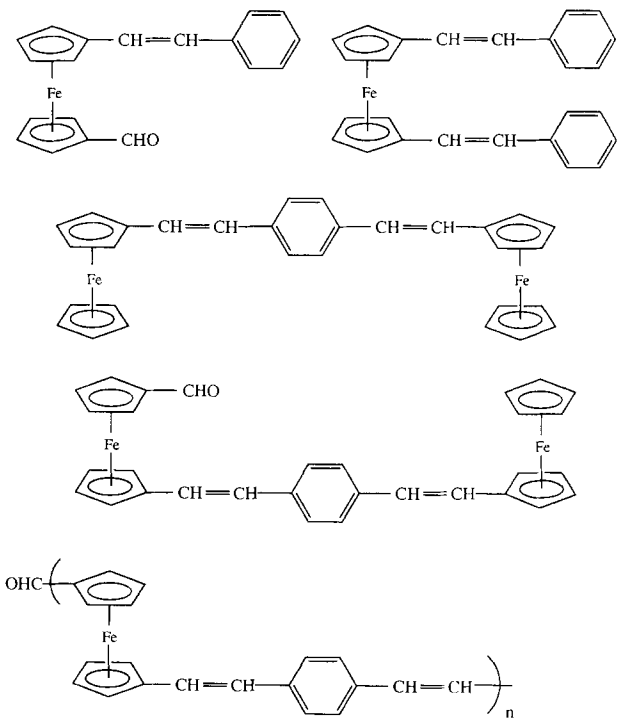


Fig. 6. The structures of some arylvinyl- and vinylferrocene derivatives studied for third-order NLO.

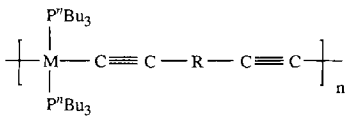


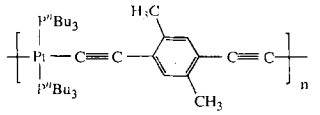
regard to γ.[151] 2) The effective conjugation is determined by the length of the arylvinyl system, the ferrocenyl group not being very significant in this respect. 3) The π-electron delocalization through the ferrocene center is less effective than through a double bond or phenyl group. 4) The d-d transition of the metal in the ferrocene moiety does not make a significant contribution to the optical nonlinearity, as opposed to the d-π* and π-π* transitions.

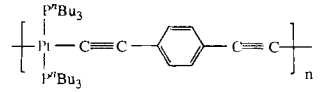
Ferrocenyl- and bis(ferrocenyl)alkynes and -polyynes are of interest and the 1,8-bis(ferrocenyl)octatetrayne has been examined for third-order NLO activity.[153] EFISH techniques (THG measurements on colored compounds have the potential to be affected by resonance enhancement) gave a value of γ of 110×10^{-34} esu which is comparable to linearly conjugated species of a similar length.[154] It is suggested that when considering γ, the conjugated triple bond linkage is poorer than a double bonded one of similar length.

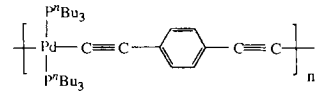
The attractiveness of ferrocenyl-based NLO materials (due to the air-, thermal-, and photochemical stability and synthetic versatility) has led to other ferrocenyl polymers, namely 1) a main-chain homopolymeric system[109, 111] and 2) ferrocenylacetylenes being synthesized.[155] However, in both of these cases, the second molecular hyperpolarizabilities have yet to be determined.

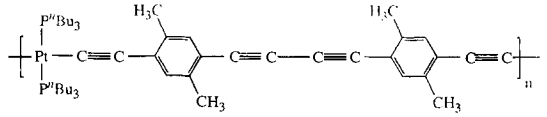
5.2. Metallapolyyne Polymers

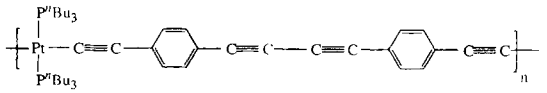
Metal-containing organic acetylene polymers were first synthesized by Hagihara et al.[156, 157] when Group 10 metals (Ni, Pd, Pt) were incorporated into conjugated acetylenic backbones (**15**). These materials were shown to possess interesting liquid











15, M = Ni, Pd, Pt, R = *p*-C_6H_4, *p*-C_6H_4-C_6H_4-*p*,

crystalline,[158] magnetic, and electronic properties. They were subsequently investigated for third-order NLO activities.[159–161] Hyperpolarizabilities (and, in many cases, solubilities) were found to be much higher than those of purely organic counterparts. Measurements were taken by THG and DFWM techniques, and Table 4 lists the γ values for some metallapolyynes. The type of metal, arene spacer, and length of conjugation were all shown to be of importance.

In recent years, reports of other metal-containing acetylide polymers have been quite plentiful. Lewis et al.[162] have formed square-planar (Ni, Pd, Pt) and octahedral (Fe, Ru, Os, Rh, Co) metal polymers by using bis(trimethylstannyl)diyne, $Me_3Sn-C\equiv C-R-C\equiv C-SnMe_3$ (R = C_6H_4, $C_6H_4-C_6H_4$), ligands. Figure 7 shows ruthenium precursor for the synthesis of such polymers. Principal interest has focused on the possibility of these polymeric complexes acting as electronic conductors and, as such, optical and band gap studies (π-π*) have been extensive. To date, no third-order NLO studies have been reported; however, other physical studies concerned with the delocalization of the π system along the polymer chain, point to these compounds having great potential as NLO materials.

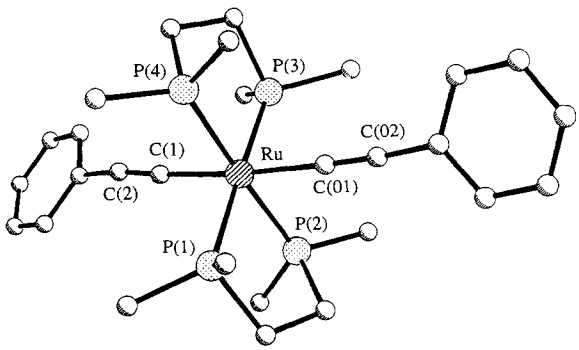

Fig. 7. Crystal structure of $[Ru(dppe)_2(C\equiv C-C_6H_5)_2]$, a precursor to metal-containing acetylide polymers. (Hydrogen atoms and phenyl groups on the phosphane ligands are omitted for clarity).

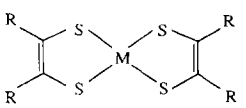
Carty et al.[163] report the synthesis of linear acetylides of the form $[Ru(CO)_2(PEt_3)_2(C\equiv C)_nR]$, whilst Marder et al.[129, 164, 165] have formed a series of metallapolyynes produced from direct alkyne C–H addition to low-valent metal complexes. Metal-to-ligand d_π-$p_{\pi*}$ charge transfer capabilities should result in excellent third-order behavior.

5.3. Polysilanes and -germanes

These compounds are conjugated polymers markedly different from carbon-based π-conjugated species and have been shown to exhibit interesting NLO properties.[166–170] The silane (or germane) polymers consist of a backbone of silicon (or germanium) with two organic side chains attached to every backbone atom. It is a σ-bonded fragment, but there is suffi-

cient orbital overlap for it to be considered a σ-delocalized system,[166] thus leading to some useful properties: a) The materials are transparent at visible wavelengths, absorbing strongly in the near ultraviolet region (as opposed to π-conjugated polymers that normally absorb in the visible). b) They are highly soluble and exhibit excellent processability and can form thin films of very good optical quality. c) They are thermally and environmentally stable. This combined with NLO activity gives them great potential for device applications. Initial THG studies[167, 168] first indicated that silicon $[Si(n\text{-}C_6H_{13})_2]_n$ ($\chi^{(3)} = 1.3 \times 10^{-12}$ esu) and germanium $[Ge(n\text{-}C_6H_{13})_2]_n$ polymers were comparable to organic species such as poly(phenylenevinylene) ($\chi^{(3)} = 7.8 \times 10^{-12}$ esu). It was also found that the $\chi^{(3)}$ value of $[MeSiPh]_n$ did not change with temperature, but did on variation of film thickness. For instance, as the thickness increases from 120 to 1200 nm so does $\chi^{(3)}$, going from 1.9×10^{-12} to 4.2×10^{-12} esu. $[Si(n\text{-}C_6H_{13})_2]_n$ did, however, show some $\chi^{(3)}$ temperature dependence, with a lower value found at 53 °C than at 23 °C, due to a conformationally more mobile and, therefore, disordered structure at the higher temperature. A series of compounds have been reported where the alkyl substituents have been varied and the data are listed in Table 5.[171] The value of

Table 5. Absorption maxima and $\chi^{(3)}$ values for a series of polysilanes.



Polymer	λ_{max} [nm]	$\chi^{(3)}$ ($\times 10^{-12}$ esu) [a]
poly(methylphenylsilane)	339	7.2
poly(ethylphenylsilane)	338	5.3
poly(*n*-hexylphenylsilane)	346	6.2
poly(*para-tert*-butylphenyl)methylsilane)	332	4.9
poly(*n*-hexyl-*n*-pentylsilane)	318	2.3
poly((4-methylpentyl)silane)	319	1.8

[a] Measured at 23 °C and at a wavelength of 1064 nm.

$\chi^{(3)}$ appears to depend on polymer orientation; for simple alkyl substitution, there is little difference between polysilanes and -germanes. Addition of conjugated side chains and optimizing polymer orientation will make them even more important NLO materials.

5.4. Metal Dithiolene Complexes

Transition metal dithiolenes (enedithiolato metal complexes) possess a strong, low-energy π-π* transition in the near IR,[172] which can be tuned by altering the metal ion, substituents, or charge state of the dithiolene. They have been used as laser Q-switch materials because of their optical stability. A series of metal dithiolenes (**16**) have featured in third-order NLO studies,[149, 173] and $\chi^{(3)}$ values were found to range from 7.16×10^{-14} to 3.8×10^{-11} esu. For instance, a platinum dithiolene complex with cyano substituents gives a $\chi^{(3)}$ value of 4.2×10^{-12} esu compared to a value of 1.4×10^{-13} esu exhibited by an analogous nickel diselenolene complex possessing CF_3 groups. Similarly, a large $\chi^{(3)}$ figure (3.67×10^{-11} esu) was obtained from a nickel dithiolene species with phenyl substituents (**16**; M = Ni, R = C_6H_5), however, it should be noted that resonant enhancement of these values can occur as the dithiolenes absorb between 700 and 1400 nm.

16, M = Ni, Pt, R = CH_3, C_6H_5

As large one- or two-photon absorptions can render a material useless with regard to all-optical switching applications, a figure of merit has been introduced as a guide.[34, 149] A low value (preferably less than 1) of $2\lambda\beta/n_z$ (λ is the wavelength of the laser, β the two-photon absorption coefficient, and n_z is the nonlinear refractive index) is required for waveguide device switching. It was shown that the dimethyldithiolate complex (**16**; M = Ni, R = CH_3) has great device application potential, whilst the analogous diphenyl species does not. Work is now in progress to form polymeric thiolene systems and to include them in host–guest or side chain polymer systems to improve processability.

Metal complexes of the related species, *o*-aminobenzenethiol (ABT) and benzenethiol have also proved very interesting.[174] Metal substitution increases the $\chi^{(3)}$ value of ABT, and an excellent figure of 2.0×10^{-9} esu for $\chi^{(3)}$ results from a nickel complex of ABT.

5.5. Phthalocyaninato metal Complexes

The phthalocyanines are an extremely interesting and useful class of compounds. They feature an extensively delocalized π system and can be thought of as two-dimensional. Most other third-order NLO compounds feature π-electron conjugation along a backbone and are pseudo-one-dimensional. This imposes some limitations and whilst γ increases with the length of the one-dimensional π-conjugated system, there is a saturation of the parameter (per repeat unit) at some length of the polymeric chain.[72] This may be due to defects in the polymeric chain but, perhaps, also to the limitations of the one-dimensional systems. This had led to considerable interest in the two-dimensional π-conjugated phthalocyanine systems and, in particular, the complexes with a wide variety of metals (Fig. 8).

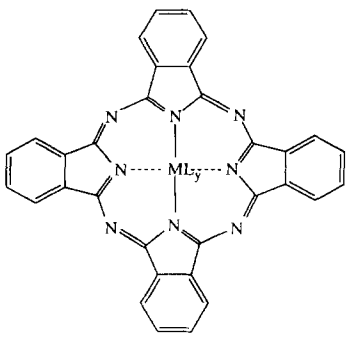


Fig. 8. The general structure of a metallaphthalocyanine complex.

A common property of most phthalocyanines is their chemical and thermal stability. They are versatile, flexible, and modifications are easily made by changing the central metal atoms or the side groups at the edge of the macrocycle. With a choice of up to 70 different metal atoms for incorporation, parameters can be carefully tailored. Several groups have studied various phthalocyanines (H_2Pc) and their metalated analogous (MPc) over recent yeast. Ho et al.[175] investigated thin polycrystalline films of chlorogallium and fluoroaluminum phthalocyanines, where the halogeno ligands were bonded to the metal atom. Different crystal structures were apparent, leading to a change in $\chi^{(3)}$ values.

Third-order nonlinear activity is known to be considerably enhanced by incorporation of the central metal atom, by the introduction of metal → ligand and ligand-metal charge transfer states. For example, the THG of alkoxy derivatives of vanadyl phthalocyanine (VOPc) is two orders of magnitude greater than that of the metal-free species.[176] This trend is also seen following DFWM measurements on metal-free tetrakis-(cumylphenoxy) phthalocyanines and the platinum and lead complexes (see Table 6). The platinum derivative gave a $\chi^{(3)}$ value

Table 6. The third-order susceptibilities of some metallophthalocyanines (after ref. [33]).

Compound [a]	Experimental Technique	$\chi^{(3)}(\times 10^{-12}$ esu)

$CuPc(C_4H_9S)_4$	THG	3.7
$CuPc(C_{10}H_{21}S)_4$	THG	26.0
$VOPc(C_6H_{13}S)_4$	THG	9.8

[a] CP4 = Tetrakis(cumylphenoxy), R = $(OSiMe(Ph)OH)_2$.

(2×10^{-10} esu), an order of magnitude greater than the lead derivative ($\sim2\times10^{-11}$ esu) and 50 times that of the parent phthalocyanine. The variations are due to the low-lying charge transfer states in the molecule. Transition metals, such as Pt, with valence d orbitals, introduce many more such states than the main group Pb. These states are not present in the metal-free species and contribute to the observed enhancement of nonlinear susceptibility. Other investigations have focussed on metal species involving Co, Ni, Cu, Zn, Pd, and Pt. With the first row metals, a decrease in γ was observed with an increased number of d electrons.[177, 178] Similar observations and results on various metallophthalocyanines are collected in Table 6.

Other investigations have focused on the role of the substituents on the aromatic rings in the phthalocyanine. The long alkylthio chain in $[VOPc(C_8H_{17}S)_4]$,[179] lowers the $\chi^{(3)}$ value (31.0×10^{-12} esu) due to a disruption of the π-electron system. Conversely, larger $\chi^{(3)}$ values can be observed for metallophthalocyanines with long alkyl chain substituents, since these result in increased steric hindrance and therefore, poorer packing or aggregation of the molecules.

The largest hyperpolarizabilities, to date, for metallophthalocyanines have been reported by Rao et al.[180] for some metal tetrabenzoporphyrin derivatives (Fig. 9). The R groups substituted at the *meso*-positions 5, 10, 15, and 20 were varied and the outer benzene rings were flourinated (X). In most cases, the coordinated metal was zinc, but magnesium was also tested. The $\chi^{(3)}$ values were in the range 1.2×10^{-8}–2.8×10^{-8} esu. A 5,10,15,20-tetra(*para*-dimethylaminophenyl)tetrabenzoporphyrinatozinc species exhibiting the greatest value due to strong electron-donating groups at the *meso* positions.

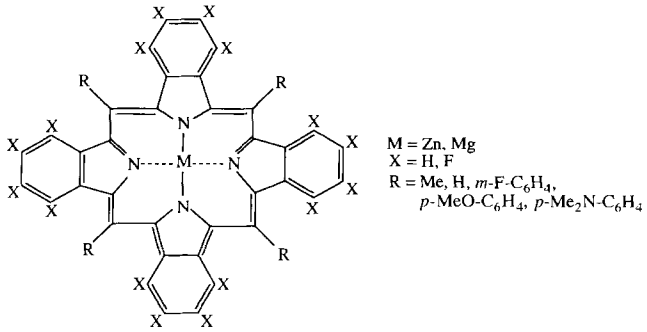

Fig. 9. The general structure of metallotetrabenzoporphyrins.

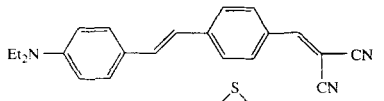

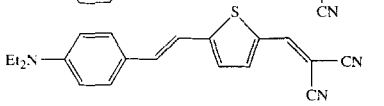

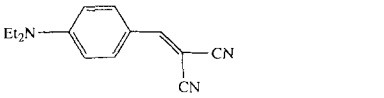

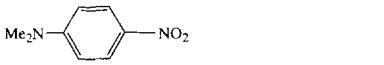

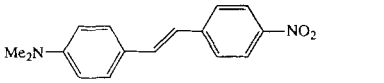

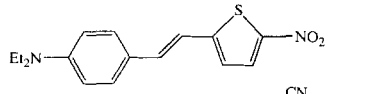

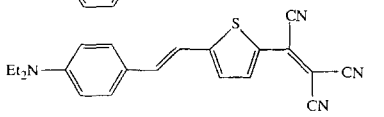

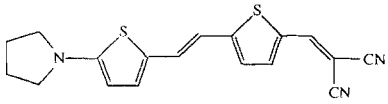

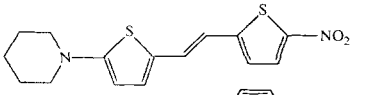

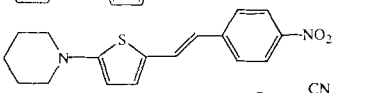

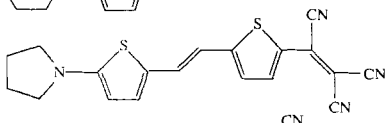

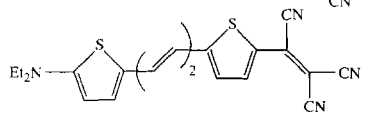

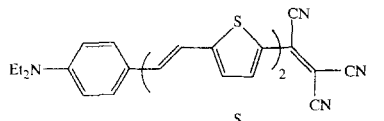

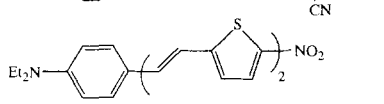

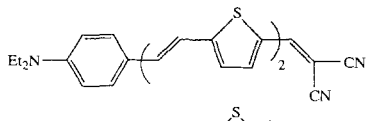

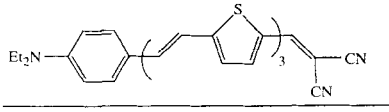

Due to other properties, phthalocyanines have become important as optical limiters.[181] Light of low incident intensity is transmitted through a sample as a linear function of the input intensity; however, at very high input intensities, a nonlinear medium will cause the output intensity to saturate at a particular value. Therefore, detectors and, in particular, eyes can be protected from bright light.

5.6. Thiophenes

Whilst these species do not really feature within the remit of this review, there has been so much recent interest in them with regard to NLO effects that brief mention should be made. Thiophenes and polythiophenes have been investigated for second- and third-order activity, respectively; the main motivation being that thiophene has a lower delocalization energy (117 kJ mol^{-1}) than that of benzene (151 kJ mol^{-1}) (the main spacer or conjugated linking group in NLO materials) and consequently, it offers better effective conjugation.[68d] Initial studies[49, 182] on replacement of a benzene ring with a thiophene ring in donor–acceptor compounds met with no significant enhancement of molecular nonlinearity ($\beta\mu$). However, investigation of some stilbene-type donor-acceptor molecules has revealed that thiophene substitution is highly important and the data obtained are listed in Table 7.[68d, 183, 184]

Obviously, the nature of the donor–acceptor end groups is important, as is illustrated in Table 7, where tricyanovinyl acceptors enhance the molecular nonlinearity far better than dicyanovinyl and nitro species. Additionally, there is a substantially red-shifted charge transfer band connected with the better charge-asymmetry in the tricyanovinyl derivatives. However, it is clear that replacement of the benzene rings with thiophene moieties has a similar effect on the nonlinearity and the charge transfer absorption band (replacement of both benzene rings in a two-ring system is far more significant than changing just one). A noticeable increase in $\beta\mu$ with increase in thiophene chain length is also observed in contrast to the benzenoid situation. In the latter, a definite saturation of $\beta\mu$ with length has been reported,[185] however, from Table 7, the values for the two-ring, three-ring, and four-ring systems (second, second-last, and last entry in Table 7, respectively) show an almost linear increase. Indeed, there is no significant saturation at the length scale considered.

Table 7. Absorption maxima and molecular nonlinearities [a] of some thiophene derivatives; showing the effect of end groups and conjugation.

	547	2300
	556	3800

[a] Values measured with 1907 nm fundamental radiation in dioxane.

The same motivation of better π-electron delocalization and increased effective conjugation has been employed in the formation of polythiophene materials. They have long been known to be conductive polymers, but due to the extended π-conjugation have recently been recognized as an important class of third-order NLO media. Various studies[186, 187] have produced very reasonable third-order susceptibilities for example a $\chi^{(3)}$ of 2700×10^{-10} esu for the polythiophene superlattice, PBTBQ (= poly(α-[5,5′-bithiophenediyl]benzylidene-block-α-[5,5′-bithiophenequinodimethanediyl]).[186] Similar traits to those observed in the second-order NLO studies have been found during the third-order (γ) investigations of some systematically derivatized α-terthiophenes.[188] The limiting conjugation length is much shorter for polyphenylenes than that for polythiophenes, and if the levelling off of the nonlinearity does happen, it occurs after at least a conjugation where $n = 6$. Substitution with a pyrrole or benzene unit of a central thiophene ring reduces the γ value due to a hindering of the conjugation. Finally, addition of polarizable moieties such as iodine or nitro groups at the end of the thiophene chains increases the hyperpolarizability due to an extension of the π-electron backbone by incorporation of these groups.

Therefore, incorporation of metallic moieties with various thiophene derivatives should have great potential in improving the NLO properties of many previously synthesized benzenoid compounds. Indeed, preliminary studies[189] concerned with band gap measurements on the platina polymers shown in Figure 10 have reinforced this opinion.

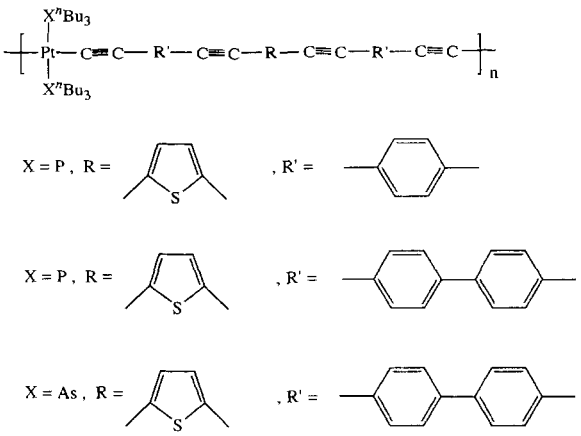

Fig. 10. Platina polymers with thiophene and benzene rings as members of the chain. $n = 24-63$.

6. Summary and Outlook

From the research detailed, it is clear that organometallic compounds are very versatile and have potential as NLO materials. By changing the transition metal, its oxidation state and incorporation of different bond geometries and coordination patterns, NLO properties can be modified. The design of second-order NLO materials continues apace as the guidelines are well understood; however, things are far less certain in the case of third-order materials and any structure–property relationships really are in their infancy. Conjugated systems have been successful but saturation points have been reached, so new designs are needed with perhaps, incorporation of polarizable heavy atoms being a step forward to increase the hyperpolarizability. Some points can be picked up, for instance, factors that

influence β in organic systems (nature of the bridge and donor–acceptor strengths) are relevant to metal-containing systems and values are quite encouraging with some phthalocyanines and dithiolenes exhibiting figures not too far from those needed for device application. Synthetic and solubility constraints have hampered the development of efficient materials but improvements continue to be made, for example thiophene substitution of benzene linking groups has recently demonstrated enhanced molecular nonlinearity, improved solubility, and ease of synthesis.

However, whilst there is great activity in this area, there is still a good deal of progress to be made. An improved understanding of the relationship between the molecular structure and the microscopic optical nonlinearities is crucial for a broadening of thought and incorporation of novel molecules. Theoretical and computational methods can be developed for predicting structural requirements necessary for large nonlinearities. To facilitate this, formation of databases will be vital. Only a very few systematic investigations covering a diversity of species and sequentially built structures have been reported. Due to the sparsity and inconsistency (different experimental and theoretical methodologies) of the available data, it is difficult to draw conclusions concerning many important points of molecular hyperpolarizability. Obviously, reliable, rapid and compatible determination of the NLO properties of the molecules and bulk materials would be helpful here.

More attention needs to be focused on the physical properties of a material, if they are to be successfully incorporated into commercially viable devices. The characteristics of a device application are important as these will dictate what is actually needed from a nonlinear material. Optical transparency, processability and speed of nonlinear response could all be crucial and indeed, the magnitude of the nonlinear response may not be the most important factor. It is unlikely that there is an ideal NLO material, just one which is most effective for a particular scenario.

It is hoped that this review will stimulate interest, as more research is vital for increasing the understanding of optical nonlinearities as well as the development of useful NLO materials. The unique characteristics of metal-containing materials mean that they, undoubtedly, have an important role to play in this area. Nevertheless, there is still scope for a leap of imagination in the design and synthesis of new and striking NLO materials, and the organometallic chemist, with a knowledge of organic chemistry and over 100 elements to choose from could be just the person to do this.

I would very much like to thank Professor, the Lord Lewis and Dr. Paul Raithby for their stimulating help and advice and introducing me to this area of chemistry. Thanks are also due to the group in Cambridge for their comments, computing skills and, in particular, encouragement along the way. Finally, I am very grateful to Darwin College, Cambridge for the award of the "Adrian Research Fellowship".

Toxins as Tools in Neurochemistry

Ferdinand Hucho*

Neurotoxins have evolved as molecules targeted specifically against molecules with an important function in the nervous system. Because of their selectivity they have been used as probes for detecting and characterizing key proteins of the nerve cell. Ion channels involved in the propagation of the action potential, proteins of presynaptic neurotransmitter exocytosis, and most importantly, neurotransmitter receptors have been and are presently being analyzed, in some cases already at atomic level by a combination of the tools of neurotoxins, molecular biology, and patch clamp electrophysiology. In this review a selection of these toxins is presented, together with their targets in the nervous system. Special emphasis is given to the recent breakthroughs in our understanding of the mechanism of action of tetanus and botulinum toxins and to the neurotoxins ranging from the plant alkaloid strychnine to the peptide toxins from poisonous snakes, which were fundamental in elucidating ligand-gated ion channels like the glycine and nicotinic acetylcholine receptors.

Keywords: neurotoxins · ion channels · biomembranes · acetylcholine receptor

1. Introduction

Progress in methodology parallels progress in science. Three methods form the basis of the present upsurge in neurochemistry: recombinant gene technology (especially in collaboration with patch-clamp electrophysiology),[1] immunology, and finally, neurotoxinology.[2, 3] Neurotoxins are components of venoms from the animal or plant kingdom that are specifically directed against the nervous system. During evolution many compounds arose, which are used by plants to protect themselves from being eaten, or by animals to defend themselves or to stop and kill their prey. The molecular variety of these substances extends from low molecular weight alkaloids to peptides and complex proteins.

Neurotoxins are molecules that are often targeted against only one function of the nervous system and thereby against one key molecule. Because of this specificity they are ideal tools[4, 5] for the neurochemist who wants to find key molecules in the nervous system and elucidate basic mechanisms of nerve functions. Nature is not wasteful: when, for example, a cobra bites its prey, it injects into it an impressive mixture of deadly substances. But they would be wasted if the wounded mouse escapes and dies in its hole from the cytotoxic, hemolytic, and cardiotoxic proteins contained in the cobra venom. Therefore the animal is first prevented from escaping by a small protein called α-neurotoxin. As we shall see below, this protein blocks with enormous efficiency the transfer of nerve impulses to the muscle needed for fleeing (or fighting). This is one example where neurochemists learned from the cobra and used an α-neurotoxin as a tool for elucidating one of the most important molecular mechanisms of transmission of nerve impulses from cell to cell.[6, 7] Neurotoxins are probes leading the scientist to structures and molecules that are fundamental for nerve activities.

2. Nerve Impulses: Electrical and Chemical

The main activity of a nerve cell is the transport of signals from one place to another.[1, 8] This transport occurs by electrical means *within* cells and (in most cases) by chemical means *between* cells. The crucial event in electrical nerve impulse *conduction* is the action potential. Chemical nerve impulse *transmission* takes place at specialized structures called synapses connecting nerve cells with others. Many of the key molecular structures and mechanisms underlying both the electrical and the chemical nerve impulse conduction have been and are still elucidated by electrophysiologists and biochemists who apply toxins as tools, amongst other techniques. Here I shall review only briefly the application of toxins in unraveling the molecular machinery propagating the action potential, because this is mostly history, while the second part of the story, the elucidation of synaptic nerve impulse transmission, is presently one of the most active topics of neurochemical research. This aspect will therefore be dealt with more extensively.

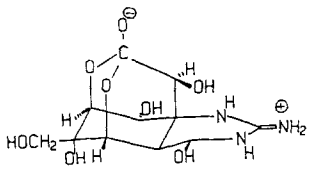
2.1. The Action Potential Is Based on the Different Kinetics of Two Types of Ion Channels

An electrical potential exists across the plasma membrane of nerve cells at rest, as for most cells, and is called the resting potential. It is a diffusion potential based on ion gradients and different permeabilities of the membrane for Na^+ and K^+ ions. The plasma membrane at rest shows only low permeability for sodium, but considerable permeability for potassium ions. The resting potential is therefore basically a potassium potential described by the Nernst equation. Upon stimulation an action potential is triggered, which is an "all-or-nothing" event self-propagating along the plasma membrane until it reaches the nerve ending. There it is converted into the chemical events forming the synaptic impulse transmission, which is the second half of our story (Section 3).

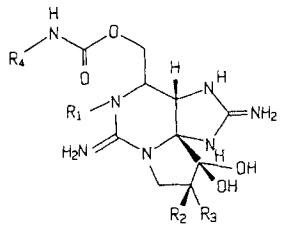
More than forty years ago, the electrophysiologists Hodgkin and Huxley showed that the action potential is the result of an early influx of sodium ions into the nerve cell and a delayed efflux of potassium ions.[1, 8, 9] These ion currents are mediated by distinct molecular entities called voltage-dependent sodium and potassium channels.[10] These ion channels have in effect been "dissected" by means of neurotoxins: First of all, some toxins interact specifically and with impressive potency with voltage-dependent sodium channels (Fig. 1). They do not influence any other type of channel. Others exclusively affect potassium channels and leave the sodium channels unchanged. Classical blockers of the voltage-dependent sodium channels are the heterocyclic guanidines tetrodotoxin (TTX, extracted originally from certain organs of the puffer fish *Tetraodon* and later found in other poisonous organisms as well)[11, 12] and saxitoxin (STX, found in the dinoflagellate *Gonyaulax*, which occasionally makes a meal for humans of the shellfish that feed on *Gonyaulax* very dangerous).

Interestingly, there are only relatively few toxins affecting voltage-dependent potassium channels.[13, 14] The electrophysiologists investigating action potentials therefore resorted mostly to tetraethylammonium (TEA) and to the amino pyridines as simple, albeit less effective, tools (which inhibit potassium current at μM–mM rather than at nM concentrations). The best natural blockers of voltage-dependent K^+ channels described to date are proteins found in scorpion venoms: noxius toxin (NTX) from *Centruroides noxius*[15] and one toxin from the scorpion *Tityus serrulatus*.[16] I should emphasize that here I am talking about effects on one specific type of potassium channel, the so-called delayed rectifier or "Hodgkin–Huxley" channel. Many other potassium channels[13] are also voltage-gated (although transiently and with differents kinetics), or gated by Na^+, Ca^{2+}, ATP or indirectly by neurotransmitters like acetylcholine (M channel) or serotonin (S channel), and there are specific toxins for them as well. We return to one of them below, when I discuss presynaptic events (Section 3), but for the complete picture of this very complex topic the reader is referred to specialized reviews.[13, 14]

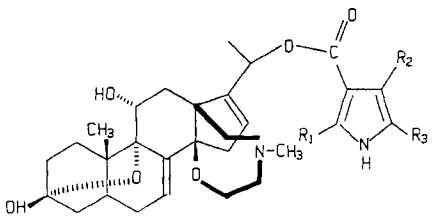


2.2. The Dissection of Sodium Channels by Means of Neurotoxins

Besides the discrimination of these two types of cation channel (the Hodgkin–Huxley sodium and potassium channels), neurotoxins have been used as tools for much more detailed research:[12, 17] Voltage-dependent sodium channels exhibit complicated kinetics with three distinct phases. Upon depolarization of the membrane the channel is rapidly opened (gated), reaches a peak permeability, and then closes (inactivates) spontaneously. Accordingly, one class of toxins promotes gating (Table 1). Representatives of these are the lipophilic alkaloids batrachotoxin, grayanotoxin, aconitine, and veratridine (Fig. 1). Others, like TTX and STX (already mentioned) block the open channel, and a third class, mainly peptide toxins from sea anemones (anemone toxins ATX I-IV) and from various scorpions (ScTX), affects the inactivation. Important in a neurochemical sense is the observation that most of these toxins bind independently to separate sites on the sodium channel protein. They can be grouped into five sets, of which each seems to have its own nonoverlapping binding site (Fig. 2 and Table 1). To accommodate so many independent binding sites, the sodium channel had to be a very large molecule.



With the help of these toxins, not only the functional domains of the Na^+ channel were defined, but also channel protein was isolated and characterized in reconstituted systems.[18–20] And finally, cDNA coding for sodium channels from various tissues was cloned and sequenced.[21] But even when recombinant



Ferdinand Hucho was born in 1939 in Berlin and is professor of biochemistry at the Freie Universität Berlin. He studied chemistry in Freiburg/Breisgau, where he also did his doctoral work on enzyme kinetics under the supervision of Kurt Wallenfels. After postdoctoral work on the regulation of pyruvate dehydrogenase multi-enzyme complexes with Lester Reed at the University of Texas at Austin, he was assistent of Horst Sund at the Universität Konstanz. He obtained his venia legendi in Konstanz in 1974 and became a professor there in 1979. In the same year he moved to Berlin. His main field of research is neurochemistry, with special emphasis on receptors, ion channels, and signal transduction mechanisms. He is an enthusiastic teacher of biochemistry.

DNA technologies come into play, toxins are indispensible tools. The cloned channels must be expressed, for example in oocytes from the toad *Xenopus*;[22] and proof that the correct and complete channel was identified comes by comparing the electrophysiology and toxinology of the cloned with the true channel. This was essential with the sodium channel, because the protein isolated biochemically from vertebrate brain as a ^{3}H-TTX-binding protein contained (in addition to a very large α-subunit of 260 kDa) two smaller (39 kDa) β-subunits.[20] The expression studies mentioned above have shown that the cDNA coding for the α-subunit alone contains all the information for the channel properties, including its electrical characteristics and its sensitivity to the various neurotoxins. The function of the small subunits is therefore still open to debate.

The primary structure of the sodium channel α-subunit, as deduced from the cloned and sequenced cDNA, is composed of four repeats of similar amino acid sequences.[21, 22] Each repeat contains six hydrophobic sequences thought to form membrane-spanning helices (Fig. 3 top). The fourth of these putative transmembrane helices, called S4, is especially rich in amino acids with positively charged side chains (located at every third position). It is assumed to be the voltage sensor responsible for opening the channel upon changes of the negative membrane potential. The exact location of the binding sites of the various toxins is largely unknown and is presently under investigation by site-directed mutagenesis in connection with expression studies. The expressed mutated channel is characterized with regard to its electrical properties and its response to the toxins. One point mutation, replacing by site-directed mutagenesis the glutamate residue in position 387 of the rat brain sodium channel by a glutamine residue, renders the channel insensitive to TTX.[23] This residue is located on the loop connecting the presumed transmembrane domains 5 and 6 of repeat I. It was concluded that the TTX-binding site is located on this loop.

Fig. 1. Toxins used as tools for characterizing voltage-dependent Na^+ channels. The chemical diversity of the toxic molecules is impressive; unfortunately, with the present state of knowledge on the three-dimensional structure of the toxins and of their target molecules, we are only beginning to predict from looking at a formula where exactly a substance binds and how it acts.

Table 1. Toxin-binding sites of the voltage-dependent sodium channel [17].

Binding Site	Ligands	Physiological Effect
1	Tetrodotoxin Saxitoxin μ-Conotoxins	inhibit ion transport
2	Veratridine Batrachotoxin Aconitine Grayanotoxin	persistent activation
3	North African α-scorpion toxins Sea-anemone toxins	inhibit inactivation enhance persistent activation
4	American β-scorpion toxins	shift activation
5	*Ptychodiscus brevis* toxin Ciguatoxins	repetitive firing persistent activation

Just to complete the picture (see Fig. 2) I should add some information concerning the voltage-dependent K^+ channel: Its primary structure suggests a similar transmembrane folding pattern.[24] But its size is only about one-fourth that of the Na^+ channel. There seems to be only one instead of four groups of six transmembrane domains (Fig. 3 bottom). Therefore, probably four of these molecules form one K^+ channel, while the Na^+ channel most likely is formed by one of the giant molecules with its four repeats. One other interesting finding should be mentioned: The loop between the presumed transmembrane domains 5 and 6 which is too short to form a membrane-spanning α-helix forms a β-strand immersed into the membrane. Four K^+ channel molecules probably contribute this structure, called the P-loop, to form the wall of the channel.[25]

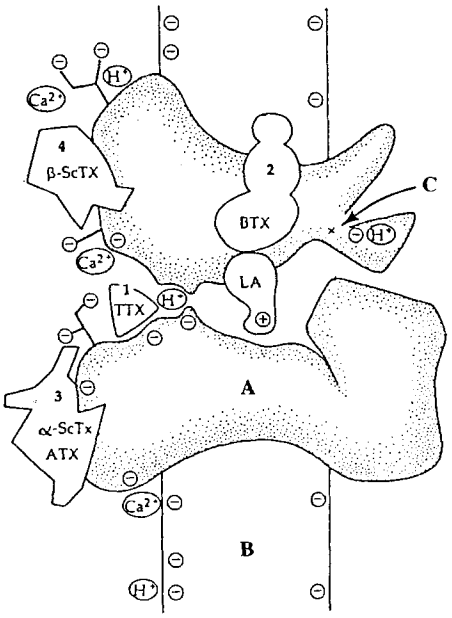

Fig. 2. Schematic drawing of the voltage-dependent Na^+ channel indicating the different binding sites of neurotoxins. The channel protein **A** (dotted region) is large enough (260 kDa) to accommodate binding sites for a variety of low and high molecular weight toxin molecules. By means of the toxins of Figure 1 it was possible to "dissect" various functional moieties of the channel protein (see also Table 2). **B**: membrane lipid, **C**: attack by pronase, iodate, and NBA. (From ref. [10], with kind permission from the publisher, Sinauer).

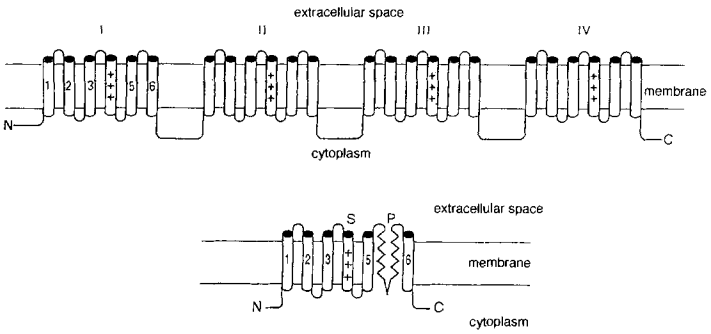

Fig. 3. Schematic representation of the primary structures of voltage-dependent Na^+ channels and Ca^+ channels (top) and K^+ channels (bottom). The cylinders represent membrane-spanning amino acid sequences, which are assumed to form α-helices. The sodium channel protein consists of one very long polypeptide chain, composed of four stretches with similar amino acid sequences (so-called repeats). These repeats probably are arranged within the neuronal membrane to form a ore, the channel proper. The potassium channel protein (bottom) consists of only one repeat. Probably four of these smaller molecules are necessary to form a channel.

3. Synaptic Transmission of Nerve Impulses

The action potential travels along the axonal membrane by opening and closing voltage-dependent Na^+ and K^+ channels and finally arrives at the nerve ending where it causes the transmission of the nerve impulse to the next cell by releasing a substance called a neurotransmitter (Fig. 4). This substance diffuses from its release site at the presynaptic side across the synaptic cleft to the postsynaptic membrane of the next cell about 20–30 nm away. Transmitter release is of great interest from various points of view for current neurochemical and cell biological research and is presently dissected by means of neurotoxins.[26]

3.1. Events on the Presynaptic Side

Transmitter molecules in nerve endings are packaged and stored in small vesicles (Fig. 5). Upon arrival of an action potential, those vesicles, located at special release sites that line up with active zones of the presynaptic membrane, fuse with the presynaptic membrane, thereby opening up and letting the transmitter escape into the synaptic cleft. The empty vesicle is retracted afterwards and refilled with transmitter. Cell biologists call this process "regulated exocytosis" to distinguish it from "constitutive exocytosis", the process that involves the cellular export of many proteins and peptides. Researchers are now asking whether the two processes might have more in common than they had previously thought. Recently, Rothman and co-workers[27a, 27b] identified various proteins, called NSF (*N*-ethylmaleimide-sensitive fusion protein) and SNAP (NSF attachment protein), which seem to be common components of the fusion apparatus involved both in intracellular vesicle traffic from the endoplasmic reticulum (ER) through the golgi apparatus to the plasma membrane and in the regulated exocytosis of synaptic vesicles. The specificity of this otherwise similar membrane transport is secured by selective "SNAP receptors" (SNAREs) directing each vesicle to its proper target. This picture of a widespread basic mechanism is strengthened by the

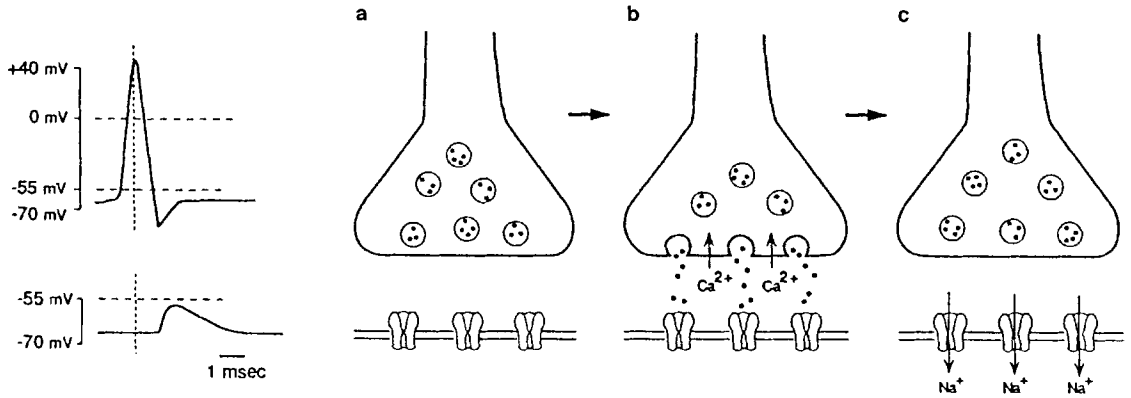

Fig. 4. Chemical nerve impulse transmission at a synapse. Left: electrical events (top diagram: presynaptic action potential; bottom diagram: postsynaptic potential; dashed horizontal lines indicate the required threshhold values). a–c) Top: Molecular events on the presynaptic side. Bottom: Response on the postsynaptic side. A large depolarizing spike, the action potential, travels down the nerve axon. Upon arrival in the nerve ending it triggers a cascade of molecular events leading to the release of neurotransmitter from the presynaptic membrane. The transmitter causes a transient depolarization through specific receptors in the postsynaptic membrane. If this depolarization reaches a threshold, an action potential is initiated postsynaptically (reproduced from ref. [28], with kind permission from Dr. E. R. Kandel).

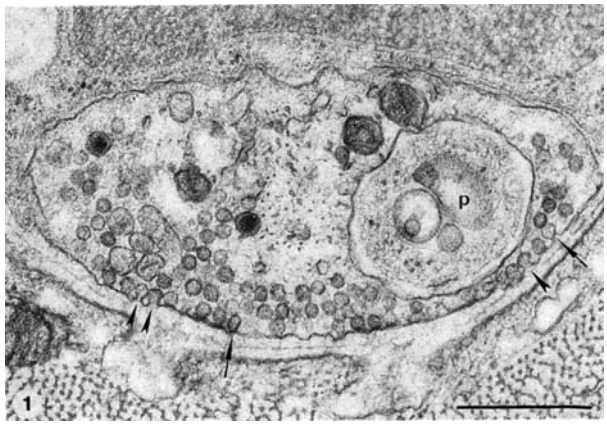

Fig. 5. Electron micrograph of a frog neuromuscular junction. The sample was quick-frozen 2.5 ms after electric stimulation in the presence of the K^+ channel blocker 4-aminopyridine. Clearly visible are some transmitter-containing vesicles in the process of fusion with the presynaptic membrane (arrow heads). Other vesicles seem to be in an earlier or later stage of the process of exocytosis (arrows). The image is reproduced from ref. [121], with kind permission from Springer-Verlag. p: Schwann cell projection invaginated by the nerve ending. Calibration bar: 0.5 μm.

observation that key features of the molecular machinery for secretion are conserved from yeast to neurons.[27c] The process has at least four steps,[28, 29] the molecular components and mechanisms of which are far from understood (Fig. 4; Fig. 6A): the mobilization and transport of vesicles from storage sites to the release sites; the docking of the vesicles to these sites; the fusion of the vesicle membrane with the presynaptic plasma membrane, triggered by Ca^{2+}; and the retraction and recycling of the empty vesicle membrane after exocytosis. Toxins are guiding us to some of the centerpieces of this complex picture.

Three sets of molecules are in the focus of research (Fig. 7): the first group are molecules of the presynaptic membrane (because it is here that docking of the vesicle, fusion, and recycling takes place); the second are proteins of the vesicular membrane (because among them must be the counterparts of the docking and fusion molecules found in the presynaptic membrane); and the third and final group are various regulators loosely associated with the vesicles, the docking sites, the cytoskeleton, or with hitherto unknown intracellular structures.

B: Control of vesicle fusion by rab, a guanine nucleotide-binding and GTP-hydrolyzing protein. (Reproduced from ref. [28], with kind permission from Dr. E. R. Kandel.)

3.2. ω-Conotoxins and N-Type Ca^{2+} Channels

Starting with the presynaptic membrane, we again encounter voltage-dependent ion channels. A key event in presynaptic transmitter release is the influx of Ca^{2+} through specific channels that are opened up by the depolarization caused by the invading action potential (Fig. 6A). Removing Ca^{2+} from the extracellular space or replacing it by Mg^{2+} causes a complete block of synaptic transmission by blocking transmitter release.

It would have been surprising if there were no neurotoxin targeted against this channel that is so instrumental for trans-

[27], with kind permission from Dr. R. Scheller.

mitter release. Indeed, the marine snails of the genus *Conus* produce a venom full of such neurotoxins.[30] Besides several peptides blocking the voltage-dependent sodium channel like TTX and STX, one group of peptides called ω-conotoxins blocks voltage-dependent Ca^{2+} channels. (The Na^+ channel blockers are called μ-conotoxins (Fig. 1). There are even peptides acting on the postsynaptic nicotinic acetylcholine receptor. They are called α-conotoxins. The three groups are between ten and around thirty amino acids long.[31]) ω-Conotoxins were the first natural substances discovered which affect voltage-dependent calcium channels. They can be used to differentiate the calcium channel subtypes. One ω-conotoxin (code number GVIA) is specific for the N-type calcium channel, the subtype involved in transmitter release.[32] It has little if any effect on the L- and T-type channels. Conotoxins will no doubt be useful for elucidating the topography of ion channels: they are small enough to be easily synthesized. This makes "wild type" and synthetic "mutant" toxins available. They can be labeled radioactively[33] and derivatized for use as photoaffinity labels.[34] Cross-linked covalently to its target protein in situ, they make possible the characterization of functional domains.

Up to now, voltage-dependent calcium channels have been biochemically investigated mainly with other tools such as synthetic drugs and cDNA cloning and sequencing. Interestingly, they turned out to be similar to the sodium channels (Fig. 3): Their largest chain (α_1, $M_r = 230$ kDa) is composed of four repeats with six hydrophobic amino acid stretches each. The S4 regions are believed to be the voltage sensors. Several other subunits are associated with the α_1 chain.[17]

3.3. Black Widow Spider Toxin

The venom of the Black Widow spider *Latrodectus tredecimguttatus* has helped researchers detect another important molecular component of the transmitter-release machinery. It contains a protein of $M_r = 125$ kDa called α-latrotoxin, which is highly poisonous (ED_{50} in mice 20 ng g^{-1}), because it causes unrestricted Ca^{2+}-independent transmitter release and complete depletion of presynaptic transmitter stores.[35] (At the neuromuscular endplate, the peptide-containing vesicles with a large dense core are not released. α-Latrotoxin seems to be a tool for discriminating constitutive and regulated exocytosis.[36]) Its binding site at the presynaptic membrane was identified as a member of the family of proteins known as neurexins.[37, 38] Neurexin may interact through its intracellular domain with proteins like synaptotagmin (Fig. 7) of the vesicle membrane.[39]

3.4. Snake Toxins Acting Presynaptically

Another component of the vesicle exocytosis machinery detected through toxins[40] is a voltage-dependent, but in contrast to the Hodgkin–Huxley channel, inactivating K^+ channel. It was found to be the target of several toxins. The most prominent of these is a group of small proteins (59–61 amino acids long) from the venom of mamba snakes, for example the α,β,γ-dendrotoxins (DTX) and toxin I. As shown first with hippocampal neurons, DTX (and toxin I even more so) facilitates transmitter release by blocking this transient K^+ channel.[41] A block of a K^+ channel means prolonged depolarization by inhibition of the repolarizing outward K^+ current. The consequence of this is a prolonged opening of the voltage-dependent Ca^{2+} channel supplying the exocytosis machinery with Ca^{2+} ions. Facilitation of exocytosis by DTX is therefore caused in the final event by increasing the calcium concentration in the nerve ending.

Perhaps the same target though on cholinergic synapses only (in the peripheral nervous system—in the CNS transmitter specificity is much less pronounced) has to be considered for the effects of β-bungarotoxin. β-Bungarotoxin is a member of the group of "phospholipase A_2 toxins" (β-bungarotoxin, notexin from the Australian tiger snake, crotoxin from the South American rattlesnake, taipoxin from the Australian Taipan, Figure 8). These are proteins from snake venoms that preferentially act presynaptically. Some of them are composed of two disulfide-linked subunits, one of which binds the target and conveys synapse specificity and the other is catalytically active, cleaving phospholipids in a Ca^{2+}-dependent way. Their action on the synapse follows a characteristic triphasic pattern:[42] an initial

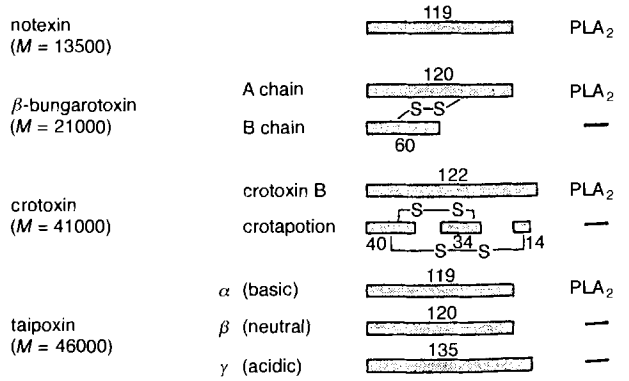

Fig. 8. Neurotoxins from poisonous snakes, with phospholipase A_2 activity. The figure shows the molecular weight, the subunit composition, the number of aminoacids in each subunit, and which subunit contains the lipase activity. Reproduced from ref. [40], with kind permission from Springer-Verlag.

depression is followed by transient facilitation and finally an irreversible blockade. β-Bungarotoxin is thought to bind to the same K^+ channel as DTX,[41,43] though at a different site. Together they may be tools for identifying this channel as a multiprotein complex with interesting regulatory properties. The phospholipase A_2 toxins also serve as tools for elucidating the role of phospholipids in exocytosis.[44]

3.5. Botulinum and Tetanus Toxin

Now, with the help of neurotoxins, we have identified three components of what we call the exocytosis machinery: an N-type voltage-dependent Ca^{2+} channel, an inactivating (A-type) K^+ channel, and neurexin, the α-latrotoxin-binding protein that is somehow involved in the calcium-dependent vesicle docking and/or fusion. A fourth protein, synaptobrevin, achieved prominence through two well-known neurotoxins from clostridia: botulinum toxin (BoTx) and tetanus toxin (TeTx) have long been studied as presynaptic blockers of transmitter release.[45] BoTx specifically blocks acetylcholine release at peripheral synapses, whereas TeTx is less selective and acts at sites in the central nervous system (CNS). But it was shown that this difference is due to the specificity of binding and uptake[46] into neurons rather than to specific toxic mechanisms at the intracellular target: when injected into neurons, both toxins prevent Ca^{2+}-dependent release of catecholamines in addition to acetylcholine.[47] More specifically, it was the light chain (M_r = 55 kDa) of the double-chain BoTx which caused the block after injection; the heavy chain (M_r = 100 kDa) is probably involved in binding to and transport through the plasma membrane. Recently the capacity of Botx to form channels in phospholipid vesicle membranes was visualized by electron cryomicroscopy and image processing.[48]

But which protein is the intracellular target and how is blockage of transmitter release brought about? These toxins led to the discovery of the central role in exocytosis of a protein from the vesicle membrane: the light chains of both BoTx and TeTx were shown to contain Zn^{2+}, and both had amino acid sequences characteristic for Zn-proteases.[49] And indeed, inhibition of their proteolytic activity by chelating the zinc ions destroyed their exocytosis-inhibiting activity. From this discovery, it was a short path to identifying the vesicle protein synaptobrevin, also called VAMP (from "*v*esicle-*a*ssociated *m*embrane *p*rotein") as the natural substrate of both enzyme toxins (Fig. 7).[50,51]

This is, however, only the introduction to an evermore complicated story. In fact there are seven isoforms of botulinum toxin, among which are BoTx A, B, C, E, F, and G. The one mentioned above that cleaves VAMP/synaptobrevin is BoTx B. Others are also zinc proteases. BoTx F cleaves VAMP/synaptobrevin too,[52] and it was shown that BoTx C cleaves syntaxin, a 35 kDa protein anchored to the presynaptic membrane and presumably participating in vesicle-docking;[53] and BoTx A blocks neurotransmitter release by selective cleavage of SNAP 25 (a synaptosomal-associated protein of M_r 25000. SNAP 25 is a member of a family of soluble, *N*SF *a*ccessory *p*roteins).[54] Actually the clostridial toxins together have among their targets important proteins involved in vesicle docking and fusion, not only in regulated but also in constitutive vesicle trafficking and exocytosis[55,56] (Table 2). SNAP 25, for example, was known as a protein involved in constitutive exocytosis. Inhibition of transmitter release by BoTx A proved that it operates in regulated exocytosis as well. They are presently used as a powerful tool kit for dissecting the molecular machinery of exocytosis. W. Huttner[26] gave credit to their importance by coining the term "exocytoxins".

Table 2. Target proteins of clostridial toxins [26].

Neurotoxin	Target	Cleavage Site	Cell type	Intracellular Localization
Tetanus toxin	VAMP/synaptobrevin	Gln76-Phe77	Neuron	Synaptic vesicle

Figure 7 gives a simplified view of our present picture of regulated exocytosis, including the proteins identified as playing an

important role. In addition to the molecules identified through the application of toxins as tools, there are others which are equally important—like the synapsins which are protein kinase substrates—and seem to be responsible for vesicle storage and mobilization. Furthermore, RAB3, a small G protein, is thought to play a regulatory role in vesicle trafficking and docking (see also Figure 6B). And finally, there are the docking proteins syntaxin and synaptotagmin. But despite this wealth of molecules and information, we still only have a relatively vague idea about the mechanisms triggering and performing vesicle transport, docking, fusion, and recycling. Toxins, because of their specific action on only one or a few key target molecules, have been and will be indispensible in unraveling this fundamental life process.

3.6. Transmitter Receptors as Postsynaptic Targets of Toxins

The transmitter released from the presynaptic nerve ending diffuses across the synaptic cleft to the postsynaptic membrane. There it is received by specific receptor proteins and triggers an effect in the receiving cell. This effect can be complex, but in the simplest case considered in this article, it is again due to an action potential. The action potential is started by a depolarization of the plasma membrane caused by an influx of sodium ions through an ion channel. To this end transmitter receptors that trigger action potentials are themselves ion channels; to distinguish them from the voltage-dependent ion channels discussed above they are called ligand-gated ion channels.[57] Ligand-gated ion channels are members of the group of type I receptors, as opposed to type II receptors which act on second messenger-producing enzymes through coupling (G) proteins. The ligand-gated ion channel can be specific for cations (Na^+, K^+, Ca^{2+}) or anions (Cl^-). An influx of negative charge into the cell would hyperpolarize it, thereby preventing the triggering of an action potential. Synapses with ligand-gated anion channels are therefore inhibitory; those with cation channels are excitatory synapses. Excitatory synapses use neurotransmitters such as acetylcholine and glutamate; inhibitory synapses use glycine or GABA (γ-amino butyric acid).[58]

So much for the neurobiological background. To return to the toxins-as-tools concept, I would like to restrict myself to a few selected systems, that is, the type I receptors for the transmitters glycine and acetylcholine. I chose the first because it shows in a very straightforward manner the successful procedure leading from applying a toxin to elucidating much of the receptor structure and the second, the nicotinic acetylcholine receptor, because it was the first and still is the best-characterized, a model for the other receptors of its class and an especially convincing example for toxins-as-tools technology.

3.7. Strychnine and the Glycine Receptor

Strychnine is not only a means for murder in many crime stories. It was also the handle which enabled the glycine receptor to be extracted from biological material and purified to homogeneity, prerequisites for partial sequencing, cloning, and cDNA sequencing, which finally led to the primary structure.[59a, 60] Strychnine as a toxin ($LD_{50} = 1\ mg\,kg^{-1}$ in man) causes motor disturbances, convulsions, and death through arrest of respiration.[2, 89] The convulsive action is based on its antagonistic effect on the inhibitory glycinergic synapses in the spinal cord.[59b] Glycine is the predominant inhibitory transmitter in the spinal chord and brain stem, while GABA plays this role mainly in the cortex and cerebellum. In 1982 the glycine receptor was isolated by affinity chromatography on a resin containing immobilized strychnine.[61] The protein is composed of three types of polypeptide chains with molecular weights of 93, 58 (β), and 48 kDa (α_1). The total M_r was about 250 kDa, representing a pentamer[62, 63] comprising the 48 and 58 kDa subunits. The 93 kDa subunit, unlike the other polypeptide chains, is a peripheral protein located at the cytoplasmic surface of the membrane and mediating the interaction of the receptor with the cytoskeleton.[64] Because of this bridging function it was recently named gephyrine.[66] ^{3}H-strychnine helped to detect the ligand binding site in the receptor complex. It can be used as a photoaffinity label and on UV irradiation is irreversibly incorporated into the 48 kDa subunit.[61, 66] Glycine competes with strychnine,[67] but though the binding sites for these two ligands seem to overlap, they are not identical.[68]

Several isoforms of the α- and β-subunits, products of different genes as well of alternative splicing, have been detected.[69, 70] Among these, a neonatally expressed isoform α_2 is especially interesting because its regulation depends on the development of the animal and its low affinity for strychnine.[71, 72] Newly born mice are relatively insensitive to strychnine, because of a single amino acid exchange in the glycine recpetor's α-subunit.[72]

The most interesting finding with the glycine receptor was its similarity with the nicotinic acetylcholine receptor.[60, 62] The primary structures of the subunits are homologous, not only to each other, but also to the other type II receptors (with the exception of the glutamate receptors). Hydropathy plots show that they are also similar in their putative transmembrane folding. Glycine, GABA, and nicotinic acetylcholine receptors are therefore grouped into one "super family" whose members may have evolved from one common ancestral receptor.[73]

These details and many more are, however, the subject of specialized reviews. In the context of this article I want to point out the role toxins play in receptor research: through binding assays and photoaffinity labeling, the toxin aids in defining receptor subunits and isolating the protein. This is a prerequisite for molecular cloning and sequencing either of genomic DNA or of cDNA, (because needed for this are oligonucleotide probes that are deduced from amino acid sequences gained from one or several receptor peptides). To prove that the DNA properly cloned and sequenced codes for the receptor under investigation, expression in a heterologous system, for example in *xenopus* oocytes, is required. There the identity of the receptor is tested electrophysiologically; one criterium for testing whether the right and complete receptor was obtained is its susceptibility to ligands including toxins. This step by step approach has now become routine in receptor research, and we shall see another classical example for this below.

3.8. α-Neurotoxins and the Nicotinic Acetylcholine Receptor

One transmitter receptor exists which we know very well, mainly because the tool kit provided by nature is especially rich in specific toxins.[74] This is the nicotinic acetylcholine receptor of the vertebrate peripheral[7] and central nervous system.[75] As I proceed in briefly reviewing some of the biochemical data collected by neurochemists (mainly over the past two decades), I shall try to enlarge upon the efficiency of some of these tools.

By the middle of the nineteenth century, more than fifty years before scientists knew anything about synapses and receptors, Claude Bernard identified the neuromuscular junction as the site of action of the arrow poison curare.[76] This can be seen as the first step in unraveling the machinery of nerve impulse transmission. But it was not before the early nineteen-seventies that another toxin became crucial for identifying, isolating, and finally characterizing in great structural detail the molecular target of D-tubocurarine, one of the neurotoxic components of the arrow poison.

This other toxin was α-bungarotoxin from the krait *Bungarus multicinctus* (a venomous snake) and a whole family of homologous peptide toxins from poisonous snakes of the genus *Elapidae* and *Hydrophiidae* (whose members include the many species of cobra and sea snakes). Chang and Lee[77] showed that it blocks synaptic transmission at the neuromuscular endplate, the synapse that uses the neurotransmitter acetylcholine for conveying nerve impulses to striated muscle. (At smooth muscle and at heart muscle another type of synapse that also uses acetylcholine is involved in nerve impulse transmission. These synapses respond to different toxins, mainly mushroom and plant alkaloids like muscarine and atropine. They are called "muscarinic cholinergic"[78] as opposed to the "nicotinic cholinergic" synapse discussed in this article; Figure 9).

α-Bungarotoxin was in effect the handle by which the nicotinic acetylcholine receptor was extracted from its membrane environment.[7, 77] It binds with very high affinity ($K_D = 10^{-11}$ M) and extreme specificity to one of the many proteins in the postsynaptic membrane (which in the case of the neuromuscular endplate is the muscle membrane). This integral membrane protein is the nicotinic acetylcholine receptor, the molecule that binds the transmitter acetylcholine released from the nerve ending when an invading action potential arrives. There are other acetylcholine-binding proteins nearby, for example, the acetylcholine esterase, which terminates the nerve impulse by hydrolyzing the transmitter, but this enzyme has no affinity towards α-bungarotoxin. Moreover, α-bungaratoxin was the tool to prove that the acetylcholinesterase and the acetylcholine receptor are different entities.[79] Initially the esterase was thought to simultaneously be the "receptor", possibly causing depolarization of the muscle membrane by letting cations pass at the interface between the protein and its lipid environment.[80]

The method by which a receptor is defined and quantitated is the binding assay. Tritiated α-bungarotoxin[81] was used for quantitative determinations of the amount of receptor protein present, for example, in the different fractions of affinity chromatography of membrane proteins solubilized in detergents. In a typical binding assay,[82] a protein fraction is incubated with

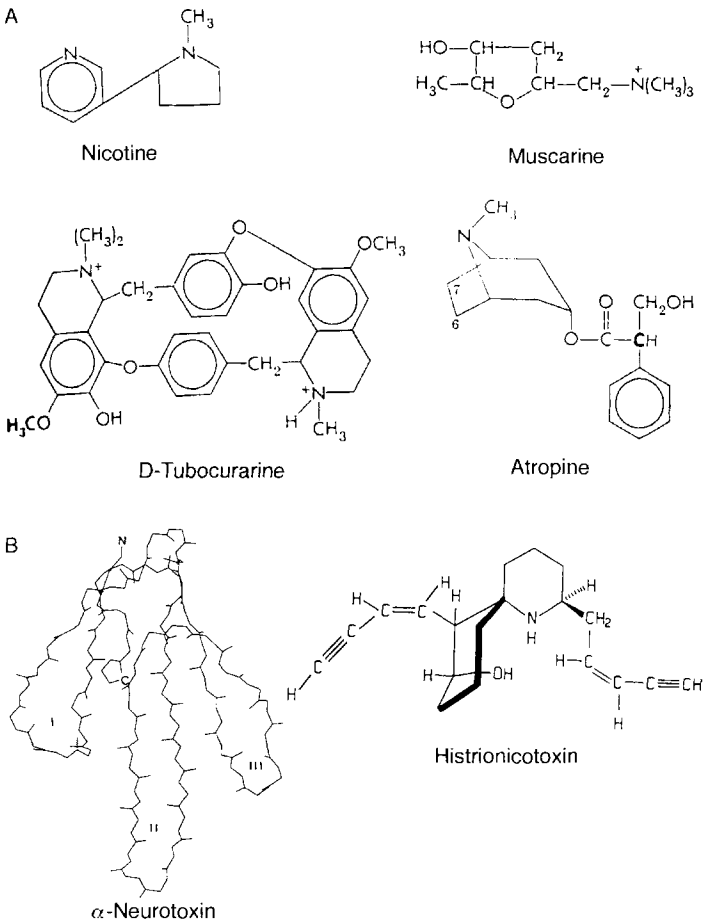

Fig. 9. Neurotoxins of cholinergic synapses. A: Toxins used for discriminating receptor types (nicotinic versus muscarinic acetylcholine receptors). B: Toxins used for discriminating receptor subsites (R versus E of the nicotinic acetylcholine receptor; see text).

^{3}H-α-bungarotoxin. After equilibration the mixture is filtered through a cation exchanger, on which the receptor and its bound radioactive toxin are retained. Unbound toxin is eluted. The radioactivity retained on the filter gives a direct estimate of the number of "binding sites" (= receptor molecules or, if one receptor binds more than one toxin molecule, fractions of this number) present in the protein mixture.

Likewise, fluorescently or radioactively labeled α-bungarotoxin was used to localize and count the receptors in the extra- and subsynaptic part of the endplate, respectively. (Subsynaptically, there are about 20000 receptors per μm^2).

With this tool at hand, the nicotinic acetylcholine receptor was rapidly purified to homogeneity and characterized biochemically. This work was primarily done by Jean-Pierre Changeux and his co-workers at the Institut Pasteur in Paris, but also—sometimes in fierce competition—by Arthur Karlin (New York), Michael Raftery (Pasadena), the Eldefrawis (Baltimore), Eric Barnard (London), and many others. Besides the toxin tool, another help was supplied by nature: the electric tissue of electric eel (*Electrophorus electricus*) and electric ray (*Torpedo spc.*). David Nachmansohn[83] had discovered that this tissue is extremely rich in cholinergic innervation. It made the isolation of receptor protein in mg quantities possible. It turned out that the fish receptor is well conserved during evolu-

tion and in its biochemistry, electrophysiology, immunology, pharmacology, and toxicology very similar to the receptor of higher vertebrates including humans.

Before I continue with the toxin-as-tool theme, I want to summarize some of the biochemical features of the nicotinic acetylcholine receptor that are the basis for the discussion of present applications of toxins in the investigation of structure–function relationships.

The nicotinic acetylcholine receptor[6, 7, 84–88] from *Torpedo californica* is a heteropentameric glycoprotein of M_r 290000. It is composed of two identical polypeptide chains (α, apparent M_r 40000, 437 amino acids) and three different ones (β, apparent M_r 50000, 469 amino acids; γ, apparent M_r 60000, 489 amino acids, and δ, apparent M_r 65000, 501 amino acids). The quaternary structure therefore is $\alpha_2\beta\gamma\delta$. All subunits are glycosylated, all are phosphorylated, and all span the membrane. Since the primary structures of the polypeptide chains was deduced from the cloned and sequenced cDNAs,[89–92] it was assumed that the four stretches of hydrophobic amino acids, each about 22 amino acids long, which are observed in all polypeptide chains, indicate that the chains span the membrane four times.[93]. Until recently it was predicted that the transmembrane part of the receptor is formed by α-helices,[94] but now we are sure that part of the transmembrane domain is formed by β-strands. Both the N- and the C-termini of the chains are extracellular. The primary structures of the four different subunits are similar, which indicates that they may have originated early in evolution from a common ancestral gene.[95] I already mentioned their similarity with other members of the superfamily of ligand-gated ion channels.[60]

So much for the structure. As to the functions, I have mentioned that the nicotinic acetylcholine receptor regulates the cation permeability of the postsynaptic membrane. Therefore, within the protein structure described above there must be at least two functional moieties, an acetylcholine- (and α-neurotoxin-) binding pocket and an ion channel regulated by it. Since the ligand-binding site and the channel interact in the same manner as interactions previously found with allosteric enzymes and transport proteins,[96, 97] there must be a third functional moiety mediating ("transducing") this interaction. This tripartite operational structure is in compliance with the general scheme of all receptor architectures.[57] They are composed of a signal-receiving (ligand-binding) part R, an effector part E that mediates the effect the signal is supposed to have on the target cell, and a transducer structure T, which couples R and E. This RTE-triune receptor concept is the basis of receptor classification into three types: type I, II, and III. The latter type comprises the growth hormone receptors, which are not the concern of this article. With the neurotransmitter receptors the type I receptors are defined as those proteins that contain R,T, and E (usually an ion channel) integrated into one protein. Type II receptors on the other hand contain R,T, and E (which is here an enzyme in most cases, although recently several ion channels have been found in this class too) on distinct and separable proteins. Examples of type I receptors are the nicotinic acetylcholine receptor, the $GABA_A$ and glycine receptors and some subtypes of the serotonine and glutamate receptors. Type II receptors are the β-adrenergic and muscarinic acetylcholine receptors, the receptors for opiates and other peptides, the dopamine receptors etc.[57]

If R, T, and E in type I receptors are not separate molecules, it is an even more difficult task to detect them within the integral protein structure. Here again toxins were indispensible tools, and again I shall prove this point using the nicotinic acetylcholine receptor as an example. The α-neurotoxins are antagonistic ligands of R,[74] while other, mostly low molecular weight, toxins bind specifically to the ion channel E.[97] It turned out that T, the part of the receptor structure transducing the ligand-binding effect to the ion channel, is located at or near this latter toxin-binding site as well.[98]

3.9. Dissection of a Receptor: 'R', the Signal-Receiving Site

The nicotinic acetylcholine receptor has its name from nicotine, a toxic plant alkaloid which, like acetylcholine, acts as an agonist (Fig. 9). Competing for the same ligand-binding site are antagonists, the most powerful of which are the toxic compounds like the arrow poison D-tubocurarine and the snake venom peptide α-neurotoxins. Agonist- and competitive antagonist-binding sites are presently mapped by affinity labeling in connection with microsequencing and by site-directed mutagenesis experiments. There are two binding sites per receptor molecule, one on each of the two α-subunits. By using ^{3}H-α-bungarotoxin in combination with other techniques (reviewed in ref. [7]) the amino acid sequence α180–200 was shown to participate directly in the toxin binding. Interestingly, the receptor from snakes has several mutations in this sequence, lowering the affinity and thereby the toxicity of its own α-neurotoxin.[99]

Recently it became apparent that other subunits participate in toxin binding as well. Photoaffinity labeling of the membrane-bound receptor with radioactive derivatives of D-tubocurarine[100] and α-neurotoxin II from a cobra venom[101] showed that the γ- and δ-subunits incorporate these toxins as well. More specifically, labeling of neighboring subunits with cobra toxin was only achieved when the photoreactive group was attached to one specific residue, lysine 26, of the peptide toxin (Fig. 10).[102] If the photo group was on lys 46, only the

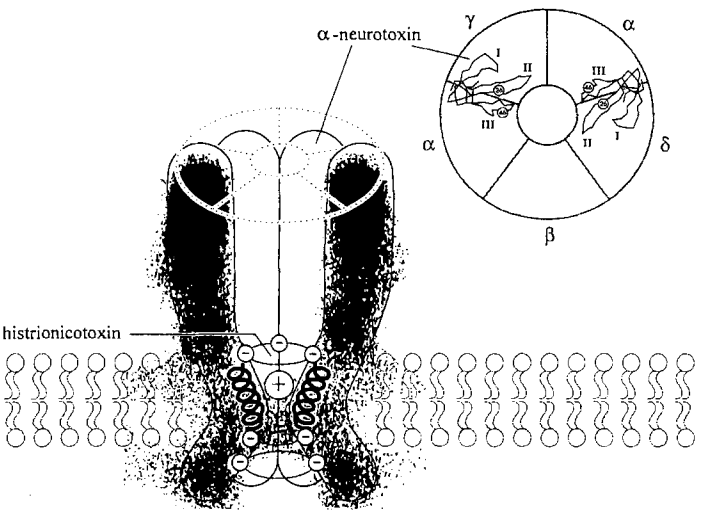

Fig. 10. Model of the nicotinic acetylcholine receptor, the prototype of a ligand-gated ion channel, which was characterized to a large extent by the use of neurotoxins.

α-subunits could be labeled. Moreover, binding studies with D-tubocurarine showed that the two α-subunits have different affinities for their ligands,[103] and competition experiments with photolabeling derivatives of cobra toxin (the lys 26 derivative) indicated that the high affinity α-subunit is located next to the γ- and the low affinity subunit to the δ-subunit. These (and other experiments reviewed elsewhere) allow several conclusions: The antagonist and agonist binding sites are located at the interface of the α- and δ-, and the α- and γ-subunits, respectively. Symmetry considerations demand an $\alpha\gamma\alpha\beta\delta$[87] rather than an $\alpha\beta\alpha\gamma\delta$[104] quaternary structure (Fig. 10).

At present the receptor surface and the quaternary structure are being mapped with α-neurotoxins as tools. In the absence of an X-ray structure this will supply us with a three-dimensional image of at least part of the receptor. This approach is especially promising since the exact tertiary structure of the toxins are known (Fig. 9B) from X-ray analysis of the crystalline proteins[104-106] and from NMR studies.[107-109] If photoreactive groups are introduced to defined side chains, these toxin derivatives can be used as yard sticks for mapping the receptor topography.[102, 110]

3.10. The Ion Channel E as the Receptor's Effector Site

Besides the competitive antagonists there are noncompetitive antagonists (Fig. 9B). These compounds do not prevent the agonist from binding to its sites on the receptor, but still block the response, that is, the ion flux through the channel. Neurotoxins helped to show that noncompetitive antagonists bind directly to the ion channel, blocking it sterically (or allosterically).[7, 96, 97] One such channel-blocking toxin is histrionicotoxin, which is isolated from the skin of South American frogs of the genus *Dendrobates*. Histrionicotoxin became the principal tool in attempts to identify the ion channel within the receptor protein.[111, 112] The main criteria for assigning any compound as a ligand of a site in the ion channel is its voltage-dependent blocking activity and its competition with the proven ion channel ligand histrionicotoxin.[97] According to these criteria[113, 114] a small organic cation, the triphenymethylphosphonium ($TPMP^+$) ion, was used to covalently photolabel the wall of the ion channel and to identify it using protein chemistry methods.[114, 115] The surprising result of these experiments was that each subunit was labeled by $TPMP^+$ in a homologous position.[115] This means that the five subunits contribute a homologous amino acid sequence to the channel wall. This sequence is one of the four hydrophobic stretches thought to span the membrane.[92] Specifically, it is the putative transmembrane helix M2. Therefore, (with the help of histrionicotoxin as a tool) for the first time a receptor's ion channel was identified (Fig. 10): E, the acetylcholine receptor's ion channel, is formed at least in part by the five putative transmembrane helices M2 of the receptor's subunits.[115, 116]

This result was compatible with experiments using quite different techniques, for example, the recombinant DNA technique in combination with patch clamp electrophysiology.[117, 118]

3.11. T, the Receptor's Transducer?

The transducer, the part of the protein coupling R to E, was found by photo affinity labeling and by site directed mutagenesis rather than with the help of neurotoxins. It is located on the same structures which form the wall of the ion channel, that is, on the helix M2.[119, 120]

4. Conclusion

This review of the recent upsurge of neurochemical discoveries due to the use of toxins as tools may give a false impression. It may seem that these tools are restricted to the elucidation of synaptic mechanisms. This is not the case. If space would allow it, I could expand to completely different areas of research such as axonal transport, neuronal development, etc. Given the success of this approach in some fields, and given the continuous discovery of new neurotoxins, it is safe to predict exciting applications of this tool-kit in future neurochemical research.

I thank Prof. Dr. Victor Tsetlin for fruitful cooperation and discussions. Part of the artwork (Figs. 3 and 10) was executed by Ms. K. von Etzel. Work from my laboratory mentioned in this article was financed by the State of Berlin, the Deutsche Forschungsgemeinschaft (SFB 312), and the Fonds der Chemischen Industrie.

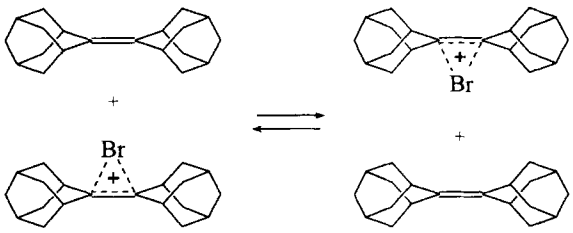
New Findings in the Electrophilic Addition of Halogens to Olefins

Rainer Herges*

According to the textbooks, both the mechanism and the theory of electrophilic addition of halogens to olefins are well understood.[1] It is all the more surprising that there is still some groundwork to be done in this field, as was demonstrated by recent synthetic, spectroscopic, and theoretical publications.



As early as 1937, Roberts and Kimball[2] explained the *anti* selectivity of the bromination of olefins by invoking a bridged bromonium ion as intermediate. Thirty years later, such intermediates were detected under "stable ion conditions" by NMR spectroscopy.[3] The halonium ions of chlorine,[4] bromine,[5] and iodine[6] with adamantylideneadamantane are even isolable as stable salts, because the subsequent nucleophilic attack of the counterion is prevented by steric hindrance in the substrate. It is generally accepted that a π complex precedes formation of such halonium ions,[7–9] and it is supposed that cation-stabilizing substituents (e.g., phenyl) at the olefin lead to distorted or even nonbridged cations (Scheme 1).

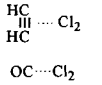
Scheme 1.

In the case of adamantylideneadamantane and some other sterically hindered olefins, the free olefin and bromine are in rapid equilibrium with the π complex and the bromonium ion.[6, 10, 11] The equilibrium constant for the formation of the π complex from olefin and bromine strongly depends on the substituents. Moreover, it was demonstrated by NMR that there is a rapid, degenerate transfer of Br^+ from the bromonium ion to the free olefin in the adamantylideneadamantane system (Scheme 2).[6, 12] According to ab initio calculations the transfer proceeds via a "spiro" transition state.

Whereas crystal structures are available for bromonium and iodonium salts,[13, 6] little experimental data exists for the π complexes. According to calculations by Cossi et al.[14] and earlier theoretical work,[15] the π complex of ethene and

Scheme 2.

bromine is about 3–4 kcal mol^{-1} more stable than the starting materials. The axis joining the nuclei in the halogen molecule is perpendicular to the molecular plane of ethene and intersects the midpoint of the double bond. No charge is transferred during complex formation.[16] The frequently used term "charge-transfer complex" is therefore not correct. Since dispersion energy is the main driving force for binding, "van der Waals complex" would be a better description. Compared to the π complex, the bromonium ion is mucher higher in energy. In vacuo (and with bromide as the counterion) the free energy difference is 40 kcal mol^{-1}. Under these conditions the bromonium ion is not likely to be formed by simple thermal activation. However, polar media like methanol lower the free energy of reaction to about +10 kcal mol^{-1}, because the very polar bromonium ion is much better solvated than the nonpolar π complex.



A nonpolar environment and low temperatures should therefore allow the π complex to be observed as a long-lived species. Indeed, as far back as the seventies, the π complex of chlorine and ethene was detected by IR spectroscopy in a nitrogen matrix at 20 K.[17, 18] A totally different and probably revolutionary method for the structural investigation of such labile molecular complexes in the gas phase was reported recently by Legon et al. in a series of papers: Both components (halogen and Lewis base) are expanded separately through a fast-mixing nozzle into the evacuated Fabry–Pérot cavity of a Fourier transform microwave spectrometer.[19] The gases mix, and the supersonic and collision-free expansion results in the molecular complexes being frozen with very low internal energies. Thus, subsequent reaction to form the usual products observed under normal conditions is prohibited. Even complexes such as $H_3P\cdots Cl_2$ can be investigated—the normally explosive course of reaction is avoided.

The rotational spectra do not only give structural information; the intermolecular (quadratic) force constants are related

to the centrifugal distortion constants, and the charge distribution can be derived from the nuclear quadrupole coupling constants. Table 1 shows an overview of halogen/Lewis base complexes investigated recently.[20]

Table 1. Bond lengths $r(B\cdots X)$ and force constants k_σ for the $B\cdots X$ bond in the halogen/Lewis base complexes $B\cdots XY$, characterized by rotational spectroscopy.

B···XY	Point group	$r(B\cdots X)$ [Å]	k_σ [N m^{-1}]	Ref.

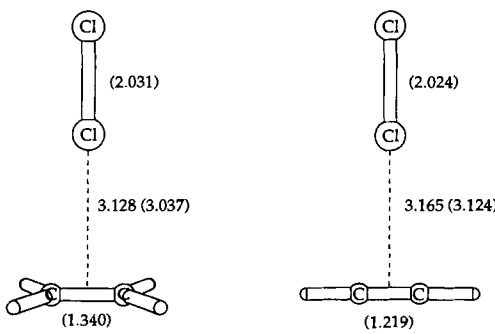
	$C_{\infty h}$	2.915	6.6	[26]
	C_{2v}	2.979	10.5	[27]
	C_{2v}	3.059	9.4	[28]
	$C_{\infty h}$	4.272–4.332 [a]	6.18–6.34 [a]	[29]

[a] Dependent on the isotopic composition.

From a mechanistic point of view, the complexes of ethene and ethyne are most interesting. The axis joining the nuclei in the halogen molecule is perpendicular to and intersects the midpoint of the double or triple bond (Fig. 1). The structural parameters of both the halogen and ethene or ethyne are not significantly changed by complexation. The small force constants k_σ (Table 1) also indicate a very weak interaction between π bond and halogen.[30] The nuclear quadrupole coupling constants of the chlorine atoms differ only slightly and are almost equal to the values observed for free chlorine. This means that there is only a small perturbation in the charge distribution on moving from the separate components to the complex. No significant polarization within the bound halogen is observed. Hence, the microwave investigations provide an impressive confirmation of the properties predicted earlier by theoretical calculations and matrix isolation.



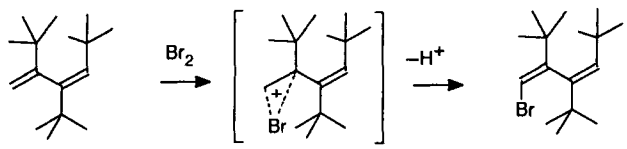


Fig. 1. Structures of the π complexes of chlorine with ethene [21] (left) and ethyne [22] (right). Bond lengths in Å (ab initio values [31] in parentheses).

Hopf et al. recently reported a fascinating, sterically hindered system that, in solution at room temperature, prevents further reaction of the π complex and bromonium ion to form the usual dihalogenated products.[32] With 1,2,3-tri-*tert*-butyl substituted butadiene, the cationic intermediate is stabilized by loss of an α proton. Thus, the overall course of reaction corresponds to that observed for aromatic electrophilic substitutions, which also proceed via a π complex and cationic intermediate (Scheme 3). In the bromination of 2,2,5,5-tetramethyl-3-hexene, the intermediate bromonium ion is stabilized by loss of a β proton. Subsequent HBr elimination yields 2,3-di-*tert*-butyl-1,3-butadiene.[33]

Scheme 3.

The examples show that long-known reactions are also worthy of closer inspection. Modern theoretical, analytical, and synthetic methods not only open novel fields of application, they are also able to contribute to the basic knowledge of mechanistic chemistry.

[8] From the very strong dependance of the reaction rate, Dubois and Garnier conclude that the nucleophilic attack of the counterion or the solvent takes place at the stage of the bromonium ion, rather than at that of the π complex. The unusually strong solvent isotope effect also suggests that the transition state of the rate-determining step is strongly polarized and most probably corresponds to the formation of the bomonium ion from the π complex: a) J. E. Dubois, F. Garnier, *J. Chem. Soc. Chem. Commun.* **1968**, 241; b) F. Garnier, R. H. Donnay, J. E. Dubois, *ibid.* **1971**, 829.
[9] There are (mostly arene-substituted) olefins that are probably not chlorinated via cationic intermediates, since the *cis* products are formed stereospifically. Not much is known about the mechanism of this "direct" addition, which probably involves the *cis* collapse of the π complex: a) S. J. Cristol, F. R. Stermitz, P. S. Ramey, *J. Am. Chem. Soc.* **1958**, *78*, 4939; b) P. B. D. de la Mare, N. V. Klassen, R. Koenigsberger, *J. Chem. Soc.* **1961**, 5285; c) P. B. D. de la Mare, R. Koenigsberger, *ibid.* **1964**, 5327; d) R. C. Mononuclear Tris(arene)–Metal Complexes

Ulrich Zenneck*

The first π-arene complex, bis(η^6-benzene)chromium, was synthesized and characterized by Fischer and Hafner almost forty years ago.[1] Are any remarkable discoveries in this area of chemistry still possible today? Since that pioneering work numerous attempts have been made to vary the bonding mode and the number of arene ligands per metal atom. Although the former was achieved after some time, a mononuclear complex with three arene ligands was synthesized for the first time only recently.[2] Considering the intensity of research in organometallic chemistry, this is quite remarkable and calls for closer examination.

If the electronic demand of a metal center is low, the cyclic delocalization of the π electrons in the arene ligands may be interrupted such that only a portion of these electrons interact with the metal. Arenes can coordinate, for example, as η^4 ligands with loss of planarity, if this assures that the 18 valence electron (VE) configuration of the transition metal complex is not exceeded. This occurs relatively easily for condensed arenes, but stable complexes with monocyclic arene ligands having analogous η^4 coordination are also known and have been structurally characterized.[3] The preferred η^4 coordination of polycyclic ligands can be explained by the difference in the resonance energies of the π electrons in the η^4-coordinated arenes, which are especially unfavorable for benzene and its derivatives.[4] In η^4-naphthalene complexes the bound 4π unit is electronically almost completely separated from the 6π unit, which is reflected in the spectroscopic and structural properties. Thus these compounds can be considered benzannelated 1,3-cyclohexadiene complexes; the NMR and UV spectra of 1,3-cyclohexadiene complexes closely resemble those of the related subunits in η^4-naphthalene complexes. The dihedral angles formed between the bound and not bound portions of the ligands are also in the same range for both types of compounds.[5]

Generally the stability of η^4-arene complexes increase within a transition metal triad with the atomic number of the metal center. The decomposition points of the (η^4-benzene)(η^6-benzene)metal(0) complexes (metal = Fe, Ru, Os) serve as an example. The iron complex decomposes at roughly −50 °C, the ruthenium complex at 0 °C, and the dynamic behavior of the osmium complex can be observed by NMR spectroscopy at up to 100 °C.[6] In addition 3d metals sometimes tend to avoid forming η^4-arene complexes; in contrast to the heavier homologues they give rise to paramagnetic 20 VE complexes with a ligand bound η^6 fashion. Thus bis(hexamethylbenzene)iron is a 20 VE sandwich complex with two unpaired electrons, whereas the diamagnetic bis(hexamethylbenzene)ruthenium is a typical (η^4-arene)(η^6-arene)metal complex.[7]

π-Arene complexes can be synthesized by three principle routes: ligand exchange maintaining the oxidation state of the metal center (suitable for cationic complexes), ligand exchange under reducing conditions (for cationic, anionic, and neutral complexes), and direct synthesis by cocondensation of metal

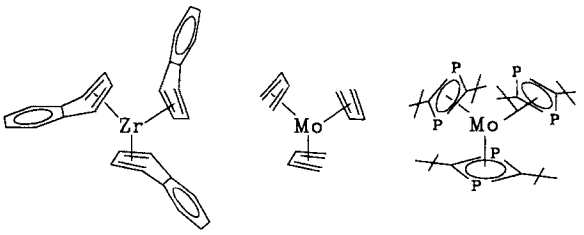
vapor and ligand (for neutral complexes). In the reactions under reducing conditions the use of arene anions has been particularly successful recently, since the anions are responsible for both the reduction and halogen–arene exchange of the metal halides typically used as starting materials. When an excess of this reducing agent based on the oxidation state of the metal is used, the elegant formation of arene metalates results.



The synthesis of bis(η^6-arene)titanates(1–) from $TiCl_4 \cdot 2THF$ and biphenyl anions[8] was the first alternative to metal vapor synthesis for the preparation of bis(arene)titanium derivatives as potential catalysts.

Surprisingly in the reaction of $ZrCl_4 \cdot 2THF$ with $KC_{10}H_8$ in the presence of [2.2.2]cryptand or [15]crown-5 (Scheme 1) Ellis

$$ZrCl_4 \cdot 2THF + 6KC_{10}H_8 + nL \xrightarrow[-60 \rightarrow 0\,^{\circ}C]{DME} [KL_n]_2[Zr(C_{10}H_8)_3] + 3C_{10}H_8 + 4KCl + 2THF$$
$$[KL_n]_2\text{-}\mathbf{1}$$

Scheme 1. $n = 1$, L = [2.2.2]cryptand; $n = 2$, L = [15]crown-5; DME = 1,2-dimethoxy methane.

and Jang obtained polyether-stabilized dipotassium salts of tris(η^4-naphthalene)zirconates(2–) **1**,[2] which deserve special attention for a number of reasons.

1 **2** **3**

– These are the first tris(arene) complexes with three independent arene ligands; the only previous example of coordination of three neutral arene ligands was the η^{18} coordination of the main group element cations Ga^+, Ge^{2+}, and Sn^{2+} in the cavity of a [2.2.2]paracyclophane.[9] This macrocyclic ligand forms a flexible cage supporting the relatively weak interactions with the cations.

– The zirconates contradict previous findings for η^4-arene coordination without immediately apparent electronic reasons. The expected product of the reaction outlined in Scheme 1 was the still-unknown bis(η^6-naphthalene)zirconate(2–), which should be analogous to bis(η^6-naphthalene)molybdenum[10] and bis(naphthalene)titanate(2–).[11]

– Based on the previously discussed relationship of η^4-bound naphthalene ligands with coordinated *cis*-1,3-dienes, one would expect the zirconates to display analogies with tris(diene)metal complexes. Although corresponding diene metalates are not yet known, molybdenum(0) in tris(butadiene)molybdenum **2**, which is isoelectronic with zirconate(2–), shows the same structural features as **1**.[12] In both cases the donor centers have a trigonal-prismatic arrangement about the metal center with metal–C distances in the range typical for coordinated olefins.

– The readily accessible salt K_2-**1** is an interesting precursor for anionic zirconium compounds such as $[Zr(CO)_6]^{2-}$.[2] Owing to the naphthalene effect,[10] the arene ligands are easily substituted. In general this is expected for naphthalene metalates, which should now be available in greater variety than by previously known analogous routes.

– The isoelectronic relationship Zr^{-II}/Mo^0 raises speculations on the further chemistry of metalates. The preparation of the tris(η^4-1,3-diphosphete)molybdenum derivative **3** was recently reported,[13] in which the Mo^0 center is surrounded by three heterocycles.

Summary: We can look forward to the rapid and highly interesting development of the chemistry of arene metalates.

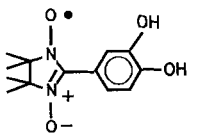
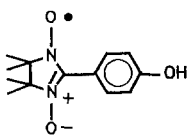
Structure Determination from Powder X-Ray Diffraction Data of a Hydrogen-Bonded Molecular Solid with Competing Ferromagnetic and Antiferromagnetic Interactions: The 2-(3,4-Dihydroxyphenyl)-α-Nitronyl Nitroxide Radical**

Joan Cirujeda, Luis Enrique Ochando, Jose Maria Amigó, Concepció Rovira, Jordi Rius, and Jaume Veciana*



Dedicated to Professor Dwaine O. Cowan

Macroscopic physical properties of molecular solids—magnetic, electrical, and optical—are generally controlled by intermolecular electronic interactions. Therefore, the knowledge of the molecular packing is crucial in order to understand and correlate the bulk properties of a given material with its microscopic characteristics. When no single crystals with suitable size and/or good quality can be grown and the crystal structure of a given compound is needed, one is forced to use the X-ray diffraction data obtained from powder samples. Consequently, the development and improvement of methods allowing structure determinations from powder diffraction data are nowadays strongly demanded.[1]



To our knowledge these methods have been used mainly to determine the crystal structures of some inorganic solids, while only very few structures of organic compounds, most having heavy atoms, have been resolved.[2] The solution of crystal structures of purely organic molecular solids from powder X-ray diffraction data measured with laboratory X-ray sources is a difficult task because the number of measurable intensities at high diffraction angles is considerably reduced. In addition, the absence of strong scatterers and the large number of light atoms prevents the direct interpretation of the Patterson function. As previously shown, one of the simplest ways of circumventing these limitations is through the combined use of molecular replacement methods and rigid-body Rietveld refinements.[1a, 3] The extension of this method to all kinds of organic compounds would be very beneficial.

Herein we present the first application of this method for the determination of the molecular packing of a complex organic compound having only s and p electrons and more than ten atoms in the asymmetric unit. We chose the molecular solid formed by the 2-(3,4-dihydroxyphenyl)-α-nitronyl nitroxide radical (**1**).[4] This open-shell molecule deserved a priori to be studied in solid form since it showed significant ferromagnetic interactions and must be an example of a molecular solid whose self-assembly is directed by hydrogen bonds. The synthesis and a detailed magneto-structural correlation of this molecular solid are also reported and discussed here.[5]

The use of hydrogen bonds as a crystal design element in the preparation of magnetic molecular materials has great potential.[6, 7] Very recently it was demonstrated that the 2-(4-hydroxyphenyl)-α-nitronyl nitroxide radical (**2**) forms a two-dimen-

1

2

sional network through hydrogen bonds and that ferromagnetic interactions are propagated along these two directions.[7] Therefore, it seemed interesting to prepare new nitronyl nitroxide radicals similar to **2** but having an additional OH group on the benzene ring, for example, radical **1**. Because this radical contains an equal number of hydrogen bond acceptor (N–O) and donor (O–H) groups that have noncollinear relative orientations and point in all three directions, we expected that these molecules would self-assemble. The resulting molecular solid, a high-dimensional hydrogen-bonded network, may have enhanced magnetic dimensionality.

Radical **1** was prepared following the usual procedure.[8] Thus, the reaction of 2,3-dimethylbutane-2,3-bis(hydroxylamine) with 3,4-dihydroxybenzaldehyde followed by the oxidation of the resulting addition product with lead dioxide yielded the radical **1**.[9] Like most catechol derivatives[10] this open-shell compound is very unstable in solution in a wide variety of solvents. This intrinsic instability, which is probably assisted by the radical character, prevents preparation of large single crystals. For this reason, only polycrystalline samples of **1** were obtained by a rapid precipitation with *n*-pentane from a concentrated chloroform solution.

One of these samples was used for the X-ray powder diffraction measurements.[11–13] The experimental and calculated diffraction patterns and the corresponding difference profile are shown in Figure 1. The crystal packing of radical **1** obtained shows some outstanding features that confirm the initial expectations based on the presence in its skeleton of two hydrogen bond acceptors, one for each of the two hydrogen bond donors. As is shown in Figure 2a, the molecules form double corrugated layers parallel to the (001) plane, which are held together by two types of strong hydrogen bonds. One type of hydrogen bond connects the OH groups at the *meta* positions of benzene rings of two neighboring radicals with the two NO groups on the same side as these OH groups. These hydrogen bonds give rise to dimers, in which molecules are arranged side by side and head to tail ($O_{meta} \cdots ON = 2.6(1)$ Å). The second type of hydrogen bonds links the neighboring dimers through the remaining OH groups in the *para* positions and the other NO groups

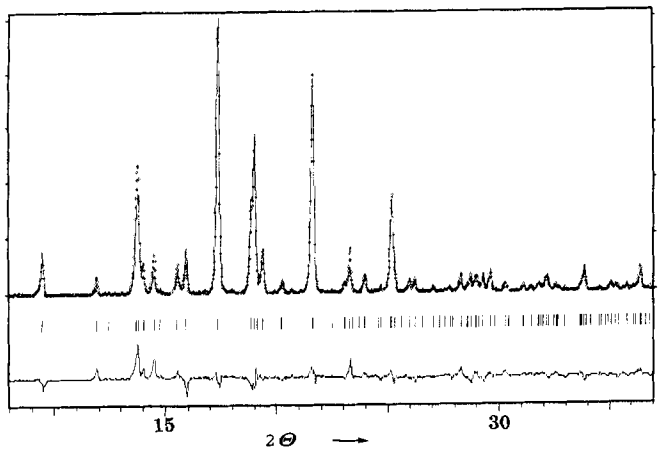

Fig. 1. Observed and calculated X-ray powder diffraction patterns for **1**, and the corresponding difference profile (bottom).

[$O_{para}\cdots ON = 2.7(1)$ Å]. The resulting relative molecular arrangement of these dimers is very similar to that observed for the molecules of radical **2** linked through similar hydrogen bonds between the *para*-OH and NO groups.[7] The shortest intermolecular contacts in **1** are found within the two-dimensional hydrogen-bonded layers; however, the forces operating between these sheets are only weaker van der Waals forces, and accordingly the intermolecular distances are greater (3.1 Å $< d \ll 4.0$ Å). The most relevant structural features in these 2D layers are the head-to-tail overlaps between the molecules of a given dimer with those located on the upper and lower layers (Fig. 2b, c). This relative arrangment gives rise to stair-shaped molecular chains parallel to the c axis.

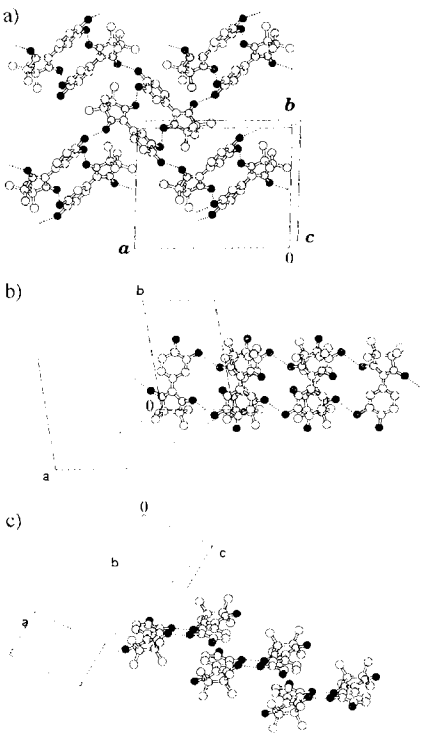

Fig. 2. Crystal structure of **1**. a) View of a two-dimensional corrugated layer parallel to the (001) plane. b) and c) Stacking of molecules in adjacent corrugated planes viewed perpendicular and parallel to the mean planes though the atoms ONCNO. Hydrogen bonds are depicted by dotted lines.

In order to rationalize the magnetic properties of **1**, we have made a detailed analysis of the intermolecular short contacts and the relative molecular orientations present in this molecular solid, taking into account the widely accepted charge transfer mechanism involving frontier orbitals.[16] This analysis suggests the presence of antiferromagnetic (AFM) interactions between the molecules of each dimer and also ferromagnetic (FM) interactions between head-to-tail overlapping molecules of contiguous layers.[17] Furthermore, very weak FM interactions are also expected to be transmitted through the hydrogen bonds involving the *para* OH groups, as occurs in the radical **2**, since both radicals have similar relative orientations in the solid. In conclusion, the molecular packing observed for **1** indicates the presence of predominant alternating FM and AFM interactions along the stair-shaped molecular chains together with other FM interactions of minor importance along other directions perpendicular to the c axis.

The temperature dependence of the static magnetic susceptibility of a polycrystalline sample of **1** was measured in the range $2 \le T \le 300$ K using a SQUID magnetometer. The plot of $\chi_m T$ versus T (Fig. 3) (χ_m = molar magnetic susceptibility) clearly

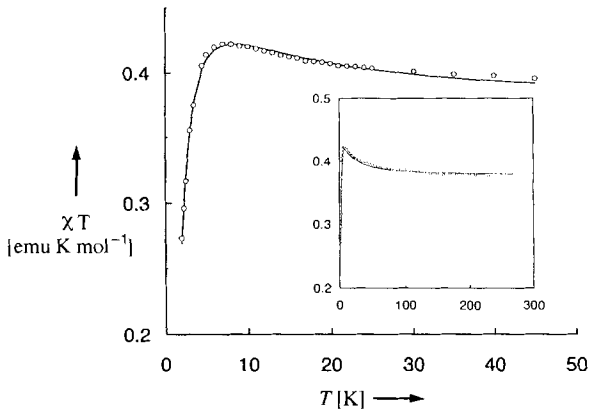

Fig. 3. Temperature dependence of $\chi_m T$ for radical **1**. The solid line corresponds to the least-squares fit (see text).

reveals an increase of the effective magnetic moment of the sample with decreasing temperature until it reaches a maximum at about 7 K. At lower temperatures the value of $\chi_m T$ decreases quite rapidly. This result indicates the simultaneous presence of both FM and AFM intermolecular interactions and confirms expectations based on the observed molecular packing. The experimental susceptibility data were then rationalized with the magnetic model suggested by this molecular packing, in other words, a linear 1D Heisenberg chain of $S = 1/2$ spins with alternating FM and AFM intermolecular exchange interactions: $\cdots$-J_{FM}-J_{AFM}-J_{FM}-J_{AFM}-$\cdots$. For this kind of chain the theory predicts a maximum in the plot of $\chi_m T$ versus T when the FM interaction dominates (i.e. when the alternating parameter, defined as $\alpha = J_{FM}/|J_{AFM}|$, is larger than one). The resulting magnetic behavior is fairly well described by the Equations (a) and (b).[18] Here $T_R = T/|J_{AFM}|$ and χ^{chain} and χ_R^{chain} are the molar and

$$\chi^{chain} T = \chi_R^{chain} T(3g^2/32|J_{AFM}|) \quad \text{(a)}$$

$$\chi_R^{chain} = \frac{AT_R^3 + BT_R^2 + CT_R^2 + D}{T_R^4 + ET_R^3 + FT_R^2 + GT_R + H} \quad \text{(b)}$$

reduced magnetic susceptibilities, respectively, of the repeating units of the chain.[19] In order to consider the weak FM ex-

change interactions, J^{inter}, between a given chain and its $z = 4$ nearest neighboring chains, occurring through the molecules linked by the *para*-O-H ··· O-N hydrogen bonds, Equation (c) was also used.[20]

$$\chi_m = \chi^{chain}/[1 - (2zJ^{inter}\chi^{chain}/Ng^2\beta^2)] \quad (c)$$

Fitting Equations (a)–(c) to the the experimental data yielded the following best-fit parameters: $J_{FM}/k_B = 9.28$, $J_{AFM}/k_B = -3.78$ ($\alpha = 2.45$), and $J^{inter}/k_B = 0.34$ K. Both the signs and the magnitudes of these values are in accord with that expected from the molecular packing and from the results for the related radical **2**.[21]

In conclusion it is shown that powder X-ray diffraction data can be used to elucidate the crystal packing of relatively complex purely organic molecular solids, including those having only s and p electrons. For this purpose it is necessary to know the molecular structure of a related parent compound as an appropriate model system. In addition, our results here confirm the ability of hydrogen bonds to connect correctly functionalized radical molecules in a controlled fashion, thus generating ferromagnetic interactions with a high degree of directionality.

[10] J. Thomson in *The Chemistry of Quinoid Compounds, Part 1* (Ed.: S. Patai), Wiley, New York, **1974**, p. 112.

[11] The specimen was prepared by filtration of a suspension of **1** in *n*-pentane on a silver filter. The powder diffraction pattern was measured on an automated RIGAKU RU-200H rotating anode diffractometer equipped with a Ge(111) curved incident beam monochromator ($Cu_{K\alpha 1}$ radiation, $\lambda = 1.5405981$ Å, 50 kV, 120 mA, divergence slit 1°, receiving slit = 0.10 mm, 2θ range measured 5–45°, 2θ range used 8–37°, step scan 0.02°, counting time = 10 s, FWHM (full width at half-maximum) = 0.13 of 2θ).

[12] The following procedure was used in the structure determination of **1** from powder X-ray diffraction data: First, a molecule was selected as a model and positioned in the unit cell. This operation requires the determination of three rotation angles and one translation vector. This six-dimensional search can be split into two successive three-dimensional searches: a) the rotational search, determination of the orientation of the model molecule, and b) the translational search, determination of the correct shift to be applied to the properly oriented model molecule. Once the model molecule is correctly positioned, it is neccessary to refine the complete structure. For such a purpose the rigid-body Rietveld refinement was carried out in which the quantity minimized is $\sum w_i(y_i^o - y_i^c)^2$, where y_i^o is the measured intensity at point $2\vartheta_i$ of the powder diffraction pattern and $y_i^c = \sum_m I_c(m)P_i(m)$ is the sum of the contributions of all the m reflections close to $2\vartheta_i$. The constant K is a scaling factor, j_m is the multiplicity of the reflection m, and $P_i(m)$ is the contribution of $I_c(m)$ to the intensity at point $2\vartheta_i$. In order to reduce the effective number of variables per observation, due to the rather large number of atoms in organic compounds, strict constraints were introduced, see ref. [3].

[13] Crystal data of **1**: $C_{13}H_{17}N_2O_4$, $P2_1/a$, $a = 15.905(3)$, $b = 11.927(3)$, $c = 7.598(1)$ Å, $\beta = 111.83(1)°$, $V = 1338(3)$ Å^3, $\rho = 1.24$ g cm^{-1}, $Z = 4$, $\mu = 0.5$ cm^{-1}, $T = 20$ °C. The X-ray diffraction pattern was indexed with TREOR [14] using 18 reflections ($2\theta < 24°$). Figures of merit (see ref. [14]) for the best solution are $M(18) = 60$ and $F(18) = 143$ (0.0042, 30). The unit cell parameters and the zero position were refined with least-squares methods. The integrated intensities of 70 reflections were extracted by fitting asymmetrical Pearson–VII profile functions. The systematic absences are consistent with the space group $P2_1/a$. The crystal structure was determined by introducing the intensities of 50 reflections into ROTSEARCH [1,3]. The selected model molecule was derived from the previously reported molecular coordinates of radical **2** [7]. The best solution supplied by the program was refined with SHELX76 [15] to a R value of 0.34. The correct position of the missing hydroxyl group from the two possible positions could be established by performing the corresponding two refinements (obtained R values were 0.284 and 0.37). The atomic arrangement with the lower R value was assumed as the correct one. The subsequent full-pattern rigid-body least-squares refinement with RIBOLS [3] converged to $R_{wp} = 0.186$ and $R_p = 0.156$. The estimated standard deviations of the Euler angles describing the orientation of the molecules are 0.63, 0.74, and 0.56°. The estimated standard deviations of the positional parameters of the center of mass of the molecule are $\sigma(x) = 0.035$, $\sigma(y) = 0.019$, $\sigma(z) = 0.031$ Å. Further details of the crystal structure are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[17] For interacting open-shell molecules the charge transfer mechanism involving frontier orbitals predicts an AFM coupling if there is a direct contact between the semi-occupied molecular orbital (SOMO) of neighboring molecules. This occurs within each dimer of radical **1**. By contrast, if such contacts are not present and only SOMO/LUMO or/and SOMO/NHOMO overlaps occur, this mechanism predicts a FM interaction. The last situation seems to be the case for molecules in adjacent 2D layers.

Barbituric Acid/2,4,6-Triaminopyrimidine Aggregates in Water and Their Competitive Interaction with a Monolayer of Barbituric Acid Lipids at the Gas–Water Interface**

Thomas M. Bohanon, Steffen Denzinger, Ralf Fink, Wolfgang Paulus, Helmut Ringsdorf,* and Marcus Weck

The principle of exercising a specific function through molecular recognition, self-organization, and competitive interaction is perfectly realized in numerous supramolecular systems in nature. Examples include cell membranes, the immune cascade, and DNA–protein complexes. Based on the century-old lock and key principle of Emil Fischer,[1] numerous experiments have focused on the transfer of molecular recognition and self-organization to synthetic systems.[2–4]

Work on the construction of tape and membrane structures by molecular recognition of substances in organic solvents, for example, cyanuric acid and melamine derivatives, and barbiturates and triaminopyrimidines,[5–8] led to recent investigations of the insertion of 2,4,6-triaminopyrimidine (**2**) in a monolayer of barbituric acid lipids at the gas–water interface.[9] It was found that a tape structure induced by hydrogen bonding is formed which catalyzes a retro-Knoevenagel reaction at a pH of 5–6 as a consequence of organization through molecular recognition.

In this connection, we describe here the interaction between free barbituric acid (**1**) and 2,4,6-triaminopyrimidine (TAP, **2**) in water without preorientation of either compound, and the formation of aggregates (Fig. 1). We were particularly interested in investigating the competitive interaction between these barbituric acid/TAP aggregates dissolved in water and the ordered, stable monolayer of barbituric acid lipids at the gas–water interface.[9]

The interaction between **1** and **2** in water was characterized in situ by FT-IR spectroscopy. The formation of these highly ordered structures through hydrogen bond formation between the two components is evident in Figures 2a–c. For the 1:1 mixture (Fig. 2c) no characteristic bands of the two uncomplexed components can be seen. The asymmetric and symmetric stretching vibrations of the carbonyl group in **1** (Fig. 2b) are shifted to approximately 1670, 1600, and 1550 cm^{-1} by complexation with **2**. An excess of one component, for example, barbituric acid (**1**), does not interfere with complex formation. This excess can be detected above the 1.1:1 ratio by the typical bands for **1**. The spectrum of the 2:1 mixture of **1** and **2** can be understood unequivocally as the addition spectrum of the complex and free barbituric acid (Fig. 2d).[10]

The structure of the aggregates of **1** and **2** is not yet determined unequivocally; both an open tape structure and a cyclic structure are feasible. Elemental analysis of crystals isolated from aqueous mixtures of the two components indicates a 1:1 ratio of barbituric acid and TAP. Although this result provides no indication of the structure in solution, it is, nevertheless, clear evidence of the ability of this complementary system to form aggregates by hydrogen bonding, even in water, thereby supporting the results obtained from IR spectroscopy.

Competitive processes between systems of varying degrees of order play a decisive role in cell biology. Special examples are recognition- and orientation-induced processes on the membrane surface and, in particular, the immune cascade. Thus, it was of interest to investigate the competitive exchange of TAP **2** between the TAP/barbituric acid aggregates in water (Fig. 1) and a ordered monolayer of barbituric acid lipids at the gas–water interface. One possibility of measuring this exchange arises from the recognition-induced cleavage of barbituric acid lipids at monolayers by TAP, which was reported recently and which was followed by means of UV/Vis reflection spectroscopy.[9] After formation of the tape structure on a 10^{-4} M subphase (pH 6.5) (as shown in Fig. 3a), the C=C bond of the barbituric acid lipid **3**[11] was completely cleaved within 15 min, whereas it is stable on the TAP-free subphase. If the hydrolysis of barbituric acid lipids in monolayers is conducted on a sub-

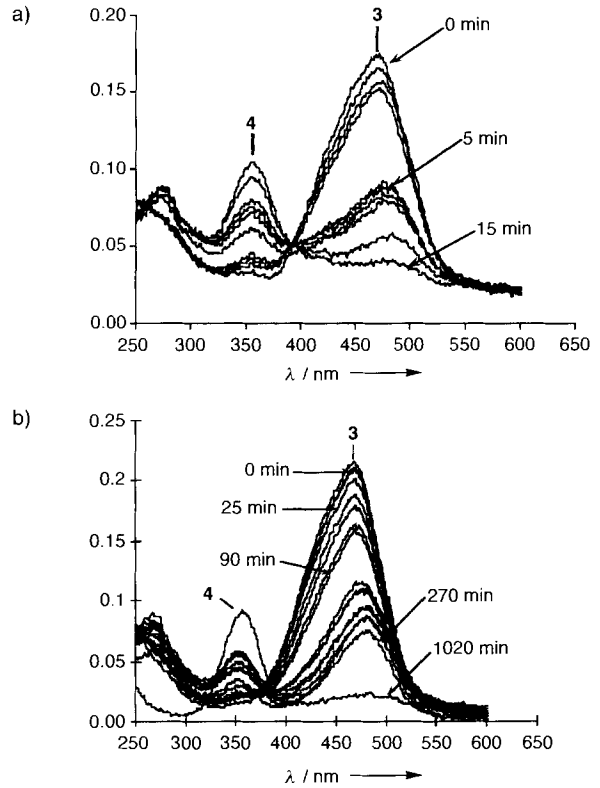

Fig. 3. UV/Vis reflection spectra of barbituric acid lipid **3** at the gas–water interface a) on a 10^{-4} M TAP subphase at pH 6.5; b) in a solution of the 1:1 barbituric acid/TAP aggregate (10^{-4} M, pH 6.5).

phase containing a 1:1 aggregate of barbituric acid and TAP (10^{-4} M, pH 6.5), then the cleavage requires 17 h (Fig. 3b).

This retarded hydrolysis of the barbituric acid lipid **3** indicates a significantly lower concentration of free TAP **2** as a result of its complexation with **1** in water. The course of this cleavage can thus be regarded as a competitive interaction between a fully complexed aggregate of **1** and **2** dissolved in water and a preoriented, highly ordered surface with structures that can recognize TAP **2** (Fig. 4). Thus, the equilibrium of complexed **2** is shifted slowly but completely to the side of the more highly ordered tape structure on the monolayer. Moreover, the barbituric acid (**1**) released by the hydrolysis hinders the insertion of TAP **2** into the monolayer. On the one hand, the acid **1** shifts the initial 1:1 ratio in its favor, but on the other it can enter the monolayer itself and must be displaced there by **2**.[12] This explains the much slower cleavage of the C=C bond towards the end of the reaction.

These IR and UV/Vis spectroscopic investigations show that the system **1**/**2** in water self-organizes to form a supramolecular aggregate stabilized by hydrogen bonding. The structure of this aggregate – whether tape or cyclic, which could be stabilized by H bonds and/or ionic bonds[13] – is not yet clarified. If an aqueous solution of this aggregate is applied to a preoriented, highly ordered surface of barbituric acid lipids, then **2** can be released from the aggregate and bind to the surface. Thus, as already described,[9] a recognition-induced retro-Knoevenagel reaction can take place. The investigation of this type of competitive molecular recognition process and subsequent reactions in water is of great importance, in particular for comparison with biological systems. It cannot be excluded that the interaction of barbituric acid derivatives with hydrogen bond acceptors and/or donors on the cell membrane may also play an important role in the effect of barbiturates as sedatives.

Experimental Procedure

The synthesis and characterization of barbituric acid lipids **3** has already been reported in refs. [9, 12]. All FT-IR spectra were recorded with a Nicolet-5DXC spectrometer equipped with an Ever-Glo light source and a nitrogen-cooled HgCdTe narrow-band detector. The samples were measured with the aid of the attenuated total reflection in a microcircle cell (Spectra-tech; ZnSe crystal) in water ($\varphi \geq 18$ MΩcm) at 20 °C with 5000 scans at 8 cm^{-1} resolution and a Happ-Genzel apodization. The water spectrum served as reference and was subtracted from the spectra of the samples. The concentration of the stock solutions was 10^{-2} M; the mixtures were allowed to stand for about 5 min after preparation before the spectra were recorded.

UV/Vis reflectance measurements on the monolayer were recorded with a spectrometer with a Universal lamp system from Spectroscopy Instruments and an ST-121 diode-array detector from Princeton Instruments. A film balance with a Wilhelmy system was employed.

Elemental analysis of the 1:1 barbituric acid/TAP crystals (dried in vacuum at 100 °C) gave ($C_8H_{11}N_3O_3$): calc.: C 37.95, H 4.38, N 38.72; found: C 37.90, H 4.35, N 38.75.

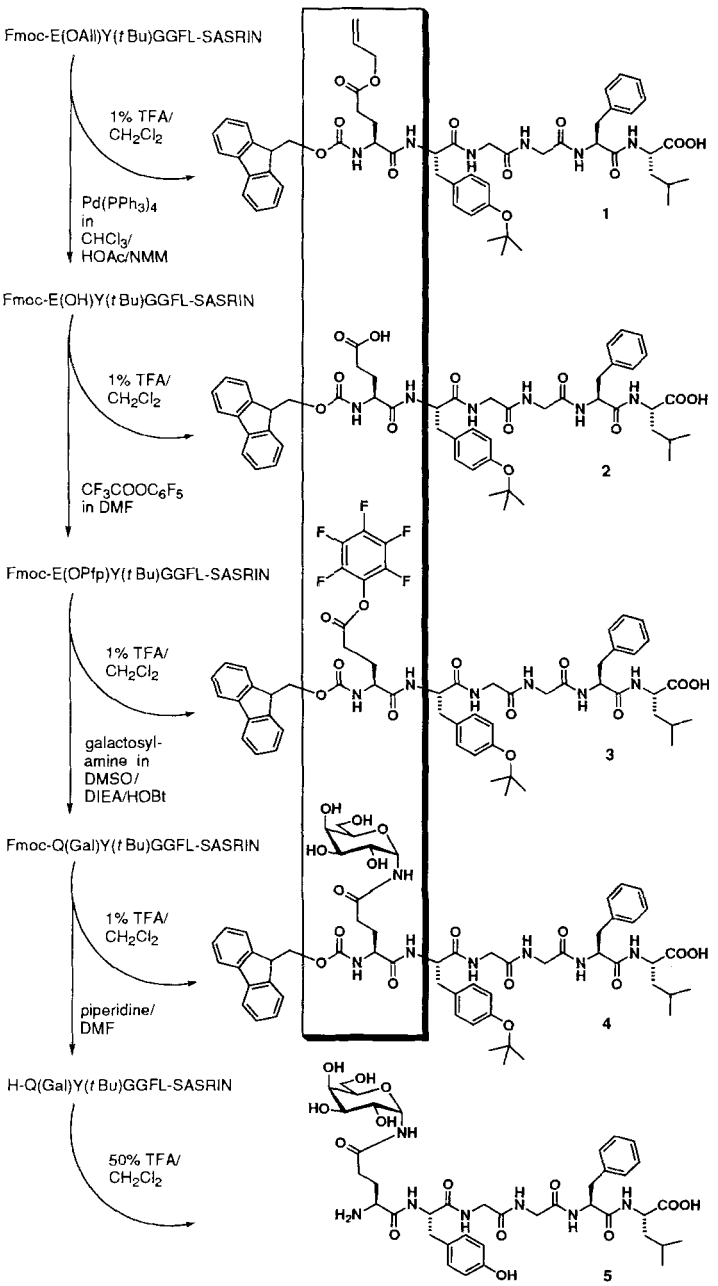
[10] In analogous investigations of the interaction of barbituric acid with other compounds capable of forming hydrogen bonds, for example urea and 2-aminopyrimidine, 1:1 aggregates were not found. In these cases all the bands of free barbituric acid appeared in addition to weak bands resulting from complex formation.
[11] The isotherm of lipid **3** shows that it has a collapse area of ca. 38 Å^2 per molecule. Above 23 °C the lipid forms a liquid–solid coexistence region; below 23 °C only a gas phase and a solid-analogous phase are observed. The UV/Vis spectra were measured on the monolayer at a subphase temperature of 25 °C and a surface pressure of ca. 5 mN m^{-1}.
[12] Detailed investigations of the cleavage by a retro-Knoevenagel reaction on the lipid monolayer and their influence on the aqueous phase through aggregates will be reported separately (*J. Am. Chem. Soc.*, submitted).
[13] Note added in proof (December 1, 1994): An X-ray structure determination carried out in the meantime by Dr. Dieter Schollmeyer, Institut für Organische Chemie der Universität Mainz, shows that by the incorporation of water molecules the individual components of the system **1**/**2** in the structure are linked to give a network by ionic and hydrogen bonds.

A Versatile Solid-Phase Synthesis of N-Linked Glycopeptides



Dirk Vetter,* David Tumelty, Sunil K. Singh, and Mark A. Gallop*

The discovery of novel glycopeptide ligands for relevant biological receptors has been greatly hindered by the difficult syntheses of these complex compounds.[1, 2] A convergent approach to glycopeptide assembly would improve their accessibility, but few studies have addressed this problem. Successful O-glycosylation was reported for the reaction of peracetylated glucose-oxazoline with resin-bound serine-containing peptides.[3] Somewhat surprisingly, complete N-glycosylation has been accomplished only in solution.[4, 5] A recent example was the synthesis of natural glycoprotein fragments by coupling *N*-acetylglucosaminylamine and related oligosaccharidylamines to aspartic acid containing peptides.[6, 7]

In this report we demonstrate a novel method for the solid-phase synthesis of N-linked glycopeptides. Work is currently in progress to apply the outlined approach to the generation of glycopeptide libraries by combinatorial methods.[8]

The key step in our strategy is the coupling of an unprotected glycosylamine to a pentafluorophenyl carboxylate (OPfp) on the side chain of resin-bound peptide. A great variety of glycosylamines are commercially available or accessible from the parent saccharides via a simple one-step derivatization using aqueous ammonia solutions.[9] The resulting 1-amino, 1-deoxysugars are β anomers, except when the neighboring 2-hydroxyl group is axial, as for mannose and lyxose, where the α anomer predominates.[10] The activated fluorenylmethyloxycarbonyl(Fmoc)- and *tert*-butyl(*t*Bu)-protected peptides were prepared by incorporation of aspartic or glutamic acid protected as allyl (OAll) esters at their β- or γ-carboxyl groups, followed by complete deallylation and Pfp ester formation.[11] Protecting group removal and cleavage from the resin afforded the free glycopeptides.

The procedure was optimized on the example Gln(Gal)-Tyr-Gly-Gly-Phe-Leu-OH (**5**).[12] The use of polystyrene resin modified with a highly acid-labile linker (super acid sensitive resin, SASRIN) allowed for the cleavage and characterization of the relevant peptide at each step of the reaction sequence.[13] The reactions are displayed in Scheme 1, and corresponding HPLC traces of the crude cleavage products are shown in Figure 1.

Scheme 1. Example of the generation of N-linked glycopeptides on a solid phase. The reaction sequence deallylation/ester activation/glycosylamine condensation (framed area) was performed on the resin-bound peptide after full assembly. Each step, including Pfp ester formation, was followed by cleavage and characterization of the resulting peptide (**1**–**5**; see Fig. 1).

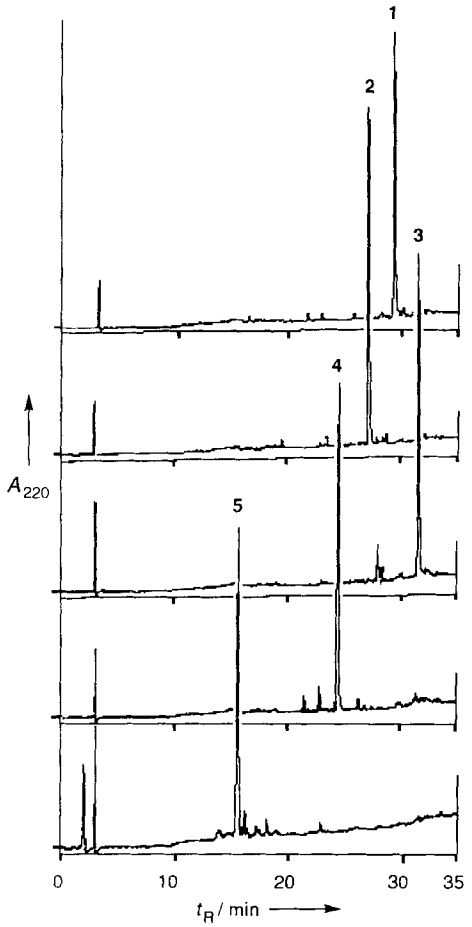

Fig. 1. HPLC traces of the crude products cleaved from the solid phase. The convergent solid-phase synthesis of a glycopeptide can thus be followed stepwise.

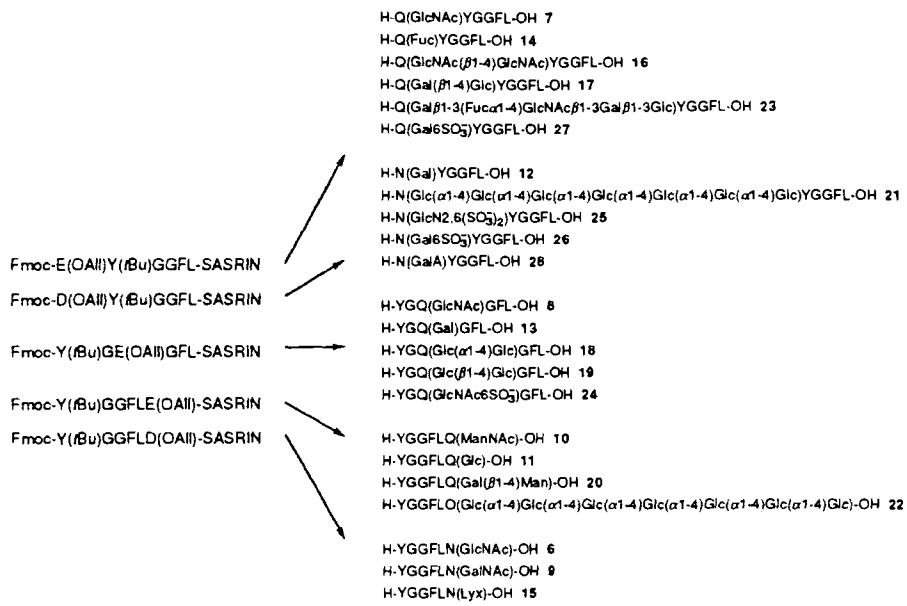

Synthesis commenced with the assembly of the fully protected peptide on the solid phase. Palladium(0)-catalyzed removal of the allyl protecting group without cleavage of the N-terminal Fmoc group was effected with a mixture of chloroform, *N*-methylmorpholine, and acetic acid.[14] Standard deprotection conditions using morpholine as the allyl scavenger consistently caused Fmoc removal.[15]

N-hydroxysuccinimidyl (Su) and pentafluorophenyl esters were each considered for solid-phase activation of the side-chain carboxyl groups of aspartic and glutamic acid; both allow for efficient amidation of the glycosylamines without concomittant esterification of the sugar hydroxyl groups. In practice, formation of the active ester was best accomplished by employing pentafluorophenyl trifluoroacetate in dimethylformamide (DMF)/pyridine. Alternatives such as carbodiimide-mediated esterification with pentafluorophenol as well as activation with bis(*N*-hydroxysuccinimidyl) carbonate were found to be inferior.[16]

Attempts to condense galactosylamine with Fmoc-E(OSu)Y(*t*Bu)GGFL-SASRIN were unsuccessful owing to loss of the Fmoc group and poor reactivity of the succinimidyl ester. Lowering the excess of glycosylamine, shortening reaction times, and using the Pfp active ester resulted in cleaner reactions with only one side product, shown to be the glutamine-containing peptide. This side product is thought to be formed by reaction of the active ester with free ammonia, which could originate from residual traces of ammonium carbonate in the sugar or through hydrolysis of the glycosylamine. A variety of approaches were examined to avoid carboxamide formation. It was found that addition of *N*,*N*-diisopropylethylamine (DIEA) and 1-hydroxybenzotriazole (HOBt) effectively suppressed formation of the side product. Undesired peptide amidation has also been observed by Lansbury et al. in the related *N*-glycopeptide synthetic strategy, where exhaustive lyophilization of the 1-amino sugars was used to remove residual ammonia.[7]

Five support-bound peptides with Glu(OAll) or Asp(OAll) and permutations of the motif Tyr(*t*Bu)-Gly-Gly-Phe-Leu were then synthesized and subsequently condensed with 18 different mono- and oligosaccharidylamines (see Scheme 2). Included in the list of the 23 glycopeptides are to our knowledge the first examples of synthetic peptides bearing carboxylated, mono- and disulfated carbohydrates. The products were purified by HPLC and characterized by FAB-MS and ^{1}H NMR spectroscopy.

The outlined convergent synthesis of glycopeptides proved advantageous in many respects. Protection of saccharide components was obviated because glycosylation was the last bond-forming step in the synthesis. In all cases the stereochemistry of the anomeric center of the parent glycosylamine was retained in the glycopeptide. Yields were quantitative for the glycopeptides prepared from the simple monosaccharides GlcNAc, GalNAc, ManNAc, Glc, Gal, Fuc, and Lyx (→ **6**–**14**) as well as from the disaccharides chitobiose, lactose, maltose, and cellobiose (→ **16**–**19**). A somewhat lower yield was obtained with Gal(β1-4)Man (→ **20**). Conversions of 50 to 80% were obtained for reactions with uncharged oligosaccharides as complex as the penta- and heptasaccharides lacto-*N*-fucopentaose II and maltoheptaose, respectively (→ **21**–**23**). Except for the reaction

Scheme. 2. 23 Glycopeptides obtained by condensing 18 different glycosylamines with five hexapeptides, which contain the motif Tyr-Gly-Gly-Phe-Leu (YGGFL) and the amino acids Glu or Asp in different positions.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0061 $ 10.00+.25/0

with GlcNAc6SO_3^- (→ **24**, quantitative), generally lower yields of 30 to 50% were encountered with the glycosylamines of charged sugars such as GlcN2,6(SO_3^-)$_2$ (→ **25**), Gal6SO_3^- (→ **26**, **27**), and galacturonic acid (→ **28**). Furthermore, yields were independent of whether the peptides were glycosylated at the N- or C-terminal positions or at the central, glycine-flanked position. Conversions were almost identical for aspartic and for glutamic acid containing peptides.

The intramolecular cyclization of activated aspartic acid containing peptides to yield succinimide or isoaspartic acid products is a well-known side reaction, particularly when the active ester is N-terminal to a small residue like glycine or alanine.[17] The optimal stoichiometry of glycosylamine, DIEA, and HOBt employed in our experimental protocol effectively suppressed aspartimide formation from Asp(OPfp) peptide intermediates.[18] A similar optimization strategy has been described in detail by Lansbury et al.[7]

Common conditions for acidic deprotection of peptide side chains were not employed in this study. Our milder protocol was sufficient to effect removal of standard peptide side chain protecting groups, and O-glycosidic bonds were left intact with one exception: in the synthesis of the representative fucose-containing glycopeptide **23**, 50% of the product was defucosylated.

The orthogonal deprotection and solid-phase activation methodology described here is fully compatible with standard Fmoc/*t*Bu protection schemes and is expected to allow for the introduction of one or more saccharide moieties at a defined position of a peptide or peptide pool. If the sugar is condensed with glutamic rather than aspartic acid, the approach is general and will form the basis for the construction of glycopeptide libraries for massive parallel screening.

Experimental Procedure

General procedures: Fmoc-Glu(OAll)-OH and Fmoc-Asp(OAll)-OH were obtained from Propeptide. Automated peptide synthesis was performed on an ABI 431A using FastMoc cycles on super acid sensitive resin (SASRIN, 0.96 mmol g^{-1}, or Fmoc-Leu-SASRIN, 0.6 mmol g^{-1}, Bachem). Cleavage of resin aliquots was performed in 1% TFA/CH_2Cl_2 as recommended. Analytical HPLC was carried out with a C18 reversed-phase column and a linear gradient of 5–95% acetonitrile in water/TFA at 1 mL min^{-1}. Preparative HPLC was performed with a C18 reversed-phase column and a linear gradient of 0–50% acetonitrile in water/TFA.

2: Deallylation of Fmoc-E[OAll]Y[*t*Bu]GGFL-SASRIN (**1**) was achieved by mixing 5 mL of $CHCl_3$, 0.66 mL of HOAc, and 0.32 mL of *N*-methylmorpholine under nitrogen atmosphere with [Pd(PPh_3)$_4$] (0.4 g, 0.32 mmol), **1** (0.2 g, 0.12 mmol; 0.6 mmol g^{-1}), and PPh_3 (0.4 g, 1.53 mmol). The mixture was stirred vigorously for 2 h at room temperature. The resin was recovered by filtration and washed with $CHCl_3$, DMF, and MeOH. The product consisted of >95% Fmoc-E(OH)Y(*t*Bu)GGFL-OH (**2**) by HPLC (t_R = 27.36 min).

3: To a solution of **2** (20 mg, 12 μmol) in 0.1 mL of anhydrous DMF were added 20 μL of pyridine and pentafluorophenyl trifluoroacetate (40 μL, 0.23 mmol; Aldrich). The mixture was agitated for 2 h at room temperature. The resin was recovered by filtration and washed with DMF and CH_2Cl_2. The product consisted of >95% Fmoc-E(OPfp)Y(*t*Bu)GGFL-OH (**3**) by HPLC (t_R = 31.53 min); FAB-MS: 1129.3 [(M + H^+)].

4: A solution of **3** (20 mg, 12 μmol) in 0.66 mL of anhydrous DMSO was mixed with galactosylamine (8 mg, 45 μmol; Sigma), 4 μL of DIEA, and HOBt (8 mg, 59 μmol; Advanced Chemtech). The mixture was stirred vigorously for 15 min at room temperature. The resin was recovered by filtration and washed with DMSO and CH_2Cl_2. The product consisted of 95% Fmoc-Q(Galβ)Y(*t*Bu)GGFL-OH by HPLC (t_R = 24.36 min); FAB-MS: 1168.5 [(M + Na^+)].

5: A solution of **4** (20 mg, 12 μmol) in 0.4 mL of 20% piperidine/DMF was agitated for 15 min at room temperature. After filtration the procedure was repeated, and the recovered resin was washed with DMF and CH_2Cl_2. The resin was then stirred vigorously with 1 mL of 50% TFA/CH_2Cl_2 for 15 min at room temperature. After filtration the procedure was repeated, and the resin was washed extensively with CH_2Cl_2. The combined filtrates were concentrated in vacuo, and the product was precipitated with ethyl ether and isolated by centrifugation. After dissolution in acetonitrile/water and lyophilization, the crude material was obtained as a white fluffy solid (6.4 mg, 8 μmol, 66% yield). The product consisted of 95% H-Q(Galβ)YGGFL-OH by HPLC (t_R = 15.52 min). Purification was achieved by preparative HPLC. The sample was collected and lyophilized to give **5** (5.6 mg, 7.0 μmol, 58% yield). FAB-MS (calculated/found): 845/868.7 [(M + Na^+)]; FAB-MS (high resolution, calculated/found): 868.3705/868.3708. The β configuration of the Gal-Gln linkage was confirmed by ^{1}H NMR spectroscopy (400 MHz, [D_6]DMSO, 25 °C, TMS): δ = 4.682 (d, J = 9.0 Hz, Gal-H1).

Diagnostic analytical data for representative glycopeptides:

12: H-N(Galβ)YGGFL-OH, FAB-MS (calculated/found): 831/854.7 [(M + Na^+)]; FAB-MS (high resolution, calculated/found): 854.3548/854.3548; ^{1}H NMR (400 MHz, [D_6]DMSO, 25 °C, TMS): δ = 0.836 (d, J = 6.40 Hz, 3H; Leu-Me), 0.892 (d, J = 6.48, 3H; Leu-Me), 1.530 (m, 2H; Leu-βHs), 1.608 (m, 1H; Leu-γH), 4.031 (m, 1H; Asn-αH), 4.689 (t, J = 8.84 Hz, 1H; Gal-H1), 6.641 (d, J = 8.52 Hz, 2H; Tyr-H3,H5), 7.045 (d, J = 8.52 Hz, 2H; Tyr-H2,H6), 7.243 (d, J = 4.68 Hz, 5H; Phe), 7.944 (t, J = 5.52 Hz, 1H; Gly-NH), 8.346 (t, J = 5.83 Hz, 1H; Gly-NH), 8.810 (d, J = 8.76 Hz, 1H; Asn-βNH), 9.205 (s, 1H; Tyr-OH).

To address the question of succinimide formation and subsequent transpeptidation during activation and condensation of the peptide side chain, compound **12** was investigated by NOE spectroscopy. The isomeric reference glycopeptides H-N(Galβ)YGGFL-OH and H-D(YGGFL-OH)-NH-Galβ were synthesized from the glycosylated amino acids Fmoc-N(Galβ)-OH and Fmoc-D(OH)-NH-Galβ, respectively, with suppression of succinimide formation. Irradiation of the amide proton of the sugar–peptide linkage resulted in a substantial NOE to the α proton of isoasparagine in the isomeric compound. This NOE was completely absent in both the asparagine-containing analogue and glycopeptide **12**. This was taken as evidence that no transpeptidation had occurred during the convergent synthesis of **12**. Details on the NOE study will be published elsewhere.

[18] However, assembly of the peptide sequence Fmoc-Y(*t*Bu)GD(OAll)GFL-SASRIN was terminated reproducibly before coupling of the final tyrosine residue. A truncated major side product (70% by HPLC, $m/z = 489$) presumably resulted from lactamization of H-GD(OAll)GFL-SASRIN.

A New Zincosilicate Zeolite with Nine-Ring Channels**

Carsten Röhrig and Hermann Gies*

In recent years zeolites have increasingly found applications as catalysts, molecular sieves, adsorbents, and ion exchangers.[1] The useful properties of these inorganic host–guest systems are based primarily on the structure of the tetrahedral framework of the host of general composition TO_2 and the possible variation of T atoms (T = Si, Al, P, B, Ga, As, Sb, Zn etc.). The guest species fill the pore space of the tetrahedral framework, and for charged frameworks these are the organic or inorganic cations necessary to achieve electroneutrality.

One aim of the synthetic work on zeolites is the search for host structures with low tetrahedral density, that is for frameworks with as few tetrahedral building units [TO_4] per 1000 Å^3 as possible. Furthermore, the materials should contain both catalytically active centers and also pore systems of well-defined geometry. In this context, the topological analysis of known zeolite structures by Brunner and Meier has shown that there is a linear correlation between the smallest ring size occurring in a zeolite structure and the tetrahedral density.[2]

Among zeolite minerals the beryllosilicate lovdarite is of particular interest because its structure contains the spiro-5 building unit, which is built from three-rings, which occur only very rarely in tetrahedral frameworks.[3] Because of the high toxicity of beryllium and the similarity of beryllosilicates and zincosilicates,[4–6] we investigated the possibility of preparing structurally related zincosilicates with low tetrahedral density; in addition, the heteroatom zinc plays an interesting role in the catalytic aromatization of olefins.

For the synthesis, one mol of $Si(OCH_3)_4$ was hydrolyzed in an aqueous solution of 44 mol H_2O, 0.08 mol tetraethylammonium hydroxide (TEAOH), 0.0–0.88 mol NaOH, 0.0–0.88 mol KOH, and 0.0–0.1 mol ZnO (partly undissolved) and placed in a teflon-lined autoclave which was kept at 160–220 °C for 12–14 days.

Depending on the reaction temperature, the concentration ratio of the alkali metal cations, and the amount of ZnO, several different zeolite-like zincosilicate phases of high crystallinity were obtained. These included the already known VPI-7[4–7] and a new phase with the laboratory code RUB-17, which both showed tetragonal-prismatic morphologies. The crystals usually were intergrown to conglomerates so that the analysis and the refinement of the structurs had to be performed on the basis of X-ray powder diffraction data.

In addition to VPI-7 and RUB-17, phases that can be identified unambigiously, a number of other zeolite-like zincosilicates formed whose X-ray powder diffractograms and ^{29}Si NMR spectra show strong similarities, but also distinct differences to those of VPI-7 and RUB-17.

The structure refinement of VPI-7[7] yielded the orthorhombic space group *Fdd*2 with lattice constants $a = 39.88(1)$, $b = 10.326(1)$, and $c = 10.219(1)$ Å, and an idealized composition $Na_{32}(Si_{56}Zn_{16}O_{144})\cdot 42\,H_2O$.

To determine the hitherto unknown structure of RUB-17, a high-resolution powder X-ray diffractogram was indexed. The space groups *C*2, *Cm*, and *C*2/*m* are in agreement with the observed, monoclinic lattice parameters ($a = 7.238(1)$, $b = 40.56(1)$, $c = 7.308(1)$ Å and $\beta = 91.8(1)°$), and the rules for systematic absences. The lattice geometry of RUB-17 is very similar to that of VPI-7, since the diagonals of an orthogonal 7×7 Å^2 plane correspond to the edges of a 10×10 Å^2 plane, that is $a_{RUB-17}\cdot\sqrt{2} \approx c_{RUB-17}\cdot\sqrt{2} \approx b_{VPI-7} \approx c_{VPI-7}$; also, $b_{RUB-17} \approx a_{VPI-7}$ and $\beta_{RUB-17} \approx 90°$. Furthermore, the comparison of the ^{29}Si NMR spectra of VPI-7 and of RUB-17 shows that RUB-17 also contains a signal for a framework silicon atom shifted to unusually low field which can only be ascribed to a Si atom in the spiro center (Fig. 1). We can thus start with the assumption that the structures of RUB-17 and VPI-7 contain similar building units. By structural modeling using the building units of VPI-7, a model for the framework structure of RUB-17 was established. A crystal-chemically acceptable distribution of the tetrahedrally coordinated Si and Zn atoms that are in addition in agreement with the chemical analysis and the NMR measurements was possible only in space group *Cm*.

An optimized DLS model[8] of a hypothetical [SiO_2] framework was used as starting model for the structure refinement with the Rietveld method. The positions of the Zn atoms in the tetrahedral framework were found from difference Fourier syntheses using the Rietveld program XRS-82.[9] This led to the

calculation of an improved DLS model of the $[(Zn,Si)O_2]$ framework which took into account the Zn–O bond lengths (1.95 Å). Further refinement (Fig. 2) yielded the positions of the non-framework constituents (Na, K, H_2O) and gave the composition of the unit cell as $K_4Na_{12}[Si_{28}Zn_8O_{72}]\cdot 18H_2O$.[10]

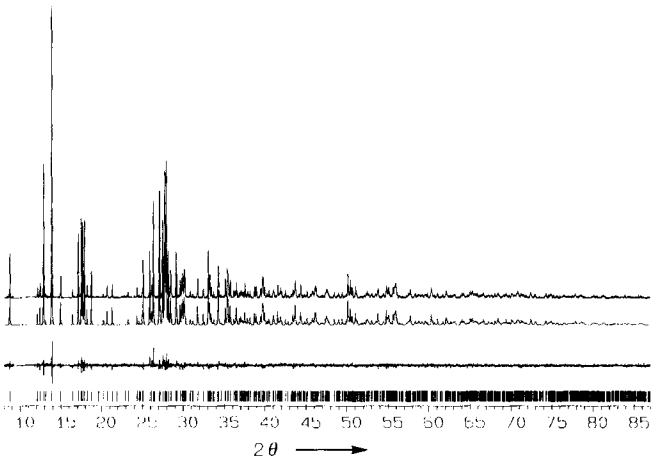

Fig. 2. Observed (top), calculated (center), and difference (bottom) curves of the X-ray diffractogram of RUB-17. Vertical bars indicate the 2θ positions of symmetry-allowed reflections.

The framework structure of RUB-17 is a member of the group of three-dimensional four-connected nets. Neglecting all O atoms, the structure can be constructed from two-dimensional 4.8^2 nets (Fig. 3). Two of these 4.8^2 nets are connected to each other by additional Si atoms and form layer-like building units (LLBUs; Fig. 4). The *spiro*-5 units **1** originate through this form of linkage. The overall structure results from the stacking of the LLBUs. For VPI-7, the LLBUs are linked to each other only by five-rings (Fig. 5 left); in RUB-17, the connection occurs alternately through four-/six-rings and five-rings (Fig. 5 right). The nonframework components Na, K, and H_2O likewise form a three-dimensional network, which is connected to the $[(Zn,Si)O_2]$ tetrahedral framework through Na–O, K–O, and H_2O–O bonds.

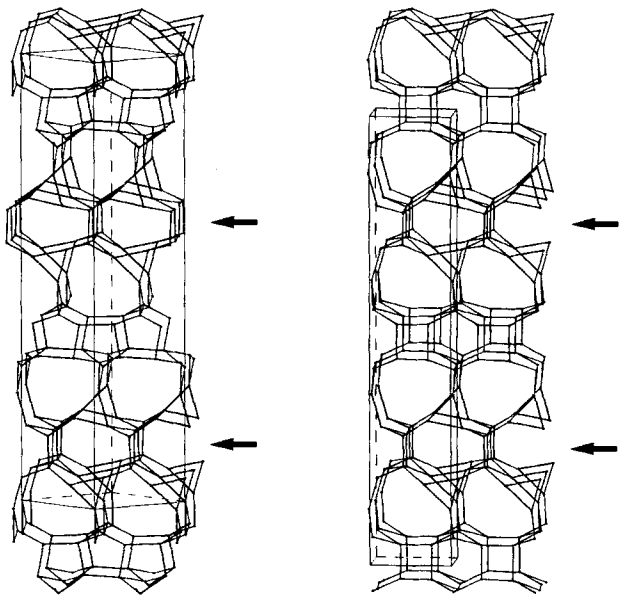

Fig. 5. Tetrahedral framework structure of the unit cell of VPI-7 (left) and RUB-17 (right). The arrows mark five-rings perpendicular to the drawing plane.

The network of alkali metal cations and water molecules plays a decisive role in the stabilization of RUB-17 and VPI-7, since thermal treatment even at relatively low temperatures leads to the breakdown of these structures. Long-term thermal treatment (24 h) at constant temperatures showed that RUB-17 is stable up to about 220 °C, whereas the structure of VPI-7 becomes amorphous already at about 130 °C. It can thus be assumed that the stacking mode of the LLBUs influences the thermal stability of these structures, that is the stacking through four-/six-rings and five-rings (RUB-17) is more stable than the stacking using exclusively five-rings (VPI-7). Accordingly, a structure such as lovdarite in which the LLBUs are connected only through four-/six-rings should be even more thermally stable than RUB-17. The synthesis of a zincosilicate with that structure would probably result in a useful material for commercial catalytic applications.

According to ^{29}Si NMR spectra, it can be assumed that the not yet identified zincosilicates are further members of this polytype series, in which the stacking sequence has not yet been determined.

Experimental Procedure

The chemical analysis of the Si:Zn:Na:K ratio using an ICP spectrometer (Philips PU 7000) gave a composition of 3.5:1:1.3:0.6. The H_2O content was determined by Karl-Fischer titration and TG analyses (Linseis) to be about 10.6 wt%. The morphology of the synthesis products was investigated by scanning electron microscopy

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0064 $ 10.00+.25/0

(Cambridge Stereoscan 250 M3). The density of the synthesized material (ρ = 2.47 g cm^{-3}) was determined with the suspension method using butyl acetate and bromoform as suspension liquids. NMR experiments were carried out on a Bruker ASX 400 spectrometer at 79.495 MHz for Si.

Molecular Recognition of Anions by Zwitterionic Host Molecules in Water**

Karin Worm and Franz P. Schmidtchen*

Cationic artificial molecular hosts are of proven utility in molecular recognition of anions.[1] However, they must inevitably be accompanied by counterions creating competition which disfavors complexation of the desired anionic guest. Electroneutral hosts would avoid this and successful examples employing polytopic Lewis acids[2] or ion–dipole interactions[3, 4] are known. In general these host–guest interactions are quite weak and cannot overcome the competition from protic solvents.

In these protic solvents the natural hosts for anions (e.g. the majority of enzymes) bind the negatively charged guests by direct contact to positively charged anchor groups. An approximately equivalent number of anionic functions are placed somewhat remote from this binding site, yielding a structural pattern with a small overall charge. This zwitterionic character of biogenic hosts combined with a well-defined network of hydrogen bonds results in the specific and enthalpically strong binding of the anionic guest ion.[5, 6]

In order to mimic this natural binding principle we designed the artificial hosts **1** and **2**. By virtue of the electrostatic repulsion of the inner cationic centers these molecules are inclined to adopt inflated conformations with cavities which may encapsulate the guest anion. Rigid substituents extend radially to the exterior carrying a negative charge at their distal ends. Internal collapse by ion pairing is avoided owing to the high connectivity of the molecular skeleton. Preliminary molecular modeling studies[7] in vacuum, however, showed that these hosts acquire an almost spherical shape due to the carboxylates approaching the neighboring quaternary ammonium centers. The arene rings then cover the tetrahedral faces. In molecular dynamics simulations a bromide ion on the outside thus has no chance to make its way into the cavity even when pushed by high kinetic energy (1000 K). Nevertheless molecular mechanics calculations find the inclusion complex more stable by about 23 kcal mol^{-1} than the next best host–guest complex with the guest anion associated from the outside. The results of our calculations support the basic concept underlying the host design, because solvation of the ionic groups most likely will disrupt their mutual interaction and will restore the accessibility of the molecular cage.

1, X = $(CH_2)_6$
2, X = $(CH_2)_8$

3

Starting from the macrotricyclic tertiary amines[8] the target compounds **1** and **2** were obtained by Menshutkin alkylation using α-bromotoluic ester, followed by hydrolysis and desalting by reverse-phase chromatography, in greater than 85% yield. The zwitterionic betaines are only sparingly soluble in water at ambient temperature, but dissolve much better on addition of salt. This correlates with a progressive shift of the ^{1}H NMR signals of the endo- and exocyclic N-CH_2 groups to lower and higher fields, respectively. The picture is compatible with the hosts taking part in chemical exchange processes which are rapid with respect to the NMR time scale. Titrations were performed at 54 °C in homogeneous solution, and the results could be easily fitted to a 1:1 host–guest binding model.[9] The derived association constants K_{ass} and maximum chemical shift differences $\Delta\delta_{max}$ are given in Table 1.[10] With Na_2HPO_4, Na_2S, γ-aminobutyric acid, and trimethylazoniaacetate (betaine) no shifting of NMR signals was observed, which makes inclusion complexation of these substrates highly unlikely. K_{ass} decreases with increasing ionic strength (i.e. 0.2 M NaF) suggesting that electrostatic interactions dominate complexation. The maximum shift difference $\Delta\delta_{max}$ roughly correlates with the size of the anion. Considering that the 1:1 stoichiometry appears to remain fixed even if a high excess of guest is applied, one is forced to assume the penetration of the guest into the molecular cavity

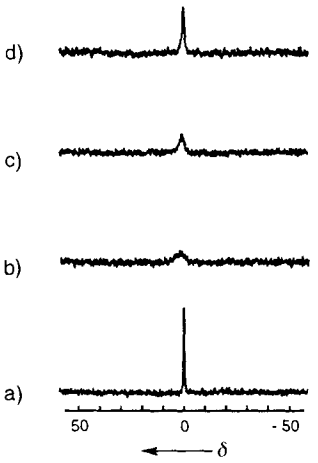
Table 1. Association constants K_{ass} of various anions with host **1** in D_2O at 327 K.

Anion	Ion radius [pm] [16]	ΔG^0_{hyd} [kcal mol^{-1}] [16]	K_{ass} [M^{-1}]	$\Delta\delta_{max}$ [Hz] [a]
Cl^-	181	−81.2	270	6.3
Br^-	196	−75.2	2150	27.0
I^-	220	−65.7	6480	54.5
I^- [b]	220		1650	55.3
CN^-	191	−70.5	950	6.9

[a] 360 MHz ^{1}H NMR determination. [b] In the presence of 0.2 M NaF.

of the tetrahedral host and consequently the formation of a well-structured complex. Another argument in favor of this view may be drawn from a competition experiment taking chloride as a probe monitoring the ^{35}Cl NMR resonance (Fig. 1). In water the quadrupolar species $^{35}Cl^-$ yields a sharp singlet, due to the rapid interchange of water and the resulting time-averaged high symmetry of the hydration sphere of the Cl^- ion. On addition of host **1** increasing amounts of complex are obtained which has a distinctly lower symmetry. As a corollary the quadrupole relaxation is augmented and leads to severe line broadening or even complete disappearance of the signal.[12] If now iodide, which forms a more stable complex with **1**, is added in portions to this mixture one observes progressive sharpening of the ^{35}Cl peak. Evidently, iodide displaces chloride from the complex. Considering the relationship between the size of host and guests the only plausible location for this process to happen is the central cavity of the host.



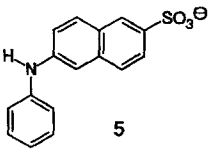


Fig. 1. ^{35}Cl NMR spectra of NaCl in D_2O at 298 K; a) 2.2×10^{-3} M NaCl; b) addition of 1.8×10^{-3} M **1**; c) addition of 5×10^{-4} M NaI to solution b); d) addition of 4×10^{-3} M NaI to solution b).

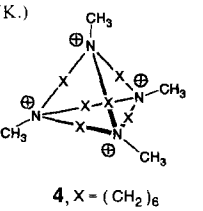
In the complexation of bromide and iodide by host **1** the ^{1}H NMR peak shift sufficed to determine the enthalpy and entropy of association from the dependence of K_{ass} on temperature (Table 2). For both anions host–guest binding is driven by enthalpy, with iodide exhibiting the distinctly better interaction. In addition negative entropies of association are found which apparently are modulated by enthalpy–entropy compensatory effects.[13] These results may be rationalized qualitatively, if one assumes that the guests have to strip off their solvation shells in the course of complexation. In relation to iodide, bromide requires the higher enthalpic expenditure for this desolvation and consequently shows a smaller overall gain in enthalpy. On the other hand, the release of tightly bound water molecules enhances entropy and thereby counteracts the inherently negative entropy of association. Although this reasoning undoubtedly covers only part of the total interaction, it provides another (though indirect) argument in favor of guest encapsulation, since only this process can serve to explain the loss of the hydration shell. One can extrapolate from the thermodynamic data that host **1** discriminates between the heavy halide ions at 0 °C by a factor of 40, whereas at 85 °C no selectivity is to be seen.

Table 2. Thermodynamic parameters of host-guest binding of bromide and iodide by host **1**.

Anion	ΔG^0 [kcal mol^{-1}]				ΔH°	ΔS°
	312 K	327 K	337 K	347 K	[kcal mol^{-1}]	[cal mol^{-1} K^{-1}]
Br^-	−5.08	−4.98	−4.91	−4.84	−7.6	−8.0
I^-	−6.17	−5.70	−5.38	−5.07	−16.7	−33.9

The bigger tetrahedral host **2**, on titration even with the biggest halide iodide, displays only rather meager shifts of the ^{1}H NMR signals, which did not allow the extraction of meaningful association constants. However, the host–guest complexation could be determined from the fluorescence intensity enhancement of the fluorophoric probe TNS **5** following the Benesi–Hildebrandt protocol.[14] Complex stability ($K_{ass} = 1.46\times10^3$ M^{-1}), which may be attributable to hydrophobic interactions, is similar to that of the complex of **5** with β-cyclodextrin ($K_{ass} = 1.5\times10^3$ M^{-1}),[15] but much weaker than with certain cyclophanes.[14]



5

The hosts **1** and **2** show that binding of heavily solvated anions is possible, indeed, using abiotic receptors of zero net charge to form well-defined host–guest complexes with respectable affinity. The structurally fixed spatial separation of positively and negatively charged substructures appears to be a mandatory requirement, which in much the same fashion is also realized in the natural receptors.

Thermal Isomerization of Indigo

Günter Haucke* and Gerhard Graness

Indigo does not undergo thermal or photochemical *trans-cis* isomerization in contrast, for example, to thioindigo.[1] Dry distillation of indigo produces aniline,[2] and irradiation in the presence of dissolved oxygen, isatin.[3] However, if indigo (**1**) is heated to 450 °C in vacuum in the vapor phase it isomerizes to dibenzonaphthyridindione (**2**) in a suprisingly smooth reaction.

1 **2**

The UV/Vis spectra of this isomerization reaction are shown in Figure 1. The occurrence of an isosbestic point demonstrates the homogeneity of this reaction (yield about 80%; in addition to a carbonized residue the only other product detected is aniline). Compound **2** was synthesized for the first time in 1934 in a relatively complicated multistep reaction.[4] It is extraordinarily thermally stable and can be sublimed at about 1000 °C without degradation.

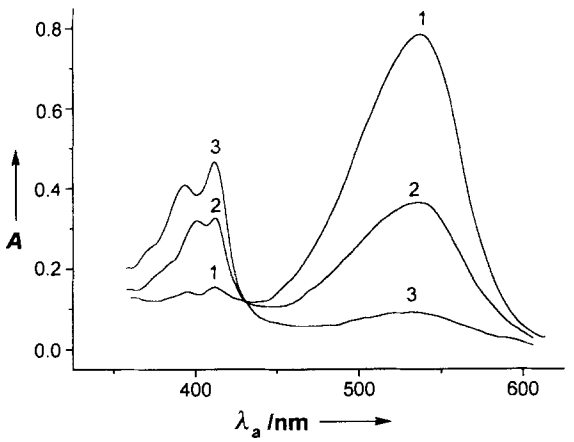

Fig. 1. Spectra recorded during the isomerization of indigo in the gas phase (1: 430 °C, indigo completely vaporized; 2: 480 °C, about 5 min after 1; 3: 500 °C, about 10 min after 1).

To obtain a better understanding of the structure and the spectroscopic properties of both isomers, and also the course of the reaction, quantum chemical calculations using the MNDO-PM3 procedure[5] were carried out.

For both **1** and **2** a nonplanar structure (pyramidalization at the N atom) was calculated. According to the calculations, the energy difference between this and a planar structure was 13.4 kJ mol^{-1} for **1** and 2.3 kJ mol^{-1} for **2**. In contrast, in the electronically excited S_1 state, an almost planar structure resulted for both molecules. The free energy of reaction at 460 °C was calculated to be $\Delta G_R = -62.8$ kJ mol^{-1}.

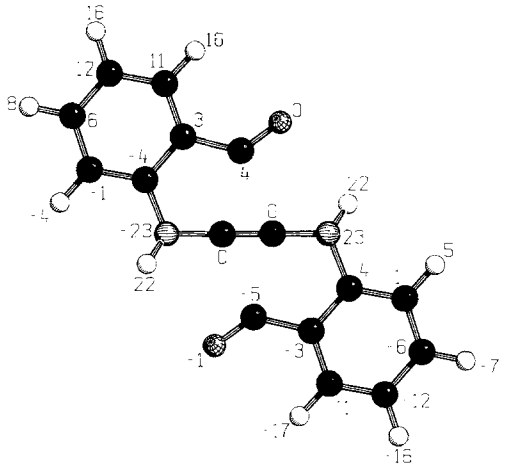
To explain the mechanism of the isomerization, saddle point calculations were made. A structure for a transition state was found and is illustrated in Figure 2. The mechanism of the isomerization can thus be conceived as follows: The bond between



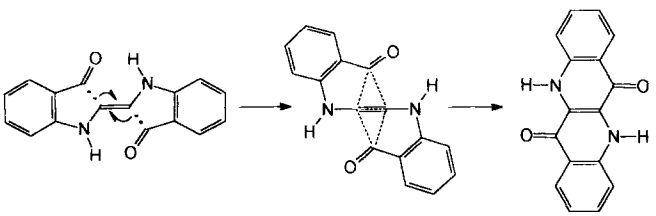


Fig. 2. Structure corresponding to the saddle point of the isomerization of indigo (PM3 calculation); the central C–C bond lies in the plane of the paper; the numbers indicate the deviations vertical to the plane of the paper in pm.

the C atom of the carbonyl group and the central C=C unit is cleaved (weakest bond in **1**). Linearization of both N–C=C units causes a C–C triple bond to be formed from the central C–C double bond. The structure of the indigo molecule changes in such a way that the distances between the C atom of each carbonyl group and both atoms of the central C–C triple bond are approximately the same. Ring formation from this transition state (**TS**) can then lead both to **2** and back to **1**.

1 **TS** **2**

If the orbital symmetry is considered, this process can also be regarded as a dyotrope rearrangement (intramolecular symmetrical transfer of two (σ bonds).[6] Such a [$\sigma_2 + \sigma_2$] process is forbidden by symmetry. However, by including the π-electron system of **1** in the four-membered transition state, the restriction can be relaxed. The very high value of the activation energy (610 kJ mol^{-1}) for the calculated transition state **TS** instead favors a stepwise process. An analogous isomerization was also observed for 5,5'-dibromo-, 4,5,4',5'-tetrabromo-, and 5,7,5',7'-tetrabromoindigo. Thioindigo and thionaphthenindigo (2,2') do not isomerize. Heating **1** in a solvent results in practically no isomerization (in DMSO traces of **2** were detected by its very intense fluorescence).

The spectroscopic properties (UV/Vis absorption and fluorescence) of **1** have been frequently investigated and discussed,[7] also with respect to the differences in absorption behavior between **1** and **2**.[8] A comparison of the absorption and fluores-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0067 $ 10.00+.25/0

cence of **1** and **2** could lead to a deeper understanding of the chromophoric system of indigoid dyes.

Experimental absorption and fluorescence data together with calculated values of both structural isomers are contrasted in Table 1. The most pronounced differences are: a) **1** absorbs at significantly longer wavelengths than **2**; b) in **1** both λ_a and λ_f are more strongly dependent on the polarity of the solvent than in **2**; c) ϕ_f of **1** is more than two orders of magnitude lower than that of **2**; d) both the absorption and the fluorescence spectrum of **2** show pronounced vibrational structure, and **2** exhibits a distinctly lower Stokes displacement (particularly apparent in benzene) than **1**. Comparison of the experimental data with the results from quantum chemical calculations reveals that the qualitative differences between **1** and **2** are in fact approximately reflected. However, quantitatively the agreement is not good; in particular the longest wavelengths calculated for the transitions of **1** are too short.

Table 1. Experimental and calculated spectroscopic data of **1** and **2** (λ_a: longest wavelength band of the absorption, λ_f: maximum of the fluorescence bands, ϕ_f: fluorescence quantum yields, DMSO: dimethylsulfoxide, TCE: 1,1,2,2-tetrachloroethane).

Experimental Procedure

The absorption and fluorescence spectra were recorded on the described compounds in the gas phase in a heated sample chamber with dimensions $5 \times 5 \times 10$ cm^3 fitted with a low-ohm heating element. Thermoelements were used to regulate and control the temperature. A 1.5 cm diameter and about 5 cm long glass tube was charged with the substances (about 0.3 mg), and after several flushes with argon the sample was melted under vacuum. The sample chamber had three mutually perpendicular viewing windows at the level of the optical axes.
The reaction products were identified by mass spectrometry and NMR spectroscopy.

The Novel Copper Polytelluride Salts $NaBa_6Cu_3Te_{14}$ and $(K_{0.60}Ba_{0.40})Ba_6Cu_{2.58}Te_{14}$: Discrete Clusters or Extended Solids?**

Xiang Zhang, Jon L. Schindler, Tim Hogan, Joyce Albritton-Thomas, Carl R. Kannewurf, and Mercouri G. Kanatzidis*

One important difference between the chemistry of Te_x^{2-} and Q_x^{2-} (Q = S, Se) ions is the tendency of the former to associate through Te–Te bonding interactions because of the more diffuse nature of the Te orbitals. While in polysulfides and polyselenides coulombic repulsions dominate their crystal chemistry, polytellurides often show attractions leading to interatomic Te···Te distances much shorter than the van der Waals distance of 4.0 Å. Examples include the alkali metal polytellurides[1] $Na_6Te(Te_5)$,[2a] Na_2Te_6,[2b] A_2Te_3 (A = K, Rb, Cs),[3] A_2Te_5 (A = Rb, Cs),[4] and $CsTe_4$,[5] [TMDH]Te_4 with the organic cation (TMDH = 2,2,5,5-tetramethyl 2,5-diazoniahexane),[6] MTe_2 solids of the pyrite type,[7] and $K_4Hf_3Te_{17}$.[8] However, compounds like $(Ph_4P)_2Te_4 \cdot 2CH_3OH$[9] and $(Me_4N)MTe_4$ (M = Cu, Ag)[10] do not exhibit such Te···Te interactions and behave more like the S and Se counterparts. Apparently interpolytelluride bonding can be turned on and off by choice of the accompanying counterions. Poor coulombic screening of the polytelluride anion and active Te···Te interactions would result with either relatively small counterions or cations with high charge-to-radius ratio (for example dipositive ions). In contrast, good coulombic screening is achieved by larger counterions or more of them in the lattice, which tend to turn inter-Te_x^{2-} interactions off. Recently we reported the compounds $K_2Cu_5Te_5$[11] and $A_3Cu_8Te_{10}$ (A = Rb, Cs),[12] which exhibited no short interpolytelluride contacts. We attempted to test the above counterion hypothesis by employing Ba^{2+} ions in place of alkali metal ions, thus reducing the number of charge-balancing species in the lattice. Here we report preliminary results from these investigations and the synthesis and characterization of **1** and **2**,

$NaBa_6Cu_3Te_{14}$ **1**

$(K_{0.60}Ba_{0.40})Ba_6Cu_{2.58}Te_{14}$ **2**

which possess a novel structure built on discrete Cu/Te clusters held together by intercluster Te···Te bonds.

Single crystal X-ray diffraction studies established that the structures were isomorphous.[13] The framework of **1** is built on a novel cluster of $[Cu_3Te_3(Te_3)_3]^{9-}$ shown in Figure 1. The

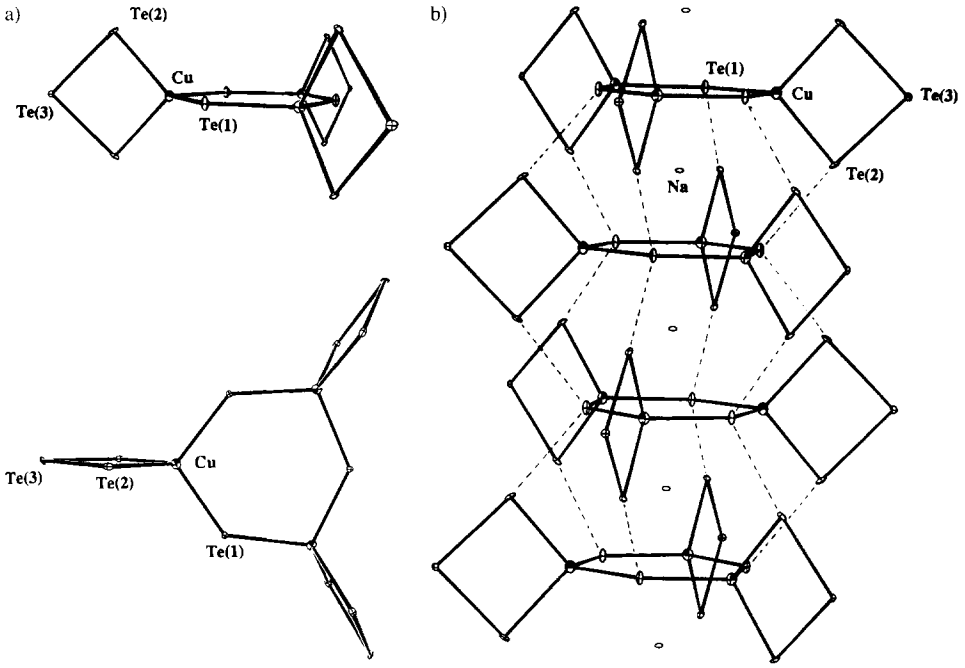

Fig. 1. a) Two views of the structure of the $[Cu_3Te_3(Te_3)_3]^{9-}$ cluster. Selected bond lengths [Å] and angles [°] inside the cluster: Te(1)-Cu, 2.588; Te(2)-Cu, 2.713; Te(2)-Te(3), 2.907(2); Te(1)-Cu-Te(1), 109.6(1); Te(1)-Cu-Te(2), 112.6(1); Te(2)-Cu-Te(2), 96.4; Cu-Te(1)-Cu, 130.4; Te(3)-Te(2)-Cu, 87.67(7); Te(2)-Te(3)-Te(2), 88.22(7). b) Structure of the one-dimensional stack of $[NaCu_3Te_3(Te_3)_3]_n^{8n-}$ clusters. The intercluster Te···Te interactions are shown by the broken lines. The Na^+ ions are sandwiched between the clusters.

entire structure is shown in Figure 2. The cluster consists of four rings, one six-membered and three four-membered. Since the larger six-membered Cu_3Te_3 ring is located on a $\bar{6}2m$ site, it must be strictly planar.[13a] The large amplitude of the anisotropic thermal parameters of all ring atoms in the c direction suggests marked deviations of these atoms from planarity. Each Cu^+ center is further chelated by a Te_3^{2-} ligand to form the four-membered $CuTe_3$ ring, which is also planar and lies perpendicular to the Cu_3Te_3 ring. The Cu^+ center is in a distorted tetrahedral environment; Te-Cu-Te angles range between 96.4(1) and 112.6(1)°. The Cu-Te bond to the monotelluride $Te(1)^{2-}$ at 2.588(6) Å, is quite normal.[11, 12, 14] The Cu-Te bonds to the Te_3^{2-} ligand are much longer (Cu-Te(2) = 2.713(2) Å), while the Te-Te bonds within the ligand are slightly longer than normal (2.907(2) Å). This highly anionic trinuclear copper cluster is unprecedented, but could be compared to the $[In_3Se_3(Se_4)_3]^{3-}$,[15] clusters in which the six-membered In_3Se_3 ring is puckered like cyclohexane. The $[Cu_3Te_3(Te_3)_3]^{9-}$ clusters stack along the c axis in staggered arrangement, and encapsulate Na^+ ions inside the column stack (see Fig. 1b). The packing, at first glance, appears somewhat unusual considering the high negative charge of the clusters. It seems doubtful that Na^+ ions alone can hold them together. A closer examination indicates significant intercluster interactions through the Te atoms. In fact, the Te(1) atom of each of the three monotellurides of one cluster is connected to two Te(2) atoms belonging to two Te_3^{2-} ligands from the neighboring clusters above and below with a Te(1)-Te(2) distance of 3.262(2) Å. This distance is still long compared to a normal Te-Te single bond but significantly shorter than the van der Waals distance (≈4.0 Å). The clusters, linked this way and shaped like a paddle-wheel, form a highly negatively charged, one-dimensional column of $[NaCu_3Te_3(Te_3)_3]_n^{8n-}$ along the c axis. These columns are surrounded by six columns of divalent barium cations. Elsewhere in the lattice discrete Te^{2-} ions (Te(4)) are each surrounded by six Ba^{2+} ions in a trigonal prismatic arrangement. Thus, this compound is a mixed salt of two different anions and two different cations and is best formulated as $NaBa_6[Cu_3(Te)_3\text{-}(Te_3)_3](Te)_2$. Considering the Te···Te interactions only, a novel zigzag $[Te_4]_n^{4n-}$ chain can be visualized with a repeating unit of [Te(1)-Te(2)-Te(3)-Te(2)]$^{4-}$ as illustrated in Figure 1b. The average charge is −1 per Te atom. This $[Te_4]_n^{4n-}$ chain is isoelectronic to the linear chains of $[Te]_n^{n-}$ in CuTe[16] and $[Te_2]_n^{2n-}$ in K_5Te_3.[17] In CuTe a Te-Te single-bond distance of 3.149 Å is present and is considered a bond with bond order 0.5.

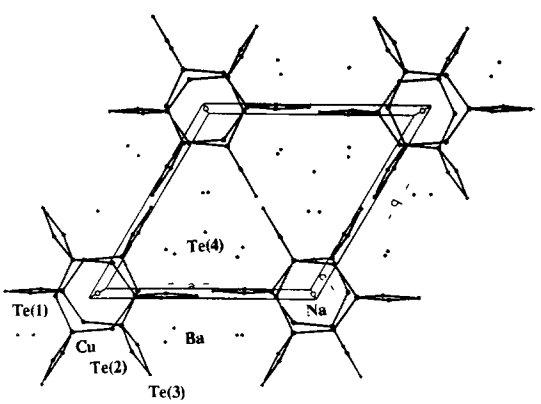

Fig. 2. ORTEP-drawn packing diagram of $NaBa_6Cu_3Te_{14}$ viewed down the c axis. Selected distances [Å] and angles [°] (other than those between clusters): Te(1)-Te(2), 3.262(2); Te(2)-Te(3), 3.912(2); Te(1)-Na, 3.334(1); Cu-Na, 3.536(2); Te(1)-Ba, 3.534(2); Te(2)-Ba, 3.586(2); Te(2)-Ba, 3.614(3); Te(3)-Ba, 3.578(3); Te(3) Ba, 3.627(4); Te(4)-Ba, 3.487(1); Te(2)-Te(1)-Te(2), 100.89(6); Te(1)-Te(2)-Te(3), 173.67(6); Te(1)-Te(2)-Cu, 98.67(6).

The structure of **2** is nearly identical to that of **1**. The primary difference is that in **2** the interstitial position is occupied randomly by K^+ and Ba^{2+} ions. Additional Cu vacancies exist in the Cu/Te framework. The K/Ba ratio of 6:4 and the Cu occupancy of 86% were both determined from the refinement of the X-ray structure analysis.[13] The disorder of K and Ba cations is attributed to the similarity of their ionic radii. This phenomenon has been found to be a common feature for the solid-state structures obtained from mixed K^+/Ba^{2+}-containing fluxes and may have important implications for their properties.[18] While the bond distances and angles found in **2** are mostly similar to those in **1**, a slightly longer Te(1)···Te(2) distance of 3.292(2) Å is

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0069 $ 10.00+.25/0

found in accordance with a slightly shorter Te(2)–Te(3) distance of 2.893(2) Å in the Te_3^{2-} ligand.

In compounds MTe_2 (M = Ti, Nb, Ir) of the CdI_2 type and other layered metal tellurides, interlayer Te···Te interactions were found to play an important role in the electronic structures and physical properties.[19] There is little doubt that the intercluster Te···Te interactions found in our compounds play a similarly crucial role. Without such interactions, these materials would be expected to be insulators assembled just from discrete cluster complexes and charge-compensating ions. Instead, preliminary charge-transport studies suggest that they possess pronounced electrical conductivity. The conductivity of **1** (nearly 0.1 S cm^{-1} at 273 K) decreases with falling temperature to 4×10^{-4} S cm^{-1} (Fig. 3 top), suggesting a semiconductor with a

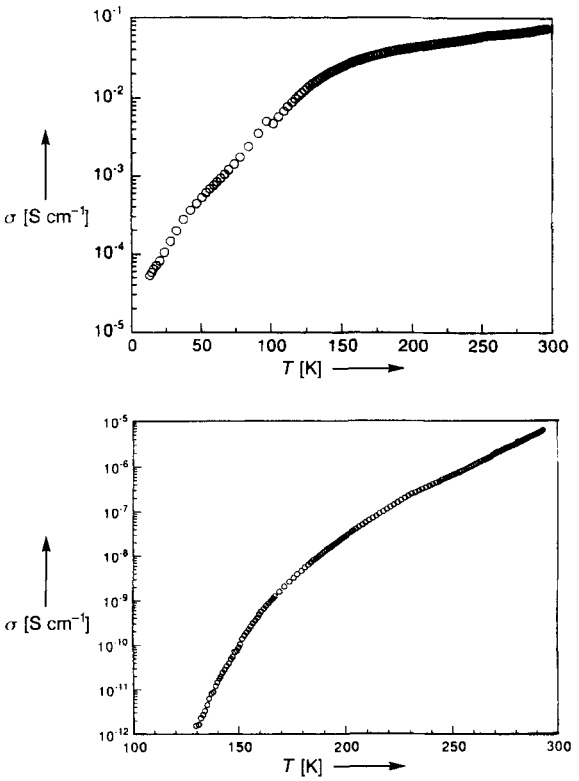

Fig. 3. Four-probe electrical conductivity data as a function of temperature for single crystals of $NaBa_6Cu_3Te_{14}$ (top) and $(K_{0.60}Ba_{0.40})Ba_6Cu_{2.58}Te_{14}$ (bottom).

relatively narrow band gap. As further evidence, diffuse reflectance spectroscopy in the UV/Vis/near-IR region for this phase shows no optical gap, but measurements in the IR region are consistent with a very small band gap. This is confirmed by the thermopower measurements, which show a relatively large Seebeck coefficient (≈ 100 μV K^{-1}) but a positive slope as a function of temperature,[20] which is reminiscent of the behavior of p-type semimetals or narrow band-gap semiconductors. Electrical conductivity and thermoelectric power measurements of **2** also indicate that it is a p-type semiconductor in the temperature range 130–300 K. The conductivity increases with rising temperature from 10^{-12} S cm^{-} at 130 K to 10^{-5} S cm^{-} (Fig. 3, bottom). Both compounds are diamagnetic. More detailed studies of electronic structure and physical properties are under way.

In summary, two novel, one-dimensional, copper polytellurides have been discovered from the reaction of copper with molten polytelluride salts. The construction of extended structures from inter-polytelluride bonding interactions is beautifully manifested in these compounds. Such interactions probably play an important role in influencing the properties. The incorporation of other ions (such as Li^+, Rb^+, Cs^+) into the interstitial positions (sites sandwiched between the Cu/Te clusters) and their effect on intercluster Te···Te bonding is currently under investigation.

Experimental Procedure

Na_2Te and K_2Te were synthesized from a stoichiometric amount of alkali metal and tellurium in liquid ammonia. Cu and BaTe were used as obtained.

1: A Pyrex tube (≈5 mL) containing Cu (0.032 g, 0.5 mmol), Na_2Te (0.261 g, 1.5 mmol), BaTe (0.132 g, 0.5 mmol), and Te (0.510 g, 4 mmol) was sealed under vacuum. The tube was heated at 400 °C for four days, and then slowly cooled at 4 °C h^{-1} to 150 °C. Black chunky crystals were obtained in nearly quantitative yield after removal of the excess $Na_xBa_yTe_z$ flux in *N,N*-dimethylformamide (DMF) under N_2 atmosphere. A composition of $Ba_{5.4}Cu_3Te_{13.2}$ was found from microprobe analysis (energy-dispersive spectroscopy/scanning electron microscopy) of a large number of single crystals. (This technique does not reliably detect Na atoms.)

2: As for **1**. A mixture of Cu (0.032 g, 0.5 mmol), K_2Te (0.206 g, 1 mmol), BaTe (0.132 g, 0.5 mmol) and Te (0.383 g, 3 mmol) was heated at 420 °C for four days. Black chunky crystals were obtained as the major product. Average composition: $K_{0.52}Ba_{5.6}Cu_{2.6}Te_{14}$ (found from the microprobe analysis; average analysis obtained from a large number (>12) of crystals). A minor product in the form of platelets is also present [20].

[13] a) Crystal data for $NaBa_6Cu_3Te_{14}$ (**1**) at −100 °C ($Mo_{K\alpha}$ radiation): $a = 14.123(2)$, $c = 9.075(1)$ Å, $V = 1567.6(6)$ Å^3, $Z = 2$, $\rho_{calcd} = 5.983$ g cm^{-3}, space group $P6_3/mcm$ (no. 193), $2\theta_{max} = 55°$; number of independent data collected: 765, data observed with $I > 3\sigma(I)$: 504, number of variables: 30, $\mu = 222.39$ cm^{-1}, $R = 0.037$, $R_w = 0.043$, GOF = 1.42. b) Crystal data for $(K_{0.60}Ba_{0.40})Ba_6Cu_{2.58}Te_{14}$ (**2**) at −100 °C ($Mo_{K\alpha}$ radiation): $a = 14.121(3)$, $c = 9.200(5)$ Å, $V = 1589(1)$ Å^3, $Z = 2$, $\rho_{calcd} = 5.963$ g cm^{-3}, space group $P6_3/mcm$ (no. 193), $2\theta_{max} = 60°$; number of independent data collected: 967, data observed with $I > 3\sigma(I)$: 502, number of variables: 31, $\mu = 222.19$ cm^{-1}, exctinction coefficient $= 0.186 \times 10^{-7}$, $R = 0.042$, $R_w = 0.047$, GOF = 1.34. The structures were solved by direct methods from SHELXS-86 [13c] and refined with the TEXSAN [13d] package of crystallographic programs. A DIFABS [13e] correction was applied to the isotropically refined data. All atoms were refined anisotropically. Although the Cu_3Te_3 ring in both compounds is found to be strictly planar, the magnitude of the anisotropic thermal parameters U_{11}, U_{22}, and U_{33}, especially of the Te(1) atom, suggest a slightly puckered conformation. The U_{33} value (thermal vibration amplitude in the *c* direction) is significantly larger than U_{11}. This is particularly true in the Na salt. The observed planar conformation could be the result of averaging over two slightly puckered ones. Attempts to resolve these two conformations were not suc-

$Na_2Ti_3Cl_8$: From Isolated Ti^{2+} Ions to $[Ti_3]^{6+}$ Clusters**

Dirk J. Hinz, Gerd Meyer,* Thorsten Dedecke, and Werner Urland*

For the ternary system Na/Ti/Cl not only the binary chlorides NaCl, $TiCl_2$, $TiCl_3$, and $TiCl_4$, and the mixed valent Ti_7Cl_{16},[1] but also the ternary compounds $NaTiCl_3$, $NaTiCl_4$, and Na_2TiCl_6 have been reported,[2] although existence of the latter has not been confirmed by structure analyses. However, the list of compounds in the Na/Ti/Cl system certainly includes the ternary chlorides Na_2TiCl_4,[3,4] $Na_2Ti_3Cl_8$, and Na_3TiCl_6,[5] which lie on the pseudobinary intersections NaCl/$TiCl_2$ and NaCl/$TiCl_3$, as well as the mixed valent $Na_5Ti_3Cl_{12}$.[5]

Of the newly discovered ternary chlorides of titanium with sodium, $Na_2Ti_3Cl_8$ has surprising properties. This may already be suspected from the nearness of the formula to $Ti_7Cl_{16} = Ti_{0.5}Ti_3Cl_8$ on the one hand and Nb_3Cl_8 [6] on the other. These contain (linked) $[M_3](\mu_1\text{-Cl})_9(\mu_2\text{-Cl})_3(\mu_3\text{-Cl})$ building blocks, within which the metal atoms are connected by means of covalent single bonds; the distances in the $[Ti_3]$ cluster in Ti_7Cl_{16} are 295 pm.[1]

If the titanium with oxidation state IV in $Ti_{0.5}Ti_3Cl_8$ is replaced with Na^+, $Na_2Ti_3Cl_8$ is obtained. In the crystal structure determined at room temperature[7] flat layers of titanium atoms (better: Ti^{2+} ions) are found in the form of a diluted closest packing of spheres, each with four equidistant neighbors ($d = 372$ pm) (Fig. 1, top). $Na_2Ti_3Cl_8$ is isotypic with $Na_2Mn_3Cl_8$:[8] closest packed layers of chloride ions are stacked AABBCC as in 3R–MoS_2; three-quarters of the octahedral sites are filled with Mn^{2+}/Ti^{2+}, one-quarter of all trigonal-prismatic sites are occupied by Na^+ in a similar fashion.

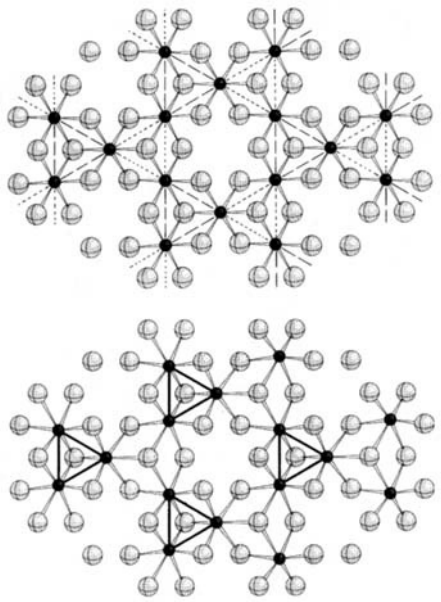

Fig. 1. Cl–Ti–Cl layer in the room-temperature form (top) and low-temperature form (bottom) of $Na_2Ti_3Cl_8$. The phase transition can be interpreted as a Peierls distortion along three directions within the titanium layer.

Magnetic susceptibility measurements were performed on a SQUID magnetometer (Quantum Design, MPMS5) at 2–300 K at a field strength of $H = 1000$ Oe. In order to take into consideration the diamagnetic correction of Na_2TiCl_4 and $Na_2Ti_3Cl_8$, tabular incremental values were employed according to Selwood.[9] The measurements revealed a drastic decrease of the magnetic moment at around 200 K on cooling (cf. Fig. 2). X-ray investigations on powder samples above and below this "critical" temperature also indicated strong alterations, which seems to be confirmed by a comparison of the lattice constants (hexagonal setting): 293 K: $a = 743.32(8)$; $c = 972.1(5)$ pm; 100 K: $a = 697.9(1)$; $c = 2027.1(6)$ pm. Owing to the shrinkage of the a axis (and consequently the dilatation of the c axis), it can be assumed that in the planes of titanium atoms parallel to (001), a transition from *isolated* Ti^{2+} *ions* (d^2 configuration) to $[Ti_3]^{6+}$ *clusters* must have occurred. The magnetic moments at 300 K ($\mu = 2.55\ \mu_B$) and 150 K ($\mu = 1.49\ \mu_B$) correspond well to those observed for Na_2TiCl_4 (300 K; $\mu = 2.56\ \mu_B$; isolated Ti^{2+} ions) and Ti_7Cl_{16} (150 K; $\mu = 1.25\ \mu_B$;[10] $[Ti_3]$ cluster).

Proof for the driving force of the phase transition observed here is provided by a single-crystal structure determination at 183 K.[7] The same crystal was used for this as for the determination at room temperature; astonishingly it was not destroyed by the considerable mechanical stresses accompanying the alteration of the lattice constants already discussed. This is probably because the phase transition, having begun at one point in the crystal, can then propagate throughout the entire crystal. The local changes occurring during the transition are shown in Figure 3. The formation of $[Ti_3]$ clusters in the planes parallel to

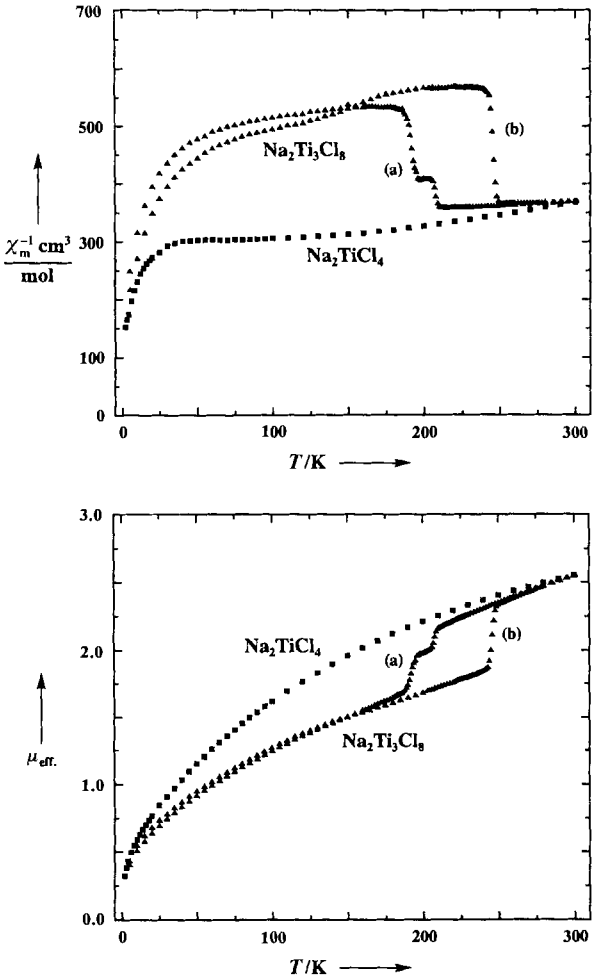

Fig. 2. The reciprocal molar magnetic susceptibility ($H = 1000$ Oe) (top) and the effective magnetic moment (bottom) for $Na_2Ti_3Cl_8$ at 2–300 K. The phase transition displays a distinctive hysteresis. On heating (curve b), the phase transition occurs quickly at about 245 K, whereas this event takes place over a wider temperature range at around 200 K on cooling (curve a). For comparison, the values for Na_2TiCl_4 [4] are also plotted.

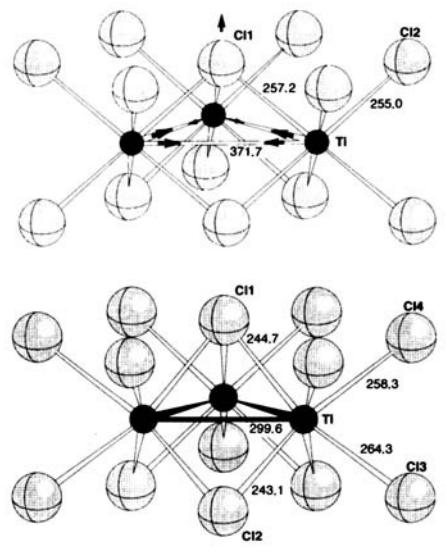

Fig. 3. Ti_3Cl_{13} units in the room-temperature form (top) and low-temperature form (bottom) of $Na_2Ti_3Cl_8$. At the phase transition the titanium atoms shift towards one another out of the octahedral centers of chlorine atoms. In the process the Cl1 atoms are forced far out of the plane of the other chlorine atoms (distances in pm).

(001) (see Fig. 1) leads to the shrinkage of the lattice constant a, the "squeezing out" of μ_3-Cl to the dilatation of the c axis.

According to this, $Na_2Ti_3Cl_8$ demonstrates a thermally activated, reversible transition, observed here for the first time. The transition occurs in a type of two-dimensional Peierls distortion from "isolated" Ti^{2+} ions (d^2 system with $\mu = 2.56\ \mu_B$ (Na_2TiCl_4)) to "discrete" [Ti_3] clusters with covalent "metal–metal single bonds" (6-electron system; $\mu = 1.49\ \mu_B$). Corresponding magnetic transitions with comparable hysteresis behavior are well known from high-spin–low-spin transitions in the transition metals (e.g. spin crossover in Fe^{II} complexes[11]).

The molar volume (V_m) of $Na_2Ti_3Cl_8$ decreases between 293 and 183 K by almost nine percent. The value $V_m = 39.5\ cm^3\ mol^{-1}$ for $TiCl_2$ at 183 K, calculated from $V_m(Na_2Ti_3Cl_8)$ at 183 K (with $V_m(NaCl) = 27.01\ cm^3\ mol^{-1}$) agrees very well with the value calculated from a pyknometrical density determination ($V_m = 38\ cm^3\ mol^{-1}$[12]). From this, and from magnetic measurements,[12, 13] it is possible to deduce that [Ti_3] clusters also exist in $TiCl_2$ at room temperature. Fundamentally, this had already been recognized by Klemm and Grimm. The CdI_2 type assumed by other authors is therefore only correct "in principle".

Experimental Procedure

Single crystals of $Na_2Ti_3Cl_8$ were obtained from the reaction of sodium with $TiCl_3$ (e.g. 44.7 mg Na and 300 mg $TiCl_3$) in the presence of titanium foil (180 mg) in a sealed niobium ampule at 525 °C (three months). Besides $TiCl_2$, NaCl, and turquoise needles of Na_2TiCl_4, the mixture of products contained a small amount of $Na_2Ti_3Cl_8$ in the form of dark green trigonal platelets, which were readily split parallel to (001). Powder preparations suitably pure for X-ray purposes were obtained by the synproportionation of $TiCl_3$ with titanium in the presence of NaCl (e.g. 1 g $TiCl_3$, 379 mg NaCl, approximately 300 mg titanium foil, molar ratio 2:2:>1) in a sealed niobium ampule. The ampule was initially heated slowly to 500 °C and then kept at 750 °C for 24 h. The reaction was then quenched with water and finally tempered at 520 °C for three weeks. The excess titanium foil was easily removed from the reaction mixture.

Homogeneous versus Heterogeneous Zeolite Nucleation

Wim H. Dokter, Harold F. van Garderen, Theo P. M. Beelen,* Rutger A. van Santen, and Wim Bras

A question of considerable debate in zeolite synthesis is the nature of the precursor gel from which the zeolite is formed and whether nucleation occurs within the gel or from the mother liquid of the synthesis mixture.[1, 2] For the synthesis of ZSM-5 and silicalite considerable evidence supports the hypothesis that crystallization occurs by transformation of the precursor gel.[3, 4] On the other hand, it has also been demonstrated that the zeolite can be formed directly from the liquid phase without the intermediacy of a gel phase.[5] Here we report on a silicalite synthesis in which the silicalite crystallites do not nucleate in a separate gel phase, but directly from the liquid phase. Even in this experimental system, in which no gel phase was expected, precursor aggregates were observed with simultaneous, real-time small- and wide-angle X-ray scattering (SAXS-WAXS). These aggregates reorganize in analogy to the heterogeneous reaction mixture before nucleation and subsequent crystallization.[2, 6]

Time-resolved small- and wide-angle X-ray scattering can be applied to study aggregation, gelation, and crystallization processes under in situ conditions. We recently reported a SAXS-WAXS study of the gel morphology changes that occur during silicalite formation in a synthesis mixture with a separate gel phase. We found significant gel transformations before nucleation of silicalite crystallites. The gel morphology could be analyzed in terms of primary particles with a radius of 14 nm and an initial surface fractal dimension of 2.7, indicating a rough surface, which reorganized into smoother particles during reaction.[2, 6] We concluded that nucleation proceeds within the gel.

The simultaneous small- and wide-angle X-ray scattering experiments were performed using beamline 8.2 at the Synchrotron Radiation Source (Daresbury Laboratories, United Kingdom). Details concerning camera geometry and data collection were presented elsewhere.[7] The spatial resolution of the SAXS quadrant detector is 400 μm, and it can handle up to 300000 counts per second.[8] The WAXS detector is a curved knife-edge INEL detector with a spatial resolution of 50 μm and can handle up to 100000 counts per second.[9] The scattering ranges covered are $0.01 < Q < 0.175$ Å^{-1} and $0.8 < Q < 3.4$ Å^{-1} for the SAXS and WAXS detectors, respectively. The SAXS data were corrected for background scattering and solvent using a procedure introduced by Vonk.[10] Fractal dimensions were determined from the parts of the scattering curves where behavior followed the power law, and particle and aggregate sizes were determined from the point of deviation from this behavior. In the determination of the slope of the scattering curve, two possible sources of error may be distinguished. The first is the natural noise present in the data, which is small, however, compared to the error introduced during background subtraction ($D_f \pm 0.05$). The crystallinity of the final product was determined with in-house XRD, which was calibrated with a fully crystalline sample of silicalite.The relation between a scattering spectrum and the species responsible for the scattering is shown in Figures 1a and 1b. For mass fractal aggregates

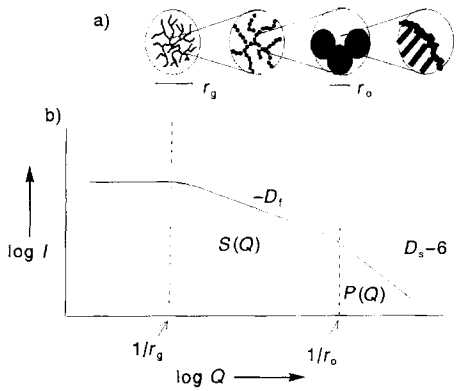

Fig. 1. a) Schematic representation of an aggregate with mass fractal and surface fractal properties; b) the corresponding plot of log I versus log Q of the small-angle scattering spectrum. $S(Q)$ = structure factor, $P(Q)$ = form factor, I = scattered intensity, Q = scattering vector, D_f = mass fractal dimension, D_s = surface fractal dimension, r_g = radius of gyration of the aggregate, r_0 = radius of gyration of primary particles.

the scattered intensity will be dominated by the structure factor, providing information about the correlation between the various primary building units present in the aggregates[11] [Eq. (a)]. Here $Q = 2\pi/\lambda \sin(2\theta)$, λ = wavelength, 2θ = scattering angle, $P(Q)$ = form factor, $S(Q)$ = structure factor, and D_f = mass fractal dimension.

$$I(Q) \sim P(Q)S(Q) \sim S(Q) \sim Q^{-D_f} \quad \text{(a)}$$

On the scale of the primary building units the form factor of the primary building units becomes dominant in the scattering pattern, thus providing information about the surface structure of these units[12] [Eq. (b)], where D_s, the surface fractal

$$I(Q) \sim P(Q) \sim Q^{-(6-D_s)} \quad \text{(b)}$$

dimension, ranges between 2 and 3. The surface fractal dimension equals 2 for a nonfractal, completely smooth surface, thus resulting in the well-known Porod relation[13] [Eq. (c)].

$$I(Q) \sim Q^{-4} \quad \text{(c)}$$

If D_s increases, the roughness of the surface increases. When $D_s \rightarrow 3$ and $D_f \rightarrow 3$, then a homogeneous distribution of mass and voids (possibly filled) throughout the sample is obtained.[14] Experimentally the parameter D_f (fractal dimension) can be determined from a plot of log $I(Q)$ versus log Q. The slope of the scattering curve α is equivalent to $-D_f$ for mass fractal scattering and equivalent to $-(6 - D_s)$ for surface fractal scattering.

The reaction mixture studied here was prepared from silicic acid powder (Baker 10.2 wt% water), NaOH pellets (Merck, >99 wt%) and tetrapropylammonium hydroxide (TPA) (Fluka 20 wt%) in the following molar ratios: SiO_2/TPA = 4.1, SiO_2/NaOH = 11.5, H_2O/SiO_2 = 11.[15] NaOH was added to the TPAOH solution with gentle stirring. The silicic acid was added to the solution and stirred until a homogeneous dispersion was obtained. This solution was heated for approximately 10 min to obtain a clear synthesis mixture. Water was added to correct for the loss due to evaporation. This synthesis mixture usually remains clear during reaction until crystallization, detectable with standard X-ray diffraction, occurs.[15] The reaction temperature was 120 °C ± 5 °C.

Our results indicate that in the homogeneous system cluster aggregation occurs before crystallization, in analogy to the heterogeneous system.[2, 6] SAXS curves and corresponding schematic aggregate structures are shown in Figures 2 and 3, respectively. As Figures 2a and 3b show, the morphology (D_f = 2.2), observed after a reaction time of 5 min is typical for aggregates condensed according to reaction-limited cluster–cluster aggregation.[16] The low rate of reaction is due to the effect of the structure-directing TPA ions.[17]

The aggregates formed under these conditions have a diameter d of approximately 6.4 nm ($d = 2 \cdot r_g$; r_g = radius of gyration) These aggregates are composed of primary particles with a radius smaller than 1.6 nm, the upper limit of the Q-values of the available SAXS range. These primary particles may be hydrated tetrapropylammonium–silicate clusters. Burkett and Davis have provided evidence for the existence of preorganized organic–inorganic composite structures in the synthesis of ZSM-5.[18] Short-range intermolecular interactions exist between the protons of TPA and silicon atoms of the zeolite precursor phase before development of the long-range order characteristic of the ZSM-5 structure.[18] Other authors observed specific silicate anions in various aqueous silica solutions

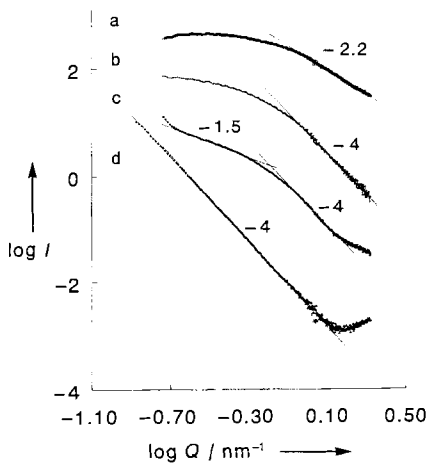

Fig. 2. Plot of log I versus log Q of the small-angle X-ray scattering spectra of the clear silicalite synthesis mixture after reaction times of a) 5 min, b) 35 min, c) 75 min, and d) 105 min.

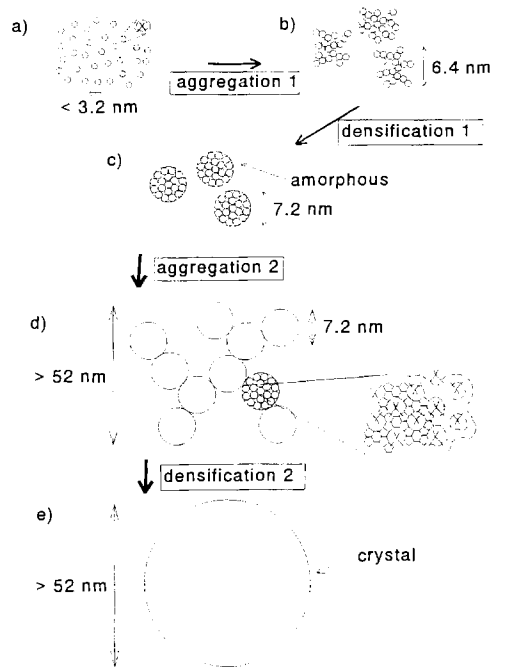

Fig. 3. Mechanism of microstructural random packing, subsequent ordering, and crystallization. a) Silicate/TPA clusters in solution; b) primary fractal aggregates formed from the silicate/TPA clusters (6.4 nm, Fig. 1a); c) densification of these primary fractal aggregates (Fig. 1b); d) combination of the densified aggregates into a secondary fractal structure and crystallization (Fig. 1c); and e) densification of the secondary aggregates and crystal growth.

which may be building blocks for zeolites or precursors of zeolites.[19, 20]

The observed silica/TPA clusters start to densify (Figs. 2b and 3c) with time into denser mass fractal aggregates and subsequently into surface fractal aggregates (Fig. 4). After a reaction

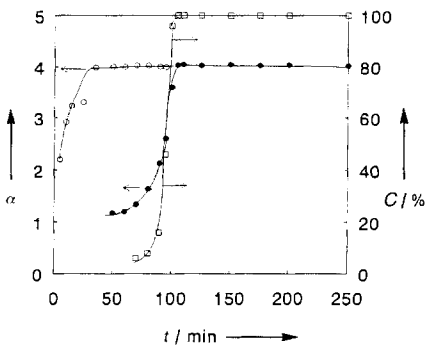

Fig. 4. Plot of crystallinity C (from WAXS) and microstructure (from SAXS) as a function of time t. The scattering slopes α obtained with SAXS are divided in the scattering slope at high Q (small radius) (○) and the scattering slope at small Q (large radius) (●) to clearly demonstrate the consistency between the microstructure and crystallization (□).

time of 35 min at 120 °C the plot of log $I(Q)$ versus log Q shows a Porod slope ($\alpha = -4$), indicative of a homogeneous dense silica/TPA structure with a smooth surface ($D_s = 2$). The size of this structure increases only very slightly (to 7.2 nm) with time. The fact that it does not decrease upon densification indicates that additional primary particles (TPA surrounded with silicate anions) are transported from solution or other silica aggregates to the densifying cluster. The size of these densified silica/TPA

particles is approximately equal to 20 silicalite unit cells. After this densification, the 7.2-nm particles aggregate again into a new, secondary fractal aggregate (Figs. 2c and 3d). The occurrence of crystalline structures is observed simultaneously with WAXS.

Figure 4 shows the time progression of the scattering slope α at large values of Q (small particles) and at small values of Q (large particles or clusters), and the degree of crystallinity as determined with WAXS. The WAXS curves are shown in Figure 5. From these plots we may conclude that crystallization

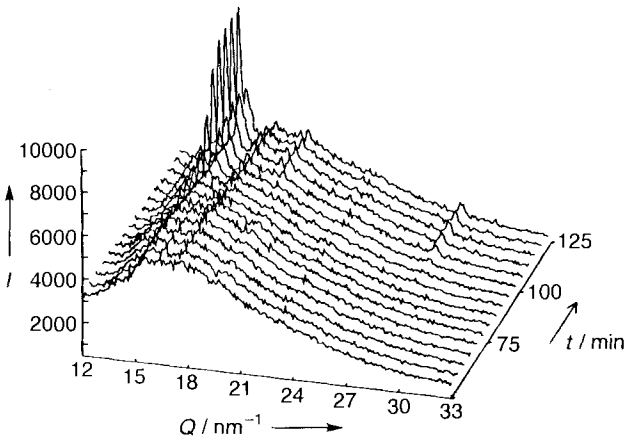

Fig. 5. WAXS spectra of clear silicalite synthesis mixtures demonstrate crystallization beteen 50 and 125 min of reaction. I = intensity, Q = scattering vector, t = time.

starts as soon as the dense silica/TPA particles 7.2 nm in diameter have been formed and aggregation into the larger secondary aggregate starts. Growth of zeolite particles occurs by transformation of the 7.2-nm silica/TPA particles that form the new secondary fractal structure (Fig. 2c). Crystallization occurs again via a surface fractal aggregate (Fig. 4) to a completely smooth (energetically more favorable) structure (Figs. 2d and 3e). They grow rapidly to a size larger than the upper size limit (low Q-limit) of the available SAXS range ($d > 52$ nm).

Crystal growth occurs by combination of the densified primary aggregates into kinetically determined secondary aggregates, indicative for growth by combination of already growing nuclei, which subsequently densify into energetically more favorable, dense, smooth particles. These results are in agreement with the results obtained by Twomey et al. who deduced from size distributions of crystals obtained from light-scattering experiments that nucleation is a continuous process and that growth occurs by agglomeration of nuclei.[21]

One interesting feature of the results presented here is that also in the homogeneous system a precursor aggregate is formed before crystallization, which is indicative of a gel transformation or gel reorganization mechanism of zeolite crystallization even in a clear silicalite solution. This is in contrast to the direct homogeneous crystallization.

For silicalite synthesized from a gelatinous reaction mixture[21] it was concluded that crystallization proceeded also according to a gel transformation mechanism. No mass fractality was observed during these experiments. The different silica source (Aerosil 380) leads to very compact amorphous surface fractal precursor particles with a initial particle size of 14 nm. Crystallization, however, starts only after the surface fractal amorphous particles have been transformed into smooth particles with $D_s = 2$. An analogous feature was observed in this study. The mass fractal aggregate had to transform into smooth, homogeneous, dense structures before crystallization starts. From this we may conclude that homogeneous and heterogeneous crystallization both require an intermediate gel phase before nucleation and crystallization can occur.

In the gel phase nucleation and crystallization occur more slowly than in the homogeneous phase, because the gel formed must first dissolve before a new phase is formed, from which crystallization can occur. This dissolution step is not required in the homogeneous phase, in which the mass transport and subsequent formation of the primary and secondary clusters seem to be the rate-determining steps. Instant crystallization may be achieved when the precursors are prepared in such a way that the desired gel phase for nucleation is obtained directly.

Orthorhombic and Monoclinic 2,3,7,8-Tetramethoxythianthrene: Small Structural Difference–Large Lattice Change**

Hans Bock,* Andreas Rauschenbach, Christian Näther, Zdenek Havlas, Angelo Gavezzotti, and Guiseppe Filippini

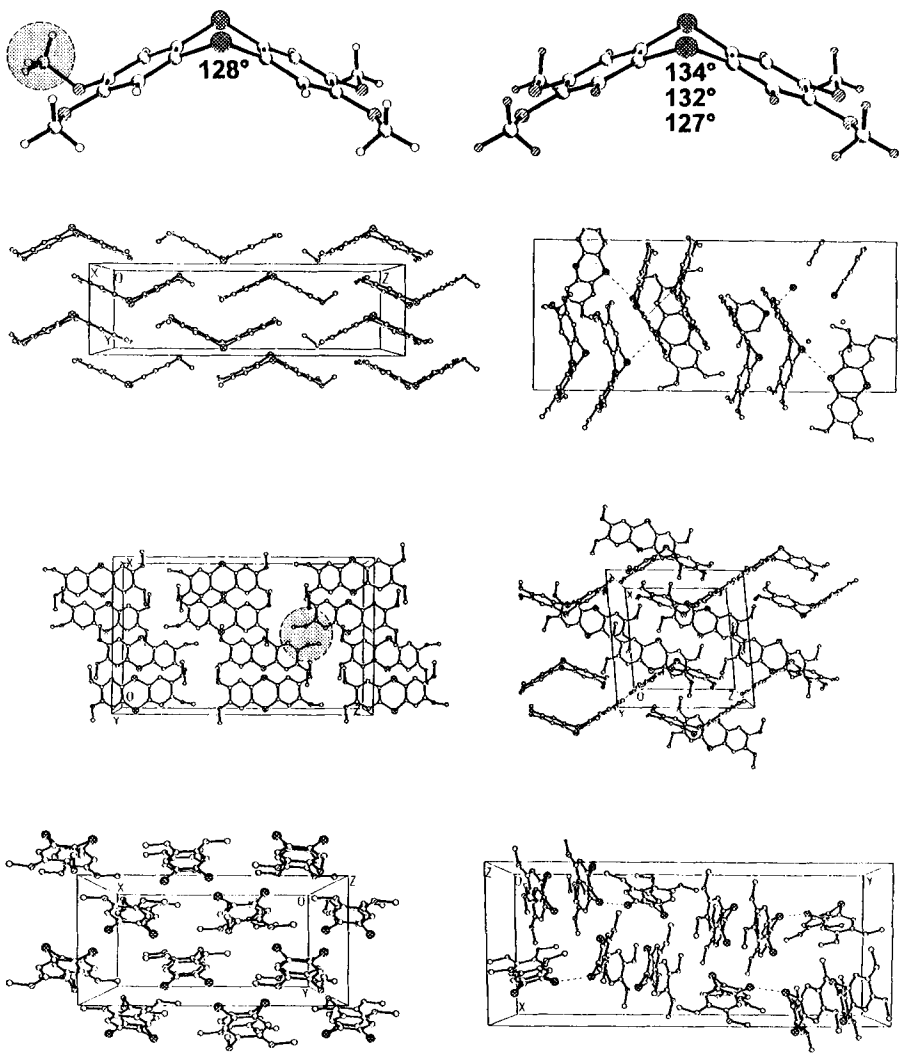
Dedicated to Professor Wolfgang Hilger on the occasion of his 65th birthday

Molecular compounds can often be isolated in several crystalline modifications that have only small differences in lattice or sublimation energies.[1–3] In addition to serendipitous discoveries,[1, 2a, 3a] frequently crystal growth under skillfully chosen optimal conditions[1, 2b, 3b, 3c]—for instance, from solution or by sublimation,[2c, 3a, 3c] from strongly polar or less polar solvents,[2c, 3c] or in the presence of cation-chelating ligands[3b]—enable certain molecular conformations to be captured "snapshots" of the molecular dynamics.

Here we again report[4a] on 2,3,7,8-tetramethoxythianthrene, which is obtained from diisopropyl ether as monoclinic[4b] and from *n*-hexane as orthorhombic crystals.[5] The structural differences on the molecular level are rather small: comparison reveals that in the orthorhombic modification only the methoxy group in the 3-position is twisted by 79° out of the plane of the adjacent six-membered ring (Fig. 1, top left). However, the small perturbation in the skeletal symmetry from C_{2v} to C_1, which does not apply to the crystallographic site symmetry, formally introduces molecular chirality.

The changes in the crystal lattices on going from the monoclinic modification containing altogether $Z = 12$ molecules of three geometries within the unit cell to the orthorhombic one with $Z = 8$ identical molecules can be plausibly discussed by beginning with the small structural perturbation (Fig. 1, top left). As can be seen from the angles in the planar form (Scheme 1 left), twisting one H_3CO group out of the C_6 plane brings some steric relief especially between the H centers in *ortho* ring position and the methyl groups, since the 228 pm distance between them is within twice the van der Waals radii $2r_H^{vdW}$ of 240 pm.

In contrast, in both the monoclinic and the tetragonal modifications of tetramethoxyselenanthrene all H_3CO substituents lie in the C_6 plane, and a databank search (Cambridge Crystallographic Data Centre),[4c] in complete agreement with PM3 calculations,[6b] suggests that for structures containing methoxy-substituted phenyl rings a planarization should be energetically favorable. Nevertheless, the conformation of the orthorhombic tetramethoxythianthrene (Fig. 1, top left) is supported by geometry-optimized PM3 hypersurface calculations: for the experimentally determined twisting of ω(CC–OC) = 79°[5] above the $O_2C_6S_2$ plane, the (negative) heat of formation is predicted to increase by -3 kJ mol^{-1}, and the local minimum of the rather shallow potential is found at a torsion angle of about 80°.[6] On the contrary, both the turning of a H_3CO



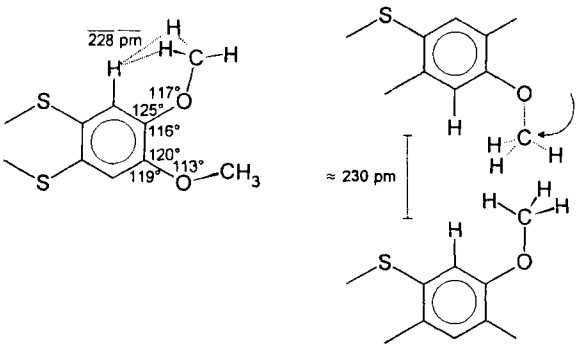


Fig. 1. Single crystal structures of the polymorphic modifications of 2,3,7,8-tetramethoxythianthrene. Left: orthorhombic (*Pbca*, ρ(300 K) = 1.437 g cm^{-3} [5], with an interplanar angle of 128° between the C_6 rings, and unit cell ($Z = 8$) in *a*, *b*, and *c* directions. The shaded circles emphasize the structural distortion by twisting of the methoxy group in 3-position and its effects on the lattice. Right: monoclinic ($P2_1/n$, ρ(300 K) = 1.395 g cm^{-3} [4b]) containing three independent molecules in the asymmetric unit with dihedral angles of 134°, 132°, and 127°, and the unit cell ($Z = 12$) in *a*, *b*, and *c* directions.

[**] Interactions in Crystals, Part 49. The project was supported by the A. Messer-Stiftung, the State of Hesse, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. Part 48: H. Bock, I. Göbel, C. Näther, B. Solouki, A. John, *Chem. Ber.* **1994**, *127*, 2197.

Scheme 1. Left: Bond angles and H···H distance in 2,3,7,8-tetramethoxythianthrene. Right: hypothetical C···C distance of about 230 pm in the orthorhombic lattice (Fig. 1: left) on attempting to twist the H_3CO group back into the plane of the six-membered ring (cf. text).

substituent below the $O_2C_6S_2$ plane and the dis- or conrotatory movement of two vicinal methoxy groups (H_3CO-CC-OCH_3) require energy.[6a] Altogether therefore, tetramethoxythianthrene displays– in close analogy to the polymorphic conformers of tetraisopropyl-*p*-phenylene diamine[3a]—a delicate balance between n_O/π-delocalization of the oxygen lone pair density and the H/H repulsion especially between H centers of the ring in *ortho*-position and of the methyl group (Scheme 1 left).

Though rather small, the structural distortion is nevertheless connected with a profound lattice change (Fig. 1), which shall be rationalized as follows: a hypothetical attempt to twist the methoxy group of the orthorhombic modification back into the plane of the phenyl ring, would enforce a nonbonding C···C distance of only 230 pm (Scheme 1 right). This would correspond to a prohibitive 42% contraction of the usual van der Waals distance between two methyl groups of 400 pm.[7] This argument explains the increased packing density due to the parallel arrangement of two twisted H_3CO substituents, each from different molecules (Fig. 1, shaded circle in the unit cell second from top, left). On the other hand, the shortest contact distance $(CH_2)H\cdots S$ resulting from the dense packing is only 281 pm and, therefore, smaller than the van der Waals radii sum of $r_H^{vdW} + r_S^{vdW} = 120 + 185 = 305$ pm by only 8%.[7]

Every tetramethoxythianthrene molecule in the orthorhombic modification is surrounded in the *a*, *b* plane by six adjacent ones (Fig. 1, bottom left), and above and below it in the *c* direction are two additional molecules. In contrast, the monoclinic modification (Fig. 1, right) contains relatively loosely packed pairs of the sulfur heterocycles with mean S···S distances of 398 pm; the third molecule lies perpendicular to this pair. The density difference at room temperature between the orthorhombic ($\rho = 1.437\ g\,cm^{-3}$) and the monoclinic ($\rho = 1.395\ g\,cm^{-3}$)[4b] modifications amounts to 2.6%. As expected,[1, 8] this is reflected in the lattice or sublimation energies calculated by the atom/atom potential approximation,[9a, b] which predicts $-34.7\ kJ\,mol^{-1}$ for the orthorhombic and $-32.3\ kJ\,mol^{-1}$ for the monoclinic modification of 2,3,7,8-tetramethoxythianthrene.[9c]

The following proposals are forwarded for discussion of the crystal growth of the two different modifications:[1–3, 10] The monoclinic crystals of lower density and lattice energy should grow from a solution in the polar diisopropyl ether rather fast and in a kinetically controlled way, whereas the orthorhombic crystals with higher density and lattice energy presumably grow under thermodynamical control from a solution in an unpolar hydrocarbon. Whether the symmetry change $C_{2v} \rightarrow C_1$ occurs partly in solution already or only on incorporation into the crystal lattice cannot be answered; however, the existence of the 2,3,7,8-tetramethoxythianthrene modifications is another example—as is the use of the monoethyltetramethylcyclopentadienyl ligand in the rapid crystallization of metal sandwich complexes[10b] –of the often useful rule of thumb that reduced molecular symmetry can promote an energetically favored crystallization.

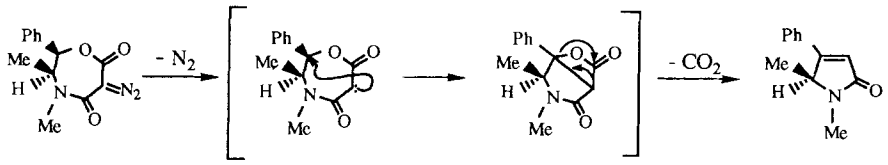
(*S*)-(+)- and (*R*)-(−)-1,5-Dimethyl-4-phenyl-1,5-dihydro-2*H*-pyrrol-2-ones by Carbene Ring Contraction and Decarboxylation of (2*R*,3*S*)-(−)- and (2*S*,3*R*)-(+)-6-Diazo-3,4-dimethyl-2-phenyloxazepane-5,7-diones**

Giorgio Chelucci and Antonio Saba*

The interest in ephedrine enantiomers as chiral auxiliaries increased after oxazepane-5,7-dione **1** was reported by Mukaiyama et al.[1] The 6-benzylidene derivative of **1** has been used as a chiral Michael acceptor,[2] a dienophile in asymmetric Diels–Alder cycloadditions,[3] and an unsaturated substrate in asymmetric cyclopropanation.[4] In the course of our studies in the field of stabilized carbenes and carbenoids generated by decomposition of α-diazocarbonyl compounds,[5] we have devoted our attention to the reactivity of (2*R*,3*S*)-(−)-6-diazo-3,4-dimethyl-2-phenyloxazepane-5,7-dione (**2**) and its enantiomer **2'**. Here we wish to report their catalytic decomposition, which affords exclusively (*S*)-(+)- and (*R*)-(−)-1,5-dimethyl-4-phenyl-1,5-dihydro-2*H*-pyrrol-2-one (**3** and **3'**).

The 6-diazooxazepanediones **2** and **2'** were easily prepared under mild conditions by a "diazo transfer" reaction with *p*-toluenesulfonyl azide (TsN_3);[6] the starting materials oxazepanediones **1** and **1'** were obtained from (−)-ephedrine and (+)-ephedrine, respectively. The decomposition reaction of **2** and **2'** was carried out in the presence of catalytic amounts of copper(I) triflate or rhodium(II) acetate dimer in CH_2Cl_2 at room temperature and was allowed to proceed until the diazo stretching band in the IR spectrum had disappeared. After filtration on neutral Al_2O_3, removal of the solvent, and crystallization of the residue, the 2-pyrrolones **3** and **3'** were obtained in good yield (Scheme 1).

The structure of the ring-contraction product **3** was determined from the mass, ^1H NMR, and ^{13}C NMR spectra



1 : (2*R*)(3*S*) **2** : (2*R*)(3*S*) **3** : (*S*)
1': (2*S*)(3*R*) **2'** : (2*S*)(3*R*) **3'** : (*R*)

Scheme 1. a) TsN_3, NEt_3, CH_3CN, room temperature, 24 h (85%); b) 5% copper(I) triflate or 5% rhodium(II) acetate dimer, CH_2Cl_2, room temperature (95%).

(Table 1), and a single-crystal X-ray diffraction study.[7] The latter confirmed the presence of a single enantiomer in the crystal and consequently the retention of configuration at the carbon bearing the methyl group, which is not involved in the process.

Ring contraction of heterocyclic α-diazo carbonyl compounds mostly proceed via a ketene (Wolff rearrangement[8]) and rarely have any synthetic value.[9] In our case, **3** was formed as a result of a transannular attack in the seven-membered heterocycle by the ketocarbene or ketocarbenoid intermediate. The regiospecific insertion into the benzylic C–H bond of oxazepane **2** can be ascribed to the greater electron density of this bond: electronic activation by the lactone oxygen[10] and by the phenyl group makes this bond more susceptible to attack by the electrophilic carbene species. In addition, it is documented that, in intramolecular C–H insertion reactions of diazoacetamides, a five-membered γ-lactam ring is more likely to be formed than the potentially competitive β-lactam.[11] The suggested straightforward mechanism of regiospecific carbene attack followed by ready CO_2 extrusion from the resulting unstable bicyclic intermediate is shown in Scheme 2.[12] Irradiation of diazo compound **2** with ultraviolet light ($\lambda = 250$ nm, in CH_2Cl_2) led to formation of the same reaction product **3**, although in much lower yield.[13]

2 **3**

Scheme 2.

The enantiomerically pure compounds **3** and **3'** open access to biologically active 4,5-disubstituted 2-pyrrolidinones, which can be considered as precursors to γ-aminobutyric acid (GABA).[14] Thus, catalytic hydrogenation of **3** gave a diastereomeric mixture of (4*S*,5*S*)-(+)- and (4*R*,5*S*)-(−)-1,5-dimethyl-4-phenyl-2-pyrrolidinone (**4a** and **4b**) in a ratio of 5.5:4.5 (Scheme 3).[15] The enantiomer **3'** was submitted to the same reductive procedure. A roughly 1:1 mixture of (4*R*,5*R*)-(−)- and (4*S*,5*R*)-(+)-1,5-dimethyl-4-phenyl-2-pyrrolidinone (**4a'** and **4b'**) were obtained. The diastereoisomeric pairs **4a**/**4b** and **4a'**/**4b'** were readily separated by chromatography on silica gel (eluant: hexane/ethyl acetate 8/2), and their configurations confirmed by NMR spectroscopy. In particular, the resonance for the 5-methyl of **4b** (Table 1) shows the well-known γ-gauche effect in the ^{13}C NMR spectrum[16] and is shifted upfield relative to that of the diastereoisomer **4a** ($\Delta\delta = 4$). Thus, **4b** can be assigned the *cis*- and **4a** the *trans*-pyrrolidinone configuration. Since the carbon bearing the methyl group is unaffected in the reaction,

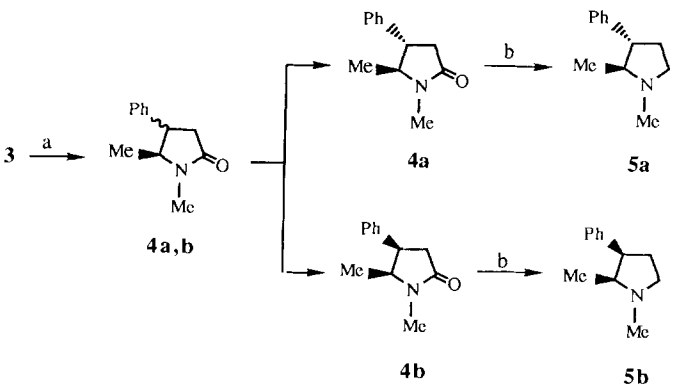
Table 1. Important physical data for **2**–**5** [a].

2: white crystals; m.p. 119–120 °C (decomp.); $[\alpha]_D^{25} = -122$ ($c = 0.52$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.42-7.29$ (m, 5H), 5.63 (s, 1H), 3.61 (q, $J = 6.9$ Hz, 1H), 3.13 (s, 3H), 1.20 (d, $J = 6.9$ Hz, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 162.3$, 157.7, 136.8, 128.6, 125.5, 80.7, 62.1, 36.1, 10.5; IR (Nujol): $\tilde{\nu} = 2935$, 2930, 2840, 2142, 1660, 1605, 1302, 1140, 735 cm^{-1}.

3: white crystals; m.p. 143–144 °C (hexane/benzene 8/2); $[\alpha]_D^{25} = +127$ ($c = 0.54$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.42$ (s, 1H), 6.35 (s, 1H), 4.51 (q, $J = 6.9$ Hz, 1H), 3.06 (s, 3H), 1.34 (d, $J = 6.9$ Hz, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 170.3$, 160.1, 131.6, 129.6, 128.8, 126.7, 120.4, 59.3, 26.7, 17.4; IR (Nujol): $\tilde{\nu} = 3060$, 2995, 2992, 2840, 1670, 1360, 895, 758, 690 cm^{-1}. MS (70 eV); m/z (%): 187 (20) [M^+], 185 (100) [$M^+ - 2H$], 157 (28) [$M^+ - 2CH_3$], 129 (52) [$M^+ - 2CH_3 - CO$].

4a: colorless oil; $[\alpha]_D^{25} = +9.5$ ($c = 0.64$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.35-7.18$ (m, 5H), 3.52 (quint, $J = 6.6$ Hz, 1H), 2.96 (dq, $J = 6.3$, 2.1 Hz, 1H), 2.85–2.77 (m, 1H), 2.84 (s, 3H), 2.57–2.48 (m, 1H), 1.25 (d, $J = 6.6$ Hz, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 173.4$, 141.4, 128.4, 127.2, 127.1, 62.9, 46.7, 38.9, 27.2, 18.4; IR (neat): $\tilde{\nu} = 2965$, 2913, 1682, 1450, 1414, 1395, 1376, 1071, 762, 703 cm^{-1}.

4b: colorless oil; $[\alpha]_D^{25} = -166.8$ ($c = 0.74$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.37-7.16$ (s, 5H), 3.86 (quint, $J = 6.6$ Hz, 1H), 3.69 (q, $J = 8.4$ Hz, 1H), 2.86 (s, 3H), 2.80–2.56 (m, 2H), 0.79 (d, $J = 6.6$ Hz, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 173.8$, 138.7, 128.4, 127.7, 126.9, 59.32, 42.3, 34.8, 27.6, 14.4; IR (neat): $\tilde{\nu} = 2968$, 2923, 1683, 1480, 1450, 1396, 1258, 755, 702 cm^{-1}.



5a: colorless oil; $[\alpha]_D^{25} = -4.4$ ($c = 0.90$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.25-7.16$ (m, 5H), 3.23 (dt, $J = 9.4$, 2.1 Hz, 1H), 2.80 (dt, $J = 9.9$, 6.9 Hz, 1H), 2.45 (dd, $J = 6.3$, 2.1 Hz, 1H), 2.40–2.29 (m, 1H), 2.33 (s, 3H), 2.14–2.05 (m, 1H), 1.87–1.77 (m, 1H), 1.03 (d, $J = 6.3$ Hz, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 144.2$, 130.1, 128.3, 127.8, 126.2, 69.9, 56.6, 52.8, 40.1, 31.4, 16.5; IR (neat): $\tilde{\nu} = 2961$, 2773, 1498, 1449, 1373, 1167, 754, 700 cm^{-1}.

5b: colorless oil; $[\alpha]_D^{25} = +15.8$ ($c = 0.72$ in $CHCl_3$); ^1H NMR ($CDCl_3$): $\delta = 7.28-7.16$ (m, 5H), 3.29–3.18 (m, 2H); 2.48–2.39 (m, 1H), 2.31 (s, 3H), 2.29–2.18 (m, 2H), 2.08–1.96 (m, 1H), 0.65 (d, $J = 6.6$ Hz, 3H); ^{13}C NMR ($CDCl_3$) $\delta = 143.8$, 138.4, 128.9, 127.8, 125.9, 64.9, 56.5, 48.4, 40.6, 31.2, 15.5.

[a] The NMR spectra were recorded at 300 MHz (^1H) and 75 MHz (^{13}C).

the absolute configurations of the stereoisomers are as shown in Scheme 3.

The analgetic activity of the 3-phenylpyrrolidines, which are analogues of Profadol and the related 3-phenyl-2-substituted pyrrolidines is well documented.[17] They can be prepared by a wide variety of methods, all affording racemates.[18] However, to our knowledge, only a single procedure for the synthesis of the homochiral (−)-*trans*-2-methyl-3-phenylpyrrolidine has been reported, based on the use of a bicyclic lactam, derived from phenylglycinol, as the chiral auxiliary.[19] Starting from enantiomerically pure **4** and **4′**, we obtained (2*S*,3*S*)-(−)- and (2*S*,3*R*)-(+)-1,2-dimethyl-3-phenyl-pyrrolidine (**5a** and **5b**), and (2*R*,3*S*)-(+)- and (2*R*,3*S*)-(−)-1,2-dimethyl-3-phenyl-pyrrolidine (**5a′** and **5b′**), respectively, by reductive cleavage with AlH_3. The absolute configurations of these 2,3-disubstituted pyrrolidines is the same as that of the parent lactams, since

Scheme 3. a) H_2, Pd/C, MeOH, followed by chromatography on silica gel (88%); b) $LiAlH_4/AlCl_3$, THF (93%).

the stereocenters present in the structure are not involved in the reductive process.

In conclusion, the (−)-ephedrine and (+)-ephedrine derivatives (−)- and (+)-6-diazooxazepane-5,7-diones **2** and **2′** can be regarded as convenient homochiral starting materials for the preparation of the four stereoisomeric 4-phenyl-5-methyl-2-pyrrolidinones and the corresponding enantiomerically pure 3-phenyl-2-methyl-pyrrolidines.

Elusiveness of Cu^{III} Complexation; Preference for Trifluoromethyl Oxidation in the Formation of $[Cu^{I}(CF_3)_4]^-$ Salts**

James P. Snyder*

1,4-Addition of organocuprates to α,β-enones is a cornerstone carbon–carbon bond-forming reaction in synthetic chemistry.[1–3] Although the mechanism of delivery of the Cu-bound moiety is not fully understood, the currently ascendent concept postulates the preliminary and reversible formation of a π-olefin complex (**1**),[4–10] transformation to a copper(III) β-adduct (**2**), and collapse to products.[7, 8, 11, 12] Skepticism about the viability of Cu^{III} intermediates has been expressed.[13] In addition, according to recent ab initio calculations using an effective core potential at copper, monoalkylcopper reagents (RCu) may add 1,4 to enones through a six-membered transition state incorporating the carbonyl oxygen atom.[14–16] By implication, copper(III) intermediates are bypassed. In this context the very recent oxidative synthesis and X-ray structure determination of stable, colorless, and presumably diamagnetic salts of the $[Cu(CF_3)_4]^-$ ion (**3**)[17, 18] along with the previously described dithiocarbamate **4**[18] are of singular importance.

1 **2**

Scheme 1.

$[Cat][Cu(CF_3)_4]$ Cat-**3**, Cat = Bu_4N, Ph_4N, $(Ph_3P)_2N$

$[Cu(CF_3)_2SC(S)NEt_2]$ **4**

The anion **3** is nearly square planar in the crystal; the four CF_3 groups are alternately located slightly above and below the mean molecular plane. The substances have been characterized as Cu^{III} salts with a d^8 configuration at the metal. The only other putative copper(III) compound with a perfluoroalkyl substituent (**4**)[18] shares with **3** a distorted square-planar structure and a pair of nearly linear CCuS bonds.

Salts of **3** have been prepared by oxidation of $Cu^{I}CF_3$. Classification of **3** as a Cu^{III} species presupposes that the metal rather than the ligand has relinquished its electrons. Let us presume the opposite, namely that oxidation has resulted in one CF_3^+ moiety in the product along with three CF_3^- units and $Cu^{I}(d^{10})$. Then, to a first approximation, $[Cu(CF_3)_4]^-$ can be considered a normal cuprate $[CF_3\text{-}Cu\text{-}CF_3]^-$ in which the copper is further coordinated to a trifluoromethyl anion and cation. Although the bonding in **3** is highly ionic, the covalent components can be illuminated by a qualitative MO correlation diagram of the ideal square-planar complex (Fig. 1). For simplicity only the Cu–C bonds are considered.

On the left side of Figure 1 four symmetry-adapted molecular orbitals are derived from the sp^3 carbon hybrid orbitals available for bonding from the four trifluoromethyl groups. The bonding and two nonbonding MOs are filled; the fully antibonding orbital is empty. On the right the copper $3d_{x^2-y^2}$ and 4s orbitals are depicted as occupied and virtual, respectively. Interaction of SS_1 orbitals of Cu(4s) and CF_3 results in the fully symmetric MO for **3** delocalized over the metal and the four trifluoromethyl groups. A second bond arises from combination of SS_2 orbitals, the metal $d_{x^2-y^2}$ orbital serving as a lone-pair donor to satisfy the electron deficiency caused by CF_3^+. Nonbonding MOs contain the third and fourth pair of electrons. The MO filling scheme implies that $[Cu(CF_3)_4]^-$ salts are associated covalently by only four bonding electrons. Further refinement of the diagram would include secondary contributions from the copper d orbitals and the fluorine atoms.

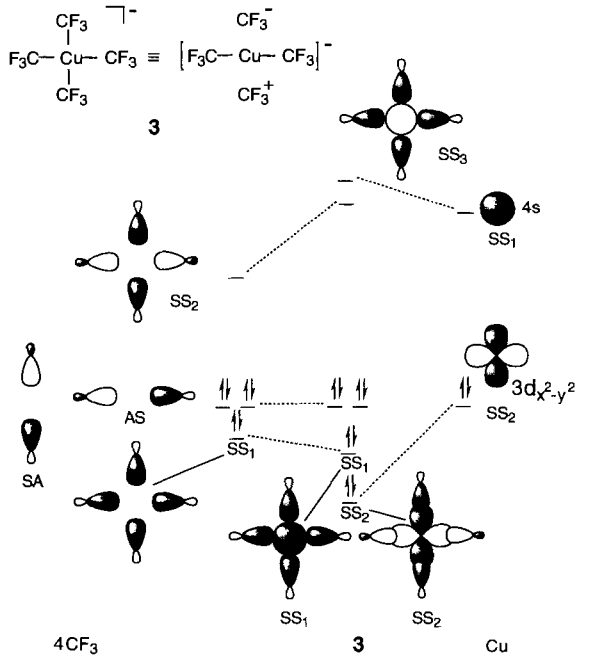

Fig. 1. Idealized MO correlation diagram for the Cu–C bonds of **3**, derived from the symmetry-adapted MOs for four C sp^3 centers (left) and Cu AOs (right). S and A designations refer to the symmetry reflected across, respectively, vertical and horizontal planes orthogonal to the plane of the paper.

In an attempt to verify this picture, calculations have been performed on the experimentally determined geometry of **3** using a 6-31G*(6d) basis set on CF_3, the Hay–Wadt effective core potential (ECP-2)[19] for the ten core electrons of copper, a double-ζ basis set for the remaining metal electrons ((9s5p5d)/[3s4p2d], split (441/2111/41)),[20, 21] and MP2 electron correlation.[22] This prescription has proved to be effective for geometries and energies of both Ti and Cu^{I} complexes.[20, 21, 23] The resulting Hartree–Fock (SCF) and correlated (MP2) wavefunctions were subsequently subjected to a natural population (NPA) and bond orbital (NBO) analysis.[27–30] To test the predicted structure in the present case, anion **3** has been optimized at the SCF level without symmetry constraints. A symmetrical structure with $r(Cu\text{–}C) = 1.967$ Å, $r(C\text{–}F) = 1.338$ and 1.343 Å, $\theta(Cu\text{-}C\text{-}F) = 113.5°$ and $\theta(C\text{-}Cu\text{-}C) = 170.0°$ results in excellent agreement with the X-ray crystal structure (e.g., $r(Cu\text{–}C) = 1.949\text{–}1.983$ Å, $\theta(C\text{-}Cu\text{-}C) = 165.0$ and 172.6°).[17]

At the experimentally determined structure of anion **3**, calculated atomic charges are high (MP2 (SCF): Cu + 0.71 (+1.1), C + 0.74 (+ 0.81), F −0.39 (− 0.44)) and Wiberg Cu–C bond orders moderate (0.29 (0.38)). A considerable degree of ionic character is further reflected by the diminutive 19% contribution of copper to the localized CuC bonding orbitals at the SCF level. It falls away altogether when MP2 correlation is included. According to NPA analysis the copper d orbitals are populated as follows: d_{xy}, d_{xz}, d_{yz}, and d_{z^2} 1.96–1.98, $d_{x^2-y^2}$ 1.77 (1.38)

[**] I am grateful to Dr. Steven Bertz (Lonza Inc.) for stimulating our interest in this problem and to Dr. Gernot Frenking (Marburg) for many helpful discussions on the use of ab initio calculations for treating copper complexes.

electrons. In addition 10.3 (9.88) electrons reside in copper's outer shells: 4s (0.53 (0.49)), 3d (9.7 (9.4)), 4p (0.04 (0.02)), 4d (0.06 (0.02)). A straightforward interpretation of the data is that copper functions as a d-base through the $3d_{x^2-y^2}$ orbital, retrieving lost electronic charge by means of backbonding to the 4s, 4p, and 3d orbitals. The analysis places 3.3 (3.1) and 7.4 (7.5) electrons at carbon and fluorine atoms, respectively. Carbon is thus depleted by +0.7 (+0.9) units of charge, while fluorine gains −0.4 (−0.5). The CF_3 groups carry 25.4 (25.5) electrons, precisely the average of three CF_3^- groups and one CF_3^+ group. Charge neutralization in anion **3** by an ammonium cation to give a contact ion-pair causes no change in the electron distribution.

Attempts were made to force the SCF wavefunction to converge on the Cu^{III} state by switching filled copper d orbitals with the LUMO, the high energy counterpart of **3**'s bonding SS_2 MO in Figure 1. The numerical experiment led to a state with 1.99–2.00 electrons in all d orbitals except d_{xy}, which had 1.1 electrons. The total energy of this state is 250 kcal mol^{-1} above the fully relaxed d_{xy} orbital with 1.97 electrons. This is consistent with the SCF result that the largely localized lone pair Cu d orbitals in **3** are 193–218 kcal mol^{-1} lower in energy than the HOMO. In the naked Cu^I monocation the same orbitals are degenerate and lie at the frontier orbital gap. An empirical argument that might be made against the interpretation of **3** as a Cu^I complex is the appearance of a quasi square-planar structure in the solid state, the common geometry for d^8 metal complexes. Though tetracoordinate d^{10} Cu^I–ligand association ordinarily produces tetrahedral structures, square-planar approximations are not unknown.[31–33]

The picture that emerges for **3** is one in which the bonding between Cu^+ and the average of $(CF_3^-)_3$ and CF_3^+ (i.e. $(CF_3^{-0.5})_4$) is principally ionic. The covalent component derived by the full calculation is in complete accord with Figure 1. Two delocalized five-center, two-electron bonds are accompanied by two nonbonding electron pairs. The description strongly implies that oxidation of $CuCF_3$ has effectively removed electrons from a CF_3 ligand, and the charge depletion is then shared equally by the four trifluoromethyl substituents in product **3**. Furthermore, the electron depletion at CF_3 depicted in Figure 1 suggests CF_3–CF_3 to be an important thermal decomposition product, as has been observed (D. Naumann and T. Roy, private communication). Similar calculations show that analogous concepts apply to **4**.[18]

The apparent willingness of a powerful electronegative moiety such as CF_3^- to undergo oxidation in preference to Cu^I underscores both the importance of the role of ligand in assessing oxidation pathways in metal complexes and the resistance of copper to assume the Cu^{III} state. The principles outlined herein can be expected to apply to the mechanism of cuprate addition as well as to contribute to a deeper understanding of other metals assigned high oxidation states in complexes.

[23] The ECP-2/MP2 combination used here provides results comparable with all-electron calculations. For Cu–F we find r(Cu–F) = 1.747 Å and μ = 5.21 D. A recent near-Hartree–Fock limit plus MP2 calculation gave 1.786 Å and 6.12 D [24] (vs. experimental values of 1.745 Å and 5.77 D [25]). For Cu–CH_3 we obtain r(Cu–C) = 1.913 Å and μ = 2.29 D. An all-electron triple-ζ optimization with correlation yielded 1.936 Å and 2.41 D, respectively [26].

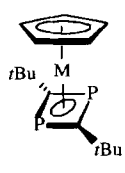
1,3,5,7-Tetraphosphabarrelene: A New Cyclic Phosphaalkyne Tetramer**



Paul Binger,* Gerald Glaser, Barbara Gabor, and Richard Mynott

The chemistry of phosphaalkynes (RC≡P) has gained considerable momentum through the use of transition-metal templates in cyclooligomerizations.[1] The cyclodimerization of *tert*-butylphosphaacetylene **5** to give the cobalt[2] and rhodium[3] η^4-1,3-diphosphacyclobutadiene complexes **1**, the unexpected formation of the tricyclic zirconium and hafnium complexes **2**

Of these metal complexes with heterocyclic ligands, only the zirconium and hafnium compounds **2** have thus far emerged as viable starting materials for the synthesis of novel phosphaheterocycles.[4b, 6] In this context, the remarkable synthesis of a symmetrical tetraphosphacubane from **2** deserves a special mention.[7] We report here the first successful cyclotetramerization of the phosphaalkyne **5** with the bis(cyclooctatetraene)–zirconium complex **4** to yield the η^4-1,3,5,7-tetraphosphabarrelene–zirconium complex **6** and the reaction of **6** with hexachloroethane to liberate the 1,3,5,7-tetraphosphabarrelene derivative **7**, a novel, cyclic tetramer of phosphaalkyne **5** (Scheme 1).

4 **6** **7**

Scheme 1. a: toluene, 2 d, 70 °C, −cot; b: pentane, 12 h, −78–20 °C, $-C_2Cl_4$, $-[(cot)ZrCl_2]$

The zirconium complex **6** was obtained as a dark green, microcrystalline solid in 81% yield after prolonged heating of **4**[8] with excess *tert*-butylphosphaacetylene **5** at 70 °C. Although we have not yet been able to grow crystals suitable for a crystal structure analysis, the structure of **6** could nevertheless be established unambiguously through spectroscopic methods (mass spectrometry; ^1H, ^{13}C, and ^{31}P NMR spectroscopy).

The mass spectrum of **6** exhibits a molecular ion peak at *m/z* 594 and a base peak at *m/z* 400 corresponding to a tetramer of **5** (Table 1). This was the first significant clue that complex **6** contained a tetramer of **5** that could be cleaved from **6** as a stable compound. In the ^{31}P NMR spectrum of **6**, three signals are observed for the four phosphorus atoms, in a ratio of 1:2:1 at $\delta = 285.3$, -113.4, and -137.6; these are assigned to the phosphorus atoms 1, 2, and 3, respectively (for the atomic numbering, see the structure formula for **6**). As a result of the very similar coupling constants ($J(P1,P2) = 8.8$, $J(P1,P3) = 7.8$ Hz), the signal for the P1 atom appears as a pseudoquartet, whereas a doublet of doublets ($J(P2,P3) = 16$ Hz) is observed for the P2 center, and a triplet of doublets for P3.

As anticipated, the ^1H NMR spectrum of **6** features three singlets for the *tert*-butyl groups in the expected region and in a ratio of 2:1:1; the protons of the η^8-bound cyclooctatetraene ligand (cot) are assigned to a singlet at $\delta = 6.89$. The ^{13}C NMR spectrum completes the structure determination for the η^4-bound 1,3,5,7-tetraphosphabarrelene in complex **6**: The four carbon atoms of the bicyclic system (C1–C3) give rise to three groups of signals. The sp^3 C atom (C3) resonates at highest field ($\delta = 37.7$). The coupling constants to the four P atoms are $J(C3,P1) = 84$ Hz (d), $J(C3,P2) = 69.6$ Hz (t), and $J(C3,P3) = 2.6$ Hz (d). As expected, the largest downfield shift to $\delta = 219.8$ is observed for the signal arising from the uncomplexed P=C bond (C1), which is split into a doublet of doublets of triplets (see Table 1). The C atoms of the π-coordinated P=C bonds (C2) give rise to a multiplet at $\delta = 76.7$, which corresponds to the X component of an ABMX system (A, B, M = ^{31}P; X = ^{13}C; $J(P1,C2)$ not detectable). A simulation of the multiplet generates a value of 56.8 Hz for $J(P2_A,P2_B)$ (for $J(C,P)$, see Table 1). The large upfield shift relative to the P=C signal in free tetraphosphabarrelene supports the presence of a strong interaction with the zirconium atom.

The η^4-bound tetraphosphabarrelene could be removed from complex **6** with the help of hexachloroethane. After the reaction mixture had been stirred for 12 h at 20 °C, **7** was obtained as a yellow microcrystalline solid in 88% yield. Compound **7** was found to be sensitive to oxidation, but surprisingly thermally stable: for example, it sublimes unchanged in vacuo above approximately 250 °C. In the absence of crystals suitable for a crystal structure analysis, the structure of **7** was determined spectroscopically. Both a correct elemental analysis and the molecular mass of 400 obtained by mass spectrometry confirm that **7** is a tetramer of **5**. Because of the symmetry of the molecule, the ^{31}P NMR spectrum shows only two sets of signals for the four P atoms in an intensity ratio of 3:1. The doublet at $\delta = 324.1$ ($J(P,P) = 13.0$ Hz) is assigned to the three equivalent phosphorus atoms of the P=C bonds, whilst the quartet at $\delta = -87.0$ corresponds to the triply coordinated P2 atom (see Table 1). Both signals lie in the expected region. The ^1H NMR spectrum of **7** contains equally few signals: two singlets are found at $\delta = 1.52$ and 2.01 in a ratio of 3:1, corresponding to the

Table 1. Selected physical data for **6** and **7** [a,b].

[a] ^1H (300 MHz, TMS), ^{13}C (75.5 MHz, TMS), ^{31}P NMR spectra (121.5 MHz, 85% H_3PO_4); **6** in [D$_8$]THF; **7** in C_6D_6; MS: Varian-CH5. [b] For numbering of the C and P atoms, see structural formulae of **6** and **7**. [c] Assignments by $^{31}P-^1H$ and $^{13}C-^1H$ correlation. [d] From simulation of the multiplets. The chemical shifts of **A** and **B** are different owing to ^{13}C isotope effects.

two distinct *tert*-butyl groups bound to C1 and C2 (see structural formula of **7** for atomic numbering). In agreement with our proposed structure, only two sets of signals are observed in the ^{13}C NMR spectrum of **7** for the four carbon atoms of the bicyclic structure: a multiplet at $\delta = 229.6$ for the three sp^2 carbon atoms (C1) and a quartet of doublets at $\delta = 102.7$ (J(C,P1) = 70.8, J(C,P2) = 7.5 Hz) for the sp^3 carbon atom (C2). The multiplet assigned to C1 is the X component of an AB_2MX spin system (A, B, M = ^{31}P; X = ^{13}C), which was likewise simulated. The chemical shifts of the *tert*-butyl signals (see Table 1) require no further explanation. Thus, the structure of **7** corresponds to that of 1,3,5,7-tetraphosphabarrelene (1,3,5,7-tetraphosphabicyclo[2.2.2]octatriene).

With the synthesis of tetraphosphabarrelene complex **6**, it has for the first time been possible to cyclotetramerize four phosphaalkyne units at a metal center. The previously known phosphaalkyne tetramers, such as, tetraphosphacubane[7] or tetraphosphatricyclooctadiene,[9] were accessed through the cycloaddition reactions of 1,3- or 1,2-diphosphets, which were in turn liberated from the corresponding metal–phosphaalkyne dimer complex (e.g., **2**). The uniformity with which the cyclotetramerization of **5** proceeds is remarkable. Comparable cyclotetramerizations of alkynes at transition-metal centers to yield barrelenes are not known, although certain metal complexes do catalyze the cyclotetramerization of alkynes to cyclooctatetraene.[10]

The question as to the pathway of this unusual tetramerization of **5** cannot be answered conclusively. A stepwise process seems plausible, with an oxidative coupling of two phosphaalkyne molecules to give the 2-zircona-1,4-diphosphacyclopentadiene **A** as the initial step. This might be followed either by a 1,2-addition of **5** to give **C** or by a [4 + 2] cycloaddition of **5** to **A** to yield **B**. Complex **6** would then be formed by a 1,2-addition of a fourth molecule of **5** to intermediate **B** and reductive elimination from **D**, or alternatively by a [4 + 2] cycloaddition of **5** to the 1,3,5-triphosphabenzene complex **E**.

Experimental Procedure

6: A solution of **4** (0.92 g, 3.1 mmol) and **5** (1.3 g, 13 mmol) in toluene (60 mL) was heated for 2 d at 70 °C. A change in color from dark violet to dark green was observed. After removal of solvent, the residue was taken up in ether (40 mL). Small amounts of insoluble material were removed by filtration through a D3 frit, and the clear solution was kept at −78 °C. After 2 d, **6** was filtered off as a dark green microcrystalline solid. Yield: 1.50 g (81%); m.p. 175 °C (decomp.).

7 from **6**: Hexachloroethane (0.47 g, 2 mmol) was added to a suspension of **6** (1.0 g, 1.68 mmol) in pentane (50 mL) at −78 °C. The mixture was allowed to warm to room temperature and was then stirred for 12 h. Insoluble [(cot)$ZrCl_2$] and excess C_2Cl_6 were filtered off, and solvent was removed from the filtrate at 0.5 mbar. The yellow-red solid residue was dissolved in ether (5 mL) and cooled to −78 °C. After 3 d, a microcrystalline yellow precipitate was filtered off and dried at 10^{-3} mbar. Yield: 538 mg (88%); m.p. 93 °C.

Oligomethylene-Bridged Vitamin B_{12} Dimers**

Bernhard Kräutler,* Tomas Dérer, Pingli Liu, Walter Mühlecker, Michael Puchberger, Karl Gruber, and Christoph Kratky*

Dedicated to Professor Karl Schlögl on the occasion of his 70th birthday

Organometallic vitamin B_{12} derivatives such as coenzyme B_{12} and methylcobalamin are cofactors of considerable biological importance either as "reversible sources of an alkyl radical"[1] or as intermediates in methyl group transfer reactions.[2] Owing to their stability in protic environment, organometallic B_{12} derivatives also hold a large potential for preparative radical reactions.[3] We report here on oligomethylene-bridged B_{12} dimers such as the tetramethylene-1,4-di-Co_β-cobalamin **D4**,[4] organometallic B_{12} derivatives of a novel structural type. Such binuclear B_{12} derivatives, which contain two thermally and photochemically labile organometallic bonds, may be considered "latent alkanediyl diradicals".[5]

In methanolic solution and under inert atmosphere 0.5 mole equivalents of 1,4-dibromobutane were added to electrochemically produced Co^I cobalamin. The color of the reaction mixture changed rapidly from green to red, indicating the alkylation of cobalt. Upon aqueous workup under exclusion of light, dark red, prismatic crystals of chromatographically uniform dimer **D4** were obtained (60% yield).

In contrast and as expected, the addition of 1,4-dibromobutane in about a hundredfold excess and under inert atmosphere to electrochemically produced Co^I cobalamin led to the almost exclusive formation of monomeric Co_β-4-bromobutylcobalamin **M4**. After crystallization, **M4** was isolated in about 80% yield.[6] Use of homologous 1,5-dibromopentane and 1,6-dibromohexane, but not of 1,3-dibromopropane,[7] resulted in analogous organometallic B_{12} dimers (**D5** in 75% yield, **D6** in 78% yield).

Characteristic UV/Vis and CD spectra of the dimers **D4**–**D6** as well as of the monomer **M4** indicated the presence of organometallic B_{12} derivatives with only weak interactions between the chromophores of the dimer moieties. In the FAB mass spectra (besides signals of fragments) the diagnostic signals of the respective molecule ions were observed (in the case of **D4** at $m/z = 2714$).

Owing to the effective C_2 symmetry of the dimers **D4**–**D6**, the number of signals of chemically inequivalent protons in the ^1H NMR spectra was reduced (Fig. 1). The NMR spectroscopic analysis of dimer **D4** by means of homonuclear (DQF-COSY and ROESY) and heteronuclear correlations (HMQC and HMBC spectra)[8] allowed complete assignment of the ^1H and ^{13}C signals; for example, the signals at high field were attributed to the protons of the cobalt-bound alkanediyl chain (four broad signals at $\delta = -0.50$ [H_a(A2)], -0.04 [H_b(A2)], 0.20 [H_a(A1)], and 0.97 [H_b(A1)]). The observation of NOE effects between groups bonded on the *endo* side of the hydrocarbon-bridged cobalamin halves of **D4** (for example, between the singlet at $\delta = 1.23$ [CH_3(17B)] and the signals at $\delta = 2.56$ [s, $CH_3(5^1)$] and $\delta = 1.85/2.20$ [AB system, $CH_2(7^1)$]), indicated spatial prox-

[**] We would like to thank Dr. E. Hoffmann (Varian, Darmstadt, Germany) and Dr. D. Moskau (Bruker-Spektrospin, Fällanden, Switzerland) for measuring the 500 MHz ^1H NMR spectra, Dr. W. Amrein and R. Häfliger (ETH, Zürich) for the FAB mass spectra, and H. Hediger and R. Dohner (ETH, Zürich) for recording the CD spectra. This work was supported financially by the Swiss National Science Foundation (Proj.-Nr. 20.29850.90) and by the Austrian National Science Foundation FWF (Proj.-Nr. P-9334 and P-9542). – FAB = fast atom bombardment, CD = circular dichroism, NOE = nuclear Overhauser enhancement, NOBA = *ortho*-nitrobenzyl alcohol.

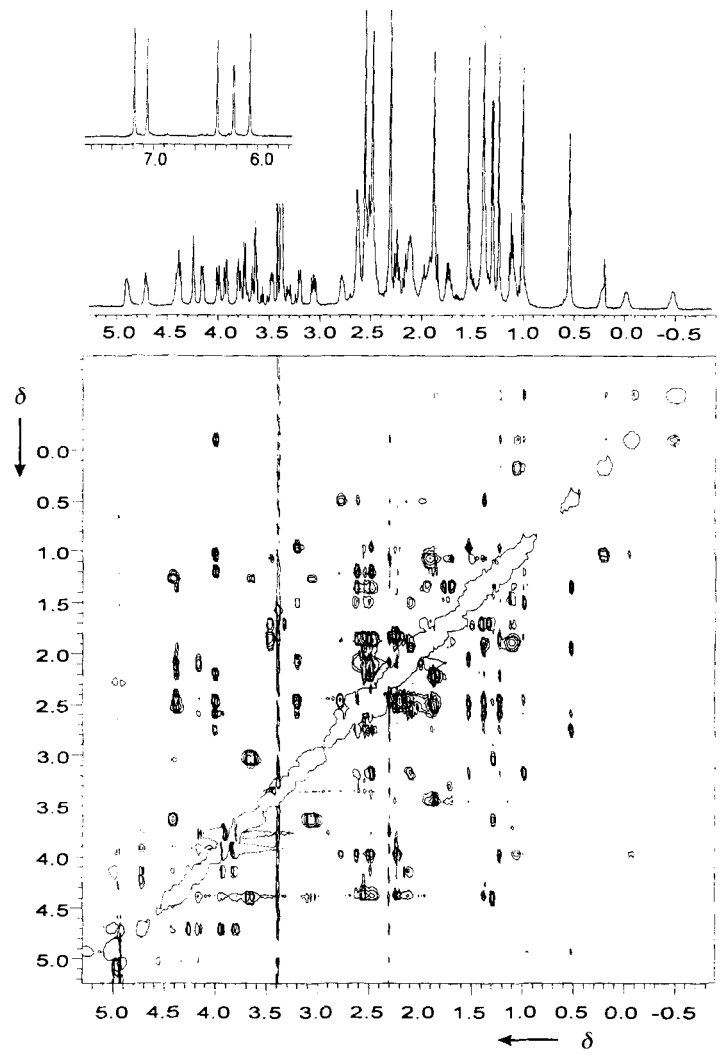

Fig. 1. Top: 500 MHz ^{1}H NMR spectrum of **D4** in CD_3OD; bottom: ROESY spectrum of **D4** in CD_3OD (see text and Table 1 for further details).

imity of these groups in **D4** (Fig. 1, bottom) due to the tetramethylene bridge.

The X-ray analysis of a single crystal of **D4** confirmed the spectroscopically deduced constitution and configuration of this dimer, as well as its effective C_2-symmetric conformation (Fig. 2).[9] The structure of the cobalamin moieties of **D4** is similar to that of monomeric, organometallic B_{12} derivatives. The ligand planes of the two cobalamin halves of **D4** are almost parallel (tilt of 2.3°). The corrin ligands form a torsional angle of about 27° with respect to the cobalt–cobalt axis, which is close to perpendicular with respect to the ligand planes. This arrangement results in a rather tight packing of the two substituted corrin units without any noticeable buildup of strain on the *endo* side. Indeed, the folding[10a] of the corrin ligands in **D4** amounts to 16.5° and is practically identical to that of methylcobalamin.[10b]

The tetramethylene chain that bridges the two cobalt centers at a distance of 6.95 Å is shielded laterally by the corrin substituents located on the *endo* side. The tetramethylene chain occurs in a close-to-staggered conformation. The two terminal C–Co bonds are both 2.00 Å long and positioned antiperiplanar with respect to the central C(A2)–C(A2′) bond. The torsion angle with respect to the latter bond amounts to 50(2)°, such that in this open-chain system an unusual synclinal conformation is observed.

Exploratory thermolytic investigations provided no hint of possible strain that might accelerate the decomposition of **D4**. This dimer decomposed five and eight times slower than its homologues **D5** and **D6**, respectively,[11] when heated at 110°C in oxygen-free ethylene glycol solution. Under these conditions the dimers **D5** and **D6** decomposed into Co^{II} cobalamin (UV/Vis) and cyclopentane or cyclohexane, respectively (^{1}H NMR). Photolysis of **D5** (oxygen-free aqueous solution, room temperature) also led to cyclopentane (^{1}H NMR, GC/MS) and Co^{II} cobalamin (UV/Vis).[12] Formation of cycloalkanes from the penta- and hexamethylene bridges of **D5** and **D6**, respectively, most probably proceeds by a yet-undocumented, but thermodynamically favorable route leading to the formation of a C–C bond by homolytic substitution: It results from the attack of an alkyl radical at the saturated carbon center of the metal-bonded alkyl ligand and occurs with simultaneous loss of a Co^{II} corrin.

Dinuclear hydrocarbon-bridged complexes often display unusual reactivities.[5, 13] The bridging tetramethylene ligand of the dimer **D4** appears to be conformationally strained as a result of its constitution and of intramolecular packing effects. In **D4** a remarkable situation therefore exists that may model possible mechanisms of enzyme activation.[1, 14]

Oligomethylene-bridged B_{12} dimers such as **D5** and **D6** may also allow the study of the formation of C–C bonds by reactions between alkyl radical and saturated organometallic functions, a subject that appears to be of interest from mechanistic and biological points of view.[15] Under mild conditions and in aqueous media **D5** and **D6** provide easy access to an extraordinary range of radical chemistry. Indeed, homolysis of the two C–Co bonds of such dimers can be initiated thermally and with

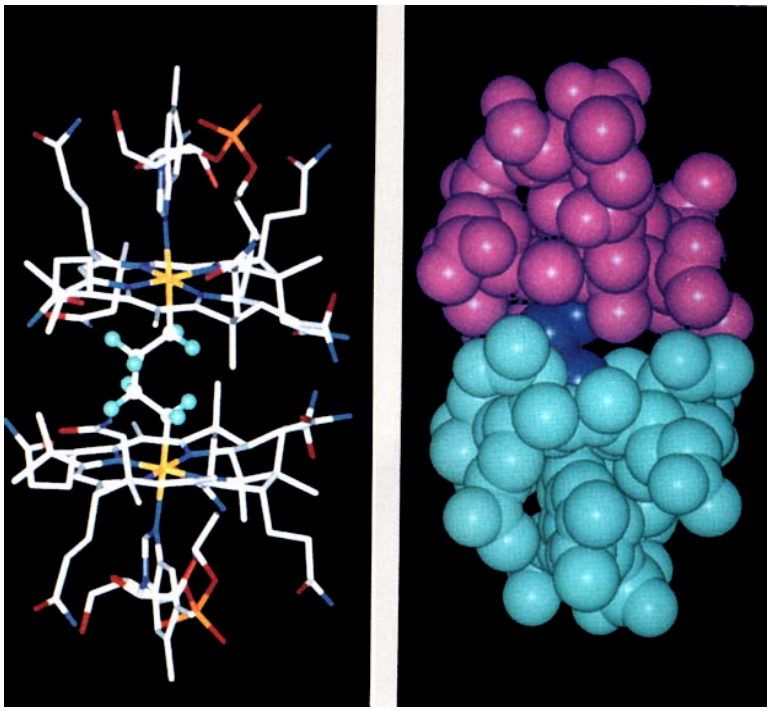

Fig. 2. Crystal structure of the dimer **D4** [9]. Left: ball-and-stick model; right: space-filling model.

visible light, and (formally) releases two organic radical centers. Depending on the sequence of homolysis events (either stepwise or synchronous), the oligomethylene bridge leads either to an (intermediate) organometallic alkyl radical or to a (1,ω)-alkyl diradical.

Experimental Procedure

D4: Under inert gas (glovebox, <10 ppm O_2), aquocobalamin chloride (100 mg, 7.23×10^{-5} mol; Roussel Uclaf apyrogene) was dissolved in 4 mL of a 0.1 M solution of tetrabutylammonium hexafluorophosphate in methanol and reduced with stirring at a mercury cathode (-1.1 V versus 0.1 V calomel electrode; residual current: approximately 0.05 mA). The solution then contained Co^I cobalamin (UV/Vis). It was protected from light and 1,4-dibromobutane (4.3 µL, 0.5 mol equiv) was added. The reaction mixture was reduced further at -1.0 V (total consumption: 16.5 C versus 14.0 C in theory). Under protection from light, the solution was added to 20 mL of distilled water and extracted with three portions of 20 mL of methylene chloride. The dark red, aqueous phase was then concentrated. Dimer **D4** crystallized at 0–5 °C from concentrated, aqueous solutions to give 58.5 mg of **D4** (60% yield).

D5 was prepared in analogy to **D4** with 0.5 equivalents of 1,5-dibromopentane. Crystallization from water/acetone yielded 74 mg (75.5%) of **D5**.

D6 was prepared in analogy to **D4** with 0.5 equivalents of 1,6-dibromohexane. Crystallization from water/acetone yielded 78 mg (78.5%) of **D6**.

M4 was prepared in analogy to **D4**, except for the addition of 100 equivalents of 1,4-dibromobutane at the beginning of the electrochemical reduction at -1.0 V. The yield of **M4** obtained from water/acetone was 83.5 mg (79%).

A Highly Symmetric Sixfold Cycloaddition Product of Fullerene C_{60}**

Bernhard Kräutler* and Josef Maynollo

Fullerenes[1] provide fascinating carbon skeletons for endo- and exohedral chemical modifications.[2, 3] Owing to their spherical structure of regularly arranged, unsaturated carbon centers, they are functionalizable in three dimensions. In recent years an increasing number of fullerene derivatives, monofunctionalized on the *exo* surface, have been produced on a preparative scale.[3, 4] A complication in the synthesis of multiple addition products at the fullerene skeleton has been the problem of regioselectivity.[5, 6] For organometallic fullerene derivatives the production and characterization of specific (often thermally labile and oxygen-sensitive) twofold and sixfold adducts have been achieved.[7]

We have been exploring Diels–Alder reactions[4] of fullerenes and report on a hydrocarbon compound with unusual symmetry properties that can be produced through a remarkably regioselective sixfold [4 + 2] cycloaddition of a 1,3-diene to fullerene C_{60}.

When an Ar_2-saturated solution of fullerene C_{60} (**1**) and an excess of 2,3-dimethyl-1,3-butadiene (**2**) in 1,2-dichlorobenzene was heated for several days under protection from light, a change of color from reddish purple to brown and, eventually, to light red-orange could be observed. Besides several other, colored products[8] in the reaction mixture, the almost colorless hexaaddition product **3** was found.[9] The mixture was separated by column chromatography (silica gel). A uniform sample of the hexaaddition product **3** was isolated in 26% yield, and its structure was secured by spectroscopic means.

The ^1H NMR spectrum ($CDCl_3$) of **3** shows only two singlets, at $\delta = 1.85$ and 2.90, due to its twelve symmetry-equivalent methyl and methylene groups.[10] The ^{13}C NMR spectrum **3** consists of only six signals: three signals at $\delta = 19.1$, 45.7, and 129.0, each for the set of twelve symmetry-equivalent carbon atoms of the six [2]buteno bridges, and three signals at $\delta = 60.1$, 142.0, and 152.0, due to twelve (twenty-four) symmetry-equivalent, saturated (unsaturated) fullerene carbon centers.[10] The C,C connectivity in **3** was deduced from C,H long-range correlations observed in the HMBC spectrum (HMBC = heteronuclear multiple bond correlation).[11] In the UV/Vis spectrum of **3** absorption bands in the visible range characteristic of fullerenes do not appear. This finding is consistent with the high degree of deconjugation of the unsaturated carbon skeleton in **3**. The absorption maximum at longest wavelength of a solution of **3** appears in the UV region at $\lambda = 348$ nm ($\lg \varepsilon = 3.87$). The positive-ion FAB mass spectrum of **3** shows a base peak at $m/z = 720$ (C_{60}^+) and signals at $m/z = 1213.5$ (6%, M^+) and 1212.5 (8%), as well as weaker signals at $m/z = 1131$, 1048, 966, 884, and 802, due to fragments from sequential loss of the butadiene addends of **3**.

The extraordinary high effective symmetry of **3** (T_h)[10] results from a sixfold Diels–Alder reaction of the 1,3-diene **2** at the six symmetry-equivalent "6-6 bonds" located between the six-membered rings of fullerene C_{60} (**1**). Whether the remarkable regiocontrol observed in the multiple Diels–Alder reaction with **1** (average effective selectivity >80% for each addition step)[12] results from thermodynamic or kinetic factors, remains to be investigated. Unlike the organometallic multiple adducts, which were reported to be thermally labile and extremely sensitive to oxidation in solution,[7] a solution of **3** stored under N_2 for twelve hours at room temperature showed no sign of decomposition according to its ^1H NMR spectrum.

The partial saturation of the carbon skeleton of the fullerene through sixfold addition results in a chromophore structure of eight completely symmetry-equivalent, strained benzene rings, each of them bridged six times. Therefore, **3** is apparently a new type of multiply bridged cyclophane.[13]

The framework of **3** shows two basic constitutional patterns, which, as far as hydrocarbons are concerned, represent a previously unknown superposition[14] of two basic, platonic bodies: the [2]buteno bridges of **3** span the network of an octahedron and the cyclically conjugated six-membered rings, that of a cube (Fig. 1).

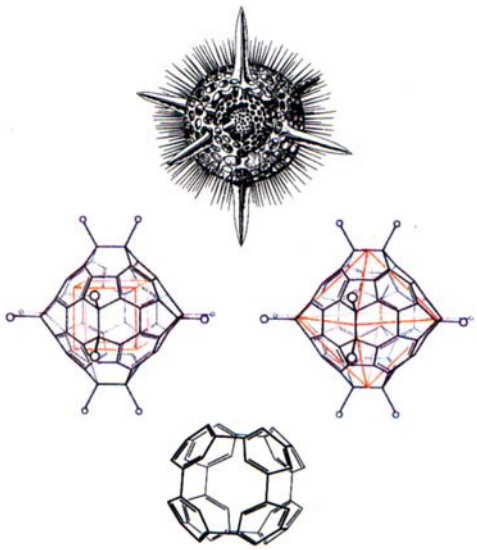

Fig. 1. Skeletal structure of the radiolarian *Hexacontium asteracanthion* (top, according to Haeckel, ref. [15]); superposition of the framework of T_h-symmetric hexaadducts (such as **3**) with a cube (middle left) and with an octahedron (middle right); structure of the residual chromophore in **3** (bottom).

The carbon skeleton of the fullerenes provides a unique basis for the formation of a great variety of molecular structures with spherical cores.[3–7] Through exohedral, covalent modification, new carbon compounds can be produced whose variety of forms and frameworks can be modeled after the (natural) structures of the silicate skeletons of radiolaria.[15] Accordingly, partially unsaturated carbon compounds such as **3** with spherical cores

derived from fullerenes through multiple, exohedral functionalization might be classified generally as "radiolarenes".

Hexaadduct **3** is an unusual hydrocarbon in many respects; its new, highly strained, multiply bridged 1,2,3,4,5,6-cyclophane structure can be constructed through "conventional" Diels–Alder reactions[4a] thanks to the high degree of strain[16] already existing in the fullerene unit.

Experimental Procedure

In a gas-tight ampule protected from light, fullerene C_{60} [4a] (**1**; 20.0 mg, 2.77×10^{-2} mol), 2,3-dimethyl-1,3-butadiene (**2**; 2.28 g, 2.77×10^{-2} mol), and hydroquinone (6.1 mg, 5.54×10^{-5} mol) [17] were dissolved in 0.5 mL of *o*-dichlorobenzene and deoxygenated by three freeze-pump-thaw cycles. The reaction mixture was then saturated with Ar and heated for 234 h at 110 °C. The reaction mixture was cooled, concentrated under vacuum (maximum temperature 35 °C), and purified by column chromatography under inert gas (silica gel, hexane/CH_2Cl_2 9:1) to give a colorless and chromatographically uniform sample of the hexaaddition product **3** besides other products. After filtration through cotton wool, addition of cyclohexane, evaporation of the solvent, and drying under high vacuum, 8.8 mg of the slightly yellow hexaaddition product **3** was obtained (7.25×10^{-6} mol, 26%). Light yellow solid, m.p. > 275 °C (decomp); ^{1}H NMR (200 MHz, $CDCl_3$, 30 °C): δ = 1.85 (s, 3*n*H), 2.90 (s, 2*n*H); ^{13}C NMR (125.7 MHz, $CDCl_3$, 30 °C): δ = 19.1, 45.7, 60.1, 129.0, 142.0, 152.0; UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 290.5 (4.21), 308 sh (4.13), 348 (3.87) nm; IR($CDCl_3$): ν = 2874, 2854, 1722, 1672, 1441, 1379, 1261, 1099, 1024 cm^{-1}; Positive-ion FAB-MS (NOBA matrix): *m/z* (%): 1214 (7.5), 1213(5.9), 1212(8.5) [1212.471, M^+, calculated for $C_{69}H_{60}$: 1212.468], 1048 (3.7) [$M^+ - C_{12}H_{20}$], 967 (4.3) [$M^+ - C_{18}H_{30}$], 884 (5.7) [$M^+ - C_{24}H_{40}$], 802 (11.7) [$M^+ - C_{30}H_{50}$], 720 (100) [C_{60}^+].

R. Karfunkel *J. Am. Chem. Soc.* **1994**, *116*, 9385.

[8] According to NMR and FAB mass spectra of incompletely separated samples, they were actually twofold to fivefold addition products of **1** and **2**.

[9] According to the nomenclature for **1** suggested in Chemical Abstracts (cf. *Chem. Abstr.* **1993**, *119*, 4461CS and *ibid.* **1992**, *116*, Index Guide, 155I), hexaadduct **3** should be named 1,9;16,17; 30,31;21,40;44,45;52,60-hexa-(2,3-dimethyl-[2]buteno)-1,9,16,17,30, 31,21,40,44,45,52,60-dodecahydro-[5,6]fullerene-C_{60}.

[10] The room-temperature NMR spectra of **3** are compatible with an effective T_h symmetry.

[11] A. Bax, M. F. J. Summers, *J. Am. Chem. Soc.* **1986**, *108*, 2093; b) cf. H. Kessler, M. Gehrke, C. Griesinger, *Angew. Chem.* **1988**, *100*, 507; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 490.

[12] The formation of **3** corroborates previous findings [3e,4,6] on the considerable selectivity of [4 + 2] cycloadditions at **1** at one of the thirty 6-6 bonds. Notwithstanding this rule, synthesis of **3** from **1** supposes a high effective regioselectivity: indeed, of the eight possible, constitutionally isomeric bisadducts, no more than two (which might be qualified as "antipodal" and "orthogonal") actually lead to the formation of **3** via three out of 46 possible regioisomeric trisadducts. Besides, the formation of **3** can only be achieved via one particular route out of 25 routes for the sixth addition of diene **2** to the constitutionally correct pentaadduct.

Photoswitchable Phase Separation in Hydrophobically Modified Poly(acrylamide)/Surfactant Systems**

Jochem J. Effing and Jan C. T. Kwak*

Self-assembling systems have been the subject of increasing interest in recent years. In aqueous systems typical building blocks for supramolecular structures are surfactants or more generally amphiphilic molecules. The self-organizing properties of these amphiphiles can be can be influenced externally by incorporating functionalities into the molecules (eg., photoactive[1] or redoxactive groups[2]). The interactions between polymers and surfactants in aqueous solutions lead to the formation of complexes with special physical properties. The resulting systems are of interest in various fields like detergency, drug delivery, and enhancement of oil recovery.[3] Of special interest are hydrophobically modified polymers that allow the strength of the hydrophobic interaction between polymer and surfactant and the structure of the complexes to be tailored to different applications.

We have recently reported evidence for an associative phase separation in a mixture of hydrophobically modified poly(acrylamide) (HPAM) and sodium dodecylsulfate (SDS).[4] The polymer was a copolymer of acrylamide and *N*-decylacrylamide with a hydrophobic monomer content of 2 mol%. Phase separation is induced by the addition of salt (Na_2SO_4); the two-phase region occurs at lower temperature. Both gel phase and supernatant phase contain surfactant and polymer. In this paper we report unusual, light-induced phase separation for aqueous polymer/surfactant systems where the polymer incorporates monomers with azobenzene groups. The idea to incorporate an azobenzene moiety as the hydrophobic side group into the poly(acrylamide)s was initiated by both the work of Shinkai et al. on photoactive surfactants[5] and of Irie et al. on the solubility properties of azobenzene-containing polymers.[6] The *trans–cis* isomerization of the chromophore results in a large change in its geometry and polarity, and therefore leads to a different strength of interaction between polymer and surfactant, which influences the phase behavior of the mixtures. Such light-induced phase separations open interesting possibilities for the design of materials (including optical switches, electrorheological fluids, etc.) with either linear or cross-linked polymers.

The hydrophobically modified poly(acrylamide)s were prepared by radical copolymerization of acrylamide and 4-acrylamidoazobenzene (2 mol% with respect to acrylamide) at 60 °C in *tert*-butylalcohol or dimethyl sulfoxide (DMSO). The initiator azobis(isobutyronitrile) (AIBN) was used in a concentration of 0.5 mol% with respect to acrylamide.[7] The composition of the copolymers was determined by UV/Vis spectroscopy.[8] For the polymer in *tert*-butylalcohol a degree of substitution of 1.2 mol% was obtained, whereas in the DMSO polymerization only 0.9 mol% azobenzene monomer was incorporated. The intrinsic viscosity (in DMSO) and thereby the molecular weight of the copolymer polymerized in DMSO is higher than the polymer obtained in *tert*-butylalcohol. The latter copolymer will be called PAM-Azo-1.2, and the former PAM-Azo-0.9.

Mixtures of ionic surfactants and these new copolymers show the same type of phase behavior as the alkyl substituted poly(acrylamide)s.[4] Figure 1 shows a series of plots of the transition (clearing) temperatures for 1 wt% solutions of PAM-Azo-0.9 and PAM-Azo-1.2 (from the two-phase region at lower temperature to the one-phase region) versus SDS concentration at different Na_2SO_4 concentrations. In the case of mixtures of the lower molecular weight PAM-Azo-1.2 with SDS, phase separation at room temperature was only observed at Na_2SO_4 concentrations above 0.4 M. For the PAM-Azo-0.9 polymer, phase separation in the presence of SDS was already observed over a small surfactant concentration range with 0.07 M Na_2SO_4 and transition temperatures to the one-phase region of 23–25 °C. With increasing salt concentration, the transition temperatures increased and the surfactant concentration range at which phase separation took place broadened. The transition temperatures for the PAM-Azo-0.9/SDS mixtures at salt concentration of 0.5 M were significantly higher than for PAM-Azo-1.2. In addition, the transition temperatures for PAM-Azo-0.9 reached their highest values at approximately half the SDS concentration relative to PAM-Azo-1.2, and the maximum was much more pronounced. The concentration range over which a two-phase region existed was, on the other hand, comparable for both polymers. The higher transition temperatures for PAM-Azo-0.9 mixtures may be a result of its higher molecular weight compared to that of the polymer formed in *tert*-butylalcohol, whereas the lower SDS concentration at which the maximum in the clearing temperature occurs may be related to the lower degree of substition with hydrophobic azobenzene units. For both polymers, phase separation was also observed in a mixture with the cationic surfactant tetradecyltrimethylammonium bromide (TTAB) when $MgSO_4$ was added, whereas only the higher molecular weight PAM-Azo-0.9 exhibited a two-phase region with TTAB in the presence of 0.5 M Na_2SO_4. Complete phase-diagram studies on these systems are in progress.

The dramatic effect on phase separation of irradiation, which leads to *trans–cis* isomerization of the azobenzene side groups, is shown in Figure 2. The phase-separated systems before irradiation are depicted on the left, and the one-phase systems after irradiation at 350 nm on the right.[9] The top system is composed of PAM-Azo-1.2 (3 wt%), SDS (32 mM), and Na_2SO_4 (0.5 M); the bottom system contains PAM-Azo-0.9 (1 wt%) in a solution of TTAB (4.5 mM) and $MgSO_4$ (0.5 M). It is important to note that this light-induced phase transition is fully reversible,

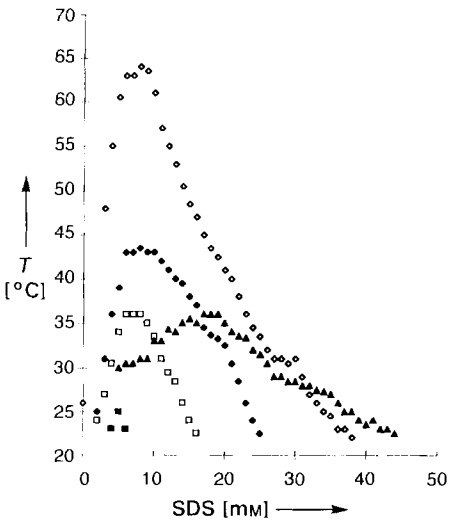

Fig. 1. Plot of the transition temperatures from the two-phase to the one-phase region for PAM-Azo-0.9 and PAM-Azo-1.2 as a function of SDS concentration at different Na_2SO_4 concentrations: PAM-Azo-0.9: ■ = 0.07 M, □ = 0.1 M, ● = 0.2 M, ○ = 0.5 M Na_2SO_4; PAM-Azo-1.2: ▲ = 0.5 M Na_2SO_4; the polymer concentration is 1 wt%.

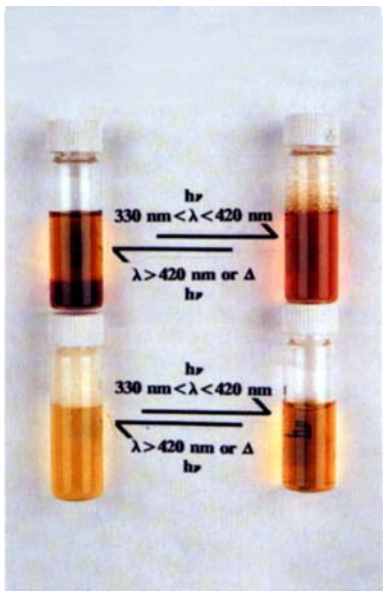

Fig. 2. Reversible transition from two-phase systems to one-phase systems on irradiation at 25 °C. Top: 3 wt% PAM-Azo-1.2, 32 mM SDS, and 0.5 M Na_2SO_4; bottom: 1 wt% PAM-Azo-0.9, 4.5 mM TTAB, and 0.5 M $MgSO_4$.

and can be repeated indefinitely. To our knowledge this is the first time that such a phenomenon has been reported for polymer/surfactant assemblies.

The binding of the surfactant molecules to the copolymers and the influence of the *trans–cis* isomerization on the strength of the hydrophobic interaction can be monitored by ^{1}H NMR spectroscopy. On binding to the azobenzene moieties, the surfactant proton peaks experience a chemical shift induced by an aromatic ring current. Figure 3 shows the changes in the chemical shifts of the methylene protons at positions 3–11 in the case of SDS and 3–13 in the case of TTAB (position 1 is defined as the carbon directly attached to the sulfate or ammonium group, respectively) in the presence of 1.5 wt% PAM-Azo-1.2 at 25 °C. Already at low concentrations (0.4 mM), the surfactants bind to the copolymer; this leads to initial chemical shift differences of $\Delta\delta = 0.23$ for SDS and $\Delta\delta = 0.13$ for TTAB. With increasing surfactant concentration, the changes become smaller as a result of the increasing ratio of bound surfactant to azobenzene moieties until the hydrophobic azobenzene groups are saturated. The concentration of free surfactant molecules then increases. For TTAB $\Delta\delta$ is already 0 at concentrations of 10–12 mM, whereas $\Delta\delta$ is still 0.07 for SDS even at 20 mM.

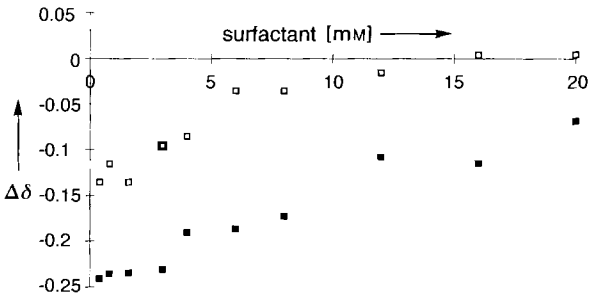

Fig. 3. Changes in ^{1}H NMR chemical shifts of SDS (methylene protons at positions 3–11) and of TTAB (methylene protons at positions 3–13) at 25 °C. ■ = SDS; □ = TTAB; $\Delta\delta = \delta$(in 1.5 wt% PAM-Azo-1.2) $- \delta$(in water).

That the binding of the surfactants is weakened if not suppressed by converting the *trans* azobenzene into its *cis* isomer can be seen from the ^{1}H NMR spectra (Fig. 4) of PAM-Azo-1.2/surfactant mixtures (0.5 wt% polymer in 2 mM surfactant solutions) before (bottom spectrum) and after (middle spectrum) irradiation of the samples at 350 nm. For comparison the spectra of the free surfactants (2 mM solutions) are also shown (top spectrum). Upon irradiation the chemical shifts of the surfactant protons move towards the values for the free surfactants and sharpen up, as can be seen most clearly for the α protons at $\delta = 3.93$ (SDS) and 3.17 (TTAB). In the case of TTAB, the peak at $\delta = 1.117$ splits upon *trans* to *cis* isomerization, so that the peak of the γ protons (at C-3) is well separated ($\delta = 1.219$) from the peak of the methylene protons at positions 4–13 ($\delta = 1.147$).

In conclusion, we have shown that light-switchable phase transitions can be obtained in polymer/surfactant systems containing azobenzene-modified poly(acrylamide)s. These hydrophobically modified polymers undergo an associative phase separation in mixtures with SDS and TTAB in the presence of salt when the azobenzene moiety is in the *trans* form. On isomerization to the *cis* form, the two-phase system clears to a single phase.

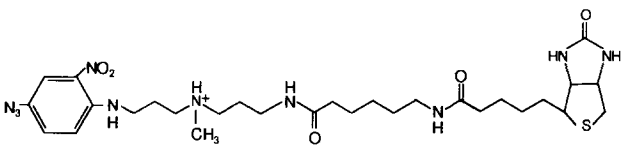
[7] In *tert*-butylalcohol the copolymer precipitated during the polymerization. After 8 h reaction time the solutions were cooled down, and the polymer filtered off. In the case of the DMSO reaction, the polymer was first precipitated in ethanol. In order to remove residual monomer from the polymer, the precipitates were each stirred in acetone for 12 h and then filtered. This process was repeated three times. Before use the copolymers were freeze-dried from an aqueous solution.
[8] For calibration we synthesized the model compound 4-propionamidoazobenzene, which has a UV absorption spectrum identical to that of the copolymer. Assuming that the extinction coefficient of the model compound and polymer bound chromophore are identical, we set up a calibration curve with the help of the model compound.
[9] A Spectroline Miniature UV Quartz Pencil Lamp (Type 36-380) was used for the irradiation. The lamp emits light from 310 to 410 nm with maxima at 350 nm (0.78 μWcm^{-2}nm^{-1}) and 365 nm (1 μWcm^{-2}nm^{-1}).



Micron-Scale Patterning of Biological Molecules**

David John Pritchard, Hywel Morgan*, and Jonathan Mark Cooper*

Techniques for controlling the architecture of immobilized biomolecular films on surfaces have a wide range of potential applications in biosensing, cell guidance, and molecular electronics. Previously, films with a predetermined molecular composition in the z direction have been produced by, for example, either Langmuir-Blodgett technology or self-assembly.[1] To date, however, it has not been possible to selectively pattern more than one type of biological molecule on the x,y plane of a surface, although Fodor et al. have synthesized multiple arrays of different oligopeptides or oligonucleotides on glass surfaces.[2] We describe here for the first time a method for patterning two or more functional proteins on a surface whilst minimizing nonspecific binding (NSB). Such a technology is important in the development of multianalyte microsensors, and we illustrate a possible application by immobilizing antibodies.

At present, patterning of molecules may be performed by using photolithographic procedures with lift-off,[3] methods that are not appropriate for biologically active molecules. Alternatively, photoactivation or photodeactivation of surface-bound coupling molecules has been used for immobilizing proteins on surfaces (e.g., with organosilanes or aryl azides).[3-6] These approaches have not, however, been used for immobilization of more than one type of functional molecule.[2-6]

We show in this paper that it is possible to selectively attach different biological molecules in precise areas of a surface by using a combination of self-assembly and photactivation. The method is based on the interaction between streptavidin (or a deglycosylated form of avidin, avidin D) and the analogue **1** (counterion: citrate) of the ligand biotin, which is functionalized with a photoactive group and is thus referred to as a photobiotin (obtained from Vector Laboratories, Peterborough, UK).

1

Photobiotin was first developed as a nucleic acid hybridization probe,[7] and has also been used to label proteins.[8] It has a terminal aryl azide group, which is stable in the dark, but forms a reactive aryl nitrene group upon exposure to light (340–375 nm) with the potential to bind an organic species.[9] The photobiotin molecule used in this study incorporates a spacer arm to minimize steric hindrance to binding. By combining the NSB properties of avidin D with the activation of photobiotin, we are able to produce discrete molecular patterning in the plane of a molecular film.

[**] This work was supported by Biotechnology and Biological Sciences Research Council (BBSRC) (Grant No GR/H31967).

The immobilization procedure is represented by Figure 1 and involves the modification of a surface with avidin D, followed by the binding of photobiotin **1** to provide a matrix onto which molecules can be "written" by means of light and a mask.

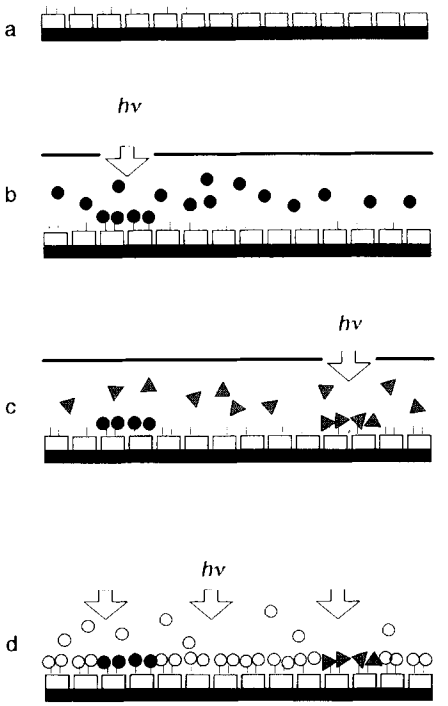

Fig. 1. A schematic representation of the immobilization procedure: a) avidin D (□) with photobiotin **1** (|) immobilized onto a surface; b) exposure of selected areas to light through a mask results in activation of the photobiotin molecule, and a protein (●) in the solution is immobilized specifically; c) unbound material is removed by washing, and the procedure repeated with a second protein (▲); d) the entire surface is exposed to light and unreacted photobiotin is blocked with casein (○).

Protein can be immobilized onto both gold and SiO_2 by this method. In the case of gold, the surface was first modified with a thiol monolayer, onto which avidin D was bound by means of a carbodiimide coupling agent. Alternatively, avidin could be immobilized onto SiO_2 by using a suitable silanization procedure and a protein coupling reagent. In either case, the avidin-modified surface was incubated in a solution of photobiotin (Fig. 1a), and selected areas of this surface were exposed to light, resulting in the activation of the photobiotin molecule. The aryl nitrene which was formed reacted with any protein present in solution and thus immobilized it onto the surface (Fig. 1b).

Patterns were "written" by exposing the surface to light through a mask in the presence of a second protein (Fig. 1c) or, further, with a *sequence* of proteins. After patterning, all unreacted photobiotin groups were neutralized by exposing the whole surface to light in the presence of a blocking molecule such as casein (Fig. 1d). The technique has the advantage that any protein that is not immobilized can be recovered, unaltered.

Biomolecular patterns were written by these techniques. The fluorescent micrographs of two proteins, rabbit IgG and rat IgG, coupled to SiO_2 are presented in Figure 2. These proteins were immobilized onto the surface, which was then exposed to goat anti-rabbit IgG labeled with tetramethylrhodamine isothiocyanate (TRITC) and rabbit anti-rat labeled with IgG fluorescein isothiocyanate (FITC), and the pattern was thus developed. Figure 2 shows that both antibodies are only immobilized onto the surface where the photobiotin had been exposed to light. The resolution of the lithographic patterning technique is limit-

Fig. 2. A photograph of SiO_2 patterned with two fluorescently labeled antibodies. The antibodies were immobilized by the photoactivation procedure described previously. Red fluorescence indicates the presence of bound rabbit IgG, and green fluorescence the presence of bound rat IgG. The lines are 10 μm wide separated by 10 μm gaps. Black areas indicate minimal nonspecific binding of antibodies. The length of the bar represents 10 μm.

ed by diffraction of light. This effect is exaggerated, since the mask is not in direct contact with the SiO_2, but is separated by a film of buffered protein solution, estimated to be 1 μm thick. Nevertheless, Figure 3 shows that 1.5 μm lines can be written by using a TRITC-labeled IgG. It should be noted that in Figure 2 the TRITC lines are less red than in Figure 3 owing to the fact that a double exposure (TRITC and FITC filters) was needed to obtain the former. This color change is not due to NSB of the FITC probe, as it occurs in the absence of the FITC label.

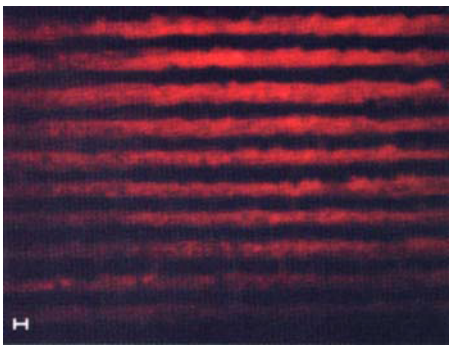

Fig. 3. Photograph of SiO_2 patterned with TRITC-labeled IgG. This illustrates the resolution obtainable with this technique. The lines are 1.5 μm wide separated by 1.5 μm gaps, and were written with a 1.5 μm mark-space mask. The length of the bar represents 1 μm.

Nonspecific binding of antibodies to other regions of the SiO_2 surface was not detectable by fluorescence microscopy. It was, however, possible to use a sensitive electrochemical assay for IgG labeled with an alkaline phosphatase (ALP) to estimate the size of NSB effects on a modified gold surface (Fig. 4). The total charge density generated as a result of NSB (trace b) was 0.43 $mC\,cm^{-2}$, whilst that for the specific binding reaction (trace a) was 23.9 $mC\,cm^{-2}$; this indicates that NSB is limited to 1.8% of total binding. Measurement of the extent of NSB with steady-state currents (minus the background reading in buffer) gave a similar value (1.9%). This value includes cross-reactivity between different antibodies as well as NSB.

The binding of ALP-labeled IgG directly onto an avidin D-coated gold electrode was also measured in an electrochemical ALP assay, and the charge density was 0.17 $mC\,cm^{-2}$, equivalent to 0.7% NSB. Such values represent a significant advance on those presently obtainable and now allow patterning of biological molecules to be carried out at microsensor arrays. The technique also has the advantage that it may be integrated with lithographic processes currently in use in device fabrication in the electronics industry.

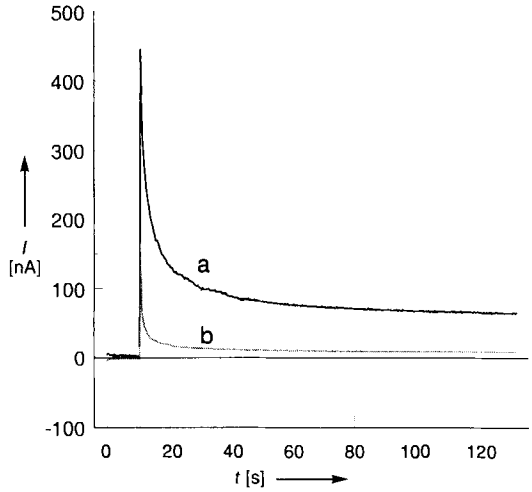

Fig. 4. Responses from two gold electrodes patterned with immobilized antibodies. Further details see Experimental Procedure.

Experimental Procedure

Antibody patterning on a SiO_2 surface: Avidin D (0.2 mg mL^{-1}) in phosphate buffered saline (10 mM phosphate buffer, 2.7 mM KCl, 137 mM NaCl), pH 7.4 (PBS buffer), was immobilized onto a 1 cm^2 disc of silanized SiO_2 [3], which was subsequently incubated in bovine serum albumin in PBS (0.2 mg mL^{-1}) at room temperature for 1 h. PBS was also used for washing between each step. The wafer was then incubated in long-arm photobiotin **1** in PBS (10 μg mL^{-1}) for 20 min in the dark, and was covered with rabbit IgG (10 μg mL^{-1}). Light activation of the photobiotin and coupling of the respective antibodies was performed with a 100 W, high-pressure mercury vapor lamp (185 mm from the surface, irradiance = 9 $mW\,cm^{-2}$) for 15 min through a mask and a Hoya SL glass filter, which removed radiation below 300 nm. No decrease in the activity of the polyclonal IgGs used in this work or of ALP was observed upon exposure to the filtered light.

The patterning process was then repeated with rat IgG (10 μg mL^{-1}). During the course of the light-activation experiment, the temperature of the wafer did not increase by more than 5°C. In order to "block" unreacted photobiotin sites, the wafer was immersed in casein in PBS (10 mg mL^{-1}) and was exposed to light for 15 min. The pattern was then "developed" in TRITC-labeled goat anti-rabbit IgG in PBS (10 μg mL^{-1}) for 60 min and then in FITC-labeled rabbit anti-rat IgG in PBS (10 μg mL^{-1}) for 60 min. All IgGs were polyclonal and were obtained from Sigma (UK).

Antibody patterning on a gold surface: Gold was modified with *N*-acetyl cysteine, onto which avidin D was bound by means of a carbodiimide coupling agent [10]. The method for immobilization of IgG was, otherwise, as described previously.

Electrochemical measurements: The gold electrodes (0.2 cm diameter) were first modified in 5 mM *N*-acetyl cysteine (Sigma) in 10 mM phosphate buffer (pH 7.0) for 2 h, and were then washed in water. The *N*-acetyl cysteine modified electrodes were incubated in a 10% (w/v) solution of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) in 10 mM phosphate buffer for 2 h at 25°C, and were washed in water. The EDC-activated electrodes were placed in a solution of avidin D in 10 mM phosphate buffer (0.2 mg mL^{-1}) for 16 h at 4°C before washing. The electrodes were then incubated in casein in 10 mM phosphate buffer (0.2 mg mL^{-1}) for 1 h at room temperature. Photobiotin **1** was assembled on the avidinated gold, and both electrodes were patterned with a goat anti-rabbit IgG. One electrode was subsequently exposed to an excess of antigen rabbit IgG (trace a), and the other to rat IgG (trace b) Finally both electrodes were incubated in the presence of an excess of ALP-labeled goat anti-rabbit IgG for 120 min and were washed. A solution of 10 mM 1-naphthyl phosphate in 100 mM tris(hydroxymethyl)aminomethane (Tris) containing 2.7 mM KCl and 137 mM NaCl was added to the electrodes, and after 5 min the electrodes were poised at + 320 mV vs. Ag/AgCl. A current was measured for 2 min owing to the electrochemical oxidation of enzymically produced 1-naphthol (which, unlike 1-naphthyl phosphate, is electroactive at this potential). When ALP-labeled goat anti-rat IgG was used in place of ALP-labeled goat anti-rabbit IgG, then both electrodes exhibited behavior similar to that seen in trace b. This demonstrates that nonspecific binding of rat IgG to electrodes coated with goat anti-rabbit IgG is minimal.

The Structural and Thermodynamic Basis for the Formation of Self-Assembled Peptide Nanotubes**

M. Reza Ghadiri,* Kenji Kobayashi, Juan R. Granja, Raj K. Chadha, and Duncan E. McRee

Design of molecular objects with predefined shapes and functions has come to the forefront of chemistry and materials research lately.[1–14] In particular, considerable effort has been devoted toward the rational design of tubular structures because of their potential utility in molecular transport, inclusion chemistry, chemical catalysis, and manufacture of novel optical and electronic devices.[15–24] Here, in the context of a new design, we provide a detailed analysis of the conformation in solution and thermodynamic basis for the peptide self-assembly process, and present the first definitive high-resolution structural model in support of the recently reported peptide nanotubes and transmembrane ion channel structures.[15–17] A cyclic peptide with a selectively N-methylated backbone has been designed and shown to self-assemble into a discrete soluble cylindrical dimer in nonpolar organic solvents. Under appropriate conditions, the peptide also assembles to produce a unique porous crystalline object having an ordered parallel array of water-filled channels of 7–8 Å diameter, the interior amphiphilic surface of which has alternating hydrophobic and hydrophilic domains approximately every 11 Å. The structural assignments and thermodynamic characterizations are supported by a variety of ^{1}H NMR techniques, FT-IR spectroscopy, and high-resolution X-ray crystallography.

Recent designs of peptide nanotubes were based on the central premise that cyclic peptides made up of alternating D- and L-amino acid residues can adopt a flat ring-shaped conformation in which the backbone amide groups are approximately perpendicular to the plane of the ring.[15–17] Furthermore, it was postulated that intermolecular hydrogen bonding and ring stacking interactions of peptide subunits in this conformation would be energetically favored under appropriate conditions and would thus produce open-ended, hollow, tubular ensembles. The key structural requirement for producing a multiply ring-stacked tubular structure was the spatial disposition of the hydrogen-bond donor and acceptor sites of the backbone on *both* faces of the (monomeric) peptide ring structure.[15–17] In the present design, however, the cyclic peptide subunit is devoid of hydrogen-bond donation from one face of the ring structure because of selective methylation of backbone amide nitrogen functionalities. Such a ring-shaped peptide subunit cannot participate in an extended hydrogen-bonded network and is therefore predisposed toward the dimeric, antiparallel stacked, cyclindrical structure—the key fundamental repeating structural motif of the larger peptide nanotube counterparts. The eight-residue cyclic peptide *cyclo*[(–L-Phe–D-*N*-MeAla–)$_4$-] (**1**) was designed for the task in hand[25] (Scheme 1). The sequence and

Scheme 1. A two-dimensional representation of the chemical structure of the peptide subunit (D and L refers to the amino acid chirality) and the self-assembled cylindrical ensemble (for clarity only four of the eight CH_2Ph groups are represented).

the choice of amino acid residues were based on the following considerations: Molecular modeling indicated that methylation of backbone amide nitrogen functionalities at all alanine residues would be sufficient to effectively prevent one face of the putative peptide ring structure from participating in intermolecular hydrogen-bonding and ring-stacking interactions. The peptide was also designed to have an allowed symmetry for favorable intermolecular packing interactions in the solid state thus permitting its detailed structural characterization by X-ray crys-

tallographic techniques. In addition, to gain a better understanding of the structural basis and the thermodynamics of the peptide self-assembly process in nonpolar media—a situation recently encountered in the design of transmembrane ion channel structures[16]—the putative peptide ring structure was decorated with hydrophobic residues to render the subunit and the resulting ensemble soluble in nonpolar organic solvents. The following studies, using ^{1}H NMR techniques, FT-IR spectroscopy, and single-crystal X-ray structural analysis, unequivocally establish the validity of our basic design hypothesis.

The ^{1}H NMR spectrum of the peptide subunit **1** in polar solvents such as deuterated methanol or dimethylsulfoxide (DMSO) displays several conformational isomers which slowly interconvert as a result of the well-known propensity of secondary amides toward *cis–trans* isomerization. Variable-temperature NMR experiments in DMSO indicate *cis–trans* conformational activation barriers on the order of 16 to 17 kcal mol^{-1}. However, in nonpolar solvents such as carbon tetrachloride (CCl_4) or deuterochloroform ($CDCl_3$) the peptide **1** exists in an all-*trans* conformation with a flat-ring-shaped backbone, which is in dynamic equilibrium with the expected cylindrical dimer (Scheme 1). Monomeric **1** displays a temperature-independent (from -40 to 55 °C in $CDCl_3$) and highly symmetrical ^{1}H NMR spectrum excluding the possibility of an intramolecularly hydrogen-bonded conformation. The preponderance of a flat-ring-shaped backbone conformation is also indicated by the observed $J_{NH,\alpha H}$ coupling constant of 7.5 Hz. Intermolecular hydrogen-bonding interactions producing the stacked dimeric ensemble are signified by the expected downfield shift of the phenylalanine N-H resonance from $\delta = 6.98$ to 8.73 ($J_{NH,\alpha H} = 8.8$ Hz) and are unequivocally established by the observed exchange and NOE cross peaks in the ROESY spectrum (Fig. 1).[26, 27] Formation of a tight hydrogen-bonded ensemble with an average intersubunit N–O distance of 2.95 Å is also evidenced by the appearance of an N–H stretching band in the infrared spectrum at 3309 cm^{-1}. As expected, the self-assembly process displays concentration- and solvent-dependent spectra with the association constants $K_a(CCl_4) = 1.4 \times 10^4$ M^{-1} and $K_a(CDCl_3) = (1.26 \pm 0.13) \times 10^3$ M^{-1} at 293 K.[28]

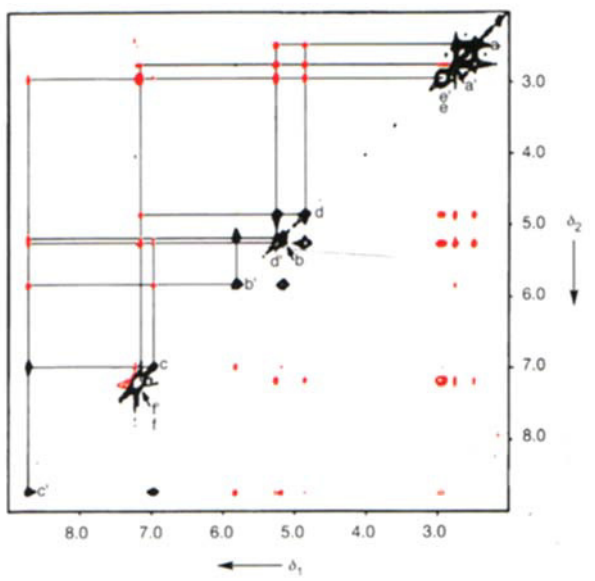

Fig. 1. Two-dimensional phase-sensitive (TPPI) ROESY NMR spectrum of the peptide in $CDCl_3$ (2.0 mM) at 298 K (exchange cross peaks are in black and the NOE cross peaks in red). Letters a–f and a′–f′ mark resonances for the monomeric peptide subunit and the dimeric cylindrical ensemble, respectively (a = NMe, b = α-H(ala), c = NH, d = α-H(Phe), e = β-H(Phe), f = Ph).

Variable-temperature studies (van't Hoff plots) establish the following thermodynamic parameters for the dimerization process in chloroform: $\Delta C_p = -203.1$ cal K^{-1} mol^{-1}, $\Delta H^\circ_{298} = -11.0$ kcal mol^{-1}, and $\Delta S^\circ_{298} = -23.7$ cal K^{-1} mol^{-1}, which clearly supports the expected enthalpic contribution of intermolecular hydrogen-bonding interactions (0.5 to 0.7 kcal mol^{-1} for each hydrogen-bonding interaction) as the major driving force in the self-assembly process. The above experiments indicate that in solution the peptide subunit adopts a flat-ring-shaped conformation, which energetically favors ring stacking and intermolecular hydrogen-bonding interactions over the nonassembled form by 4.0 to 5.6 kcal mol^{-1}, depending on the solvent employed. It follows then that the gain in free energy of stabilization will be additive as the number of ring-stacking interactions increase. This is particularly relevant to the structures of the recently designed self-assembled nanotubes and transmembrane ion channels.[15–17]

Colorless prismatic crystals suitable for X-ray analysis were obtained from the solutions of **1** in water-saturated dichloromethane by vapor-phase equilibration with hexane. The solid-state structure[29] is a cylindrical dimeric ensemble, analogous to the solution structure deduced from the ^{1}H NMR and FT-IR analyses, and thus corroborates very well the nanotube structures previously derived primarily from the analysis of electron diffraction patterns[15, 17] (Fig. 2). It consists of a flat-ring-shaped cyclic peptide subunit with backbone amide groups perpendicular to the plane of the ring and a crystallographic four-

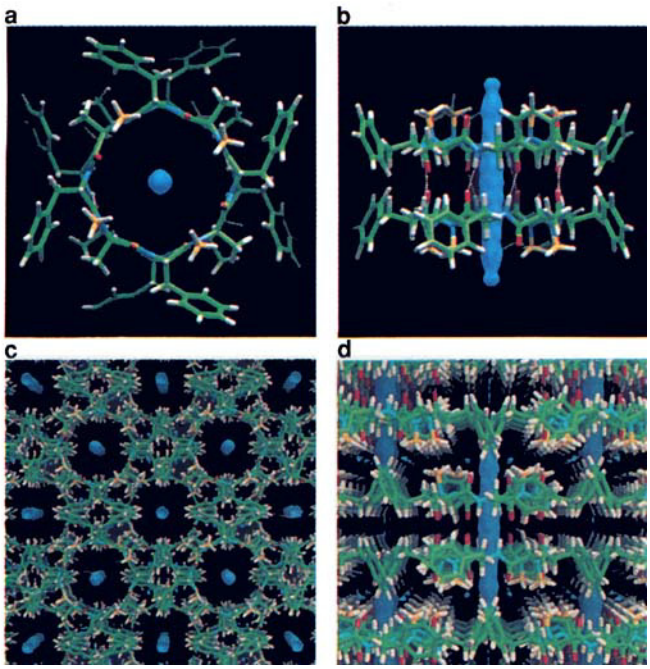

Fig. 2. Crystal structure of the cylindrical dimer and the crystal lattice showing the electron density for water. In order to display the positions of water molecules, the solvent was omitted from the model and an $F_o - F_c$ electron density map calculated. The map shows the position of solvent atoms and is illustrated as a blue isosurface at the level of 4 σ. a) View of the dimer down the crystallographic fourfold axis, *c* (space group *I*422). b) View of the dimer along the twofold axis, *a* or *b*. The rod-shaped solvent electron density in the center of the cylindrical ensemble represents the time-averaged position of several overlapping water binding sites. c) Crystal lattice with solvent electron density viewed along the *c* axis, showing the channels traversing the crystal. The figure is two unit cells wide, two unit cells high, and 1.5 unit cells deep. d) As in c) but viewed along the *a* or *b* axis. The solvent density is much reduced in the proximity of the hydrophobic phenyl groups and is fairly uniform in the center of the dimer. In the extended nanotube structures, which are not interrupted by N-methylated amide groups, the water electron density would form a continuous tube throughout the entire nanotube.

fold rotation axis parallel to the c axis passing through the center of the peptide ring (Fig. 2a). Two peptide subunits (**1**) are closely stacked in an antiparallel orientation and are related by a twofold rotation along either the a or b axis (Fig. 2b). The β-sheet-like cylindrical ensemble is stabilized by eight intersubunit hydrogen-bonding interactions with an intersubunit N–O distance of 2.90 Å. The distance of 2.95 Å inferred from the observed N–H stretching band at 3312 cm^{-1} in the FT-IR spectrum is remarkably consistent with the crystallographic measurements. The cylindrical dimer has an approximate van der Waals internal diameter of 7.5 Å and a volume of 450 $Å^3$. The tubular cavity is filled with partially disordered water molecules, establishing the hydrophilic internal characteristics of the peptide nanotube structures (Fig. 2). The dimer packs in the crystal in a body-centered fashion to produce a continuously channeled superlattice along the c axis (Fig. 2c and d). The interior surface characteristics of the channels alternate approximately every 11 Å between the hydrophobic domains, created by the aromatic phenyl moieties and the hydrophilic interior of the peptide dimer. Water molecules near the hydrophobic domains are considerably more disordered, displaying only a weak residual electron density. The observed electron density for water is the time-average of water molecules binding at several overlapping sites, which suggests a facile movement of loosely held water molecules within the cavity. This observation, which can be attributed to the lack of a discrete, strong binding site (or sites), is an important attribute of the peptide nanotube structures and may be useful for rationalizing the remarkable transport efficiencies of the recently described transmembrane ion channels.[16]

The design principle described above is expected to have a number of potential applications. Appropriately designed subunits with hydrogen bonding possible only in one direction can be used as tube terminators or capping agents and may be used to gate the self-assembled transmembrane ion channel structures. The unique amphiphilicity of the noncentrosymmetric channeled crystals may be useful for binding both hydrophobic and hydrophilic substrates, thus extending the potential utility of peptide nanotubes as molecular inclusion devices and nonlinear optical materials.

[25] The linear form of the target sequene H(-L-Phe-D-N^2-Me-Ala-)$_4CO_2H$ was synthesized according to standard solid-phase methods and then cyclized in solution to furnish the desired cyclic peptide subunit using the following procedure: A solution of the linear peptide in DMF (1 mM) was treated with 2-(1-H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (3 mM), 1-hydroxybenzotriazole (3 mM), and diisopropylethylamine (1% v/v) at 5 °C for 12 h to give the desired cyclic peptide in 70% yield after reverse-phase HPLC purification.
[26] A. Bax, D. G. Davis, *J. Magn. Reson.* **1985**, *63*, 207–213.
[27] ROESY experiments were performed on a Bruker AMX-500 with 300 ms spin lock (mixing) time using Bruker's standard pulse program. Data were processed with FELIX software. Time domain data was apodized with skewed sine-bell squared window functions. Zero-filling was used to obtain the final data size of the 1024 × 1024 complex matrix.
[28] The association constants reported are the lower limits because of the presence of small amounts of included water in the peptide samples. When water is rigorously excluded (4 Å molecular sieves) the association constant $K_a(CDCl_3) = 1260\,M^{-1}$ is approximately doubled to $K_a(CDCl_3) = 2540\,M^{-1}$. The value of $K_a(CCl_4)$ reported was measured in a mixture of 84% CCl_4 and 16% $CDCl_3$ for reasons of solubility.
[29] Data were collected on a Rigaku AFC6R diffractometer equipped with a rotating copper anode ($Cu_{K\alpha}$) and a highly oriented graphite monochromator. The structure was solved in the space group $I422$ with a final R factor of 8.87%, weighted R factor of 10.35%, and residual electron density of 0.64 $e\,Å^{-3}$ for 983 unique reflections with $F > 4.0\sigma(F)$. The unit cell parameters are $a = b = 16.78$, and $c = 21.97$ Å.

β-Sheet Peptide Architecture: Measuring the Relative Stability of Parallel vs. Antiparallel β-Sheets**

Kenji Kobayashi, Juan R. Granja, and M. Reza Ghadiri*

In memory of Professor Linus C. Pauling

Among the most commonly occurring protein secondary structures, β-sheets are the least studied because well-characterized peptide model systems are not available.[1–3] In particular, despite a number of theoretical studies implicating the possible role of amino acid residues and cross-strand interactions between side chains in directing the folding characteristics of β-sheet structures,[4] to date no direct experimental evidence has been forthcoming to establish the underlying energetic factors

that may favor the formation of parallel or antiparallel arrangements. Here we describe the design, synthesis, and characterization of a novel model structure for β-sheets and provide the first direct evaluation of the thermodynamic preference for the antiparallel vs. parallel β-sheet formation. Within the constraints of the present model, our studies establish for the first time the significant role of backbone–backbone hydrogen-bonding interactions in favoring the formation of the antiparallel β-sheet structure.

The de novo design of peptides with well-defined β-sheet structures has been hampered primarily by the propensity of extended hydrophobic or amphiphilic polypeptides toward nonspecific intermolecular aggregation, by lack of control over the relative sheet register, and by the inability to predict or control the extent of the backbone twist in such structures.[5] Moreover, there has been no study to date that documents the formation of parallel and antiparallel β-sheet structures starting with the same or similar peptide sequence(s), which might allow direct assessment of the role of backbone–backbone interactions and cross-strand interactions between side chains in such arrangements. In the preceding article, we described the design of an antiparallel β-sheet cylindrical ensemble based on the self-assembly of flat ring-shaped cyclic peptide subunits with a specifically N-methylated backbone.[6] This unique β-sheet ensemble is free of the complications commonly plaguing β-sheet model systems and constitutes the basis structure for the present study.

The cyclic octapeptides **1**–**3** were designed for the task in hand. They all share the following basic design principles: The peptides are made up of eight alternating D- and L-amino acids which adopt a flat ring-shaped conformation in nonpolar organic solvents and stack to form cylindrical β-sheet arrangements.[6, 7] Solution-phase ^{1}H NMR studies as well as high-resolution X-ray structural analysis have indicated that all backbone ϕ and ψ dihedral angles reside within the accessible β-sheet regions of the Ramachandran map.[8] The present design satisfies the two criteria essential for directing the formation of parallel and/or antiparallel β-sheet ensembles. It provides absolute control over the facial selectivity of the strand in intermolecular hydrogen-bonding interactions between the backbones and the means of rigorously regulating the relative sheet register thereby setting the identity of the cross-strand nearest neighbor residues. The facial selectivity is directed by the N-methylated amide functionalities of the backbone, which prevent one face of the peptide ring structure from participating in intermolecular hydrogen bonding. Control over the sheet register is the direct consequence of the alternating D- and L-conformations of the backbone, which constrains the β-sheet structure so that only homochiral residues can make up the cross-strand β-sheet neare pairs. This restriction is engendered by the requirement for the intermolecular hydrogen-bonding pattern which is dictated by the juxtaposition of amide hydrogen-bond donor and acceptor sites, as well as by the large steric interactions between side chain and backbone in alternative sheet-register and side-chain arrangements. Therefore, as the result of the above design features, enantiomerically pure peptides such as **1**–**3** can only form homodimeric antiparallel β-sheet structures. However, the same structural reasoning would dictate that a β-sheet structure made up of two enantiomeric peptide subunits must necessarily form the corresponding heterodimeric *parallel* β-sheet arrangement.

With this basic design notion in hand, we set out to measure the relative stability of parallel vs. antiparallel β-sheet structures using the two enantiomeric forms of the same peptide sequence (peptides **1** and **2**). A racemic solution containing an equal amount of peptides **1** and **2** can produce an equilibrium mixture of the parallel ensemble **1** · **2** and the enantiomeric antiparallel **1** · **1** and **2** · **2** β-sheet structures (Scheme 1). Formation of diastereomeric **1** · **2** and **1** · **1** (or its enantiomer **2** · **2**) complexes can be conveniently monitored by ^{1}H NMR spectroscopy. Previously, we have shown that peptide **1** or **2** can self-assemble in nonpolar organic solvents to form the predicted antiparallel β-sheet structure.[6] The structural and thermodynamic characteristics of the β-sheet structure have been established with high-resolution X-ray crystallography and 1D and 2D ^{1}H NMR spectroscopy. A particularly diagnostic feature in the ^{1}H NMR spectrum of peptide **1** or **2**, which signifies formation of the antiparallel β-sheet structure, is the resonance for the intermolecularly hydrogen-bonded NH proton at $\delta = 8.73$ having a

Scheme 1. The strategy employed for measuring the relative stability of the parallel and antiparallel β-sheet structures is schematically illustrated. For simplicity, only the backbone structures of the ensembles are illustrated (D and L refer to the chirality of the amino acid residues). Note that in all three ensembles only homochiral residues make up the nearest neighbor cross-strand pairs as indicated by the partial labeling of the αH_a positions. Association constants (K_a) were measured directly by analyzing the ^{1}H NMR spectra [6].

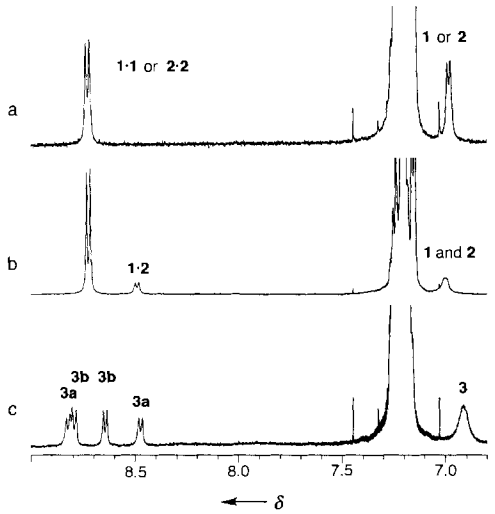
$J_{NH,zH}$ coupling constant of 8.8 Hz (the NH proton of the free peptide subunit resonates at $\delta = 6.98$ with $J_{NH,zH} = 7.5$ Hz) (Fig. 1a). However, an equal mixture of the enantiomeric peptides **1** and **2**, in addition to the previously assigned ^{1}H NMR peaks for the antiparallel structure (**1** · **1** and **2** · **2**), displays a new set of ^{1}H NMR resonances for the parallel structure (**1** · **2**).[9] The NH proton's signal for the parallel β-sheet structure appears at $\delta = 8.49$ with the $J_{NH,zH}$ coupling constant of 8.8 Hz signifying the similarity of the backbone conformation in both parallel and antiparallel β-sheet structures (Fig. 1b). The



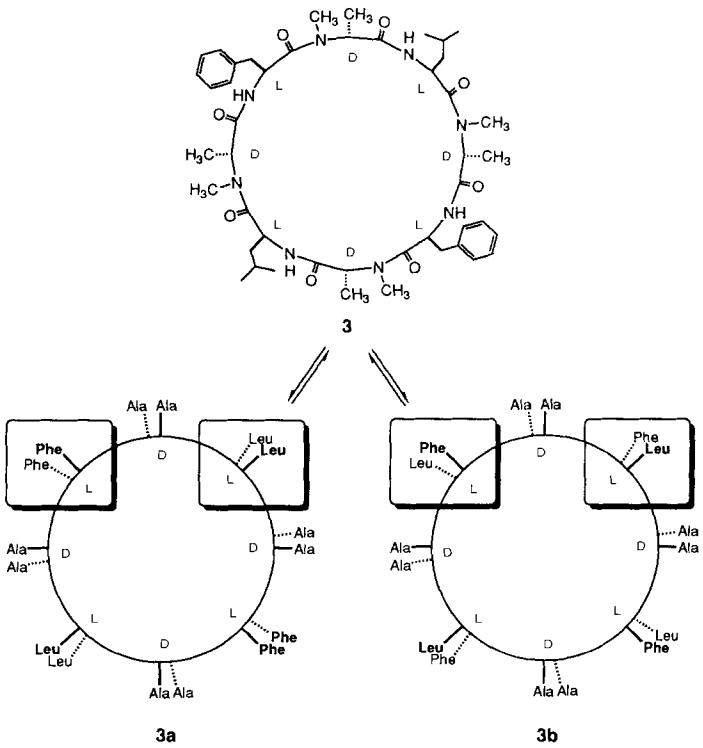


Fig. 1. The NH signals of the ^{1}H NMR spectrum (500 MHz in $CDCl_3$ at 293 K) of a) enantiomerically pure peptides **1** or **2** (1 mM), b) a racemic mixture of peptides **1** and **2** (10 mM), and c) peptide **3** (3.0 mM). All resonances were assigned based on the analysis of the ROESY spectra [6]. The labels refer to the position of the NH resonances: $\delta(\mathbf{1}) = \delta(\mathbf{2}) = 6.98$, $\delta(\mathbf{3}) = 6.92$; $\delta(\mathbf{1} \cdot \mathbf{1}) = \delta(\mathbf{2} \cdot \mathbf{2}) = 8.73$; $\delta(\mathbf{3a}) = 8.48$ and 8.83, and $\delta(\mathbf{3b}) = 8.65$ and 8.80; $\delta(\mathbf{1} \cdot \mathbf{2}) = 8.49$. All β-sheet ensembles display $J_{NH,zH}$ coupling constants of 8.8 Hz.

relative intensity of the ^{1}H NMR resonances was used to assess the free energy of stabilization of the two β-sheet arrangements. The above studies indicate that the antiparallel β-sheet structure ($\Delta G_{293} = 4.56$ kcal mol^{-1}, $K_a(CDCl_3) = 2540$ M^{-1} at 293 K)[6] is more stable by 0.8 kcal mol^{-1} than the parallel arrangment ($\Delta G_{293} = 3.76$ kcal mol^{-1}, $K_a(CDCl_3) = 640$ M^{-1} at 293 K).

An important consideration is whether the measured stability difference between the parallel and the antiparallel β-sheet structures is due to the difference in the backbone–backbone hydrogen-bonding pattern, or whether there exists a significant energetic contribution from the cross-strand side chain–side chain interactions,[4] which may favor a particular β-sheet arrangement. Peptide **3** was designed to probe the origin of the observed structural selectivity. In addition to the phenylalanine and alanine residues, the peptide contains two leucine residues in order to exaggerate any existing cross-strand interactions between side chains. The peptide subunit **3**, unlike peptides **1** and **2** which are fourfold symmetric, has only a twofold symmetry along the axis perpendicular to the plane of the ring structure.[10] Therefore, two diastereomeric antiparallel β-sheet ensembles can be formed: in one isomer (**3a**) D-Ala ··· D-Ala, L-Leu ··· L-Leu, and L-Phe ··· L-Phe residues form the cross-strand pairs, while in the other isomer (**3b**) D-Ala ··· D-Ala, and L-Leu ··· L-Phe residues make up the nearest neighbor pairs (Fig. 2). If significant cross-strand interactions between side chains exist, then formation of one ensemble should predominate.[10] Analysis of the ^{1}H NMR spectrum of the peptide **3** is

Scheme 2. Schematic representation of the self-assembly of peptide **3** producing two diastereomeric antiparallel β-sheet ensembles **3a** and **3b** (amino acid side-chain positions in the top strand are indicated by the solid lines and the bottom strand by the dashed lines). Boxed residues emphasize the differences between the two β-sheet ensembles **3a** and **3b** in the juxtapositioning of cross-strand nearest neighbor side chains.

indicative of an almost equal mixture of the two expected **3a** and **3b** isomers (Fig. 1c).[11] This study clearly establishes lack of any significant contribution (~ 50 cal mol^{-1} at 293 K) from interactions between side chains toward structural stability, which is the expected outcome considering the hydrophobic side chains and the nonpolar solvents employed in the above studies. Therefore, the observed thermodynamic preference for the antiparallel structure reflects the underlying differences in the recognition of the backbone–backbone pattern in the parallel vs. antiparallel β-sheet arrangements.

In summary, the present study provides the first rigorously characterized model for β-sheet structure that assesses the contribution of backbone–backbone interactions and cross-strand interactions between side chains in directing the formation of parallel and antiparallel β-sheet arrangements. It should be expected that changes in the polarity of the medium may produce significant and additive energetic contributions, emanating from cross-strand interactions between side chains, toward stabilizing a particular β-sheet arrangement. The availability of the simple β-sheet model system presented here may now provide the means for the detailed characterization of underlying factors which favor the β-sheet structural fold.

[8] The cyclic peptide structure, although representing a limiting form of backbone twist, has backbone ϕ and φ angles (-128.4 and 126.7°, respectively, for Phe and 131.5 and $-146.2°$, respectively, for Ala) that are well within the allowed β-sheet regions of the Ramachandran map.

[9] This species has been fully characterized by the observed exchange and NOE cross peaks in the ROESY spectrum. Additional support for the formation of this new dimeric ensemble was provided by deuterium labeling studies. The amide backbone protons of peptide **1** were first exchanged with deuterium ($96 \pm 2\%$ incorporation) and then mixed with an equal amount of peptide **2**. Analysis of the ^{1}H NMR spectrum, comparing the intensity of the NH resonances to those of the α and β protons and of the side chain, indicated a $50 \pm 4\%$ reduction in the NH signal intensity, thus unequivocally establishing the dimeric state of the new β-sheet ensemble.

[10] Because of the fourfold symmetry along the axis perpendicular to the plane of the ring, the enantiomeric peptides **1** and **2** can only form one type of antiparallel β-sheet ensemble (four equivalent hydrogen-bonding positions) in which Ala-Ala and Phe-Phe residues make up the near neighbor cross-strand pairs. However, in the case of peptide **3** in which only a twofold symmetry along the same axis exists, two diastereomeric β-sheet structures are possible. Because both ensembles have identical hydrogen-bonding interactions between the backbones, the relative population of the two diastereomers will be dictated by the difference in the energetic contributions of the nearest neighbor cross-strand interactions between side chains.

[11] All NMR resonances, including the sets belonging to **3a** and **3b** ensembles, were assigned with the aid of ROESY spectroscopy. ^{1}H NMR studies indicate the formation of a 48:52 (± 0.5) mixture of the two diastereomers corresponding to $\Delta\Delta G_{293} = 48 \pm 14$ cal mol^{-1}. We were unable to assign with high confidence which set of signals belonged to the diastereomers **3a** or **3b**. Therefore, for illustrative simplicity we have arbitrarily assigned each set of resonances to **3a** or **3b** in Figure 1.

Synthesis and Structure of a Dendritic Polysilane**

Joseph B. Lambert,* Jodi L. Pflug, and Charlotte L. Stern

The chemistry of oligo- and polymeric silanes, $(-SiR_2-)_n$, has blossomed over the last 20 years.[1] These molecules are of interest for their structural, electronic, optical, and chemical properties. These advantageous properties, however, can be offset by the lability of the Si–Si bonds, which have low bond dissociation energy in polysilane chains compared with C–C bonds in hydrocarbon chains.[1] The Si–Si bonds can be isomerized by acid catalysts and can be cleaved by nucleophiles, electrophiles, or light.[2] On a different front, the last 10 years have seen the rapid rise in the study of dendritic polymers, whose repeatedly branched structure emanates from a single core.[3] Such materials tend toward the shape of a sphere, and many bonds are inaccessible to attack by reagents in solution.

We have sought to prepare dendrimers composed entirely of polysilane chains, with the expectation that the less accessible inner Si–Si bonds would exhibit high stability. Because the dendritic structure contains a multiplicity of branching sites, the longest polysilane chain is repeated many times. Such structural redundancy means that a single Si–Si scission most likely will not alter the optical or electronic properties that make polysilanes important.

Except for a few simple compounds with a core Si bonded to three or four Si atoms, that is, so-called zeroth generation dendrimers such as $(Me_3Si)_4Si$, to our knowledge there are no known dendritic polysilanes. We report herein the preparation and crystal structure of the first such example, methyl[tris(permethylneopentasilyl)]silane (**1**),[4] in which the longest poly-

$[(Me_3Si)_3SiSiMe_2]_3SiMe$ **1**

silane chain of seven silicon atoms is repeated 27 times in the dendritic structure. The core silicon atom in **1** is bonded to a methyl group and to three dimethylsilyl groups that serve as spacers to the next branching point, which is a silicon atom to which three trimethylsilyl groups are attached. Scission of one of the peripheral Si–Si bonds in a tris(trimethylsilyl)silyl group still would leave 21 intact Si_7 pathways. Even scission of two such Si–Si bonds would leave 15 or 16 Si_7 pathways, depending on whether the two Si–Si bonds are in respectively the same or different tris(trimethylsilyl)silyl groups. Scission of a Si–Si bond on either side of a spacer dimethylsilanediyl group would remove one of the three dendrons or wedges but still leave nine Si_7 pathways. This molecule therefore illustrates the redundancy present in dendritic polysilanes.

The dendrimer **1** was prepared starting from commercially available tris(trimethylsilyl)silane, which was converted in 90% yield to methyl[tris(trimethylsilyl)]silane by sequential treatment with chloroform (or carbon tetrachloride) and methyllithium. Treatment of the resulting silane with chlorotrimethylsilane and aluminum trichloride according to the method of Ishikawa et al.[5] yielded methyl[tris(chlorodimethylsilyl)]silane in 75% yield after purification by distillation. A single chlorine atom on one of the $SiMe_3$ substituents deactivates the group to further demethylation/chlorination; thus the reaction time and temperature were chosen to ensure that the trichlorinated level was reached. Subsequent reaction of the trichlorinated silane with tris(trimethylsilyl)silyllithium[6] in methyltetrahydrofuran at -15 °C yielded the dendrimer **1** in 85% yield after recrystallization.

The white solid **1** does not sublime but softens around 150 °C. The highest cluster in the mass spectrum has its largest peak at m/z 945, which corresponds to loss of methyl from the expected largest peak in the parent isotopic cluster, which would occur at $(M + 2)$ or 960. The most abundant peak, at m/z 305, corresponds to the permethylneopentasilyl group (one wedge). The ^{29}Si NMR spectrum contains peaks at $\delta = -69.6$ from the core silicon, at $\delta = -26.7$ for the silicon atoms of the spacer (Me_2Si), at $\delta = -124$ for the silicon atoms at the first generation branching point, and at $\delta = -9.44$ for the peripheral

trimethylsilyl silicon atoms. To form a second generation dendrimer, each of the nine trimethylsilyl groups could be converted to dimethylsilyl spacer groups which could then bind to new tris(trimethylsilyl)silyl groups.

The structure of dendrimer **1** was confirmed by X-ray crystallography (Fig. 1).[7] The three neopentasilyl groups are arranged so that the molecule has a threefold axis of symmetry through the Si–C bond of the core silicon atom. There are two equally populated arrangements present in the asymmetric unit, differing in configuration at the core silicon. As a result, there is an effective mirror plane perpendicular to the C_3 axis, and the molecule appears to lie on a sixfold inversion center. There is slight disorder of the trimethylsilyl groups, which enlarges the thermal ellipsoids and raises the *R* factor.

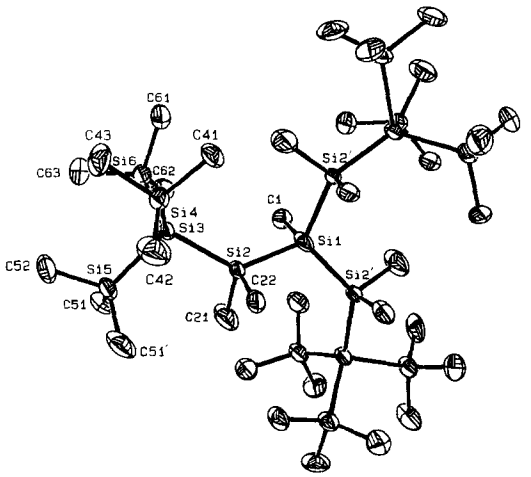

Fig. 1. The crystal structure of **1**.

There is considerable steric interaction between the three permethylneopentasilyl groups. As a result, the three dimethylsilyl groups around the central Si atom flatten toward the methyl group, as indicated by the enlarged Si2-Si1-Si2′ angle (116.10(4)°) and the diminished Si2-Si1-CH_3 angle (101.54(7)°). The most significant distortion that relieves the steric interaction is the considerable increase in the Si1-Si2-Si3 angle (130.4(1)°), which is largely compensated for by the decrease in the CH_3-Si2-CH_3 angle (97.8(3)°). The only other significant (>5°) angular distortion is of Si2-Si3-Si6, which opens up to 119.9(1)°. Steric congestion in **1** also is reduced by stretching Si2–Si3 (2.390(3) Å) (no other Si–Si distortions differ by more than 0.03 Å from the normal length of 2.340 Å as found for example in hexamethyldisilane[8]). Extreme bond stretching has been found in hexa-*tert*-butyldisilane (2.697 Å),[9] but this molecule does not have easily distortable Si-Si-Si angles and therefore is forced to take the more expensive route of bond stretching. These results suggest that two dimethylsilyl spacers between branching points would provide a more strain-free molecule.

The 27 Si_7 pathways in the dendrimer are not equivalent in the solid. Each pathway is defined by four dihedral angles. Although not always exactly 60 or 180°, they nonetheless may be broadly classified as *gauche* (G) or *anti* (A). In the crystal there are three AGAA, six GGAA, six GAGA, and twelve GAGG pathways (see Fig. 1). There is no all-*anti* pathway, usually associated with optimal electronic delocalization. Nonetheless, the λ_{max} at 272 nm is lower in energy than that of the linear heptasilane (266 nm), and almost identical to that of octasilane (272.5 nm),[10] which presumably exist predominantly in *anti* forms.[11] At least as measured by UV absorption, this dendrimer with its multiplicity of conformational pathways has molecular orbitals with similar delocalization to that of linear polysilanes of the same length.

The redundancy of pathways is most remarkably manifested by the extinction coefficient of the absorption maximum at 272 nm. Linear polysilanes of length six to eight have extinction coefficients in the range $2-4\times10^4$,[10] but the dendrimer **1** exhibits an extinction coefficient of 3.4×10^5, more than an order of magnitude larger than that of the linear heptasilane. Thus, the multiplicity of pathways dramatically enhances the extinction coefficient without appreciably changing the absorption maximum.

We are currently engaged in the preparation and characterization of other dendritic polysilanes, whose electronic properties should be as interesting as those of linear polysilanes and whose chemical and environmental stability should exceed that of linear polysilanes, because of steric inaccessibility of many of the Si–Si bonds and redundancy of pathways.

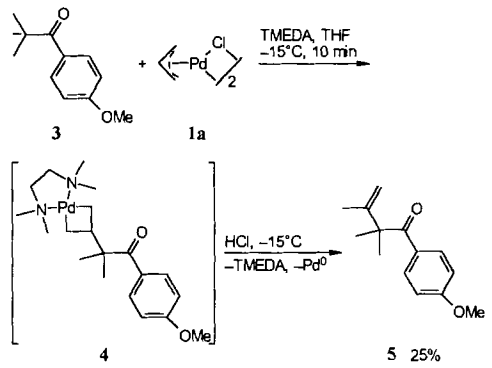
Isolation and X-Ray Crystal Structure of a Palladacyclobutane: Insight into the Mechanism of Cyclopropanation**

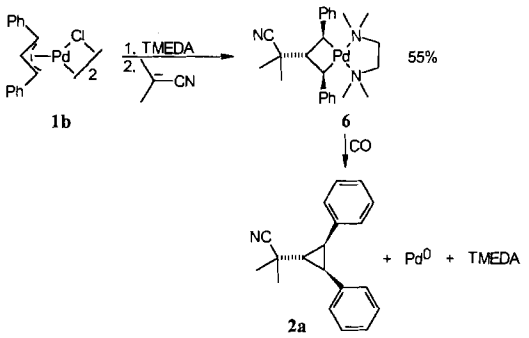
H. M. R. Hoffmann,* Andreas R. Otte, Andreas Wilde, Stephan Menzer, and David J. Williams

The reaction of (η^3-allyl)palladium complexes with nucleophiles is of general synthetic and fundamental, mechanistic interest.[1] We report here on the preparation, isolation, and full characterization of a palladacyclobutane, the structure of which affords insight into the mechanism of cyclopropane formation.

We have previously shown that a nucleophilic cyclopropanation of (η^3-allyl)palladium complexes is feasible (Scheme 1),[2-4] provided that the following is taken into account: 1) Sterically hindered, less stabilized nucleophiles (pK_a range of protonated carbanions 20–30) give the highest yields;



Scheme 1. R = H, aryl, alkyl; R′ = H, aryl, *not* alkyl. LDA = lithium diisopropylamide, TMEDA = *N,N,N′,N′*-tetramethylethylenediamine.



2) TMEDA is the most successful ligand and cosolvent—other bidentate N,N-donors (e.g., sparteine) provide lower yields; 3) added carbon monoxide accelerates and facilitates cyclopropane formation; and 4) the reaction temperature must be carefully optimized and depends on the pK_a and reactivity of the attacking nucleophile (e.g., deprotonated esters, amides, sulfones, fluorene, nitriles, and deprotonated ketones). The electrophilicity of the (η^3-allyl)palladium complex also varies depending on the structure of the allyl ligand. The optimum temperature is in the range −60 °C to −15 °C.

It has been suggested that "reductive elimination of cyclopropane is a fast process, as no palladacyclobutane has been isolated."[5] Indeed, attempts to isolate palladacyclobutanes from the reaction of η^3-allyl complex **1a** and benzenologous ester enolate **3** at −15 °C were not successful (Scheme 2). However, we assumed metallacyclobutane **4** to be the reactive intermediate, since addition of concentrated aqueous HCl at −15 °C caused an immediate precipitation of palladium black. On workup olefin **5** was isolated. This product is thought to arise as a result of monoprotonation of a carbon–palladium σ bond in **4** and β-hydride elimination. We then tried to prepare palladacyclobutanes with two secondary rather than two primary (cf. **4**) alkylpalladium bonds; this would allow us to take advantage of the "aryl effect".[4]

The reaction of (η^3-1,3-diphenylallyl)palladium with deprotonated isobutyronitrile in THF/TMEDA[6] at −15 °C (Scheme 3) gave a yellow solution, which, on warming to room temperature, furnished a yellow powder. This was isolated, purified and identified by chemical and spectroscopic means. A cyclopropane product was not observed. The compound was kinetically inert at room temperature, and also stable to air and water. When carbon monoxide was passed over a dichloromethane solution of these crystals, palladium precipitated and the substituted cyclopropane **2a** was formed (by reductive elimination). ^{1}H and ^{13}C NMR data suggested that palladacyclobutane **6** was the isolated intermediate (Scheme 3, Table 1).

[a] APT (*a*ttached *p*roton *t*est): spin echo based selection of multiplicities of ^{13}C NMR signals. Quaternary C and CH_2 carbon atoms give positive signals (↑), while CH and CH_3 give negative signals (↓).

Slow evaporation of a dichloromethane solution of **6** at room temperature provided single crystals suitable for X-ray crystallography (Fig. 1).[7] The molecule is virtually symmetric and has an average noncrystallographic C_s symmetry about the plane perpendicular to the coordination plane and bisecting the C(6)–C(7) bond (Fig. 2, top). The two phenyl rings are approximately coplanar (5° between their mean planes) and oriented orthogonally (89°) with respect to the C(2)-Pd-C(4) plane. This arrangement of the two phenyl rings optimizes orbital overlap of the two Pd–C σ bonds with the aromatic π electron systems.

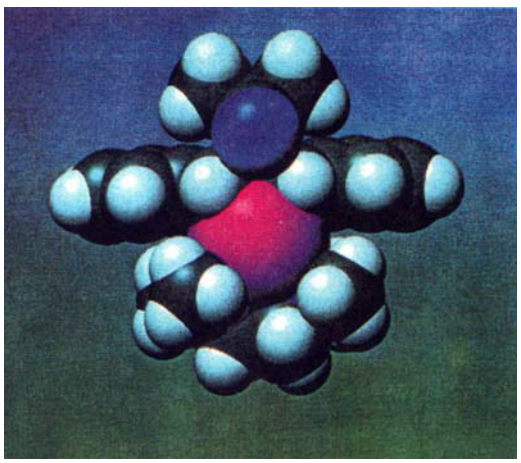

Fig. 2. Crystal structure of **6** (top view). Top: ball-and-stick representation. Bottom: space-filling model.

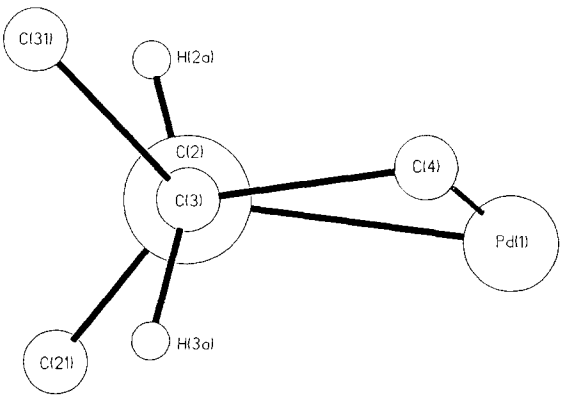
The ligands around the Pd atom adopt a distorted square-planar geometry with internal ligand angles at Pd of 69.8(2)° within the palladacyclobutane moiety and 81.7(2)° within diazapalladacyclopentane. The palladacyclobutane ring is not flat, but slightly folded at a fold angle of 161.4° about the C(2)–C(4) diagonal (i.e., 18.6° out of plane). As a consequence of this slight folding,[8] there is unfavorable near-eclipsing of the substituents attached to C(2) and C(3) and of those at C(3) and C(4) (Fig. 3).[9, 10] The Pd–C bond lengths [Pd–C(4) 2.048(4), Pd–C(2) 2.060(5) Å] are within the normal range. However, the Pd–N bonds [2.230(4) and 2.233(4) Å], which are *trans* to a Pd–C sp^3 bond, are unusually long; this is consistent with a *trans* effect.[11]



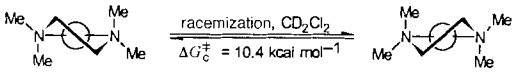


Fig. 3. Selected torsion angles in **6**.

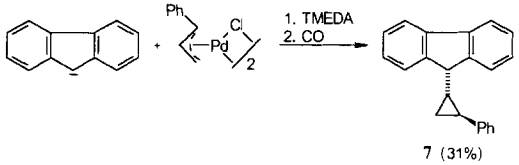
The distance between the two *ortho* aromatic hydrogens pointing inwards is small (2.57 Å); the palladium atom is therefore screened from attack from the bottom face of the molecule. However, the top face is comparatively accessible (Fig. 2, bottom), and reaction of the palladium center with carbon monoxide is thus possible.[12] β-Hydride eliminations are generally fast reactions, but require a synperiplanar conformation. In the case at hand, the torsion angles are not far from 90° (Pd-C(4)-C(3)-H(3) 107° and Pd-C(2)-C(3)-H(3) −107°), and alkene formation is thus effectively blocked.

The NMR spectrum (solvent CD_2Cl_2) of **6** is temperature-dependent. The ^{13}C signals of the four $N(CH_3)_2$ carbon atoms are not equivalent and appear as two singlets; this is consistent with the ^1H NMR spectrum (two singlets, 6H; cf. ref. [9]). At −80 °C the two ^{13}C signals of the $N(CH_3)_2$ carbons split into four signals ($T_c \approx 233$ °K; $\Delta G_c^{\ddagger} = 10.5 \pm 0.5$ kcal mol^{-1}), and the singlet corresponding to the CH_2CH_2 group is transformed into two singlets ($T_c \approx 208$ °K; $\Delta G_c^{\ddagger} = 10.4 \pm 0.5$ kcal mol^{-1}). Moreover, there are two Pd*C*HPh singlets ($T_c \approx 218$ °K; $\Delta G_c^{\ddagger} = 10.3 \pm 0.5$ kcal mol^{-1}), and the singlet due to the geminal dimethyl carbon atoms ($C(CH_3)_2CN$) splits into two singlets. However, the singlets assigned to the quaternary ($C(CH_3)_2CN$), cyano, and ring (C(3)) carbon atoms remain sharp down to −90 °C. These results are consistent with the following conformational fluctuations: The molecule loses its "dynamic C_s symmetry"; instead, two equally populated enantiomers (C_2 symmetry) appear, which interconvert (racemize) (Scheme 4).[13]

At room temperature the aromatic carbons appear as four discrete signals (2 × *ipso*, 4 × *ortho*, 4 × *meta*, 2 × *para*). At −80 °C signals of the *ipso* and the *para* C atoms are each split into two, as expected for the hindered racemization discussed

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0101 $ 10.00+.25/0



Scheme 4. Racemization of **6** in CD_2Cl_2 (the broken circle denotes the Pd atom; other atoms omitted). Schematic representation: The deviation of the methylene carbons from the N-Pd-N plane is only about 0.026–0.05 Å.

above. However, signals corresponding to the *ortho* and *meta* C atoms each split not into two, but four signals. Thus, all twelve aromatic carbon atoms become inequivalent. Hindered racemization is accompanied by a freezing of the phenyl group rotation. We assume that the barrier to rotation of the phenyl group is comparable to that of racemization. The barrier to rotation about the C–Ph ($\Delta G_c^{\ddagger} = 10$ kcal mol^{-1}) indicates a significant steric hindrance. Each phenyl group is jammed by one opposing N-methyl group.[9]

The crystal structures of **6** and the final product **2a**[14] allow us to map out the reaction pathway of (η^3-1,3-diphenylallyl)palladium complex **1b** with deprotonated isobutyronitrile in the presence of TMEDA. The bulky nucleophile does not attack the electron-rich metal center, but instead the central carbon atom of the allyl ligand, and palladacyclobutane **6** is formed. Because of the mutual repulsion between the two phenyl groups in **6**, the spontaneous reductive elimination to the *cis*-diphenyl cyclopropane **2a** from palladacyclobutane **6** is impeded. However, cyclopropanation is accelerated, and yields are generally improved by passing carbon monoxide over the reaction solution.[12, 15] Carbon monoxide is not only sterically accessible, but also a strong π acid. By attacking the 16-electron metallacycle from the top face (Fig. 2, bottom) carbon monoxide removes electron density from palladium and thus facilitates reductive elimination and conversion of the 1,3-propanediyl ligand into the corresponding cyclopropane. It seems likely that the transformation of **6** to **2a** in the presence of carbon monoxide proceeds via an 18-electron transition state or intermediate.[12] In any event, the transannular C(2)···C(4) distance in **6** (2.35 Å) must be contracted substantially to approximately 1.55 Å in **2a**, corresponding to the new C–C bond.[14]

The question arises as to whether the nucleophilic enolate initially attacks the η^3-allyl complex at palladium through its heteroatom (i.e., oxygen), and the palladacyclobutane is subsequently formed by a favorable intramolecular pathway. We have found that the anion of fluorene ($pK_a = 23$), which is devoid of all heteroatoms, is also capable of inducing cyclopropanation (Scheme 5). Thus direct attack of the hindered nucleophilic carbon at the central position of the allyl ligand seems to be the more likely mechanism.

Scheme 5.

In summary, we have established the experimental conditions for converting a range of η^3-allyl Pd complexes into cyclopropanes. Palladacyclobutane is a key intermediate, the structure of which permits an in-depth analysis of the reaction pathway. With the synthesis and full characterization of the title heterocycle, we have contributed a new type of metallacycle to the growing class of metallacyclobutanes, which are of general relevance in catalysis.[16]

[7] Crystal data for **6**: orthorhombic, $a = 10.737(4)$, $b = 11.023(2)$, $c = 20.284(7)$ Å, $V = 2400.5(14)$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\rho_{calcd} = 1.34$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 7.9$ cm^{-1}, 2507 independent observed reflections with [($|F_o| > \sigma|F_o|$), $2\theta \leq 55°$], refined to $R = 0.032$, $R_w = 0.032$. Siemens P4 diffractometer, ω scans, $Mo_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods, and the non-hydrogen atoms refined anisotropically. There is a 50:50 up–down/down–up disorder (static rather than dynamic) of the C(6)–C(7) bond; these atoms were refined subject to refined C–C and C–N distance constraints. H atoms were assigned isotropic thermal parameters and allowed to ride on their parent carbon atoms. Further details of the crystal structure investigation are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[8] Conformational analysis of cyclobutane and heterocyclic analogues: R. M. Moriarty, *Top. Stereochem.* **1974**, *8*, pp. 271–421. A square-planar, D_{4h}-symmetric cyclobutane is fully eclipsed and has internal angles of $4 \times 90°$ (= 360°). Usually cyclobutanes try to escape this unfavorable conformation by puckering.

[9] The slight puckering of the palladacyclobutane ring is accompanied by approach of one of the N-methyl groups N(5) and N(8) towards the π faces of the adjacent phenyl groups (2.58 Å and 2.67 Å, respectively). ^{1}H NMR evidence indicates that this close contact persists in solution [the signals of $N(CH_3)_2$ are inequivalent ($\delta = 2.36$ (6H, s), 1.44 (6H, s)); i.e., anisotropic shielding by two facing phenyl rings causes an upfield shift of almost 1 ppm].

[10] The only related system is a bis(methoxycarbonyl)-substituted palladacyclobutan-3-one (a substituted 2-oxopropanediyl); however, this exhibits substantial folding (53°) of the four-membered ring, accompanied by pyramidalization at the carbonyl center. Furthermore, a β-hydride elimination is structurally impossible in this case. R. D. W. Kemmitt, P. McKenna, D. R. Russell, L. J. S. Sherry, *J. Chem. Soc. Dalton Trans.* **1985**, 259.

The Stabilization of the Rb^- Ion in $Na_{16}Rb_7Sb_7 = Na_{16}(RbRb_6)Sb_7$**

Hans Georg von Schnering,* Raúl Hector Cardoso Gil, Wolfgang Hönle, Armin Burkhardt,* Georges Krier, and Ole Krogh Andersen

Dedicated to Professor Manuel Cardona on the occasion of his 60th birthday

We have started to reexamine binary compounds of the alkali metals with elements of the fifth main group (pnictides M_3X),[1] because great controversy surrounds the details of these simple structures (exact composition, superstructures, symmetry). In both structure types, Li_3Bi and Na_3As, the E1 atoms each occupy two structurally and chemically different positions in the ratio of 2:1, and, therefore, we also tried to prepare ternary compounds. Considering that both Na_3Sb and Rb_3Sb crystallize in the hexagonal Na_3As structure type, the preparation of "Na_2RbSb" should show if and how the structure adapts to the different sizes of Na and Rb.

However, during the synthesis $Na_{16}Rb_7Sb_7 \triangleq Na_{2.29}RbSb$ crystallized in the form of brittle, silver shiny cuboctahedra with metallic luster.[2] The compound was characterized by chemical analysis,[3] structural determination,[4] and electrical conductivity measurements.[4] Also, to better understand the results obtained, crystal chemical considerations and quantum chemical calculations were carried out. The compound, which readily decomposes in air to give a gray material that has not yet been characterized, was found to be a semiconductor, with $E_g = 0.33$ eV. The composition itself is indicative of an unusual electron distribution, since in a semiconducting antimonide, all of the valence electrons should be localized by forming Sb^{3-} ions, which, however, in $Na_{16}Rb_7Sb_7$ would only require 21 of the 23 valence electrons of the alkali metal atoms.

$Na_{16}Rb_7Sb_7$ crystallizes cubically in the space group $Fm\bar{3}m$ (no. 225), isotypical to $Sc_{11}Ir_4$,[6] and is the first representative of this $cF120$ structure type with main group elements. Indeed, this structure is similar to the Li_3Bi type ($a' = 2a$), as the following comparison will show: $[(Li_{16}(Li_8))Bi_8]_4 \triangleq [(Na_{16})(Rb_6\square_2)(Sb_7Rb)]_4 \triangleq [(Sc_{16})(Sc_6\square_2)(Ir_8)]_4$. The Li_3Bi structure is built of condensed Bi_{12} cuboctahedra, each centered by one further Bi atom, which is enveloped by a Li_8 cube ($Bi_{12/4}BiLi_8$). The remaining Li atoms ($Li_{8/8} + Li_{6/2}$) are located in the octahedral holes of the Bi packing. In the $cF120$ structure of $Na_{16}Rb_7Sb_7$, six of the Sb atoms form a three-dimensional net of condensed Sb_{12} cuboctahedra. However, only every second cuboctahedron is occupied by the seventh Sb atom, surrounded by a Na_8 cube. A Rb_6 octahedron is located in the other cuboctahedron, and in its center lies the seventh Rb atom (instead of a Sb atom). This centered $[RbRb_6]$ octahedron is also surrounded by eight Na atoms, but they are shifted to the periphery of the Sb_{12} cuboctahedron, namely into its eight triangular faces. By this shift, precisely the defects in comparison to the initial Li_3Bi structure are forced: $[(Li_8)(Li_{6/2}Li_{8/8})(Bi_{12/4}Bi)] + [(Li_8)(Li_{6/2}Li_{8/8})(Bi_{12/4}Bi)] \rightarrow [(Na_8)(\square\square_3)(Sb_{12/4}Sb)] + [(Na_8)(\square Rb_6)(Sb_{12/4}Rb)]$. Structure and electron distribution are immediately explained with the assumption that in this compound a Rb^- ion is stabilized: $(Na^+)_{16}(Rb^+)_6Rb^-(Sb^{3-})_7 = (Na^+)_{16}(RbRb_6)^{5+}(Sb^{3-})_7$!

The coordination of the individual atoms can be seen in Figure 1. The distances d(Sb–Na) and d(Na–Na) correspond to those in Na_3Sb, if the trigonal-planar coordination at Na2 is considered. The distances d(Rb1–Rb2) in the $(RbRb_6)$ octahedron, with the Rb^- ion in the center of a two-electron cluster Rb_5^{5+}, are 3.580 Å, which is significantly less than those found in Rb_3Sb (3.83–4.42 Å). The enormous expansion of the Na2 cube around this cluster, a distinct sign of the reduced attractive forces by the formal substitution of Sb^{3-} by Rb^-, is made especially clear by comparing the distances between the atoms of the cuboctahedral centers and the atoms of the surrounding Na_8 cube: d(Rb2–Na) = 4.48 Å $\gg$ d(Sb2–Na1) = 3.449 Å.

Even though the existence of the Rb^- ion with cryptands is known through the work of Dye et al.,[7] for $Na_{16}Rb_7Sb_7$ extensive studies are necessary to justify such an assumption. These

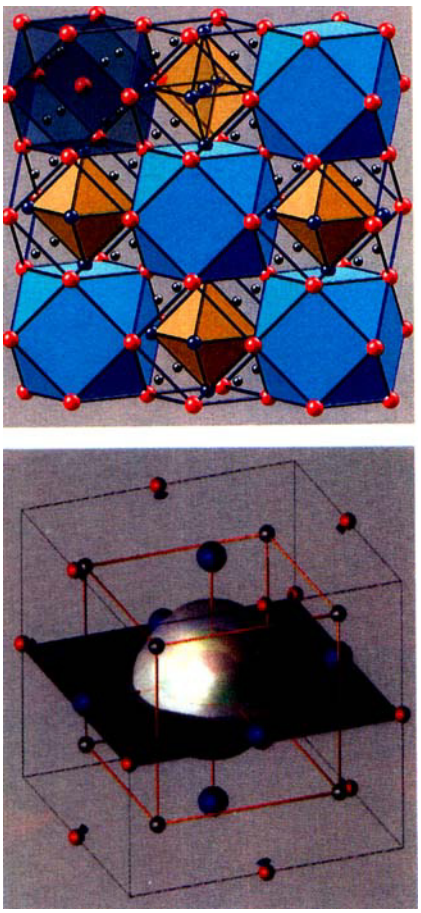

Fig. 1. Top: Segment of the cubic $Na_{16}Rb_7Sb_7$ structure parallel to a (100) face. Condensed Sb_{12} cuboctahedra (blue) are centered alternating by Sb (red spheres) and the octahedral $(RbRb_6)^{5+}$ cluster (yellow octahedra) inside transparent cuboctahedra; Rb = blue spheres. The Na atoms (silver colored) surround the two different centers Sb and $RbRb_6$ as cubes of different size. Na1 is coordinated tetrahedrally by four Sb atoms, Na2 trigonally planar by three Sb atoms. Bottom: One eigth of the unit cell with origin in $(\frac{1}{4}\frac{1}{4}\frac{1}{4})$. Rb2 in the center is surrounded octahedrally by Rb1 atoms (blue). The ELF is represented on a cross section running through the octahedral basis using the color table given in reference [12]. The iso density values extending nearly spherically around Rb2 are colored according to ELF. The two outer isosurfaces (0.002 ea_0^{-3}) mark the region of high density accumulation labeled with an arrow in Fig. 3 between Rb1 and Rb2. This region is characterized by high ELF values (white).

[**] Thanks are due to the Fonds der Chemischen Industrie for financial support. We would also like to thank Andreas Savin, Olle Gunnarsson, Volker Eyert and Ove Jepsen for fruitful discussions, as well as Yuri Grin and Ortrud Buresch for the polyhedral representation and for the chemical analysis, respectively.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0103 $ 10.00+.25/0

were carried out experimentally and theoretically. By direct reaction of Na, Rb, Sb, and NaI, the isotypic compound, $Na_{16}Rb_6ISb_7$ is formed quantitatively. With I^- at the Rb2 position a structure is formed which can be accepted without further discussion. Corresponding reactions also result in the formation of isotypic compounds with Au^- and Na^-.[11]

In the same way, calculations of the electrostatic lattice potentials by the Ewald method[8] give a positive potential at the Rb2 site for the $Na_{16}Rb_7Sb_7$ structure (c.f. for Li_3Bi as well), suitable only for a E^- particle, even at variation of the charges. The tight-binding LMTO band structure, and the electron localization function ELF[9, 10] were calculated with the program package TB-LMTO.[11, 12] The exchange correlations potential from reference [13] have been used; gradient corrections according to reference [14] were also considered. Figure 2 shows the calculated band structure of $Na_{16}Rb_7Sb_7$. The 21 low-lying bands, with mainly Sb-p character between -0.9 and -3.4 eV are completely filled. From the above-lying broad band continuum of Na and Rb states one impurity band is split off, extending from the Fermi edge to the upper edge of the Sb bands. This band is formed predominantly by the 5s orbitals of the Rb2 atoms.

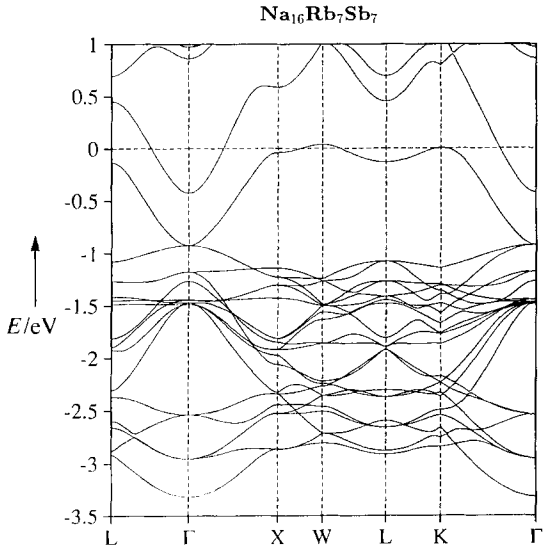

Fig. 2. The band structure of $Na_{16}Rb_7Sb_7$; all energies are given relative to the Fermi level. The crystallographic coordinates of the special k points are: Γ (000), L ($\frac{1}{2}\frac{1}{2}\frac{1}{2}$), X (010), W ($\frac{1}{2}$10), K ($0\frac{3}{4}\frac{3}{4}$).

Almost parallel to this band, about 0.5 eV higher, extends a band of Na2 character. This band, which crosses the Fermi energy around the Γ point, would lead to the conclusion that $Na_{16}Rb_7Sb_7$ should exhibit semi-metallic behavior with an indirect band gap of -0.4 eV, which is contrary to the observed semiconducting behavior. This discrepancy arises from the use of the local density approximation (LDA), which tends to underestimate the band gap, as well documented in the case of silicon.[15, 16] However, this error does not change the overall ground state properties (i.e. electron density).

By comparing the SCF-LMTO potential character C, it can be seen that compared to the surrounding Rb1 atoms (-1.19 eV) the 5s orbital of the central Rb2 atom (-2.54 eV) is lowered by 1.35 eV due to the Madelung contribution of its environment. Therefore, it lies close to the 3s orbitals of Na1 (-2.70 eV) and Na2 (-2.64 eV). This Madelung induced lowering of the Rb2 potential causes the impurity band together with the, compared to the Na 3s orbital, larger range of the Rb 5s orbitals.

Figure 3 shows along the Sb1–Rb1–Rb2 line the density of those electrons, whose energy lies between the Fermi energy and the upper edge of the Sb bands. Besides strong density oscillations in the region of the cores, a density accumulation between the rubidium atoms is clearly noticeable (arrow in Fig. 3). Its maximum is moved from the bond center by approximately 13% towards the central Rb2 atom. To investigate whether directed Rb–Rb bonds are present, a three-dimensional density grid was calculated.

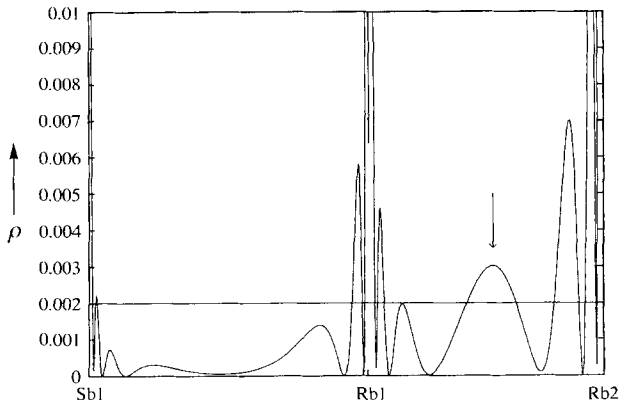

Fig. 3. The electron density resulting from the impurity band along the line Sb1 (center of the neighboring cuboctahedron)–Rb1 (corner of the octahedron)–Rb2 (center of the octahedron). The density ϱ is given in atomic units $e\,a_0^{-3}$. The iso value ($0.002\ e\,a_0^{-3}$) used for the representation of the partial charge density (bottom of Fig. 1) resulting from the impurity band is marked as a horizontal line.

Figure 1 (bottom) shows a section of the structure, which corresponds to one eighth of the unit cell. In its center is Rb2, octahedrally surrounded by Rb1 atoms. The Na2 atoms form a cube with the corner points above the octahedral faces. The Sb2 atoms form a cuboctahedron with the corner points above the edges of the octahedron. To illustrate the course of the ELF besides the isodensity surfaces, a sectional plane runs through the basis of the Rb_6 octahedron, colored by the ELF with the aid of a color scale. A ring of high localization (white) around Rb2 is clearly noticeable. The high ELF values (white) coincide with the marked (arrow) density accumulation between Rb1 and Rb2 in Figure 3, which extends almost spherically around the central Rb2 atom (Fig. 1, bottom). Thus, no directed Rb–Rb bonds are present. Furthermore, no considerable contributions of other atoms are indicated.

The crystal chemical interpretation, the successful substitution of Rb^- by I^- and by Au^-, and the electrostatical analysis, as well as the calculated band structure, allow the formal description of Rb2 as a stabilized and polarized Rb^-. However, the majority of this charge is located in the overlap area between Rb1 and Rb2. To avoid the suggestion of extreme charge separation, the additional density can be assigned to the lowest a_{1g} orbital of the cluster Rb_7^{5+}. Both descriptions are equivalent, since the contribution of the Rb2–5s orbital, due to its location in the cluster interior, is expected to dominate this cluster orbital.

[12] To keep the calculation effort for 30 atoms of the third and fifth period in the primitive unit cell within reasonable bounds an efficient linear muffin tin orbital (LMTO) basis set consisting of 44 basis functions (16 Na 3s + 7 Rb 5s + 21 Sb 5p, Sb 5s in core) was used. Orbitals with higher l value were downfolded. The band character was determined by projection onto orthonormal orbitals. The atomic sphere approximation (ASA) requires the representation of the unit cell volume as sphere packing. Since $Na_{16}Rb_8Sb_8$ is almost closely packed no empty spheres were necessary. The sphere radii have been chosen in such a way that the overlapping muffin tin potential reproduces the full potential as good as possible (Na1: 1.94, Na2: 1.90, Rb1: 2.12, Rb2: 2.15, Sb1: 1.94, Sb2: 1.90 Å). The charge density as well as the electron localization function (ELF) were calculated from the resulting wave functions. For the three-dimensional representation of these quantities the density is displayed as isosurface colored by the corresponding ELF values ($0 \leq$ ELF ≤ 1). Regions of high localization appear in white, towards lower values the colors change from brown over yellow and green to blue (topological color table).

The Colors of C_{60} Solutions**

Javier Catalán,* José L. Saiz,* José L. Laynez, Nadine Jagerovic, and José Elguero*

It is surprising that solutions of an apolar compound like C_{60} are different colors, depending on the solvent used.[1, 2] For instance, it has been described that C_{60} solutions are pink in fluorobenzene (FB), magenta in toluene (T), bluish-violet in methoxybenzene (MOB), brownish in 1,2-dimethoxybenzene (12DMOB), and brown-yellow in 1,2,3,5-tetramethylbenzene (1235TMB). These observations cannot be explained by the influence of the solvent; neither the solvent polarity nor the solvent polarizability play a role.

Ermer[1] reported the color of C_{60} solutions in a series of aromatic solvents with different π-donating ability (nitrobenzene, benzene, anisole, and 12DMOB) and suggested that the UV/Vis spectra of these solutions should be analyzed with regard to charge transfer (CT) effects. CT complexes have been proposed by Wang et al.[3, 4] and by Rao et al.[5, 6] to explain the interaction between C_{60} and *N,N*-dimethylaniline, and by Williams and Verhoeven to explain the interaction between C_{60} and 12DMOB or an alkoxicalix[8]arene sulfonate.[7]

Independently, Scrivens and Tour[2] have studied the solubility of C_{60} in a series of 30 aromatic solvents (benzene and naphthalene derivatives) and reported the color of the corresponding saturated solutions. If one examines these data, it appears that, with some exceptions, there is a correlation between color and solubility. Thus, in those solvents where C_{60} is less soluble (from 0.3 mg mL^{-1} in pyridine to 1.4 mg mL^{-1} in *tert*-butylbenzene) the saturated solutions are pink. In the intermediate zone (from 1.5 mg mL^{-1} in benzene to 17.9 mg mL^{-1} in 1,2,4-trimethylbenzene) the saturated solutions are magenta. Finally, for the solvents in which C_{60} is most soluble, for instance 1235TMB (20.8 mg mL^{-1}) and 1-bromo-2-methylnaphthalene (34.8 mg mL^{-1}), the saturated solutions are brownish. Quinoline is an exception since, although the solubility of C_{60} is only 7.2 mg mL^{-1}, the color of the solution is brownish.

Ruoff et al.[8] in a study of the solubility of C_{60} in a series of 47 solvents, aromatic as well as non-aromatic, do not discuss the color of the solutions but report that "in the case of cyclohexane, we noticed that initial addition of the solvent to C_{60} resulted in a fairly intense purple color, which would indicate a high solubility. However, upon filtration through the 0.45 mm filter, only a faintly colored solution was obtained. Most of the color was from a fluffy purple solid that remained suspended in the solution for long periods". The solubility of C_{60} in cyclohexane is very low, 0.002 mg mL^{-1}.[8]

Considering all these reports, we will try in this paper to answer two fundamental questions: 1) Does the color of a saturated solution of C_{60} change by dilution or on standing? 2) In the zone of concentrations explored, does C_{60} obey the Lambert–Beer law? This last question is related to the possibility that C_{60} should be partly monomeric and partly aggregated or

in suspension depending on the concentration. Answering these two questions will help to understand why C_{60} changes in color with the solvent.

Figures 1, 2, and 3 show a series of solutions of C_{60} in 12DCB (1,2-dichlorobenzene), 1235TMB, and 12DMOB, respectively. The corresponding concentrations for tubes 1 to 10 are given in Table 1. In the three series, the tubes with the same numbers have approximately the same concentration.

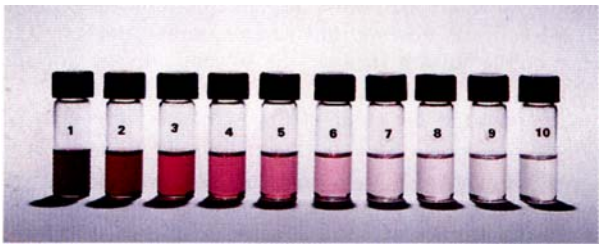

Fig. 1. Solutions of C_{60} in 12DCB. Concentrations see Table 1.

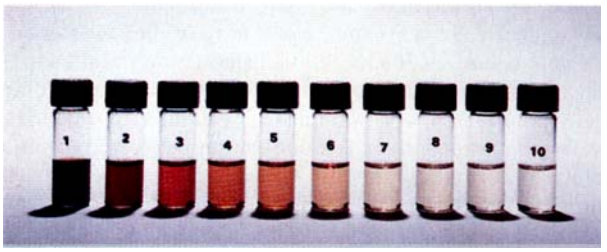

Fig. 2. Solutions of C_{60} in 1235TMB. Concentrations see Table 1.

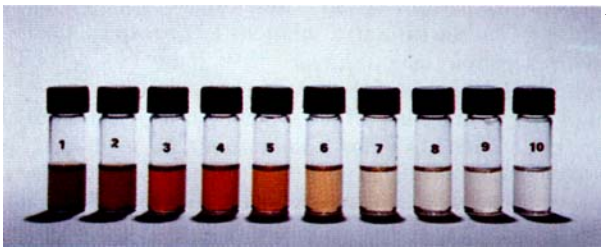

Fig. 3. Solutions of C_{60} in 12DMOB. Concentrations see Table 1.

As Figure 1 shows, the concentrated solutions of C_{60} in 12DCB are a beautiful magenta color which fades but does not change on dilution. All these solutions have *identical* UV/Vis spectra between 700 and 300 nm which almost perfectly superimpose when they are standardized for an optical path of 1 cm and a 1 M concentration. Consequently, the Lambert–Beer law is obeyed.

Concentrated solutions of C_{60} in 12DMOB (Fig. 3) have a red-brownish color which on dilution initially turns red (up to 2×10^{-3} M), then orange (1×10^{-3} M), and finally yellow (from 1×10^{-4} M downwards). Nevertheless, the corresponding spectra obey the Lambert–Beer law and this is the reason why, when standardized to an optical path of 1 cm and a 1 M concentration, all of them are *identical*. We have checked that the most concentrated solutions do not contain aggregates larger than 0.45 mm, since neither the color nor the spectra change when these solutions are filtered through a 0.45 mm filter.

A similar phenomenon happens with solutions of C_{60} in 1235 TMB (Fig. 2), where the color changes from brownish to yellow when the concentration changes from 5×10^{-3} M to 2×10^{-5} M.

In all cases, the Lambert–Beer law is obeyed. If the absorbance is plotted against molar concentration (14 points), for instance, at 333 nm, the values $R = 0.994$ for 12DCB, $R = 0.998$ for 1235TMB, and $R = 0.990$ for 12DMOB are obtained. The extinction coefficients have been determined at 410, 470, 520, 580, 600, and 650 nm, wavelengths which correspond to the violet, blue, green, yellow, orange, and red zones of the spectrum, respectively. These values and those for other solvents are given in Table 2.

Table 2. Molar extinction coefficients ε [L mol^{-1} cm^{-1}] of C_{60} in different solvents.

Solvent	ε_{410}	ε_{470}	ε_{520}	ε_{580}	ε_{600}	Color
toluene (T)	2561	438	826	678	788	magenta
isopropyl-benzene (IPB)	1834	338	623	514	609	magenta
chlorobenzene (CB)	2313	444	843	662	794	magenta
1,2-dichloro-benzene (12DCB)	3170	616	979	786	887	magenta
fluorobenzene (FB)	3224	976	847	572	548	pink
methoxy-benzene (MOB)	5744	423	773	691	769	bluish-violet
1,2-dimethoxy-benzene (12DMOB)	6600	3570	1725	1060	1050	brownish
1,2,3,5-tetramethyl-benzene (1235TMB)	10332	734	1040	827	917	brown-yellow

For the same concentration (7×10^{-4} M), the three solvents 12DCB, 1235TMB, and 12DMOB show differences in color which are clearly apparent in Figure 4. Figure 5 shows the differences in color for a 1.1×10^{-4} M concentration of C_{60} in a wide range of solvents. These colors remain unaltered for several weeks. Concerning the relationship between color and solubility,[2] it must be pointed out that the color of C_{60} solutions depends on both the solvent and the concentration.

Fig. 5. From left to right: Solutions of C_{60} (1.1×10^{-4} M) in the solvents, T, FB, CB, MOB, IPB, 12DCB, 12DMOB, and 1235TMB. Abbreviations see Table 2.

The UV/Vis absorption spectrum of C_{60} in an "inert" solvent like *n*-hexane for wavelengths higher than 300 nm is characterized by an intense peak at 332 nm. In the visible part, in which C_{60} absorbs near 630 nm, the most noticeable features are the transparency in the blue (424–492 nm), already noted by Ajie et al.,[9] as well as in the red (650 nm). *The human eye sees a beautiful purple color as a consequence of the combination of lack of both these absorptions.*

The results of our experiments rule out 1) the existence of aggregates or suspensions in the zone of higher concentrations, because in these solutions there are no changes due to filtration and also because the Lambert–Beer law is always obeyed, and 2) that the color changes of C_{60} with the concentration are due to the existence of CT complexes between C_{60} and some aromatic compounds, because in these solvents the spectra are superimposable if the concentrations are scaled (this eliminates an effect of the concentration on the proportions of species optically active in the visible region).

Since due to the apolar nature of the fullerene C_{60} the absorption spectra are rather insensitive to solvents, neither significant bathochromic nor hypsochromic shifts are observed. Figure 6

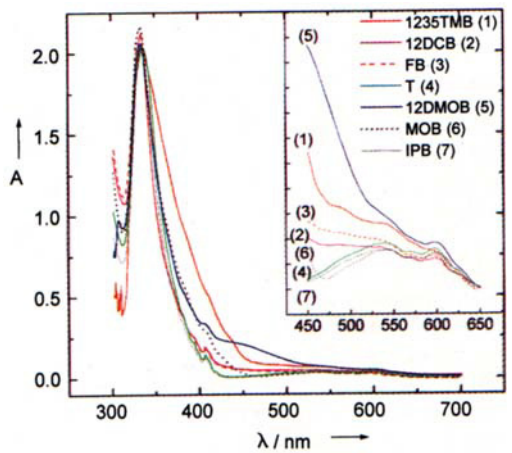

Fig. 6. UV/Vis spectra of C_{60} in several solvents (7×10^{-5} M).

shows the UV/Vis spectra for the different solvents used in this study at the same concentration (7.3×10^{-5} M). Consequently, we conclude that the phenomenon originates mainly from differences in the absorption intensity in the 400–500 nm range, which are perceived by the human eye as differences in color.

Experimental Procedure

The C_{60} used was obtained from MER Co. and has a degree of purity of >99.5%. Solvents with a purity better than 99% (Aldrich) were used when available (fluorobenzene (FB), toluene (T), chlorobenzene (CB), methoxybenzene (MOB), isopropylbenzene (IPB), 1,2-dichlorobenzene (12DCB), 1,2-dimethoxybenzene (12DMOB). The solvent 1,2,3,5-tetramethylbenzene (1235TMB) was also obtained from Aldrich but of technical grade.

The UV/Vis spectra of C_{60} solutions were recorded in a Cary 210 spectrophotometer using cells with an optical path of 0.1 or 1.0 cm. For the most concentrated solutions the instrument becomes saturated due to the large values of the absorbances; in these cases, a Cary 5 spectrophotometer and a variable optical path cell were used (optical path = 0.005 cm).

Photosensitized Formation of 8-Hydroxy-2′-deoxyguanosine in Salmon Testes DNA by Furocoumarin Hydroperoxides: A Novel, Intercalating "Photo-Fenton" Reagent for Oxidative DNA Damage**

Waldemar Adam,* Jean Cadet, Francesco Dall'Acqua, Bernd Epe, Danaboyina Ramaiah, and Chantu R. Saha-Möller

Oxidative DNA damage plays a significant role in mutagenesis and carcinogenesis,[1] in which oxidation products of the DNA bases are formed by reactive oxygen species such as hydroxyl and alkoxyl radicals,[2] singlet oxygen,[3] and even the superoxide ion.[2a] The mutagenic[4–6] DNA oxidation product 8-hydroxy-2′-deoxyguanosine (8-OHdG)[7] has been studied intensively in recent years.[2] Since hydroxyl radicals are implicated as the reactive species in oxidative DNA damage,[1] it was of

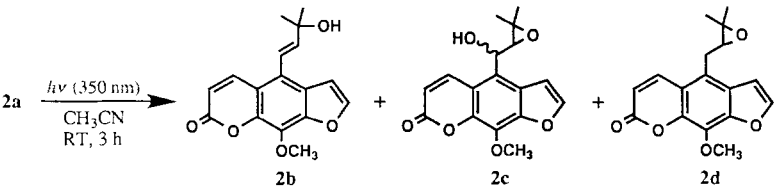
8-OHdG 8-OxodG



interest to assess the role of hydroxyl radicals in the formation of 8-OHdG. The conventional chemical sources of hydroxyl radical, for example, Fe^{2+}/H_2O_2 (Fenton reaction),[9] are not properly suited for such investigations because they generate, besides hydroxyl radicals, other reactive intermediates such as superoxide ion or metal oxygen species.[10] Therefore, efficient methods for the generation of hydroxyl radicals are required, which circumvent the use of transition metals.

Recently we reported[11] that the furocoumarin hydroperoxides **1a** and **1a′** as well as **2a**, and **2a′**, readily available by photooxygenation[12] of imperatorin (**1**) or the alloimperation derivative **2**, cause single strand breaks and endonuclease-sensitive DNA modifications in supercoiled bacteriophage PM2 DNA upon UV irradiation ($\lambda = 360$ nm). Presumably these lesions derive from hydroxyl radical-type oxidative activity, since the different modifications are formed in the same ratio as for the γ irradiation of dilute DNA solutions.[11] Here we present our new results, which substantiate unequivocally that these DNA-intercalating furocoumarin hydroperoxides are indeed effective photochemical sources for hydroxyl radicals. Hence, these novel furocoumarin hydroperoxides constitute the first intercalating "photo-Fenton"[13] reagents and they induce significant amounts of the DNA oxidation product 8-OHdG in salmon testes DNA on UVA irradiation ($\lambda = 350$ nm).

Among the furocoumarin hydroperoxides **1a**,**a′** and **2a**,**a′**, the derivative **2a** was the most active DNA-damaging agent in endonuclease assays.[11] Therefore, as representative example, the photochemistry of **2a** was studied in detail to corroborate the formation of hydroxyl radicals in the photolysis of this hydroperoxide and to provide mechanistic insight for their generation. Thus, irradiation of **2a** (105 mg, 0.330 mmol) in acetonitrile (70 mL) at 350 nm (Rayonet photoreactor) for 3 h at ambient temperature under a nitrogen gas atmosphere led to complete conversion of the hydroperoxide affording the alcohol **2b** (2%), a 80:20 diastereomeric mixture of hydroxy epoxide **2c** (40%), and the epoxide **2d** (8%), along with substantial amounts (25%) of undefined material of higher molecular weight (Scheme 1). The quantum yield ($\phi = 0.85 \pm 0.04$) of the photochemical decomposition of **2a** was determined by the potassium ferrioxalate actinometry.[14] The formation of these photoproducts is explained in terms of the homolysis of the hydroperoxide moiety initiated by intramolecular energy transfer from the photoexcited furocoumarin chromophore. The prerequisite exothermicity for efficient energy transfer is fulfilled in that the triplet energy E_T of the furocoumarin chromophore (cf. for 8-methoxypsoralen $E_T = 63$ kcal mol^{-1})[15] is higher than that of the hydroperoxide moiety.[16]

The generation of hydroxyl radicals in the photolysis[17] of hydroperoxide **2a** (3.16 mg, 10 μmol) in benzene under a nitrogen gas atmosphere was confirmed by detection of phenol (1.6% based on hydroperoxide consumption). The low yield of phenol in this reaction can be rationalized in terms of further

Scheme 1.

oxidation by hydroxyl radicals to catechol and 1,4-hydroquinone.[18]

It was reported that adamantane is oxidized by hydroxyl radicals to 1-adamantanol, 2-adamantanol, and adamantanone.[13, 19] However, we could not detect any oxidation product of adamantane when **2a** (3.16 mg, 10 μmol) was irradiated[17] in the presence of adamantane (13.6 mg, 100 μmol) in acetonitrile (70 mL, degassed) under a nitrogen gas atmosphere. On the other hand, the photolysis under atmospheric conditions afforded 1-adamantanol (3.3%), 2-adamantanol (0.3%), and adamantanone (1.7%).[15] Presumably the adamantane oxidation products were formed by the reaction of molecular oxygen with the initially generated adamantyl radicals.[18b]

Furthermore, ESR-spectral evidence for hydroxyl radicals was obtained by spin trapping with 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO). Thus, on irradiation of hydroperoxide **2a** in the presence of DMPO,[20] the characteristic[21] 1:2:2:1 quartet ($a_N = a_H = 14.90$ G and $g = 2.0053$) was observed in the ESR spectrum for the resulting nitroxyl radical. A similar spectrum was obtained for hydroperoxide **2a′**.

Once it had been established that the furocoumarin hydroperoxides are efficient photochemical hydroxyl radical sources, we investigated the formation of 8-hydroxy-2′-deoxyguanosine (8-OHdG) by this novel intercalating photo-Fenton reagent. For this purpose a solution of salmon testes DNA (50 μg mL^{-1}) and furocoumarin hydroperoxide (20–50 μM) **1a′** or **2a** in 5 mM phosphate buffer (1 mL) at pH 7 was irradiated ($\lambda = 350$ nm) at 0 °C for 15 to 30 min (Table 1). After irradiation, the modified DNA was digested by nuclease P1 and alkaline phosphatase and subsequently analyzed by HPLC (amperometric detection at 650 mV)[22] by using a 80:20 mixture of 0.05 M citrate buffer (pH 5) and methanol as eluent. The results are given in Table 1.

As the data in Table 1 reveal, the hydroperoxide **2a** is more efficient than **1a′** in forming 8-OHdG in DNA. Furthermore, control experiments showed that the extent of 8-OHdG formation was not influenced by D_2O, whereas in the presence of 2% *tert*-butyl alcohol about 30% inhibition occurred (Table 1, entries 3–5 and 9–12). Since for the corresponding furocoumarin alcohols **1b′** and **2b** under similar photolysis conditions only insignificant amounts of 8-OHdG were observed (Table 1, entries 7 and 13), and the furocoumarin hydroperoxides **1a′** and

[a] DNA (50 μg mL^{-1}) was irradiated in 5 mM phosphate buffer (1 mL) at pH 7.0 with furocoumarin hydroperoxide at 0 °C. [b] For comparison, the furocoumarin alcohols **1b′** and **2b** were also investigated. [c] Volume% of reaction solution. [d] Blank was 6 pmol per 50 μg DNA, in parentheses the yields in percent based on guanine consumption are given (50 μg DNA contains ca. 31.2 nmol of guanine); error ca. ±10% of the stated values. [e] Yield based on furocoumarin hydroperoxide consumption.

2a did not form any 8-OHdG without irradiation, the DNA oxidation product 8-OHdG generated in the photolysis of **1a′** and **2a** derives mainly from hydroxyl radicals produced by photosensitized homolysis of the hydroperoxide bond.

For the furocoumarin hydroperoxide **2a** the maximum yield of 8-OHdG (1.82% based on hydroperoxide consumption) was achieved at a hydroperoxide concentration of 20 μM after 30 min irradiation (Table 1, entry 9). Prolonged irradiation (up to 90 min) did not change the yield of 8-OHdG significantly. In fact no peroxide could be detected in the reaction solution by KI test after 30 min irradiation time. The reason for the low yield of 8-OHdG may be due to other DNA modifications such as strand breaks, base-free sites, and oxidation products of DNA bases other than 8-OHdG.[23, 24]

Recently it was reported that irradiation of DNA (260 mg mL^{-1}) in phosphate buffer with γ radiation (50 Gy) under an oxygen gas atmosphere induced 8-OHdG in 0.14% yield.[25] Since the photolysis of **2a** (Table 1, entries 9 and 12) produced 8-OHdG in higher yield (1.8% for **2a** based on hydroperoxide consumption), we suspected that the hydroxyl radicals were formed at least partly in the DNA matrix by photolysis of the DNA-intercalated hydroperoxide **2a**. The quite inefficient inhibition of 8-OHdG formation (ca. 30%) in the photolysis of furocoumarin hydroperoxides versus about 70% inhibition of this DNA damage induced by γ radiation (free hydroxyl radicals),[11] substantiates also intercalation of these hydroperoxides and is in accord with our previous results[11] on DNA damage caused by furocoumarin hydroperoxides.

Therefore, we have examined whether the furocoumarin hydroperoxides investigated herein undergo intercalation, a prerequisite for photoactivity directly in the DNA matrix.[26, 27] Indeed, the formation of a molecular complex between salmon testes DNA and furocoumarins **1a′** and **1b′** was confirmed by strong quenching of the fluorescence,[28] as had been observed previously for other intercalating furocoumarins.[21] From the fluorescence data, the binding parameters of the DNA complexes were calculated according to McGhee and von Hippel[29] (Table 2). As the data reveal, the furocoumarins examined herein form molecular complexes with DNA at least as efficiently as 8-methoxypsoralen (8-MOP). Furthermore, **2a** binds more strongly with DNA than **1a′**. Presumably, the higher efficiency of the hydroperoxide **2a** in comparison to **1a′** to form 8-OHdG (Table 1, entries 2 and 9) is due to its higher DNA binding constant (Table 2).

Table 2. Binding parameters [a] of furocoumarins with salmon testes DNA.

Furocoumarin	K [M^{-1}] [b]	n [c]	$1/n$ [d] 10^{-2}
1a′	6130	60	1.7
1b′	3900	45	2.2
2a	23900	22	4.5
8-MOP [e]	740	8	12.8

[a] Calculated according to McGhee and von Hippel [29]. [b] Association constant. [c] Number of nucleotides occluded by a bound furocoumarin. [d] Frequency of binding sites. [e] Taken from ref. [27].

To assess whether the present furocoumarins, like psoralen,[30] indeed intercalate into DNA when complexed with the macromolecule, we carried out linear flow dichroism (LD) measurements. The LD spectrum[31] of an aqueous solution of the hydroperoxide **2a** in the presence of DNA exhibited a characteristic negative dichroism between 310 and 360 nm, which indicates that the complexed **2a** assumes a position parallel to the DNA bases.[30] Similar negative LD spectra were observed for the furocoumarins **1a′** and **1b′**.

In summary, the results demonstrate that the readily available intercalating and photosensitizing furocoumarin hydroperoxides **1a′** and **2a** serve as convenient sources for the generation of hydroxyl radicals. On near-UVA irradiation these novel photo-Fenton reagents promote efficiently the mutagenic DNA oxidation product 8-hydroxy-2′-deoxyguanosine (8-OHdG). The advantage of this new type of photo-Fenton reagent lies in the fact that hydroxyl radicals can be generated directly in the DNA matrix by photosensitization and the concentration-dependent formation of 8-OHdG can be quantitatively assessed. Because of these favorable properties, the furocoumarin hydroperoxides, in particular the 8-methoxypsoralen derivative **2a**, can be applied as effective hydroxyl radical sources for the investigation of biologically important reactions such as DNA oxidation and cleavage,[23, 32] protein cleavage,[33] crosslinking of biopolymers,[34] and lipid peroxidation.[35] To develop still more effective photoactive hydroxyl radical sources, the optimization of the photosensitizing and intercalating properties of such reagents will be required.

Solid-State and Solution Structures of $[\{NW(OC(CH_3)_2CF_3)_3\}_3]$ and Factors Favoring the Metathesis of C–N and W–W Triple Bonds in Reactions Involving Organic Nitriles and Ditungsten Hexaalkoxides**

Malcolm H. Chisholm,* Kirsten Folting-Streib, Darin B. Tiedtke, Frédéric Lemoigno, and Odile Eisenstein*

In a paper entitled "Transition Metal Nitrides, Organic Polyenes and Phosphazenes. A Structural and Orbital Analogy"[1] the authors stated, "Perhaps the most interesting conclusion we can draw for transition metal nitrides is that there should be substantial stability for a benzene analogue. Does this mean that the benzene analogue will have all equal bond lengths? We are not sure." Hoffmann et al. drew the limiting structures **A**.[1]

A

Following this theoretical prediction, Roesky et al.[2] reported the synthesis of the first trimeric metal nitride $[\{Cp^*Ta(Cl)N\}_3]$ ($Cp^* = \eta^5$-C_5Me_5), a triazatrimetallabenzene containing a central planar Ta_3N_3 moiety with Ta–N bond lengths that were statistically equivalent (Ta–N = 1.84(2) to 1.90(2) Å). Subsequently, Wolczanski et al. reported the structure of a related trimeric nitride $[\{Cp^*Ta(Me)N\}_3]$ having a similar planar, symmetrical Ta_3N_3 core.[3] They carried out an extended Hückel molecular orbital (EHMO) calculation on an idealized molecule $[(X_2TaN)_3]$ of C_{3v} symmetry and established that the trimer had the familiar π-type MOs with *a* and *e* symmetry as in benzene. These $[(X_2TaN)_3]$ molecules (d^0 tantalum center) with idealized tetrahedral metal centers are analogues of the trimeric phosphazenes $(X_2PN)_3$. We describe here the preparation and structure of a trimer of type $[(X_3WN)_3]$ (d^0 tungsten center) that has a quite different structure to the tantalum trimers above involving a planar W_3N_3 ring with alternating short and long W–N distances.

Whereas $[W_2(OtBu)_6]$ and nitriles react rapidly in hydrocarbon solutions to give $[N{\equiv}W(OtBu)_3]$ and $[R'C{\equiv}W(OtBu)_3]$ (R' = Me, Ph),[4] the related compounds $[W_2(OR)_6]$, where $R = tBuMe_2Si$[5] and $(CF_3)(CH_3)_2C$, are inert toward acetonitrile, except for the reversible, low-temperature formation of adducts $[W_2(OR)_6(NCMe)_2]$.[6] However, we found that benzonitrile and aryl nitriles (ArC≡N) reacted under similar conditions to give nitrides $[\{NW(OR)_3\}_x]$ and PhC≡CPh or ArC≡CAr.[7] For *p*-X-C_6H_4C≡N, we found that the rate was significantly influenced by X and followed the order X = Cl > H > OMe. These reactions were followed with ^{13}C- and ^{15}N-labeled nitriles by NMR spectroscopy. In the presence of

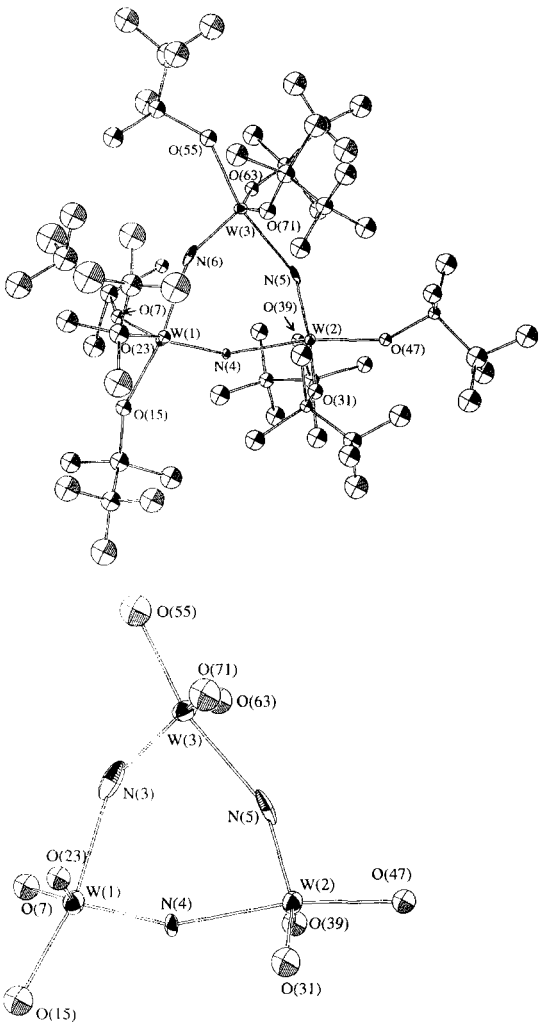
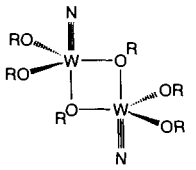
ten equivalents of PhC≡N, there was no evidence for an intermediate, and we presume that [PhC≡W(OR)$_3$] reacts rapidly with the excess PhC≡N to give PhC≡CPh and [{N≡W(OR)$_3$}$_x$].[7]

The molecular structure of the fluoroalkoxide derivative **1** was determined in the solid state from a single-crystal X-ray study (Fig. 1).[8] There is a central planar W_3N_3 moiety in **1**, and

[{NW(OC(CH$_3$)$_2$CF$_3$)$_3$}$_3$] **1**

the local geometry about the tungsten can be described in terms of a distorted trigonal bipyramid. The W–N bond lengths alter-





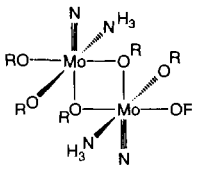


Fig. 1. Crystal structure of **1** (ORTEP representation). Top: view of the complete molecule. Bottom: view of the central $N_3W_3O_6$ skeleton. Selected bond lengths [Å] and angles [°]: W(1)-N(4) 1.732(15), W(2)-N(5) 1.682(19), W(3)-N(6) 1.717(19), W(1)-N(6) 2.159(20), W(2)-N(4) 2.125(5), W(3)-N(5) 2.159(18), W-O_{eq} 1.904–1.913 (1.907 average), W-O_{eq} 1.860–1.909 (1.891 average); N(4)-W(1)-N(6) 84.9(7), N(4)-W(2)-N(5) 84.9(7), N(5)-W(3)-N(6) 87.6(7), W(1)-N(4)-W(2) 154.5(10), W(2)-N(5)-W(3) 153.6(9), W(1)-N(6)-W(3) 150.7(9), O_{eq}-W-N_{eq} 167.6 (average), O_{axial}-W-N_{eq} 106.4 (average), O_{axial}-W-O_{eq} 90.8 (average), O_{eq}-W-O_{eq} 141.8 (average), O_{eq}-W-N_{eq} 109.6 (average).

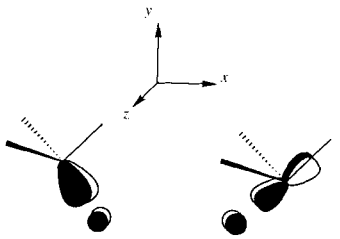
nate markedly between 1.72(2) (average) and 2.14(2) Å (average), and the N-W-N angles are acute (85–88°), while the W-N-W angles are obtuse. Three fluoroalkoxido ligands lie in the W_3N_3 plane, while three of the remaining six lie above and three below the plane. About each tungsten, the fluoroalkoxido ligand in the W_3N_3 plane is located in a near *trans* configuration to the long W–N bond, while the short W–N bond and the remaining two alkoxido ligands define the equatorial plane of the trigonal bipyramid. ^{15}N NMR studies have shown that the trimeric structure remains intact in solution, as a central resonance is observed flanked by two sets of satellites due to coupling to ^{183}W (I = 1/2, 14% natural abundance; ^1J = 84 and 40 Hz).[10]

The crystal structure of **1** is in marked contrast to that of the symmetrical triazatrimetallabenzene of [(Cp*TaXN)$_3$].[2, 3] It is also different from the infinite polymeric compound [(*t*BuO)$_3$W≡N]$_x$[9] with its alternating short triple and long dative bonds. However, for R = *t*BuMe$_2$Si, solution NMR data reveal that the product is dimeric in solution and has terminal, rather than bridging nitrides. We propose that the dimer in solution has the structure **2**.

2:R = Si*t*BuMe$_2$



3:R = SiMe$_3$

Of particular relevance to our claim that there are terminal nitrido ligands are the values of $\tilde{\nu}$(W–N) = 1169 (^{14}N) and 1138 cm^{-1} (^{15}N), which may be compared with $\tilde{\nu}$(W–N) = 1014 (^{14}N) and 993 cm^{-1} (^{15}N) for [N≡W(O*t*Bu)$_3$]$_n$ and $\tilde{\nu}$(Ta–N) = 960 (^{14}N) and 930 cm^{-1} (^{15}N) for [Cp*Ta(Me)N]$_3$.[3] Furthermore, the ^{15}N NMR signal[10] shows one set of satellites of 14% intensity due to ^{183}W coupling (^1J = 103 Hz). This is further supported by the structure **3** (shown above), which was determined by DeCock et al.[11] and may be viewed as a bis(amino) adduct of a molybdenum analogue. Cryoscopic molecular weight determinations in benzene (1052 g mol^{-1}) also confirmed the dimeric nature of the siloxide compound in solution.

Thus, complex **1** is a cyclic trimer with alternating long and short W–N bonds whose structure persists in solution.[12] The related siloxide adopts a dimeric structure (akin to that seen for [{MeC≡W(O*t*Bu)$_3$}$_2$]) with terminal nitrido ligands. We now return to the structural nature of the W_3N_3 ring and the factors influencing the geometry of the six-membered ring. Two factors can induce an alternation of the bond length in a planar six-membered ring [(L$_n$M)$_3$N$_3$]. The orbitals of the T-shaped ML$_3$ fragment, even if symmetrically positioned with respect to the plane bisecting the N-M-N angle, can induce a second-order Jahn–Teller distortion of the π electron system that favors M–N bond alternation. Alternatively, a *fac* ML$_3$ fragment can bond to the two nitrogen centers; the M–N bonds are then intrinsically nonequivalent. This leads naturally to bond alternation within the six-membered ring. The fragment [Cp*TaX] (X = Cl and Me) forms two equivalent Ta–N bonds. As mentioned by Wolczanski et al.,[3] the second-order Jahn–Teller effect in [(Cp*TaMe)$_3$N$_3$] is too small owing to the large energy gap between the a_2 and a_1 orbitals, which could otherwise induce bond alternation in the six-membered ring. EH calculations[13] on other model compounds of type [(L$_n$M)$_3$N$_3$] (ML$_n$ = d^0-ML$_2$ and d^0-ML$_3$, where ML$_3$ is a T-shaped fragment situated in the bisector plane of the N-M-N angle) show that the energy difference between the corresponding a_2 and a_1 is similar

to that obtained in the case of [Cp*MX] (d^0 metal center). Small differences are observed in the overlap factor, which is found to favor a slightly larger mixing of a_2 and a_1 in the distorted C_3 structure in the case of T-shaped ML_3. This is due to the fact that the d_{xz} and d_{yz} metal orbitals can both overlap equally well with the nitrogen p_z orbitals, since they both are equivalent nonbonding orbitals in a local trigonal bipyramid. However, this effect remains small.

A more noticeable difference is associated with the intrinsic site preference for ligands in a trigonal bipyramid, which results from σ and π effects. Although OR groups have been seen to be *trans* to each other in some complexes,[14] the strong *trans* influence[15] of the alkoxide ligand should result in a preference for a *fac* over a *mer* geometry. Therefore, one of the OR ligands on each W is apical and the other two are equatorial; as a result, one nitride is equatorial and one apical. The equatorial nitride forms a stronger π bond to the metal than the axial nitride, since the unoccupied metal orbital **I** is strongly hybridized away from the equatorial alkoxide and overlaps strongly with nitrogen π orbital. In contrast, the unoccupied orbital **II** involved in π bonding with the axial nitride is a pure d orbital, which overlaps less with nitrogen p_z orbital.

I **II**

An EH calculation on the model compound $[\{W(OH)_3\}_3N_3]$ with W–N bond lengths that are all identical confirms this analysis: the π-overlap population is larger for the equatorial N (0.29) than for the apical N (0.25). The WN total overlap populations differ by the same amount. The orientation of the $W(OR)_3$ group with one apical OR in the plane of the ring does not seem to be a consequence of the WN bond alternations. In the cyclotungstaphosphazene $[(NPPh_2NPPh_2N)WF_3]$, the authors suggest that one F occupies an apical site and the two others, equatorial sites of the pentacoordinated W center. These conclusions were based on the ^{19}F NMR spectra.[16]

In conclusion, the present work reports the first example of the alternation of long and short M–N bond within a six-membered, M_3N_3-containing ring and reveals how subtle electronic factors associated with the steric and electronic requirements of a d^0-ML_n fragment greatly influence whether the metal nitride structure is an infinite polymer, a dimer, or a cyclotrimer or -tetramer.[17] The electronic factors that influence the metathesis of the M≡M and C≡N bonds are under investigation.

Experimental Procedure

1: Benzonitrile (150 μL, 1.5 mmol) was added to a solution of $[W_2(OC(CH_3)_2CF_3)_6]$ (175 mg, 0.15 mmol) in 10 mL of dry, degassed benzene at 25 °C. The solution was stirred at 25 °C for 24 h, and the solvent removed under vacuum. Sublimation of the impurities followed by recrystallization in dry, degassed hexanes gave X-ray quality, pale yellow crystals in 68% yield.

2: Benzonitrile (150 μL, 1.5 mmol) was added to a solution of $[W_2(OSi^tBuMe_2)_6]$ (175 mg, 0.15 mmol) in 10 mL of dry, degassed benzene at 25 °C. The solution was stirred at 25 °C for 24 h, and the solvent was reduced to 2 mL under vacuum. Dry, degassed acetonitrile (10 mL) was added, the solution filtered under an inert atmosphere, and the solid washed with 2 mL of dry, degassed acetonitrile to afford the product in 78% yield.

[8] Summary of crystal data for **1**: M = 1744.40, monoclinic, $P2_1/c$, a = 22.481(5), b = 11.367(2), c = 22.573(2), β = 94.60°, V = 5749.66 Å^3, Z = 4, ρ_{calcd} = 2.015 g cm^{-3}. The structure was solved by locating the three W atoms by the Patterson method with SHELXS-86. The remaining non-hydrogen atoms were located in successive iterations of least-squares refinement and difference Fourier calculations. Almost all of the hydrogen atoms on the main molecule were evident in a later difference map. The full-matrix least-squares refinement was completed with anisotropic thermal parameters, and the hydrogen atoms were in fixed, idealized positions. The final $R(F)$ was 0.0503 and $R_w(F)$ was 0.0513 for 356 variables and 3827 reflections considered observed. The asymmetric unit contained one half molecule of hexane located at a center of symmetry. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58362.

received little attention; the only examples are $[\{Cp^*Ta(N)Cl\}_n]$ ($n = 3,4$) $[\{Cp^*V(N)Cl\}_2]$, $[CpOs(N)(CH_2SiMe_3)_2]$ and $Li[Cp^*W(N)Me_3]$ ($Cp = \eta^5\text{-}C_5H_5$, $Cp^* = \eta^5\text{-}C_5Me_5$).[2a-e] The tantalum and vanadium compounds can be thought of as aggregates of varying nuclearity of the hypothetical mononuclear fragments $\{Cp^*M(N)Cl\}$ (M = V, Ta). Here we report on the aggregation of a $\{Cp^*Mo(N)Cl_2\}$ transient to form the first examples of Cp^*Mo^{VI} nitrido complexes, which illustrate the electronic and steric effects of the Cp* ligand in the chemistry of nitrido complexes. The general interest is related to the search for stable models[3] of poorly understood metathesis catalysts obtained by in situ alkylation of nitridomolybdenum(VI) complexes.[4] Another point of interest is the reactivity of the nitrido ligand[5] and how this is influenced by the presence of the cyclopentadienyl ring.

The standard synthetic strategy (Scheme 1)[5] introduces the nitrido ligand and two oxidizing equivalents from an azide. Our

Scheme 1.

starting material is the recently reported **1**.[6] When NaN_3 in acetonitrile was employed as the azide source, gas evolution ensues and a purple solution is obtained, from which purple crystals of **2** · 0.25 CH_2Cl_2 (see Scheme 2) are collected in 39% yield after crystallization from dichloromethane/ether/pentane. Elemental analyses and NMR spectra indicate that the compound has incorporated one CH_3CN molecule per two $\{Cp^*Mo(N)Cl_2\}$ units (see Scheme 2). Reaction of **1** with $(CH_3)_3SiN_3$ in CH_2Cl_2 also proceeds with gas evolution, but a emerald-green solution is now obtained. Crystals of paramagnetic (EPR) **3** (see Scheme 2) were isolated in 43% yield by diffusion of *n*-hexane; **3** crystallizes with two molecules of CH_2Cl_2. The structures of both compounds were elucidated by X-ray crystallography.

$[\{Cp^*MoCl_3\}_2]$ **1**

$[Cp^*_2Mo_2Cl_4(N)(N_2CCH_3)]$ **2**

$[Cp^*_4Mo_5N_5Cl_{10}]$ **3**

The structure analysis of **2** (Fig. 1)[7] shows that acetonitrile forms part of a symmetric six-membered Mo_2N_3C ring, which is the first known example of a dimetallatriazene. The molecule can also be described as a dinuclear molybdenum complex with nitrido and acetamidinato(3−) bridging ligands. The planes defined by C1, C2, N2, N3 and Mo1, N1, Mo2 are twisted by an angle of 16.7° along the virtual twofold axis N1-C1-C2. Although the ring is hence not quite planar, the π-electron density is evidently delocalized: the Mo−N1 distances of 1.790(7) Å (Mo1−N1) and 1.851(7) Å (Mo2−N1) are intermediate between those for the typical Mo≡N bond (1.64 Å)[8] and a Mo−N dative bond [e.g., 2.16(1) Å in $[\{MoNCl_3(OPCl_3)\}_4]$;[9] 2.18(3) Å in $[\{MoNMe_2(OtBu)\}_4]$ $(tBuC_5H_4N)_2$[3a]] and slightly shorter than those for the Mo=N double bonds, as for instance

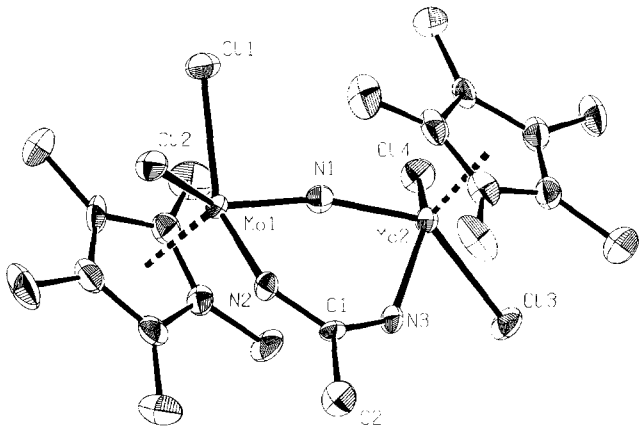

Fig. 1. PLATON diagram of the molecular structure of **2**. Relevant distances [Å] and angles [°]: Mo1-N1 1.790(7), Mo2-N1 1.851(7), Mo1-N2 2.089(8), Mo2-N3 2.082(7), N2-C1 1.34(1), N3-C1 1.33(1), Mo-Cl (average for Mo1 and Mo2) 2.432(2), Mo1-N1-Mo2 161.4(4), Mo1-N2-C1 132.8(6), Mo2-N3-C1 131.9(6), N2-C1-N3 123.6(7)

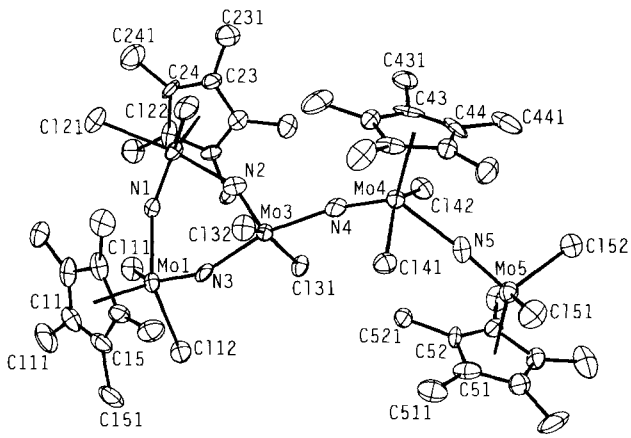
in $[\{MoN[S_2P(OCH_3)_2]_2\}_4]$ (av 1.868(12) Å).[10] The open Mo1-N1-Mo2 angle of 161.4(4)° indicates strong participation of the π electrons to the Mo−N1 bonding. The other two Mo−N bond lengths (Mo1−N2 and Mo2−N3) are considerably longer (av 2.086(8) Å) and the Mo-N-C angles more closed (av 132.4(6)°), consistent with less multiple bond character for the bonds between the Mo centers and the $(CH_3CN_2)^{3-}$ nitrogen donors. The C−N bonds (av 1.34(1) Å) are typical of partial double bond character, as found for instance in aromatic N-heterocycles (in the 1.32−1.35 Å range).[11] The coordination geometry around the Mo atoms can be described as a four-legged piano stool with two *cis*-chloro ligands, the bridging nitrido ligand, and one of the CH_3CN_2 nitrogen atoms occupying the four basal positions. The two four-legged piano stools share a common vertex identified by the nitrido ligand in such a way that the two Cp* ligands are *anti* with respect to each other.

The structure of the pentanuclear mixed-valence complex **3**[12] (Fig. 2) is unusual and shows that the molecule can be



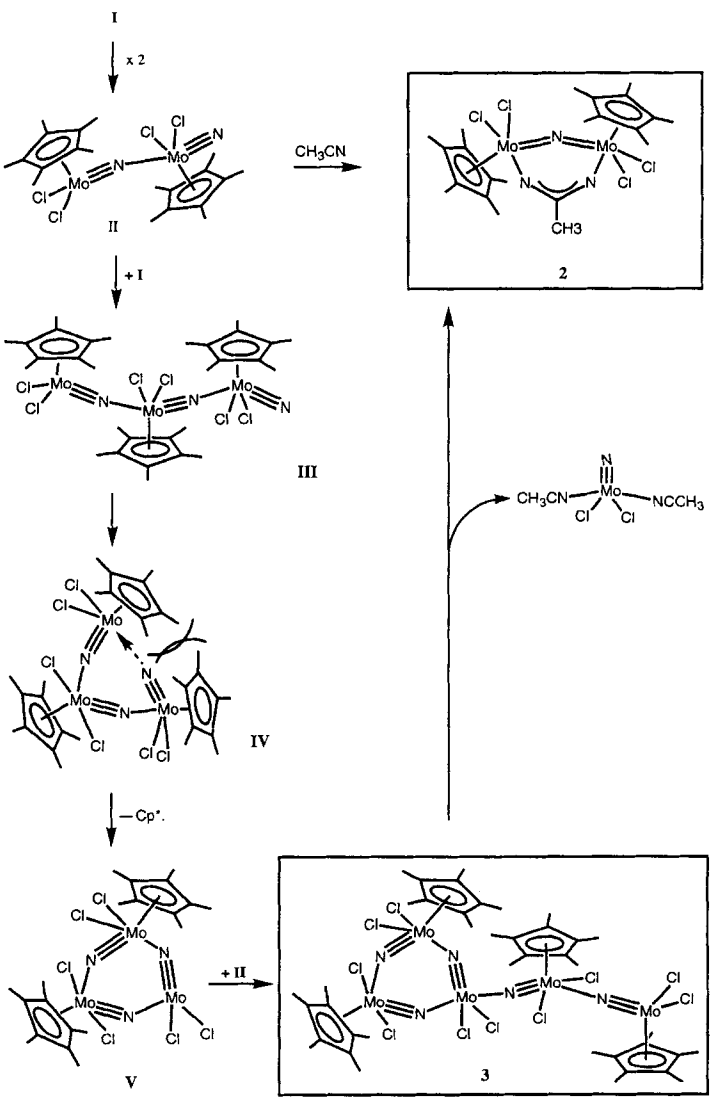


Fig. 2. ORTEP diagram of the molecular structure of **3**. Relevant distances [Å] and angles [°]: Mo1-N1 2.14(2), Mo1-N3 1.70(2), Mo2-N1 1.73(2), Mo2-N2 2.12(2), Mo3-N2 1.68(2), Mo3-N3 2.09(2), Mo3-N4 2.13(2), Mo4-N4 1.69(2), Mo4-N5 2.21(2), Mo5-N5 1.69(2), Mo-Cl (average for Mo1, Mo2 and Mo4) 2.407(10), Mo-Cl (average for Mo3) 2.378(6), Mo-Cl (average for Mo5) 2.284(7), N1-Mo1-N3 80.9(7), N1-Mo2-N2 81.8(7), N2-Mo3-N3 85.3(8), N2-Mo3-N4 107.7(8), N3-Mo3-N4 166.4(7), Cl31-Mo3-Cl32 155.0(2), N4-Mo4-N5 130.7(7), Mo1-N1-Mo2 158.5(9), Mo2-N2-Mo3 154.4(11), Mo1-N3-Mo3 157.2(11), Mo3-N4-Mo4 167.0(12), Mo4-N5-Mo5 175.3(11).

described as an aggregate of four $Cp^*Mo(N)Cl_2$ moieties and a central $Mo(N)Cl_2$ unit. One $Cp^*Mo(N)Cl_2$ dimer forms a trimetallatriazene together with the nitridomolybdenum(v) center, whereas the other dinuclear unit is coordinated in a chain-like fashion to the central Mo atom. The assignment of the oxidation state v to Mo3 is in agreement with the geometry and structural parameters of comparable compounds such as $[Mo(N)X_2L_2]$ ($X^- = L = Cl^-$; $X = N_3^-$, $L = N{\equiv}Mo(N_3)(Et_2PCH_2CH_2PEt_2)_2$).[13]

The Mo_3N_3 cycle in **3** is almost planar (the largest distances from the least-squares plane are 0.098 Å for N2, and −0.051 Å for N3) and contains localized, alternating Mo≡N triple (av 1.70(3) Å) and N → Mo dative bonds (av 2.12(3) Å). Theoretical work predicts particular stability for compounds containing a cyclic M_3N_3 moiety,[14] regardless of whether the Mo–N multiple bonds are delocalized or not. Compound **3** is the first example of a cyclic M_3N_3 unit with localized bonds. This localization is probably the result of the single d electron on Mo3, which encourages square-pyramidal coordination geometry for Mo3 and the presence of only one multiple bond in the apical position at this metal center. The Mo–N bonds are also localized in the lateral chain, as illustrated in the drawing of **3** in Scheme 2. There are four different coordination geometries in **3**: *cis*-$Cp^*MoN_2Cl_2$ for the Mo1 and Mo2 centers (analogous to the Mo centers in **2**), square-pyramidal (MoN_3Cl_2) for Mo3, *trans*-$Cp^*MoN_2Cl_2$ for Mo4, and an unprecedented three-legged piano stool (Cp^*MoNCl_2) for Mo5. The existence of the latter geometry in **3** suggests that the mononuclear species $[Cp^*MoNCl_2]$ **I** is more nucleophilic at the nitrido ligand than it is electrophilic at the metal.

Scheme 2.

As in the structure of **2**, the six-membered ring in **3** has the two Cp* rings on opposite sides of the Mo_3N_3 plane. A molecular model where the two Cp* ligands are placed on the same side of the ring reveals an unbearable steric situation. This is because the four-legged piano stool geometry forces the Mo–Cp* vectors to lie almost perpendicular to the Mo_3N_3 plane. Based on this observation, we suggest that a trinuclear $(Cp^*MoCl_2N)_3$ compound, in which two Cp* rings would be forced to reside on the same side of the three-membered ring, cannot exist. In the related trimer of tantalum reported by Roesky et al.,[2a] a greater distance between the Cp* rings is allowed by the three-legged piano stool geometry around the metals.

A possible route for the formation of compounds **2** and **3** follows from Scheme 2. The hypothetical $Cp^*Mo(N)Cl_2$ intermediate **I** oligomerizes to **II** and **III** because of the pronounced basicity of the nitrido ligand. In acetonitrile, these intermediates are likely to be coordinated by a solvent molecule at the unsaturated metal center. Subsequent addition of **II** could lead to a $[Cp^*MoCl_2N]_\infty$ polymer (a polymeric Cp* metal nitride, e.g. $[Cp^*Ta(N)Cl]_\infty$, has been observed[2b]) but other alternatives are available to intermediates **II** and **III**. A CH_3CN adduct of **II** can cyclize to afford **2** directly through attack of the nucleophilic nitrido ligand at the C atom of the ligand. In CH_2Cl_2, **III** can cyclize but, in doing so, a strong steric interaction is established between two Cp* rings (e.g. see **IV**). Therefore, one Cp* ring is likely to be lost at this stage to give **V**. The reaction is completed by coordination of **II** to the unsaturated Mo^V center.

The EPR spectrum of **3** in CH_2Cl_2 shows a resonance at $g = 1.965$ ($a_{Mo} = 46.0$ G), similar to those reported for other pentacoordinated Mo^V nitrido complexes.[13, 15] Compound **3** reacts with THF to form a yellow solution with a new EPR resonance at $g = 1.957$ ($a_{Mo} = 48.5$ G), which we assign to $[MoNCl_2(thf)_2]$. On the other hand, acetonitrile reacts with **3** to form a purple solution containing **2** as shown by NMR spectroscopy and exhibiting an EPR spectrum ($g = 1.957$, $a_{Mo} = 48.9$ G) which we assign to $[MoNCl_2(CH_3CN)_2]$.

Our results indicate that the less encumbering Cp ligand should be capable of stabilizing a trimeric $[\{CpMoNCl_2\}_3]$ structure, while Cp* is not. With regard to the possible existence of a dinuclear $[\{Cp^*Mo(\mu\text{-}N)Cl_2\}_2]$ structure analogous to that of Doherty's vanadium compound,[2c] no evidence of such a structure exists and the observation of an open-chain dinuclear unit in the structure of **3** suggests that it is unstable. Important factors may be the greater tendency of Mo (with respect to V) to reach an electronically saturated configuration, and the ability of all bridging N atoms to act as eight-electron donors in **3**, whereas in a (hypothetical) $[\{Cp^*Mo(\mu\text{-}N)Cl_2\}_2]$ structure with a Mo-N-Mo angle smaller than 120° the N atoms could at best provide six electrons to the metal centers.

In conclusion, the electron-donating character of Cp* and the availability of lone pairs for π bonding on the chloro ligands enhance the nitrido nucleophilicity and suppress electrophilicity at the electronically unsaturated metal center. Based on these principles, compounds of type $[Cp^*Mo(\equiv N \rightarrow A)Cl_2]$ (A = Lewis acid) appear to be reasonable synthetic targets.

Experimental Procedure

2: A suspension of $[Cp^*Mo(CO)_2Cl_3]$ (207 mg, 0.53 mmol) in CH_3CN (30 mL) was kept at 60 °C for 30 min. NaN_3 (34 mg, 0.52 mmol) was added to the resulting burgundy solution and the mixture was stirred at 25 °C for 30 min (gas evolution and color change to purple). The mixture was evaporated to dryness and the residue was extracted with CH_2Cl_2. After filtration, the solution was layered with a mixture of Et_2O (15 mL) and pentane (15 mL) and cooled slowly to −35 °C. Purple crystals of $\mathbf{2} \cdot 0.25\,CH_2Cl_2$ (67 mg, 39%) were isolated by decanting off the mother liquor and drying the solid under vacuum. ^1H NMR (CD_2Cl_2, 25 °C): $\delta = 2.52$ (s, 3H, N_2CCH_3), 1.99 (s, 30H, Cp*). Analysis for $C_{22.25}H_{33.5}Cl_{4.25}Mo_2N_3$ ($= \mathbf{2} \cdot 0.25\,CH_2Cl_2$). Calc.: C, 38.48; H, 4.86; N, 6.05, Cl 22.97. Found: C, 38.18; H, 4.96; N, 5.88, Cl 22.49. A crystal suitable for X-ray analysis was chosen under mother liquor.

3: A suspension of $[Cp^*Mo(CO)_2Cl_3]$ (351 mg, 0.892 mmol) in CH_2Cl_2 (30 mL) was heated under reflux for 2 h. To the resulting solution of $[\{Cp^*MoCl_3\}_2]$ [6], $(CH_3)_3SiN_3$ (125 μL, 108 mg, 0.94 mmol) was added and the mixture was stirred at 25 °C for 30 min (gas evolution and color change to emerald green). Diffusion of a 50 mL *n*-hexane layer gave black crystals of $\mathbf{3} \cdot 2\,CH_2Cl_2$ (124 mg, 43%). EPR (CH_2Cl_2, 25 °C): $g = 1.965$, $a_{Mo} = 46.0$ G. Analysis for $C_{42}H_{64}Cl_{14}Mo_5N_5$ ($= \mathbf{3} \cdot 2\,CH_2Cl_2$): Calc.: C, 31.24; H, 3.99; N, 4.34. Found: C, 31.17; H, 4.29; N, 4.34.

An Ab Initio Investigation of the Rh^I-Catalyzed Hydroboration of C=C Bonds: Evidence for Hydrogen Migration in the Key Step**

Andrea E. Dorigo and Paul von Ragué Schleyer*

The uncatalyzed hydroboration of alkenes has been studied extensively experimentally[1] and theoretically,[2, 3] and its mechanism is understood in detail. The synthetic usefulness of the Rh^I-catalyzed hydroboration reaction has been demonstrated by Evans recently.[4, 5] That the diastereoselectivity of the reaction is opposite to that observed for uncatalyzed hydroborations is of particular interest. While a mechanism[5–7] (Fig. 1)

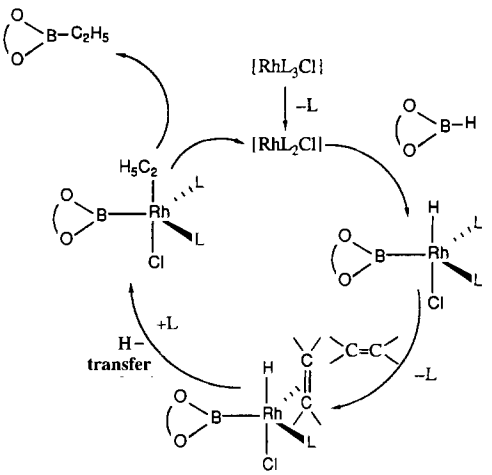

Fig. 1. Proposed mechanism [4, 5] for Rh^I-catalyzed hydroboration of C=C bonds.

has been proposed, the nature of the intermediates involved and the key step in the reaction are uncertain. Here we describe an ab initio study[8] of the potential energy surface for the addition of BH_3 to C_2H_4 catalyzed by $[Rh(PH_3)_3Cl]$. Our calculations show that hydrogen, rather than BH_2, migrates to the double bond in the key step. The results also support the existence of several 14-electron complexes as reaction intermediates and provide a possible explanation for the reaction diastereoselectivity.

Initial pseudopotential HF/LANL1DZ[8, 9] geometry optimizations followed by RMP2/LANL1DZ optimizations were carried out for all stationary points. The resulting structures are shown in Figures 2–5. All the RHF wavefunctions were stable to UHF expansion. Single-point MP4(SDQ) energies on the MP2/LANL1DZ geometries used the LANL1DZ basis set augmented with f functions on rhodium (f exponent = 0.35[9]), d functions[10] on the carbon and boron atoms, and p functions[10] on the H atom being transferred from the BH_3 unit to the C=C bond. This basis set is denoted as LANL1DZ(POL) here. Single-point MP4(SDQ) calculations were also carried out using a basis set (referred to as basis set II in the following) differing from LANL1DZ in that the 4s and 4p electrons of Rh

are included in the valence space instead of being described by the effective core potential; the relative energies at both the MP2/II//MP2/LANL1DZ and the MP4(SDQ)/II//MP2/LANL1DZ levels were similar to those at the MP2/LANL1DZ level. For the first step of the reaction—the addition of BH_3 to **1** to give **2**—QCISD(T)/LANL1DZ(POL) single-point calculations were also performed. Absolute energies at MP2/LANL1DZ, MP4(SDQ)/II, and MP4(SDQ)/LANL1DZ(POL) are given in Table 1 for all the reaction intermediates as well as for BH_3, PH_3, and C_2H_4; QCISD(T)/LANL1DZ(POL) energies are given for **1**, **2**, and BH_3. We discuss the MP2/LANL1DZ-optimized structures and the relative energies at the MP4(SDQ)/LANL1DZ(POL) level, unless otherwise noted.

Table 1. a) Absolute energies [−a.u.] at the MP2/LANL1DZ (**1**–**14**), MP4(SDQ)//II, MP2/LANL1DZ(POL), and MP4(SDQ)/LANL1DZ(POL) levels (**1**–**12**). b) Absolute energies [−a.u.] of **1**, **2**, and BH_3 at the QCISD(T)/LANL1DZ(POL) level.

In accord with the proposed mechanism[5, 6] (Fig. 1), we assumed the active catalytic species to be $[Rh(PH_3)_2Cl]$[11] (**1**, Fig. 2). Addition of BH_3 to **1** gives the 16-electron complex **2**, which is more stable than the reactants by 76.4 kcal mol^{-1} at MP4(SDQ)/LANL1DZ(POL), and by 64.9 kcal mol^{-1} at QCISD(T)/LANL1DZ(POL). Entropically, the reaction is disfavored by 37.5 cal mol^{-1} K^{-1},[13] which corresponds to a $T\Delta S$ value of 11.2 kcal mol^{-1} at 298 K. The free energy of **2**, based on the difference of 64.9 kcal mol^{-1} at QCISD(T)/LANL1DZ-(POL), is therefore 53.7 kcal mol^{-1} lower than that of **1** and BH_3. Formation of **2** is followed by loss of a PH_3 unit to give **3**, which is 33.0 kcal mol^{-1} higher in energy than **2** and PH_3, and by addition of C_2H_4 to **3** to give **4**, which is 34.1 kcal mol^{-1} lower in energy than isolated **3** and C_2H_4 molecules. No barrier was found for the formation of **4**, a 16-electron species, from the 14-electron complex **3**.[12, 13]

The C_2H_4 unit of **4** can be attacked intramolecularly, either by a hydrogen atom or by the BH_2 group of the BH_3 fragment, to give, respectively, **6** and **7** (Fig. 3). Structure **6** is strongly favored at all levels of theory (Table 1); indeed, **7** is even less

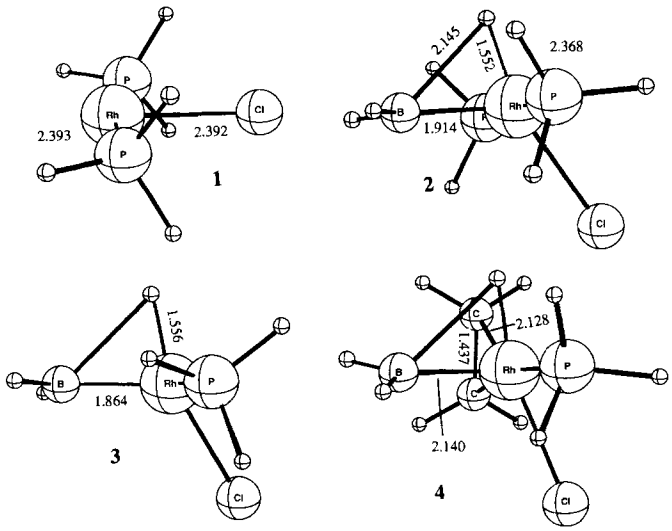

Fig. 2. MP2/LANL1DZ-optimized structures for **1**–**4**.

stable (by 10.8 kcal mol^{-1}) than the transition structure **5** that connects **4** and **6**. This result indicates, in agreement with the experimental proposal,[5] that H migration is favored both kinetically and thermodynamically over BH_2 migration. Structure **5** is only 4.1 kcal mol^{-1} higher in energy than **4** and 1.8 kcal mol^{-1} higher than **6**; the negative eigenvalue of **5** (transition structure vector) corresponds to lengthening of the breaking[14] B—H bond and of the C=C bond. We note that **6**, though formally a 14-electron species, is not a high-energy intermediate, since it benefits from the agostic interaction involving donation of the electrons of a C—H bond to the electron-deficient Rh center. In fact, the resulting Rh—H distance in **6** (1.832 Å) is not much greater than the length of the fully formed Rh—H bond in **7** (1.497 Å). This agostic interaction also explains the greater stability of **6** relative to **7**. Both species are 14-electron complexes, and the electron-deficient rhodium center is stabilized more effectively by the agostic interaction with the C—H bond (in **6**) than by the analogous interaction with the B—H bond (in **7**).

Formation of **6** may be followed either by addition of PH_3, with a subsequent internal rearrangement to give the hydroborated product, or by internal rearrangement to give **9**, followed by PH_3 addition yielding the product complex, **10**. We consider the latter possibility first. Rearrangement of **6** to **9** is exothermic by 6.7 kcal mol^{-1}, and takes place via transition structure **8**, which lies 9.8 kcal mol^{-1} above **6**. Addition of PH_3 to **9**, giving **10**, is exothermic by 26.0 kcal mol^{-1} at MP4(SDQ)/LANL1DZ(POL). No attempts were made to locate a transition structure between **9** and **10**, since the barrier is not expected to be significant. Structure **10** is substantially more stable than the isolated **9** and PH_3 molecules; moreover, addition of PH_3 to **9** is not expected to be the rate-determining step, given that intermediate **9** is substantially lower in energy than intermediate **6**. Loss of $C_2H_5BH_2$ from **10** gives back **1**, which reenters the catalytic cycle. At MP4(SDQ)/LANL1DZ(POL), **10** is more stable than **1** and $C_2H_5BH_2$ by 75.1 kcal mol^{-1}. A better estimate of the energy required for this step can be obtained by considering that the QCISD(T)/LANL1DZ(POL) stabilization (64.9 kcal mol^{-1}) of **2** relative to BH_3 and **1** is smaller than the MP4(SDQ)/LANL1DZ(POL) value (76.4 kcal mol^{-1}) by 11.5 kcal mol^{-1}, and that the $T\Delta S$ value for this process is −11.2 kcal mol^{-1}. Thus, we estimate the free energy of the formation of $C_2H_5BH_2$ and **1** to be (75.1 − 11.5 − 11.2), or 52.4 kcal mol^{-1}.[15] The computed stability of $C_2H_5BH_2$ with respect to BH_3 and C_2H_4 is 32.7 kcal mol^{-1}.

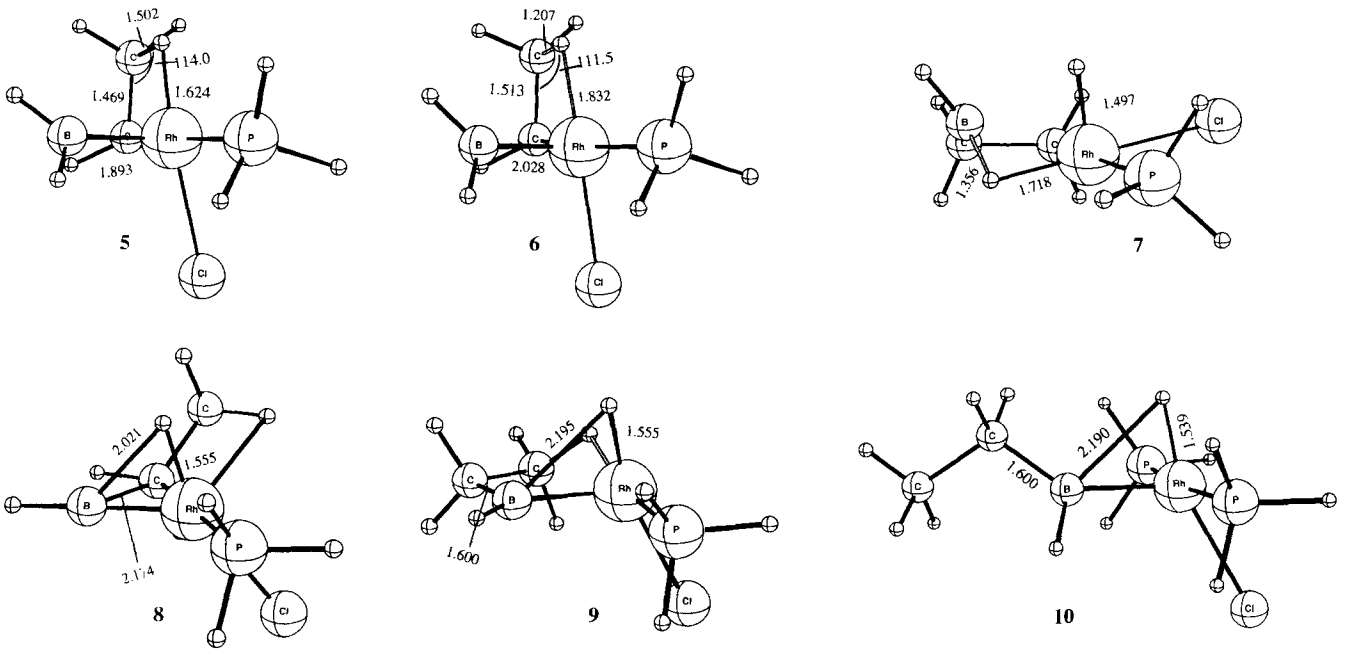

Fig. 3. MP2/LANL1DZ-optimized structures for **5**–**10**.

The alternative to the **6** → **8** → **9** → **10** pathway first involves addition of PH_3 to **6**, followed by intramolecular B–C bond formation leading to **10**. Addition of PH_3 to **6** leads to a complex (**11**, Fig. 4) with an association energy of 9.6 kcal mol^{-1}. Intermediate **11** then rearranges to **10** via transition structure **12**. The latter is only 6.5 kcal mol^{-1} higher in energy than **11**. Hence, the **6** → **11** → **12** → **10** pathway appears to be more favorable than the **6** → **8** → **9** → **10** pathway, which involves initial C–B bond formation followed by PH_3 addition.

Another pathway is possible in principle: starting from **2**, addition of C_2H_4 might give **13** (Fig. 5). This species can either lose PH_3 (to give **4**), or undergo a rearrangement with H migration similar to that described for **4**. Energies for an analogous "associative"[12] mechanism have been computed for the hydrogenation of ethylene; however, both experimental and computational evidence militates against the involvement of such processes. Both Nöth[6] and Evans[5] favor a dissociative mechanism such as the one leading to **4**; kinetic evidence in favor of this is described by Evans. Moreover, the related hydrosilylation reaction[16] can take place *intra*molecularly, and with initial migration of the silyl group according to Bosnich.[16] Inspection of **13** shows that the only Rh-bound group that can migrate to the C=C bond is the hydrogen atom, since the other moiety ($-BH_2$ in the case of **13**, or $-SiR_3$ for hydrosilylation reactions) lies *trans* to the C=C group. Indeed, even formation of a structure analogous to **13**—in which an SiR_3 groups replaces a BH_2 group—would be impossible for a molecule in which the silicon atom were connected by a three-atom chain[16] to the C=C bond.

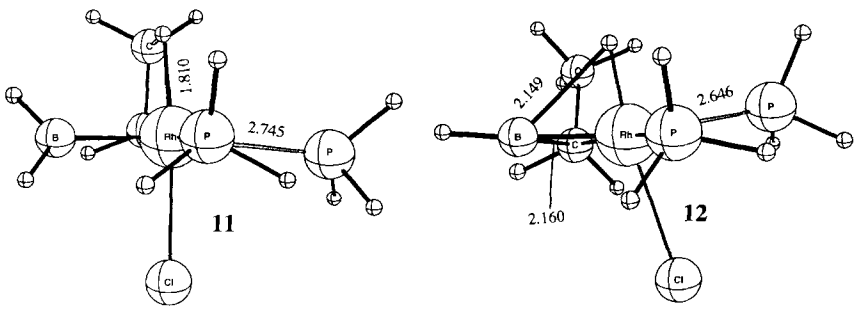

Fig. 4. MP2/LANL1DZ-optimized structures for **11** and **12**.

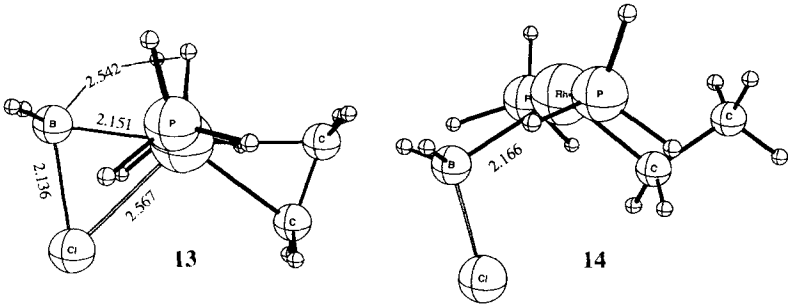

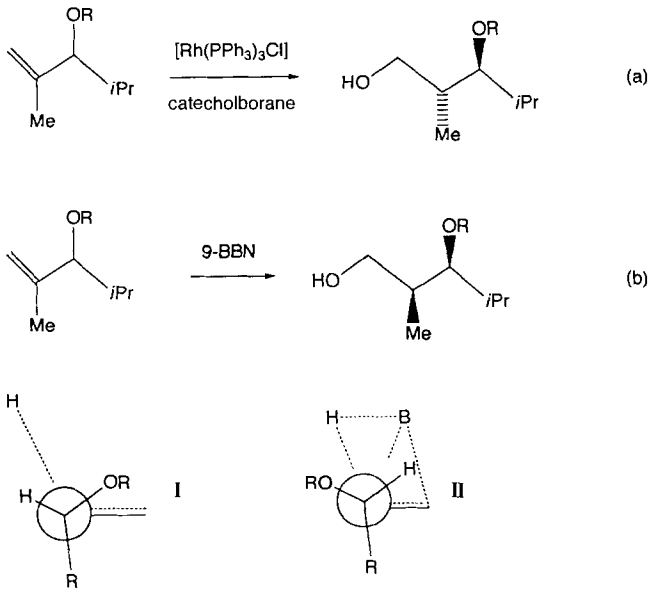

Fig. 5. MP2/LANL1DZ-optimized structures for **13** and **14**.

Evidence against the associative mechanism also comes from computation of both **13** and **14**, which is analogous to the computation of a key intermediate[12] for the associative pathway in the hydrogenation reaction. Although both species are thermodynamically quite stable—**13** is 12.9 kcal mol^{-1} more stable than **2** and ethylene, while **14** is 7.2 kcal mol^{-1} less stable than **13** (only MP2/LANL1DZ//MP2/LANL1DZ energies were calculated for these species)—the structures and bonding analysis of both species, but of **14** in particular, indicate that they are complexes of BH_2Cl with a rhodium species. In contrast to the hydrogenation study, for an associative hydroboration no minimum could be found corresponding to a complex retaining Rh–Cl bonding.[12] Thus, while **14** is a fairly stable isomer on the potential energy surface, we do not believe that it is an intermediate.

Experimentally,[4] the catalyzed hydroboration of chiral allylic alcohols and ethers gives diastereoselectivity opposite to that observed without catalysis.[4, 17] A representative example is shown in Scheme 1. While we have not examined the reaction

Scheme 1. Stereoselectivity of the uncatalyzed [Eq. (a)] and catalyzed [Eq. (b)] hydroboration of chiral ethers, and proposed transition structure models (**I** and **II**, respectively) for the two reactions. 9-BBN = 9-borabicyclo[3.3.1]nonane.

of chiral alkenes, the switch in diastereoselectivity due to Rh^I catalysis can be rationalized by considering transition structure **5**, where the angle of attack of the hydrogen atom is about 114° (Fig. 3). Allylic substituents are expected to adopt a conformation that minimizes repulsive steric interactions with the incoming hydrogen atom, like conformation **I** shown in Scheme 1. Here, the alkyl group occupies the least hindered position (*anti* to the attacking hydrogen), while the allylic hydrogen atom occupies the most hindered position (inside). In contrast, the conformation **II** preferred in the uncatalyzed hydroboration leads to the opposite diastereomer.[2] The different conformational preferences in the two transition structures are due to the steric and electronic requirements of the electron-deficient BR_2 group. In the catalyzed reaction this group is not involved in the attack of hydrogen on the C=C bond.

In conclusion, our study[18] confirms the suggestion[4] that H migration is preferred to BH_2 migration in the key step of the Rh^I-catalyzed reaction. This step helps explain the reaction diastereoselectivity. Our study also lends support more generally to the intermediacy of 14-electron intermediates, which also may be involved in related reactions such as Rh^I-catalyzed hydrosilylations of C=C bonds.[16] For the latter it has been suggested[16] that the trialkylsilyl group migrates first, followed by the hydrogen in a later step. This mechanistic preference may be explained in the same way as the preference for H migration over BR_2 migration: the silyl group migrates because it can stabilize the electron-deficient metal center more effectively. The results of our investigations into these silyl systems will be reported subsequently.

[7] Brown and Lloyd-Jones have suggested that, for the reaction of catecholborane with phosphane-free rhodium catalysts, β-hydride elimination competes with addition of a second molecule of borane: J. M. Brown, G. C. Lloyd-Jones, *J. Am. Chem. Soc.* **1994**, *116*, 866.
[8] All calculations used the Gaussian 92 program: M. J. Frisch, G. W. Trucks, M. Head-Gordon, P. M. W. Gill, M. W. Wong, J. B. Foresman, B. G. Johnson, H. B. Schlegel, M. A. Robb, E. S. Replogle, R. Gomperts, J. L. Andres, K. Raghavachari, J. S. Binkley, C. Gonzales, R. L. Martin, D. J. Fox, D. J. Defrees, J. Baker, J. J. P. Stewart, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1992**. See also J. B. Foresman, Æ. Frisch, *Exploring Chemistry with Electronic Structure Methods: A Guide to using Gaussian*, Gaussian Inc., Pittsburgh, PA, **1993**.
[9] An effective core potential was employed for rhodium in which the nine valence electrons were described by a double-ζ basis set. See: P. J. Hay, R. W. Wadt, *J. Chem. Phys.* **1985**, *82*, 270.
[10] The f exponent of 0.35 for Rh is also used in K. Balasubramanian, D. W. Liao, *J. Chem. Phys.* **1988**, *92*, 6259. C d exponent: 0.8; B d exponent: 0.6; H p exponent: 0.11.
[11] a) Detailed calculations on **1** have also been reported by N. Koga, K. Morokuma, *J. Am. Chem. Soc.* **1993**, *115*, 6883. See also *J. Phys. Chem.* **1990**, *94*, 5454. Note added in proof (September 20, 1994): we found that the triplet state of **1** is lower in energy than the singlet; however, as one of the referees also pointed out, facile intersystem crossing in **1** implies that computation of subsequent steps on the singlet surface is justified. The value which we calculate for the free energy of the final elimination step (52.4 kcal mol^{-1}) is based on the energy of singlet **1**. Assuming the triplet to be 9.7 kcal mol^{-1} more stable than the singlet (as calculated by Koga and Morokuma) the free energy of the final elimination step becomes 42.7 kcal mol^{-1}. Other factors [15] may lower this value further. b) According to Dedieu, the *cis* isomer of **1** is favored (A. Dedieu, *Inorg. Chem.* **1980**, *19*, 375); this isomer is also favored at HF/LANL1DZ, and is close in energy to **1** at all levels considered. However, an attempt to optimize the complex of BH_3 with the *cis* isomer of **1** led to the formation of a structure having a B–Cl bond, which is clearly not involved in the addition of BH_3 to C_2H_4.
[12] Similarly, no barrier has been found for the addition of C_2H_4 to a 16-electron intermediate in the Rh^I-catalyzed hydrogenation of C=C bonds: C. Daniel, N. Koga, J. Han, X. Y. Fu, K. Morokuma, *J. Am. Chem. Soc.* **1988**, *110*, 3773.
[13] a) The entropies of **1**, BH_3, and **2** are 96.1, 46.4, and 105.0 cal mol^{-1} K^{-1}, respectively. b) While formation of **3** is disfavored enthalpically, it is favored entropically. The entropies of **2**, **3**, and PH_3, calculated from numerical frequency computations, are 105.0, 89.6, and 50.3 cal mol^{-1} K^{-1}; thus, dissociation of **3** into **2** and PH_3 is favored by 34.9 cal mol^{-1} K^{-1}, which corresponds to 10.4 kcal mol^{-1} at 298 K. The free energy for the dissociation of **2** can be thus estimated to be 22.6 (= 33.0 − 10.4) kcal mol^{-1}. Similarly, the entropies of **3**, C_2H_4, and **4** are 89.6, 52.5, and 106.7 cal mol^{-1} K^{-1}; **4** is therefore formed with a loss of entropy of 35.4 cal mol^{-1} K^{-1}, corresponding to 10.5 kcal mol^{-1} at 298 K. Thus, the free energy for the formation of **4** can be estimated at −23.6 (− 34.1 + 10.5) kcal mol^{-1}.
[14] Some residual B–H bonding is present in **2**, **3**, and **4**, in spite of the fairly large B–H distance. The Wiberg bond index is 0.13, 0.14, and 0.13, respectively.
[15] Experimental systems involve stabilized boranes, such as catecholborane or 4,4,6-trimethyl-1,3,2-dioxaborane (TMDB) (for a review, see K. Burgess, M. J. Ohlmeyer, *Chem. Rev.* **1991**, *91*, 1179). For these systems the interaction with **1** or analogous rhodium catalysts is certainly smaller than the values which we calculate for BH_3. Likewise the final reductive elimination step should be energetically less unfavorable than calculated here.
[16] S. H. Bergens, P. Noheda, J. Whelan, B. Bosnich, *J. Am. Chem. Soc.* **1992**, *114*, 2121.
[17] W. C. Still, J. C. Barrish, *J. Am. Chem. Soc.* **1983**, *105*, 2487.
[18] Note added in proof (December 12, 1994): A recently published theoretical mechanism (D. G. Musaev, A. M. Mebel, K. Morokuma, *J. Am. Chem. Soc.* **1994**, *116*, 10693) differs significantly from our proposal. The dissociative mechanism [5, 6] we favor was not computed. Moreover, BR_2 migration was favored over H migration in the key step, in contrast with the experiments by Evans et al. [5] and our conclusions.

Conflicts of Conscience

Fritz Haber—Chemiker, Nobelpreisträger, Deutscher, Jude. By *D. Stoltzenberg*. VCH Verlagsgesellschaft, Weinheim, 1994. XIV, 669 pp., 93 figures, 8 tables, hardcover DM 98.00.—ISBN 3-527-29206-3

Dietrich Stoltzenberg's new book is the first substantial and truly comprehensive biography of Fritz Haber (1868–1934) ever published—sixty years after Haber's death and at a time when German literature is the forum for a lively debate about the subject.

The author of his biography is himself a chemist, as well as a son of the industrialist Hugo Stoltzenberg (one of Haber's co-workers as early as the gas-warfare days of World War I) and the chemist Margarethe Stoltzenberg-Bergius (a sister of F. Bergius, developer of the coal-hydrogenation process and one-time assistant to Haber). Stoltzenberg has therefore been familiar with Haber and his career since childhood, a genuine stroke of luck for this particular biographer of the Nobel laureate. The resulting account of Fritz Haber's career is as well-informed, engaging, and authoritative as one would expect, and it offers a balanced and fair examination of every stage of the subject's life. Despite his obvious empathy with Haber the man, Stoltzenberg is not uncritical, and he is certainly not deferential—a temptation to which many biographers unfortunately succumb. Nevertheless, Stoltzenberg often introduces his criticism in subtle ways and between the lines. The overall treatment is to the point, albeit occasionally very detailed.

Haber's career is examined very thoroughly and documented by many new sources, with appropriate attention to his origins in a Jewish family, his early schooling and education at a number of universities, and his doctoral work in the field of organic chemistry. Haber undertook several years of academic and practical apprenticeship followed by internships in various industries before finally presenting a habilitation thesis in physical chemistry to the University of Karlsruhe (1896). A 17-year sojourn in Karlsruhe, rightfully characterized by Stoltzenberg as Haber's "personal and scientific climax," earned for him a reputation as an outstanding electrochemist, and it led to the creation of a chair in physical chemistry equipped with all the facilities necessary for industrially oriented research. The Karlsruhe years also witnessed the solution to the nitrogen-fixation problem, ensuring the availability for the first time of an adequate supply of nitrogenous fertilizers for agriculture through Haber's epochal development of an ammonia synthesis based on the catalytic hydrogenation of nitrogen. This was the famous Haber process, later known as the Haber–Bosch process, for which a Nobel Prize was awarded in 1918. The ammonia work necessarily entailed close and fruitful collaboration with chemical industry, an involvement which together with the Janus-faced character of ammonia itself (a starting material not only for fertilizers but also explosives) and Haber's own intellectual propensities (C. Engler described him in a letter to BASF as "a sharp and adroit dialectician") laid the groundwork for points of friction that certain contemporary critics and their present-day apologists subsequently transformed into major stumbling blocks.

In 1911 Haber became director of the newly created Kaiser Wilhelm Institute for Physical Chemistry and Electrochemistry in Berlin-Dahlem. The Institute personnel were later merged with staff from the War Ministry, after which Haber occupied various official positions within the Ministry itself, eventually becoming director of the Chemical Division ("Haber's Office")—and thereby the "instigator of chemical warfare." His tireless and ultimately self-destructive efforts in this capacity led to the systematic development and subsequent battlefield deployment of poison gas, which was to become another stumbling block for Haber and a major source of the controversy that continues to surround him. After World War I he occupied himself with various chemical projects (including attempts to exploit the gold reserves in sea water) and miscellaneous contributions to scientific policy and the support of scientific research. On April 30, 1933, at the age of 64, he submitted his formal resignation, expressed in the most emphatic of terms both verbally and in writing—one month after the government organized its first boycott and enacted the first of the laws directed against the Jews. Haber died in 1934.

Based on Haber's curriculum vitae alone it is difficult to understand the intensity of the dissonant debate over guilt and entanglement provoked by his career, or to explain the current renaissance of the controversy, but the extent of the polarization itself is readily demonstrated. "Haber was more than a great leader of science—he was a great man. His rich, full life, the institutions he made, his service to his country, even his failures—all were on the grand scale." These noble words were delivered by J. E. Coates on the occasion of the 1937 Haber Memorial Lecture (*J. Chem. Soc.*, 1939). Coates was a student of Haber's, but he was also an Englishman, and the sentiments quoted above were expressed on the eve of yet another war. How different they are from the charges of Haber's critics (often non-chemists), typical exponents of "the modern interpretation of history" and "flagbearers of enlightenment" who reinterpret lives lived in the past "from the perspective of the present," or even "in the spirit of a modern approach to life." Here the talk is all of "scandal," with Haber's life portrayed and interpreted in a temporal context devoid of all trace of understanding, even understanding with respect to Haber's unique aberrations, which are

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

said to "cast a deep shadow over his life and work" (Stoltzenberg).

What purpose do such comments serve, and what do they add to the discussion concerning Fritz Haber, a discussion in which we are still engaged 60 years after his death? Fritz Haber was not simply a highly respected chemist; he was also a divided and torn human being whose legacy to mankind includes both an ingenious procedure for synthesizing ammonia and the "Haber product," $W = c \times t$, intended for use as a standard in assessing the lethal power of chemical weapons. The study of Haber's life and character anticipates in an exemplary way the broader debate over guilt and entanglement as it applies to scientists generally, including the progenitors of the atomic and hydrogen bombs: Otto Hahn, Robert J. Oppenheimer, and Edward Teller. Haber serves as an especially attractive case-study for ideologues, because through him they purport to be able to construct the continuous and calamitous sequence: Haber = criminal = chemical industry = industry in general = capitalism = evil = antisocial.

Several biographies, including Stoltzenberg's, make explicit reference to one particular saying attributed to Haber: "im Frieden für die Menschen, im Krieg für das Vaterland" ("in peacetime for mankind, in war for the Fatherland"), words that are no more but at the same time no less valid or repulsive than the British "Right or wrong: my country." Limitations that may also have been implicit in the sentiments so expressed—once a topic of national debate that has since turned global—no longer lend themselves to accurate reconstruction, but fairness demands that the remark at least be viewed against the background of the times. Haber was a converted Jew; at various stages in his life he was subjected to all the misgivings Jewishness evoked in Germany even during the reign of the Kaisers. Like many others he attempted to confront prejudice with extraordinary personal deeds coupled with an ardent display of "Germanness," perhaps even with a rash and precipitous form of patriotism. This problematic situation was a matter of some discussion subsequent to 1918 in connection with responsibility for the Great War. Haber believed there had been solid grounds for introducing poison gas into the fighting, especially on the German side. He never denied or repudiated this stance, and he accepted full responsibility for it. Stoltzenberg thoroughly explores this important facet of Haber's understanding of the very personal meaning of Germanness.

Stoltzenberg's biography also conveys—as far as possible 60 years after the protagonist's death—a sense of Haber's fate as that of an understanding, sensitive, and at the same time tragic individual: tragic in terms of his association with weapons that have since been outlawed and problems peculiar to the intersection of science with politics; tragic also in the personal sphere, with two unhappy marriages, the first of which ended in his wife's suicide, and the experience of being hounded out of office just six months short of retirement. Today we can only speculate about the extent to which all of this led to a guilt complex evolving gradually and through psychosomatic processes into a state of autostress, which perhaps culminated in his precarious state of health and early death.

But why is there so much posthumous hate, or at best such posthumous lack of understanding? Ideologues and others not given to reflection find it child's play to label Fritz Haber posthumously as a criminal, because by present-day standards he did assume a tremendous burden of personal guilt; besides, he is no longer able to defend himself. The fact that he was also a scientist—indeed, an outstanding scientist: a Nobel laureate—makes Haber a particularly valuable commodity for ideologues; they can attack Fritz Haber the personally vulnerable individual, and then transform him into a symbol for science, industry, and capitalism generally. For champions of a simplistic point of view the conclusion is perfectly straightforward: anyone not opposed to Haber and gas warfare and the synthesis of ammonia must automatically be an enemy of socialism and peace—ergo, a vile human being.

Another phenomenon that must also be taken into account is the way Haber's opponents present their retrospective interpretation of a life lived at another time, with the subject of a biography used essentially as a vehicle for criticizing the history and conditions of another era. As Stoltzenberg's biography makes clear, it is simply dishonest to ignore influences of the times and the circumstances that prevailed, including in this case a restrictive national perspective and the situation inevitably facing a baptized Jew. In short, one cannot overlook the cumulative effect of a host of political currents, cultural influences, questions related to an individual's personal origins, historical consciousness, and the like. Moreover, Fritz Haber cannot be regarded as representative simply because contrasts may be apparent between certain aspects of his behavior then and what we might regard as permissible today with our (superior!) wisdom and understanding. This would be tantamount to denying the temporal qualities associated with every human life, and critiquing every utterance from the past according to the standards of today. Doing so requires that we abandon all sympathy for the world of our parents and grandparents, and a lack of sympathy is equivalent to a lack of understanding. Stoltzenberg does demonstrate sympathy in his writing, and with it a measure of anxiety, and he transmits his feelings to the reader. It is also important to reiterate that Haber's own contemporaries and colleagues viewed him with considerably more understanding, and despite the difficult circumstances of the time the obituaries they prepared articulate far more *noblesse* than the words of many of today's "know-it-alls."

What remains is the recognition that we can only *attempt* to understand Fritz Haber. We cannot relieve him of his tragedy, nor of his entanglements with guilt. He anticipated in encapsulated form that which should characterize every scientist: the upright integrity of a researcher who knows himself to be one with the spirit and morals of his age and of his contemporaries of all nationalities. A tendency to cast this premise in doubt, as some now do, is one of those inexplicable, irrational manifestations of the German soul. That Haber was also the victim of disdain and a political movement's will to exterminate physically those whom it dismissed on ethnic grounds should actually be regarded as an honor.

Haber also leaves us with a question, one that needs to be addressed by every scientist: precisely when does progress become transformed into a weapon, thus triggering an obligation on the part of the individual scientist to engage in emphatic and articulate opposition? Progress cannot be prevented, but one can most assuredly insist that it not be misused. Haber's ultimate tragedy lies in the fact that he failed to recognize this distinction.

FT-NIR Atlas. By *M. Buback* and *H. P. Vögele*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 1067 pp., hardcover DM 880.00, $ 570.00.—ISBN 3-527-28567-9/1-56081-744-5

With the increasing use of modern Fourier transform (FT) infrared spectrometers, the NIR spectral region (4000–

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0120 $ 10.00+.25/0

10000 cm^{-1}), which was previously rather neglected, has become readily accessible and is of interest to many analytical laboratories. This *FT-NIR Atlas* is the first volume in a series of "SpecBooks" which are planned to cover all the most important spectroscopic methods. It contains the first ever collection of digital NIR spectra. Unlike the many conventional spectra atlases that have a long tradition based on "analog" spectra, the *FT-NIR Atlas* is a "hard copy" which has been generated, largely automatically, from a digital data bank to produce a collection of NIR spectra of 1957 compounds.

The arrangement of this spectra collection is similar to that in the *Merck FT-IR Atlas*. For each substance two spectra are shown separately, covering the ranges 3800–7200 cm^{-1} (NIR I, on a scale of about 250 cm^{-1} per cm) and 6300–10500 cm^{-1} (NIR II, on a scale of about 625 cm^{-1} per cm), which results in a very clear presentation. Alongside each spectrum are listed up to seven of the strongest peaks, which considerably simplifies making comparisons with experimentally observed spectra. Each compound is identified by its structural formula, systematic name, and molecular formula. The CAS Registry number, manufacturer's catalog number, and physical properties such as molar mass, density, melting point, etc. are also listed. In cases where the compound was not available in a sufficiently pure form for recording a true spectrum, the exact composition of the mixture is given in an appendix. The selection of the 1957 compounds included is, of course, arbitrary; however, as it is based on collecting together compounds from current catalogs of chemicals this ensures that it includes many of the compounds most commonly found in laboratories.

The volume is very well produced, and even fine details of the spectra are clearly discernible. The introduction gives a short and succinct account of the experimental and theoretical background. Separate indexes according to molecular formula, compound name, and CAS Registry number are provided. However, many users will have difficulties in locating compounds by name; for example, triphenylmethane is listed as "Benzene, 1,1′,1″-methylidynetris-". Here it would definitely have been sensible to also include common trivial names in the index. A further criticism concerns the structural formulas; these are shown without the hydrogen atoms, a convention which takes a little getting used to.

Despite the fact that this presentation in book form is in competition with the electronic data bank, with all the latter's advantages, it will certainly find an established place in spectroscopic and analytical laboratories. Its advantages are that the spectra are simply within arm's reach, without the bother of a flickering VDU screen, and several spectra can be directly compared. The only obstacle to its becoming widely available will be the present impoverished state of many university libraries.

Activated Metals in Organic Synthesis. By *P. Cintas*. CRC Press, Boca Raton, USA, 1993. 236 pp., hardcover $ 59.95.—ISBN 0-8493-7863-X

This book describes in detail the applications of activated metals in organic and organometallic chemistry. The first part (Chapters 1–3) covers metal vaporization methods, a number of other metal activation methods (such as the Rieke, metal–anthracene, and ultrasonic methods), and the use of metal–graphite compounds. Each method is discussed in considerable detail, clearly explaining its advantages and disadvantages. The most important reactions are collected together in equation form, and the experimental details of the most useful activation methods are described clearly and concisely (including, for example, the preparation of Rieke zinc, of iodine-activated magnesium, and of activated nickel from nickel diisopropoxides).

The second part (Chapters 4–8) is concerned with the use of activated metals in organic synthesis. Many examples are given together with references to recent work (150–200 literature citations per chapter), providing an important and valuable resource for the preparative organic chemist and for everyone who uses metals in synthesis. Chapter 4 describes the use of activated metals in reductions. Chapter 5 then deals with reductive couplings of carbonyl compounds, giving a very good review which ranges from the classical pinacol coupling to the McMurry coupling. Additions to carbonyl compounds are described in Chapter 6, treating the Barbier reaction (in which the reactive organometallic species is generated in the presence of the electrophile) and reactions of the Reformatsky type in separate sections. However, this classification is not followed consistently, as the section on the Barbier reaction also includes two-stage organometallic reactions. The treatment of the important reactions is very good, with clearly set out equations to give the reader a sound grasp of the principles. The discussion of the Reformatsky reaction is especially detailed (including the structures of the reagents, the role of zinc activation, the extension to other metals, and the stereoselectivity of the reaction). Chapter 7 is devoted to cyclizations, in which activated metals offer an important means of generating reactive intermediates (e.g. Simmons–Smith reactions and metal-initiated free radical cyclizations). The final chapter describes zinc-mediated ring-opening reactions of sugar derivatives and applications to the stereoselective synthesis of chiral acyclic polyhydroxy building blocks.

To summarize, the book gives a good overview of synthetic applications of activated metals, which is an important area of modern organic chemistry. It makes easy reading, is very detailed, and is suitable for post-graduate and advanced chemistry students, as well as for industrial chemists involved in research and development. It should be available in every university library.

Cluster Chemistry. By *G. González-Morega*. Springer, Heidelberg, 1993. 302 pp., paperback DM 98.00.—ISBN 3-540-56470-5

Cluster Chemistry by G. González-Morega was announced as "the first (book) to be appropriate for disseminating and especially for teaching this contemporary topic." Notwithstanding an ever growing number of monographs covering various aspects of this field of science, there is indeed a need for a textbook which can form the basis of an advanced undergraduate or graduate course and, most of all, lead the "novice" who is familiar with the basic principles on to the more advanced topics.

The introductory section (Ch. 1) on "Current Concepts in Modern Chemistry" is concerned with the fundamental aspects of the theory of atomic structure and chemical bonding as may be found in most textbooks on general and/or inorganic chemistry. The following chapter on "Transition Metal Cluster Chemistry" is the first major section dealing with the topic of the book. Beginning with a discussion on the classification of clusters (naked/ligated, high valence/low valence) and the principal types of ligands, a sur-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0101-0121 $ 10.00+.25/0

vey of (primarily) molecular clusters according to their nuclearity is given. The coverage is extensive rather than intensive, and it is arguable whether long reference lists of compounds are particularly useful at this stage. There are several confusing statements, such as: (p. 68) "The study of cluster hydrides is of considerable interest since ... they are intimately associated with important catalytic processes, e.g. Fischer Troppch (!) processes for ammonia and methane synthesis"; (p. 76) "Solid angles and distortion degree in open structures depend on a number of factors as, for instance, the number of electrons, the nature of disposable orbitals, and the properties of ligands" ... and so on ...

Instead of reading the section on "Bonding in Metal Clusters", those who wish to get familiar with this very important aspect of cluster chemistry should rather consult the original papers cited by the author. In Sections 2.4 ("Synthesis of Cluster Compounds"), 2.5 ("Cluster Reactivity") and 2.6 ("Cluster Catalysis") various aspects of these topics are discussed on the basis of the review literature of the 1980s. Chapter 3 is devoted to "Main Group–Transition Metal Mixed Clusters", a chapter which "deals mainly with compounds in which the main group elements may be considered as cluster vertexes of the polyhedron." I found it difficult to appreciate why hydrido clusters, clusters with interstitial atoms, etc., which were already in part covered in the previous chapter require a separate section. The statements in the sub-section 3.1.3 on "Proton Magnetic Resonance" of hydrido clusters are entirely incorrect and should be avoided by the reader.

In Chapter 4 several aspects of (among others) alkali metal suboxides, boranes, Zintl ions and, more extensively, fullerenes are discussed. The book concludes with a brief section on iron–sulfur cages in proteins.

Unfortunately, this book is riddled with typographical errors, incorrect citations, journal hybridizations (there are 15 references to "*J. Am. Chem. Soc., Dalton Trans.*" in Table 3.2 alone) as well as several factual errors (too many to list in a review). It is only with these reservations that it might be useful to the graduate student interested in cluster chemistry.

Clusters and Colloids. From Theory to Applications. Edited by *G. Schmid.* VCH Verlagsgesellschaft, Weinheim/ VCH Publishers, New York, 1994. 555 pp., hardcover DM 249.00.— ISBN 3-527-29043-5/1-56081-753-4

Clusters and Colloids edited by G. Schmid is clearly written for a readership familiar with the fundamental aspects of cluster chemistry and colloid science (as is pointed out by the editor in the introductory chapter). The choice of the topics is such that this book may complement other currently available monographs on clusters but, most of all, takes into account the very recent developments in this area of science. Distinguished researchers in the fields of high nuclearity cluster chemistry and colloid science offer a multifaceted and in depth account of the current state of the art.

In the first main section of the book (Ch. 2) N. Rösch and G. Pacchioni give a clearly structured and critical survey of the theoretical methods employed in the investigation of naked and ligated metal clusters. The potential and weaknesses of the different approaches are outlined and compared, which makes this section excellent reading for those (experimentalists, in particular) who wish to acquire a sound "second level" knowledge in this area. A concise overview of the physical methods for the investigation of the electronic structures of clusters is also given, although this part of the chapter is somewhat less critical towards the original literature.

Chapter 3 by D. Fenske, G. Longoni and G. Schmid is devoted to the whole area of ligated high nuclearity clusters ("Clusters in Ligand Shells"). Longoni's survey of low-valent organometallic clusters is probably the best contemporary review of the area of high nuclearity carbonyl clusters, while Fenske gives a well structured account of the rapidly expanding area of the structural chemistry of transition metal clusters containing bridging main group elements. Whether Schmid's section on "super clusters", which clearly lie outside the regime of "conventional" molecular clusters, would have been more appropriately placed next to (or before) the chapter on transition metal colloids at the end of the book is a matter of personal taste. The clarity of the presentation in this section should, however, be commended.

In "Clusters in Cages" (Ch. 4) S. Kawi and B. C. Gates review investigations of clusters encapsulated in zeolite cages. Particular emphasis is placed upon the analytical methods used, as is also the case in J. S. Bradley's section on "The Chemistry of Transition Metal Colloids" (Ch. 6). Both emphasize the importance of methodological aspects in the development of a field of research, a notion which is particularly apparent in the long history of research in colloid chemistry and physics.

Sandwiched between these two chapters is a survey of "Discrete and Condensed Transition Metal Clusters in Solids" by A. Simon, covering not only the structural systematics but also the structure–property relationships in this important area of solid state chemistry. This section is extremely well written and offers both the "non-solid state" cluster chemist and the specialist in that area the quintessence of more than two decades of research on clusters in solids.

As a whole, this is indeed a well-integrated, readable book and the editor and contributors are to be congratulated on their achievement. It is strongly recommended to anyone who wishes to learn about the more advanced aspects of cluster chemistry and to become addicted to the beauty of cluster compounds.

Disulfide-Reductase Inhibitors as Chemotherapeutic Agents: The Design of Drugs for Trypanosomiasis and Malaria

R. Heiner Schirmer,* Joachim G. Müller, and R. Luise Krauth-Siegel

Viewed globally, parasitic diseases such as malaria and Chagas' cardiopathy pose an increasing threat to human health and welfare. Recognition of this problem and the challenge of synthesizing a quinine-like antimalarial agent sparked off the development of the chemical industry about 100 years ago. Our contribution deals with aspects of drug design, a young branch of pharmaceutical chemistry. As drug targets the flavoenzyme, glutathione reductase, and the recently discovered parasite enzyme, trypanothione reductase, were chosen. Based on the knowledge of the structure of these molecules, the modeling of enzyme inhibitors as potential chemotherapeutic agents against parasites has become possible. In addition, biochemical and clinical observations are considered since chemical principles of biological evolution can serve as guidelines for the pharmaceutical chemists. The picture shows two erythrocytes destroyed by malaria parasites. In the center of the photograph a parasite is just leaving its host cell through the ruptured cell membrane. Its target could be a neighboring healthy erythrocyte.

Keywords: drug design · enzyme inhibitors

1. Introduction

Drug design applies biomolecular recognition mechanisms to chemotherapeutic problems.[1] The first step is always the determination of the three-dimensional structure of a protein or another macromolecule that plays an important role for a particular pathogen or disease process. Then by means of computer modeling, inhibitors of this target molecule can be proposed.[2] These molecules are synthesized, tested for their chemotherapeutic activity, and if they are promising, improved further. An example of this principle was the development of the peptidase blocker Captopril, an important compound for the treatment of hypertension.[3] The latest success of drug design is guanidinoglycal, an enzyme inhibitor that is active against influenza viruses.[4, 5]

Our review deals with the need to develop novel compounds to combat parasitic infectious diseases. Two disulfide reductases, the antioxidative enzymes trypanothione reductase and glutathione reductase, were chosen as target molecules for the design of parasiticidal drugs.

2. Clinical Pictures of Malaria

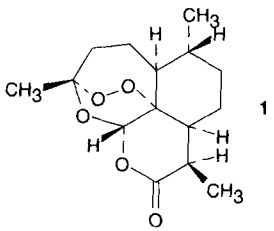
In the last 25 years malaria has regained its former position as the greatest threat to the health and economic prosperity of mankind.[6, 7] According to figures published by the World Health Organization, 1500 million people live in areas where malaria is endemic, 300 million cases are recorded each year, and more than 2 million—mostly children under five years of age—die from malaria; an unknown number of children are left crippled or chronically ill.

The causative agents of malaria are protozoa (*Plasmodium species*) that are transmitted through the blood-sucking anopheles mosquitoes. Humans become ill when the malaria parasites multiply in the erythrocytes (the red blood cells). The clinical picture is dominated by high fever and a debilitating feeling of illness. The *vivax malaria* is known to give rise to a bout of fever every 48 h. Each fever attack requires from the infected patient an energy expenditure of up to 20000 kJ. When undernourished children are affected, the exhaustion from the bouts of fever can starve them to death.

A severe burden is also placed on the immune system. If only 1% of erythrocytes are affected by malaria, every 48 hours the rupture of the infected cells will release 10–20 g of foreign proteins directly into the bloodstream. Thus malaria is the septicaemia par excellence. Many lines of evidence indicate that the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0202-0141 $ 10.00+.25/0

immune system, in particular the network of interleukins, was programmed during evolution to be highly effective in combating not bacteria and tumor cells, but intracellular parasites.



Consequently, basic principles of the body's defence against tumor cells are expected to be revealed by studying parasitic diseases. Our recommendation that cancer research should include parasitic diseases also has a political dimension: a much greater proportion of research funding is spent on each patient suffering from cancer than is spent on each human being dying of malaria.

Even more perilous than *vivax malaria* is *malaria tropica* which is caused by *Plasmodium falciparum*. In this form of the disease the course of the fever is less characteristic, and the feared complication is cerebral malaria, which manifests itself as hallucinations, headaches, convulsions, and severe disturbances of consciousness. Five percent of the children who survive cerebral malaria suffer permanent neurological damage such as hemiplegia, blindness, or speech impairment.[8a] On account of its widespread distribution, malaria is the most serious brain disease in the world.

Chronic malaria is a serious health problem principally because of the resulting anaemia. The mental changes accompanying it led to the colloquial use of the word "spleen", which originally referred to the peculiarities of a person with an enlarged spleen caused by malaria.

The development of a vaccine against malaria has so far not fulfilled expectations. Nevertheless, a synthetic peptide vaccine developed by Patarroyo and colleagues in Colombia has procured partial protection against *P. falciparum* infection in field trials.[8b]

Malaria pathogens are most adaptable to chemical changes in their environment. Following the introduction of a new drug, it can be anticipated that *Plasmodium falciparum* will develop resistance within a few years. Chloroquine (resochin), the drug of choice a decade ago, is ineffective today in most regions where malaria is endemic. Only with the worldwide appearance of resistant strains of the parasite did scientists become interested in the mechanism of action of this compound. At present the most attractive hypothesis is that chloroquine blocks a parasite-specific heme polymerase.[8c] Tourism and, above all, military travel to distant regions were largely responsible for the spread of chloroquine-resistant pathogens.

1

At the present time there is no agent that can offer protection against malaria in all regions of the world; the need for novel chemotherapeutic agents is therefore acute. The most promising compounds now are derivatives of Qinghaosu (Artemisinin, **1**), which was isolated in 1971 by Chinese chemists from the leaves of Artemisia species.[9b]

3. Chagas' Heart Disease (American Trypanosomiasis)

Like the plasmodia, the interrelated Trypanosomes, Leishmanias, and Crithidias are also unicellular parasites. These three protozoa belong to another order, the Kinetoplastida; the name refers to their typical propeller-like flagellum (Fig. 1, left). Crithidias are only pathogenic for insects. Trypanosomes and leishmanias, on the other hand, cause severe infectious diseases of man and domestic animals in tropical countries. Examples of

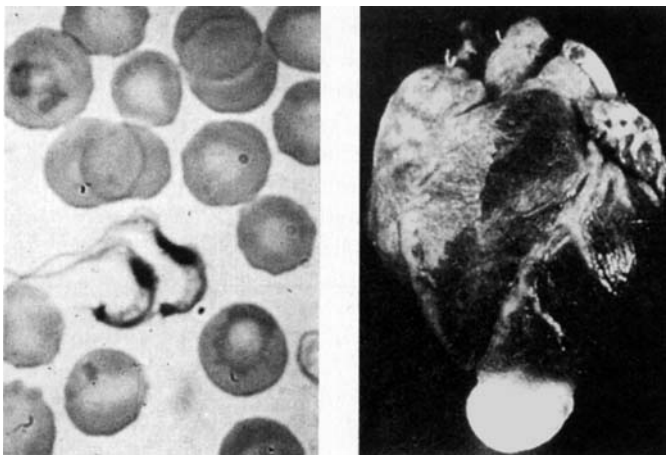


Fig. 1. The causative agent of Chagas' disease, the scourge of South America, is *Trypanosoma cruzi*. In the center of the left hand photograph two trypanosomes can be seen surrounded by erythrocytes; their destinations are, for instance, heart muscle and nerve cells. In many patients the disease becomes chronic, leading to complete destruction of the heart. After years or decades, sudden death can occur due to conduction disorders or rupture of the heart. Typical for Chagas' disease is the bulging and thinning of the apical region of the left heart ventricle (see bottom of the right-hand photograph). The pathogenesis of the disease with its insidious cell destruction resembles the "broken heart" described in fiction [e.g., The Lady of the Camelias by A. Dumas fils (1848) which formed the subject of the opera "La Traviata" by F. M. Piave and G. Verdi (1853)].

Heiner Schirmer was born in 1942 and studied medicine and philosophy in Basle and Heidelberg. In 1966 he obtained a doctorate under Caspar Rüegg with a thesis entitled "Arterial contractile protein". After clinical work and postdoctoral research at Dartmouth Medical School, NH, he went to the Max Planck Institute for Medical Research in 1970, where he worked together with Georg Schulz on the structural analysis of nucleotide-binding proteins. In 1976 he was Bicentennial Lecturer in Boston and Philadelphia. Since 1980 he has been professor at the Biochemical Institute II, University of Heidelberg; his major research interest is the biochemistry of intracellular parasites.

these are Chagas' disease, which occurs in Latin America (pathogen: *Trypanosoma cruzi*), African sleeping sickness (*Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*), oriental sore (*Leishmania tropica*), Kala azar (*Leishmania donovani*), as well as the devastating cattle disease Nagana (*Trypanosoma congolense*).

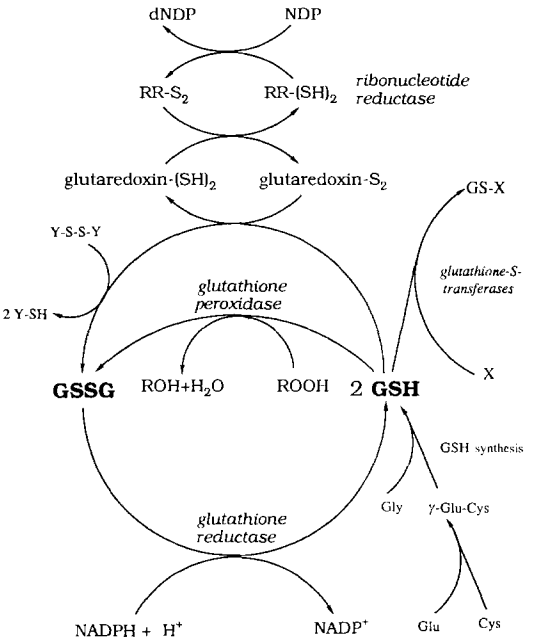
In collaboration with Klaus-Dieter Hungerer, Behringwerke Marburg, we have mainly worked on *Trypanosoma cruzi*, the causative agent of a chronic disease affecting the heart and other organs (Fig. 1, right). Blood-sucking bugs act as vectors. The disease—described by Carlos Chagas in 1909 and named after him—is the most serious socio-medical problem in South America. According to an estimate by the World Health Organization more than 20 million people from the lower socio-economic groups are infected with *T. cruzi*. In the USA about 100000 people are affected, probably due to transfusion of blood and blood products originating from South America.

In biochemical terms a common feature of trypanosomes and malaria parasites is their need for a highly efficient thiol metabolism to protect them from reactive O_2 derivatives and other oxidants.[9a] This Achilles heel of parasites, their sensitivity to oxidative stress,[10, 11] is a promising point of attack for drug design.

4. Oxidative Stress as a Chemotherapeutic Strategy

Per day a human being consumes 800 litres of oxygen, 5% of which (that is, 50 g) is converted by side reactions into reactive oxygen species such as $O_2^{\bullet-}$, $HO_2^{\bullet}$, $ONOO^-$ (pernitrite), $HO^{\bullet}$, and H_2O_2.[12] These compounds are cytotoxic because of their ability to modify nucleic acids, thiol-containing proteins, and membrane lipids. There are numerous metabolic pathways for the detoxication of reactive oxygen species; when these antioxidative systems are challenged, the cell or the tissue is regarded as being under "oxidative stress".[12]

Oxidative stress is not simply an undesirable consequence of aerobic life; it also represents an important principle of the organism's chemical defense against invaders: during the "respiratory burst" reaction of activated leukocytes and macrophages, specific membrane-bound oxidases ($NADPH + 2O_2 \rightarrow NADP^+ + H^+ + 2O_2^{\bullet-}$) produce superoxide anions. These radicals serve as starting material for the synthesis of chemical agents that combat bacteria, parasites, and tumour cells. In the Haber–Weiss reaction ($O_2^{\bullet-} + H_2O_2 \rightarrow O_2 + HO^- + HO^{\bullet}$), for instance, highly toxic OH radicals are generated from $O_2^{\bullet-}$.[12d]



Furthermore, numerous pharmacologically and toxicologically active compounds exert their effects, as so-called redox cyclers, by producing reactive oxygen species. For example, a redox cycler X can be reduced by flavoenzymes to the radical anion $X^{\bullet-}$ [Eq. (a)], which then reacts with oxygen [Eq. (b)].

$$NADPH + 2X \longrightarrow 2X^{\bullet-} + NADP^+ + H^+ \quad (a)$$

$$2X^{\bullet-} + 2O_2 \longrightarrow 2X + 2O_2^{\bullet-} \quad (b)$$

Thus the net reaction catalyzed by the redox cycler X is that of leukocyte respiratory burst oxidase. Known redox cyclers are nifurtimox, a drug used in the treatment of Chagas' disease,[9a] the cytostatic agents mitomycin C and doxorubicin, as well as the herbicides paraquat[13a] and diquat. It is noteworthy in this context that the antimalarial agent Qinghaosu (**1**) contains an *endo* peroxide group which is essential for its action.[9b]

Clinical and epidemiological observations have provided further evidence that oxidative stress is an important mechanism for the destruction of parasites and tumour cells.[12c] Specifically, congenital as well as acquired factors that produce oxidative stress in erythrocytes offer partial protection against malaria.[10] The best known example is glucose-6-phosphate dehydrogenase deficiency ($G6PDH^-$; the minus sign of the superscript denotes the deficiency). $G6PDH^-$ is the most common inherited enzyme abnormality in man. It exists in more than 300 genetic variants and affects 400 million people worldwide.[14a] The functional defect involves limited availability of NADPH through the hexosemonophosphate pathway. In erythrocytes this leads to an impairment of the glutathione redox system (Scheme 1) with a consequent marked increase in oxidative stress.[14b] The additional oxidative load due to the parasite[15a] may lead to premature liberation of immature nonviable parasites.

Scheme 1. The glutathione redox cycle. In the center of the cycle is the tripeptide glutathione (GSH, γ-glutamylcysteinylglycine) that is formed from the amino acids in an ATP-dependent pathway. GSH takes part in the detoxication of organic hydroperoxides (ROOH), in the production of deoxyribonucleotides (deoxynucleosidediphosphates, dNDP) for DNA synthesis [18] as well as in thiol–disulfide exchange reactions. In these reactions two GSH molecules are oxidized to the disulfide (GSSG). GSH is regenerated by reduction with NADPH (catalyzed by glutathione reductase). In erythrocytes NADPH is supplied by the enzyme glucose-6-phosphate dehydrogenase (G6PDH). GSH not only detoxicates peroxides. So-called glutathione-S-transferases allow the elimination of a variety of cytotoxic substances by conjugation with glutathione. In addition these enzymes take part in the synthesis of certain leukotrienes and hence in the control of many (patho)physiological processes [19b].

Favism is a special form of glucose-6-phosphate deficiency which is restricted to regions where malaria was or is endemic. It is characterized by episodes of hemolytic anemia, which are often precipitated by a meal of fava beans. Since these beans (*Vicia faba*) have been a principal source of protein in Mediter-

ranean countries from time immemorial, this food source might be expected to have led to a natural selection against glucose-6-phosphate-dehydrogenase deficiency. In actual fact, however, the frequency of the mutated G6PDH gene is at its highest in these countries.[14c] The inborn enzyme defect and the nutritional factor exert a synergistic effect in the protection against *P. falciparum*. The antimalarial principles of the fava bean, namely the β-glucosides of the pyrimidines isouramil and divicine have been isolated. These compounds act as redox cyclers producing H_2O_2, which in turn leads to oxidative stress in $G6PDH^-$ cells.[14b] Thus it is likely that fava beans confer some protection from malaria also in persons with normal G6PDH genes.[*]

Since the $G6PDH^-$ phenotype results in a deficiency of NADPH, the substrate of glutathione reductase, favism corresponds clinically to functional insufficiency of glutathione reductase in erythrocytes.[12e] This is also consistent with the observation that inherited glutathione reductase deficiency, a rare condition, results in a disease resembling favism.[16] On this basis the inhibition of glutathione reductase, a pharmacological phenocopy of G6PDH-deficiency, represents a promising approach towards the chemotherapy of malaria.[10, 13b, 17]

4.1. Detoxication of H_2O_2 and Organic Peroxides by the Glutathione Reductase Cycle

The main defence system against reactive oxygen species is the glutathione redox cycle, which involves the enzymes glutathione reductase (GR) and glutathione peroxidase (Scheme 1). The flavoenzyme glutathione reductase [EC 1.6.4.2] catalyzes the NADPH-dependent reduction of glutathione disulfide (GSSG, oxidized glutathione) to glutathione (GSH) [Eq. (c)]. Thus GR

$$GSSG + NADPH + H^+ \xrightleftharpoons{GR} 2GSH + NADP^+ \quad (c)$$

is the link between a pyrimidine nucleotide redox system and a thiol/disulfide redox system in the cell.[16, 19a, 20] By means of the GR-catalyzed reaction the ratio of the intracellular concentration of GSM to that of GSSG is maintained at greater than 20,[12a] while the GSH concentration in animal cells is about 3 mM. GSH takes part in many biological functions, including the detoxication of cytosolic hydrogen peroxide and organic peroxides by means of the selenium-dependent glutathione peroxidase (Scheme 1). Superoxide radicals and hydrogen peroxide are reduced by the combined action of this enzyme and two other antioxidative enzymes, namely, superoxide dismutase [EC 1.15.1.1] and catalase [EC 1.11.1.6] [Eqs. (d)–(f)].[12a]

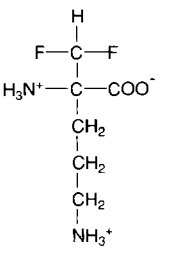
$$2O_2^{\cdot-} + 2H^+ \xrightarrow{\text{superoxide dismutase}} O_2 + H_2O_2 \quad (d)$$

$$2H_2O_2 \xrightarrow{\text{catalase}} O_2 + 2H_2O \quad (e)$$

$$H_2O_2 + 2GSH \xrightarrow{\text{glutathione peroxidase}} GSSG + 2H_2O \quad (f)$$

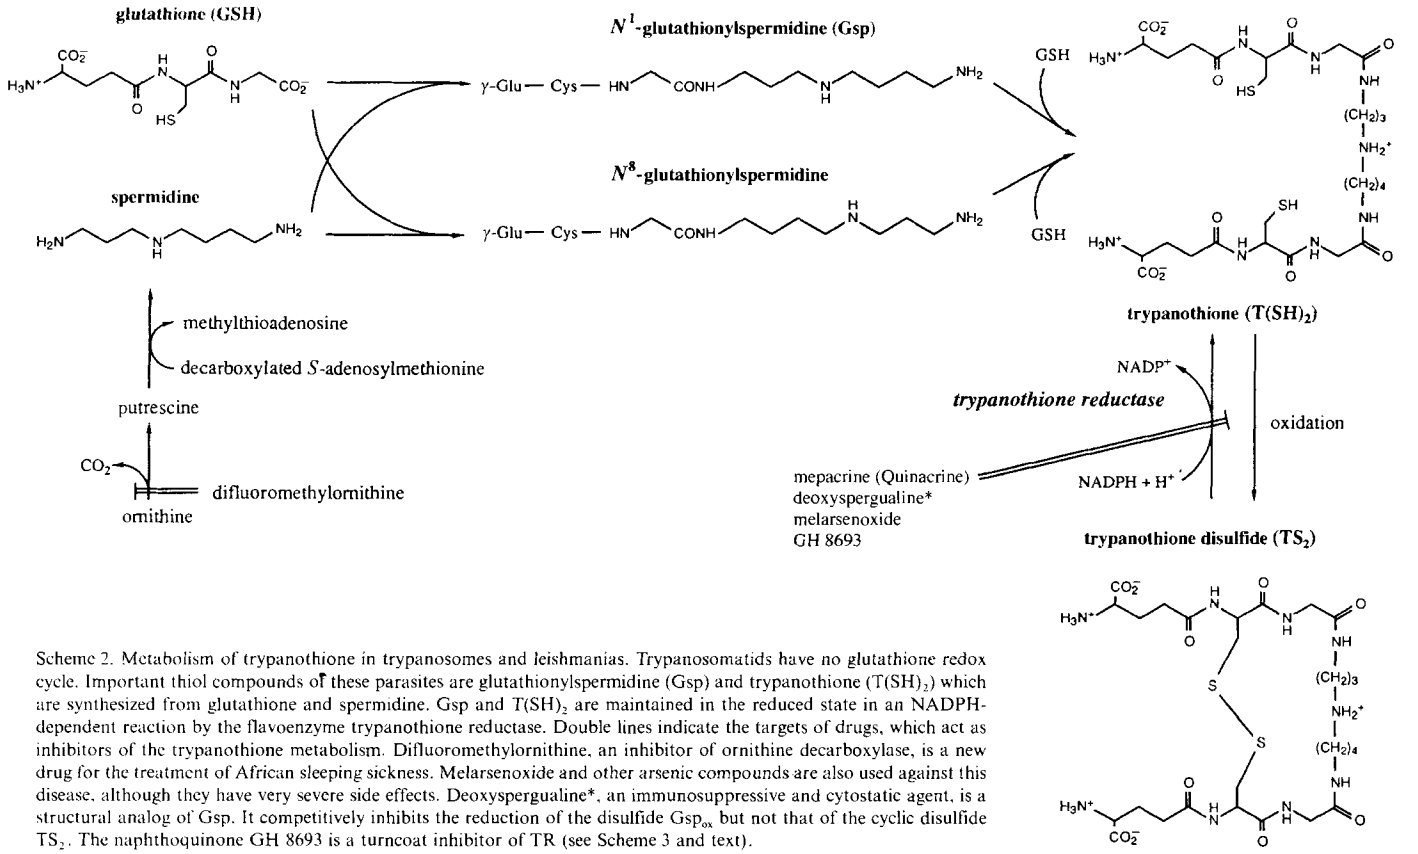
[*] It has been suggested that chimpanzees use certain plants not only for food but mainly as a prophylaxis against pathogens. The antimalarial principles in these plants are under investigation at present [15b]; vernodalin, a sesquiterpene from *Veronia amygdalina*, is a particularly promising compound.

A comparison of the two H_2O_2-scavenging enzymes in red blood cells showed that glutathione peroxidase [Eq. (f)] is active at much lower H_2O_2 concentrations than catalase [Eq. (e)].



4.2. Trypanothione and Other Glutathionylspermidines in Trypanosomes and Leishmanias

Trypanosomes and their relatives exhibit a large number of metabolic reactions not seen in other microorganisms and higher organisms.[21] One possible explanation for this is the long period of independent evolution (300 million years) of the Kinetoplastida, which are one of the oldest eukaryotic lineages. Be that as it may, the metabolic pathways specific to these parasites, for example the trypanothione metabolism,[22, 23] constitute promising targets for the rational development of therapeutic agents.



In contrast to almost all other organisms whose intracellular redox equilibrium depends on the glutathione/glutathione reductase system (Scheme 1), trypanosomatids have no glutathione reductase. Their most important thiols are compounds in which the tripeptide glutathione is linked by an amide bond to the triamine spermidine (Scheme 2).[24] Trypanothione [$T(SH)_2$] and monoglutathionylspermidine (Gsp) are maintained in the reduced state by the NADPH-dependent enzyme trypanothione reductase.[25, 26] At least in some trypanosomatids, 4-mercaptohistidine (ovothiol A) is another major thiol compound.[27a, b] Trypanosomes lack the enzymes catalase and glutathione peroxidase, which in other organisms degrade H_2O_2 and organic hydroperoxides. H_2O_2 might be detoxicated in uncatalyzed reactions (for example, $H_2O_2 + T(SH)_2 \rightarrow 2H_2O + TS_2$).[27c]

Trypanosomes and leishmanias are substantially more sensitive to oxidative stress than their biological hosts. This is consistent with the fact that nifurtimox (Lampit) and benznidazol (Radanil), the only drugs available for the treatment of Chagas' disease, are redox cyclers. As nitroarenes, they give rise to the formation of reactive oxygen species.[9a] Both compounds are, however, only effective in the acute stage of Chagas' disease, and they have serious side effects. There is also a need for new compounds against other forms of trypanosomiasis.

Surprisingly, most of the agents with known activity against trypanosomes affect the recently discovered trypanothione metabolism (Scheme 2). A case in point is the treatment of sleeping sickness with arsenic compounds developed by Paul Ehrlich. Fairlamb et al.[28] were able to show that melarsen-oxide forms a 1:1 stoichiometric adduct with the dithiol trypanothione. In addition, enzymes with spatially adjacent thiol groups (for example, TR and GR) are inhibited by trivalent aromatic arsenicals. The naphthoquinone GH 8693, synthesized by the late Graeme Henderson of the Rockefeller University, acts in vitro as a trypanocide against *T. cruzi* and is a turncoat inhibitor of TR (see Scheme 3).[29] A major breakthrough was achieved in 1990 with the introduction of difluoromethylornithine (eflornithine, **2**) as a most effective drug against the chronic form of sleeping

2

Scheme 2. Metabolism of trypanothione in trypanosomes and leishmanias. Trypanosomatids have no glutathione redox cycle. Important thiol compounds of these parasites are glutathionylspermidine (Gsp) and trypanothione ($T(SH)_2$) which are synthesized from glutathione and spermidine. Gsp and $T(SH)_2$ are maintained in the reduced state in an NADPH-dependent reaction by the flavoenzyme trypanothione reductase. Double lines indicate the targets of drugs, which act as inhibitors of the trypanothione metabolism. Difluoromethylornithine, an inhibitor of ornithine decarboxylase, is a new drug for the treatment of African sleeping sickness. Melarsenoxide and other arsenic compounds are also used against this disease, although they have very severe side effects. Deoxyspergualine*, an immunosuppressive and cytostatic agent, is a structural analog of Gsp. It competitively inhibits the reduction of the disulfide Gsp_{ox} but not that of the cyclic disulfide TS_2. The naphthoquinone GH 8693 is a turncoat inhibitor of TR (see Scheme 3 and text).

sickness. Unfortunately, the example of eflornithine also illustrates the difficulties of financing the production of a compound for exclusive use in the so-called Third World.[30a] Difluoromethylornithine inhibits spermidine synthesis by the parasite (Scheme 2); due to the short in vivo half-life of human ornithine decarboxylase, the polyamine metabolism of the host is unaffected.[21] Eflornithine is also completely inactive against the pathogens responsible for South American trypanosomiasis because *T. cruzi* produces spermidine by another pathway[21, 22, 30b] or obtains it from the patient's blood.

5. The Three-Dimensional Structures of Glutathione and Trypanothione Reductase as a Basis for Drug Design

Trypanothione reductase is an obvious choice for drug design, since it is pathogen-specific and does not occur in man. In contrast, the selection of human erythrocyte glutathione reductase as a target for antimalarial agents requires some explanation. Firstly, as set out in Section 4, we follow a principle provided by nature itself. Secondly, it was shown for many patients treated with 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU or carmustine; see Section 6.1) that GR is not essential for normal erythrocyte function; the reduced lifespan of GR-deficient red blood cells (30 days instead of 100 days) is tolerable.[16] Thirdly, the problem of unfavorable evolutionary selection is avoided: drugs directed against parasite structures also select for drug-resistance among parasites.[31] This, of course, is much less pronounced for chemotherapeutic agents directed against a host protein. Finally, the membranes of parasitized erythrocytes become permeable to relatively large anionic compounds ($M_r < 600$).[32] Many of the known inhibitors of glutathione reductase fall into this category.[*]

It should also be noted that tailored inhibitors of glutathione reductase are not only of interest as drugs for the treatment of malaria but also as cytostatics, as probes for studying the detoxication metabolism, and as herbicides.[23]

Human glutathione reductase is one of the most thoroughly studied enzymes. The amino acid sequence[33a] and the three-dimensional structure at 1.5 Å resolution are known.[33b] The binding of the substrates,[34] substrate analogs, and inhibitors,[16, 35, 36] as well as the stereochemistry of catalysis[37] have been studied in great detail. The cDNA of glutathione reductase was cloned and sequenced with the result that an even more detailed structure–mechanism analysis of the enzyme has become possible with site-directed mutagenesis.[38]

GR is a homodimer consisting of subunits with an M_r of 52000. The enzyme has two identical active sites; amino acids of both protein subunits are involved at each catalytic site. As shown in Figure 2, the isoalloxazine ring of the prosthetic FAD group forms a barrier between the substrate compartments: NADPH binds to the *re* side and glutathione disulfide (GSSG) to the *si* side of the flavin ring. The *si* side of the flavin is also in close contact with the redox-active dithiol/disulfide of the protein. Catalysis takes place in such a way that the reduction

[*] We have isolated glutathione reductase from *Plasmodium falciparum* in pure form and characterized it, but it has not yet been obtained in crystalline form. The corresponding gene segment has recently been sequenced by S. Müller and R. Walter at the Bernhard-Nacht-Institut in Hamburg, Germany. It may be possible to use differences between the host and parasite glutathione reductases for designing drugs against the enzyme of the malaria parasite.

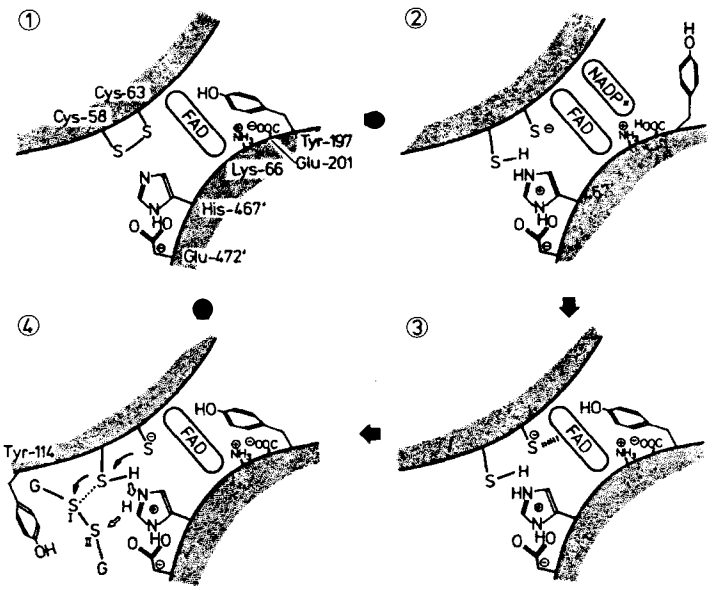


Fig. 2. Catalytic cycle of glutathione reductase [19a, 34, 37]. The enzyme glutathione reductase (GR) cycles during catalysis between the oxidized form E and the two-electron reduced form EH_2. ① The oxidized form of GR, E_{ox}, is characterized by a closed disulfide bridge between Cys 58 and Cys 63. ② Reduction of the disulfide with the coenzyme NADPH. Here the complex between the reduced enzyme EH_2 and the product $NADP^+$ is shown. ③ Release of $NADP^+$ results in formation of EH_2. This state is characterized by a charge-transfer interaction between the thiolate form of Cys 63 and the flavin ring (||||). ④ The three catalytic steps leading to the formation of two molecules of GSH from GSSG. The light arrows depict presumed proton shifts during the formation of the mixed disulfide between Cys 58 and glutathione I; this reaction leads to the liberation of one molecule of glutathione (GSH II). The solid arrows indicate the movement of electrons during the cleavage of the mixed disulfide. This causes the release of GSH I and converts the enzyme back to its oxidized form E_{ox}.

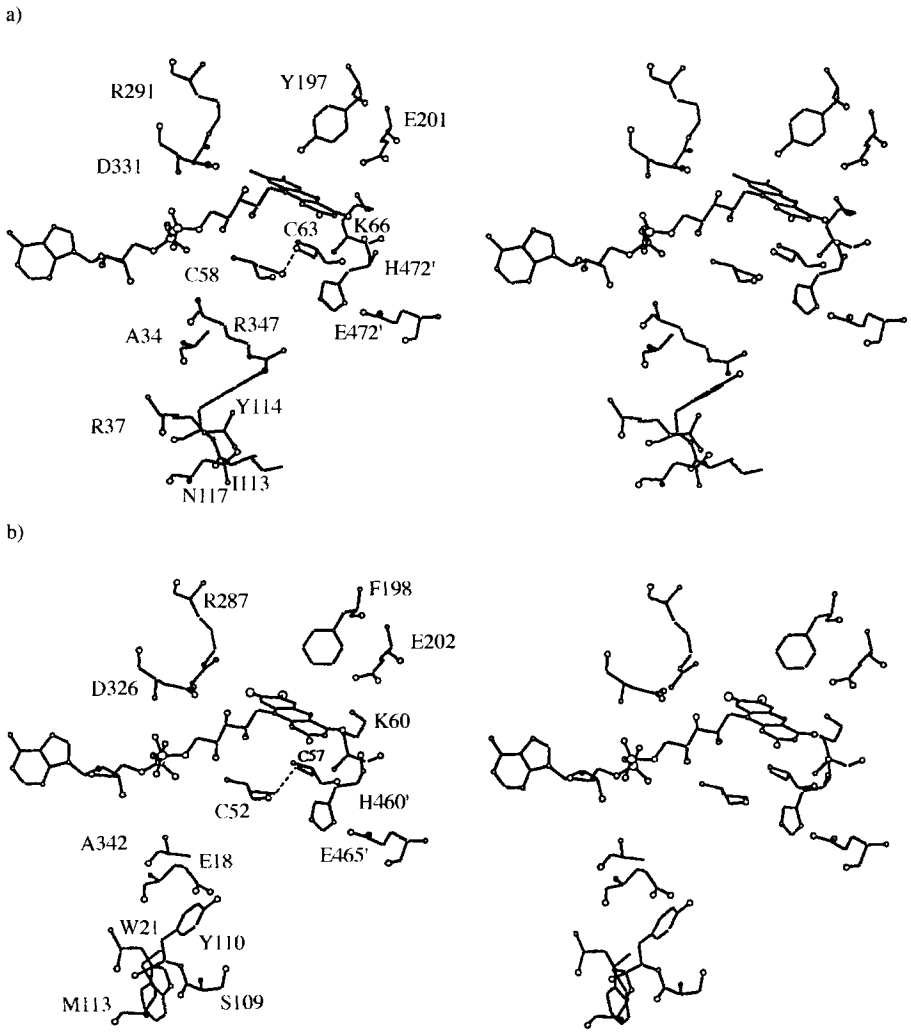
equivalents of NADPH are carried via the flavin ring to the disulfide bridge of the protein with the result that the dithiol Cys 58 – Cys 63 is formed. After binding of glutathione disulfide (GSSG) a series of thiol-disulfide exchanges leads to the release of two molecules of GSH and to reoxidation of the active site dithiol to give the disulfide. This completes the catalytic cycle.

The three-dimensional structures of trypanothione reductase from *Crithidia fasciculata*[39, 40] and *Trypanosoma cruzi*[42] have recently been elucidated. This is also the case for the binary complexes *C. fasciculata* TR – Gsp_{ox},[40b] *C. fasciculata* TR – $NADP^+$,[40c] and *T. cruzi* TR · NADPH.[42] TR is an FAD- and NADPH-dependent disulfide reductase[19a] and hence shares many physical and chemical properties with GR, the closely related host enzyme.[26] The most important difference between the two reductases is the mutually exclusive specificity for the disulfide substrate: TR reduces only the glutathionylspermidine conjugate, whereas GR is specific for glutathione disulfide.

The active site of TR with the redox-active disulfide/dithiol and the flavin ring in the center is very similar to that of GR (Fig. 3). All amino acid residues of GR that are directly involved in catalysis are conserved in TR.[41, 42] The binding region for the disulfide substrate is—by virtue of the different orientation of two α-helices—more spacious in TR than in GR.



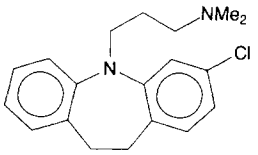


Fig. 3. A comparison of the active sites of glutathione reductase (a) and trypanothione reductase (b) [42, 43]. The isoalloxazine ring of FAD forms the center of the active site. The redox-active disulfide bridge of the protein is represented by a broken line. At several equivalent positions, TR from *Trypanosoma cruzi* and human GR contain different amino acids, namely: Glu18 (corresponding to Ala34 in GR), Trp21 (Arg37), Ser109 (Ile113), Met113 (Asn117) and Ala342 (Arg347). (The numbering is different for the two proteins because of amino acid insertions and/or deletions along the polypeptide chains.)

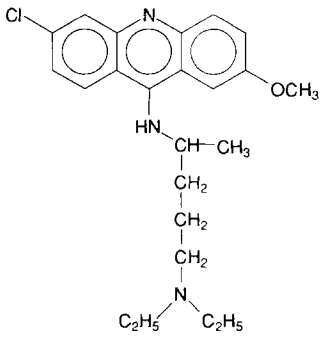
Of the 19 residues which in GR participate in the binding of GSSG, only five are not conserved in TR (legend to Fig. 3). Remarkably, three arginine residues at the active site of GR are replaced by neutral or acidic residues in TR.[42,43] These exchanges reflect the different charges on the substrates. Whereas GSSG when bound to GR has two negative C-terminal ends (the carboxylate groups of the glycine residues), the TR substrates TS_2 and Gsp_{ox} (Scheme 2) have one and four positive charges, respectively, in the corresponding region. Site-directed mutagenesis of TR and GR,[41,44,45] as well as the structural analysis of the TR·Gsp_{ox} complex[40b] have confirmed the importance of certain amino acid positions for substrate specificity. Indeed, exchanging only a few amino acid residues is sufficient to convert a TR into a GR and vice versa.

The next goal is the crystallographic investigation of enzyme–inhibitor complexes. An understanding of the interactions between protein and ligands is fundamental for the synthesis of specific, high-affinity inhibitors.

5.1. Derivatives of Tricyclic Antidepressants Fitting the Spermidine Niche of Trypanothione Reductase



By comparing the substrate-binding sites of trypanothione reductase and glutathione reductase, Benson et al.[46a] discovered a hydrophobic niche in TR. The GR structure contains polar residues in the corresponding region. Using the computer-assisted programs of Goodford,[2] the authors probed this niche with different molecular fragments and classified the probes according to energetically and geometrically favored binding positions in TR. The subsequent molecular modeling showed that tricyclic compounds of the phenothiazine type—well known as antidepressant drugs—happened to contain the best-fitting probes as part of their structure. Enzyme kinetic studies confirmed that compounds such as clomipramine (**3**) are competitive inhibitors of trypanothione reductase and are therefore candidates for lead substances for the synthesis of novel trypanothione reductase inhibitors. It had long been known that these compounds do not inhibit glutathione reductase.[46b]

3

First experiments with the phenothiazines showed promising results in terms of their ability to kill trypanosomes in stored blood. The advantage of these agents as lead compounds in drug design lies in the fact that their toxicology and pharmacology have been thoroughly studied, and a few have already been approved for clinical use although at a low dosage. One possibility of improving on the lead compound, clomipramine, is obvious. On binding to TR, the tricyclic system is apparently held in a form twisted around its middle axis.[46a] All other parameters being equal, a synthetic derivative that could achieve receptor complementarity without conformational strain would bind to TR with much higher affinity. As the next step, of course, the nature of the binding of these drugs to the enzyme needs to be confirmed by X-ray diffraction analysis of crystalline TR–inhibitor complexes.

Another tricyclic compound with trypanocidal properties is the acridine derivative, mepacrine (Primaquine, Atebrin; **4**). Like chlomipramine it is a competitive inhibitor of TR but not of GR.[31] Recently we managed to bind mepacrine to crystalline TR and to elucidate the structure of the enzyme–inhibitor complex.[46c]

4

Studies on a number of riboflavin analogs that are more potent inhibitors of GR[47a] than TR showed that the selectivity of the TR inhibitors described above depends not simply on the presence of a tricyclic ring system. The riboflavin analogs most likely bind between the subunits of glutathione reductase in a cavity larger than that in trypanothione reductase.[47b]

5.2. Communication Policy of Organisms: Flexible Compounds Inside—Rigid Ring Systems for the Environment

The examples of mepacrine and clomipramine show that a rigid ring system fits into a protein niche whose biological function is the binding of a *flexible* structure, namely the spermidine chain of trypanothione. This finding is consistent with the rule that for its own housekeeping functions each organism favors compounds that do not bind too tightly to their physiological partners. The weak binding is due to the loss in entropy when many rotations around single bonds in the ligand are arrested.[48,49] The reversibility of complex formation appears to be fundamental for the biochemistry of an organism.

In contrast, biomolecules that are synthesized in order to exert effects on other individuals often form rigid cyclic structures. In many cases these structures are further stabilized by bridging atomic groups. Cyclization leads to order in a chemical structure; the entropy costs associated with the binding of such a molecule to a receptor are relatively small, and the free energy of binding is thereby shifted to negative, that is, more favorable values. Examples of ligands for "foreign" receptors include antibiotics, pheromones and other aromatic attractants, plant alkaloids, as well as animal poisons. Many drugs are also polycyclic compounds with restricted conformational freedom. Such compounds are not only suitable as tightly binding ligands; in addition they are resistant to degradation by hydrolytic enzymes. This is particularly true for rigid peptide mimetics; the analogous flexible structures are hydrolyzed within seconds by peptidases of the target organism: peptidases and other hydrolases preferably attack molecules that have great conformational freedom.

The degree of ring formation and bridging in otherwise similar ligands allows subtle control of binding to a receptor and hence of a physiological function. Even the introduction of a double bond in the alkyl moiety of a ligand can increase the affinity constant by an order of magnitude (see Appendix). Much of this knowledge is derived from a model system in which the interactions of the antibiotic ristocetin A with *N*-acetyl-D-alanyl-D-alanine, a fragment of the bacterial cell wall, can be analyzed and quantified in a systematic way.[48,49]

Table 1. Aspects of enzyme inhibition with reference to chemotherapy.

Inhibitor type	Principle	Examples
Polycyclic compounds with five- and six-membered aromatic rings (see Sections 5.1 and 5.2 and Appendix).	The limited number of single bonds with free rotation reduces the entropy costs for complex formation. In addition, rigid compounds are resistant to destruction by hydrolytic enzymes [48,49].	– Active principle of many natural products (antibiotics, alkaloids, pheromones) – competitive inhibition of TR by mepacrine [31] and tricyclic antidepressants [46a] – inhibition of GR by flavin analogs [47].
Slowly dissociating ligands (see Section 6.1).	K_{diss} (as quotient of the half-lives of complex formation and dissociation) should be $<10^{-8}$ M. If the $t_{\frac{1}{2}}$ of complex formation is >100 ms, the complex is infinitely stable on a biological time scale [52].	– Half-life of the physiological GR-FAD complex >1 month – Kinetic stabilization due to slow conformational changes [4] of the guanidinoglycal–sialidase complex (treatment of influenza).
Substrate analogs (see Section 6.1).	Computer-assisted studies of the active site using functional groups provide short cuts to appropriate substitutions in the substrate molecule [2,4].	– Inactivation of the sialidase of influenza viruses by guanidinoglycal [4,5]. – Inhibition of GR by dinitrophenylglutathione (Fig. 4).
Suicide inhibitors (see Section 6.1).	A substrate analog is converted by the enzyme into a reactive intermediate, which then blocks the enzyme irreversibly [52].	– difluoromethylornithine (**2**) as an inhibitor of ornithine decarboxylase (chemotherapy of African sleeping sickness) – allopurinol as an inhibitor of xanthine oxidase (pharmacological prevention of gout).
Syncatalytic inhibitors (see Section 6.1).	A reactive group of the enzyme becomes exposed during the course of the catalytic cycle and is then modified by the inhibitor.	– Covalent modification of Cys 58 of GR by BCNU (chemotherapy of tumors and malaria) and of Cys 52 of TR [29,35].
Turncoat inhibitors (see Section 6.1).	The ligand inhibits the physiological reaction of the enzyme and promotes an unwanted side reaction.	– induction of oxidase activity of GR by the herbicide paraquat (methylviologen; 1,1′-dimethyl-4,4′-bipyridinium dichloride) [13a]. – induction of oxidase activity in TR by GH 8693, a trypanocidal naphthoquinone [29,55b] (see Scheme 3).
Ligand chimeras (see Section 6.2).	Two ligands of the enzyme are bridged by a suitable linker, which is tailored on the basis of the known protein structure. The K_{diss} of a ligand chimera represents the product of the individual dissociation constants.	– specific inhibition of adenylate kinase by diadenosine pentaphosphate (**5**), a compound in which an additional phosphate forms a bridge between the two substrates ATP and AMP [55a]. – affinity labeling of glutathione synthetase by adenosine-5′-polyphospho-5′-pyridoxal [56] [a].
Peptide mimetics (see Section 6.3).	Rigid peptide analogs inhibit the physiological enzyme-peptide interaction.	– inactivation of angiotensin-converting enzyme (ACE) by captopril (treatment of hypertension; treatment of cardiac insufficiency in Chagas' disease) [3]. – inhibition of plasmodium hemoglobinase by a peptide mimetic with antimalarial activity [57a].
	Peptides and peptide analogs prevent the intra- or intermolecular interactions of a protein. This can lead to destabilization and intracellular degradation of the protein [59].	– dimerization inhibitors of the ribonucleotide reductase of herpes simplex virus [58] and of human GR [59]. – association inhibitors of a protein assembly that amplifies cellular signalling [60].

[a] The principle of connecting two molecular groups by a designed bridge has also been used for stabilizing the quaternary structure of hemoglobin [57b]. This was a critical step for the development of blood substitutes.

6. Design of Inhibitors with High Affinity and Selectivity

What are the prospects of developing drugs with high affinity and selectivity, that is, agents which can be administered in almost stoichiometric or even substoichiometric amounts relative to their receptors? Examples and the principles involved are discussed in the following sections and listed in Table 1.

6.1. Substrates as Lead Compounds

6.1.1. Reversibly Binding Inhibitors

Typical examples of inhibitors that are substrate analogs are the antimalarial pyrimethamine, which binds to dihydrofolate reductase from *P. falciparum* with a K_{diss} of 10^{-10} M,[52] and guanidinoglycal, an inhibitor of influenza virus sialidase developed by drug design.[4,5] Since in the development of such reversibly binding inhibitors the law of mass action serves as a guide, let us consider the binding of the ligand L to the receptor R.

From Equation (g) it follows that K_{diss} is that concentration of free ligand L at which the concentrations of RL and R are

$$K_{diss} = [R][L]/[RL] = k_{diss}/k_{ass} \quad (g)$$

equal. Thus, when $[L] = 100\,K_{diss}$, the enzyme is inhibited to greater than 99%.[*] Drug design should aim at inhibitors with

[*] In this context the volume of the relevant cells is significant: the volume of the bacterium *Escherichia coli* is 10^{-15} L, of the malaria pathogen *Plasmodium falciparum* about 10^{-14} L, and of a human erythrocyte 10^{-13} L. According to the law of mass action, if K_{diss} for a given enzyme–inhibitor complex is 10^{-11} M, only 0.6 of a free L molecule will be required to produce 99% enzyme inhibition in the bacterial cell, whereas the corresponding figures in Plasmodium and erythrocytes are 6 and 60 molecules, respectively. Furthermore, it is worth noting that many enzymes are present only in very low numbers per cell. In view of these small numbers, it is doubtful whether the law of mass action is applicable at all. In the case considered here, however, about 10000 molecules of the enzyme glutathione reductase are present in each erythrocyte, and the concentration of TR in trypanosomes is even 10 times greater.

a K_{diss} of less than 10^{-8} M, otherwise [L] must be very high in order to sustain the inactive complex, which could lead to an unacceptable dosage regimen, rapid excretion, or unwanted side effects of the ligand L.

In addition, for the treatment of infectious diseases, slowly dissociating compounds are desirable in order to switch off an enzyme molecule "permanently" once it has been complexed. An RL complex is kinetically stabilized if k_{diss}, the rate constant for dissociation, is small; k_{diss} values less than 10^{-5} s^{-1} mean that the half-life of the RL complex is greater than 18 h. For synthetic[4] as well as physiologically important ligands (for instance, specific peptids as inhibitors of proteases), a slow conformational change of the complex (RL → R*L*) often takes place. In this way the half-life of the complex ranges from days to months; the complex can hence no longer decompose within a biologically meaningful time period. (When treating diseases one must, of course, bear in mind that the target R may continue to be produced by surviving cells.)

6.1.2. *Suicide Inhibitors*

A variation of this theme is the possibility that a substrate analog is converted by the target enzyme to a product which forms an extremely long-lasting complex with the enzyme or covalently blocks the active site. Well-known suicide inhibitors are the anti-sleeping sickness drug difluoromethylornithine (**2**), which blocks ornithine decarboxylase of *Trypanosoma brucei gambiense* (see Scheme 2), and the antiviral agent fluorouracil, an inhibitor of thymidylate synthase.[52]

6.1.3. *Syncatalytic Inhibition*

The principle resembles suicide inhibition in that only the actually performing enzyme is blocked, but not the enzyme in its resting state. For example, GR and also TR are inhibited by the cytostatic agent 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU = carmustine). However, this does not apply to the form of the enzyme normally present in vitro (E_{ox}), but only to the NADPH-reduced EH_2 (Fig. 2): In statu nascendi the thiolate group of Cys 58 reacts with chloroethyl isocyanate, a decomposition product of BCNU, to give the chloroethylcarbamoyl ester. X-ray diffraction analysis of the covalently inhibited enzyme shows that the carbamoyl group—attached by hydrogen bonds and van der Waals forces—fits snugly into its binding site.[35] These additional noncovalent interactions between enzyme and inhibitor ensure the stability of the carbamoyl ester. In the case of low molecular weight thiol compounds, the carbamoylation by BCNU is easily reversible.[53]

BCNU and the better tolerated 1-(2-chloroethyl)-3-(2-hydroxyethyl)-1-nitrosourea (HeCNU) are active antimalarials when tested in cell culture and on animals. (Interestingly, HeCNU does not produce carbamoylation but alkylation of Cys 58 in GR.[11]) Furthermore, tumor patients treated with BCNU are susceptible to numerous other infectious diseases but, to our knowledge, not to malaria.

These observations suggest the design of carbamoylating drugs, which in contrast to BCNU itself, are capable of differentiating between the active sites of human glutathione reductase, trypanothione reductase, and liponamide dehydrogenase of *T. cruzi*, an enzyme related mechanistically to TR and GR.[31,43b]

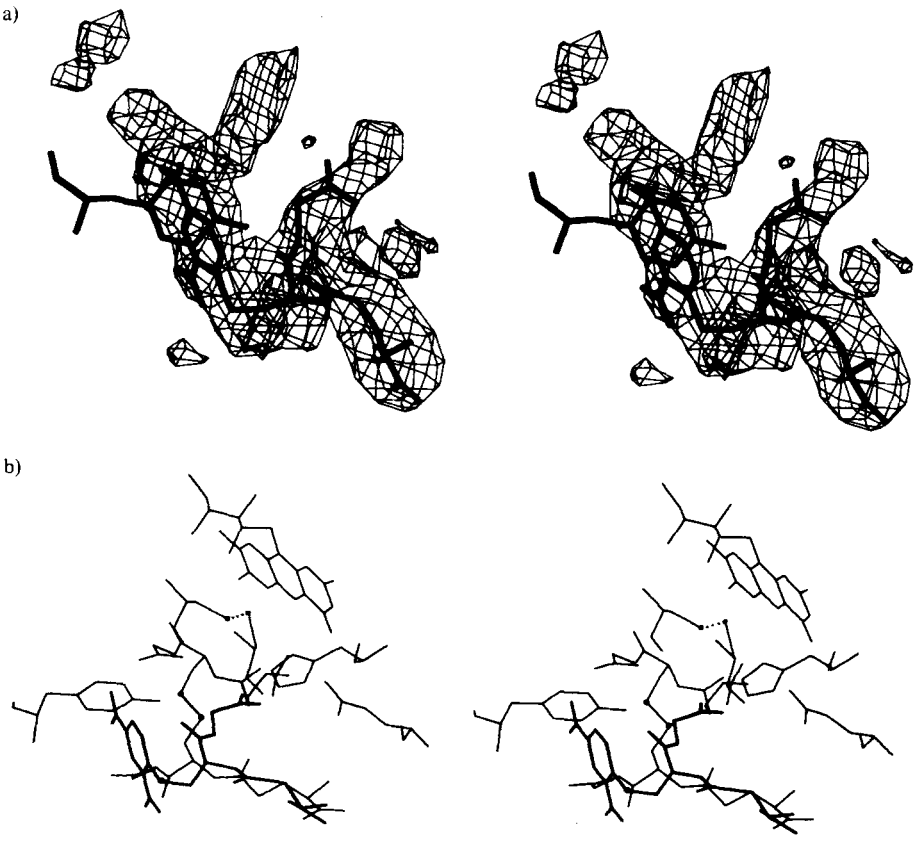


Fig. 4. a) Stereoview of the binding of 2,4-dinitrophenylglutathione (DNPG) to the GSSG binding site of glutathione reductase [36]. The difference electron density is given in bird-cage representation. Tyr 114 is shown in its undisturbed position. On binding DNPG the ring of Tyr 114 rotates about the C_α–C_β bond. The positive electron density, which arises from this movement, appears above and behind the tyrosine ring. The γ-glutamyl part of DNP-glutathione with its characteristic free α-L-amino acid moiety is located at the lower right-hand side. b) Comparison of the binding of GSSG and DNPG (stereoview). DNPG is represented in bold (with the γ-glutamyl at the lower right). The remaining structures drawn as thin lines are sections of glutathione reductase with bound GSSG. All molecular parts drawn as thin lines can be identified in Fig. 2, where they are given in approximately the same view, that is, the riboflavin moiety of FAD (at the top), Tyr 114 (outside left), the redox active dithiol Cys 58–Cys 63, His 467', and Glu 472'. (Residues of the other subunit are primed.) Comparison of the binding of GSSG and DNPG shows that only the γ-glutamyl parts—held in position by Lys 67 and Glu 473' (not shown)—do overlap. The position of the sulfur atom in DNPG is different from both sulfur atoms of bound GSSG. If the structure of the inhibitor–GR complex had been elucidated before the enzyme–substrate complex, we would probably have predicted the substrate binding incorrectly.

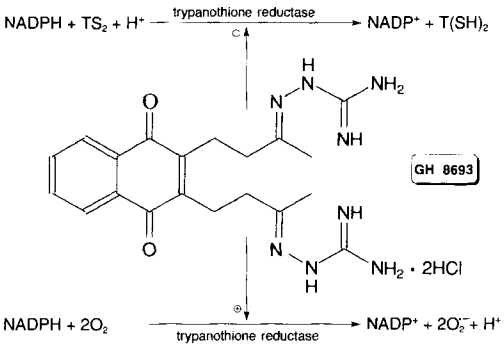
6.1.4. *Paradoxically Binding Substrate Analogs*



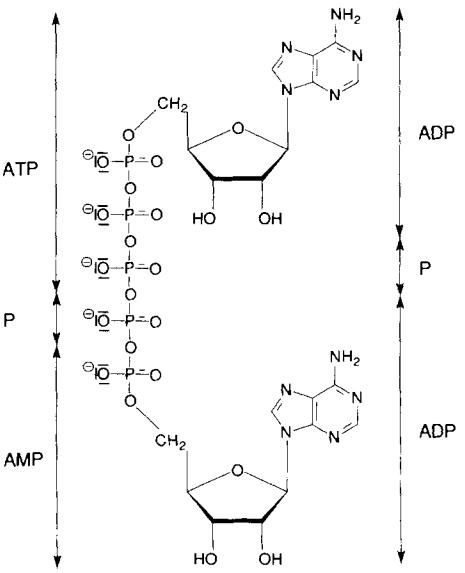
In choosing compounds as leads for inhibitor design, one should take into account that the individual atomic groups of the substrate are not equally important for the molecular recognition process.[51] In compounds with great conformational freedom only a few clearly defined fragments bind to the enzyme with high affinity, and that not all bond rotors are fixed on complex formation. In this context the approach of Goodford[2] is particularly successful for probing the binding sites of a receptor using, for example, single NH_3^+ groups or carboxylate groups instead of complete ligands.

As an example of the unexpected binding of a substrate analog to an enzyme, let us consider the action of 2,4-dinitrophenylglutathione (DNPG) as an inhibitor of GR[36] (Fig. 4). DNPG is formed in the liver from 1-chloro-2,4-dinitrobenzene by conjugation with glutathione. The DNP-glutathione conjugate is fixed to the GSSG binding site but the glutathione part is bound, unlike the two glutathione residues of GSSG. Only the γ-glutamyl part of DNP-glutathione adopts an expected position (Fig. 4b). In retrospect, this is not surprising since the γ-glutamyl part contains that characteristic part of the glutathione molecule which is not present in other peptides: a negatively charged carboxylate and a positively charged ammonium group in a rigid steric configuration.

The overall binding mode of the glutathione moiety of DNPG is thus determined by the non-glutathione part of the molecule. This is probably true for many other glutathione derivatives as well. In a crystallographic study, Janes and Schulz[54b] showed that the imprecise binding of substrate analogs to GR is a biologically meaningful molecular mechanism which prevents processing of nonphysiological substrates. It is worth emphasizing that the γ-glutamyl group with its α-amino acid moiety is a characteristic feature of glutathione and can therefore be used for probing putative glutathione-dependent enzymes.

6.1.5. *Turncoat Inhibitors*

A strong impact on the redox metabolism of trypanosomes is expected from GH 8693 and other "turncoat inhibitors". This concept[11, 29] is illustrated in Table 1 and Scheme 3. GH 8693



Scheme 3. The trypanocidal compound GH 8693 as a turncoat inhibitor of trypanothione reductase. At micromolar concentrations GH 8693 [55b] acts as an inhibitor of trypanothione reductase [29] (upper equation, inhibition constant $K_i = 1$ μM). At higher concentrations of GH 8693, trypanothione reductase catalyzes the reduction of O_2 to give a superoxide radical (lower equation, Michaelis constant $K_m = 15$ μM). Thus binding of GH 8693 to TR changes the antioxidative function of the enzyme into a prooxidative one—hence the name turncoat inhibitor [11, 29], sabotage inhibitor, or subversive substrate [55b].

binds to NADPH-reduced trypanothione reductase from where it transfers electrons to molecular oxygen to create two superoxide radicals. Concomitantly the reduction of the cognate substrate TS_2 is inhibited. Thus, in terms of overall balance, an antioxidative enzyme is converted into a prooxidative one.

Turncoat inhibitors exert a variety of effects that can be exploited for the chemotherapy of parasitic diseases:[31] NADPH and O_2 are wasted, the thiol/disulfide ratio is lowered, and the resulting reactive oxygen species can trigger lipid peroxidation and other chain reactions. Since turncoat inhibitors undergo redox cycling, they act as catalysts.

6.2. Ligand Chimeras

Most proteins bind very different types of ligands at sites physically separated from one another. Two ligands can be chemically linked by an adaptor moiety whose length and chemical criteria must be tailored to the protein structure. This molecular modeling leads to ligand chimeras with high affinity for the receptor.[55a, 56] In Table 1 diadenosinepentaphosphate (**5**), a disubstrate analog of adenylate kinase (ATP + AMP $\rightleftharpoons$ 2 ADP), is shown. For GR and TR, numerous combinations are conceivable in view of the many known ligands—substrates, cofactors, and inhibitors. A case in point is a chimera containing a tricyclic ring system (see Section 5.1) and a turncoat inhibitor (see Section 6.1) at an appropriate distance.

5

The kinetic stability of the enzyme–ligand complex also needs to be considered (Table 1). The half-life of the diadenosinepentaphosphate–adenylate kinase complex is only about 1 s. For this reason unmodified diadenosinepentaphosphate is more suited to diagnostic or emergency medicine than to long-term chemotherapy of infectious diseases.

6.3. Blocking Protein Folding and Organization by Catalytically Acting Peptide Mimetics

Many pathogen proteins such as trypanothione reductase from *T. cruzi*,[42] the enzymes of the AIDS virus, or ribonucleotide reductase of the herpes simplex virus are obligatory dimers; each subunit is inactive in itself. Since compounds that affect protein–protein interactions are highly specific inhibitors, dimeric proteins are especially interesting as target molecules for drugs.

The ribonucleotide reductase of the herpes simplex virus[58] consists of two subunits, one large and one small. A nonapeptide whose sequence corresponds to the C-terminal region of the small subunit displaces the small from the large subunit thereby separating the two. In this way ribonucleotide reductase is inactivated. In principle, such inhibitory peptides could act catalytically, that is, even in substoichiometric amounts: the separated subunits are often unstable and are degraded by the proteases of the cell. The more stable contact surface inhibitor is then released and can attack the next dimer.

We have carried out detailed studies on the inhibition of dimerization and its consequences for human glutathione reductase.[59] Each subunit contributes essential functional groups to both catalytic sites; the monomer thus cannot be active. In addition, peptides that correspond to the complementary contact surfaces of the protein subunits appear to inhibit the formation of the active enzyme. The site at which the subunits are in closest contact was chosen for mutagenesis (Fig. 5); it is formed by the parallel helices 439–454 and 439′–454′.[33b] By means of the exchanges (Gly446 → Glu and Gly446′ → Glu′) the smallest side chains (the H atoms of the glycine residues) were replaced by bulky negatively charged groups at positions of the contact surface facing each other.[59] This mutation not only prevented dimer formation; each monomer behaved like an unordered polypeptide chain, that is, in none of the four domains were structural elements detectable by physical and chemical methods. The biological stability of this protein was investigated in bacterial cells. While normal human glutathione reductase remains stable and active over many hours, the protein mutant was quantitatively degraded within minutes.

As a first step towards the development of dimerization inhibitors of glutathione reductase we plan to synthesize analogs of the peptide 439-454 and to fix them in their native conformation (which is a slightly deformed α-helix) (Fig. 5). The principles and methods for the synthesis of stable peptide mimetics have been summarized in monographs by Wieland[61] as well as in several recent reviews.[62–65]

The dimerization of proteins can be seen on the one hand as a special case of protein folding and on the other as an example for the formation of protein ensembles. The development of peptide mimetics is therefore an especially promising field for drug design as such compounds can exert effects both on the folding process and on protein–protein interactions. Since peptide mimetics normally lead to destabilization and subsequently to degradation of the target protein, they can affect pathophysiological processes at very low doses.

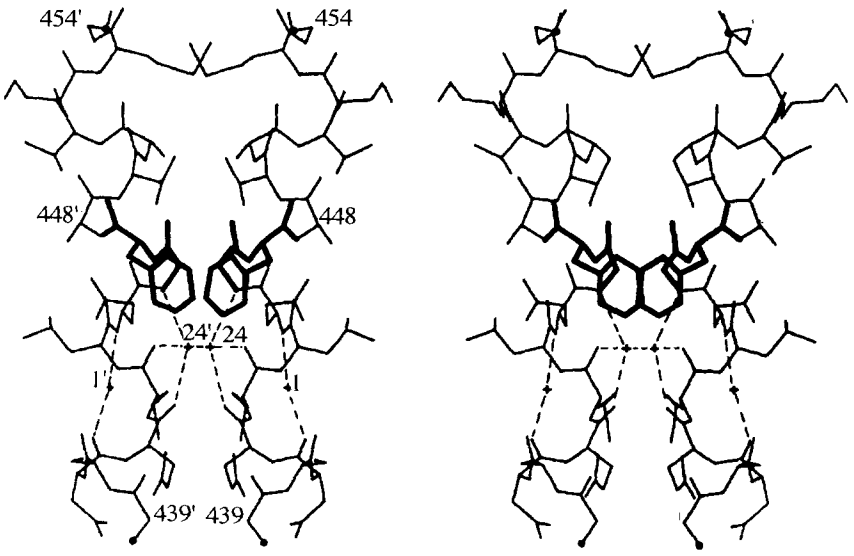


Fig. 5. Stereoview of the closest contact between the subunits of glutathione reductase. The helices 439–454 and 439′–454′ are shown. The amino acid residues Gly446 and Phe447 of both chains are indicated in bold. The exchange of Gly446 and 446′ for Glu residues results in a disordered GR-mutant which is degraded by intracellular proteases [59]. A peptide analog preventing the contact of the subunits at this site would probably have the same effect as the mutation and suppress intracellular glutathione reductase activity even in catalytic amounts.

7. Future Prospects

Drug design is not simply an extension of the repertoire of pharmaceutical chemistry. The analysis of ligand–receptor interactions leads in many ways to new concepts in structural chemistry and molecular biology. Not least because of its importance for medicine, glutathione reductase is one of the best understood enzymes[66] and a promising protein for industrial applications.[16, 67]

Research on parasites is not only necessary on humanitarian grounds. It also serves as a driving force for progress, since only interdisciplinary efforts will lead to a better knowledge and control of these mysterious pathogens.[67d] In developed countries the major parasitoses are mistakenly ignored. Parasitic diseases are not only of interest to Western societies as life-threatening complications of AIDS. Other problems like allergies, cancer, and hereditary diseases assume their own perspectives only against a background of man's natural situation, which was and is largely primed by the confrontation with challenges like starvation and parasitic diseases.[6, 7]

Appendix: On the Stability of a Protein–Ligand Complex

The Gibbs–Helmholtz Equation (h), gives the free energy of binding of a ligand to a macromolecule in which $\sum\Delta G$ consists

$$\sum\Delta G = \sum\Delta H - \sum T\Delta S \qquad \text{(h)}$$

of numerous negative (that is, favorable) and positive (that is, unfavorable) elements.

According to our present state of knowledge it is not possible to calculate with sufficient accuracy the free energy of biologically or pharmacologically interesting interactions. The following considerations[48-51, 68-72] are, however, useful if $\sum\Delta G_0$ is known for a lead compound and only one chemical grouping of the ligand is to be changed at a time. According to Equation (i),

$$\Delta G_0 = 2.3\,RT\lg K_{diss} \quad \text{(i)}$$

a change in ΔG_0 of 5.7 kJ mol^{-1} at 300 K signifies a change in the inhibitor constant K_{diss} of 10. Fixing a single bond rotor of the ligand in the right configuration—for example by introducing a double bond[70]—can result in a reduction (that is, an improvement) of the inhibitor constant by a factor of 10 [see c)]. The following contributions to ΔG need to be taken into account (all the values refer to 300 K):

a) ΔG_{R+T}, the overall entropy loss due to bimolecular association: Ligand and macromolecule, each regarded as rigid, lose their entropies of translation and rotation on forming a complex. ΔG_{R+T} is unfavorable and can be estimated from Equation (j),[70] where M_r is the relative molecular mass of the ligand.

$$\Delta G_{R+T} = (20\lg M_r + 10)\ \text{kJ mol}^{-1} \quad \text{(j)}$$

b) ΔG_h, the entropy gain of water (hydrophobic effect): On complex formation, hydrocarbon groups are often withdrawn from contact with water. ΔG_h is negative (favorable) and amounts to about -20 kJ mol^{-1} per nm^2 of hydrophobic area.[49, 71] It is very difficult to estimate the entropy gain of H_2O molecules released to bulk water when a hydrogen bond between ligand and protein is formed (for this aspect see two controversial papers[49, 70] by Williams).

c) ΔG_r, the entropy loss due to restricted rotation about single bonds: Complex formation arrests rotation for numerous single bonds; the free energy ΔG_r required is 3.5–6.0 kJ for each rotor.[49, 70] When rigid ligands are bound, no bond rotors of the ligand are fixed. This explains the prevalence of aromatic and other rigid molecular structures among drugs and poisons.

d) ΔG_i, the free energy of interaction between complementary groups: ΔG_i relates to the situation when ligand and protein are already oriented in the optimal position for noncovalent interactions. Thus ΔG_i can be regarded as the "intrinsic binding energy". Water molecules are often integral parts of the contact surfaces. For instance, in the glutathione reductase–GSSG complex, there are ten "direct" and 14 water-mediated interactions between ligand and enzyme.[34, 54]

Complementarity and hence selective binding means that many pairs are formed between the contact surfaces, each pair consisting of two dipoles, or two electrically counter-charged groups, or two nonpolar groups. The dipoles normally form hydrogen bonds and the electric charges salt bridges; the nonpolar pairs are held together by dispersion forces. The ΔG_i value (-2 to -20 kJ mol^{-1} for hydrogen bonds, up to -30 kJ mol^{-1} for salt bridges, and -0.1 kJ mol^{-1} for a pair of nonpolar partner atoms[50, 70, 71]) are determined by Coulomb's law. Consequently, the attractive forces also depend on the relative orientation of the partners and on the microscopic dielectric constant, ε, which as a rule is unknown. For the interior of a protein, ε is assumed to be 10 to 20 times smaller than for water.

To improve the polarization of a chemical group it is often favorable to have a metal ion as a partner on the complementary surface. Examples are the binding of O_2 to the iron ion of hemoglobin and the fixation of the methyl group of ethanol by the zinc ion of alcohol dehydrogenase.[70]

Although salt bridges (ion pair bonds) have favorable ΔG_i values, their contribution to the stabilization of a receptor–ligand complex is in general small. The reason is that numerous bond rotors must be oriented and arrested [see c)] before the ionic groups can come together at the optimal salt bridge distance.[72]

e) ΔG_{vdW}, the change in van der Waals energy: One must also take into account the change in the van der Waals interaction energy[50] that occurs on a complex formation. The rule is that attractive forces are weak and repulsive forces very strong. A single unfavorable van der Waals contact can prevent the formation of a complex that otherwise would be favorable.

f) ΔG_{conf}, the change in conformational energy:
Before or after binding the ligand, the receptor can find itself in a conformation with strained bond angles or interatomic distances. Consequently the formation of a low affinity complex in rapid preequilibrium can be followed by slow conversion into a high affinity complex.[4, 54] The formation of such kinetically stabilized complexes are irreversible on a biological time scale (see also Section 6.1).

The factorization of the binding energy as discussed in a) to f) indicates that molecular recognition has not yet achieved the status of a science, that is, we are generally not in a position to make reliable predictions. Therefore, new approaches such as the problem-oriented use of genetic algorithms[73, 74] are urgently required.

A problem which is often overlooked is that of specifically bound water molecules. In the structure of glutathione reductase there are more than 100 of these molecules, some of which even do not exchange with the bulk aqueous phase.[33b] Many intra- and intermolecular contacts of macromolecules are mediated by individual molecules or even networks of water. Recently it has been shown that H_2O molecules—as noncovalent extensions of DNA bases—even serve as selective recognition structures for a specific protein–DNA interaction.[75] These facts must be accounted for in ligand design and in estimations of interaction energies. All energy terms discussed above, as well as the microscopic dielectric constant may be influenced by bound water molecules. For these reasons we suggest that each structurally defined water molecule in a receptor should be given the status of a *cofactor*, as it is accepted for bound metal ions such as the zinc ions in alcohol dehydrogenase. Apart from remaining (type 1) water molecules, there can also be type 2 water molecules coming in with the ligand.[34] This implies that a receptor–ligand complex is only described satisfactorily when all water molecules with a structural or functional role have been identified.

The colleagues to whom we are indebted are listed as authors in the Reference section. In particular we would like to thank Dr. K.-D. Hungerer, Behringerwerke Marburg, Frau Irene König, Heidelberg, and Prof. K. Lingelbach, Hamburg. Frau Helga Alt

was responsible for the preparation of the manuscript. Our work has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Federal Ministry for Research and Technology (BMFT).

Design, Synthesis, and Properties of Molecule-Based Assemblies with Large Second-Order Optical Nonlinearities

Tobin J. Marks* and Mark A. Ratner*

The design, synthesis, characterization, and understanding of new molecular and macromolecular assemblies with large macroscopic optical nonlinearities represents an active field of research at the interface of modern chemistry, physics, and materials science. Challenges in this area of photonic materials typify an important theme in contemporary chemistry: to create new types of functional materials by the rational construction of supramolecular assemblies exhibiting preordained collective phenomena by virtue of "engineered" molecule–molecule interactions and spatial relationships. This review surveys several approaches to, and the microstructural and optical properties of, second-order nonlinear optical materials built from noncentrosymmetric assemblies of chromophores having large molecular hyperpolarizabilities. Such types of materials can efficiently double the frequency of incident light, exhibit other second-order nonlinear optical effects, and contribute to the knowledge base needed for new photonic device technologies. Systems described include chromophore macromolecule guest–host matrices, chromophore-functionalized glassy macromolecules, thermally crosslinked chromophore–macromolecule matrices, and intrinsically acentric self-assembled chromophoric superlattices.

Keywords: NLO materials · nonlinear optics · polymers · self-assembly · thin films

1. Introduction

One of the great challenges in contemporary chemical synthesis is the construction of multimolecular arrays with preordained collective properties by virtue of "engineered" interactions/spatial relationships between preselected constituent molecular building blocks. Although the art of chemical synthesis has advanced to the point in which many classes of complex molecules are now readily accessible, rational approaches to the production of structurally controlled multimolecular assemblies is at a far more primitive level.[1] Second-order molecule-based nonlinear optical (NLO) materials,[2] in which microstructural acentricity is a key design requirement, represent one such chemical challenge and are the subject of the present review. However, it must be emphasized that similar synthetic issues are relevant in the design and construction of molecular "metals"[3] and "ferromagnets",[4] as well as biomimetic photosynthetic structures,[5] self-assembling catalytic/enzymatic ensembles, and a host of other fascinating problems in supramolecular science.[1]

The large current scientific and technological interest in NLO materials[6] based upon electronically delocalized organic and metal-organic molecular chromophoric[2] building blocks stems from the demonstrated possibilities of very large nonresonant responses, ultrafast response times, low dielectric constants and dielectric losses, high optical damage thresholds, and the intrinsic tailorability of the constituent molecular structures.[2] When such materials are incorporated into glassy polymeric structures, the additional attractions of supramolecular organization, improved mechanical/dimensional stability, improved optical transparency (versus typical organic single crystals), and ready processability into thin-film waveguiding structures can be envisioned. Such characteristics are attractive for the fabrication of high-performance photonic devices for optical signal processing, telecommunications, computing, data storage; indeed the first prototype devices have recently been demonstrated.[2, 7] Needless to say, many basic scientific issues and challenges constitute the fundamental knowledge base that must be acquired before such experimental results can become viable technologies.

The purpose of this article is to review synthetic and physicochemical efforts to rationally design, construct, and understand new classes of molecule/macromolecule-based second-order NLO materials. Space limitations do not permit exhaustive discussion of all research being performed at academic and industrial laboratories worldwide. Therefore, the present discussion is necessarily selective and oriented toward the interests of the authors, focussing most heavily upon recent activities closest to the central theme of this article: construction of acentric chro-

mophore–polymer assemblies. As the present discussion unfolds, it will also be seen that modern quantum chemical formalisms can, and we believe should, play a key role in the design and understanding of new NLO materials. While reference to these activities is made in the present review, a full discussion of what is becoming a very active field can be found in reference.[8]

2. Origin of Molecular/Multimolecular NLO Phenomena

The fundamental relationship describing the induced change in molecular dipole moment (polarization) upon interaction with an oscillating external electric field (light) can be expressed in a power series [Eq. (a)].[2, 6] Here p_i is the electronic polariza-

$$p_i = \sum_j \alpha_{ij} E_j + \sum_{j \leq k} \beta_{ijk} E_j E_k + \sum_{j \leq k \leq l} \gamma_{ijkl} E_j E_k E_l + \ldots \qquad \text{(a)}$$

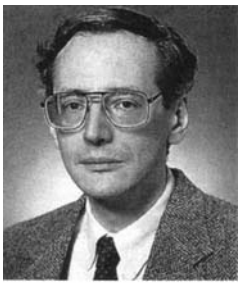
tion induced along the ith molecular axis, E_j is the jth component of the applied electric field, α is the linear polarizability, β the quadratic hyperpolarizability, and γ the cubic hyperpolarizability. The terms beyond the first describe a nonlinear response to the radiation field and account for the terminology "nonlinear optics." Importantly, the even order tensor, β, which is responsible for doubling the frequency of incident light (second harmonic generation, SHG), linear electrooptic effects, and frequency mixing, vanishes in a centrosymmetric environment.

The macroscopic polarization arising from an *array* of molecules is given by Equation (b), where the χ's are macroscopic

$$p_I = \sum_J \chi^{(1)}_{IJ} E_j + \sum_{J \leq K} \chi^{(2)}_{IJK} E_J E_K + \sum_{J \leq K \leq L} \chi^{(3)}_{IJKL} E_J E_K E_L + \ldots \qquad \text{(b)}$$

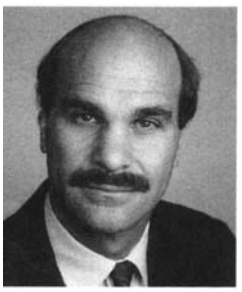
susceptibilities. The macroscopic susceptibilities are related to the corresponding molecular terms α, β, γ, etc. by local field corrections (intermolecular interactions) and the density of chromophores as in Equation (c) for frequency doubling. Here

$$\chi^{(2)}_{IJK}(-2\omega;\omega,\omega) = N \sum_{ijk} f_{Ii} f_{Jj} f_{Kk} \beta_{ijk}(-2\omega;\omega,\omega) \langle a_{Ii} a_{Jj} a_{Kk} \rangle \qquad \text{(c)}$$



N is the number of molecules per unit volume, the f's are poorly understood local field corrections, and the a's are projectors of unit vectors along the molecular axes onto the laboratory axes.

How the second-order molecular response depends upon the frequency of input radiation (the dispersion) is an important consideration and one that only recently has been investigated in experimental detail (see Section 6). The simplest theoretical description (the "two-level model") pragmatically describes the second-order molecular response in terms of electronic charge transfer excitation between the ground state g and an electronically excited state e [Eq.(d)].[2] Here f is the oscillator strength

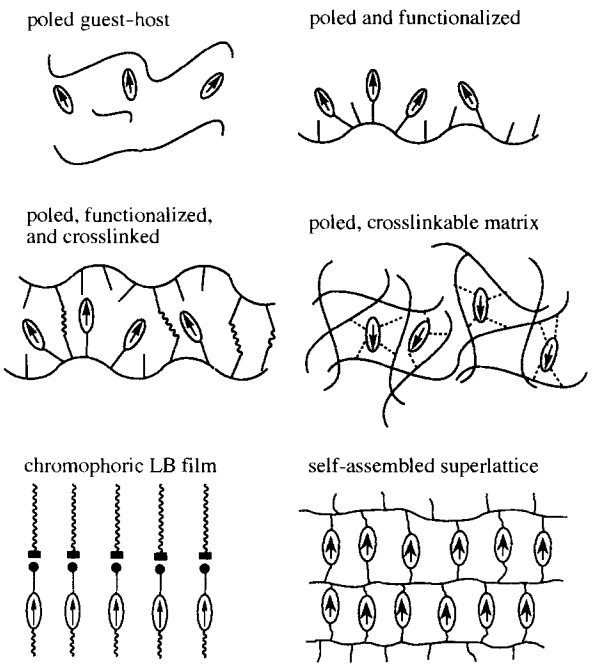


$$\beta_i(-2\omega;\omega,\omega) = \frac{3e^2}{2} \frac{\hbar\omega_{ge} f \Delta\mu_{ge}}{[(\hbar\omega_{ge})^2 - (\hbar\omega)^2][(\hbar\omega_{ge})^2 - (2\hbar\omega)^2]} \qquad \text{(d)}$$

and $\hbar\omega_{ge}$ is the energy of the charge transfer optical excitation between the ground the excited state, and $\Delta\mu_{ge}$ is the difference in dipole moment between the two states. The two-level formula predicts a pair of NLO resonances (enhancements) for each input frequency ω; one at the fundamental energy ($\hbar\omega$) and the other at twice the incident frequency ($2\hbar\omega$). Clearly the nonlinear response will be largest near these resonant frequencies; however, for actual devices it is usually desirable to avoid extensive absorption of the generated light and/or photochemical damage of the sample.

From the foregoing discussion, it can be seen that the observed nonlinear response of a material is ultimately governed by the optical characteristics of constituent molecular chromophores, the frequencies of the input radiation, and the overall

Tobin J. Marks was born in Washington, D. C., in 1944. He received a B. Sc. degree in chemistry from the Unversity of Maryland in 1966 and a Ph.D. degree in inorganic chemistry from the Massachusetts Institute of Technology in 1970, working with F. A. Cotton. He moved to Northwestern University as an assistant professor in 1970. He is currently Charles E. and Emma H. Morrison Professor of Chemistry and Professor of Materials Science and Engineering at Northwestern. His research interests include the design, synthesis, and physicochemical properties of unusual molecules and molecule-derived materials.



Mark A. Ratner, Professor of Chemistry at Northwestern University, was educated at Harvard, Northwestern, Aarhus, Munich, and New York. His research centers on the use of theoretical methods and insights to understand, to correlate, and to predict experimental behaviors. Current interests in his research group center on transport and mesoscopic phenomena in molecular materials.

spatial organization (e.g., noncentrosymmetry for $\chi^{(2)}$) that can be imposed upon large ensembles of these constituents. The scientific challenge here lies in devising new and more efficient approaches to the synthesis and processing of polymeric NLO systems for maximum performance characteristics as well as in developing deeper understandings of organizational and motional processes within polymer films, of interfaces between polymers and other surfaces, and of the electronic structural aspects of how single molecules and molecule ensembles interact with electromagnetic radiation.

3. General Synthetic Strategies for Polymeric NLO Materials

For polymer-based second-order ($\chi^{(2)}$) materials, the crucial synthetic problem, beyond optimizing the individual responses of the constituent chromophores (not a topic of this article), is to maximize the chromophore number density (cf., Eq.(c)), while achieving and preserving maximum acentricity of the microstructure. Various strategies to achieve these ends are depicted in Scheme 1, and will be discussed in the approximate order in which they have been investigated.

Scheme 1. Design motifs for molecular/polymer NLO materials.

One pioneering approach to polymeric second-order materials was to dissolve ("dope") NLO chromophores in glassy polymer matrices and then to align the dipolar chromophore molecules with a strong orienting electric field (poling), while heating near the matrix glass transition temperature T_g (the temperature at which the material undergoes a transition from the glassy to rubbery state).[9] The performance of such materials after cooling and removal of the electric field is limited by the low chromophore number densities which can usually be achieved before phase separation occurs and by the physical aging/structural relaxation characteristics inherent to all glassy polymers.[10, 11] These lead to loss of free volume and eventual randomization of the poling-induced preferential chromophore orientation. Hence, the SHG efficiency of such "guest–host" materials (Scheme 1 top left) is generally short-lived except in cases of extremely high matrix T_g values. In addition, we have observed that the chromophore constituents are not strongly bound in such matrices (they frequently sublime out during poling at higher temperatures) and that these materials readily undergo dielectric breakdown[12] during poling (possibly due to the mobility of ionized molecular constituents).[13]

A second traditional approach to the construction of efficient film-based SHG materials has been to incorporate NLO chromophores into acentric Y-type Langmuir–Blodgett (LB) films (Scheme 1 bottom left).[14, 15] A priori, such an approach offers far greater net chromophore alignment than is possible in a poling field (where net alignment is Boltzmann statistically determined), temporal stability of the chromophore alignment, and controlled film thickness. While recent results with LB film-based NLO films have been encouraging, significant problems appear to arise in many cases from the fragility of the films, the temporal instability of chromophore alignment (even near room temperature), the problem of scattering microdomains, and the structural regularity of layer deposition that is possible.[14, 15]

Covalently linking selected high-β chromophores to the backbones of high-T_g glassy polymers (Scheme 1 top right) potentially offers several advances over poled chromophore–polymer guest–host systems.[16] These include achieving considerably higher chromophore number densities without chromophore phase separation, greater thermal and chemical stability of the chromophore–polymer structure, and possible hindrance of dielectric breakdown processes. Moreover, initial design plans envisioned that covalent attachment to the polymer backbone might impede acentricity-degrading chromophore reorientation processes. Many of these advantages have indeed been realized (see Section 4.2 and 4.3). Nevertheless, all poled chromophore–glassy polymer ensembles are kinetically unstable with respect to relaxation to the thermodynamic equilibrium state of globally random orientation. Thus, the need for complete immobilization under the most adverse of anticipated device operating conditions (perhaps 70 °C or greater for five years; perhaps brief excursions to 300 °C or more during fabrication) has stimulated efforts to achieve even greater chemical control over polymer chain dynamics. The question was therefore asked as to whether chromophore–polymer structures could be aligned in an electric field while *simultaneously* effecting crosslinking reactions which would "lock" the chromophore units in their aligned orientations (Scheme 1 middle).[17] The progress made toward these goals will be discussed in Section 5.

A totally different strategy for the synthesis of second-order chromophore–polymer matrices is one in which artificial superlattices would be constructed in a layer-by-layer fashion using covalent self-assembly techniques (Scheme 1 bottom right).[18] In principle, such an approach could achieve far higher degrees of net chromophore alignment than electric field poling, and far greater alignment temporal stability than a typical glassy polymer which is subject to physical aging. However, such an approach places considerable demands on the design of the

appropriate chromophoric building blocks and assembly methodologies, not to mention physical characterization techniques that must provide information on the state of completion of microstructures evolving on the dimensional scale of 10–20 Å per synthetic operation. Nevertheless, such superlattices can be synthesized and preliminary data reveals structural regularity and *very large* $\chi^{(2)}$ responses (see Section 6).

In the following sections we survey by class, some highlights in the synthesis and characterization of the second-order chromophore–polymer structure classes introduced above.

4. Poled Chromophore-Functionalized Polymers

4.1. Response of Functionalized Polymer to Electric Field Poling

The response of embedded chromophores to a poling field has been described by Singer et al. for the simplified case of isolated molecules in the gas phase ("the oriented chromophore gas model", Eqs. (e) and (f)).[9a, b] An excellent overview of the

$$d_{33} = 1/2[Nf^{2\omega}f^{\omega}f^{\omega}\beta_{zzz}L_3(p)] \quad \text{(e)}$$

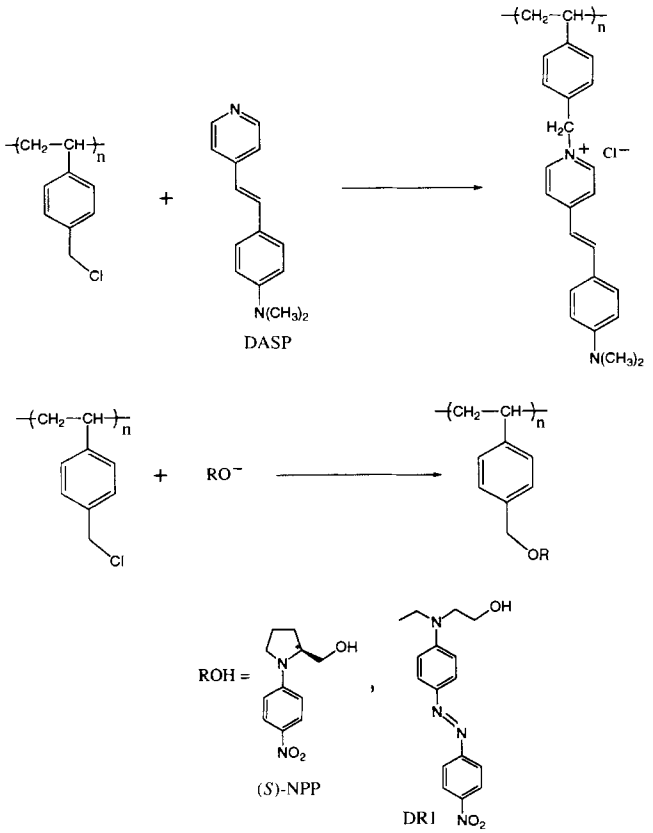
$$p = \frac{f^0\mu E_p}{kT} \quad \text{(f)}$$

theory can be found in reference [2g]. Here d_{33} is the second harmonic index (formally $1/2\ \chi^{(2)}_{333}(-2\omega;\omega,\omega)$), which expresses the efficiency of second harmonic generation by the material (two input photons of frequency ω produce an output photon of frequency 2ω) and $L_3(p)$ is the third order Langevin function. The 3-axis is the uniaxial axis defined by the direction of the poling field [Eqs. (g)–(i); $P^{2\omega}$ is the second harmonic polarization].[6] It is assumed that the poled glassy thin film is uniaxial and belongs to point group ∞mm. It can be shown by symmetry that $d_{31} = d_{15}$. It is pragmatically assumed that the chromophore molecules are rodlike with the dipole moment along the molecular long axis and that β_{zzz} (z refers to the molecular axis) is the only nonzero element of the molecular hyperpolarizability tensor. N in Equation (e) is again the chromophore number density, the f stands for the local field (environmental) factor at the indicated frequencies, μ in Equation (f) is the chromophore dipole moment, and E_p is the poling field. This noninteracting chromophore model also predicts that $d_{33} = 3d_{31}$.

$$P_x^{2\omega} = 2d_{15}E_xE_z \quad \text{(g)}$$

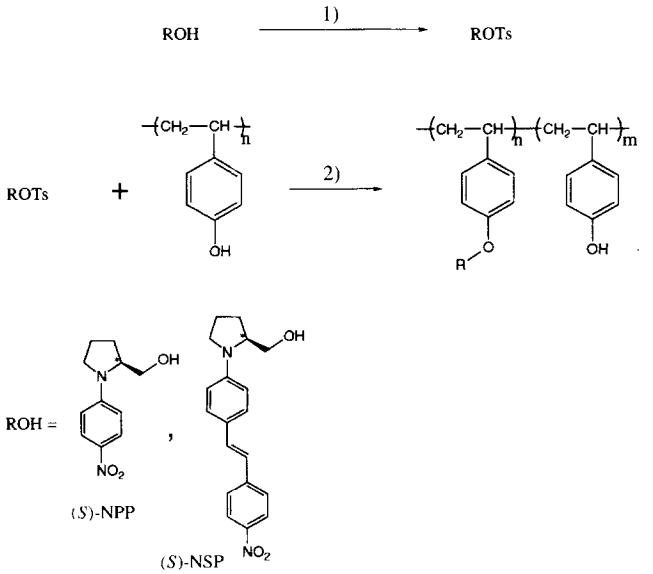
$$P_y^{2\omega} = 2d_{15}E_yE_z \quad \text{(h)}$$

$$P_z^{2\omega} = d_{31}E_x^2 + d_{31}E_y^2 + d_{33}E_z^2 \quad \text{(i)}$$



In terms of chromophore design, Equations (e) and (f) predict that β_{zzz} and μ should be maximized for optimum NLO response. While the applicability of Equations (e) and (f) to real systems is an important, incompletely resolved question, chemically oriented semiempirical formalisms are now available that allow efficient computation and origin analysis of β_{ijk}, μ, and λ_{max} (the latter is crucial for laser compatibility optimization) for both organic and metal-organic chromophore molecules, without resort to tedious empirical synthetic efforts.[8, 19] The degree to which d_{33} conforms to Equations (e) and (f) is most relevant at (desired) high N values, where chromophore–chromophore interactions become non-negligible. The macroscopic aspects of these effects are addressable by synthesis, spectroscopy, and poling/NLO characterization (see Section 4.2 and 4.3). Theoretical studies on multichromophore clusters have also proven valuable in analyzing the consequences of close, chromophore–chromophore interactions in determining β for local clusters.[20] These are summarized in another review.[8] The "oriented chromophore gas" model must also be generalized for high chromophore number densities, where the orientations may be attenuated by interchromophore dipolar interactions.[21]

The most detrimental aspect of chromophore–chromophore interactions is likely to be the formation of statistically centrosymmetric aggregates when N becomes large. One way to frustrate this might be to employ chiral chromophores, since chiral molecules must necessarily crystallize in acentric space groups.[2] The importance of chromophore–chromophore interactions can also be probed by comparing the properties of polymers functionalized with both homochiral and racemic chromophore molecules (see Section 4.2). Another issue in chromophore design arises when immobilizing, crosslinking processes are desired. Synthetic approaches must imbue the chromophores with chemical functionality appropriate for crosslinking, with both protected and unmasked forms of the crosslinking functional groups ideally available. Needless to say, useful chromophores should have acceptable environmental stability.



Polymer backbones suitable for NLO chromophore functionalization should have good film-forming characteristics, good optical transparency (preferably amorphous microstructures), appropriate reactivity for functionalization and/or crosslinking, good environmental stability (including dielectric breakdown strength), and minimum microstructural mobility (as judged by T_g, T_β (T_β = the temperature of the highest secondary transition, frequently associated with side-group rotations), and other chain/sidechain motional indices).

4.2. Poled Polystyrenes and Related Backbones

Initial systems investigated included functionalized polystyrenes derived from chloromethylated polystyrene (PS)[16] and functionalized poly(*para*-hydroxystyrene)[13a] (PHS). The former was straightforwardly functionalized with the high-β chromophore Disperse Red 1 (DR1) and the chiral prolinol chromophores NPP by a Williamson ether synthesis, while a saltlike, high-β stilbazolium group (DASP) was introduced by quaternization (Scheme 2). PHS forms tenacious coatings on many substrates and exhibits higher T_g values than PS (ca. 155–180 °C vs. ca. 105 °C, presumably due to the extensive hydrogen bonding network)[22] and can be readily functionalized using the *para*-toluenesulfonates of chiral (*S*)-NPP[17c, 23, 24a, b] and (*S*)-NSP[24c, d] (Scheme 3) in yields of up to about 90% of the phenol groups. Table 1 summarizes d_{33} and other data for these polymers subsequent to film casting, annealing (to remove volatile impurities), and poling by either contacting electrodes or a corona discharge.[25] (The former allows more precise control of the poling field but is more subject to film dielectric breakdown.

Scheme 2. Synthesis of chromophore-functionalized polystyrenes.

Scheme 3. Synthesis of chromophore-functionalized PHS. 1) *p*TsCl, pyridine, 0 °C; 2) NaH, N-methylpyrrolidone (NMP).

The latter achieves greater but less readily quantified poling fields, but may leave small amounts of residual charge on the surface.[10c] Importantly, largely nonresonant (cf. Eq. (e)) d_{33} values (up to 80×10^{-9} esu) considerably in excess of the d_{36} of KH_2PO_4 (1.1×10^{-9} esu) and the d_{31} of $LiNbO_3$ (14.2×10^{-9} esu) can be achieved. At high functionalization levels, the chromophore number density of NPP-PHS is about 60% of that of crystalline NPP.[23]

Table 1. SHG coefficients for chromophore-functionalized polystyrenes [a].

Material	Functionalization level (% phenyl rings)	$d_{33}\times10^9$ [esu] [b]
(PS)CH_2-DR1	12.5	2.7 [c]
(PS)CH_2-DASP	4.5	0.12 [c]
(PS)CH_2-(*S*)-NPP	36.0	3.8 [c]
(*S*)-NPP-PHS	16	13 [d]
(*S*)-NPP-PHS	36	45 [d]
(*S*)-NPP-PHS	48	58 [d]
(*S*)-NPP-PHS	62	66 [d]
(*S*)-NPP-PHS	75	72 [d]
(*S*)-NPP-PHS	90	80 [d]
(*S*)-NSP-PHS	42	50 [d]
(*S*)-NSP-PHS	77	160 [d]

[a] Measured within 30 min of poling; $\lambda = 1064$ nm. [b] Experimental SHG coefficients. [c] Contact poling; $E_p = 0.8-1.2$ MVcm^{-1}. [d] Corona poling; $E_p = 3-4$ MVcm^{-1}.

The (*S*)-NPP-PHS model system[17c, 24a, b] has been studied in detail with respect to the validity of the chromophore gas model. There is an approximately linear relationship between d_{33} and N, which is *independent* of whether the chromophore is homochiral or racemic (Fig. 1). The form of Equations (e) and

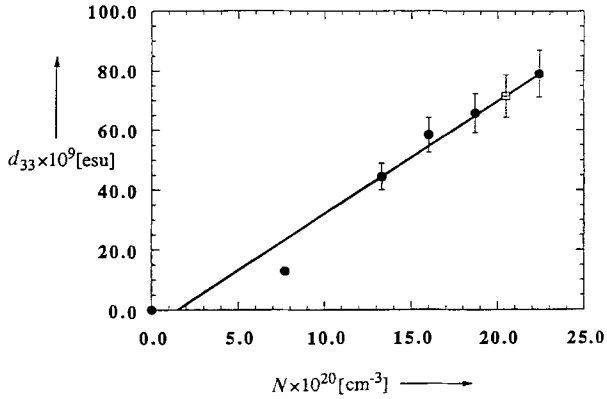


Fig. 1. SHG coefficients of (*S*)-NPP-PHS films poled at 0.3 MVcm^{-1} as a function of chromophore number density N. The value marked with ⊟ is for a polymer prepared from racemic NPPOH.

(f) also predicts that d_{33} will scale linearly with poling field at relatively low fields, but will saturate when $f^0\mu E_p \approx kT$. This point will be reached in the case of the (*S*)-NPP-PHS model system when $E_p > 1.3$ MVcm^{-1} and Figure 2 shows that d_{33} does indeed "saturate" at higher poling fields. While these NLO results and transmission optical spectra are in accord with minimal chromophore–chromophore interaction effects, various polymer dynamic properties are markedly sensitive to the chromophore functionalization level (see Fig. 3a).

Figure 3 shows d_{33} temporal stability data for representative poled (*S*)-NPP-PHS films. Four factors influence the rate of SHG decay: 1. Traces of residual solvent (THF) are detected by FT-IR spectroscopy and have a plasticizing effect on the polymer matrix (verified by DSC). Annealing the films at high temperatures removes THF and enhances the temporal stability. 2. Increasing chromophore functionalization levels has a deleteri-

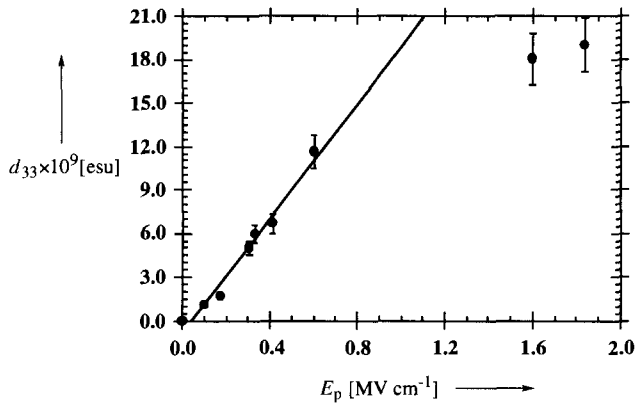

Fig. 2. SHG coefficient of (*S*)-NPP-PHS films (48% chromophore functionalization level) as a function of contact poling field, E_p. The line is a least-squares fit to the low-field data points.

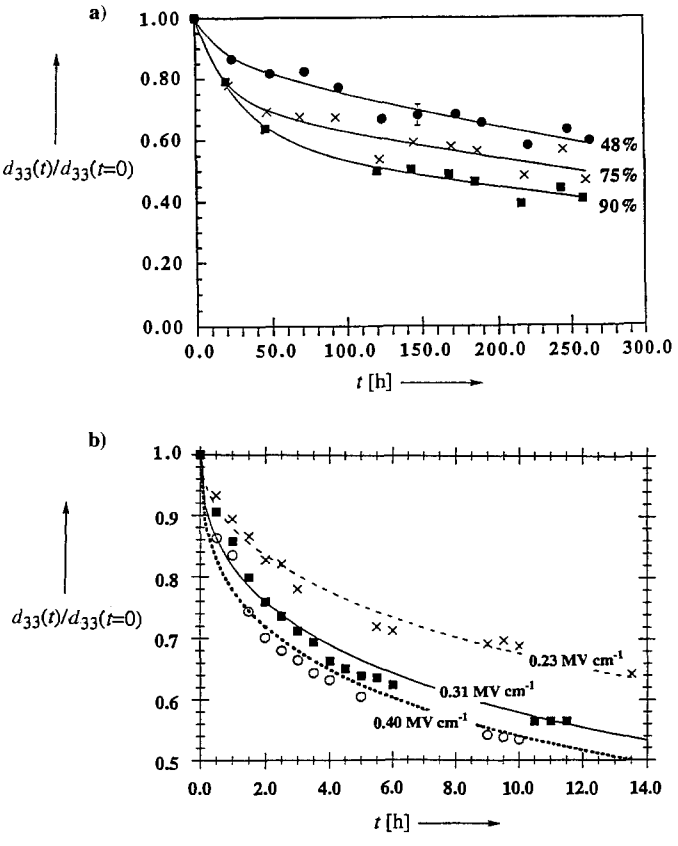

Fig. 3. a) The effect of the functionalization level on the SHG temporal characteristics of poled (*S*)-NPP-PHS films. Samples were corona poled at 133 °C. Curves represent least-squares fits to a biexponential function [Eq. (j)]. A representative error bar is provided on the 48% (*S*)-NPP-PHS transient. Decay measurements taken at 25 °C. b) Effect of applied poling field strength on the temporal characteristics of d_{33} for a contact-poled (*S*)-NPP-PHS film (36% functionalization level) after cessation of poling. Electric field poling was terminated at $t = 0$. Lines through data points represent nonlinear least-squares fit to Equation (j).

ous effect on d_{33} temporal stability (Fig. 3a), and enhanced mobility of the chain structure is also mirrored in falling T_g values and FT-IR spectroscopic evidence for diminished ArOH ··· HOAr hydrogen bonding.[13, 24] 3. Increasing poling field magnitudes, which displace the microstructure in increasing degrees from thermodynamic equilibrium, also result in lowered d_{33} temporal stability (Fig. 3b; greater driving force to return to equilibrium). 4. Physical aging of the film in the poling field and attendant reduction in free volume leads to enhanced d_{33} temporal stability.[24a, b]

Data of the type shown in Figure 3 convey much fundamental information on macromolecule dynamics and how it depends on polymer architecture, processing, physical aging, etc. In most cases, a biexponential [Eq. (j)] or phenomenological Kohlrausch–Williams–Watts (KWW) stretched exponential expression [Eq. (k)] can be successfully fit by numerical regression techniques to the $d_{33}(t)$ decay data (comparable statistical r values).[26, 27]

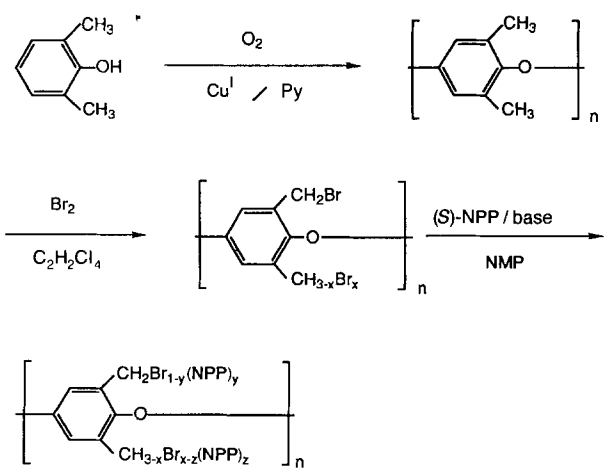
$$d_{33} = [Ae^{-t/\tau_1} + (1 - A)e^{-t/\tau_2}]d_{33}(0) \quad \text{(j)}$$

$$d_{33} = e^{-(t/\tau)^{\beta}}d_{33}(0)(0 < \beta \leq 1) \quad \text{(k)}$$

The biexponential expression can be viewed as a "two-state" description of chromophore reorientation dynamics, for example in liquidlike/large free volume and glasslike/small free volume matrix microenvironments.[28] The KWW expression describes the dynamics in terms of a manifold of relaxation processes.[26, 27] It will be seen that the below-T_g relaxation of most poled NLO polymers can usually be simulated by either of these simple models. Fitting (*S*)-NPP-PHS $d_{33}(t)$ data to Equation (k) yields τ and β parameters[24a, b] which reveal a strikingly narrower distribution of relaxation times and considerably reduced rotational mobility than found in typical guest–host systems.[26, 27] Similar conclusions have been reached by researchers at IBM in studies of chromophore-functionalized polyacrylates.[27e] In regard to temperature dependence, conventional liquid diffusion-like descriptions for polymer motion such as the Williams–Landel–Ferry (or equivalent Vogel–Tamman–Fulcher) equation [Eq. (l); where τ is the relaxation

$$\lg\frac{\tau(T)}{\tau(T_g)} = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)} \quad \text{(l)}$$

time; and C_1, C_2 arbitrary, but well-studied constants] are not strictly applicable to systems far below T_g.[27] Apparent activation energies for chromophore reorientation above T_g in (*S*)-NPP-PHS[24a, b] are considerably greater than in typical guest–host materials.[26, 27] Application of Equation (l) argues that poled polymer T_g values must be in excess of 250–300 °C for practical device lifetimes at operating temperatures on the order of 70 °C.[27e] The development of polymer dynamic theories applicable to the present NLO polymer systems is in an early stage.



In contrast to the above findings on chromophore-functionalized (*S*)-NPP-PHS, attempts to prepare NLO-active NPP + PS and NPP + PHS guest–host materials were less successful.[13] Phase separation and matrix opacity were observed at chromophore concentrations as low as about 5 mol%. Dielectric breakdown was frequently observed at low poling fields, and d_{33} decay was more rapid than all but the most highly functionalized/lowest T_g NPP-PHS matrices.

(*S*)-NSP-PHS (Scheme 3) specimens have also been prepared over a range of functionalization levels.[24c, d] T_g parame-

ters are as high as 185 °C and corona-poled film d_{33} values (partly resonant-enhanced) are as high as about 160×10^{-9} esu (Table 1).[24c, d]

4.3. Polyphenylene Ethers

Holding the (*S*)-NPP chromophore moiety constant, polyphenylene ethers have been investigated with the goal of learning the effects of increasing matrix T_g values, while achieving similar or higher chromophore number densities than the NPP-PHS system. Poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) is a high-strength, amorphous engineering thermoplastic with T_g about 205–210 °C and excellent film-forming characteristics.[29] PPO can be prepared by the oxidative coupling of 2,6-dimethylphenol[30] (Scheme 4). Bromination[31] yields

Scheme 4. Synthesis of chromophore-functionalized PO.

PPO-Br_x materials with functionalization levels on the order of 1.6–1.8 Br per repeat unit. (*S*)-NPP can then be introduced as shown in Scheme 4 to obtain 1.4–1.6 NPP per repeat unit with T_g values near 173 °C.[32] Film casting followed by annealing and either contact or corona poling affords nonresonant d_{33} values as high as 65×10^{-9} esu. Assuming approximate additivity of PPO and NPP densities, it is estimated that the chromophore number densities are about 70% of that of crystalline (*S*)-NPP.

SHG temporal stability data for representative poled (*S*)-NPP-PPO films are shown in Figure 4. Fitting a biexponential expression to the data [Eq. (j)] yields rather large τ_2 values, especially for the contact-poled film (ca. 400 days).[32] In situ SHG poling experiments have also been carried out on NPP-PPO films.[32] Importantly, chromophore orientational response begins far below the experimental T_g value. Furthermore, d_{33} increases more rapidly as T_g is approached (in accord with greater polymer mobility) and reaches a maximum as the temperature begins to decrease (in accord with the temperature-dependence of Equations (e) and (f)).

Slab waveguiding structures have been fabricated from (*S*)-NPP-PPO films.[32] Using standard prism coupling techniques, two TE modes are observed. The refractive index at 0.633 μm

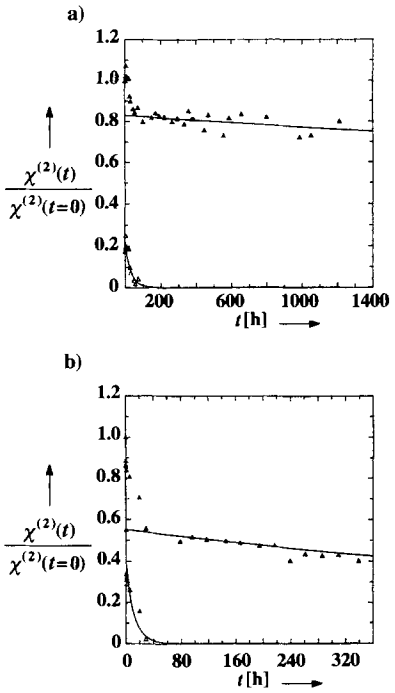


Fig. 4. Temporal characteristics of the SHG coefficient of (*S*)-NPP-PPO films (1.43 NPP moieties per repeat unit). Decay data taken at 25 °C. The solid lines each show the two exponential components of the least-squares fit of Equation (j). a). Contact poled at 2.1 $MVcm^{-1}$; b) corona poled.

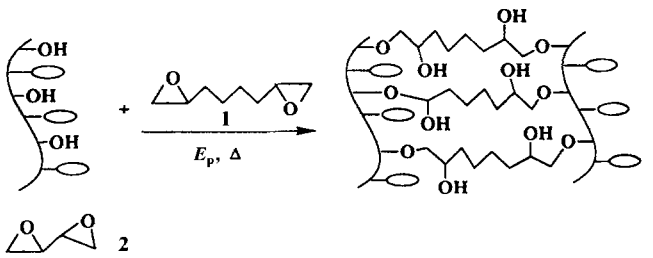

is 1.584 ± 0.001 and the loss coefficient, α, is estimated to be $\leq 1\ dBcm^{-1}$ at $= 0.633\ \mu m$ (dB = decibel). This degree of transparency is compatible with waveguiding device requirements.[7]

5. Poled, Thermally Crosslinked NLO Polymers

Further chemical control over the randomization of poling aligned chromophore dipoles can be achieved by "locking" them in place simultaneous with poling. Thermal crosslinking of polymer structures is known to effect the densification/vitrification/free volume decrease of reactive matrices to a degree that can be controlled by the temperature and duration of curing. Initially, this approach was pursued with chromophore-functionalized PHS[17c] and with chromophore-embedded matrices; however, impressive advances have also been achieved by other groups using complementary strategies (see Sections 5.2–5.4).[17a, b, 33] Several other dividends of this approach include greater film resistance to dielectric breakdown, cracking, and delamination.

5.1. Crosslinked, Chromophore-Functionalized Polystyrenes

Films of (*S*)-NPP-PHS were cast from solutions also containing 1,2,7,8-diepoxyoctane (**1**, DEO) or 1,2,3,4-diepoxybutane (**2**), (Scheme 5).[17c, 24a] Optimum epoxy crosslinking conditions[34, 35] can be established by parallel experiments in which the ring-opening process is monitored by FT-IR spectroscopy[36] of films cast on KBr plates. The films from NPP-

Scheme 5. Simultaneous poling and crosslinking of chromophore-functionalized PHS.

PHS and **1** or **2** were partially cured at 100 °C for 1 h and then at 100 °C and 10^{-4} Torr for 24 h. This procedure brings about partial crosslinking as well as removal of residual traces of solvent and other plasticizing volatiles. The annealed NPP-PHS films were next corona poled at 180 °C for 1 h. For optimum polymer/diepoxide stoichiometries (see Fig. 6), such conditions induce high degrees of crosslinking, while as noted above, corona poling provides higher electric fields than contact poling techniques without ready dielectric breakdown. The poled films were then cooled to room temperature and physically aged for 1 h prior to removal of the corona field. The crosslinked films are impervious to organic solvents and more resistant to cracking than noncrosslinked films. Good transparency characteristics are illustrated by the successful fabrication of waveguides of the type described in Section 4.3 for NPP-PPO.

SHG temporal decay data for the poled, crosslinked NPP-PHS films were fit by least-squares techniques to the aforementioned, phenomenological biexponential expression of [Eq. (j)]. In Table 2 are set out d_{33}, τ_1, τ_2 data for NPP-PHS films as a

Table 2. SHG coefficients (d_{33}) and temporal decay parameters for corona-poled, NPP-PHS films as a function of thermal crosslinking [a].

function of crosslinking procedure. The corona-poled nonresonant d_{33} values are generally comparable to those previously achieved for contact-poled NPP-PHS samples at comparable functionalization levels. Equally important, SHG efficiency is not adversely affected by the crosslinking chemistry, except at very high levels of crosslinking agent (see Fig. 6). In regard to d_{33} temporal stability, Figure 5 compares the effects of simultaneously corona poling and crosslinking (*S*)-NPP-PHS with 0.5 equivalents **1** per available phenol OH group to two films poled in an essentially identical manner but without an epoxy

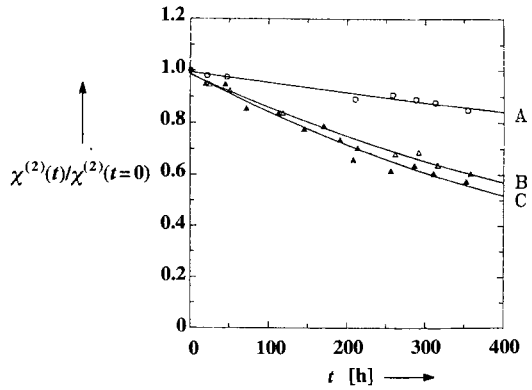

Fig. 5. Temporal characteristics of the SHG coefficient d_{33} for corona-poled (*S*)-NPP-PHS films. A: Simultaneously poled (180 °C) and crosslinked with 0.5 equiv **1** per phenol OH; B: Poled at 180 °C. C:) Poled at 150 °C. The solid lines are from fits of Equation (j).

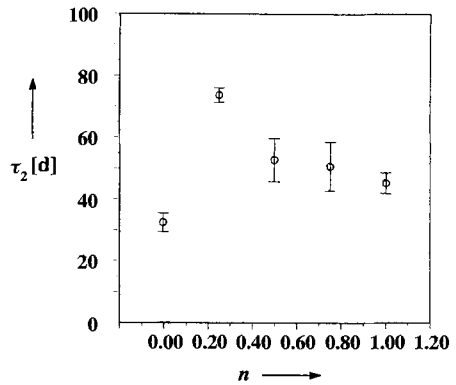
crosslinking agent. The increase in SHG temporal stability is clearly evident and translates into 3.0-fold and 3.3-fold increases in τ_1 and τ_2, respectively. For the films that have not been crosslinked, higher poling temperatures (150–180 °C) result in a decrease in the short-term decay component of $d_{33}(t)$ versus samples annealed at lower temperatures (cf. B and C in Fig. 5). The effect of the epoxy crosslinking/densification methodology on chromophore mobility should be a complex function of crosslinking temperature, stoichiometry, and diepoxide reagent. Figure 6 shows the effect on the $d_{33}(t)$ τ_2 parameter of increasing



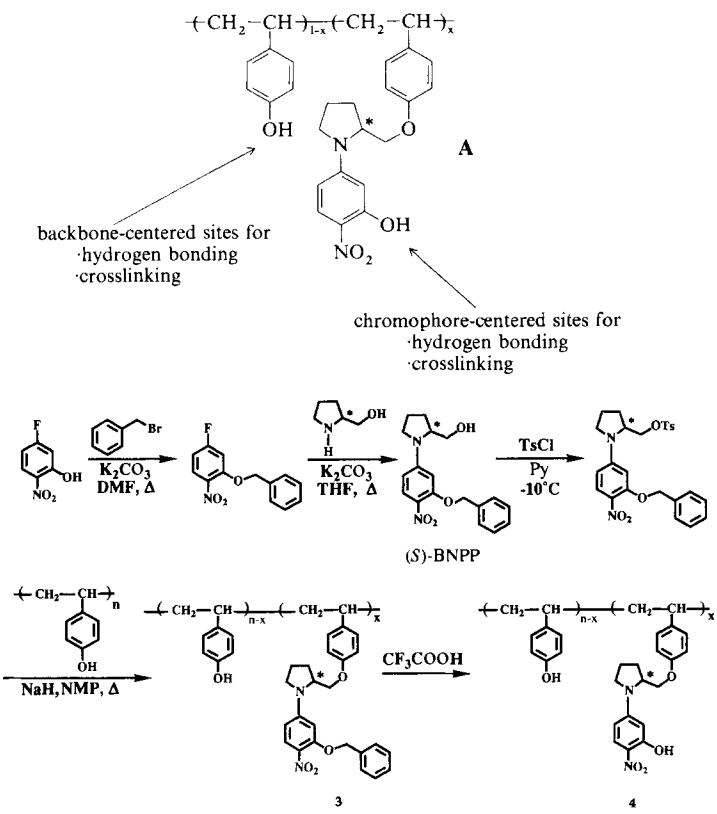


Fig. 6. Long-term SHG decay parameters [Eq. (j)] of poled (*S*)-NPP-PHS films simultaneously corona poled and crosslinked with the indicated equivalents n of **2** per available phenol OH.

the stoichiometric ratio of crosslinking agent for constant poling procedure. Note that τ_2 rises to a maximum at relatively low diepoxide to available phenol OH ratios, then declines at higher ratios. FT-IR spectroscopy reveals residual, unreacted epoxide groups (incomplete crosslinking) at the higher **2** to OH ratios, and it is reasonable that dangling, unreacted epoxide sidechains have a plasticizing effect on the matrix. At **2** to OH ratios greater than about 0.5, the matrix becomes opaque after casting and curing, indicating phase separation and leading to a decrease in measured d_{33} values.

The NPP-PHS results raise questions as to the optimum polymer architectural strategies for crosslinking (both covalent and hydrogen bonding) to achieve maximum chromophore immobi-

Scheme 6. Top: NPP-PHS polymers **A** with different crosslinking possibilities. Bottom: Synthetic approach to polymers of type **A** with site-selective hydrogen bonding or crosslinking. DMF = dimethylformamide.

lization. This issue was systematically addressed with a modified family of NPP-PHS structures **A** with both backbone only and backbone + chromophore-centered crosslinking (Scheme 6 top).[37] The synthetic approach to these polymers is shown in Scheme 6 bottom. An hydroxyl-functionalized analogue of (*S*)-NPP (HNPP), protected with a benzyl group ((*S*)-BNPP), was synthesized as shown in Scheme 6. Tosylation and reaction with deprotonated PHS yields (*S*)-BNPP-PHS (**3**). Subsequent deprotection with trifluoroacetic acid then yields (*S*)-NHPP-PHS (**4**). Polymers **3** and **4** were purified by repeated precipitation and drying under high vacuum at elevated temperatures.

Films of polymers **3** and **4** were cast from THF solutions and dried under high vacuum. Crosslinking experiments were carried out by introducing an equimolar (1:1 epoxy unit/OH group) quantity of **1** or polyepoxide **5** into the polymer/THF solutions. Optimum crosslinking conditions were established through independent experiments monitored by FT-IR spectroscopy (vide supra). All films were corona-poled (1 h, $T \geq 140\,^{\circ}C$.

In Table 3 are compiled T_g data and initial d_{33} coefficients for the films examined in this study. The T_g data reflect the consequences of benzylation (**3**), which diminishes matrix-immobilizing hydrogen bonding,[22] of increasing backbone functionalization, which not unexpectedly enhances chain mobility,[38] and of thermal epoxide crosslinking, which clearly has the greatest inhibitory effect on chain mobility. The SHG coefficients, measured at 25 °C within 10 min of cessation of poling, are relatively large, reflecting both the substantial chromophore number densities as well as the anticipated $\mu\beta_{vec}$ value (β_{vec} = vector component of β in the direction of the dipole moment) of HNPP.[37] Film d_{33} temporal characteristics for the following six HNPP-PHS-based systems are compared in Figure 7: a) no protection

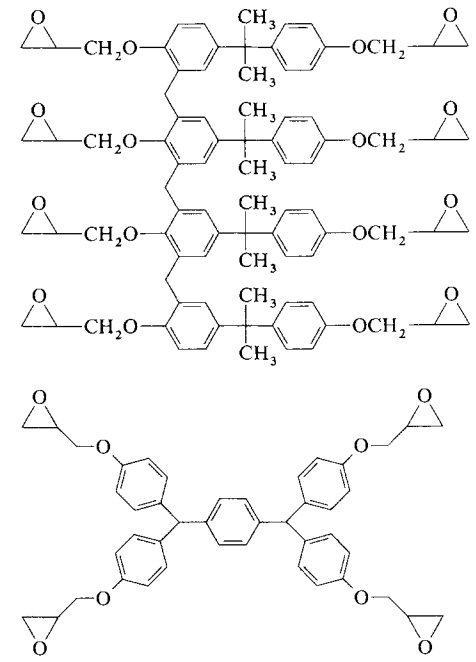

Table 3. SHG frequency doubling efficiency and temporal stability parameters for corona-poled [a] HNPP-PHS films.

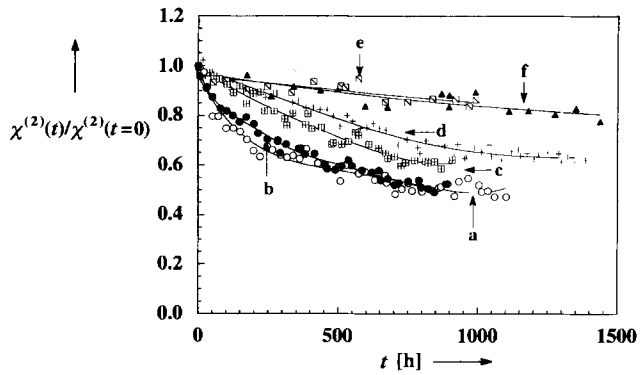

Fig. 7. Temporal characteristics at 25 °C of the SHG coefficient of six corona-poled films from **3** or **4** (35% functionalization level) having differing degrees of HNPP/PHS protection and/or either **1** or **5** crosslinking. The solid lines represent fits of Equation (j).

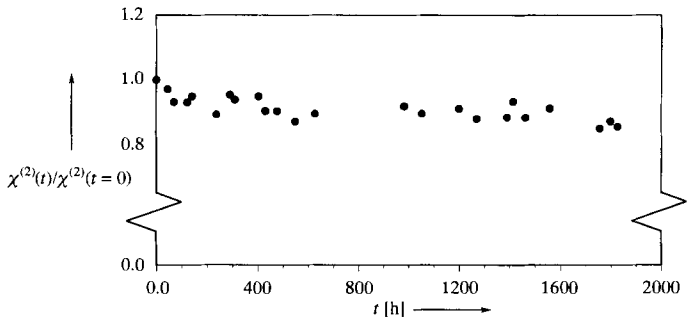
or crosslinking; b) HNPP protection (BNPP derivatives) but no crosslinking; c) BNPP derivatives and **1**-crosslinking at the PHS backbone hydroxyl residues only; d) **1**-crosslinking at both HNPP and PHS positions; e) BNPP derivatives and **5**-crosslinking at the PHS backbone; f) **5**-crosslinking at both HNPP and PHS positions. Several trends are evident. First, while T_g values afford a gross measure of matrix mobility, they only provide a qualitative guide to the temporal stability of SHG efficiency (cf., a) versus b)). The data also demonstrate that any ArOH ··· HOAr hydrogen bonding interactions involving the chromophore moieties have little if any effect on $d_{33}(t)$ over and above those provided by the polymer backbone OH groups. Although crosslinking at the PHS functionalities alone (c) affords a significantly lower T_g material than HNPP-PHS (a), the effect on $d_{33}(t)$ is clearly opposite and large. Bifunctional crosslinking that *directly involves* the chromophore substituent affords the greatest stabilization of SHG efficiency (and correspondingly, the highest T_g). However, it is also evident that polyepoxide crosslinkers effect the greatest degree of SHG temporal stabilization and that the effect appears less sensitive to local crosslink architecture.

The $d_{33}(t)$ data are satisfactorily fit to either biexponential [Eq. (j)] or stretched exponential [Eq. (k)] decay functions. Time constants derived from the former model are compiled in Table 3. These quantitatively amplify the above discussion, with the τ_2 values/SHG temporal stability parameters rivalling those of many stable NLO chromophore-functionalized glassy polymer systems. Fitting at the same level of confidence ($r = 0.98-0.99$) to the more phenomenological KWW stretched exponential [Eq. (k)] yields β values which support considerably higher degrees of immobilization than in NPP-PHS.[24a, b] The knowledge base from the above experiments has now been applied to crosslinking (*S*)-NSP-PHS (see Scheme 3) with polyepoxides **5** and **6**.[24c, d] T_g values as high as 260 °C have been achieved with partially resonant-enhanced d_{33} values of about 100×10^{-9} esu. As can be seen in Figure 8, the SHG temporal stability of corona-poled **6**-(*S*)-NSP-PHS films at 100 °C *in air* is excellent.



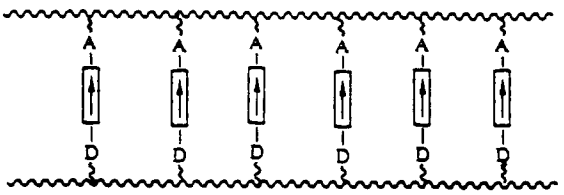


Fig. 8. Temporal characteristics of the SHG coefficient at 100 °C in air of a corona-poled (*S*)-NSP-PHS film crosslinked with polyepoxide **6**.

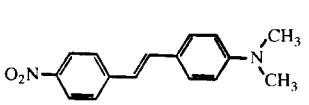
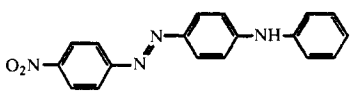
Dalton et al.[33b, c, g, i] have made important advances in poled second-order materials using a "double-ended" chromophore approach (**7**). As in the functionalized PHS systems, a chromophore-functionalized macromolecule (in this case, a donor–acceptor substituted azo chromophore appended to a polyacrylate) is crosslinked with a difunctional isocyanate. After corona



7



poling, impressive SHG temporal stabilities are observed at 90 °C in air, with d_{33} values (partially resonant-enhanced) of $120 \times 10^{-9}-150 \times 10^{-9}$ esu.

5.2. Embedding Chromophores in Totally Crosslinked Matrices

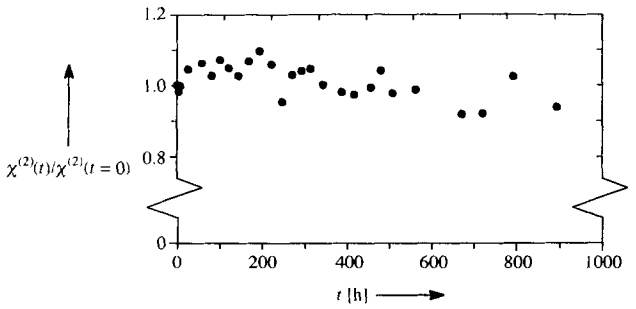
To determine whether NLO guest chromophores can be immobilized in highly crosslinked matrices, experiments were carried out in which high-β 4-(dimethylamino)-4′-nitrostilbene (DANS, **8**) and Disperse Orange 1 (DO1, **9**) were dispersed in an

8

9

optical grade epoxy resin, which could then be simultaneously poled and thermally cured.[17a, b] In such experiments, solutions of the chromophores were mixed with the epoxy resin and the solvent stripped from the solution. The chromophore-doped resin was next mixed with the amine crosslinker and the resulting fluid introduced between transparent ITO glass electrodes. Partial crosslinking of the matrix at 80 °C prior to poling is required to avoid dielectric breakdown. Poling fields were next gradually applied and maintained for measured periods of time at 80–150 °C. Films were cooled to room temperature prior to removal of the field. Typical d_{33} values at zero time are in the range $0.1 \times 10^{-9}-1.0 \times 10^{-9}$ esu. These magnitudes agree well with those expected for the (relatively low) chromophore number densities employed ($N = 0.4 \times 10^{19}-1.9 \times 10^{19}\,cm^{-3}$), assuming literature $\mu_z\beta_{zzz}$ values for the chromophore and the applicability of Equation (e).

The SHG temporal characteristics of the chromophore-doped/epoxy matrices depend strongly upon the crosslinking conditions. In poling field/temperature cycling experiments carried out as a function of curing time, the decay rate of d_{33} gradually declines as progressive crosslinking increases the degree of chromophore immobilization. After long curing times at 80 °C, for $d_{33}(t)$ Equation (j) yields $\tau_1 = 7$, $\tau_2 = 72$ days for the DANS-doped epoxy matrix and $\tau_1 = 8$, $\tau_2 = 142$ days for the DO1-doped epoxy matrix. The lower d_{33} decay rate of the latter matrix presumably reflects a slower reorientation rate for the larger DO1 chromophore. Furthermore, simultaneous curing and contact poling of a DO1-doped matrix at 150 °C yields a chromophoric matrix for which only minor decay in d_{33} can be detected over a period of many days at room temperature (Fig. 9).



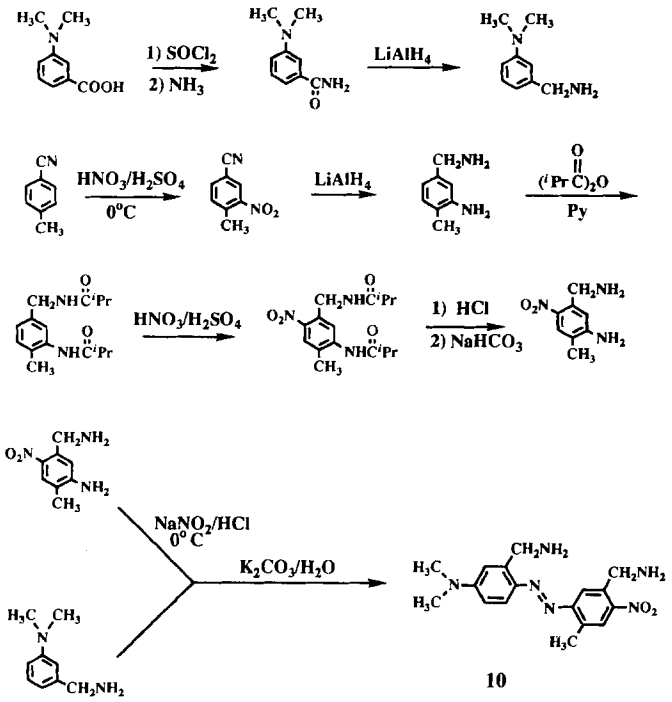


Fig. 9. Temporal characteristics at room temperature of the SHG coefficient d_{33} of epoxy films containing **9** and simultaneously corona poled and cured at 150 °C.

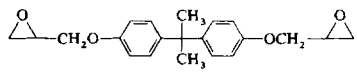


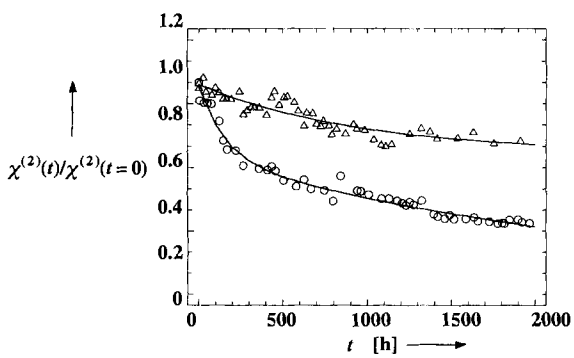
5.3. Matrices with Chromophoric Co-Monomers

While the strategy in Section 5.2 achieves significant chromophore immobilization, it also suffers from the low chromophore number densities which can be achieved. An attractive alternative would be to design a crosslinkable matrix in which one active component was a high-β chromophore molecule. Simultaneous poling and thermal crosslinking would then lead to an acentric matrix with a very high NLO chromophore number density. One synthetic approach is illustrated in Scheme 7.[39] Three design issues were addressed in the invention of **10** as a reactive co-monomer: 1) Substituted azo compounds with electron donating and accepting substituents in the 4,4′ positions were selected since such structures are known to exhibit large π-electron-based β_{vec} values. 2) Two reactive amine functionalities were placed along the direction of the chromophore dipole moment to maximize incorporation of the chromophore into the matrix and to impede d_{33}-eroding reorientation processes transverse to the dipole moment direction. 3) Aminomethyl rather than amino moieties were chosen so that the reactive functional groups would be electronically decoupled from the chromophore π-electron system.

Scheme 7. Synthetic approach to a high-β epoxy co-monomer (**10**).

The effects of both difunctional (**11**) and polyfunctional (**5**) epoxide reagents were investigated. Reaction mixtures of the difunctional chromophoric co-monomer **10** and the appropriate di- or polyepoxide were prepared by dissolving both components in THF (1:1 stoichiometric ratio of N–H bonds to epoxide moieties). After evaporation, the resulting films were partially crosslinked by heating in vacuo to remove any residual solvent and to improve dielectric stability. Parallel T_g and FT-IR-monitored experiments established optimum crosslinking conditions.[39] After corona poling at 130 °C for 2 h, the films were cooled to room temperature over a period of 1 h before removing the poling field. T_g data for these films reflect both a high degree of vitrification/immobilization as well as documented effects of epoxide multifunctionality. The d_{33} values are relatively high (7×10^{-9}–20×10^{-9} esu), exceeding those of the previously discussed guest–host materials by more than a factor of 10 (see Section 5.2). Nevertheless, the present film SHG efficiencies are somewhat less than might be expected on the basis of the chromophore $\mu\beta_{vec}$ value and estimated number density (ca. 6×10^{20} cm^{-3}). Film optical spectra and the effects of varying the poling atmosphere argue that this result is unlikely to be a consequence of chemical degradation. Rather, it appears that a non-negligible fraction of the chromophores are partially immobilized under the prepole crosslinking conditions (necessary to support the corona charge), hence slowly responsive or unresponsive to the poling field. Alternatively, the matrix densification process may be accompanied by a β_{vec} decreasing[40] twist of the chromophore structure from aryl ring coplanarity (not, however, obvious from the UV/Vis spectra).

The temporal stability of the SHG efficency at room temperature of poled, crosslinked **10** + **11** and **10** + **5** films (Fig. 10) reveals that $d_{33}(t)$ stabilities equal or exceed those of many pre-



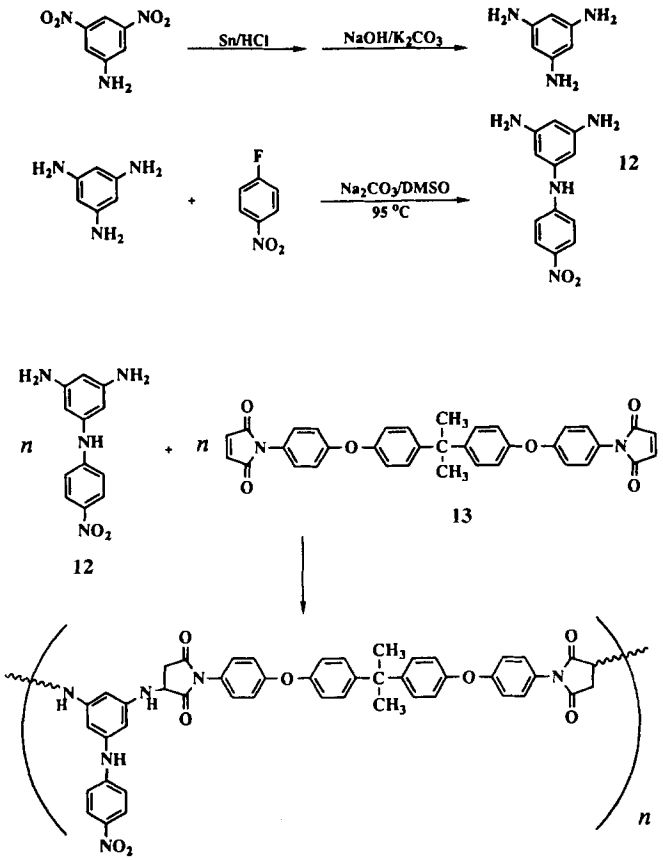


Fig. 10. SHG temporal characteristics at 25 °C for crosslinked, corona-poled films prepared from the reactive chromophoric co-monomer **10** (see Scheme 7) and polyepoxide reagent **5** (△) and the diepoxide **11** (○). Solid lines represent fits of Equation (j). Samples were stored at room temperature.

viously described guest–host systems. Furthermore, the superior immobilization characteristics of the polyepoxide-based matrices are evident. A biexponential [Eq. (j)] or stretched exponential [Eq. (k)] model can be fit to the $d_{33}(t)$ data by nonlinear regression techniques. The impressive SHG temporal stability of the **10** + **5** crosslinked matrices prompted additional quantitative temporal stability measurements at elevated temperatures.[39] The d_{33} decay (especially the initial decay) is, as expected, more rapid at 85 °C. Nevertheless, the long-term decay time constant is still on the order of four months. The KWW model [Eq. (k)] yields β values in accord with a narrower distribution of relaxation times than found for simple guest–host systems.

5.4. Crosslinked Polyimide Systems

As polymeric materials, polyimides[41] display great structural versatility as well as impressive thermal stability, T_g values, processability, and optical transparency (high-quality waveguides can be fabricated from polyimides).[42] Furthermore, polyimides have recently been utilized as presumably noninteracting hosts in poled, high-T_g guest–host NLO materials.[43] Chromophoric co-monomer **12** was designed for compatibility with polyimide polyadditions and was straightforwardly synthesized as shown in Scheme 8.[44] Films containing **12** and bismaleimide co-monomer **13** were cast from THF and thermally prepolymerized prior to poling. Verification of the course of the polymerization is provided by IR and NMR spectroscopy.

Scheme 8. Synthesis and implementation of a bismaleimide-compatible chromophoric co-monomer. DMSO = dimethylsulfoxide.

Independent thermal crosslinking experiments establish the DSC-derived T_g-curing temperature T characteristics shown in Figure 11. The near linearity of the plot is a further indication that the polymerization chemistry is well-behaved, and T_g values

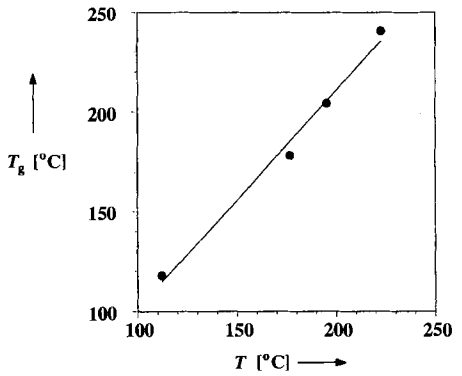

Fig. 11. DSC-determined glass transition temperature T_g as a function of polymerization temperature for **12**-doped polyimide specimens. Polymerization reactions were carried out at each temperature for 1 h. The symbol • denotes an experimental data point. The solid line is drawn as a visual aid. The T_g values were measured at a heating rate of 10 K min^{-1}.

as high as 240 °C rival the highest achieved to date. Corona poling of the **12** + **13** films was carried out over a range of temperatures (vide infra). SHG indices ($\lambda = 1064$ nm) are in the range of 11×10^{-9}–15×10^{-9} esu; these are reasonable for model chromophores with this architecture and number density. They are higher than those exhibited by typical guest–host polyimides[43] and can likely be increased as poling/crosslinking procedures are refined. SHG temporal stability data at 120 °C in air for a **12** + **13** polyimide film are shown in Figure 12. It was

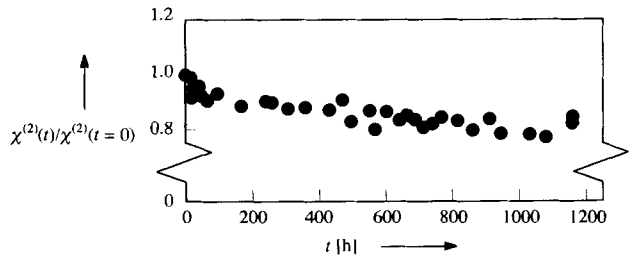

Fig. 12. SHG temporal characteristics at 120 °C in air for a corona-poled film prepared from reactive NLO chromophore **12** and bismaleimide **13** (see Scheme 8).

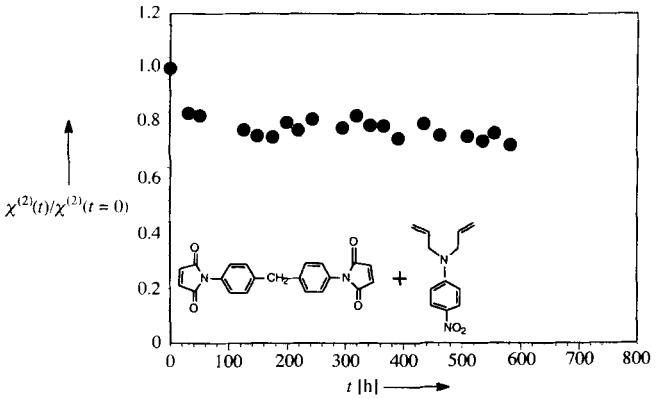
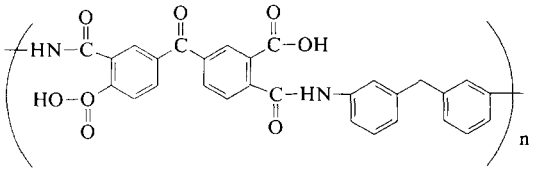
found that increases in the prepoling temperature are accompanied by increases in the achievable poling temperature, above which SHG signal loss and film damage become apparent. At 85 °C in air, there is only minor (ca. 10–15%) decay in SHG efficiency over the first 24 h, and within the precision of the measurements, negligible to very minor decay over several months.

Ultra-high-T_g polyimides can also be prepared using addition reactions between bismaleimides and diallylarenes.[41] While details of the mechanism have not been fully elucidated, addition and crosslinking appears to involve both "ene" reactions and sequential Diels–Alder additions.[45] Application of this approach to poled, NLO-active polymers has recently

been carried out using *N*,*N*-diallyl-*p*-nitroaniline and a bismaleimide (Fig. 13).[46] T_g values as high as 350°C have been measured, and SHG temporal stability is reasonably good *in air at 150°C*.





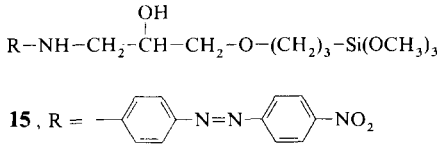


Fig. 13. SHG temporal characteristics at 150°C in air of a corona-poled film prepared from *N*,*N*-diallyl-*p*-nitroaniline and a reactive bismaleimide.

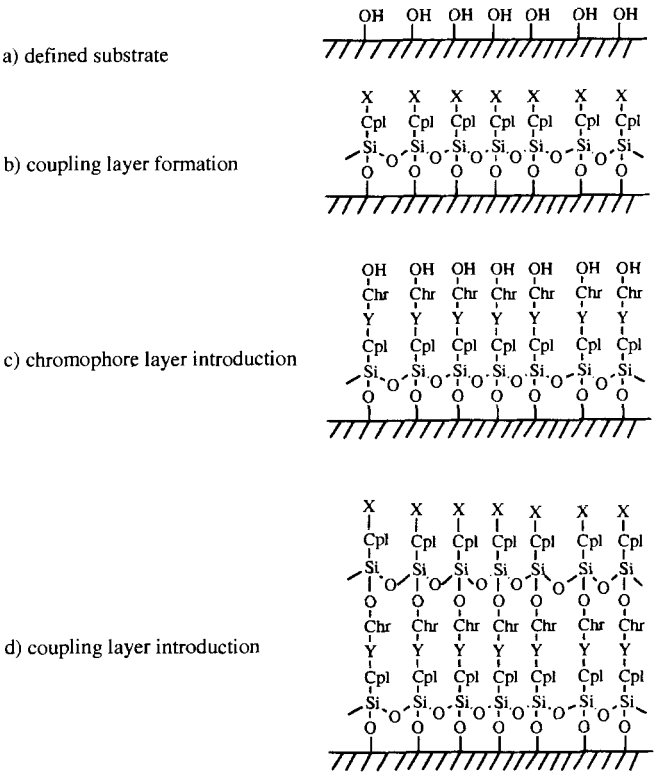
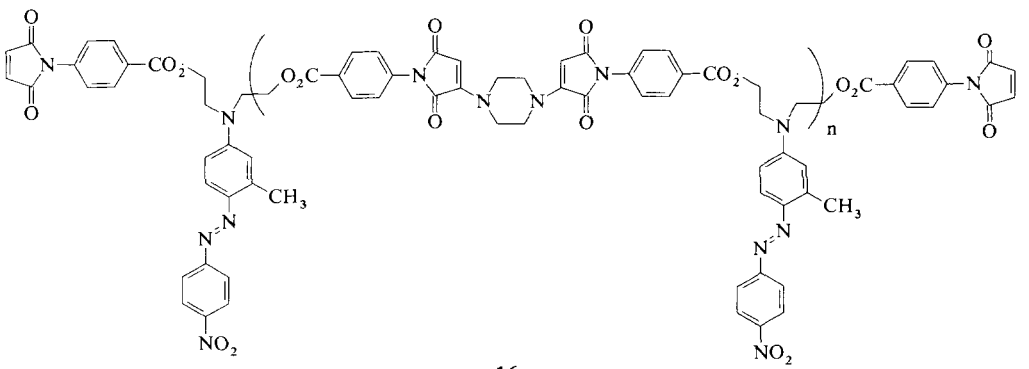
Tripathy et al. have taken a different approach to NLO-active polyimides in which a "polyamic acid" polyimide precursor (**14**) is condensed with a chromophoric siloxane (**15**).[33d] Good

14



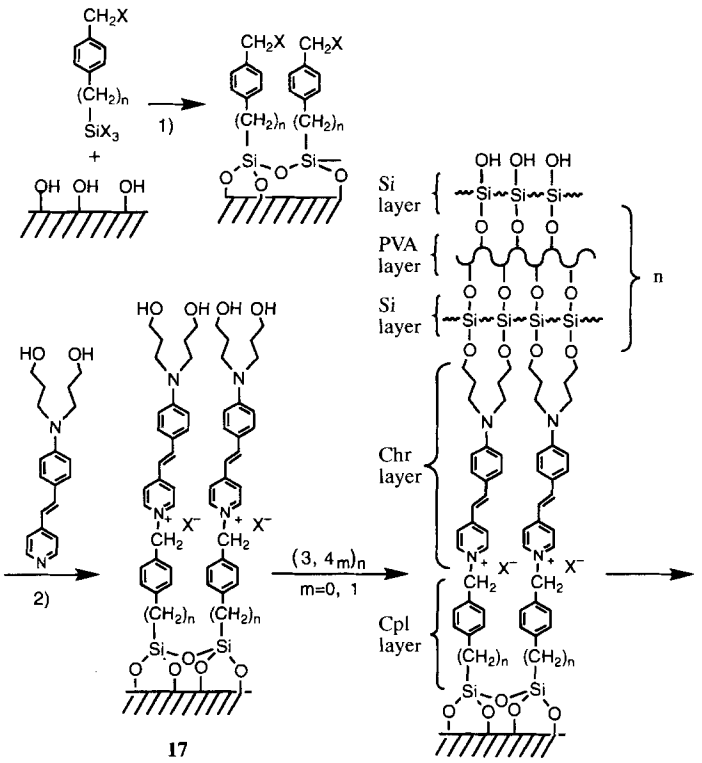
15, R =



SHG temporal stability is observed for fully crosslinked samples (ca. 20% decay after 150 h in air). Resonant-enhanced d_{33} values are comparable to those of other poled polymers with donor–acceptor substituted stilbene and azo chromophores (see Section 5.1). Topolsky et al.[33j] reported another type of crosslinkable, chromophore-functionalized bismaleimide (**16**). T_g values are about 180°C, while d_{33} values appear comparable to the other examples mentioned above. Temporal stability plots are only reported for several hours at 200°C (ca. 30% decay), so that it is difficult to compare these materials to other crosslinked systems.

6. Chromophoric Self-Assembled Superlattices

An alternative approach to poled polymers and LB films would be the construction of covalently linked, chromophore-containing multilayer structures (see Scheme 1 bottom right). In principle, such materials offer greater net chromophore alignment and number densities than poled films and far greater structural control and stability than LB films. The general strategy employed for superlattice construction is shown in Scheme 9,



Scheme 9. Strategy for covalently linked NLO multilayers. Cpl = spacer for the coupling reaction, Chr = chromophore.

16

where the basic siloxane technology follows from reactions originally developed by Sagiv et al.,[47,48] and refined by Ulman, Whitesides, and others.[49–51]

A first-generation, test-of-concept synthetic approach to multilayer NLO materials is shown in Scheme 10.[18] Noteworthy features include a stilbazole

Scheme 10. Strategy for the synthesis of self-assembled NLO multilayer materials. 1) Benzene, 25 °C, 115 °C cure; 2) reflux in *n*PrOH; 3) $Cl_3SiOSiCl_2OSiCl_3$ in THF, 115 °C cure; 4) polyvinyl alcohol (PVA) in DMSO. X = I, Cl.

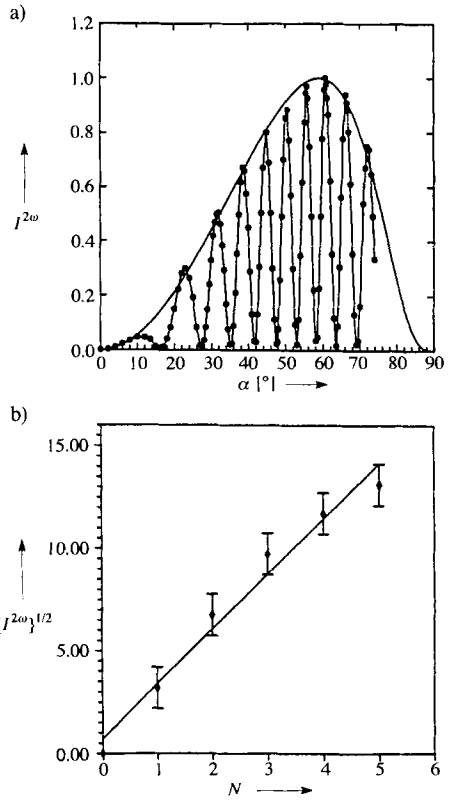


Fig. 14. a) SHG intensity $I^{2\omega}$ in arbitrary units as a function of fundamental beam incident angle α from a glass slide having a self-assembled CplChr monolayer on both sides. The interference pattern arises from the phase difference between the SHG waves generated at either side of the substrate during propagation of the fundamental wave. The solid envelope is a theoretical curve generated for $\chi^{(2)}_{zzz}/\chi^{(2)}_{zyy} = 3$. b) Plot of the square root of SHG intensity versus the number of chromophore layers *N* in the multilayer superlattice. The straight line is the fit to the experimental data.

chromophore precursor in which layer-building quaternization (step 2) affords both an anchored high-β center (**17**; β_{vec} (0.65 eV) $\approx 180 \times 10^{-30}$ cm^5 esu^{-1}) and diagnostic changes in the optical spectrum. In addition, soft polymeric layers are introduced transverse to the stacking direction (steps 3 and 4) to promote structural stability. The course of multilayer evolution on clean SiO_2 substrates can be monitored by optical spectroscopy (growth of chromophore absorption at 510 nm); XPS spectroscopy (initial diminution of Si, O signals; growth and persistence of C, N, I signals); advancing contact angles in accord with expected surface functionalities and which repeat in each 1–4 cycle; null ellipsometry in general accord with expected layer dimensions (thickness in notation of Scheme 9: CplChrSi ca. 34 Å; CplChrSi(PVA)Si(PVA)SiCplChr ca. 100 Å; CplChrSi(PVA)Si(PVA)SiCplChrSi(PVA)Si(PVA)SiCplChrSi(PVA)Si(PVA)Si ca. 235 Å), and NLO characteristics (vide infra). These films adhere strongly to glass, are insoluble in common organic solvents and strong acids, and at first were only effectively removed by diamond polishing. In initial research, assemblies with up to five chromophore layers were constructed.[18, 52]

Transmission SHG measurements (parallel-polarized geometry, $\lambda = 1064$ nm) reveal no in-plane anisotropy in the signal as samples are rotated about the film normal. This indicates that the films possess uniaxial symmetry about the normal and that the distribution of chromophore molecular orientations does not have an azimuthal dependence. Figure 14a shows SHG intensity as a function of incident angle for a glass slide coated on both sides with a self-assembled monolayer (CplChr). Two features are noteworthy. First, nearly complete destructive interference is observed over many randomly selected locations on the films, indicating that the quality of the structures on the two sides of the substrate is nearly identical and uniform. Second, the data envelope from the transmission SHG measurements can be described very well by Equation (m).[53] Here ψ is the average

$$\chi^{(2)}_{zzz}/\chi^{(2)}_{zyy} = 2\cot^2\psi \qquad \text{(m)}$$

angle between the surface normal and the chromophore molecular orientation (β_{zzz}), and, in early work, was found to be in the range 35–39° from both transmission and reflection measurements.

It is found that $d_{33} \approx 200 \times 10^{-9}$ esu for these multilayer materials and $d_{33} \approx 700 \times 10^{-9}$ esu for a single CplChr monolayer of 22 Å estimated thickness. This SHG efficiency considerably exceeds that of typical poled polymers, compares favorably with the best LB films,[14, 15] and is consistent with high chromophore number densities and degrees of acentric alignment. Moreover, the large magnitude of d_{33} suggests that the formation of centrosymmetric aggregates, which commonly occurs in LB films and which greatly depresses achievable bulk nonlinearities, is not important here. Temporal stability studies reveal less than 10% decline in the SHG efficiency of a five-layer structure in the course of six weeks. Since these multilayers are extremely thin in comparison to the wavelength $\lambda = 1064$ nm and hence to the expected coherence length, the SHG signal intensity should scale quadratically with the number of chromophore layers.

This is diagnostic and is commonly employed to assess structural regularity in LB films.[14, 15] As can be seen in Figure 14b, the adherence to quadratic behavior is good, indicating that it is possible to maintain the same degree of noncentrosymmetric chromophore ordering in the additions of successive layers.

These initial results raised key questions about the scope and mechanism(s) of the multilayer assembly process. In terms of substrate scope, it has been found that the multilayer structures can be assembled on borosilicate glass, float (ultra-smooth) glass, ITO surfaces, as well as on the native oxide coatings of single crystal Si and Ge.[52] By modifying deposition and curing conditions, the commercially available chloro coupling reagent (X = Cl in Scheme 10) can be substituted for the difficultly handled iodo reagent (X = I).[18] Since the commercial reagent is a mixture of *meta* and *para* isomers, a synthetic route to the pure *para* isomer was also developed.[54] In preliminary studies, it was found that multiple immersions[52c] interspersed with brief exposure to ambient temperatures form Cp layers with higher and more uniform functional group coverage as judged by XPS, advancing contact angles, and the d_{33} of the resulting chromophore-functionalized surfaces.[55] This preliminary result can be understood in terms of the limited availability (ca. 5 nm^{-2}) of surface SiOH groups, requiring additional water for interchromophore Si-O-Si condensation.[49] When this methodology is employed, the PVA layer in Scheme 10 is no longer required to form robust multilayers.[54]

To better understand the chromophore incorporation step 2 (Scheme 10) in situ SHG techniques have been employed to monitor the quaternization process in real time.[56] This approach allows real time studies of the quaternization kinetics and the average chromophore tilt angle [ψ, Eq. (m)] as a function of reaction extent and conditions. In the first experiments (Fig. 15), it was found that the assembly kinetics do not con-

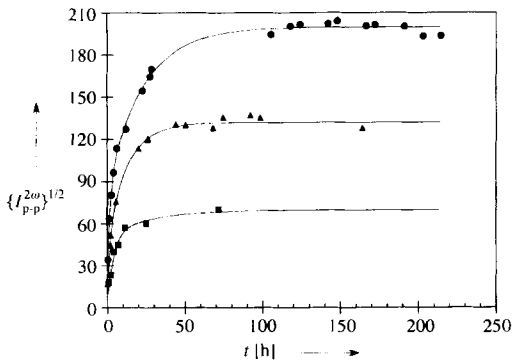

Fig. 15. In situ analyzed time evolution of the SHG signal resulting from step 2 in Scheme 10 in *n*PrOH at 60 °C. The SHG (only the I_{p-p} is presented) data are shown for different prefunctionalization conditions (step 1, Scheme 10, 2 × 18 h (●), 64 h (▲), 18 h (■)); the solid lines are theoretical curves [Eq. (n)].

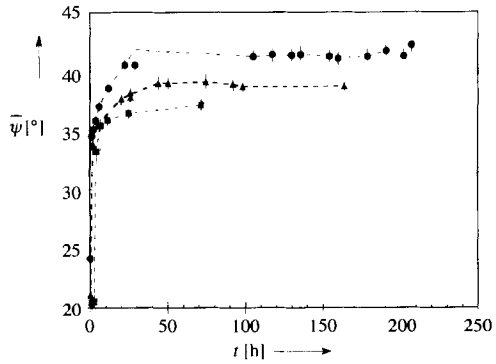
form to a simple Langmuir model, but rather are better described by a biexponential expression [Eq. (n)] involving rapid

$$(I^{2\omega})^{1/2}(t) = (I^{2\omega})^{1/2}(t = \infty)\,(1 - \alpha_1\, e^{-k_1 t} - \alpha_2\, e^{-k_2 t}) \qquad \text{(n)}$$

initial coverage (k_1) followed by a slower second phase (k_2). Evidence for "fast" and "slow" phases in alkylthiol self-assembly kinetics on gold (as well as Langmuirian behavior) has been reported previously,[57] and deviations from Langmuirian kinetic behavior in other chemisorption processes are not uncommon.[58] Calibrated transmission SHG measurements on completely functionalized films yield, in combination with β_{zzz}^{calcd}[19] and an estimated film thickness of about 25 Å, d_{33} and the chromophore surface density, N_s.[56] For the substrates exposed to 2 × 18 h silanization followed by the stilbazole chromophore precursor, these quantities are 150×10^{-9} esu and 2×10^{14} molecules per cm^2, respectively. The latter value, 49 $Å^2$ per molecule, compares favorably with that for LB films containing essentially the same chromophore substituent,[59] and allows estimation of the actual initial Langmuirian adsorption rate constant, $k_1 = 5.4 \times 10^{-12}\ cm\,s^{-1}$.

By monitoring p-polarized SHG intensity as a function of incident light polarization and assuming a one-dimensional chromophore (a single, dominant β component), the average tilt angle of the principal chromophore β component with respect to the surface normal can be determined in situ [Eq. (m)]. Measurements on the self-assembly process (Fig. 16) reveal that ψ increases rapidly in the early stages of monolayer formation and then reaches a plateau somewhat sooner than $(I^{2\omega})^{1/2}$ (Fig. 15). A significant tilt angle increase with increasing chromophore coverage suggests a collective response to packing forces.



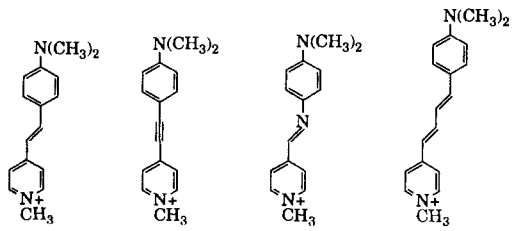


Fig. 16. Average chromophore tilt angle Ψ as a function of reaction time for the in situ data sets of Fig. 15 (2 × 18 h (●), 64 h (▲), 18 h (■)). Error bars represent the dispersity in 10–20 measurements (the dashed lines serve as a visual aid).

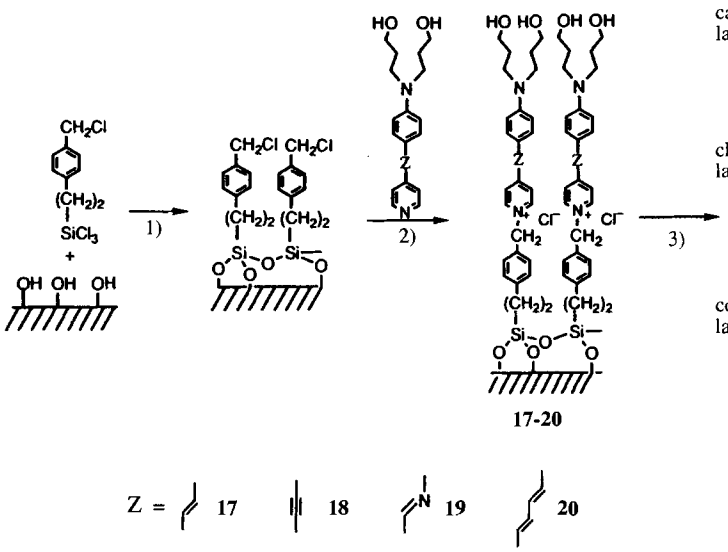
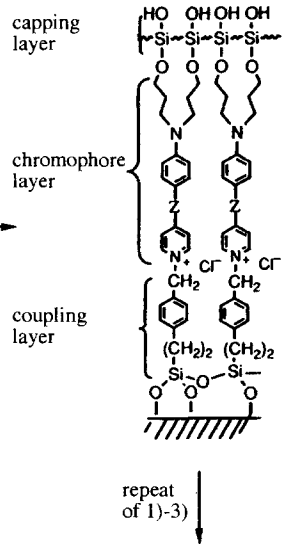


These in situ SHG results suggest a qualitatively two-stage monolayer assembly process for step 2 Scheme 10: Initial, rapid coverage in which isolated chromophore dipoles are reoriented away from the surface normal direction with increasing coverage, presumably due to chromophore–chromophore electrostatic/steric interactions. Subsequent slower, presumably electrostatically/sterically encumbered assembly in which the chromophore tilt angle changes little. These results furthermore illustrate the general efficacy of SHG techniques in probing the microstructural evolution of thin film materials in situ.



There is no reason to believe that stilbazolium chromophores will be optimum in Scheme 9, and a major effort has been made to target improved chromophore architectures in terms of transparency considerations, shape, enhanced optical nonlinearities, and amenability to additional chemical modification. Scheme 11 summarizes the chromophore structures in various stages of investigation,[60] tabulating semiempirical ZINDO-derived[19] linear and nonlinear optical properties; Scheme 12 shows the

β_{vec} (0.65 eV)	178	171	92.6	343

Scheme 12. Construction of chromophoric self-assembled multilayer NLO materials. 1) Toluene, 25 °C; 115 °C cure; 2) reflux in *n*PrOH/toluene (80°C); 3) $Cl_3SiOSiCl_2OSiCl_3$ in THF, 115 °C.

construction of multilayers with the analogous chromophores. Since the alkynyl-containing structure **18** offers a rigid-rod geometry (suggesting potentially denser packing) and a blue-shifted λ_{max} (hence greater transparency), it has been the subject of recent investigation. Quaternization on a moderately covered substrate initially affords a monolayer exhibiting a rather modest NLO response; however, addition of the capping layer results in a major increase in SHG efficiency (Fig. 17).[52e] This observation can be interpreted in terms of a major monolayer structural reorganization in which introduction of the siloxane layer brings the average chromophore alignment closer to the direction of the substrate normal (Scheme 13). The structural picture is also supported by optical spectroscopic and grazing angle X-ray reflectivity measurements.[52d, e] As can be seen in Figure 18, alkynyl-derived NLO superlattices with nine layers can be constructed with good structural regularity.

As noted above, there is little experimental information on the input frequency dependence of NLO response for second-order polymeric materials. Such information is essential to a fundamental understanding of NLO phenomena as well as to engineering a device. Optical parametric amplification (OPA) instrumentation, which provides tunable input radiation over a broad range, has recently been designed at Northwestern University with this issue in mind.[60] Figure 19 shows the input frequency dependence of $\chi^{(2)}$ for a self-assembled structure based on chromophore **18**. It can be seen that the response does not adhere to the simple form implied by Equation (d). More importantly, the on-resonance re-

Scheme 13. Influence of a capping layer on the orientation of the chromophores in a monolayer.

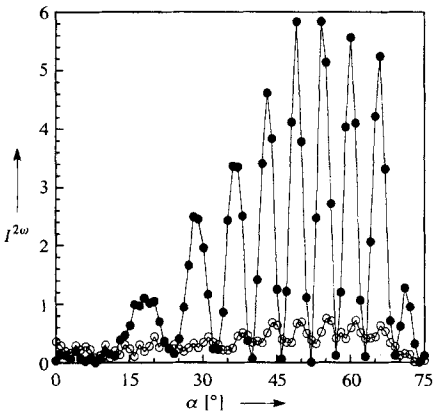

Fig. 17. SHG intensity $I^{2\omega}$ as a function of fundamental beam incident angle α from a glass slide having a self-assembled alkynyl chromophore **18**-derived monolayer on both sides. The interference pattern arises from the phase difference between the SHG waves generated at either side of the substrate during propagation of the fundamental wave. ○: Before the capping with $Cl_3SiOSiCl_2OSiCl_3$ step. ●: After the capping step.

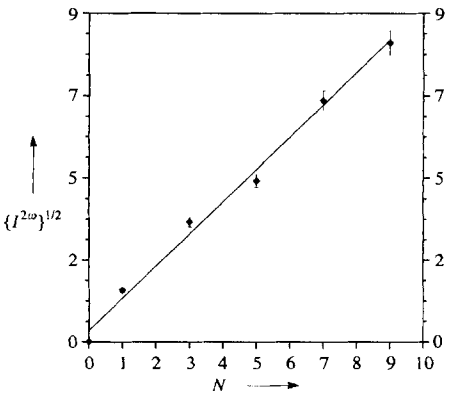

Fig. 18. Plot of the square root of SHG intensity versus the number of chromophore layers *N* in alkynyl chromophore **18**-derived multilayer superlattices. The straight line is the fit to the experimental data.

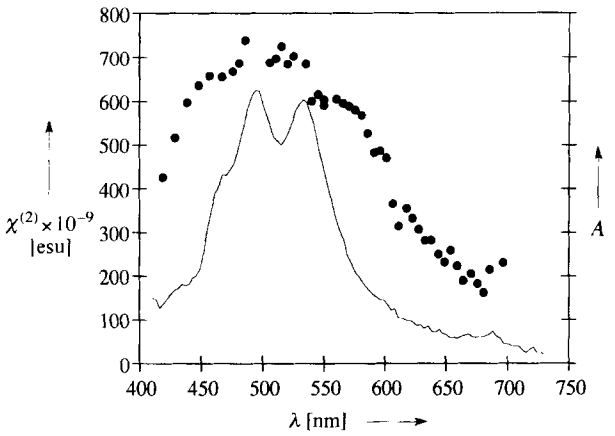

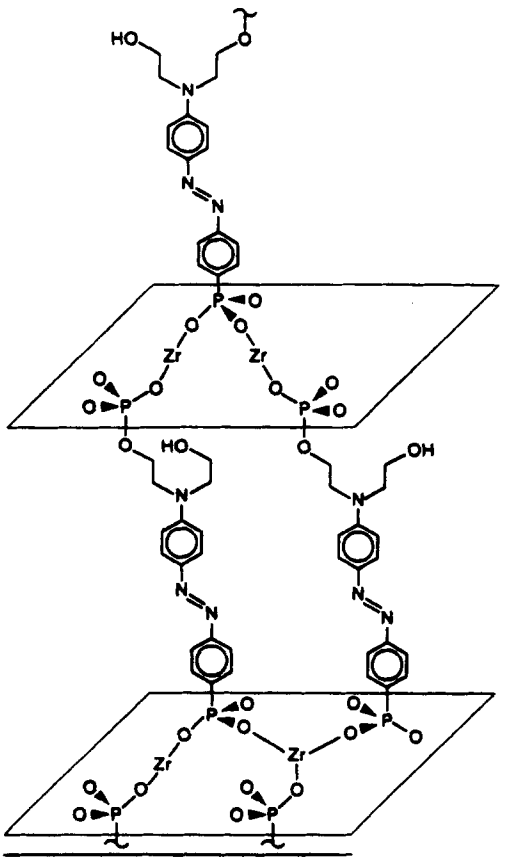

Fig. 19. SHG wavelength λ dependence of $\chi^{(2)}$ (dark points) for a self-assembled film constructed from chromophore **18** and the linear absorption spectrum (solid line, A = absorption in arbitrary units). Note that $\chi^{(2)}$ dispersion is plotted as a function of the *output* wavelength for comparative purposes. Thus, the resonances at about 500 nm in the optical spectrum correspond to the about 1000 nm resonance in the $\chi^{(2)}$ dispersion.

sponse approaches 10^{-6} esu while even the off-resonance response is near 10^{-7} esu![60]

Another self-assembly approach to intrinsically acentric chromophoric multilayer has been reported by Katz et al.[51a,b] Alternating layers of donor–acceptor phosphonate-substituted azo chromophore molecules and zirconyl salts[51c,d] are deposited from aqueous solution (**21**). Up to 32 layers were deposited. Good structural regularity is suggested by linear $(I^{2\omega})^{1/2}$ vs. number of layer plots, while partly resonant-enhanced d_{33} values are about 25×10^{-9} esu (the β for this chromophore is rather low). The SHG signal of this material is reported to be stable to 150 °C, at which point chromophore decomposition occurs.

21

7. Summary and Outlook

Major advances in the construction and performance of polymer-based NLO materials have been made in the past six years. Key developments in the poled polymer area have included the progression from guest–host to chromophore-functionalized to crosslinked systems. It is now known that chromophore number densities approaching those of molecular crystals can be achieved and that these modifications can be compatible with good processability. High T_g materials can now be prepared and further chromophore immobilization can be achieved with simultaneous poling and crosslinking. The first devices (e.g., spatial light modulators) have been fabricated with non-crosslinked chromophore-functionalized polymers, and their performance is encouraging with respect to competing inorganic materials/technologies.[7] Nevertheless, many fundamental, knowledge base issues must be addressed before ultimate materials can be constructed.

The constraints on the degree to which poling-induced chromophore orientation can be maintained over long periods of time above room temperature in glassy polymer-chromophore matrices are not well-understood and present a daunting challenge to polymer synthesis, processing, and theory. How high can T_g values be pushed and to what degree will T_g, T_β, etc., be an accurate measure of chromophore/backbone mobility? What theoretical descriptions are appropriate for physical aging/polymer relaxation far below T_g? Finally, we do not understand which poling/physical aging/curing protocols are most appropriate for maximum microstructural alignment and the temporal stability thereof. For devices fabricated from poled polymers, we need to know more about optical loss, dielectric breakdown, $\chi^{(2)}$ dispersion, and optical damage mechanisms, active layer-buffer layer compatibility, the uniformity, isotropy, and temperature/thermal expansion dependencies of the refractive indices, as well as the thermal stability limits of many polymer structural linkages. We have very little data on the NLO response of real chromophore–polymer matrices as a function of laser input wavelength (dispersion).[60] Many of these answers can only come from carefully planned syntheses, fastidious data collection, and an active interface with strong theoretical capabilities.

In the chromophore design sphere, major advances have been made in developing computationally efficient chemically-oriented theoretical formalisms for targetting new chromophores and understanding which structural and electronic features control linear and NLO response. What is not understood for real materials is how medium and chromophore–chromophore interactions modify/can be used to tune, the response of the individual chromophore molecules. Equally intriguing is the prospect of fundamentally new mechanisms (e.g., octupolar[61]) which might further enhance second-order NLO response. From a chromophore synthetic standpoint, the limits of thermal/environmental stability that can be achieved in highly polar, conju-

gated, donor–acceptor π-electron systems have yet to be defined and is a crucial issue.

Self-assembled chromophore multilayer structures have now been demonstrated which do not require electric field poling to achieve a highly acentric microstructure. Several systems display very large optical nonlinearities, frequently exceeding those of poled polymers. Key questions which must be addressed concern the thermal/chemical robustness of such structures, the structural regularity which can be achieved, the efficiency with which multilayer construction can be achieved, and ultimate film morphology (smoothness). Other optical and NLO questions about the constituent building blocks and aggregates are essentially the same as for poled polymer matrices (vide supra).

It is important to close by emphasizing that besides obvious technological attractions, the study of molecule–macromolecule-based NLO materials grapples with fundamental synthetic and theoretical questions generic to many other areas of contemporary materials chemistry. All involve the rational construction and attendent physical characteristics of structurally precise multimolecular assemblies. These are new, difficult types of problems for chemists, and ones the investigation of which will no doubt produce very large knowledge dividends for decades to come.

This work would not have been possible without the generous financial support of the National Science Foundation through the Northwestern Materials Research Center (grant DMR-9120521) and the Air Force Office of Scientific Research (contracts 90-0071 and 93-1-0114). The contributions of our enthusiastic and dedicated coworkers and colleagues have been inestimable. Their names can be found in the references cited.

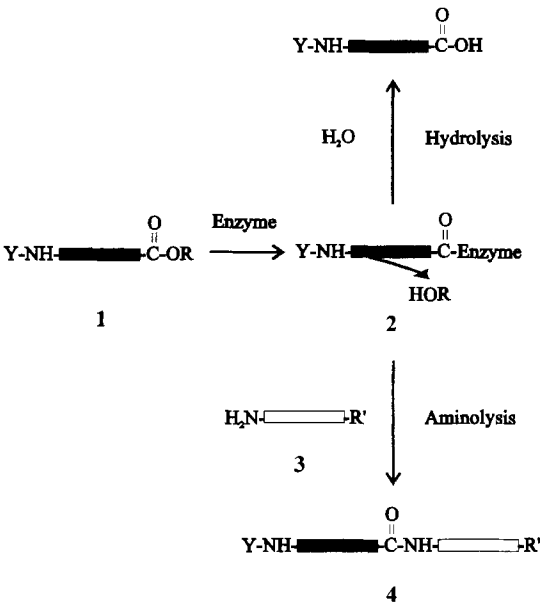
Peptide Ligases—Tools for Peptide Synthesis



Hans-Dieter Jakubke*

Following the first chemical formation of a peptide bond by Theodor Curtius in 1881 in the laboratory of Hermann Kolbe in Leipzig, chemical peptide synthesis[1] developed over the next ninety years culminating in the first total synthesis of an enzyme. Ribonuclease A (RNase A), composed of 124 amino acid residues, was constructed by condensation of fragments in solution[2] as well as by solid-phase synthesis.[3] Roughly ten years later Yajima and Fujii[4] synthesized RNase A according to an improved conventional synthetic strategy and obtained the first crystalline synthetic enzyme having full enzymatic activity. But an ideal, universally applicable method for chemical formation of the peptide bond has still not been found. Since chemosynthetic reactions are typically conducted with residues having chiral centers, racemization is a constant concern. Even stepwise chain extension using urethane protecting groups, which are supposed to prevent racemization, may be affected; chemical linkage of peptide fragments is yet more unreliable.

A recent paper[5] describes a new synthesis of RNase A, in which an enzyme was used for the first time to couple fragments obtained by solid-phase synthesis to form a protein. The idea of using enzymes to make peptide bonds is about as old as chemical peptide synthesis itself. In 1898, evoking the reversibility of chemical reactions, van't Hoff predicted that enzymes could be used to catalyze the formation of peptide bonds. This idea was first taken up in 1938 by Max Bergmann and confirmed experimentally.

Owing to the stereo- and regiospecificity of enzymes, their application for the formation of peptide bonds certainly offers a list of advantages over chemical procedures, for example mild reaction conditions, no need for permanent protection of functional groups in side chains, racemization-free course of reaction, and simple scale-up after optimization of the process. To make full use of these advantages, however, a close to universally applicable peptide ligase is needed,[**] which in principle would display high catalytic efficiency for all theoretically possible combinations of amino acids; in other words, it should be nonspecific and not affected by the side chain functions of the amino acids to be coupled. Since an ideal biocatalyst like the ribosomal peptidyl transferase is not available, and multienzyme complexes in bacterial peptide synthesis are limited to specific purposes, only proteases can be used for formation of the peptide bond. Two different mechanistic strategies for the application of proteases can be described.[6]

In comparison to equilibrium-controlled peptide synthesis, kinetically controlled synthesis[7] offers the possibility of more targeted manipulations. Following this approach for reactions with low enzyme requirements and short reaction times, mechanistic considerations limit the enzymes employed to serine and cysteine proteases. Unfortunately, proteases are not perfect acyl transferases; owing to their limited specificity, other undesired reactions may take place parallel to acyl transfer, for example hydrolysis of the acyl enzyme **2**, secondary hydrolysis of the peptide product **4**, and other undesired cleavages of possible protease-labile bonds in **1**, **3**, and **4** (Scheme 1).

Scheme 1.

To eliminate or minimize these disadvantages, the enzyme can be engineered and/or the reaction medium and the mechanistic features of the process can be adjusted as shown schematically in Figure 1.[8] Undesired hydrolytic side reactions may be eliminated by adapting the medium. Protease-catalyzed syntheses in monophasic organic solvents or in biphasic aqueous–organic

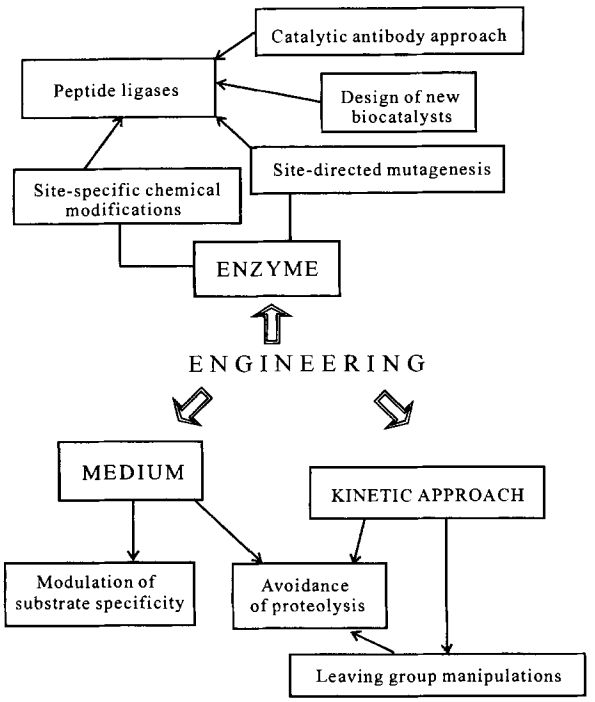
[**] In deviation from EC nomenclature, the term peptide ligase here refers to a biocatalyst for the formation of the peptide bond.



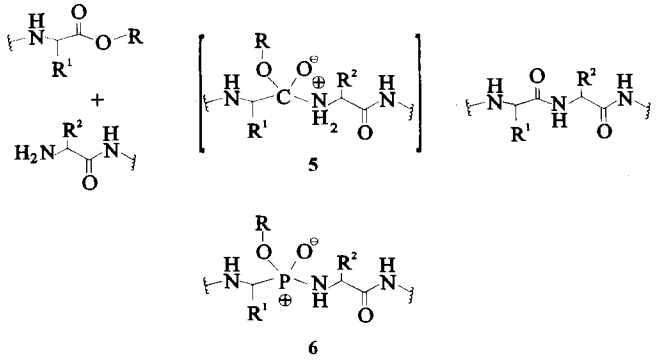


Fig. 1. Possibilities for engineering enzymatic peptide synthesis at different levels.

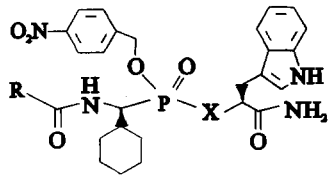
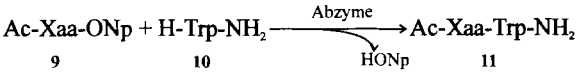
systems proceed with minimal proteolytic side reactions. Since the reactants are better soluble in organic media, the chemical and enzymatic steps can be accomodated. Side reactions can also be eliminated and yields of peptides increased by direct reduction of the water content of the reaction medium, for example in syntheses in frozen aqueous systems and reactions in dense media. Another option in modifying a kinetically controlled reaction is manipulating the leaving group so that the enzyme reacts exclusively with the acyl donor **1** and not with the peptide product **4** or the amino component **3**. Then even protease-labile products can be obtained in good yields. Two recent reviews give an overview of the current possibilities for manipulation.[8, 9]

The term enzyme engineering[10] (see Fig. 1) describes a range of techniques from deliberate chemical modification to remodeling a wild-type enzyme by gene technology. "Subtiligase", a mutant of subtilisin BNP', was prepared by Jackson et al.[5] by protein design and used in a further total synthesis of RNase A. This work, which combines solid-phase synthesis of oligopeptides and enzymatic coupling of these fragments, demonstrates the state of the art in peptide synthesis and proves impressively the potential of enzymes for the formation of peptide bonds. Average yields of roughly 75% were obtained in the fragment condensations. The excellent leaving group of the Phe-NH_2-modified carboxamido methyl ester, which even in unmodified form was found to be a very good acyl donor in other syntheses,[11] and the use of a considerable excess of acyl donor ensured that most of the side reactions were suppressed. The total yield after the five fragment condensations was 15%, and after the folding of the final product, 8%. Thus starting with 100 mg of the initial peptide (residues 98–124), RNase A can be obtained on a 10-mg scale. The fragments (77–97, 64–76, 52–63, 21–51, 1–20) were chosen such that the C-terminal residues, Tyr^{97}, Tyr^{76}, Val^{63}, and Ala^{20}, were the closest to matching the substrate specificity of the subtilisin mutant. A similar strategy was also used in the synthesis of three variants of RNase A, in which the two histidine residues His^{12} and His^{119} at the active center were exchanged individually and simultaneously for L-4-fluorohistidine; the affect of these substitutions in the three analogues of RNase A was studied in detail.

Substrate binding at the active site[7] plays a crucial role in protease-catalyzed peptide bond formation. Unfortunately, a simple C-N ligase is not capable of developing different substrate binding regions, for example by induced fit, for the structurally diverse amino acid side chain functionalities. According to Linus Pauling the action of an enzyme depends on the complementarity of the active site to the transition state structure of a reaction, as shown in Scheme 2 for peptide bond formation.



Scheme 2.



Given the fact that the enzyme should not bind the substrate very strongly but must stabilize the transition state considerably, it is unlikely that a relatively simple enzyme can act as a universal peptide ligase. This premise was recently confirmed by reports by Hirschmann et al.[12] and by Jacobsen and Schultz[13] on peptide bond formation with catalytic antibodies (abzymes). Analogues of the transition state were used as haptens to induce antibodies with the correct arrangement of catalytic groups. The idea behind both strategies is illustrated in Scheme 2 by the transition state analogue **6** synthesized by Hirschmann et al.[12] When these haptens are injected in animals, their immune systems generate antibodies against them. Since the structure of the tetrahedral intermediate **5** is also greatly affected by the amino acid side chains R^1 and R^2, it is doubtful whether a universally applicable catalytic antibody can be generated for peptide bond formation. The structures of the transition state analogues **7**, **8a**, and **8b** were changed deliberately, in particular by incorporation of a cyclohexyl group, such that the abzymes that catalyzed the reaction of **9** and **10** would have broad substrate specificity (Scheme 3).

The abzyme-catalyzed dipeptide syntheses gave all possible stereoisomers in yields of 44 to 94%. The abzymes did not catalyze the hydrolysis of either the dipeptide products or the activated esters employed. Jacobsen and Schultz[13] elicited antibodies against a neutral phosphonate diester transition state analogue, which significantly accelerated the coupling of an N^{α}-acylalanine azide with a phenylalanine derivative relative to the

uncatalyzed reaction. The application of catalytic antibodies exploits the fundamental property of the immune system, generating binding sites in the folds of the antibodies which are analogous to the active sites in enzymes. Proof of this is provided by the determination of the three-dimensional structure of a catalytic antibody developed for peptide cleavage.[14] The active site of this antibody contains a Ser-His dyad and thus has great similarities with the active sites of serine proteases.

These sensational findings will certainly initiate a new era in the construction of peptide ligases. Now with the emergence of catalytic antibodies for peptide synthesis, the arsenal of methods is augmented, and the prospects for future progress are bright. However, extensive development is needed before this approach is applied as routinely as enzymatic peptide synthesis currently is, and this perspective emphasizes the importance of the chemoenzymatic synthesis of RNase A.

Keywords: catalytic antibodies · ligases · peptide synthesis · RNase A · subtilisin

Chemical Engineering Dynamics

Modelling with PC Simulation

1994. XX, 701 pages with 430 figures.
Hardcover. DM 276.-/ öS 2153.-/ sFr. 256.-.
ISBN 3-527-28577-6

In this book, the reader is guided through the complex study of dynamic chemical engineering systems by the unique combination of a simplified presentation of the fundamental theory (Part 1) and direct hands-on computer experimentation with the provision of 85 accompanying computer-based simulation examples (Part 2) supplied on diskette.

The ISIM digital simulation language is very simple to use and its powerful interactive nature enables the readers to create their own simulations, based on their own specific problems. This powerful dynamic ISIM software is ready to run on any DOS personal computer.

The treatment employed in this book is well tried and tested, based on over 20 years experience in teaching an international post-experience course. Whether for the teacher, the student, the chemist or engineer, this book serves as the key to a greater understanding of chemical engineering dynamics through the fun and enjoyment of active learning.

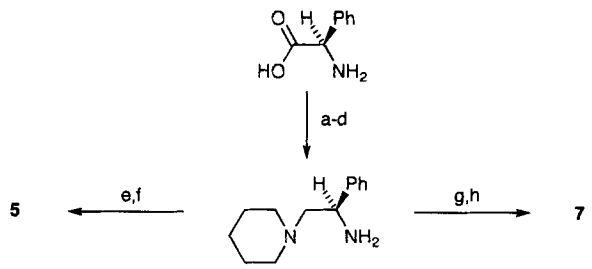
Catalytic Asymmetric C–C Bond Formation: New Enolato- and Organolithium Chemistry

David J. Berrisford*



Organolithium reagents are a cornerstone of the development and practice of modern organic chemistry. The pivotal role of these reagents reflects their early introduction in undergraduate chemistry courses. Although the enormous interest in catalytic asymmetric C–C bond formation[1, 2] has provided a number of practical solutions in other areas, highly enantioselective, *catalytic* reactions of organolithium reagents generally remain elusive. The complex solution equilibria,[3] so characteristic of lithioanions, continually frustrate attempts to discover viable catalytic processes. Two recent pieces of work[4, 5] have made valuable advances towards this goal.

Koga et al. have discovered[4] a remarkable catalytic process for the asymmetric benzylation of lithium enolates derived from silyl enol ethers **1** and **3** (Scheme 1). Previously, stereocontrolled

Scheme 1. Asymmetric benzylation of lithium enolates. a) 1. MeLi/LiBr, toluene; 2. 5 mol% **5**, 2 equiv **6**, 10 equiv $PhCH_2Br$, −45 °C, 18 h (76%, 96% *ee*); b) 1. MeLi/LiBr, Et_2O; 2. 10 mol% **5**, 2 equiv **6**, 10 equiv $PhCH_2Br$, −45 °C, 18 h (52%, 90% *ee*).

lithium enolate alkylation has been restricted to either diastereoselective processes[2a, c] requiring the covalent attachment of a chiral auxiliary, or to reactions with stoichiometric amounts of external ligands.[2b] Indeed, the new catalytic reaction is a development of an earlier stoichiometric benzylation of **1** which achieves a 92% *ee* of **2** using ligand **7**.[6] The new process differs from the former stoichiometric procedure in a number of respects. The structure of the chiral ligand is modified to **5**. This ligand must be used in conjunction with an excess of an additional achiral ligand exemplified (Scheme 1) by the optimum choice **6**. Both polydentate chiral ligands (**5**/**7**) are prepared[7] in straightforward manner from phenylglycine (Scheme 2). The new ligand **5** delivers increased enantioselectivity under stoichiometric conditions (up to 97% *ee* for **2**) and maintains the level of asymmetric induction under defined catalytic conditions. Under optimal conditions, a 96% *ee* (76% yield) of **2** can be realized using 5 mol% of **5** in toluene. Careful experimentation has shown that switching to 1,2-dimethoxyethane (DME) as solvent retains almost all the high enantioselectivity and has a beneficial effect on conversion (90% *ee*/91% yield). Lower ligand loading (< 5 mol%) has a deleterious effect on both conversion and enantioselectivity.

Scheme 2. a) CBZ-protection; b) piperidine/$PO(OEt)_2CN$ (76%); c) HBr/AcOH (100%); d) $LiAlH_4$ (67%); e) $Me_2N(CH_2)_2N(Me)CH_2CO_2H/PO(OEt)_2CN$ (69%); f) BH_3·THF (63%); g) $MeO(CH_2)_2OCH_2CO_2H/PO(OEt)_2CN$ (83%); h) BH_3·THF (74%).

The study constitutes a further example of how efficient catalytic reactions can be achieved despite the presence of complex solution equilibria.[8] Originally, this chemistry was developed in a nondonor solvent rather than using an excess of donor as solvent. In so doing, the effects of additives, both chiral and achiral, are maximized. Enolate generation in the catalytic system is accomplished by the reaction of silyl enol ethers with methyllithium. This procedure avoids the formation of an additional secondary amine, which, in principle, could compromise the asymmetric induction by forming mixed aggregates[9] with the lithium enolate.

Incorporation of lithium bromide and an achiral, bidentate ligand in addition to **5** are essential for selectivity. The effects of the achiral ligands are the most revealing part of the study. The bidentate ligand **6** and its analogues provide a substantial rate acceleration. Without the additional ligand, conversion drops precipitously under catalytic conditions. Simple tertiary diamines are the most effective additives, tetramethylethylenediamine being slightly inferior to the preferred propyl analogue **6**. Use of DME as an additive does not accelerate the reaction. However, the presence of DME has little effect on the enantiomeric excess and hence can substitute for toluene as the reac-

tion solvent. It is proposed that the achiral additive sequesters[10] the excess of LiBr that is generated as the benzylation reaction proceeds. Under stoichiometric conditions without additional LiBr, the enantiomeric excess increases with time and conversion, indicating the beneficial *in situ* role of the salt. However, excess of LiBr slows the reaction prohibitively (< 1% conversion). The results implicate a kinetically dominant mixed aggregate comprising lithium halide, lithium enolate, and chiral ligand. The subtleties of the mechanism clearly warrant considerable further investigation.

These intriguing effects of the additive ligands on the reaction rate and stereoselectivity are reminiscent of those discovered[11] in simple lithium enolate aldol reactions. Related halide effects[12] are reported in other enolate reactions. The addition of lithium chloride has a beneficial effect on the asymmetric deprotonation[13] of ketones by chiral lithium amides, so implicating a reactive lithium amide–lithium chloride aggregate.[14]

Although, the catalytic procedure uses a two-stage method to generate the enolate, it should be possible to use direct ketone enolization by an appropriate lithium amide base. The catalytic alkylation reaction is limited as yet to two enolates and a single example of a reactive alkyl halide. The full scope of this process remains to be determined, particularly with respect to the range of compatible substrates and electrophiles. Nevertheless, Koga et al. have discovered a significant example of catalytic lithium enolate chemistry and one that holds considerable promise for future development.

Another recent contribution[5] by Denmark et al. illustrates an effective method for promoting the nucleophilic addition reactions[2] of organolithium reagents to imines. The chemistry is a development of earlier methodology.[15] The organolithium additions to *N*-aryl imines, for example **8**, are promoted by C_2-symmetric bis(oxazoline) ligands, such as **10**, or (−)-sparteine **11** (Scheme 3) with high asymmetric induction. Notably, the oxazoline ligands deliver excellent selectivities for aliphatic imines. Both methyl- and vinyllithium additions can be promoted by **10** with significant enantioselectivities (**9a**, R = Me: 91% *ee*, Table 1). However, ligand **11** is beneficial for the *n*-butyl- and phenyllithium additions (**9c**, R = *n*Bu: 91% *ee*, Table 1). In certain cases, decreasing the ligand loading to a practical 20 mol% retains most of the ceiling enantiomeric excess. Substrate enolization, which is often a problem for aliphatic imines, does not compete to a significant extent. Moreover, the *N*-aryl amine products can be deprotected by using published methodology[15] to afford the corresponding primary amines. This chemistry is, therefore, complementary to asymmetric hydrogenation[16] of imines, and offers an alternative entry into important amino compounds.

Scheme 3. Asymmetric nucleophilic addition to an aliphatic imine.

Table 1. Reaction conditions for the nucleophilic addition of RLi to **8** as well as yields and enantiomeric excesses *ee* of the products **9**.

R	*T* [°C]	Ligand (equiv.)	Yield [%]	*ee* [%]
Me	−63	**10** (1.0)	96	91
Me	−63	**10** (0.2)	81	82
$CH=CH_2$	−78	**10** (1.0)	95	89
$CH=CH_2$	−78	**10** (0.2)	82	82
*n*Bu	−94	**11** (1.0)	90	91
*n*Bu	−78	**11** (0.2)	91	79

The chemistry is further proof of the utility of naturally occurring (−)-sparteine.[17] The oxazoline ligands are prepared from *tert*-leucine. An important issue currently being addressed[5] is the structure of the active organometallic complex. The disparity between the enantioselectivity of the stoichiometric and catalytic runs could result from competing "uncatalyzed" addition. It is also possible that the product[18] lithium amide affects the selectivity to some degree through mixed aggregation phenomena.

These studies are beneficial in two respects. Efficient or improving asymmetric methodology is of primary importance, especially in such a fundamental area. Additionally, this work provides new insights[3] into the complex solution behavior of these commonplace organometallic reagents.

Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples I: Laser Mass Spectrometry**

Jörg Lantzsch, Bruce A. Bushaw, Günter Herrmann, Heinz-Jürgen Kluge, Ludwin Monz, Sabine Niess, Ernst W. Otten, Richard Schwalbach, Martin Schwarz, Judith Stenner, Norbert Trautmann, Klaus Walter, Klaus Wendt,* and Klaus Zimmer

Strontium-90 is one of the most toxic radionuclides known; only naturally occurring polonium-210 (from lead-210), radium-226, and several nuclides of the actinides have a greater toxicity.[1] The reason for the toxicity of strontium-90 is its long half-life of 28.5 years combined with its permanent and complex accumulation occurring in bones.[2] Strontium-90 is a high yield nuclear fission product of both uranium-235 and of plutonium-239, and was distributed worldwide during the above-ground nuclear weapon tests in the 1950s and 1960s. In the Federal Republic of Germany the average surface coverage of strontium-90 at the beginning of the 1980s was 2 kBq m^{-2}.[3] This value increased only marginally due to the deposition of strontium-90 from the Chernobyl accident at the end of April 1986; measurements from air filters and rainwater in the Mainz region indicated an increase of 0.02 kBq m^{-2}.[4] However, it took two weeks before reliable data on the deposition were available—much too long in the case of acute contamination. It became clear just how inadequate the usual radioactivity measurements are for the determination of strontium-90 in environmental samples containing a mixture of fresh fission products.

In this and the two following communications[5, 6] alternative physical detection methods and chemical separation techniques are reported for strontium-90 and -89 in fresh fallout. These methods and procedures were developed in a coordinated approach by three groups, with the goal of producing reliable analytical results within one day. Two procedures were tested as alternatives to the radiometric methods: resonance ionization spectroscopy using lasers in a collinear geometry on a mass-separated atomic beam and accelerator mass spectrometry.[5] Furthermore, a chemical separation technique was devised using liquid–liquid extraction with crown ethers. A rapid method was also developed for the determination of radioactive strontium isotopes by ion exchange chromatography with subsequent on-line β-detection.[6]

The determination of strontium-90 in fresh fallout is difficult, since it is obscured by the shorter lived strontium-89 ($t_{1/2}$ = 50.5 d); the $^{89}Sr/^{90}Sr$ activity ratio in Chernobyl fallout was between 11/1[7] and 17/1[4] compared to about 200/1 for fallout from nuclear weapon tests.[8] Since the two strontium isotopes are pure β^- emitters they are not detected by the otherwise powerful analysis of fallout mixtures by high resolution γ radiation spectroscopy. Rather, they must be chemically isolated and analyzed by a far less specific measurement of β^- rays. For detection of small amounts of strontium-90 in an excess of strontium-89 at an overall low level of activity, different properties of the decay products have long been used:[9] Yttrium-90 is a β^- emitter with $t_{1/2}$ = 64 h, while yttrium-89 is, in contrast, stable. Yttrium-90 grows from strontium-90 in the purified strontium fraction, and after several days it is chemically separated, measured, and the activity decay followed over a few days, to confirm its identity. This yields the strontium-90 activity; the difference between this and the total β^- activity of the purified strontium fraction gives the strontium-89 activity.

The delay in waiting for the formation and decay of yttrium-90 can be avoided by using the differences in β^- decay energies (^{90}Sr 0.55 MeV, ^{89}Sr 1.49 MeV) to simultaneously measure both strontium isotopes. Both nuclides are counted together using a liquid scintillator, but only strontium-89 is registered by means of Cherenkov radiation. This procedure reaches its limit at a high $^{89}Sr/^{90}Sr$ ratio and low activity.[10]

The usual chemical separation process[9] for strontium is inadequate for fresh fallout. The strontium and barium in the sample solution are precipitated with concentrated nitric acid as nitrates; this removes among other components inactive calcium, which can be present in significant amounts. Barium is then separated from strontium by chromate precipitation. This step is particularly critical, because in fresh fallout the fission product barium-140 ($t_{1/2}$ = 12.8 d) is about four times more abundant than strontium-89, and its daughter product lanthanum-140 ($t_{1/2}$ = 40 h) accompanies yttrium-90 in the separation thus resulting in a false measurement of the yttrium-90 activity.

In the following, a procedure is presented for the detection of strontium-90 and -89 by a combination of laser spectroscopy and mass spectrometry.[11a] The technique was developed for air-filter samples, since here the presence of fresh fission products is the easiest to recognize. With the method, it should be possible to record concentrations of 1×10^8 atoms per 1000 m^3 air, corresponding to 1.5×10^{-14} g and activities of 80 mBq ^{90}Sr and 16 Bq ^{89}Sr. These were typical concentrations found in Germany after the Chernobyl accident. The main problem with mass spectrometric and optical detection is the presence of up to 10^{18} stable strontium atoms (150 µg)—up to 82.6% ^{88}Sr—in such samples. Therefore, a selectivity of 10^{10} is required for the radioisotopes to be detected over the stable strontium-88. Furthermore, an efficiency of 10^{-5} is necessary for the overall process to keep the statistical error small for a sample of 10^8 atoms. The implementation of the procedure including sampling and chemical treatment should require a maximum of one day and allow the simultaneous measurement of both isotopes strontium-89 and -90.

We use a combination of conventional magnetic mass separation, collinear laser excitation of a fast atomic beam, field ion-

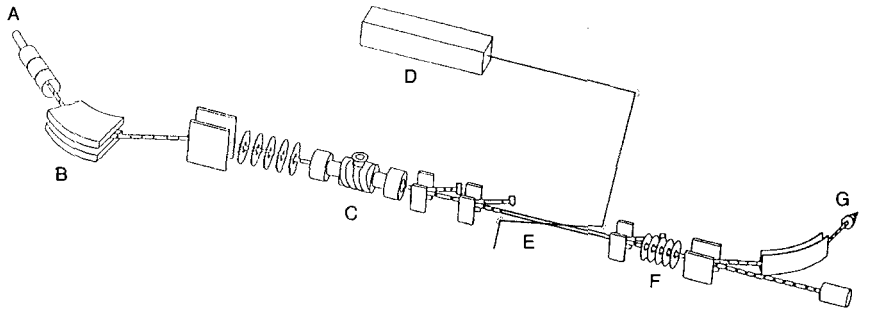

Fig. 1. Schematic representation of the apparatus for laser mass spectrometry. A = 33 keV ion source, B = mass separator, C = charge exchange cell, D = argon ion laser, E = optical excitation, F = field ionization, G detector.

ization of the excited atoms, and particle detection of the ions (Fig. 1).[11b]

The chemically isolated strontium from an air sampling filter is loaded into an ion source where it is reduced, vaporized, and then ionized on a hot tungsten surface. The positive ions are extracted and accelerated to an energy of 33 keV. Mass separation in a 60° sector field magnet provides an inital suppression of the stable isotopes by up to seven orders of magnitude. The ion beam is then neutralized by charge exchange with cesium vapor in a heated cell to produce a beam of fast atoms. The different velocities of the isotopes in this beam cause an artificial isotope shift (Doppler shift) of the resonance frequency in the subsequent optical excitation. In addition this results in very narrow linewidths,[12] and leads to the required isotopic selectivity. The velocity of the ion beam is adjusted by applying a potential to the charge exchange cell to achieve a match to the resonance frequencies of the desired isotopes. In the next stage, where the optical excitation occurs, the atomic beam is superimposed at an angle of 2° with a UV laser beam from a continuous argon ion laser at a fixed wavelength (364 nm). This geometry allows all the advantages of collinear laser spectroscopy, while preventing a loss of selectivity due to the Stark effect in the electric fields.[11b] The absorption of a laser photon causes a resonant and selective excitation of the desired strontium isotope into a high-energy Rydberg state. These excited atoms are then ionized in an electric field. The resulting ions are deflected from the beam path and energy analyzed by a cylindrical condensor and then counted by means of a particle detector. The necessary high efficiency is achieved by the particle detection.[13]

The method was first tested by using synthetic samples with known levels of strontium-90 in the presence of high levels of stable strontium (up to 10^{18} atoms). The lines of optical resonance for strontium-90 and for the naturally occurring reference isotope strontium-84 (0.56% abundance) were measured alternately over a period of about one hour, with ^{90}Sr measured 90% of the time. The number of events obtained at the two resonance frequencies yields the ratio $^{90}Sr/^{84}Sr$. Since the amount of stable strontium in the original sample is known from X-ray fluorescence spectroscopy, the absolute amount of strontium-90 in the sample can be ascertained. A systematic error of about 10% is associated with the method, the statistical error is limited only by counting statistics. With this method it was possible to detect 10^7 atoms of ^{90}Sr in 10^{17} atoms of stable strontium. The required isotopic selectivity of 10^{10} is thus achieved and the limit of detection is even lower than required.

For strontium-89 its nuclear spin of 5/2 makes determination difficult, since it leads to complex hyperfine splitting of the optical resonance. Moreover, in the mass separation strontium-89 lies directly adjacent to the most abundant stable isotope strontium-88. This results in a reduction in selectivity and worsens the limit of detection by an order of magnitude. With synthetic samples it has so far been possible to measure 10^9 atoms of ^{89}Sr in 10^{16} atoms of stable strontium.

To demonstrate the usefulness of the procedure parts of an air filter that was exposed to the passage of the Chernobyl clouds between April 15–30, 1986, at the GSF in Neuherberg near München were processed and measured. The total sampling volume was about 2×10^5 m^3 air, while each measured segment corresponded to a volume of about 1000 m^3. Figure 2 shows typical results. The level of ^{90}Sr measured was 1.5×10^9 atoms, corresponding to a ^{90}Sr concentration of 1.2 mBq m^{-3} at the time of sampling. This result is in good agreement with radiometric measurements[14] performed with a much larger section of the air filter.

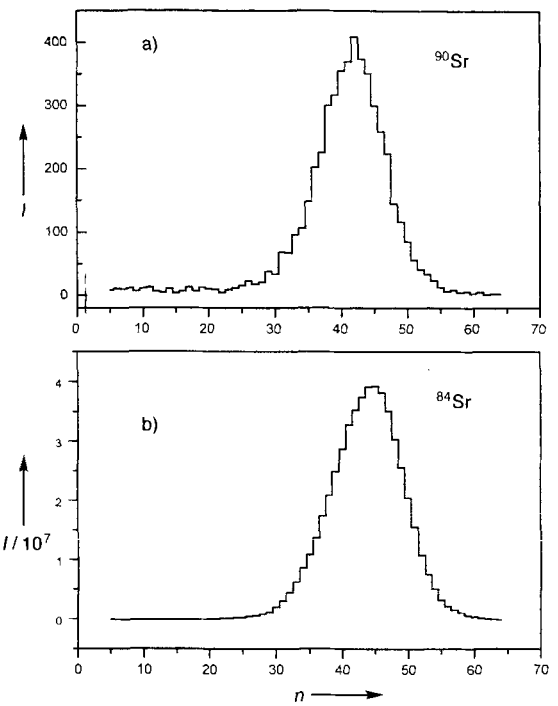

Fig. 2. Strontium-90 in an air filter exposed at the GSF Neuherberg (near München) during and after the reactor accident in Chernobyl. Resonance signals (plot of the intensity I [number of the events measured] against the channel number n) a) for ^{90}Sr and b) for the reference isotope, stable ^{84}Sr. A level of 1.5×10^9 atoms ^{90}Sr, corresponding to a concentration in the air of 1.2 mBq m^{-3} at the time of sampling, was recorded.

The initial chemical separation of strontium used for the above measurements does not have to be especially selective, since fission products in other mass ranges, such as barium-140, are separated during mass selection. Also isobaric stable impurities, such as zirconium-90, do not lead to significant interference because of the high elemental selectivity of laser excitation. This is in contrast to accelerator mass spectrometry which has also been suggested for the detection of strontium isotopes.[5, 15] The essential requirement for the chemical separation is eliminating large additions of carrier for strontium and barium. Such a procedure has been devised based on liquid–liquid extraction with crown ethers.

This process begins with ashing the air filter at 700 °C and then dissolving the ash in 3 M nitric acid. After spiking with 10^{17} atoms of stable strontium the total strontium content is determined by X-ray fluorescence with an accuracy of better than 5%. The alkaline earth metal carbonates are precipitated from the dilute sample solutions by addition of ammonium carbonate. The precipitate is dissolved in 6 M nitric acid and the pH of the solution adjusted to 3–5 with lithium hydroxide. After addition of picrate as counterion Sr^{2+} and Ba^{2+} are separated from Ca^{2+} by extraction into dicyclohexano[18]crown-6. After back-extraction with 3 M hydrochloric acid Ba^{2+} is removed with dibenzo[24]crown-8, again in the presence of picrate. The Sr^{2+} remaining in the aqueous phase is purified from residual picrate on a cation exchange column, eluted with 6 M hydrochloric acid and the eluate is evaporated. After dissolution in 20 µL 3 M nitric acid the strontium fraction is loaded into the ion source for measurement. An average chemical yield of 70% was measured by using radiotracers. This separation procedure is also suitable for radiometric methods which require larger amounts of carrier material.

Details of the laser spectroscopy results and the chemical separation process will be published in the near future.

Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples II: Accelerator Mass Spectrometry (AMS)**

Fatma Arslan, Martin Behrendt, Werner Ernst, Eberhard Finckh,* Gunther Greb, Friedrich Gumbmann, Martin Haller, Stefan Hofmann, Ralf Karschnick, Matthias Klein, Wolfgang Kretschmer, Jochen Mackiol, Gerhard Morgenroth, Christian Pagels, and Markus Schleicher

The quantitative determination of extremely small quantities of rare isotopes is conveniently performed by accelerator mass spectrometry (AMS), which is also operated in the Tandem Accelerator Laboratory of the Universität Erlangen–Nürnberg. The measured ratio of the concentrations of the rare and the abundant isotopes can be in the range 10^{-9} to 10^{-15}. Such ratios cannot be satisfactorily determined by conventional mass spectrometry. Instead, special nuclear physical methods must be applied that require energies in the MeV range only achievable using an accelerator. One of these methods has been used routinely for several years for the determination of ^{10}Be and ^{14}C;[1, 2] it is also suitable for elementary analysis.[3]

The equipment at Erlangen is schematically illustrated in Figure 1.[4, 5] In the sputter ion source, Cs vapor is thermally ionized (about 1000 °C) at a spherical Ta surface, and the Cs^+ ions

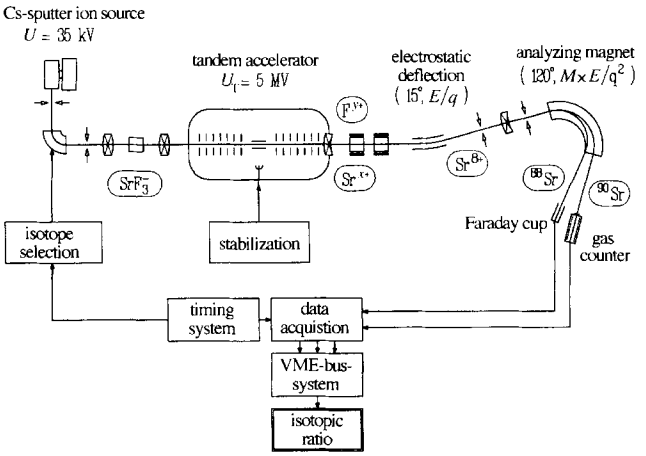

Fig. 1. Schematic representation of the AMS equipment at Erlangen (see text for further details).

are focused on the sample by suitable electric fields. This causes negative ions to be expelled from the sample. In order to achieve an ion beam of optimum quality (i.e., a high ionic current with low emittance), the electric fields in the source were optimized by computer simulations.[6] The negative ions are separated according to their mass in the 90° injection magnet. The isotopes

to be measured are injected cyclically into the tandem accelerator, where they undergo a charge reversal at a typical energy of 5 MeV, giving an n-fold positively charged state, and are then accelerated to $(n+1)\times 5$ MeV. The molecular ions resulting from the charge reversal are in a highly positively charged state, and decompose to form positively charged atoms.

The mass spectrometer consists of an electrostatic deflecting field (15°) and a 120° analyzing magnet. This magnet is equipped with second order (split pole) image correction, and optimized for high mass dispersion. In the focal plane 3 m beyond the end of the magnetic field the ^{88}Sr and ^{90}Sr isotopes are separated by 8 cm from each other. The imaging properties of this spectrometer were calculated by us, and the results of tests with various Sr and Zr isotopes were in agreement with predictions.

Furthermore, in the beam path before and after the accelerator are several electrostatic focusing lenses, deflection plates for adjusting the beam, and beam-defining slits. The beam tubes of the equipment are evacuated by several mechanical and cryogenic pumps ($p < 10^{-3}$ Pa).

The ions of the more abundant isotope are measured as an ionic current in a Faraday cup in the focal plane of the 120° magnet. The less abundant ions are detected separately in a $\Delta E - E$ gas detector. In this way, the energy loss ΔE in the first part and the residual energy E in the second part of the gas-filled ionization chamber are determined simultaneously. The number of events is then plotted versus the ΔE-E plane. The signal due to the ions of the isotope being determined appears at a definite position in this plane. Background ions, which appear in the detector because of rare events such as scattering by the residual gas, give other ΔE and E values and can be distinguished. For light ions, the separation of isobaric ions is also possible. These differ only in energy loss, so that there is no residual background. In the case of the heavy ^{90}Sr ions, the ΔE measurement is not sufficient to separate them from the isobaric ^{90}Zr ions. A limit of detection of ^{90}Sr ions is thus imposed by the effectiveness with which it is possible to remove the ^{90}Zr present in the sample by chemical pretreatment of the sample. Therefore, a high standard of sample preparation is required (see also ref. [7]).

The basic difference from secondary ion mass spectrometry (SIMS) consists in the decomposition of the molecular ions during charge reversal in the accelerator and in the special methods for detecting the ionized atoms, which, at the high energies used, are very sensitive to atomic number Z and mass number A of the ions. However, the great technical complexity of AMS is only acceptable if simpler methods are not adequate.

Only negative ions can be accelerated in the tandem accelerator. As Sr does not form negative ions, a negative molecular ion must first be formed, which then decomposes into its components on charge reversal in the accelerator. Extensive testing has been carried out to determine the most suitable molecule (Table 1) and hence to establish the chemical nature of the AMS sample. The optimum molecular ion is SrF_3^-, which can be extracted from a SrF_2 sample producing relatively high currents. For the sputtering process, the sample must have good thermal and electrical conductivity. The SrF_2 is therefore mixed with a suitable powdered metal (high purity Au; mass ratio SrF_2:Au = 1:2), ground in a pestle and mortar, and compressed in the sample holder at a pressure of 1500 MPa (15 kbar). A target that contains 10 mg SrF_2 yields negative ions in the sputtering source for a period of 2–3 h.

Table 1. Electric currents of negative ions from various strontium compounds. Powdered Au or Ta must be added to cause electrical conductivity.

Test material	Ion	Current [nA]	Test material	Ion	Current [nA]
SrF_2 + Ta	SrF^-	150	$SrCl_2$ + Au	$SrCl^-$	150
SrF_2 + Au	SrF^-	200	SrS	SrS^-	100
	SrF_3^-	300	$SrCO_3$ + Au	SrO^-	<2

Ions of different masses are already well separated after the 90° injection magnet. A mass spectrum recorded after this magnet (Fig. 2) contains not only the signals for SrF^- and SrF_3^-, but

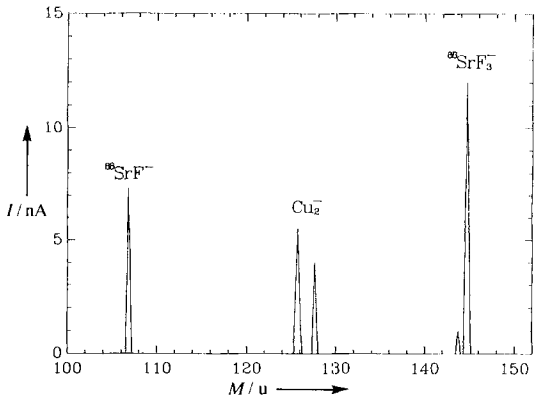

Fig. 2. Section of the mass spectrum recorded after the 90° injection magnet. I is the ionic current.

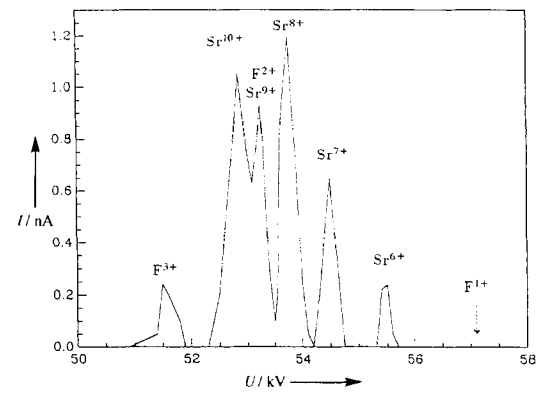
also two signals for Cu_2^-. For the ^{90}Sr measurement, the magnetic field of the injection magnet is set for $^{90}SrF_3^-$ ions. As a determination of the abundant $^{88}SrF_3^-$ ions is also necessary as a reference value, these ions are injected every 30 ms for 5 ms instead of $^{90}SrF_3^-$. Switching between the two types of ion takes place by applying a suitable high voltage to the chamber inside the 90° magnet at a constant magnetic field. Since this can occur very rapidly, slow changes of the ion transmission through the accelerator can be eliminated.

Decomposition of the injected SrF_3^- ions takes place after charge reversal, and ionized atoms with various positive charges are formed. These cations are then separated (Fig. 3) in the



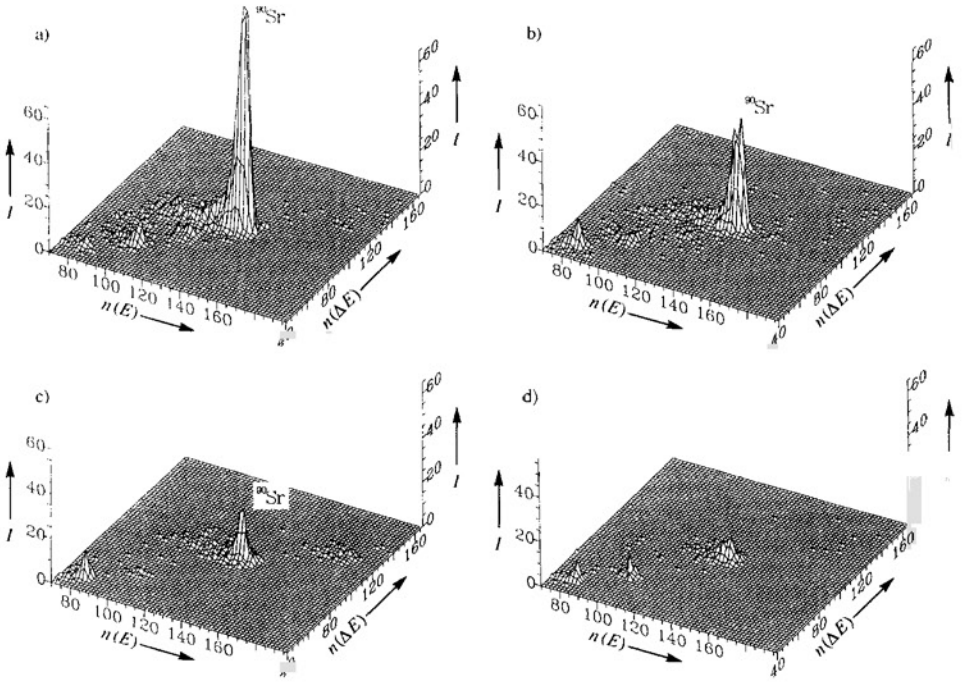


Fig. 3. Separation of the ionized atoms with various positive charges by the electrostatic sector field. The ionic current I due to the molecular fragments is plotted against the applied voltage U.

electrical sector field (see Fig. 1). The signal for Sr^{8+} is intense, and is well separated from its neighbors. It is therefore used for the ^{90}Sr measurements.

This method of analysis was tested by using samples containing known concentrations of ^{90}Sr taken from a commercially available standard material. Two inactive reference samples and three

The intensity I (number of measured events) is plotted versus the channel number $n(\Delta E)$ which is proportional to the energy loss ΔE, and versus the channel number $n(E)$, which is proportional to the residual energy E. ^{90}Sr ions appear at a definite energy loss ΔE and a certain residual energy E. The background contribution is determined from the spectrum of the inactive sample (below right).

^{90}Sr samples were investigated: high purity ("Optipur") SrF_2, inactive SrF_2 prepared from $SrCO_3$ by treatment with high purity HF, and three samples of SrF_2 of different activity prepared from $SrCO_3$ ("Suprapur") with addition of a ^{90}Sr standard. This was obtained by diluting 1 mL of $^{90}SrCl_2$ solution which had an activity of 7700 Bq with H_2O ("Nanopur"). The $^{90}Sr/^{88}Sr$ ratios for the three active samples were 1.4×10^{-9}, 7×10^{-9}, and 14×10^{-9}.

For the measurements, a source voltage of $U = 35$ kV was used, with an acceleration voltage of $U_T = 5$ MV in the tandem accelerator. With the selected ion (Sr^{8+}), this corresponds to a beam energy of 43 MeV after the charge reversal and the second acceleration. Because of the energy losses on decomposition of the molecule, the energy of the Sr ions is somewhat less than $(8+1) \times 5$ MeV. The measured ^{88}Sr ionic current in the focal plane of the 120° analyzing magnet was 1.5 nA. Typical ΔE–E spectra for the inactive sample and the three active samples are shown in Figure 4. From the intensity of the ^{90}Sr signal, the activity of each sample can be calculated after normalization based on the number of ^{88}Sr ions. As can be seen from the spectrum of the inactive sample, a small background due to ^{90}Zr is present which cannot be distinguished from the ^{90}Sr. This limits the sensitivity of the ^{90}Sr determination.

Other impurities in the sample (e.g., Ag, Al, Cu) are only noticeable at higher concentrations, and can be avoided by a suitable pretreatment. This background was minimized in a large number of measurements; considerable improvements resulted from the use of Au as a mixed substance (instead of Ag as is used in ^{14}C determinations) and of a Ta insert in the copper sample holder. The advantage of using the heavy elements Au and Ta is that they can be completely removed in the injection magnet due to their high mass. Light elements, on the other hand, can form molecular ions (e.g., with F) with a mass similar to that of the SrF_3^- ions, and these consequently appear in the accelerator.

The isotope ratios $^{90}Sr/^{88}Sr$ were determined from the 6–10 separate measurements (10 min measuring time per sample). The results are listed in Table 2. The stated measuring errors were determined from the spread of the data. The values for the inactive sample must be taken as the background measurement which must be subtracted from the values for the active samples. The results, corrected in this way, agree well with the isotope ratios calculated from the activity of the standard within the limits of error.

Table 2. Results of measurements on samples of known activity, and two inactive samples (blank and "Optipur"). The result for the blank is the value for the background, presumably due to zirconium, and must be subtracted from the values for the calibrated samples. The errors ($\pm 1\sigma$) are determined from several individual measurements.

Sample [a]	measured	after subtracting background
1(14)	14.4 ± 0.9	13.12 ± 0.94
2(7)	7.09 ± 0.5	5.81 ± 0.57
3(1.4)	2.25 ± 0.13	0.97 ± 0.31
blank	1.28 ± 0.28	
Optipur	1.15 ± 0.15	

[a] Values in parentheses give the $^{90}Sr/^{88}Sr$ ratio $\times 10^9$.

The measurements carried out with the AMS equipment in Erlangen have shown that rapid ^{90}Sr analyses are possible at levels as low as 10^{-9} using pure starting materials. However, using environmental samples containing fission products, for example those prepared from air filters, an optimized chemical pretreatment is necessary. The level of ^{90}Zr must be reduced below 10^{-9}, and other impurities (e.g., Al, Cu, Ag) must be effectively removed.

Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples III: Development of a Fast Analytical Method**

Juan Alfaro, Thomas Apfel, Herbert Diercks, Arndt Knöchel,* Rahul Sen Gupta, and Klaus Tödter

The nondestructive determination of the ^{90}Sr and ^{89}Sr content in a given sample is impossible due to the lack of characteristic γ-lines for these pure β^- emitters. This determination, however, is especially important in the case of nuclear accidents as Sr^{2+} isotopes are deposited, like Ca^{2+}, into the bones where they damage the blood-forming organs, an effect that is worsened by their long biological half-life. In combination with the relatively high ionization density of the β^- radiation released and the long physical half-life, this leads to a high radiotoxicity, especially for ^{90}Sr.

As other nuclides contribute to the essentially nonspecific β^- radiation, it is necessary to remove all accompanying nuclides before analyzing the Sr isotopes. The established standard method consists of a series of precipitation steps, the quality of which is crucially dependent on the exact precipitation conditions.[1] The ^{90}Sr content is then determined from the daughter nuclide ^{90}Y, which must first be formed and separated. The accuracy and the detection limit is therefore dependent on reaching the equilibrium between the radioactive Sr and Y isotopes. A detection limit of 1 mBq kg^{-1} is possible, but this requires an analysis time of 2–3 weeks, unacceptably long in the case of accidents.

This became apparent shortly after the reactor accident at Chernobyl when there were no analytical techniques for the determination of $^{89}Sr/^{90}Sr$ contents that where sufficiently fast and reliable to estimate the spread and extent of the Sr contamination.[2] The separation of strontium by personnel unaccustomed to the technique was especially problematic. Even the presence of additional equipment did not allow an increase in sample throughput to meet the short-term need.[3]

[**] This work was supported by the Bundesministerium für Umwelt, Naturschutz und Reaktorsicherheit as well as the Fonds der Chemischen Industrie. We thank Dr. Heinemann, KFA Jülich, and Dr. Vogl, Bundesamt für Strahlenschutz, for providing us with samples and some measurements.

In order to overcome these shortcomings, the German Federal Minister of the Environment, Nature Conservation, and Nuclear Safety (Bundesminister für Umwelt, Naturschutz und Reaktorsicherheit) stimulated the development of methodologies to enable the collection of data by precision analyses which would allow model calculations of the spread of contaminated aerosols. The results of these calculations were then to be used to perform well-targeted, rapid analyses of food, soil, and plant samples. For the detection of radioactive strontium isotopes, a rapid method was developed that lends itself to automation, performs an on-line measurement of the Sr isotope contents, minimizes the educational requirements for the operators, and minimizes possible sources of errors. The analytical techniques developed under these premises are based on ion chromatographic separation[4] of Sr with a subsequent flow detection.[5] They are schematically summarized in Figure 1.

It was necessary to optimize existing sample preparation steps or even to develop new ones in some cases in order to be able to exploit the full capabilities of ion chromatography coupled with on-line detection.

Milk samples are ashed without time-consuming drying steps directly in an electrically heated, quartz-glass fluidized bed reactor at 650 °C.[6] Using a special injection system, the milk is added with a flow rate of 5 mL min^{-1}—the flow rate is limited by the size of the reactor—directly into the heated fluidized bed of quartz sand. The use of compressed air to generate the fluidized bed leads to a soot-free ash which can be removed together with the sand from the reactor, after a cool-down period of approximately 20 minutes. The strontium can be extracted from this mixture with 20% HCl with a yield of over 99%. The solution is then evaporated to dryness and the residue is taken up in a 2% $(NH_4)_2H_2EDTA$ solution (pH = 5). This solution is subjected to ion chromatography in order to separate Sr^{2+}.

Airborne dust samples, together with the filter material, are either oxidatively pyrolyzed in the newly developed fluidized bed apparatus[7] or ashed in a muffle oven. The residue is solubilized in a microwave-assisted system (MLS-1200, Milestone) using a mixture of three parts HCl, one part HNO_3, and 1/30 part HF over a period of 45 minutes. The solution is evaporated to dryness, the residue is then taken up in a 2% $(NH_4)_2H_2EDTA$ solution (pH = 5) and ion chromatography is used to separate Sr^{2+} from this solution.

For the examination of soil samples, 100 g of the homogenized and ashed sample are subjected to Soxhlet extraction with 20% HCl. Subsequently, iron is removed to about 99% from the solution in the form of the hexachloro complex using an anion exchange resin (Dowex 1X-4). This is necessary because iron interferes with the further treatment of the sample. The iron-free solution is then evaporated to dryness in a rotary evaporator. The residue is taken up, with mild heating, in the 2% $(NH_4)_2H_2EDTA$ solution (pH = 5) and ion chromatography is again used to separate Sr^{2+} from this solution. (The residual iron left on the column can be removed by washing with water.)

The ion chromatographic separation of strontium isotopes exploits the strong affinity of Sr^{2+} ions to a highly acidic cation exchange resin[8] in combination with the formation of, compared to other cations, less stable Sr^{2+}–EDTA complexes.[9]

After the solubilized and conditioned sample solution is put onto a cation exchange column, metal ions such as ZrO^{2+}, Y^{3+}, Fe^{3+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Mn^{2+}, Ru^{3+}, Co^{2+}, and Ln^{3+} (Ln = rare earth element) do not interact with the exchange resin at this pH due to the high stability of their EDTA complexes. These ions therefore pass freely through the column. Ca^{2+}

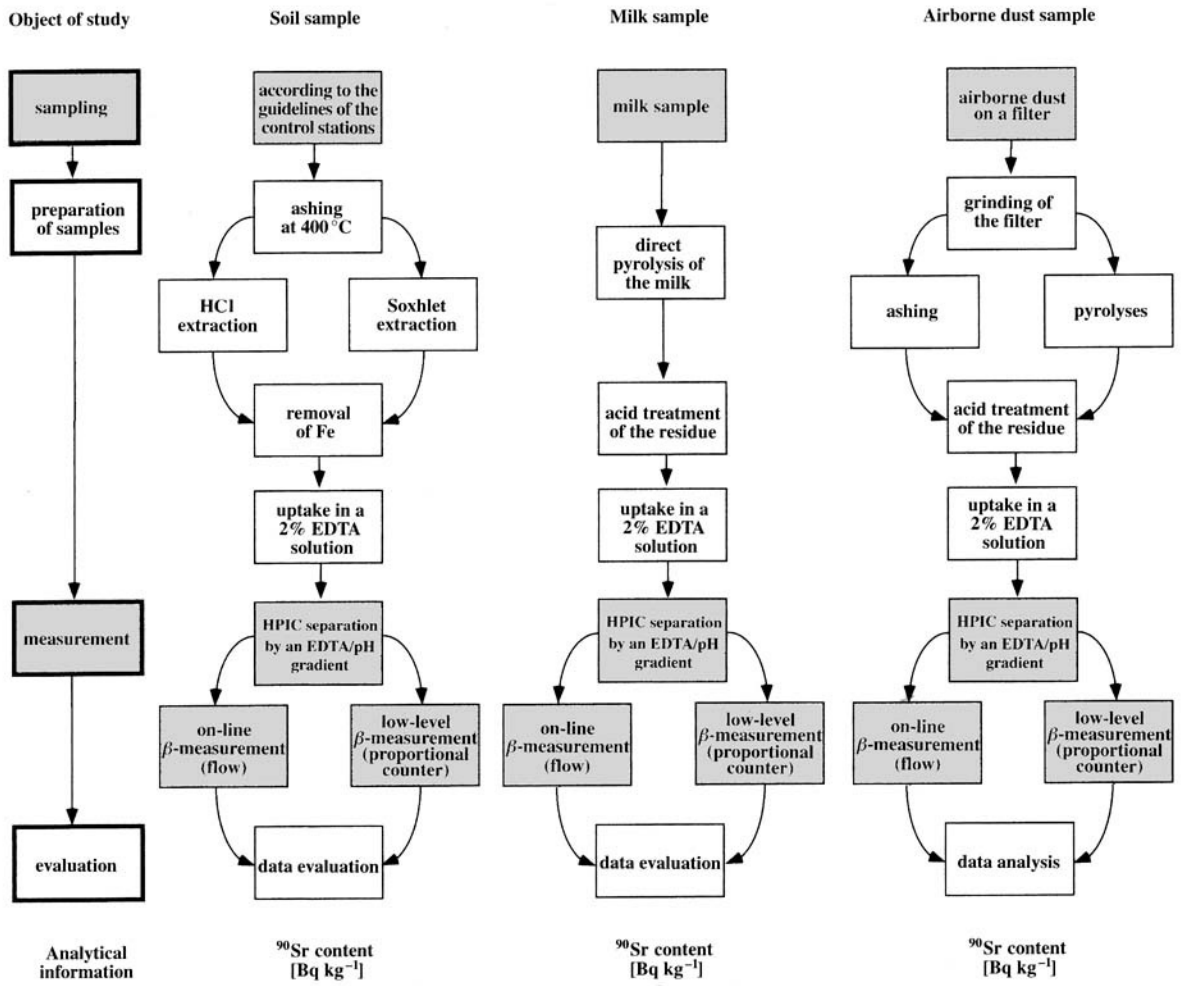

Fig. 1. Analytical method for the determination of ^{90}Sr. EDTA = ethylenediaminetetraacetate, HPIC = high performance ion chromatography.

forms less stable EDTA complexes and is retained to a small degree, while Sr^{2+}, Ba^{2+}, and Ra^{2+} are retained quantitatively on the column.

Using an EDTA-controlled pH gradient, these nuclides can by eluted in a stepwise manner. The completeness of the separation was tested with the radiotracers $^{54}Mn^{2+}$, $^{59}Fe^{3+}$, $^{65}Zn^{2+}$, $^{60}Co^{2+}$, $^{22}Na^{+}$, $^{85}Sr^{2+}$, $^{137}Cs^{+}$, $^{131}Ba^{2+}$, $^{140}La^{3+}$, $^{103}Ru^{3+}$, and $^{95}Zr^{4+}$. It was possible to demonstrate that the separation is quantitative at the concentration levels that typically occur in accident situations.

A glass column with a volume of 2 mL allows, at pH = 6, the complete separation of 0.2–4 mg of Sr^{2+} in a maximum volume 4 mL, from 200 mg of Ca^{2+}; Ba^{2+} only elutes at pH > 7. High matrix element concentrations, typically found in soil samples, require correspondingly larger columns.

Figure 2 shows a typical result of the analysis of a simulated airborne dust sample. A 2 mL column was used. The 5 mL sample contained 200 μg of Sr^{2+} and a total of 18 mg of other ions. Owing to the very small eluted volume, the immediate subsequent on-line detection of strontium is possible, using a β^--HPLC detector, without having to take the formation of the daughter nuclide ^{90}Y into consideration. Optimized detector settings and parameters made it feasible to simultaneously detect ^{90}Sr (E_{max} = 0.5 MeV) and ^{89}Sr (E_{max} = 1.5 MeV) in the two independent monitor channels, up to a ratio of 1/20. When less favorable $^{90}Sr/^{89}Sr$ ratios are present, the ^{90}Sr content can be determined via subsequently formed ^{90}Y. In this case, after

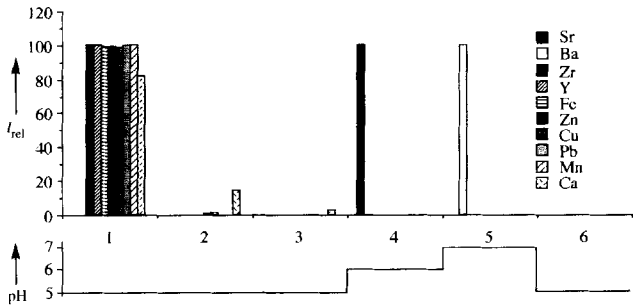

Fig. 2. Separation of strontium from a simulated airborne dust sample using an EDTA/pH gradient. The recurrence I_{rel} [%] is plotted versus the number of the fraction; the fraction volume was 10 mL. The ions were detected by total reflection X-ray fluorescence analysis (TRFA) [10] (Seifert, Ahrensburg).

the removal of accompanying elements, the strontium is left on the column overnight; ^{90}Y is eluted immediately when the system is re-started and comes off in a narrow band and can be detected in the stream.

Figure 3 shows the schematic setup of the automated HPLC apparatus. It is controlled by a computer and consists of two high-pressure gradient pumps, an autosampler, a motorized switching valve, separation columns with volumes of 15 and 2 mL for preseparation and focusing, a β^--detector, and a fraction collector.

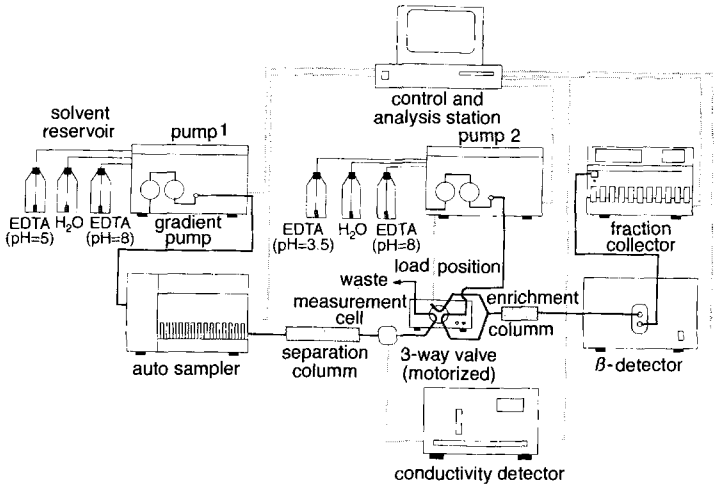

Fig. 3. HPLC apparatus for the separation and determination of radioactive strontium isotopes (HPLC components obtained from Gynkotek, Munich; flow β^--detector LB 506-C, laboratory of Prof. Berthold, Wildbad).

The complete set of procedures listed in Figure 1 was tested by using standard solutions; the method for soil samples has been applied to Russian samples from the area of Clincy as well as to strontium-doped reference samples provided by the Federal Agency for Nuclear Safety (Bundesamt für Strahlenschutz).

The soil samples were first ashed at 450 °C and subsequently, in accordance with the published official requirements,[11] either extracted directly with HCl or subjected to an HCl Soxhlet extraction. The iron matrix was removed from the HCl solution in the form of hexachloroferrate(III) by anion exchange. After complete evaporation of the solvent and redissolution in 2% $(NH_4)_2H_2EDTA$, the pH was adjusted to 5. As described above, Sr^{2+} is preseparated on the 15 mL column, focused on the second ion exchange column (2 mL), and the $^{90}Sr^{2+}$ was detected online in the throughput. For control purposes, the Sr fractions were collected immediately after the separation and subjected to off-line measurements using a low-level counter equipped with 10 proportional counting tubes.

In addition, the soil samples were examined by γ-spectroscopy before the extraction, after the drying and homogenizing steps. The recovery was determined after each step using TRFA.[10]

[a] Bundesamt für Strahlenschutz, Neuherberg.

It is obvious that the new technique is able to quantitatively detect ^{90}Sr in soil samples. The deviations (68.3%) are in the usual error range of 10–15%; however, it should be noted that the stated confidence intervals are based on only two parallel determinations, assuming the t-distribution.[12]

Figure 4 shows the chromatogram for a separation of a standard sample doped with ^{90}Sr/Y, ^{103}Ru and ^{137}Cs.

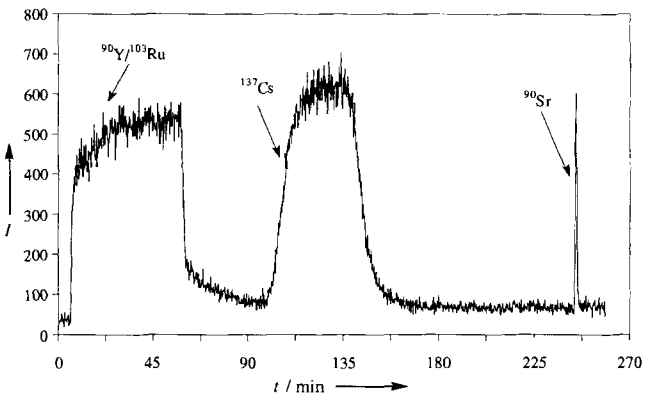

Fig. 4. Chromatogram (β^--HPLC detector) of a standard soil sample treated with ^{90}Sr/Y, ^{103}Ru, and ^{137}Cs.

The characteristic data for these analytical procedures, obtained by calibration methods,[11] indicate that in the studied range of activities (9–150 Bq), systematic errors can be excluded with a statistical certainty of 95%. An additional F-test[12] allows the exclusion of systematic deviations between the measured data with a statistical certainty of 99%.

The newly developed method for the separation of Sr isotopes is also suitable for sample preparation needed for accelerator mass spectrometry (AMS)[13] and resonance ionization mass spectrometry.[14]

Diastereoselective Coupling of Anodically Generated Radicals Bearing Chiral Amide Groups**

Bruno Klotz-Berendes, Hans J. Schäfer,* Matthias Grehl, and Roland Fröhlich

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

Anodic decarboxylation of carboxylic acids provides radicals (Kolbe electrolysis) and carbocations (non-Kolbe electrolysis) selectively and directly for synthesis.[1] The radicals may be used for homo- or heterocoupling reactions and for inter- or intramolecular additions to double bonds. The configurations of stereogenic centers at C3 or more distant positions of the carboxylic acids are retained, while those at C2 are completely lost.[2] By contrast, the use of chiral auxiliaries could lead to the formation of a stereogenic center at C2. Such induction has not yet been described for Kolbe electrolysis, whilst some cases are known for non-Kolbe electrolyses.[3] Recently diastereoselective cyclizations by the coupling of photochemically generated radicals have also been described.[4]

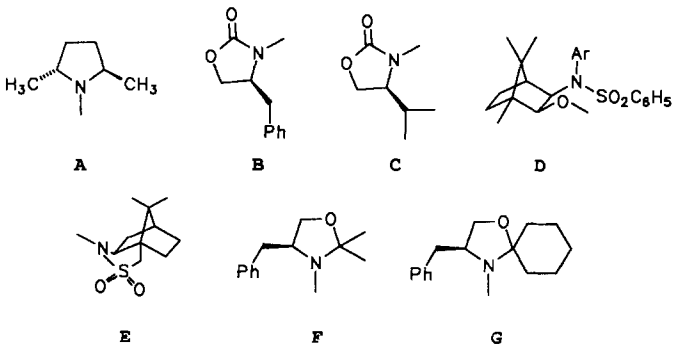
[**] Electroorganic Syntheses, Part 60. This work was supported by the Fonds der Chemischen Industrie and the EC Human Capital and Mobility Programme (no. ERBCHRXCT 920073). Part 59: C. Zielinski, H. J. Schäfer, *Tetrahedron Lett.* **1994**, *35*, 5621–5624.

We report here on diastereoselective radical couplings by means of Kolbe electrolysis with formation of a stereogenic center. This was achieved by electrolyzing 2-substituted malonic acid amides **1**, which have a chiral auxiliary linked through the amide function, in the presence of co-acids **2**. Seven auxiliary groups **A**–**G** in malonic acid amides **1** and carboxylic acids **2** with substituents of varying size at C2 were used to check their effect on the diastereoisomeric ratio of the coupling product (**5**:**6**).



Malonic acid amides **1a** and **1b** were prepared in 58–73% yields by partial hydrolysis of the appropriate diethyl malonates (with KOH in ethanol), followed by acid chloride formation (with $SOCl_2$), reaction with the hydrochloride of **A**–**H** (in the presence of triethylamine in absolute dichloromethane), and subsequent hydrolysis of the ester group (with 20% KOH in ethanol). The **A**–**H** auxiliary was prepared by the method of

	R^1	Auxiliary
a	$CH_2C_6H_5$	**A**
b	C_4H_9	**A**
c	tC_4H_9	**A**
d	$C_2H_5C(CH_3)_2$	*rac*-**A**
e	tC_4H_9	**B**
f	tC_4H_9	**C**
g	tC_4H_9	**D**
h	tC_4H_9	**E**
i	tC_4H_9	**F**
j	tC_4H_9	**G**

R^2–CO_2H **2**

	R^2
a	C_6H_{13}
b	C_4H_9
c	$tC_4H_9CH_2$
d	$(C_3H_7)_2CH$
e	$C_2H_5O_2C(CH_3)_2C$

Masamune et al.[5] Precursors of **1c** and **1d** were prepared in 26 and 21% yields, respectively, by first condensing the corresponding diethyl malonate with acetone (zinc chloride in Ac_2O),[6a] treating the product with ethyl- or methylmagnesium iodide in the presence of CuCl,[6a] and finally, partially hydrolyzing the ester.[6b] In analogy to the synthesis of **1a**, **b**, these malonates were then converted to **1c**, **d** via the acid chlorides with yields of 75–84%. **1e** could not be prepared in the way described for **1a**–**d**. The ethyl ester of the corresponding ethyl 2-*tert*-butylmalonamide with auxiliary **B**[7] could not be selectively hydrolyzed.[8] Therefore, **1e** was prepared by treating the dianion of 3,3-dimethylbutanoic acid with benzyl chloroformate (87%). The acid was converted to the acid chloride and

then, by means of the lithium salt of **B**, into the amide (93%), from which the benzyl group was removed by hydrogenation (56–58%). For the syntheses of **1f–i** the above-mentioned acid chloride was treated with either lithium salts of **C**[9] and **D**[10] or with the non-lithiated auxiliaries **E**,[11] **F**,[12] and **G**[13] to give the corresponding amides; again the benzyl groups were removed by hydrogenation.

Carboxylic acids **1** were electrolyzed in a one-compartment cell together with a five- to tenfold excess of the co-acid **2**. The diastereomers **5** and **6** [Eq. (a)] were isolated in yields from 13 to

(a)

69% (based on **1**) (Table 1). The main by-products arise from disproportionation of radical **3** formed from **1**. During the electrolysis of **1g** with **2** no conversion was observed.

Table 1. Diastereoselective mixed Kolbe electrolyses between 2-substituted malonic acid amides **1** and co-acids **2**.

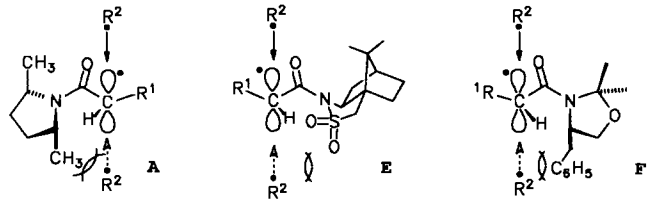
12	**i**	**c**	**l** (1:2.7) [e]	33	46
13	**j**	**c**	**m** (1:2.6) [f]	20	45



[a] The assignment of the stereochemistry at C2 was based on an independent asymmetric synthesis [14]. [b] The configuration of **5b** was assigned based on a ^{1}H NMR spectrum corresponding to that of **5a**. [c] Unequivocal assignment of the configuration at the new stereogenic center could not be made since neither an independent synthesis, as in [a], was possible nor did the positions of the signals in the ^{1}H NMR spectrum differ characteristically. [d] The assignment of the configuration at C2 is supported by three characteristic signal shifts in the ^{1}H NMR spectrum of **5** compared with those of **6**: a) the high-field shift of the methine protons in auxiliary **A**, b) the low-field shift of the methine protons on C2, and c) the high-field shift of the protons in the methyl groups of the *t*Bu and the *iso*-pentyl residues. [e] The configuration at C2 has been confirmed by an X-ray structure analysis [15]. [f] The configuration of **6m** was assigned based on a ^{1}H NMR spectrum corresponding to that **6l**.

The coupling most likely occurs through free radicals. Since carboxylic acids with a stereogenic center at C2 yield completely racemic products in Kolbe electrolysis,[2a] participation of the electrode by means of adsorption or face-selective shielding of the intermediate radical is largely excluded. The diastereoselectivity is, therefore, induced by the chiral amide group. The intermediate radical **3** occurs preferentially in the (*Z*) configuration [Eq. (b)],[16] in which the stereogenic center of the chiral auxiliary shields one face more effectively than the other.[16b]

(b)

As can be seen from Table 1, the chiral, C_2-symmetrical *trans*-2,5-dimethylpyrrolidine[17] **A** is the most effective auxiliary (entries 1–10), followed by Oppolzer's camphor sultam[18] **E** (entry 11), and the oxazolidines **F** and **G**[19] (entries 12, 13). With the oxazolidines **B** and **C** practically no face differentiation was observed. Thus in the electrolysis of **1e** or **1f** with **2b–d** diastereoisomeric excesses of 0–13% were achieved. The configuration at the stereogenic carbon atom of the predominant diastereoisomer arising from radical combination is in accord with the mechanistic picture developed for the addition of radicals substituted with an auxiliary.[20] Accordingly, the groups and atoms R^1, C$^\cdot$, C(=O), and N lie in a plane (Scheme 1). In

Scheme 1. Preferred direction for the approach of the co-radical to the auxiliary-substituted radical.

auxiliary **A** coupling from the *si* face is hindered by the axial 2-methyl group on the pyrrolidine[17] such that coupling of the co-radical occurs more or less preferentially on the *re* face. In **E** the axial oxygen atom of the sulfonyl group,[18] and in **F** and **G** the axial benzyl groups, exert the opposite effect.

The structure of the predominant diastereomer **6k** (Fig. 1)[15] reflects the preferred configuration of the intermediate radical **3** and the favored *si* coupling with **4**. Diastereoselectivity with auxiliaries **B** and **C** is small; here, obviously, the carbonyl group and not the benzyl residue of the auxiliary is oriented *syn* to the

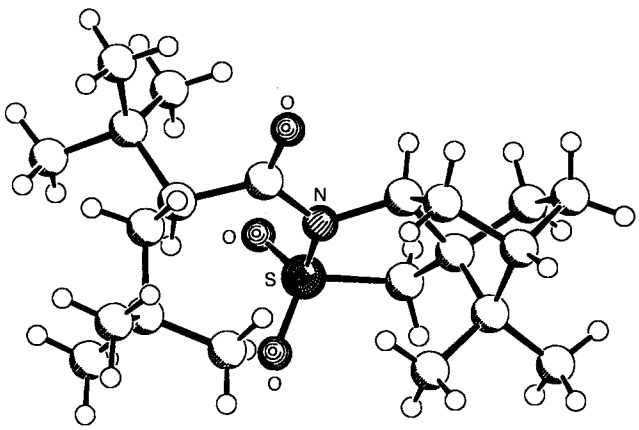


Fig. 1. Schakal plot of the crystal structure of **6k**.

radical C atom such that face differentiation is hardly possible. As expected, the diastereoselectivity of the coupling increases with an increase in size of the co-radical (entry 7 < 8 < 9 < 10).

Since radical coupling is very fast,[21] that means with a very low activation energy, according to the Hammond principle a very early transition state is to be expected, in which steric interaction between radicals **3** and **4** is still minimal. Nevertheless, the use of proven auxiliaries and large co-radicals leads to a remarkable diastereoselectivity even in intermolecular radical coupling.

Experimental Procedure

5k, **6k**: Carboxylic acid **1h** (203 mg, 0.568 mmol) and co-acid **2c** (660 mg, 5.68 mmol) were dissolved in 13 mL of dry methanol, neutralized to an extent of 5% with 0.31 mL of a 1 M solution of KOH in dry methanol, and electrolyzed in a circulation cell with a steel cathode and a platinum anode (4 cm^2) (electrode distance: 0.5 mm) at a current density of 600 mA cm^{-2} at 30–35 °C. The electrolysis was stopped when the pH reached 8–9, and the solvent was distilled off. The residue was taken up in diethyl ether, washed with saturated sodium hydrogen carbonate solution, and dried ($MgSO_4$). The diastereomeric excess in the residue was determined by capillary gas chromatography, and the diastereoisomers were isolated by flash chromatography and HPLC. ^1H NMR of **6k**: δ = 0.89 (s, 9H, $CH_2C(CH_3)_3$), 0.96 (s, 3H, $C(CH_3)_2$), 1.00 (s, 9H, $CHC(CH_3)_3$), 1.15 (s, 3H, $C(CH_3)_2$), 1.30–1.48 (m, 2H, camphor; dd, J = 14.0, 1.2 Hz, 1H, $CH_2C(CH_3)_3$), 1.82–1.99 (m, 3H, camphor; not completely resolved dd, J = 14.0, J = 10.7 Hz, 1H, $CH_2C(CH_3)_3$), 2.12–2.16 (m, 2H, camphor), 2.74 (dd, J = 10.7, J = 1.2 Hz, 1H, $CHC(CH_3)_3$), 3.47 (d, 2H, J_{AB} = 13.8 Hz, SCH_2), 3.83 (dd, J = 7.3, J = 5.8 Hz, 1H, CH_2CHN). ^{13}C NMR of **6k**: δ = 20.0 (q, $C(CH_3)_2$), 20.9 (q, $C(CH_3)_2$), 26.1 (t, CH_2), 27.6 (q, $CH_2C(CH_3)_3$), 29.3 (q, $CHC(CH_3)_3$), 30.5 (s, $CH_2C(CH_3)_3$), 33.6 (t, CH_2), 35.7 (s, $CHC(CH_3)_3$), 39.1 (t, CH_2), 44.5 (d, CH_2CHCH_2), 44.8 (t, $CH_2C(CH_3)_3$), 47.3 (s, C1, $C(CH_3)_2$), 49.5 (d, CHCO), 53.4 (t, SCH_2), 66.7 (d, CHN), 176.0 (s, CO-amide).

A Rhodium-Mediated, Stepwise Trimerization of an Alkyne That Does Not Lead to a Benzene but Selectively to a Hexadienyne Derivative**

Helmut Werner,* Martin Schäfer, Justin Wolf, Karl Peters, and Hans Georg von Schnering

Dedicated to Professor Günther Wilke on the occasion of his 70th birthday

Since the pioneering work by Reppe et al.[1] it is well known that various transition metal compounds catalyze the cyclotrimerization of alkynes to benzene derivatives.[2] With regard to the mechanism of the reaction, it is generally assumed that initially two alkyne molecules coordinate to the metal atom, that in the

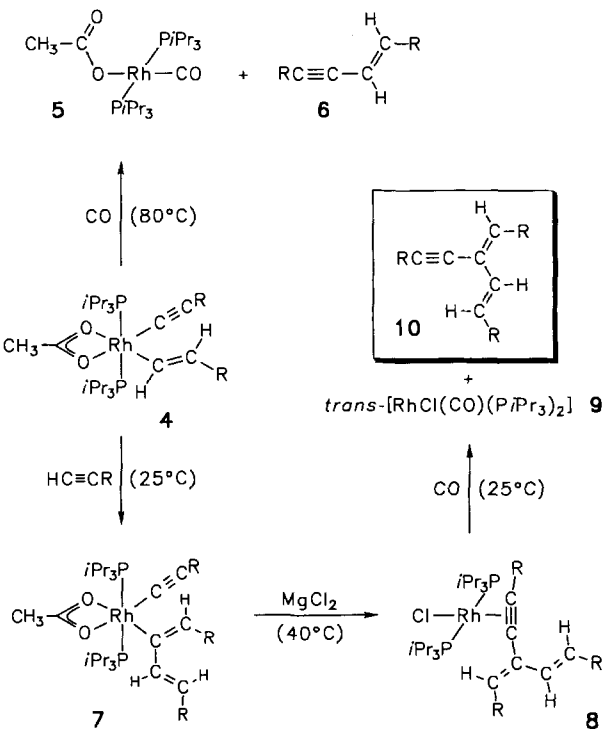
[**] This work has been supported by the Volkswagen Stiftung, the Deutsche Forschungsgemeinschaft (SFB 347), and Degussa AG.

next step by oxidative coupling the formation of a metallacyclopentadiene occurs, and that finally this reactive intermediate reacts with another alkyne to give the cyclic trimer. Vollhardt in particular has transformed the [2 + 2 + 2] cycloaddition of alkynes or of alkynes and olefins mediated by cyclopentadienylcobalt compounds into a useful and widespread synthetic methodology.[3]

We have recently shown that the dimerization of two 1-alkynes in the coordination sphere of rhodium can lead to the formation of either enynes (e.g., (*Z*)-PhCH=CHC≡CPh) or butatrienes (e.g., (*E*,*Z*)-PhCH=C=C=CHPh).[4] Key intermediates are the alkynyl(vinylidene) metal complexes *trans*-[Rh(C≡CR)(=C=CHR)($P i Pr_3$)$_2$], which are formed from [Rh(η^3-$CH_2C_6H_5$)($P i Pr_3$)$_2$] and two equivalents of HC≡CR (R = Ph, *t*Bu), and which react with CO or HCl by C–C coupling. In the continuation of this work, by using the acetatorhodium(I) complex **1**[5] as the starting material we have now achieved the trimerization of a 1-alkyne that selectively yields a hexadienyne instead of a benzene derivative.



The preparation of the intermediate **4**, which plays a decisive role in the C–C bond formation, is outlined in Scheme 1. Com-

Scheme 1. R = CO_2Me.

pound **2**, formed on oxidative addition of H_2 to **1**,[6] reacts first with HC≡CCO_2Me in pentane at −20 °C to yield the alkynyl(hydrido) complex **3**, which on further treatment with an equimolar amount of methyl propiolate (pentane, 25 °C) quantitatively gives the alkynyl(vinyl)rhodium(III) derivative **4**. Due to the ^{1}H and ^{31}P NMR spectroscopic data there is no doubt that the two substituents at the C=C bond as well as the two phosphane ligands at the rhodium center are *trans* disposed.[7]

Compound **4** is thermally quite stable and under normal conditions inert in presence of carbon monoxide. If, however, a solution of **4** in benzene under a CO atmosphere is warmed to 80 °C, a reaction takes place giving complex **5**[6] and the (*E*)-butenyne **6** almost quantitatively (Scheme 2). Surprisingly, compound **4** reacts with methyl propiolate (also in benzene) even at room temperature. In contrast to the reaction with CO, a colorless crystalline solid **7** is isolated in 78% yield instead of a butenyne. Compound **7** was found to be a derivative of **4** with a 2-butadienyl instead of a vinyl group as a substituent. As Figure 1 illustrates[8] the metal center of **7** is octahedrally coordinated with the two phosphane ligands in *trans* position. The atoms O1, O3, C4, and C9 are in a plane but are not located at the corners of a square due to the small bite angle of the acetato ligand (O1-Rh-O3 58.8(2)°). Most noteworthy is the unsymmetrical coordination of the CH_3CO_2 group; while the distance Rh–O3 (2.151(5) Å) is similar to the Rh–O distances of **1** (2.170(3) and

Scheme 2. R = CO_2Me.

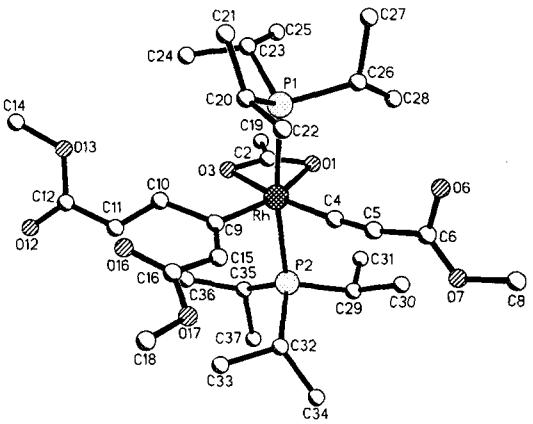


Fig. 1. Crystal structure of **7**. Selected bond lengths [Å] and angles [°]: Rh-P1 2.431(3), Rh-P2 2.407(3), Rh-O1 2.260(6), Rh-O3 2.151(5), Rh-C4 1.937(8), Rh-C9 2.015(9), C4-C5 1.195(11), C5-C6 1.46(1), C9-C10 1.48(1), C9-C15 1.35(1), C10-C11 1.32 (1), C11-C12 1.43(1), C15-C16 1.43(1), C2-O1 1.25(1), C2-O3 1.27(1); P1-Rh-P2 171.5(1), O1-Rh-C9 159.5(3), O3-Rh-C4 170.0(4), O3-Rh-C9 100.7(3), O1-Rh-O3 58.8(2), O1-Rh-C4 111.4(3), C4-Rh-C9 89.1(4), P1-Rh-O1 90.8(2), P1-Rh-O3 93.3(2), P1-Rh-C4 85.0(3), P1-Rh-C9 90.5(3), P2-Rh-O1 85.7(2), P2-Rh-O3 91.6(2), P2-Rh-C4 89.0(3), P2-Rh-C9 95.5(3), Rh-C4-C5 176.9(7), C4-C5-C6 169.0(9), Rh-C9-C10 109.5(6), Rh-C9-C15 129.5(7), C9-C10-C11 128.9(8), C9-C15-C16 130.0(8), C10-C11-C12 124.8(9), C10-C9-C15 120.9(8), Rh-O1-C2 88.6(6), Rh-O3-C2 93.1(5), O1-C2-O3 119.4(8).

2.174(3) Å)[5], the Rh–O1 bond length (2.260(6) Å) is significantly longer. The C_4 unit is linked through C9 to the metal center and has the thermodynamically more favored (*E*) configuration at both C=C bonds (C9–C15 and C10–C11). Both halves of the butadienyl ligand are twisted around the C9–C10 bond, the torsion angle (61.8°) being distinctly larger than in the square-planar complex *trans*-[Rh{η^1-(*Z*)-C(=CHPh)CH=CH_2}(CO)($P i Pr_3$)$_2$] (46.5°).[9] With regard to the mechanism of formation of **7** we assume that initially by partial cleavage of the CH_3CO_2-Rh chelate bond one molecule of HC≡CCO_2Me is added to the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0202-0192 $ 10.00+.25/0

rhodium center. This step is followed by a rearrangement of the 1-alkyne to the isomeric vinylidene ligand, and finally a vinyl-vinylidene coupling analogous to the reaction of *trans*-[Rh(CH=CH$_2$)(=C=CHPh)(P*i*Pr$_3$)$_2$] with CO[9] occurs.

Similar to **4**, compound **7** is thermally stable and even on heating to 60 °C no C–C coupling takes place. However, the coupling of the butadienyl and the alkynyl ligands at rhodium can be easily achieved if a solution of **7** in diethyl ether is treated with an excess of $MgCl_2 \cdot 6H_2O$ and Na_2CO_3 and then stirred for 4 h at 40 °C. From the crude reaction product, deep red air-stable crystals of **8** have been isolated in 79% yield, the spectroscopic data of which are closely related to those of alkynerhodium(I) complexes of general composition *trans*-[RhCl(RC≡CR′)(P*i*Pr$_3$)$_2$].[10] The X-ray crystal structure analysis of **8** (see Fig. 2)[8] reveals a somewhat distorted square-planar coordination around the metal center with the atoms Cl, P1, P2, C2, and Rh in the same plane. The C1 atom of the alkyne unit is located significantly above this plane. Despite of the unsymmetrical coordination of the RC≡CR′ ligand to the metal center, the bond lengths Rh–C1 (2.02(1) Å) and Rh–C2 (2.00(1) Å) are nearly identical, a situation which is different to that of the structurally related diynerhodium(I) compound *trans*-[RhCl(η^2-Me$_3$SiC≡CC≡CSiMe$_3$)(P*i*Pr$_3$)$_2$].[11] We note that the butadienyl substituent at the C≡C bond still has the (*E*,*E*) configuration which proves that during the C–C coupling no (*E*)/(*Z*) isomerization takes place. In contrast to **7**, however, the C_4 unit in **8** is *s-trans*. The torsion angle [C8-C7-C6-C12] (4.9°) as well as the dihedral angles between the planes [C1,C2,C3]/[C6,C12,C13] (1.4°) and [C1,C2,C3]/[C7,C8,C9] (4.7°) confirm that the C_6 core of the hexadienyne ligand is almost coplanar. The C≡C bond lies perpendicular to the plane [Cl,Rh,P1,P2], as is expected according to the Dewar/Chatt/Duncanson bonding scheme.

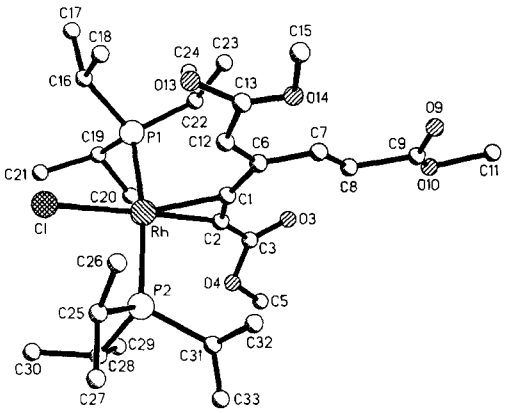

Fig. 2. Crystal structure of **8**. Selected bond lengths [Å] and angles [°]: Rh-P1 2.371(3), Rh-P2 2.369(3), Rh-Cl 2.337(3), Rh-C1 2.02(1), Rh-C2 2.00(1), C1-C2 1.21(2), C2-C3 1.40(2), C1-C6 1.54(2), C6-C7 1.38(2), C6-C12 1.35(2), C7-C8 1.34(2); P1-Rh-P2 168.9(1), Cl-Rh-C1 149.9(3), Cl-Rh-C2 174.8(3), Cl-Rh-P1 88.5(1), Cl-Rh-P2 86.0(1), P1-Rh-C1 92.6(3), P1-Rh-C2 89.9(3), P2-Rh-C1 96.9(3), P2-Rh-C2 94.6(3), C1-Rh-C2 35.1(5), C1-C2-C3 140.9(12), C2-C1-C6 160.4(10), C1-C6-C7 118.9(13), C1-C6-C12 118.3(11), C7-C6-C12 122.6(13), C6-C7-C8 125.5(15), C7-C8-C9 129.0(15).

Similar to the butenyne complex *trans*-[RhCl(η^2-PhC≡CCH=CHPh)(P*i*Pr$_3$)$_2$][4] compound **8** also reacts with CO at room temperature, the ligand displacement being indicated by an instantaneous change of color from deep red to light yellow. Equimolar amounts of both the rhodium carbonyl compound **9**[12] and the hexadienyne derivative **10** are obtained in quantitative yield, the latter of which has been characterized by GC/MS and ^{1}H NMR spectroscopy (Table 1). It should be emphasized that in contrast to the reaction of [Ni(CO)$_2$(PPh$_3$)$_2$] with methyl propiolate,[2b] in the stepwise rhodium-mediated trimerization of HC≡CCO$_2$Me no cyclic $C_6H_3(CO_2Me)_3$ isomer can be detected. As far as we know only in the oligomerization of ferrocenylethyne, catalyzed by [Ni(CO)$_2$(PPh$_3$)$_2$], a branched trimer (*E*,*E*)-FcC≡C-C(=CHFc)CH=CHFc [Fc = (η^5-C$_5$H$_5$)-Fe(η^5-C$_5$H$_4$-)], structurally related to **10**, is formed apart from the corresponding butenyne and benzene derivatives but merely in 45% yield.[13]

Table 1. Selected spectroscopic data of compounds **7**, **8**, and **10** (omitting the ^{1}H and ^{13}C NMR data for phosphane ligands).

7: IR (C_6H_6): $\tilde{\nu}$ = 2100 (C≡C), 1710, 1683 (C=O), 1565, 1530 (C=C and OCO) cm^{-1}; ^{1}H NMR (400 MHz, C_6D_6): δ = 8.36 [d, *J*(H,H) = 15.8 Hz, C*H*=CHCO$_2$Me], 6.72 [m, d in ^{1}H{^{31}P}, *J*(Rh,H) = 2.4 Hz, RhC=C*H*CO$_2$Me], 6.34 [d, *J*(H,H) = 15.8 Hz, CH=C*H*CO$_2$Me], 3.44, 3.38, 3.37 (all s, CO$_2$CH$_3$), 1.68 (s, RhO$_2$CCH$_3$); ^{13}C NMR (100.6 MHz, C_6D_6): δ = 184.32 [dt, *J*(Rh,C) = 1.2, *J*(P,C) = 1.2 Hz, RhO$_2$CCH$_3$], 167.04 (s, CH=CHCO$_2$Me), 163.85 [dt, *J*(Rh,C) = 3.5, *J*(P,C) = 0.7 Hz, RhC=CHCO$_2$Me], 163.57 [dt, *J*(Rh,C) = 30.6, *J*(P,C) = 7.8 Hz, Rh*C*], 153.67 [d, br, *J*(Rh,C) = 1.4 Hz, RhC=CCO$_2$Me], 147.95 (s, br, *C*H=CHCO$_2$Me), 126.90 [t, br, *J*(P,C) = 2.5 Hz, RhC=*C*HCO$_2$Me], 118.26 (s, CH = *C*HCO$_2$Me), 111.81 [dt, *J*(Rh,C) = 51.4, *J*(P,C) = 16.8 Hz, Rh*C*≡C], 100.46 [dt, *J*(Rh,C) = 10.1, *J*(P,C) = 2.0 Hz, RhC≡*C*], 51.19, 51.06, 50.61 (all s, CO$_2$*C*H$_3$), 24.81 (s, RhO$_2$*C*CH$_3$); ^{31}P NMR (162.0 MHz, C_6D_6): δ = 26.28 [d, *J*(Rh,P) = 93.2 Hz].

10: ^{1}H NMR (200 MHz, C_6D_6): δ = 8.78 [d, *J*(H,H) = 15.9 Hz, C*H*=CHCO$_2$Me], 6.66 [d, *J*(H,H) = 15.9 Hz, CH=C*H*CO$_2$Me], 5.95 (s, C=C*H*CO$_2$Me), 3.28, 3.20, 3.15 (all s, CO$_2$CH$_3$).

We are currently investigating whether the generation of the hexadienyne **10** from compound **8** is also possible with methyl propiolate. If this can be achieved, the ligand displacement process should generate instead of **9** the alkynyl(hydrido)rhodium(III) complex **3** which could initiate a catalytic cycle. In this context we note that Klein et al.[14] have recently shown that the cobalt cluster [Co$_3$(μ_3-H)(μ_2-CO)$_3$(PMe$_3$)$_6$] reacts catalytically with phenylacetylene at 100 °C to give the linear hexadienyne PhC≡CC(Ph)=CHCH=CHPh which stereochemically is different from **10**. The mechanistic route leading to this trimer is unknown. Therefore, to the best of our knowledge the formation of **10** from three molecules of a 1-alkyne represents the first example of an oligomerization reaction for which the stepwise course has been largely elucidated by the isolation and structural characterization of several important intermediates.

Electrochemical Synthesis of a Redox-Active Polymer Based on Buckminsterfullerene Epoxide**

Milan Fedurco, David A. Costa, Alan L. Balch,* and W. Ronald Fawcett*

Despite the interest in forming polymeric materials containing C_{60} units, little progress toward preparation of such substances has been made. Rao et al.[1a] described the photoinduced polymerization of solid C_{60} films. Takahasi et al.[1b] used a high-frequency plasma to induce polymerization in a sublimed film containing C_{60} and C_{70}. Diederich et al. recently described the electrochemical conversion of a dihydromethanofullerene into a conducting polymer.[2] Copolymers between C_{60} and the diradical xylylene have also been formed in toluene solution.[3]

We describe here the formation of an insoluble conducting film on an electrode from fullerene epoxide $C_{60}O$.[4–6] Unlike most other conducting polymers formed electrochemically,[7, 8] this film is grown in a cathodic reaction and incorporates cations. Combination of cationic conducting material with anionic conducting material, for example that based on polypyrrole,[9] is of potential importance in the production of microelectronic devices such as transistors. In addition, conducting polymers have been extensively studied for use in high energy density batteries.[8]

Initial experiments were carried out by means of cyclic voltammetry at a gold electrode (area ca. 7×10^{-3} cm^2) in a toluene/acetonitrile solution (4/1 volume ratio) containing 0.1 M tetrabutylammonium perchlorate (TBAP) and 0.4 mM $C_{60}O$.[10] Current–potential data on the forward sweep using square-wave voltammetry were similar to those reported by Suzuki et. al[11] with four irreversible reduction steps at potentials roughly equal to those for C_{60}. These authors used 1,2-dichlorobenzene as solvent, a system in which electropolymerization does not occur. Current–potential data obtained at a sweep rate of 100 mV s^{-1} are shown for the first 17 cycles in Figure 1a. The

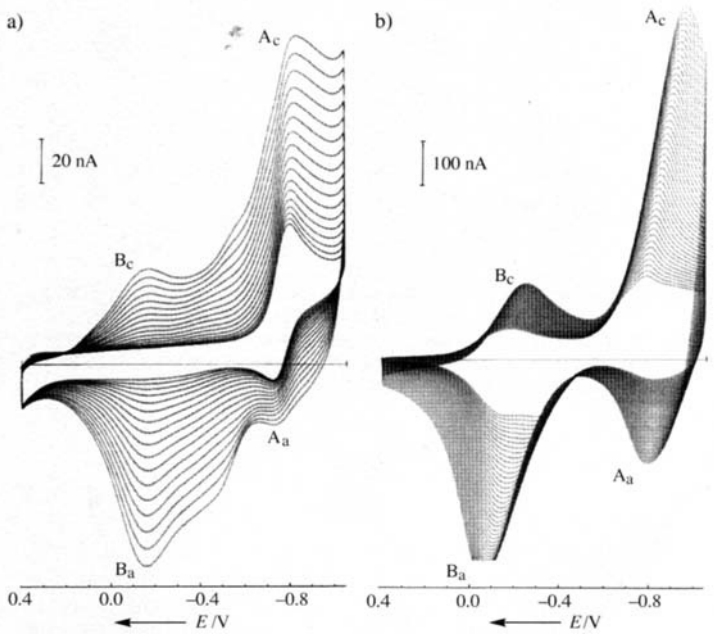

Fig. 1. a) Cyclic voltammograms (scan rate 100 mV s^{-1}) between +0.4 and −1.05 V for the reduction of $C_{60}O$ at a gold electrode in a toluene/acetonitrile mixture containing 0.1 M TBAP. The current at the initial reduction peak A_c (−0.79 V) increases in subsequent cycles, and new peaks (B_a and B_c) appear at more positive potentials. Data are shown for the first 17 cycles. b) As in (a) but for the 33rd to 75th cycle.

current peak A_c on the first sweep toward negative potentials (−0.79 V vs the Ag/Ag$^+$ reference) is attributed to formation of the anion radical $C_{60}O^{\cdot -}$. Its anodic counterpart A_a observed on the return sweep is considerably reduced in magnitude, presumably because of a follow-up chemical reaction involving polymerization [Eq. (a)].

$$C_{60} + C_{60}O^{\cdot -} \longrightarrow C_{60}\text{–}O\text{–}C_{60}\text{–}O^{\cdot -} \qquad \text{(a)}$$

After several cycles major peaks B_c and B_a develop at more positive potentials (−0.15 V), and a orange-brown film can be seen forming on the electrode. The fact that peaks B_c and B_a

occur at the same potential demonstrates that they arise from a process involving material attached to the electrode. They are attributed to incorporation of TBA^+ ions into the film on the negative sweep (B_c) and expulsion of same ions on the positive sweep (B_a). The minor peaks that develop between peaks A and B are associated with electrode reactions involving dimers or trimers, which are in the solution near the electrode and eventually become incorporated in the film. The development of the cyclic voltammetric curves up to 75 cycles is shown in Figure 1b. It is clear that the film continues to grow in thickness due to formation of $C_{60}O^{\bullet -}$ during the sweeps toward negative potentials, but the shape and position of the waves at more positive potentials are distorted owing to the increasing resistance of the deposited film. Similar results were obtained on other electrodes including glassy carbon, graphite, mercury, platinum, and glass coated with indium-doped tin oxide (ITO). Thick films were brown in color, and uniform in thickness (3–5 μm) according to depth profilometry. The deposit adhered very strongly to solid electrodes but formed as a powder on mercury. The measured current densities are smaller than those obtained earlier for the formation of polypyrrole.[8, 9] This probably reflects a lower conductivity of the $C_{60}O$ polymer due to differences in structure and the nature of the ion moving.

Additional experiments performed with a gold electrode modified with the deposit demonstrated that the film has both ionic and electronic conductivity. When an electrode with a thick film is transferred to a toluene/acetonitrile solution containing 0.1 M TBAP but no $C_{60}O$, continuous cycling in the potential region from 0.4 to −1.2 V resulted in cyclic voltammograms with the same peaks as those in Figure 1, whose heights now remained constant with further cycling (see Fig. 2).

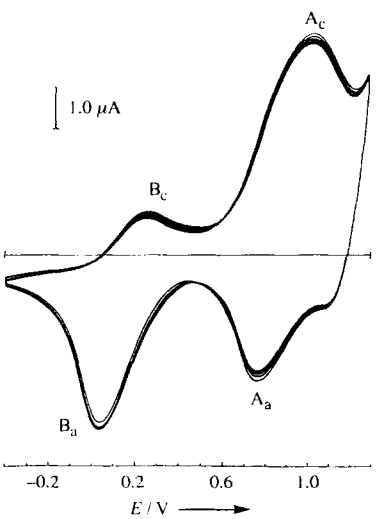

Fig. 2. Cyclic voltammograms obtained at a gold electrode covered by a $C_{60}O$ polymer film in a toluene/acetonitrile solution containing 0.1 M TBAP but no $C_{60}O$ (scan rate 100 mVs^{-1} between 0.4 and −1.2 V, Ag/Ag^+ reference electrode).

The processes leading to current at A and B now do not involve further growth of the film. However, if the potential range for cycling is restricted to the range 0.4 to −0.5 V, the peaks at B_c and B_a disappear after a few cycles. This suggests that maintaining the electrode potential at positive potentials results in the ejection of TBA^+ ions from the film and a reduction in its ionic conductivity. When the potential range is extended again in the negative direction to −1.2 V, the current peaks A reappear and the current at B is restored after roughly ten cycles. The current at A_c is now attributed to reduction of the polymer to give it a net negative charge, and the return of the features at B, to the resumption of the process by which TBA^+ ions move in and out of the polymer film. Reversible voltammetric waves for the oxidation of ferrocene are observed both at the unmodified and modified electrode, suggesting that the film is also electronically conducting.[9]

The role of ionic conductivity was also demonstrated in a transfer experiment in which a well-developed polymer film (ca. 50 cycles) was transferred from the toluene/acetronitrile solution to an acetonitrile solution containing 0.1 M $LiClO_4$ but no $C_{60}O$. All cathodic and anodic peaks decreased continuously in this medium when the electrode was cycled at the same scan rate (100 mVs^{-1}). This result can be attributed to the poor solubility of the Li^+ ion in the hydrophobic polymer environment. When the electrode is returned to the toluene/acetonitrile solution containing TBAP, the current–potential characteristics are restored after a few cycles. Presumably TBA^+ is better able to move in the hydrophobic environment created by the $C_{60}O$ polymer units.

It was also noted that the polymer can be deposited from the toluene/acetonitrile solution containing 0.1 M TBAP with the electrode potential of −1.2 V. This supports our conclusion that the mechanism involves polymerization of a species produced by reduction of $C_{60}O$.

The brown film has been characterized by a variety of techniques. Laser desorption time-of-flight mass spectrometry in the negative-ion mode confirms the presence of fullerene units within the polymer. The spectrum obtained under high laser power shows a prominent signal at m/z 720 due to C_{60}^- as well as a signal due to $[(C_{60})_2O_2]^{\bullet -}$; other signals occurred up to m/z 400 000. Mass spectra in the positive-ion mode confirm the presence of TBA^+ ions in the film, since an intense peak at m/z 242 is observed. The IR spectrum of the film dispersed in potassium bromide shows absorptions at 2962, 2879, 1460, 1396, and 802 cm^{-1}, which arise from the TBA^+ ion, at 1095, 1026, and 617 cm^{-1} due to perchlorate anions, a weak band at 517 cm^{-1}, which is the prominent band in C_{60} and $C_{60}O$ (the other fullerene features are covered by the absorptions listed above), a sharp band at 1257 cm^{-1} assigned to the C-O-C stretch of the polymer, and bands at 3425, 3131, and 1620 cm^{-1} ascribed to water molecules that may be present due to absorption from air. The UV/Vis absorption spectrum of the film is dominated by fullerene-like features with three prominent absorptions at 224, 272, and 342 nm and a broad weaker shoulder at approximately 490 nm.

Polymer films prepared on polycrystalline gold and ITO electrodes were further studied by scanning electron microscopy (SEM) and scanning tunneling microscopy. Figure 3 shows an SEM image of the $(C_{60}O)_n$ polymer grown to a thickness of 3 μm on polycrystalline gold by electrochemical deposition. The bubblelike structures on the surface result from the formation of new nuclei in the cathodic sweep of the cyclic voltammogram. Micrographs of polymer deposited on ITO electrodes were quite different; the polymer surface was almost featureless at the same magnification. The same system was examined by scanning tunneling microscopy with films 3 μm thick, and equivalent results were obtained. The fact that these experiments are possible provides further evidence of the conductivity of the electrochemically deposited layer. Electronic conductivity, probably involving a hopping mechanism, must be assumed in films of this thickness. SEM studies were also carried out with electrochemically deposited films consisting of polypyrrole, and polypyrrole on $(C_{60}O)_n$. The polypyrrole film was formed on an ITO electrode by cycling the potential between −0.5 and 0.8 V

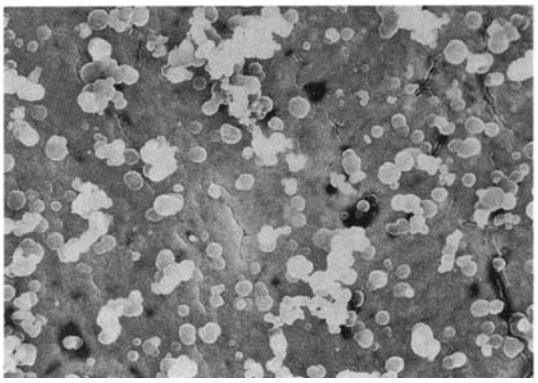

Fig. 3. Scanning electron micrograph of the $(C_{60}O)_n$ polymer film formed electrochemically on a gold disc (the length of the bar corresponds to 1.7 μm). The bubblelike structures on the surface are characteristic of the nucleation and growth processes from the toluene/acetonitrile solution containing TBAP.

in the same toluene/acetonitrile mixture containing 0.1 M TBAP and 0.01 M pyrrole. The morphology of these films was clearly different from that of the $(C_{60}O)_n$ polymer. An electron micrograph of a $(C_{60}O)_n$ polymer film on ITO with a subsequent deposit of polypyrrole is shown in Figure 4. The original $C_{60}O$ film was grown electrochemically under the same conditions

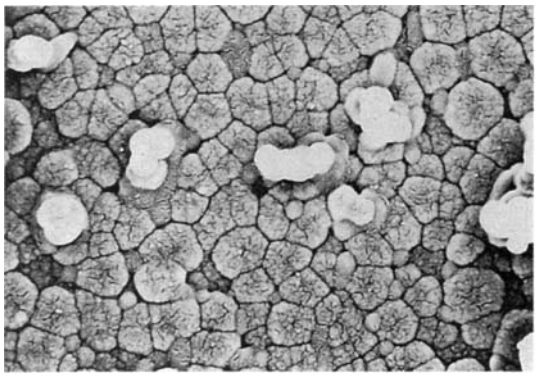

Fig. 4. Scanning electron micrograph of a $(C_{60}O)_n$ polymer film formed electrochemically on an ITO electrode with a subsequent deposit of polypyrrole (see text; the length of the bar corresponds to 1.1 μm)). The polypyrrole nuclei appear as bubblelike structures on the surface with a clearly different morphology from the $(C_{60}O)_n$ substrate polymer.

described above to a thickness of roughly 3 μm. It was then placed in a pyrrole solution for electrochemical deposition of polypyrrole and cycled in the potential range from −0.5 to 0.8 V ten times. The bubblelike nuclei formed on a background of different morphology are clearly visible on the micrograph. The reverse process, deposition of the $C_{60}O$ polymer on a polypyrrole substrate, was also carried out successfully. These results are clearly important with respect to the possible development of microelectronic devices, since the nature of the ionic conductors in the two polymers is clearly different.

In conclusion, the present study has shown that a covalently linked, redox-active fullerene polymer can be obtained through electrochemical reduction of $C_{60}O$. The electrochemically deposited films have mechanical and electrical properties that may make this material technologically important. Further studies of their properties and the electrochemical polymerization of other derivatized fullerenes are in progress.

[**] Antibiotics from Basidiomycetes, Part 48. This work was supported by the Deutsche Forschungsgemeinschaft. Part 47: R. Velten, D. Klostermeyer, B. Steffen, W. Steglich, A. Kuschel, T. Anke, *J. Antibiot.*, **1994**, *47*, 1017–1024.

acrylate unit[2] led to the synthesis of a large number of analogues, culminating recently in the first presentation of products for commercial development.[3]

We have discovered a new class of β-methoxyacrylate antibiotics, 9-methoxystrobilurins **3** and **4**, which combine the structural features of **1** and **2** and have fungicidal activity.

3

4

9-Methoxystrobilurin A (**3**) was isolated from the culture filtrate (CF) of an Ethiopian *Favolaschia* species[4] by adsorption on Mitsubishi resin (Diaion HP21) and subsequent elution with acetone. Pure **3** was obtained by chromatography of the crude product (92.2 mg L^{-1} CF) on silica gel (Kieselgel 60, Merck; cyclohexane/EtOAc = 7:3), followed by preparative high-performance liquid chromatography (Merck Lichrosorb Diol, 7 μm, cyclohexane/*tert*-butyl methyl ether = 95:5) with a yield of 2.4 mg L^{-1} CF.

According to its high-resolution electron-impact (EI) ionization mass spectrum, **3** has the empirical formula $C_{17}H_{20}O_4$; the fragment ions *m/z* 121 and 75, which are characteristic for strobilurin A (**1**; X = H), are present in the spectrum.[5] The signals of the (*E*)-β-methoxyacrylate unit can be identified in the NMR spectra (Table 1),[5] whilst the 9-H signal of the strobilurin side chain is absent. An additional methoxy signal at $\delta_H = 3.61$ and the chemical shifts of C-9 and C-10 typical of conjugated vinyl ethers at $\delta_C = 152.7$ and 118.1 indicate that the antibiotic is 9-methoxystrobilurin A (**3**). The (*E*) configuration of the C-9 double bond is verified by the nuclear Overhauser enhancement (NOE) between the methyl and methoxy groups. The *cis* configuration of these groups causes an upfield shift of the ^{13}C NMR signal of the methyl group at position 14 compared with that of strobilurin A, from $\delta_C = 23.9$ to $\delta_C = 16.3$.

9-Methoxystrobilurin K (**4**), $C_{27}H_{36}O_7$, was isolated from the lyophilized mycelium of the *Favolaschia* culture by extraction with methanol, and was purified following the same procedure as for **3** (yield 2.8 mg L^{-1} culture). According to its ^1H and ^{13}C NMR spectra (Table 1), the compound is a 9-methoxystrobilurin with a 1,1-dimethyl-2-propenyloxy and a 3-methyl-2,3-epoxybutyloxy group at the 2- and 3-position, respectively, of the central phenyl unit. The position of the substituents was obtained from the inversely detected heteronuclear multiple-bond correlation spectrum (HMBC spectrum,[6] Fig. 1) and

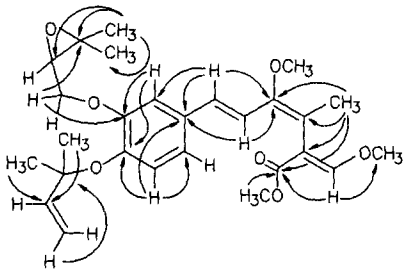

Fig. 1. ^1H-^{13}C long-range couplings for **4** from the HMBC spectrum.

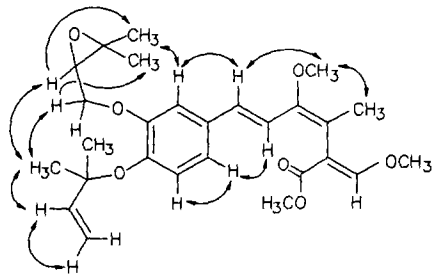
^{13}C–^1H decoupling experiments. The stereochemistry of the hexatrienyl side chain was obtained from the NOESY spectrum (Fig. 2). This leads to structure **4** for 9-methoxystrobilurin K.



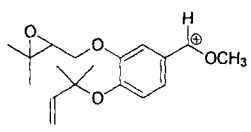


Fig. 2. Selected NOE correlations for **4**.

The typical fragmentation of the strobilurins[5] in the EI mass spectrum of **4** results in fragment **5** (base peak *m/z* 305); consecutive loss of the dimethyl and epoxyalkyl groups from **5** produces the intense fragment ions at *m/z* 237 and 153.

5

The fact that the 9-methoxystrobilurins **3** and **4** occur together with the oudemansins and strobilurins in the *Favolaschia* culture indicates that these compounds are biosynthetically related.[8]

Like the strobilurins and oudemansins, **3** and **4** inhibit a large number of fungi and yeasts in plate diffusion tests at low concentrations (Table 2). No antibacterial activity could be detected. The 9-methoxy derivatives like other strobilurins[10] are strong respiratory inhibitors. Respiration of *Penicillium notatum* is completely inhibited by 0.3 μg mL^{-1} 9-methoxystrobilurin A (1.04 μM) and 9-methoxystrobilurin K (0.64 μM). The

Zygorrhynchus moelleri	13 i	20 i	–	13 i

[a] Diameter 6 mm.

respiratory inhibition due to 9-methoxystrobilurin resembles that of strobilurin A and oudemansin A, which shows that substitution of a methoxy group at C-9 on strobilurin A does not influence its effect on respiration. The 9-methoxy derivatives, like strobilurin E,[11] have cytostatic properties. HeLa S3 cells show pronounced inhibition of growth and changes in morphology in the presence of 2 µg mL^{-1} (6.94 µM) **3** and 4 ng mL^{-1} (8.47 nM) **4**. Whilst the cytostatic activity of **3** is similar to that of strobilurin A in this test system, the extraordinarily large effect of **4** on the HeLa S3 cells is comparable with that of strobilurin D (**6**).

[7] 4-Hydroxystrobilurin D, which is related and has an (*S*)-2-(3-methyl-2,3-epoxybutyloxy) substituent [8], exhibits an optical rotation of $[\alpha]_D^{22} = +22$ ($c = 0.3$, $CHCl_3$). Because of the different chromophore, the negative rotation of **4** ($[\alpha]_D^{22} = -8.8$ ($c = 0.8$, $CHCl_3$)) does not allow any reliable conclusions about the absolute configuration to be drawn. The CD curves also show no obvious mirror-image trend.

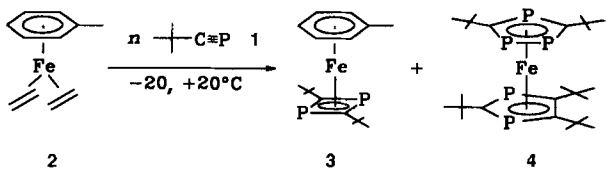
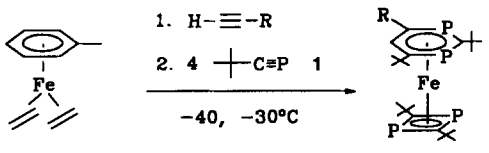
2,4-Di-*tert*-butyl-1λ^3,3λ^3-diphosphinines: Targeted Synthesis at Iron(0) Centers and Oxidative Release**

Dieter Böhm, Falk Knoch, Susanne Kummer, Uwe Schmidt, and Ulrich Zenneck*



Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

Trivalent phosphorus atoms and CR fragments are isoelectronic building blocks that can occupy equivalent positions in many organophosphorus compounds, for example in heteroarenes. The simplest member of this group, λ^3-phosphinine (phosphabenzene)[1] is known, as well as many of its substitution products.[2] Phosphinines can act as σ-donor ligands, utilizing the lone pair on phosphorus, and also as cyclic η^6 ligands.[2] Of the three possible diphosphinine isomers, only 2,3,5,6-tetrakis(trifluoromethyl)-1λ^3,4λ^3-diphosphinine has so far been prepared in solution and spectroscopically characterized.[3] There is also very little known about phosphorus-rich benzene analogues. A cyclotrimerization product of *tert*-butylphosphaethyne **1**[4] has been characterized as a π-bound triphosphadewarbenzene.[5] A second trimerization product of **1** was postulated to be a coordinated 1,3,5-triphosphinine;[6] this, however, has not yet been definitively proven.[7] We report here an efficient synthesis of 1λ^3,3λ^3-diphosphinines in the coordination sphere of iron(0) by [2 + 2 + 2] cycloaddition of two phosphaalkynes and a terminal alkyne. The release of these 1λ^3,3λ^3-diphosphinines under oxidative conditions is also discussed.



The reaction of bis(η^2-ethylene)(η^6-toluene)iron **2**[8] with *tert*-butylphosphaethyne **1** at moderate temperatures (maximum room temperature) yields, apart from the cyclodimerization of **1** to a coordinated 1,3-diphosphete in (η^4-2,4-di-*tert*-butyl-1,3-diphosphete)(η^6-toluene)iron **3**, a surprising formation of five-membered rings. This leads to a pentaphosphaferrocene, penta-*tert*-butyl-(1,2,4-triphospholyl)(1,3-diphospholyl)iron (**4**).[9] During this reaction, at least one phosphaalkyne molecule must undergo cleavage of the triple bond,[9] and the trimerization of the phosphaalkyne **1** is avoided in this case. Normally, this reaction predominates during the interaction of **2** with alkynes.[10]

[**] Reactive π Complexes of Electron-Rich Transition Metals, Part 14. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. D. Sellman for the time on the X-ray diffractometer. Part 13: C. Brodt, S. Niu, H. Pritzkow, M. Stephan, U. Zenneck, *J. Organomet. Chem.* **1993**, *459*, 283.

The reaction of **2** with acetylene at −40 °C or with terminal alkynes at −30 °C, followed by a reaction with **1**, leads to a suppression of the five-membered ring formation, and apart from small quantities of **3** and **4**, the stable sandwich complexes **5a–e**, which contain 2,4-di-*tert*-butyl-1λ^3,3λ^3-diphosphinines

5a, R = H (55%)
5b, R = $CH_2OC(O)CH_3$ (35%)
5c, R = n-C_4H_9 (40%)
5d, R = CH_2OH (35%)
5e, R = CH_2OCH_3 (35%)

and 2,4-di-*tert*-butyl-1λ^3,3λ^3-diphosphete as ligands, are obtained. If **1** is added to **2** before the addition of the alkyne, the same products result; however, the yields of **5a–e** are significantly lower. The [2 + 2 + 2] cycloaddition of two molecules of **1** and one acetylene molecule (or a different alkyne) is regiospecific in two ways: only 1,3-diphosphinines are formed, but no 1,4-derivatives, and the substituent introduced with the alkyne always ends up in the position neighboring the P atom. The reaction fails with 3,3-dimethylbutyne and internal alkynes; functional groups on 1-alkynes, such as hydroxyl, ethers, or esters, are tolerated.

According to the spectroscopic data (Table 1) and the single-crystal X-ray structure analyses of **5a** (Fig. 1) and **5b**,[11] the

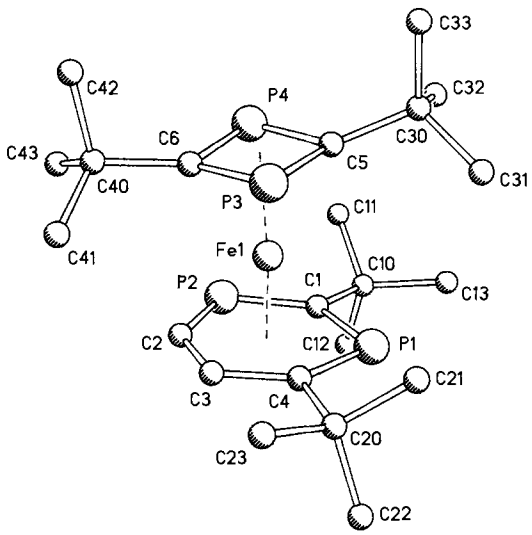

Fig 1. Structure of **5a** in the crystal. Selected bond lengths [Å] and angles [°]: Fe–P1 2.388(5), Fe–P2 2.387(6), Fe–P3 2.288(5), Fe–P4 2.306(5), Fe–C1 2.218(14), Fe–C2 2.163(17), Fe–C3 2.223(16), Fe–C4 2.173(15), Fe–C5 2.166(16), Fe–C6 2.110(14), P1–C1 1.738(16), P1–C4 1.763(16), P2–C1 1.760(15), P2–C2 1.769(17), P3–C5 1.769(17), P3–C6 1.770(15), P4–C5 1.782(17), P4–C6 1.774(17), C1–C10 1.584(23), C2–C3 1.436(23), C3–C4 1.510(22), C4–C20 1.519(23), C5–C30 1.524(24), C6–C40 1.542(20); C1-P1-C4 105.7(7), C1-P2-C2 103.0(8), C5-P3-C6 80.9(8), C5-P4-C6 80.5(7), P1-C1-P2 131.0(10), P2-C2-C3 131.8(13), C2-C3-C4 120.8(14), P1-C4-C3 127.5(12), P3-C5-P4 99.1(9), P3-C6-P4 99.3(7).

η^6-ligated 1,3-diphosphinines are essentially planar six-membered heteroarenes. The deviations of the ring atoms from the least-squares planes of the 1,3-diphosphinines range from + 3.1 to −1.9 pm for **5a** and +1.8 to −1.6 pm for **5b**. The data agree well with those obtained for η^6-coordinated phosphinines.[1,2] The distance between two of the sp^2 ring carbon atoms of **5a** (C3 and C4) is surprisingly large (151 pm), the same length as the single bond between C4 and C20. In contrast, the equivalent C3–C4 distance in **5b** (142 pm) is in the expected range. The reasons behind the large C–C distance in the ring of **5a** are not yet clear.

Table 1. Selected spectroscopic data for **5a,b** and **6a,b** [a].

5a: All NMR spectra represent the slow exchange limit. ^{1}H NMR (269.60 MHz, C_7D_8, 243 K, TMS): δ = 1.55 (s, 18H, Me at C10 and C20), 0.86 (s, 9H, Me at C30), 1.07 (s, 9H, Me at C40), 5.53 (ddd, 1H, H at C2, J(H,H) = 9.4, J(H,P) = 35.5, J(H,P) = 0.7 Hz), 6.10 (ddd, 1H, H at C3, J(H,P) = 5.5, J(H,P) = 8.5 Hz); ^{31}P{^{1}H} NMR (109.37 MHz, C_7H_8, 295 K, 85% H_3PO_4 (ext.)): δ = 10.8 (ddd, 1P, P2, J(P,P) = 12.4, J(P,P) = 8.7, J(P,P) = 5.4 Hz), 27.8 (d, 1P, P1, J(P,P) = 12.4 Hz), 30.7 (br, 1P, P4), 40.0 (br, 1P, P3); ^{13}C{^{1}H} NMR (67.7 MHz, C_7D_8, 298 K, TMS): δ = 34.8 (t, Me a C10, J(C,P) = 19.7 Hz), 32.8 (d, Me at C20, J(C,P) = 16.9 Hz), 30.8 (s, Me at C30), 33.3 (s, Me at C40), 40.7 (t, C10, J(C,P) = 36.7 Hz), 39.0 (d, C20, J(C,P) = 38.4 Hz), 35.2 (t, C30, J(C,P) = 11.3 Hz), 35.7 (t, C40, J(C,P) = 11.3 Hz), 133.5(dd, C1, J(C,P) = 73.3, J(C,P) = 84.6 Hz), 122.8 (dd, C4, J(C,P) = 71.1, J(C,P) = 4.5 Hz), 101.5 (t, C5, J(C,P) = 57.5Hz), 107.9 (t, C6, J(C,P) = 57.5 Hz), 90.7 (dd, C2, J(C,P) = 62.1, J(C,P) = 3.1 Hz), 91.3 (t, C3, J(C,P) = 8.5 Hz); EI-MS (70 eV): m/z (%): 482 (73) [M^+], 28 (100).

The NMR spectra (^1H, ^{13}C, ^{31}P) of **5a** are temperature-dependent owing to the hindered rotation of both cyclic ligands, which carry two *tert*-butyl groups each. The rotation barrier $\Delta G^{\ddagger}_{rot}$ is 55 kJ mol^{-1}. For **5b–e**, the NMR spectra represent the rapid exchange limit. Line broadening is observed for some signals only below $-80\,^{\circ}C$, hence $\Delta G^{\ddagger}_{rot}$ is smaller than 30 kJ mol^{-1}. This can be explained by the interaction between the R substituents and one of the *tert*-butyl groups of the diphosphete.

The compounds **3** and **5a–e** are structurally analogous complexes in which the toluene and the diphosphinine ligands, which, to our knowledge, are described here for the first time, occupy equivalent positions. Consequently, the spectroscopic properties of these species are quite similar.[9] There are, however, big differences in the redox behavior: while **3** can be reversibly oxidized and, at low temperatures, reduced electrochemically, the anions and cations of **5a** are so short-lived that on the time scale of cyclic voltammetry, they decompose completely even at low temperatures.[12] Only in situ EPR spectroscopy on the redox products yielded indications of the existence of the ions 5^+ and 5^-. A similar difference has been observed for ferrocene and the pentaphosphaferrocene derivatives **4**[13] as well as (pentamethylcyclopentadienyl)(pentaphospholyl)iron.[14] The latter two species do not yield stable cations, while the ferrocenium ion can be isolated in the form of salts.

We assume the mechanism of formation to proceed by an initial replacement of one or both ethylene ligands in **2** by the alkyne. Subsequently, four molecules of **1** are added in a stepwise fashion and the toluene ligand is lost. The two heterocycles are probably formed via ferraphospha- and ferradiphosphacyclopentadiene intermediates, respectively. Stable cycloaddition products of this type have been demonstrated for a $1\lambda^3$-phospha-3-zirconacyclopenta-1,4-diene[15] and a $1\lambda^3,4\lambda^3$-diphospha-2-rhodacyclopenta-3,5-diene.[16]

The oxidative decomplexation of the 1,3-diphosphinines succeeds with $FeCl_3$ or halogenated hydrocarbons at elevated temperatures. The most useful reaction for preparative purposes is the treatment of **5a** and **5b** with CCl_4, which releases **6a** and **6b**, respectively.

a, R = H

b, R = $CH_2OC(O)CH_3$

According to their NMR spectra (^1H, ^{13}C, ^{31}P), the stable free 1,3-diphosphinines **6a,b** can be classified as π^6 heteroarenes (Table 1). The relationship to phosphinines is clearly apparent and the spectroscopic findings are incompatible with alternative structures, such as Dewar-diphosphinine, diphosphaprismane, or diphosphabenzvalene. This has also been confirmed by comparing the ^1H, ^{13}C, and ^{31}P NMR spectra of **6a** and **6b** with those of the isomers of phosphinine.[17] The successful release of **6a** and **6b** completes their synthesis from simple precursors at the transition metal center. The novel rings are now available for further work. Studies concerning their organoelement and coordination chemistry are currently underway. Metal complexes of **6a** and **6b** with labile co-ligands are of particular interest as potential catalysts, for instance for the synthesis of pyridines.[18]

Experimental Procedure

5a–e: A solution of **2** (0.52 g, 2.5 mmol) was prepared in toluene (70 mL) at $-40\,^{\circ}C$, under an inert gas atmosphere. The mixture was either saturated with acetylene or treated at $-30\,^{\circ}C$ with 2-propynyl acetate (0.74 g, 7.5 mmol). At $-30\,^{\circ}C$, **1** (1.0 g, 10 mmol) in toluene (20 mL) was added, and the solution was allowed to warm to room temperature over a period of 3 h. The solvent was subsequently removed under vacuum (0.01 mbar). The black residue was taken up in petroleum ether and filtered through a small amount of Al_2O_3 (5% H_2O), which was washed with petroleum ether. The solution was reduced in volume and subjected to chromatography on SiO_2 (5% H_2O).

The reaction with acetylene and the use of petroleum ether as eluant yielded **5a** (662 mg, 1.37 mmol, 55%) as dark red, analytically pure crystals. A second fraction afforded the isolation of **3** in 12% yield.

The reaction with 2-propynyl acetate combined with the use of petroleum acetate/toluene (5:1) as eluant led to the isolation of **5b**. After recrystallization, **5b** was obtained in an analytically pure form (387 mg, 0.7 mmol, 35%).

Compounds **5c–e** can be prepared in an analogous manner (see Scheme 2 for yields).

6b: **5b** (1.06 g, 1.9 mmol) was dissolved in CCl_4 (20 mL), and the solution was heated to reflux. After 1 h the solution was filtered through Al_2O_3 and the solvent was distilled off. Subsequent vacuum distillation (2 Pa) yielded **6b** as the first fraction (130 °C) in the form of a yellow oil (143 mg, 0.48 mmol, 25%). Further fractions collected at higher temperatures contained only small portions of **6b**. The diphosphinine **6a** was obtained from **5a** in an analogous manner.

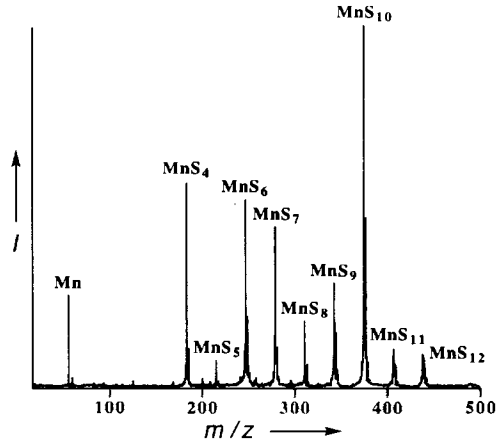

Fig. 1. Mass spectrum of the (positive) products of the reaction between Mn^+ and S_8 at $2-3\times10^{-8}$ mbar. The spectrum was recorded after a reaction period of 10 s, that is, after all of the Mn^+ has reacted.

Formation and Structures of New Metallo- and Metallapolysulfanes, $[MS_y]^+$ ($y = 2-16$)**

Ian Dance,* Keith Fisher, and Gary Willett

Amongst the growing knowledge and understanding of the reactions of ligands with bare metal ions in the gas phase[1] there is scanty information about reactions with sulfur,[2, 3] although metallapolysulfane ions are known to be formed in reactions with ethylenesulfide.[3, 4] While investigating the formation and structures of clusters $[M_xS_y]^-$ generated subsequent to laser ablation of metal sulfides,[5] we observed the formation of $[MS_y]^+$ ions, presumably from elemental sulfur released during laser ablation. Subsequently we discovered that there is a general reaction of $M^+_{(g)}$ with $S_{8(g)}$ to form series of metallapolysulfane complexes $[MS_y]^+$ for most elements of the periodic table. We report here on the ions $[MS_y]^+$ ($y = 2-16$) for first row transition metals, and present some results of density functional computations of the structures of major species.

The metal ions $M^+_{(g)}$ were generated by laser ablation of the metal (Ti, V, Cr, Co, Ni, Cu, Zn), metal oxide (Sc), or the metal sulfide (Mn, Fe) in the ion trap of a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer, while a capillary containing sulfur provided a background sulfur pressure of $2-3\times10^{-8}$ mbar. The trapped metal ions M^+ were allowed to undergo collisional cooling for periods of 0.1–2 s, then all other ions were ejected from the cell, and the reactions of the thermalized M^+ ions with the excess S_8 [6] were monitored for periods of up to 100 s. A representative spectrum for Mn is shown in Figure 1.

The major and minor products for all of the first row transition metals are listed in Table 1, with indications of the reaction time scales. The conversion of the M^+ ions appears to be pseudo first order for all metals. Only in the case of Zn^+ ions is the S_8^+ ion a major product. This is probably formed by charge transfer between the S_8 molecules and one of the zinc polysulfanes, not by rapid resonant charge transfer with the Zn^+ ions.[7]

Table 1. Positive ion products of the reactions of thermalized metal ions $M^+_{(g)}$ with excess sulfur vapor at $2-3\times10^{-8}$ mbar.

Metall	Major products (t/s)	Minor products
Sc^+	$[ScS_4]^+$ (1–5), $[ScS_{10}]^+$ (5–50), $[ScS_{12}]^+$ (>50)	$[ScS_2]^+$, $[ScS_6]^+$, $[ScS_8]^+$, $[ScS_9]^+$, $[ScS_{11}]^+$, $[ScS_{13}]^+$, $[ScS_{14}]^+$ [a]
Ti^+	$[TiS_4]^+$ (<8), $[TiS_8]^+$ (>8)	$[TiS_6]^+$, $[TiOS_6]^+$ [b], $[TiS_{10}]^+$, $[TiS_{12}]^+$ [a]

Cu^+	$[CuS_4]^+$ (<20), $[CuS_{12}]^+$ (>20)	$[CuS_4(H_2O)]^+$ [b], $[CuS_8]^+$, $[CuS_{10}]^+$, $[CuS_{13}]^+$, $[CuS_{16}]^+$
Zn^+	$[S_8]^+$	$[ZnS_4]^+$, $[ZnS_4(H_2O)]^+$ [b], $[ZnS_{10}]^+$, $[ZnS_{12}]^+$

[a] Formed in traces. [b] Formed from adventitious water.

The reactivity patterns for M^+ plus S_8 can be summarized as: 1. The relative rates of reaction of M^+ with S_8 are $(Fe \approx Sc) > (Ti \approx V \approx Cr \approx Mn) > (Co \approx Ni) > (Cu \approx Zn)$. These follow atomic number, except for the enhanced reactivity of Fe^+. 2. For all metals except Zn, $[MS_4]^+$ is the first major product. 3. At longer times the major products are $[MS_6]^+$ for M = Co; $[MS_8]^+$ for M = Ti, V, and Cr; $[MS_{10}]^+$ for M = Sc, Mn, Fe, and Ni; and $[MS_{12}]^+$ for M = Sc and Cu. 4. The highest mass ions are $[MS_{10}]^+$ for M = V, Cr, Fe, Co, and Ni; $[MS_{12}]^+$ for M = Ti, Mn, and Zn; $[MS_{14}]^+$ for M = Sc; and $[MS_{16}]^+$ for M = Cu. 5. $[MS_y]^+$ with y odd are not abundant, except for $[VS_7]^+$ and $[MnS_7]^+$.

What are the structures and structural principles for these new complexes? In order to answer this question we used established ab initio density functional theory[8] to explore the structure-energy surfaces of the complexes by optimization of a variety of postulated structures. Jones et al., for example, used local density functional methods coupled with molecular dynamics to map the energy surfaces for sulfur molecules.[9] Here we outline key results for the ions $[MS_4]^+$, $[MS_8]^+$, and $[MS_{12}]^+$: details of all calculated geometrical and electronic structures will be presented separately.

[**] Financial support from the Australian Research Council is gratefully acknowledged, as is the generous provision of computing resources by Australian Numerical Simulation and Modelling Services.

For the ubiquitous small complex $[MS_4]^+$, we first explored the obvious structural possibilities, namely tetrahedral $[M(S)_4]$, pseudo-tetrahedral $[M(S_2)_2]$, the monocyclic chelate $[MS_4]$, and $[M(\eta^4\text{-}S_4)]$, in which the number of S–S bonds ranges from 0 to 4. During energy minimizations of these isomers for M = Sc, V, Mn, Co, and Cu, it became apparent that the most favorable binding energies often occurred for low symmetry arrangements of S_2 groups around the metal atom. The principal geometrical features for the $[MS_4]^+$ ion can be described in terms of the six structures **1a–f** shown in Figure 2. The D_2 symmetric structure

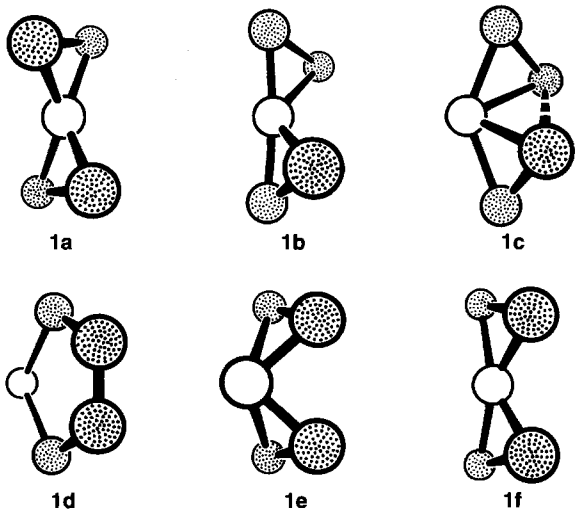

Fig. 2. Stable structures 1 for $[MS_4]^+$ ions.

1a is a pseudo-tetrahedral complex $[M(S_2)_2]$ in which the S_2 groups are most separated, while in **1b** (C_2 symmetry) the S_2 groups approach such that one S-M-S angle is close to 180°. The complex **1c** (C_2 symmetry) exhibits secondary bonding (ca. 2.5 Å) between two S_2 groups, while in **1d** (C_{2v} symmetry) the S_2 have joined to form an S_4 group which chelates the metal atom. In the C_s symmetric isomer **1f** the coordination of the metal atom approaches rectangular planar, while in **1e** (C_s symmetry) the metal atom lies out of the plane of the two S_2 groups. For Sc, isomers **1a**, **1c**, and **1e** have very similar energies and are the most stable; for V and Mn, isomer **1b** is the most stable, about 28 kJ mol^{-1} more stable than isomer **1a**; for Co, isomers **1a,b** are close in energy and isomer **1f** is about 20 kJ mol^{-1} less stable; and for Cu, isomer **1d** is most stable . The general preference for coordination of η^2-S_2 units, except at the end of the transition series, is consistent with the dissociation of S_2 units from $[FeS_y]^+$ on collisional activation.[3, 4b]

The structures of the complexes $[MS_8]^+$, which are prominent for the earlier transition metals, have been investigated by calculations on $[VS_8]^+$. The most stable isomer is **2a**, in which four η^2-S_2 groups are arrayed around V in stereochemistry intermediate between square planar and tetrahedral (see Fig. 3). The isomer **2b** with a relative energy of + 41 kJ mol^{-1} is similar geometrically but has two secondary S–S interactions (2.45 Å) connecting the S_2 groups as two pairs. Closure of these secondary interactions leads to the bis-chelate $[V(S_4)_2]^+$ structure **2c** with an energy of + 83 kJ mol^{-1}. The structure **2d** (V-centered *cyclo*-S_8) is geometrically feasible, but very much less stable at + 400 kJ mol^{-1}. The stability order for the isomers of $[MS_8]^+$ is metal dependent, and for $[CuS_8]^+$ the bis-chelate isomer **2c** is the most stable. Isomer **2a** is geometrically similar to the homoleptic peroxo-complexes $[M(O_2)_4]^{z-}$ of Cr, Mo, and Nb.[10]

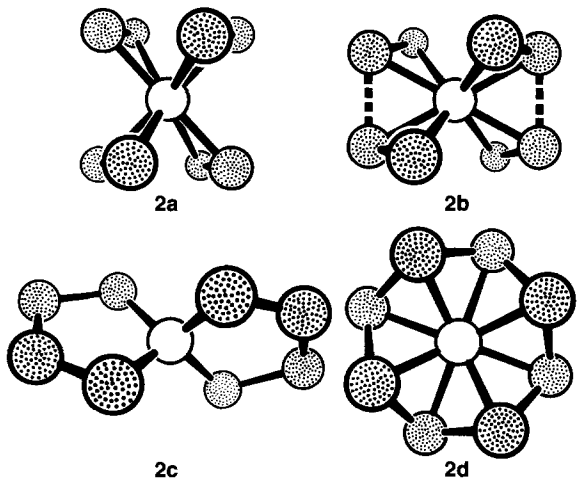

Fig. 3. The structures of four isomers for $[VS_8]^+$. **2a**: $E_{rel} = 0$, V–S 2.45 Å, S–S 2.02 Å; **2b**: $E_{rel} = +41$ kJ mol^{-1}, V–S 2.43, 2.52 Å, S–S 2.04, 2.45 (broken line) Å; **2c**: $E_{rel} = +83$ kJ mol^{-1}, V–S 2.25 Å, S–S 2.15 (1–2, 3–4), 2.08 (2–3) Å; **2d**: $E_{rel} = +400$ kJ mol^{-1}, V–S 2.58 Å, S–S 2.22, 2.25 Å.

ordinate Cu atom within a *cyclo*-S_{12} ring is the most stable. Two other isomers with a six-coordinate Cu atom are **3b** with two *cyclo*-S_6 ligands (1,3,5 connections) at relative energy $+19\ kJ\,mol^{-1}$ and **3c**, a tris-S_4 chelate complex ($+76\ kJ\,mol^{-1}$). A four-coordinate Cu atom is found in **3d** with a single chelating S_{12} ligand (1,4,9,12 connections) and in **3e** with two S_6 chelate ligands, which occur at $+34$ and $+86\ kJ\,mol^{-1}$, respectively. The isomer **3f** is a CuS_{12} monocycle with linear coordination of Cu, and has an energy of $+83\ kJ\,mol^{-1}$ relative to **3a**. There are many other feasible configurations and conformations under investigation, but it appears that here chelating structures with shorter S_y chains are less stable than structures which maximize the number of S–S bonds.

An obvious structure for the $[CuS_{16}]^+$ ion is a sandwich of the Cu^+ ion between two S_8 cycles: precedent for this is found in the $[Ag(S_8)_2]^+$ ion crystallized with AsF_6^-.[11] We note another interesting possible structure type for $[CuS_{16}]^+$ and $[CuS_{13}]^+$: when Cu^+ is tetrahedrally coordinated it fits well within *cyclo*-S_{16}, generating four fused CuS_5 cycles with multiple conformations. Excision of the central S_3 of one cycle yields a chelated structure for the $[CuS_{13}]^+$ ion with the same tetrahedral coordination.

We recognize the connections of this new metallo-/metallapolysulfane chemistry to the metal plus S_8 reactions of Rauchfuss et al.,[12] and to the structures of metal complexes of polythiacycloalkanes.[13, 14] The difference is that our metal reactants are all formally oxidation state +1. Finally, we note that this is the third phase of general metal polysulfide chemistry, which diversified immensely when it was transferred from protic to aprotic media,[15–17] and is now diversifying further on transport to the pristine gas phase.

Formation of an Alkylperoxoiron(III) Complex during Oxidations Catalyzed by μ-Oxodiiron(III) Complexes**

Stéphane Ménage, Elizabeth C. Wilkinson, Lawrence Que, Jr., and Marc Fontecave*

Mononuclear[1] and binuclear non-heme iron complexes[2] have been recently shown to catalyze the oxidation of hydrocarbons by alkyl hydroperoxides such as *tert*-butyl hydroperoxide (TBHP) and cumene hydroperoxide (CHP) and thus provide good models of non-heme iron-based monooxygenases like methane monooxygenase.[3] It has been suggested that the catalytic activity of these systems depends on the ability of the iron sites to bind the peroxide and generate oxidizing high-valent iron species.[4] While a peroxoiron(III) intermediate is likely to be a key intermediate in oxygenations catalyzed by enzymes or model systems, such a complex has never been observed during catalysis and characterized. Recently, a transient, highly unstable, high-spin alkylperoxo complex of iron in a non-heme environment was observed and characterized during reactions of a mononuclear iron(II) complex with TBHP or CHP.[5] Whether this complex catalyzes alkane functionalization was not specified. We have observed a transient complex during oxidation of alcohols by TBHP or CHP catalyzed by a non-heme oxo-bridged diiron(III) complex, and herein we report its spectroscopic characterization as an alkylperoxoiron(III) complex.

We have previously demonstrated that complex **1**, in which two $[Fe(bpy)_2(H_2O)]$ units (bpy = 2,2′-bipyridine) are bridged

$[Fe_2O(bpy)_4(H_2O)_2(ClO_4)_4]$ **1**

by an oxo group, is a very efficient catalyst for the oxidation of alkanes and alcohols by TBHP.[4] At room temperature, in acetonitrile as solvent, and with benzyl alcohol as substrate, a deep bluish green complex **2** appeared almost instantaneously after the addition of the peroxide and then slowly disappeared after one minute, when all of the oxidant had been consumed.[6] Running the experiment at $-10\,^{\circ}C$ allowed slower accumulation of

complex **2** and permitted its spectroscopic characterization. The UV/VIS spectrum of **2** exhibits a broad absorption band at 640 nm (ε/Fe = 1700 ± 200 $M^{-1}cm^{-1}$; Fig. 1). In the analogous reaction with CHP the absorption band was blue-shifted to 627 nm. Resonance Raman spectra of frozen complex **2** at 77 K with 628-nm laser excitation revealed two strong res-

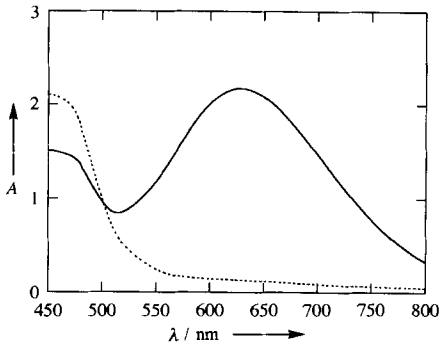

Fig. 1. Electronic spectra of complex **1** (0.7 mM; ···) and complex **2** (——) in the presence of 200 equiv benzyl alcohol. **2** was generated by addition of 50 equiv CHP to the solution of **1** at −10 °C.

onance-enhanced Raman features at 808 and 678 cm^{-1} (Fig. 2), which were not affected by the presence of $H_2{}^{18}O$. These bands shifted to 805 and 696 cm^{-1} when CHP was used, and to 814, 742, 696, and 668 cm^{-1} when [D_9]TBHP was used, demonstrating that the alkylperoxo moiety remains intact in intermediate **2**. The energies of these bands are in the range characteristic for O–O vibrations for peroxides (750–950 cm^{-1}) and comparable to those found for the only characterized alkylperoxoiron(III) complex.[5, 7] Though a precise assignment of these vibrations has not been made, the accumulated data suggest that these features arise from an iron-bound alkylperoxo moiety and that the longest wavelength band arises from an alkylperoxo-to-iron(III) charge transfer transition.

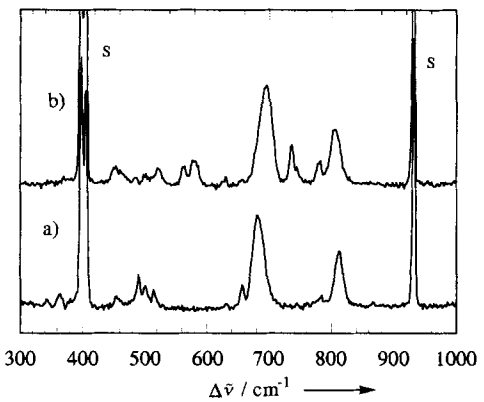

Fig. 2. Resonance Raman spectra (excitation at λ = 627.6 nm, 77 K) of complex **2** obtained with a) TBHP and b) CHP as oxidant in acetonitrile in the presence of benzyl alcohol. Peaks labeled with S arise from solvent.

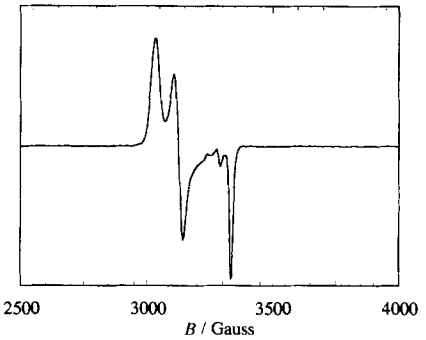
When the reaction was monitored by EPR spectroscopy, a rhombic EPR signal (g_1 = 2.18, g_2 = 2.12, g_3 = 1.98) appeared during the reaction (Fig. 3). The time-dependent variation of the intensity of this EPR signal strictly coincided with the variation of the 640-nm absorption band, strongly suggesting that



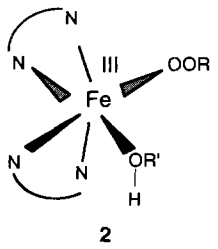


Fig. 3. EPR spectra of complex **2** at 100 K in acetonitrile. Experimental conditions: power 5 mW; modulation 3.2; time constant 0.128 s.

the blue-green complex **2** is also the EPR-active species. The characteristic features of the EPR signal demonstrate that complex **2** is not a binuclear species but rather a mononuclear low-spin rhombic (with reference to its EPR spectrum) iron(III) complex. Such a spectrum has also been observed for synthetic heme–peroxide complexes,[8] "activated bleomycin",[9] and related models.[10] Its intensity accounts for as much as 0.8 spin per iron atom.[11] Our spectroscopic studies strongly suggest that complex **2** contains an alkylperoxo moiety bound to a mononuclear iron(III) center.

There are still some questions regarding the nature of the sixth ligand. A possibility is that the alkylperoxo moiety binds to the metal center in an η^2 coordination mode as proposed for the high-spin iron(III) complex [Fe(6TLA)OO*t*Bu]$^{2+}$ (6TLA = tris[(6-methyl-2-pyridyl)methyl]amine).[5] However, the spectroscopic properties of complex **2** differ markedly from those of [Fe(6TLA)OO*t*Bu]$^{2+}$, and we suggest that in our case η^1 coordination is more likely. Since complex **2** is observable only in the presence of alcohols (methanol, cyclohexanol, phenol), it is likely that an alcohol occupies the sixth coordination site. The following observations are consistent with this hypothesis. First, the shape of the $S = 1/2$ EPR signal varies depending on the alcohol. Secondly, the absorption maximum of the intermediate shifted to 620 nm when phenol was used.[12, 13] Thirdly, the intermediate did not form with sterically hindered phenols such as 2,3,4-trimethylphenol. We thus propose the structure shown in Scheme 1 for complex **2**.

2

Scheme 1. Proposed structure for complex **2**. $\overset{\frown}{N\,N}$ = bpy.

Our data demonstrate for the first time that during oxidations of substrates by alkyl hydroperoxides catalyzed by a binuclear iron(III) complex, a mononuclear peroxoiron(III) intermediate is formed. The binding of the peroxide to the metal center is probably essential for its activation. Whether this complex is the active species or a precursor of a more oxidizing intermediate remains to be firmly established.

[11] The EPR signal was quantified by double integration with copper sulfate as a standard at 100 K.

[12] The transient species can be generated by using 30 equiv phenol or 4-methylphenol instead of 200 equiv benzyl alcohol. All the phenol was consumed during the oxidation process, and 1,4-benzoquinone and 1,4-hydroquinone were obtained as major products.

[13] This band was not observed in the absence of TBHP, indicating that it does not arise from a phenolate-to-iron(III) charge transfer transition.

A New Type of Trinuclear Oxoiron(III) Cluster**

Jean-Marc Vincent, Stéphane Ménage, Jean-Marc Latour, Azzedine Bousseksou, Jean-Pierre Tuchagues, André Decian, and Marc Fontecave*

The search for polynuclear oxo- and/or hydroxo-bridged iron complexes has been motivated by their implications in natural systems.[1] The simplest diiron(III) centers have been structurally identified in the active site of hemerythrin, methane monooxygenase, and ribonucleotide reductase, in which they are involved in dioxygen transport or activation.[2] Recent studies have revealed the potential of synthetic model complexes containing a Fe-O-Fe unit as catalysts for the oxidation of alkanes by peroxides.[3] Moreover, such centers are early intermediates in the formation of large hydroxo(oxo)iron aggregates in the interior of ferritin, the multisubunit iron-storage protein.[4] Information on the transition of binuclear oxo-bridged iron(III) complexes into clusters of higher nuclearity is sparse, and mechanisms of the first steps of the formation of the ferritin iron core are still ill-defined. Our recent investigations of the chemical reactivity of dibridged μ-acetato(μ-oxo)diiron(III) model complexes showed that complex **1** could, in the presence of an organic base, generate complex **2**, which has an unprecedented triiron core.[5] Herein we report the preparation, the X-ray structure, and the spectroscopic and magnetic properties of this new type of carboxylato(oxo)iron cluster.

$[Fe_2O(phen)_4(OAc)](ClO_4)_3$ **1** $[Fe_3O_2(phen)_6(OAc)_2](ClO_4)_3$ **2**

The core of the cation of **2** · EtOAc shown in Figure 1 consists of a bent triiron chain[6] which can be described as two identical (μ-oxo)diiron(III) units with a common central iron atom. As a result there is a pseudo-C_2 axis within the molecule passing through the central Fe2 atom. All three metal centers have a N_4O_2 coordination environment with pseudo-octahedral symmetry. Each Fe center coordinates the nitrogen atoms of two bidentate phenanthroline ligands. One oxo and one monodentate acetato ligand complete the coordination sphere of the terminal iron atoms, and two μ-oxo ligands that of the central iron atom. The distances and angles are comparable to those observed in (μ-oxo)diiron(III) complexes (average Fe-O-Fe angle 160.6°, average Fe···Fe distance 3.536 Å).[2] The length of the Fe–O bonds to the acetato ligand (average Fe–O distance 1.965 Å) are in the usual range. As previously observed for $[Fe_2O(Me_2bpy)_4(CF_3CO_2)_2]$, in which the trifluoroacetato ligand is also monodentate, the carbonyl oxygen atom of the carboxyl group lies above the phenanthroline plane, suggesting $\pi-\pi$ interactions.[3e] As expected, the Fe–N bonds *trans* to the strong electron-donating μ-oxo ligand are longer (2.271(8) and 2.283(8) Å for the terminal Fe atoms and 2.337(8) Å for the central one) than those *cis* (average 2.164 Å), because of the *trans* effect. The presence of two oxo ligands at the central iron atom is responsible for longer Fe–O_{oxo} bonds (1.814(7) and 1.823(7) Å compared to 1.771(7) and 1.775(6) Å at the terminal iron atoms). The *trans* effect also explains why the configuration in which the two oxo ligands are *cis* with respect to the central iron is favored (O1-Fe2-O4 104.7°). This configuration

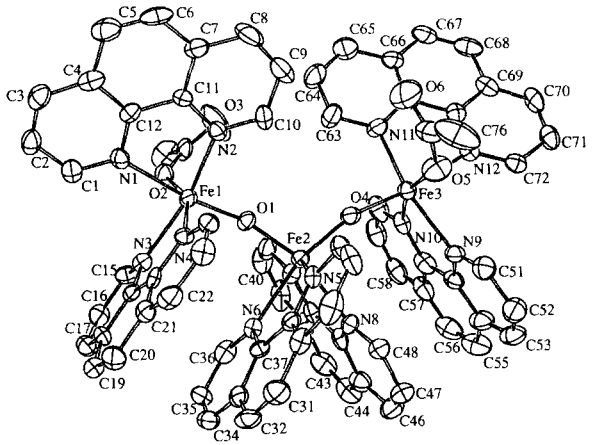

Fig. 1. ORTEP representation of the structure of the cation of **2** (ellipsoids at 50% probability). Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe1-O1 1.775(6), Fe1-O2 1.971(7), Fe1-N1 2.283(8), Fe1-N2 2.164(8), Fe2-O1 1.814(7), Fe2-O4 1.823(7), Fe1-N5 2.140(8), Fe2-N6 2.337(8), Fe2-N8 2.329(8), Fe3-O4 1.771(7), Fe3-N9 2.189(8), Fe3-N10 2.260(9), Fe3-N11 2.142(9), Fe3-N12 2.271(8), Fe3-O5 1.961(8); Fe1-O1-Fe2 160.3(4), Fe2-O4-Fe3 161.1(4).

also allows stacking of the phenanthroline rings, which probably contributes to the stability of the structure. As a result, the triiron chain is bent with an Fe-Fe-Fe angle close to 120°, affording a 6.135-Å separation between the terminal iron atoms. Only two other triiron(III) complexes with similar structures have been reported.[7, 8] One contains two bis(μ-carboxylato)(μ-hydroxo) bridges and the second, one bis(μ-carboxylato)(μ-hydroxo) bridge and one bis(μ-carboxylato)(μ-oxo) bridge; however, in both complexes the three iron atoms are perfectly aligned. In both cases, the oxo and hydroxo ligands are *trans* with respect to the central iron, and the Fe–O(H) distances are longer than those in **2**. Complex **2** is thus the first trinuclear complex with two μ-oxo and no carboxylato bridges.

The magnetic susceptibility of **2** has been measured from 2 to 300 K at field strengths of 0.5, 1, 2, and 3 Tesla.[9] The value of the $\chi_M T$ product (4.24 $cm^3 K mol^{-1}$ at 300 K) decreases to a minimum value of 4.19 $cm^3 K mol^{-1}$ at around 200 K and increases again to a plateau at 4.21 $cm^3 K mol^{-1}$ from 100 to 25 K (Fig. 2). At lower temperatures the $\chi_M T$ product exhibits a steep

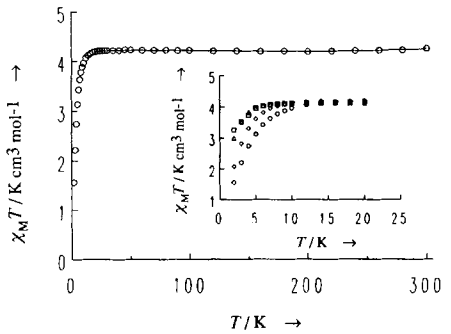

Fig. 2. Temperature dependence of the product of the molar susceptibility χ_M and the temperature T at 3 Tesla. The solid line is the result of the simulation over the range 30–300 K with the parameters indicated in the text. The inset shows the same data in the range 2–20 K at field strengths of 0.5 (□), 1 (△), 2 (◇), and 3 (○) Tesla.

decrease which is strongly field dependent. This behavior is consistent with a strong antiferromagnetic coupling of the Fe_3^{III} unit, leading to a $S = 5/2$ ground state which is disturbed by zero-field effects at low temperature. The high-temperature data ($T \geq 30$ K) can be described with the Heisenberg exchange Hamiltonian [Eq. (a)], which takes into account both the ex-

$$\mathcal{H} = -J[S_1S_2 + S_2S_3] - J'S_1S_3 \qquad \text{(a)}$$

change interaction (J) between vicinal iron atoms and that (J') between the terminal iron atoms. The calculation led to the following best-fit values: $g = 1.96$, $J = -168\ cm^{-1}$, $J' = +5\ cm^{-1}$. The large absolute value of J is quite in line with the short Fe–O distances (1.771–1.824 Å).[10] To confirm the value of the external coupling constant J', the fitting was repeated with $J' = 0$; this resulted in a significantly poorer fit and a larger value for the exchange interaction, $J = -183\ cm^{-1}$. In the related (μ-hydroxo)(μ-oxo)triiron complex the J' value was three times larger ($11\ cm^{-1} < J' < 24\ cm^{-1}$).[8]

No satisfactory simulation of the low-temperature data was obtained upon treating **2** as a $S = 5/2$ spin system with axial and rhombic zero-field splittings. This discrepancy might be explained by local anisotropies and the possible misalignment of the g tensors of the three Fe atoms, owing to the low symmetry of the complex.

The X-band EPR spectrum of complex **2** at 90 K in frozen acetonitrile (Fig. 3) displays three features centered at $g = 8.5$,

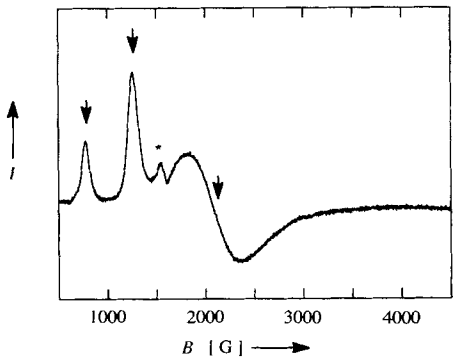

Fig. 3. X-band EPR spectrum of complex **2** in acetonitrile (2 mM) at 90 K. Experimental conditions: gain = 5×10^4; microwave power = 10 mW; modulation = 3.2; frequency = 9.411 GHz; time constant = 1.28 ms. The g values in the text were calculated from the signals marked with arrows. The signal marked with an asterisk is attributed to an impurity.

5.3, and 3.0. This differs greatly from the spectra of the two other bridged Fe_3 complexes and the linear cluster $[Fe_3S_4(SR)_4](Et_4N)_3$, in which only one strong feature is observed at $g = 4.3$.[11, 12] Lowering the recording temperature from 90 to 6 K led to an increase of the relative intensity of the $g = 8.5$ transition and a decrease of the other signals, demonstrating that the former derives from the ground state of the magnetic system (data not shown in Fig. 3). This spectrum may be consistent with an overall $S = 5/2$ ground state with $E/D < 1/3$. According to the $S = 5/2$ rhombograms, a graphic solution gives an E/D value of roughly 0.15.[13] This result explains the difficulty in fitting the magnetic data at low temperature when only an axial zero-field splitting parameter is applied. The use of E and D tensors in the exchange Hamiltonian will require further investigation.

The Mössbauer spectra of complex **2** recorded at 293, 80, and 4.2 K are consistent with the presence of two nonequivalent structural units associated with two different values of the quadrupole splitting (ΔE_Q) parameter (Fig. 4).[14] Line broad-

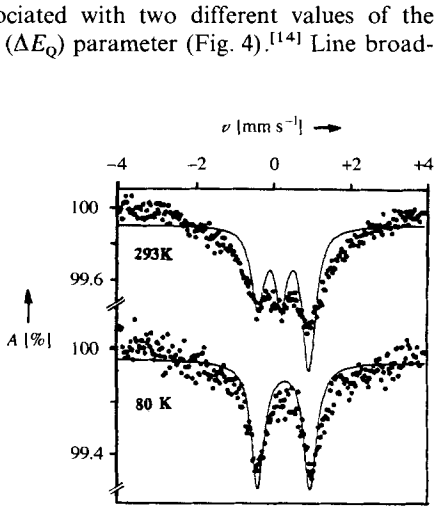

Fig. 4. Mössbauer spectra for a microcrystalline sample of complex **2** at 293 and 80 K.

ening arising from magnetic relaxation effects, which are often observed in paramagnetic high-spin Fe^{III} complexes,[15] does not allow straightforward analysis of the Mössbauer spectra. It is worth noticing that the line broadenings are different for the two sites: the pattern exhibiting a large quadrupole splitting is weakly temperature dependent, while the pattern characterized by a small ΔE_Q becomes increasingly ill defined with decreasing

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0202-0206 $ 10.00+.25/0

temperature, without reaching, however, the static situation of a well-resolved paramagnetic hyperfine structure at 4.2 K.[16] The parameters of the doublet characterized by the larger quadrupole separation have been measured from the spectrum recorded at 80 K (δ/iron foil at 293 K = 0.50(1) mm s^{-1}, ΔE_Q = 1.39(2) mm s^{-1}) and are consistent with those of (μ-oxo)diiron(III) complexes (δ = 0.36–0.56(1) mm s^{-1}, ΔE_Q = 1.3–1.8 mm s^{-1}).[1, 2] Those of the doublet characterized by the smaller separation have been obtained only from the spectrum recorded at 293 K and not that at 80 K because of line broadening (δ = 0.72(1) mm s^{-1}, ΔE_Q = 0.67(2) mm s^{-1}). These parameters indicate that the corresponding iron site is in a less distorted octahedral environment. Close inspection of the structural data shows that though the N_4O_2 coordination environments of the three iron atoms are roughly equivalent, the central iron atom has the most distorted octahedral coordination (based on the standard deviation for the Fe–N distances and the average L-Fe-L angle deviation from 90°) and should thus be associated with the doublet exhibiting the larger quadrupole splitting (ΔE_Q = 1.39(2) mm s^{-1}). The crystallographically pseudo-equivalent terminal iron atoms have less distorted ligand environments and are not distinguished from each other in the Mössbauer spectra.

Complex **2** further illustrates the rich and growing chemistry of carboxylato(oxo)iron compounds. Its unprecedented structure with a bent triiron unit gives rise to unusual spectroscopic and magnetic properties. This is the first example of the transformation of a (μ-oxo)diiron(III) unit into a complex with a triiron chain. Complex **2** may represent a missing link in the series of precursors for mineralized iron(III) compounds (e.g., the polyiron core of ferritin).[1e] The presence of an exchangeable acetato ligand might allow further controlled polymerization of the iron chain.

Experimental Procedure

The synthesis of **1** is described in ref. [3e]. **2** · EtOAc: Addition of 1,2-dimethylimidazole (4.5 µL, 1.5 equiv) to **1** (30 mg, 25 µmol) in 3 mL of acetonitrile resulted in a red solution. Crystals were obtained by vapor diffusion of ethyl acetate into the mother liquor and gave satisfactory analysis (60% yield). Anal. calcd for $[Fe_3O_2(C_{12}H_8N_2)_6(CH_3CO_2)_2](ClO_4)_3 \cdot C_4O_2H_8$: C 53.82, H 3.47, N 9.42, Cl 5.95, Fe 9.38. Found: C 53.44, H 3.58, N 9.62, Cl 5.97, Fe 9.20. UV/VIS (CH_3CN, 25 °C): 378 nm (12700 M^{-1} cm^{-1}).

[16] To prove these relaxation phenomena it is necessary to reach a static state and observe the internal magnetic field. This can be obtained by applying a weak magnetic field. When an external magnetic field of 2 Tesla was applied at 7 K, the magnetic fluctuations were frozen, and analysis of the resulting Zeeman spectrum allowed us to measure an internal effective magnetic field of roughly 3.9 T.

Mutually Interpenetrating Sheets and Channels in the Extended Structure of [Cu(4,4'-bpy)Cl]**

O. M. Yaghi* and Guangming Li

In memory of Mouannes A.-F. Yaghi

The development of synthetic strategies for the design of solid-state structures from soluble components is of intense current interest.[1] The building-block approach has been utilized for the rational assembly of inorganic[2] and organometallic[3, 4] crystalline solids. We have initiated a program aimed at using this approach in the preparation of crystalline materials possessing open-framework structures with cavities or channels. Simple ligands such as 4,4'-bipyridine (4,4'-bpy) are chosen for their demonstrated ability to act as rods linking together metal centers to give extended solids with diverse topologies.[5] This report shows how chloro-bridged Cu^I dimers with M–M bonding may be combined with 4,4'-bpy to form sheets of [Cu(4,4'-bpy)Cl]-containing cavities with dimensions of nearly 16 × 26 Å.

[**] This work was supported by the U. S. National Science Foundation (Grant CHE-9224279) and the Petroleum Research Fund, administered by the American Chemical Society (PRF No. 28175-G3); 4,4'-bpy = 4,4'-bipyridine.

In the overall structure, these sheets are interlocked with other sheets to form a three-dimensional, neutral network containing a two-dimensional, intersecting system of channels of smaller aperture.

Crystals of [Cu(4,4′-bpy)Cl] were obtained by diffusing solutions of CuCl and 4,4′-bpy into ethylene glycol. The compound was formulated by elemental analysis[6] and characterized by X-ray single-crystal analysis.[7, 8] The extended structure is made up of the building-block unit shown in Figure 1: dimeric

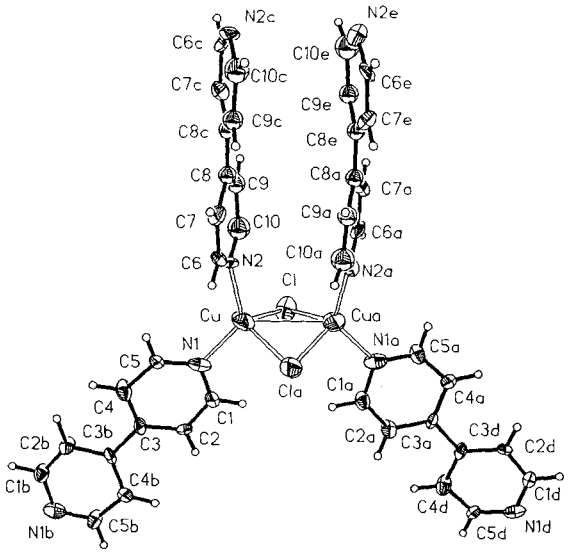

Fig. 1. A perspective drawing of the μ_2-chloro-bridged dinuclear building-block unit present in crystalline [Cu(4,4′-bpy)Cl] Non-hydrogen atoms are represented by thermal vibration ellipsoids drawn to encompass 50% of electron density. Hydrogen atoms are represented by arbitrarily small spheres. Atoms labeled with a–e are related to atoms without these letters by the following symmetry operations: for a, $1-x, 1/2-y, z$; b, $-1/4+y, 1/4+x, 1/4-z$; c, $3/4-y, 3/4-x, -1/4-z$; d, $5/4-y, 1/4-x, 1/4-z$; and e, $1/4+y, -1/4+x, -1/4-z$. Selected interatomic distances [Å] and angles [°]: Cu-Cl 2.415(6), Cu-Cla 2.475(6), Cu-Cua 2.763(7), Cu-N1 1.97(1), Cl-Cu-N1 105.1(5), Cl-Cu-N2 108.3(4), Cl-Cu-Cla 104.9(2), N1-Cu-Cla 99.6(4), N2-Cu-Cla 115.5(5), N1-Cu-N2 125.6(6), Cl-Cu-Cua 56.6(2), Cu-Cl-Cua 68.8(2), Cua-Cu-Cla 54.6(2), N1-Cu-Cua 101.9(4) (cf. ref. [8]).

Cu^I centers are bridged by two chloro ligands, and each metal atom is linked to two 4,4′-bpy ligands to form a slightly distorted tetrahedron with N2-Cu-N1 = 125.6(6)°, N1-Cu-Cla = 99.6(4)°, and Cl-Cu-Cla = 104.9(4)°. In addition, the N1 and N2 pyridine rings are twisted by 22.0(5)° and 15.60(4)° relative to the N1b and N2c rings. These distortions are due to the fact that each 4,4′-bpy acts as a bismonodentate ligand linking two Cu^I dimeric units, as shown in Figure 2; this results in formation of an infinite hexagonal array made up of Cu^I dimers with M–M bonding and 4,4′-bpy ligands, and containing pores measuring around 16 × 26 Å. However, in the absence of large guest molecules to fill the pores during the molecular assembly process, other perpendicular and symmetry-equivalent sheets of the same structure and composition are found to occupy the pores. Although, these two infinite sheet arrays are mutually perpendicular, they are not bound to each other, but are instead interlocked, like catenanes, as independent two-dimensional networks.[9]

The overall structure thus formed is a neutral three-dimensional framework, in which the interpenetrating two-dimensional networks fill up most of the pore space with channels of only small diameter (≈ 2 × 4 Å) remaining open (Figs. 3 and 4). It was

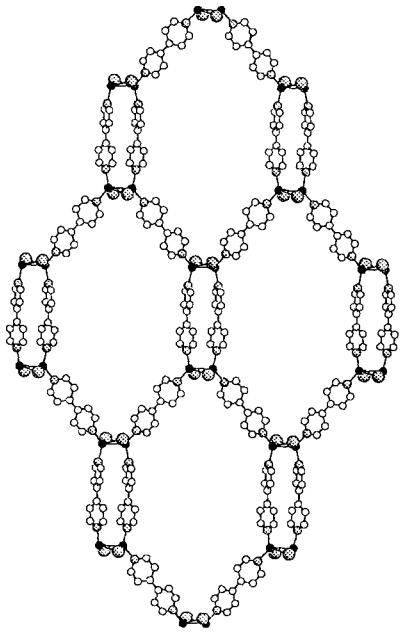

Fig. 2. A SCHAKAL drawing showing how the organization of the building-block unit $[Cu(4,4'\text{-bpy})Cl]_4$ results in the construction of infinite porous sheets that are a fragment of the crystal structure of [Cu(4,4′-bpy)Cl]. The hydrogen atoms on the bipyridine units have been omitted for clarity. Dark spheres, Cu; large shaded spheres, Cl; small shaded spheres, N; and open spheres, C.

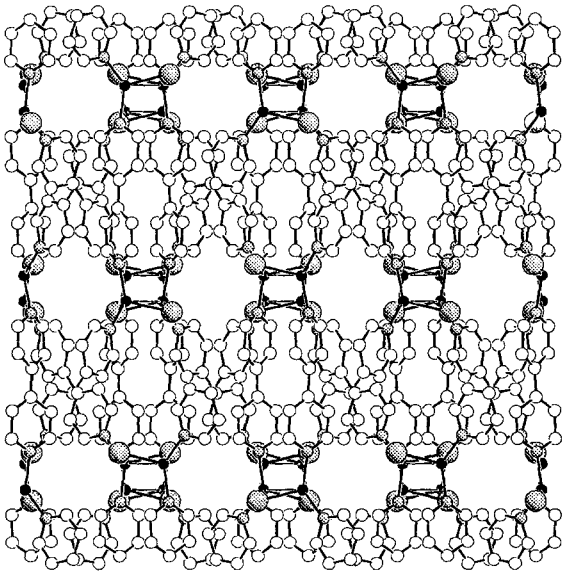

Fig. 3. A SCHAKAL drawing of the overall crystal structure of [Cu(4,4′-bpy)Cl] showing how infinite sheets are interlocked to fill the pores (shown in Fig. 2) leaving only small empty channels in the structure. The omissions and shadings are as in Figure 2.

found from the X-ray analysis that these channels are too small to accommodate acetonitrile or dimethyl sulfoxide (DMSO) solvent molecules as guests in the crystal. This was confirmed by thermal gravimetric analysis performed on a 35.306 mg sample, which showed that the material begins to degenerate at 175 °C to give only pyridine, chloride, and copper metal. Also, ^{13}C CPMAS (cross polarization magic angle spinning) solid-state NMR data showed only resonances due to the 4,4′-bpy carbon atoms and none that could be attributed to possible guest species.

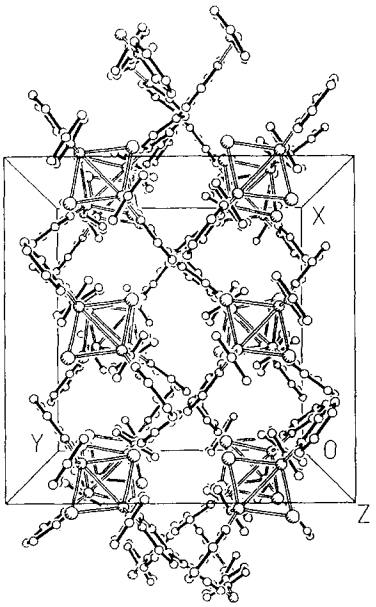

Fig. 4. A plot of the structure showing the unit cell packing and the perpendicular interpenetrating arrangement of the Cu–Cu units. Small partially shaded spheres, N; medium-sized partially shaded spheres, Cu; large partially shaded spheres, Cl; open spheres, C.

The size of the channel openings is very similar to those observed in some zeolite molecular sieves, such as, analcime (2.2–2.4 Å) and natrolite (2.6 × 3.9 Å),[10, 11] where water (kinetic diameter ≈ 2.8 Å) is known to penetrate and diffuse into the channels. We found that the material synthesized is stable in air indefinitely and in boiling water for up to 1 h. Currently, we are attempting to evaluate its potential use in water adsorption and in gas separation processes.

Experimental Procedure

[Cu(4,4′-bpy)Cl]: The addition of an acetonitrile solution (10 mL) of 4,4′-bpy (0.78 g, 5.0 mmol) to an acetonitrile solution (50 mL) of CuCl (0.50 g, 5.0 mmol) resulted in the immediate formation of a dark red, microcrystalline material. This solid was collected and washed with ethanol (3 × 20 mL) followed by diethyl ether (3 × 20 mL), and dried under vacuum for 24 h to give 1.2 g (94%) [7]. Crystals suitable for X-ray single-crystal analysis were obtained by diffusing a DMSO solution of 4,4′-bpy (0.10 M) into an acetonitrile solution of CuCl (0.10 M) through ethylene glycol (3 mL). This results in the formation of red, rectangular parallelepiped-shaped crystals at the acetonitrile/ethylene glycol interface. Alternatively, large crystals were obtained by diffusing solutions of the reactants in a 5 mm thick mineral oil.

[7] The homogeniety of the bulk product was confirmed by comparison of the observed and calculated X-ray powder diffraction patterns. The calculated pattern was produced by using the SHELXTL-XPOW program with the single-crystal data.

[8] Single crystals of [Cu(4,4′-bpy)Cl] were analyzed at 20 °C. Tetragonal, space group $I4_1/acd$, (no. 142) with $a = 14.246(4)$, $c = 38.596(12)$ Å, $V = 7833(3)$ Å^3, $Z = 16$, $\rho_{calcd} = 1.731$ g cm^{-3} and $\mu_a(Mo_{K\alpha}) = 2.46$ mm^{-1}. A total of 1345 independent absorption-corrected reflections having $2\theta(Mo_{K\alpha}) < 45.8°$ (the equivalent of 0.6 $Cu_{K\alpha}$ spheres) were collected on a computer-controlled Nicolet autodiffractometer with full 2.00° wide ω scans and graphite-monochromated $Mo_{K\alpha}$ radiation. The structure was solved by direct methods (SHELXTL-PC) and the resulting structural parameters were refined by least-squares techniques to converge ($R1$ (unweighted, based on $|F|$) = 0.050 for 465 independent absorption-correction reflections having $2\theta < 45.8°$ and $I > 2\sigma(I)$) using counter-weighted full-matrix least-square techniques and a structural model which incorporated anisotropic thermal parameters for C8, C9, and C10 and for all hydrogen atoms. The hydrogen atoms were fixed at idealized sp^2-hybridized positions with C–H bond lengths of 0.96 Å, and their isotropic thermal parameters were fixed at values 1.2 times the equivalent isotropic thermal parameters of the carbon atoms to which they are covalently bonded. Further details on the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58460.

[9] Interlocking of supramolecular structures is an interesting area in chemical topology, and it has been observed in molecular organic and very few extended inorganic systems: a) J. P. Investigation of Self-Assembled Supramolecular Species in Solution by IL-ESMS, a New Mass Spectrometric Technique**

Keith C. Russell, Emmanuelle Leize, Alain Van Dorsselaer, and Jean-Marie Lehn*

The spontaneous assembly of complementary components into designed architectures has developed recently into a central theme of supramolecular chemistry.[1] In particular, hydrogen bonding has been used for the generation of supramolecular assemblies in solution, in liquid crystals, and in the solid state.[2–5] Whereas solid-state structures may be determined by X-ray crystallography, procedures are greatly needed for investigation of organized species formed in solution, in particular to determine whether their structures are the same as in the solid. Vapor-phase osmometry, membrane osmometry, and gel permeation chromatography have been used and generally yield molecular weights with degrees of error that can be as large as

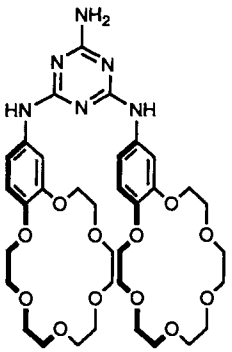
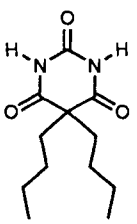
a single assembly unit; in addition they only give an average of all species in solution.



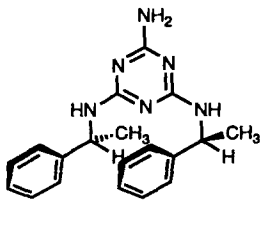
Electrospray mass spectrometry (ESMS)[6] has emerged as a mild method for the characterization of a large range of molecules such as proteins,[7] oligonucleotides,[8] and coordination compounds.[9] No energy is required to ionize the sample, since a solution of preformed ions is used, and only minimal energy is necessary for transferring the ions from solution into the gas phase. A number of noncovalent association complexes have also been examined by ESMS. They include enzyme–substrate, enzyme–product, receptor–ligand, and oligonucleotide associations.[10] Moreover, it is possible to follow by ESMS the formation of metal coordination assemblies under equilibrium conditions and obtain information about the different species present in solution.[11]

Hydrogen-bonded supramolecular assemblies, which are usually stable only in solvents of low polarity, are uncharged in these solutions and thus cannot be studied by ESMS. It is therefore crucial to develop a general method for the examination of such neutral associations in solution. The use of ESMS-active tags, for example cation-binding crown ethers and protonatable dimethylaniline groups, has permitted the characterization of neutral organic molecules such as vitamin D and fullerene derivatives.[12, 13]



We describe here an ion-labeling electrospray mass spectrometry (IL-ESMS) method for the characterization of self-assembled species formed from complementary hydrogen-bonding components in organic solution.

The complementary partners barbituric acid and triaminopyrimidine or triaminotriazine assemble through formation of six hydrogen bonds into species that have been characterized in the solid state by X-ray crystallography. Three types of supramolecular structures have been found depending on the nature of the components: a linear strand (ribbon or tape),[14–16] an undulating strand (or crinkled tape),[16] and a macrocycle (or rosette).[16]



Our goal was to develop ESMS-active tags for the study of hydrogen-bonded supramolecular assemblies with the intent of observing the individual species present in a solution of the self-assembling complementary components **A** and **B**. This may also permit us to estimate the ability of ESMS to characterize labile polyassociated species. Related systems include oligonucleotide duplexes, which are considerably more stable, since the smallest ones studied by ESMS thus far comprised eight base pairs; the partners were held together by a total of 18–24 hydrogen bonds as well as stacking interactions.[10f].

A

B

C

The triazines **A** and **C** were synthesized by reaction of 4′-aminobenzo[18]crown-6 (2 equiv, Janssen Chemicals), or (*R*)- then (*S*)-α-methylbenzylamine (1 equiv each) with 6-amino-2,4-dichloro-1,3,5-triazine[17] at high concentration (76 and 85% yield, respectively). The barbiturate **B** was obtained as previously described.[18] All materials gave the expected spectroscopic data.[19]

Since hydrogen-bonded assemblies such as those formed by the **A**/**B** pair are expected to be destroyed on protonation, ionization was achieved by complexation of potassium ions by the crown ether groups of component **A**. Equimolar mixtures of the partners **A** and **B** (10^{-2} M) in dichloromethane were treated with KPF_6 ($M = 184.1$ Da) (solution S_1, Table 1) and then studied by ESMS. The compositions of the ions observed are listed in Table 2.

Table 1. Composition of the solutions studied by ESMS.

Solution	Components, stoichiometry	Solvent	Concentration [a]	Salt [b]
S_1	**A** + **B**	CH_2Cl_2	10^{-2}	KPF_6
S_2	**A** + **B**	CH_2Cl_2	10^{-3}	KPF_6
S_3	**A** + **B**	CH_2Cl_2	10^{-2}	KPF_6 [c]
S_4	**A** + **B**	benzene	10^{-2}	KPF_6
S_5	**A** + **B**	CH_2Cl_2/pentane (1/1)	10^{-2}	KPF_6
S_6	**B** + **C**	CH_2Cl_2	10^{-2}	–
S_{6a}	**A** + **B** + **C**	CH_2Cl_2	10^{-2}	KPF_6
S_{6b}	**A** + 20**B** + 20**C**	CH_2Cl_2	10^{-2}	KPF_6
S_{6c}	**A** + 20**B** + 20**C**	CH_2Cl_2	10^{-3}	KPF_6
S_7	**A**	CH_2Cl_2	10^{-2}	–

[a] Single-component solutions; in M. [b] Saturated salt solution unless indicated otherwise. [c] Solution half-saturated with salt.

The ES mass spectrum of S_1 (Fig. 1) was measured at $V_c = 10$ V to minimize possible fragmentation of the assemblies. Indeed, at $V_c > 20$ V hydrogen-bonded complexes began to fragment owing to their relatively weak association.[20] Peaks at m/z 412.4 and 969.4 correspond to the differently charged molecules of **A**; the more abundant species is [**A**, $2K^+$, PF_6^-]. As partner **B** was not ionized, it was not detected. Peaks at m/z 1209.7 and 1886.9 correspond to an $\mathbf{A_3B_3}$ complex. The ion giving the peak at m/z 1209.7 is not an unspecific aggregate of **A** and **B**, because it is not a singly charged ion (isotope pattern not resolved with a resolution of 1500 at m/z 1300). A less intense peak at m/z 1329.8 is observed for the doubly charged ion of $\mathbf{A_2B_3}$. The same signals were found for the **A**/**B** mixture at 10^{-3} M (S_2), although the peaks were less intense.

The charge state of these three peaks was confirmed by the ESMS study of S_3 (Fig. 2). S_3 contains half as much KPF_6 as S_1 does, and thus more peaks corresponding to complexes of composition $\mathbf{A_3B_3}$ and $\mathbf{A_2B_3}$ occur, by the loss of one or more KPF_6 units (m/z 1148.5, 1087.3, 1025.7, and 1237.9, respectively). The detection of the ion [**A** + K^+] (m/z 785.5) as the base peak indicates a redistribution of charge states of **A** by loss of KPF_6. A m/z difference of 61.2 (= $M(KPF_6)/3$) obtained between the four peaks at m/z 1025.7, 1087.3, 1148.5, and 1209.7

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0202-0210 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 2

Table 2. Summary of m/z values of ions detected by ESMS for **A** and the complexes **M** (= $\mathbf{A_3B_2}$, $\mathbf{A_2B_3}$, and $\mathbf{A_3B_3}$) [a].

	A	$\mathbf{A_2B_3}$	$\mathbf{A_3B_2}$	$\mathbf{A_3B_3}$
M [b]	746.8	2214.5	2721.0	2961.3
$\mathbf{M} + K^+$	785.5	–	–	–
$\mathbf{M} + K^+ + KPF_6$	969.4	–	–	–
$\mathbf{M} + 2K^+$	412.4	–	1399.0	1519.1
$\mathbf{M} + 2K^+ + KPF_6$	–	1237.9	1491.0	1611.0
$\mathbf{M} + 2K^+ + 2KPF_6$	–	1329.8	1582.9	1703.0
$\mathbf{M} + 2K^+ + 3KPF_6$	–	–	1674.9	1794.9
$\mathbf{M} + 2K^+ + 4KPF_6$	–	–	–	1886.9
$\mathbf{M} + 3K^+$	–	–	–	1025.7
$\mathbf{M} + 3K^+ + KPF_6$	–	–	–	1087.3
$\mathbf{M} + 3K^+ + 2KPF_6$	–	–	–	1148.5
$\mathbf{M} + 3K^+ + 3KPF_6$	–	–	–	1209.7

[a] Graphic representations of the assemblies are given in Figs. 1–3. For the 2:3 assemblies (second and third columns) only one of the possible superstructures is shown. [b] Calculated molecular weights of complexes **M**.

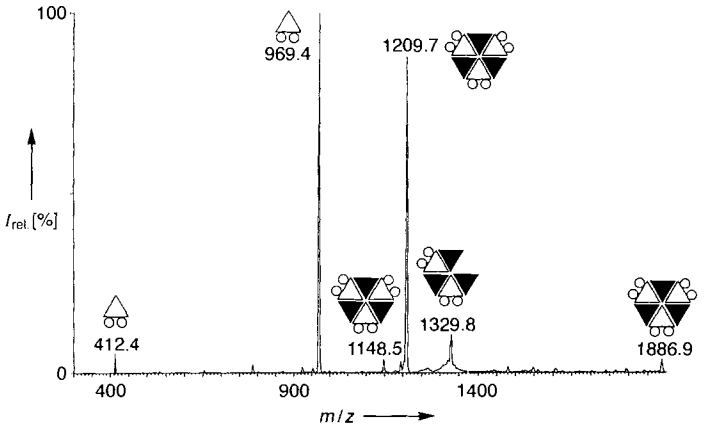


Fig. 1. ES mass spectrum of S_1 (Table 1). The observed ions are summarized in Table 2. The schematic representations of the complexes composed of **A** and **B** do not indicate the contributions of the K^+ ions and KPF_6 molecules to the m/z values.

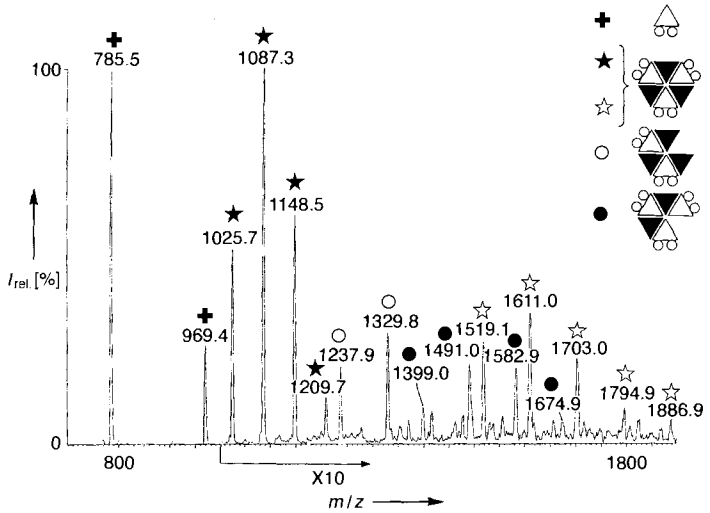

Fig. 2. ES mass spectrum of S_3 (Table 1). The observed ions are summarized in Table 2.

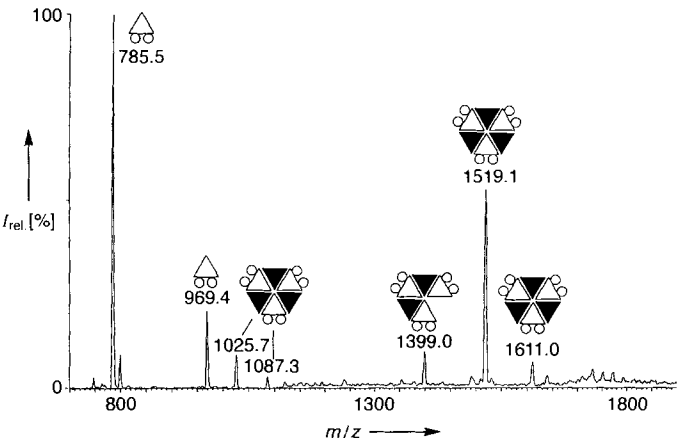
(Table 2) corresponds to the loss of three, two, and one KPF_6, respectively, from the ion at m/z 1209.7, indicating that these peaks indeed arise from triply charged ions. A m/z difference of 92.5 (= $M(KPF_6)/2$) for the series of peaks m/z 1519.1, 1611.0, 1703.0, 1794.9, and 1886.9 (Table 2) corresponding to the loss of four, three, two, and one KPF_6, respectively, from the ion at m/z 1886.9, and for peaks m/z 1237.9 and 1329.8 (Table 2) corresponding to the loss of one KPF_6 from the ion at m/z 1329.8, confirm the doubly charged state of these ions. The peaks at m/z 1399.0, 1491.0, 1582.9, and 1674.9 (Table 2) result from the doubly charged ions of the complex $\mathbf{A_3B_2}$, which were not present in the spectrum of S_1.

The addition of 10% MeOH (a solvent known to disrupt hydrogen-bonded assemblies) to S_1 eliminated all peaks from the mass spectrum corresponding to assemblies of **A** and **B**; only a single intense peak at m/z 969.7 for $[\mathbf{A} + 2K^+ + PF_6^-]$ was seen. The results obtained provide evidence that the assemblies observed were indeed those present in solution (no additional assembly in the gas phase), and that ion–molecule reactions were not taking place.[21]

The ES mass spectra recorded in less polar solvents such as benzene (S_4, Fig. 3) and pentane/dichloromethane 1/1 (S_5)



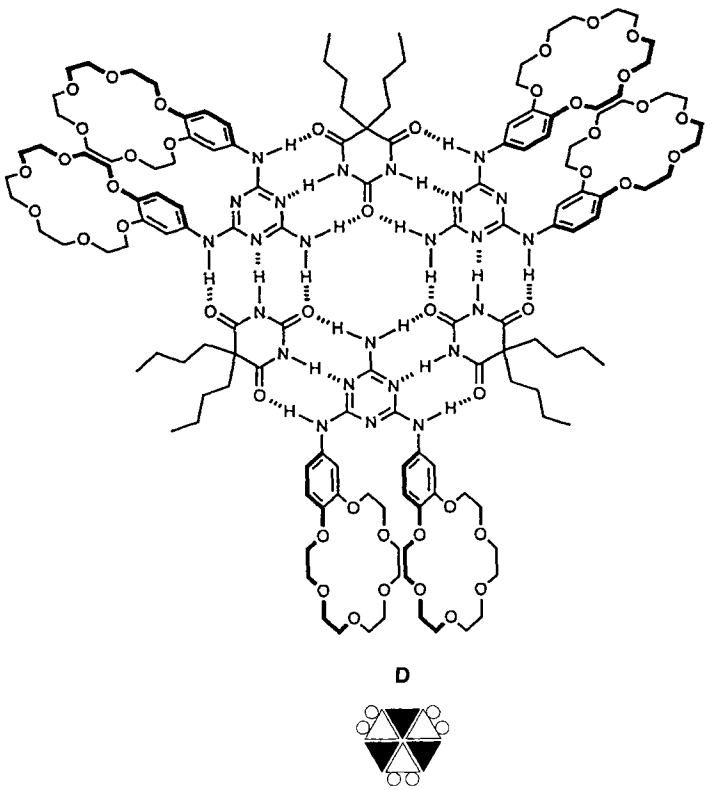


Fig. 3. ES mass spectrum of S_4 (Table 1). The observed ions are summarized in Table 2.

showed the characteristic doubly charged ions (m/z 1519.1, 1611.0) and triply charged ions (m/z 1025.7, 1087.3) of the complex $\mathbf{A_3B_3}$, as well as the doubly charged ion (m/z 1399.0) of $\mathbf{A_3B_2}$ (Table 2). In contrast to the spectra obtained in dichloromethane, no adducts of KPF_6 were found for these ions, and the doubly charged state was most abundant. This difference can be explained by poorer solvation of KPF_6 by these solvents as compared to dichloromethane.[22]

These ESMS studies have thus allowed the characterization of three complexes in solution: $\mathbf{A_3B_3}$, $\mathbf{A_2B_3}$, and $\mathbf{A_3B_2}$. Assembly $\mathbf{A_3B_3}$ was the predominant species detected. Since no larger complexes were observed, we can attribute to $\mathbf{A_3B_3}$ a closed structure of a supramolecular macrocycle (**D**), similar to that observed for related systems in the solid state.[16] Such a structure could explain the higher stability of $\mathbf{A_3B_3}$ relative to that of $\mathbf{A_3B_2}$ and $\mathbf{A_2B_3}$. Indeed, in contrast to $\mathbf{A_3B_2}$ and $\mathbf{A_2B_3}$, the $\mathbf{A_3B_3}$ assembly was not influenced by the amount of salt introduced to ionize the complexes.[23] The possible structures for $\mathbf{A_3B_2}$ and $\mathbf{A_2B_3}$ in solution again could be a linear ribbon, and undulating ribbon, or a partial rosette (Fig. 4).

ESMS has proved its utility for the characterization of hydrogen-bonded complexes, but only species containing charged groups under near physiological conditions have previously been observed. For neutral assemblies that are destroyed by protonation the present results indicate that charge may be introduced through ion binding to a suitably designed compo-

nent. Thus component **A** in the presence of a complexable salt allows neutral species that would otherwise not be evident to be characterized by ESMS. By extension, this points to an *ion labeling method* applicable to the study of any self-assembled structure in solution capable of incorporating the labeling agent **A** added in trace amounts. In the absence of salts the label **A**, as well as any assembly it is part of, is invisible to ESMS, since it has no charge ("ion label" OFF). But in the presence of a salt, **A** coordinates a cation and the "ion label" containing species become visible by ESMS ("ion label" ON). This was tested by the introduction of **A** into a preformed assembly of **B** · **C**.

Fig. 4. Possible architectures of the assemblies composed of 2×3 units: supramolecular macrocycle or rosette (left), ribbon or tape (center), undulating ribbon (right). White and black triangles represent components **A** or **C** and **B**, respectively.

The ESMS study of the species present in an equimolar mixture of **B** and **C** (10^{-2} M in dichloromethane; S_6) was performed by mixing with label **A** (10^{-2} M in dichloromethane; S_7) in two proportions, S_6:S_7 = 1:1 (S_{6a}) and 20:1 (S_{6b}). No peaks were observed in the spectrum of S_{6a} before addition of salt (label OFF). After the addition of KPF_6 to the solution (label ON), the spectrum (Fig. 5a) showed two major species, the ion label **A** (*m/z* 969.4) and the complex $\mathbf{A_2B_3C}$ (*m/z* 1497.1), as well as three other complexes, $\mathbf{A_3B_3}$ (*m/z* 1209.7), $\mathbf{AB_2C}$ (*m/z* 1784.4) and $\mathbf{AB_3C_2}$ (*m/z* 2359.2). In the spectrum of S_{6b} (Fig. 5b) the major species observed were **A** and $\mathbf{AB_3C_2}$; as expected the intensity of the peak corresponding to $\mathbf{A_2B_3C}$ was very weak. The peaks for assemblies $\mathbf{A_3B_3}$ and $\mathbf{AB_2C}$ disappeared, and two new species were present: **ABC** (*m/z* 1544.3) and $\mathbf{AB_2C_2}$ (*m/z* 2119.0).

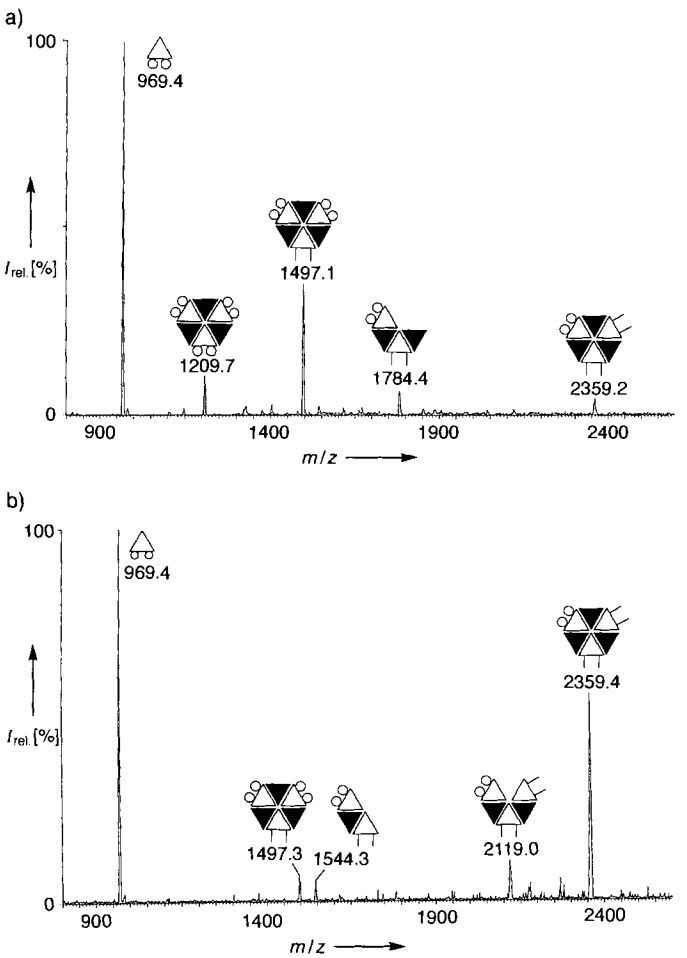

Fig. 5. ES mass spectra of solutions S_{6a} (a) and S_{6b} (b). **A** (M = 746.8) is characterized by the peak *m/z* 969.4 [$\mathbf{A} + 2K^+ + PF_6^-$], $\mathbf{A_3B_3}$ (M = 2961.3) by *m/z* 1209.7 [$\mathbf{A_3B_3} + 6K^+ + 3PF_6^-$], $\mathbf{A_2B_3C}$ (M = 2548.9) by *m/z* 1497.1 [$\mathbf{A_2B_3C} + 4K^+ + 2PF_6^-$], $\mathbf{AB_2C}$ (M = 1561.8) by *m/z* 1784.4 [$\mathbf{AB_2C} + 2K^+ + PF_6^-$], $\mathbf{AB_3C_2}$ (M = 2136.5) by *m/z* 2359.2 [$\mathbf{AB_3C_2} + 2K^+ + PF_6^-$], **ABC** ($M$ = 1321.5) by *m/z* 1544.3 [$\mathbf{ABC} + 2K^+ + PF_6^-$], $\mathbf{AB_2C_2}$ (M = 1896.2) by *m/z* 2119.0 [$\mathbf{AB_2C_2} + 2K^+ + PF_6^-$].

Thus, when a large proportion of ion label was introduced, the major species was $\mathbf{A_2B_3C}$, whereas when the proportion of **A** was low, the $\mathbf{AB_3C_2}$ complex became most abundant. These observations are in agreement with a statistical incorporation of the ion label **A** into the neutral assembly. Again, no assemblies with molecular weights greater than that of a six-component species were observed, suggesting that this assembly also prefers a macrocyclic rosette architecture (Fig. 4). The same species were found for the 1/20/20 **A**/**B**/**C** mixture at 10^{-3} M (S_{6c}).

In conclusion, we have shown that electrospray mass spectrometry can be used to study hydrogen-bonded self-assembled species. We have developed a new methodology for which we suggest the name ion-labeling electrospray mass spectrometry (IL-ESMS), which can be used to observe discrete neutral assemblies in solution. The present results indicate that the range of species likely to be studied by ESMS can be extended to labile supramolecular species formed by self-assembly. In the cases studied the highest molecular weight species observed is a six-component entity, most likely possessing the closed structure of a supramolecular macrocycle **D**. By designing appropriate ion-labeling components that combine an ion binding site (such as a crown ether or a cryptand) with specific recognition groups, it should become feasible to extend this IL-ESMS procedure to

the investigation of a wide variety of hydrogen-bonded supramolecular assemblies and more generally of self-assembly through any type of intermolecular interaction. Such work is currently in progress in our laboratory.

Experimental Procedure

Positive-ion ES mass spectra were obtained on a VG BioQ triple quadrupole apparatus with a mass-to-charge (m/z) range up to 4000 (VG Bio Tech Ltd, Altrincham, UK). The electrospray source was heated to 50 °C. The sampling cone voltage (V_c) [6] was at 10 V to avoid fragmentation of the assemblies. Sample solutions were introduced into the mass spectrometer source with a syringe pump (Harvard type 55 1111; Harvard Apparatus Inc., South Natick, MA, USA) at a flow rate of 6 $\mu L\,min^{-1}$. Calibration was performed using protonated horse myoglobin. The resolution was usually about 500 at m/z 1000 (10% height). Scanning was performed from m/z 200 to 2200 in 15 s. The data system was operated as a multichannel analyzer, and several scans were summed to obtain the final spectrum. Samples for ESMS were prepared by dissolving equimolar amounts of the components in the appropriate solvent (dichloromethane, benzene, pentane) to achieve the concentrations listed in Table 1. Solutions containing salts were prepared by adding 0.5 mg of salt (KPF_6, $NaClO_4$, CsCl) in 0.5 mL of solution and sonicating briefly. The solution was removed from the excess salt with a pipette and directly analyzed. Labeling experiments were performed by adding the desired ratio of equimolar solutions of the inactive label (**A** without KPF_6) and the assembly of interest, and then adding KPF_6 as previously described.

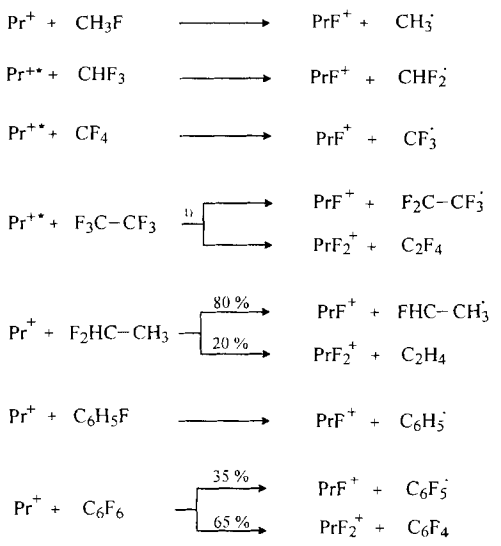
[21] For studies at the rather high concentration (10^{-2} M) used in this work, ion–molecule reactions in the gas phase might occur in the ES source. To be certain that peaks observed for assemblies $\mathbf{A_3B_3}$, $\mathbf{A_2B_3}$, and $\mathbf{A_3B_2}$ were not an artifact of ESMS, we studied a solution in which **A** was replaced by benzo[18]crown-6 (18C6), a compound unable to form hydrogen bonds. The only peaks observed in the ES mass spectrum of this solution corresponded to ions $18C6/K^+$, $(18C6)_2/K^+$ and $(18C6)_2/2K^+$. No peaks for possible assemblies of **B** and macrocycle were observed.
[22] The ionization of the complexes in S_1 was also examined by adding $NaClO_4$ and CsCl, instead of KPF_6. With $NaClO_4$ the results were similar to those obtained with KPF_6: adducts of KPF_6/K^+ were replaced by adducts of $NaClO_4/Na^+$. In contrast, with CsCl, $\mathbf{A_3B_3}$ was the only complex detected, but in two charge states: $[\mathbf{A_3B_3} + 3Cs^+]$ and $[\mathbf{A_3B_3} + 2Cs^+]$. The difference in the ionization might be explained by the specific complexation of the alkali metal ions by the crown ether. Indeed, Cs^+ is known to form the sandwich complex $(18C6)_2/Cs^+$, while Na^+ and K^+ give the complexes $18C6/Na^+$ and $18C6/K^+$.
[23] Interestingly, $\mathbf{A_2B_3}$ was present only for large amounts of salt and $\mathbf{A_3B_2}$ only for smaller quantities of salt.

Gas-Phase Activation of Fluorocarbons by "Bare" and Coordinated Praseodymium Cations**

Christoph Heinemann, Norman Goldberg, Inis C. Tornieporth-Oetting, Thomas M. Klapötke, and Helmut Schwarz*

Dedicated to Professor Josef Seibl on the occasion of his 70th birthday



The activation of the strong carbon–fluorine bond by transition metal complexes is a formidable task in organometallic chemistry.[1] Immense industrial interest in this field is due to the widespread use of fluorocarbons and mixed fluorohalocarbons, which takes advantage of their high thermal and chemical stability. Evidence for the involvement of these substances in the mechanisms of stratospheric ozone depletion has made their future use questionable, and there is now a need for selective and efficient chemical conversion. Similar to the growing body of information on C–H and C–C activation of hydrocarbons, gas-phase studies on the intrinsic reactivities of "bare" and ligated transition metal cations[2] are expected to help in the understanding of the molecular mechanisms in the transition metal assisted cleavage of a C–F bond. In this vein, we report on the activation of various aliphatic and aromatic C–F bonds by "bare" Pr^+ ions and small praseodymium complexes PrL^+ (L = O, F) as observed by Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS). Furthermore, we present the first observation of *neutral* praseodymium monofluoride PrF and praseodymium difluoride PrF_2 in the gas phase by means of neutralization–reionization mass spectrometry (NRMS).

In solution-phase chemistry, the homolytic cleavage of C–F bonds in perfluorinated olefins has been achieved with electrophilic divalent lanthanide reagents of the type $LnCp^*_2$ (Ln = Eu, Sm, Yb; $Cp^* = C_5Me_5$).[3] As a first example for

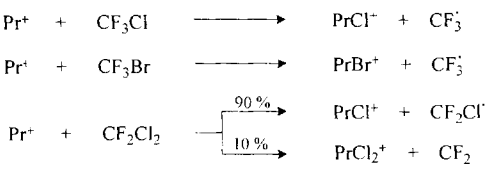
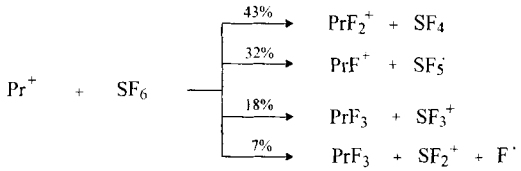
intermolecular activation of saturated fluorocarbons, Bergman et al. reported recently that the actinide complex $[(MeC_5H_4)_3U(tBu)]$ can abstract a fluorine radical from a variety of fluoroalkanes.[4] In the gas phase the anionic tricarbonylmanganese complex $[Mn(CO)_3]^-$ was shown to activate C–F bonds,[5] and cationic fluorolanthanide complexes LnF^+ (Ln = La, Ce, Pr) as well as UF^+ have been observed in nuclear fission experiments with ^{235}U in the presence of CF_4.[6] In line with these observations we find that in ion/molecule reactions of Pr^+ and a variety of fluorocarbons, homolytic cleavage of C–F bonds is a quite general phenomenon (Scheme 1).



Scheme 1. Pr^{+*} represents a Pr^+ ion that is kinetically or electronically excited prior to reaction. Thermally excited Pr^+ does not react. 1) Because this reaction is endothermic no relative intensities can be given.

In the simplest example Pr^+ formally abstracts a fluorine atom from methyl fluoride (bond dissociation energy, $E_B(H_3C-F) = 112.8 \pm 0.3$ kcal mol^{-1})[7] to form the PrF^+ ion. The reaction rate is 16% of the theoretical collision rate k_{coll}[8] ($k_{exp} = 3 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}; $k_{coll} = 19 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}). In the corresponding reaction with 1,1-difluoroethane ($E_B(H_3CFHC-F) = 113$ kcal mol^{-1}) an additional double defluorination pathway gives rise to PrF_2^+ ($PrF^+ : PrF_2^+ = 4:1$). However, fluorine abstraction from CF_3H ($E_B(F_2HC-F) = 128 \pm 3$ kcal mol^{-1}), CF_4 ($E_B(F_3C-F) = 132.4$ kcal mol^{-1}), and C_2F_6 ($E_B(F_3CF_2C-F) = 127$ kcal mol^{-1}) is observed only if the Pr^+ ions are not properly thermalized prior to reaction, that is, if they are kinetically or electronically excited. Since a reliable value for the bond dissociation energy of PrF^+ is not available, it remains unclear whether cleavage at the C–F bond is endothermic, whether the initially formed ion/molecule complex has too short a lifetime (this may especially apply for the unpolar and unpolarizable CF_4 and C_2F_6 molecules), or whether a substantial activation barrier is operative. However, assuming that for cleavage of a simple single bond the barrier should be at most very small, one may tentatively derive an upper value of 131 kcal mol^{-1} for $E_B(Pr^+-F)$ from the *non*observation of C–F bond activation in CHF_3.

Similar to its reactions with aliphatic fluorocarbons Pr^+ cleaves the aromatic C–F bond in fluorobenzene ($E_B(C_6H_5-F) = 125.3 \pm 2.3$ kcal mol^{-1}) at nearly 80% of the theoretical collision rate ($k_{exp} = 11 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}; $k_{coll} = 14 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}). For comparison, this lanthanide cation is unreactive towards benzene. The reaction with C_6H_5F provides a lower limit for the bond strength of PrF^+, from which we derive an experimental bracketing value of 127 ± 4 kcal mol^{-1}. In contrast to Pr^+, the less "fluorophilic" Fe^+ ion promotes the loss of hydrogen fluoride from fluorobenzene, resulting in the formation of the cationic iron–benzyne complex $[FeC_6H_4]^+$[9]. In the reaction of Pr^+ with hexafluorobenzene ($E_B(C_6F_5-F) = 116.6 \pm 16$ kcal mol^{-1}), the double defluorination pathway resulting in the formation of PrF_2^+ and C_6F_4 predominates over the abstraction of a single fluorine atom. This experiment supports earlier conjectures from solution chemistry[1, 10] that tetrafluorobenzyne, the existence of which is still unproved to the best of our knowledge, is an intermediate in the activation of hexafluorobenzene by electron-deficient lanthanide complexes.



In the reactions of mixed fluorohalocarbons with Pr^+ (Scheme 2), we observed exclusive activation of the weaker

Scheme 2.

C–Cl or C–Br bonds of the substrate (e.g. $E_B(Cl_2FC-F) = 122.7$ kcal mol^{-1}, $E_B(ClF_2C-Cl) = 88.7$ kcal mol^{-1}), although C–F bond activation is thermochemically possible. These experiments provide lower limits of 88.7 and 56.8 kcal mol^{-1} for the bond dissociation energies of Pr^+-Cl and Pr^+-Br, respectively.

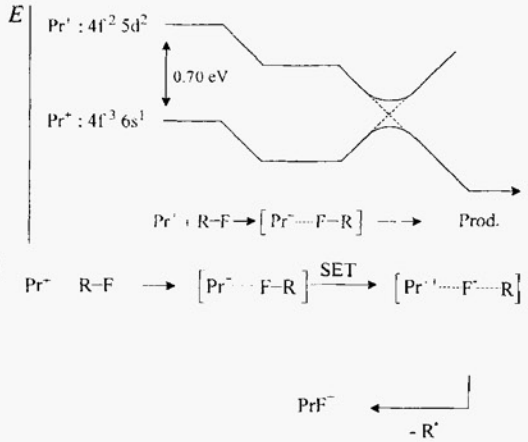
Finally, the unpolar and highly unreactive sulfur hexafluoride molecule SF_6 is also activated by Pr^+ in a kinetically efficient process ($k_{exp} = 7.8 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}; $k_{coll} = 7.1 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}) (Scheme 3). Here we observe,

Scheme 3.

in addition to PrF^+ and PrF_2^+, the sulfur fluoride ions SF_3^+ and SF_2^+ as primary reaction products, similar to the results recently reported for the corresponding reaction of Sc^+.[11] The exothermic formation of the SF_x^+ species is in accord with their experimental heats of formation[7] and appears to be driven by the stability of neutral PrF_3.

If one follows the commonly accepted view[12] that the 4f electrons of the lanthanide elements are usually chemically inert, then it is indeed quite remarkable that Pr^+ shows the observed reactivity towards fluorocarbons. In particular, the electronic ground state configuration of this cation[13] ($4f^3 5d^0 6s^1$) should not be suitable for insertion into a single bond, a process for which a minimum of *two* valence electrons (i.e. *non*-f electrons) appears necessary.[14] Formally, one may think of a two-electron donation from the metal cation to the σ^* orbital of the

C–X bond to be activated. In accord with this argument, Pr^+ has been shown to be unreactive with most hydrocarbon substrates.[14, 15] Since we have no indication that excited states of Pr^+ were not efficiently quenched in our experiments, we propose two possible mechanistic scenarios (Fig. 1) to explain the observed ground-state reactivity of Pr^+ with fluorocarbons.



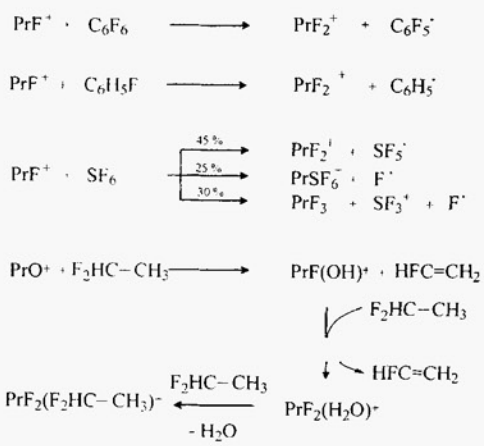


Fig. 1. Mechanisms for C–F bond activation by ground-state Pr^+ ions. a) Curve-crossing model involving the low-lying $4f^25d^2$ electronic configuration of Pr^+ (Prod. = products); b) Single electron transfer (SET) followed by fluorine transfer in the initially formed ion/molecule complex.

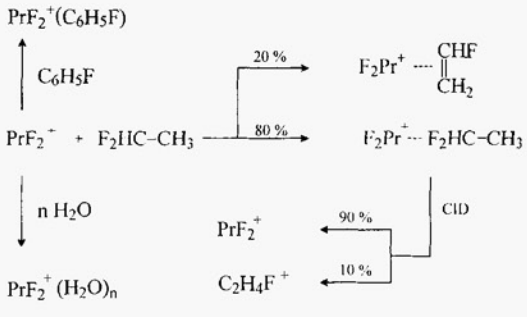
1) A curve-crossing model, favored by the strong spin–orbit coupling present in the lanthanide series (Fig. 1a):[13] Here, transitions from the potential energy surface of the Pr^+ ground state to a potential energy surface of an appropriate low-lying excited state of Pr^+ (lowest state with $4f^25d^2$ configuration: +0.70 eV; lowest state with $4f^25d^16s^1$ configuration: +0.94 eV[13]) can occur due to avoided crossings. Essentially, this results in a lowering of the activation barrier for the insertion of the ground state metal cation into the activated bond.[16] 2) Single-electron transfer (SET) from Pr^+ to the fluorine atom of the substrate in the initial ion/molecule complex (Fig. 1b): This step is followed by C–F bond cleavage, as postulated in similar cases in solution chemistry.[1]



In addition to the reactions of "bare" Pr^+ ions, small praseodymium complexes PrL^+ (L = O, F) also induce C–F bond activation in various substrates (Scheme 4). PrF^+ reacts with C_6H_5F by abstraction of a fluorine atom, indicating that the second fluorine atom in PrF_2^+ has a bond dissociation energy comparable to the first one ($E_B(FPr^+-F) > 125$ kcal mol^{-1}). However, the secondary processes are often significantly slower than the primary reactions (e.g. for $Pr^+ + SF_6$ $k = 7.8 \times 10^{-10}$ cm^3 s^{-1} molecule^{-1}; for $PrF^+ + SF_6$ $k = 5 \times 10^{-11}$ cm^3 s^{-1} molecule^{-1}). Since PrF^+ has a open-shell $4f^3$ electronic configuration,[17] its reactivity is even more surprising than that of Pr^+ and indicates that the 4f electrons of lanthanide ions can in fact be chemically active if the driving force for the reaction is sufficiently large and solvation effects are absent. We note in passing that PrF^+ can be oxidized by N_2O to form the mixed fluorooxo complex $PrOF^+$ with praseodymium in a formal oxidation state of +IV.

Even more interesting is the reactivity of PrO^+ (generated from Pr^+ and N_2O), a species with an extremely strong Pr^+–O bond ($E_B(Pr^+-O) = 191$ kcal mol^{-1}[7]), which is generally unreactive with hydrocarbons. For example, we only observed formation of an adduct complex when this cationic oxide was exposed to benzene, while for the less oxophilic FeO^+ oxygen transfer to the unsaturated substrate has been reported.[18] However, upon reaction of PrO^+ with 1,1-difluoroethane, very slow (relative reaction rate 1% compared to the "bare" Pr^+ cation) addition of hydrogen fluoride to PrO^+ takes place (Scheme 4). In kinetically more efficient subsequent reaction steps an additional molecule of HF is added to this complex, and H_2O is replaced by one molecule of the substrate. These observations suggest that the overall reaction proceeds via a mixed cationic fluorohydroxo complex and the cationic difluoropraseodymium complex, whereby the formerly strongly bound oxygen ligand becomes part of the loosely bound water molecule. Elimination of HF from the substrate proceeds presumably by a 1,2 mechanism, since the most promising substrate for 1,1 elimination of HF, trifluoromethane, is not activated by PrO^+. With reference to the theoretical analysis of other surprisingly slow ion/molecule reactions involving transition metal oxo cations,[16] the very small reaction efficiency in the PrO^+/1,1-difluoroethane system suggests that a spin–orbit-mediated curve-crossing mechanism (Fig. 1) may be operative in this case as well.

While PrF_2^+ is unreactive with CF_4 and SF_6, we observed formation of adduct complexes with water, fluorobenzene, and 1,1-difluoroethane (Scheme 5). Collision-induced dissociation of the $F_2Pr^+-F_2HC-CH_3$ adduct complex at low energies leads only to PrF_2^+. At higher collision energies the appearance of the $C_2H_4F^+$ ion (accompanied by formation of the neutral PrF_3) suggests that in the adduct 1,1-difluoroethane coordinates to the cationic transition metal center through a fluorine atom. These observations point to results from solution-phase chemistry, where precoordination of the substrate molecule to the transi-

Scheme 4.

Scheme 5. n = 1,2

tion metal center prior to activation of the C–F bond has been deduced from solvation effects.[3] In addition to adduct formation, PrF_2^+ also induces loss of hydrogen fluoride from this substrate, resulting in the formation of the $CHF{=}CH_2{-}PrF_2^+$ complex.

As a general conclusion we note that the strength of the praseodymium–fluorine bond is apparently the driving force in the reactions of the praseodymium cation with different fluorocarbons. Overall, Pr^+ activates exclusively C–F and not C–H or C–C bonds. However, as already stressed in a recent review,[1] the unfavorable thermodynamics of these systems severely restrict the design of *catalytic* cycles[1b] for C–F bond activation.

The stability of rare earth fluorides is not restricted to the most common +III oxidation state, as shown by the characterization of various lanthanide subfluorides by spectroscopic techniques[19] and their preparative-scale synthesis.[20] However, neutral praseodymium(I) fluoride and praseodymium(II) fluoride are unknown in the condensed phase, and solid lanthanide(II)fluorides with exact LnF_2 stoichiometry have only been characterized for Ln = Sm, Eu, Yb, and presumably Tm.[20] Among the lanthanide fluorides studied in the gas phase,[17a, 19] neutral PrF and PrF_2 are still missing. In this context, we have applied the technique of neutralization–reionization mass spectrometry (NRMS)[21] to PrF^+ and PrF_2^+. The NRMS spectra (Fig. 2) give clear evidence that neutral

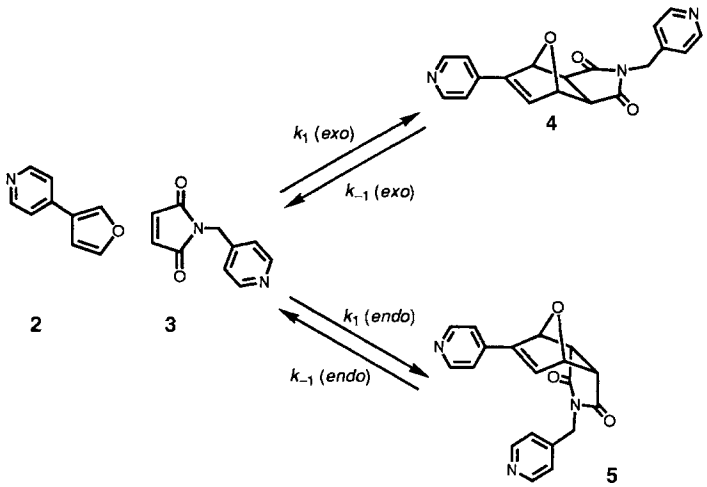
praseodymium mono- and difluoride are in fact stable chemical species, at least under gas-phase conditions.

Experimental Procedure

Ion/molecule reactions under thermal conditions were performed using a Spectrospin CMS-47X Fourier transform ion cyclotron resonance mass spectrometer equipped with an external ion source (for details see ref. [22]). $^{141}Pr^+$ ions were generated by laser desorption/laser ionization by focusing the beam of a Nd:YAG laser (Spectron Systems; $\lambda = 1064$ nm) onto a piece of pure praseodymium metal (Strem, 3N REO). The ions were transferred to the analyzer cell by a system of electrostatic potentials and lenses, decelerated, trapped in the field of a superconductive magnet (Oxford Instruments, maximum field strength: 7.05 T), and thermalized with pulsed-in argon (maximum pressure ca. 5×10^{-5} mbar). Reactants were admitted to the cell by means of a leak valve at a stationary pressure of $(1-5) \times 10^{-8}$ mbar (as measured by an uncalibrated ion gauge, BALZERS IMG070). Reaction products were analyzed by their high-resolution mass spectra, and their pathways were investigated by using MS/MS and double-resonance techniques. All rate constants were derived from the pseudo-first-order decay of the starting ion and are reported with an estimated accuracy of ±30%.



For the neutralization–reionization (NRMS) experiments a large-scale four-sector tandem mass spectrometer was used [23]. The PrF^+ ions were produced by fast-atom bombardment (FAB) of PrF_3 [24], whereas PrF_2^+ was generated in a chemical ionization source by ionizing tris(hexafluoroacetylacetonato)-praseodymium (Strem) in the presence of NF_3. The mass-selected ions were neutralized in the first part of a tandem collision cell upon collisions with xenon (80% transmission, T). Ions that did not undergo neutralization in this region were deflected from the beam of neutral molecules by an electrode (charged at 1000 V) situated between the two collision cells. Neutralized molecules were reionized by colliding them with oxygen (80% T). The *minimal* life time t, which can be derived from the transit time of the neutral particles to travel from the first to the second part of the tandem-collision cell, is of the order of 10 μs.

Free-Energy Profile for a Host-Accelerated Diels–Alder Reaction: The Sources of *exo* Selectivity**

Christopher J. Walter and Jeremy K. M. Sanders*

The use of free-energy profiles[1] for enzyme-catalyzed reactions has transformed the study of enzyme mechanisms, because the dependence of the height of the energy barrier on substrate variation and on enzyme mutation allows one to dissect out rationally the important contributions to binding and catalysis.[2] We have now applied this approach to enzyme mimics as exemplified by the porphyrin trimer **1**[3] and have examined its

exo-selective acceleration of the Diels–Alder reaction shown in Scheme 1.[4, 5] There are as yet few effective enzyme mimics for bimolecular reactions, because the design rules governing their operation are not understood;[6, 7] in particular the importance of factors such as substrate strain, host flexibility, solvation, and quality of fit is not yet clear. We have begun to uncover the rules for our hosts by elucidating some of the binding and kinetic parameters for the reactions in Scheme 1, and in doing so have acquired some insight into the *exo* selectivity of **1**. We also demonstrate the accelerated conversion of *endo* adduct to *exo* adduct by **1**.

The Diels–Alder reaction has rich stereo- and regiochemistry, stringent geometrical requirements, and no need for external reagents, and it has been the subject of related studies using catalytic antibodies.[8] The reaction also offers the possibility of altering stereo- and regiochemistry through controlling the transition state within a cavity. We have used a furan-derived diene and maleimide-derived dienophile, because this combination reacts reversibly,[9] giving the opportunity of studying the kinetics, and therefore the approach to the transition states, in both the forward and reverse directions.[10] The reaction in Scheme 1 was inhibited by strongly bound products; this could have been avoided by engineering a second step,[8] but the apparent disadvantage of lack of turnover is outweighed by the direct access to the transition state energies available from a study of the unimolecular reverse reactions as described below.

The equilibrium constant for the reaction shown in Scheme 1 is quite large (k_1 (*exo*)/k_{-1} (*exo*) is approximately 5000 M^{-1} in $C_2H_2Cl_4$ at 30 °C, decreasing to 400 at 60 °C), but the equilibrium at millimolar concentrations lies on the side of the starting compounds. The relative orientations of the pyridine groups in the two adducts are very different, and molecular models suggested that the *endo* adduct would fit less well into the cavity of the trimer than the *exo* adduct would. The measured binding constants confirm this; the *exo* adduct binds around 15 times more strongly in $C_2H_2Cl_4$ at 30 °C (9×10^6 M^{-1} vs 6×10^5 M^{-1}) and six times more strongly at 60 °C (4.6×10^5 M^{-1} vs 8×10^4 M^{-1}). In the absence of porphyrin trimer, the *endo* adduct obtained by kinetic control is a significant product at low temperature, while the *exo* adduct obtained by thermodynamic control is the only product detected at high temperatures; at 60 °C the *exo*/*endo* ratio is roughly 4 initially, but the *endo* adduct then disappears.

Addition of one equivalent of trimer to the two reactants (0.9 mM each in $C_2H_2Cl_4$) accelerates the forward Diels–Alder reaction around 1000-fold at 30 °C and 200-fold at 60 °C, yielding the *exo* adduct as the only detectable product.[4, 5] The initial

reaction rate in the presence of trimer is almost temperature independent under these conditions, because as the temperature is raised, the increase in the intrinsic rate of the reaction inside the porphyrin cavity is almost exactly offset by weaker substrate binding.[5]

The forward and reverse reactions shown in Scheme 1 were followed at 60 °C by NMR spectroscopy in the absence of trimer. The derived rate constants (Table 1) were obtained by

Table 1. Rate constants for the forward and reverse Diels–Alder reaction in the presence (+) and absence (−) of trimer **1** [a].

	− Trimer	+ Trimer
$k_1(exo)$	220 (±40) $s^{-1} mol^{-1} dm^3$	ca. 1000 s^{-1} [b]
$k_{-1}(exo)$	0.55 (±0.1) s^{-1}	0.7 (±0.2) s^{-1}
$k_1(endo)$	50 (±20) $s^{-1} mol^{-1} dm^3$	ca. 10 s^{-1} [b]
$k_{-1}(endo)$	12 (±5) s^{-1}	4 (±2) s^{-1}

[a] At 60 °C in $C_2D_2Cl_4$. All rate constants have been multiplied by 10^6. [b] Estimated from heights of the energy barriers in Fig. 1; the value for $k_1(exo)$ within the cavity is a lower limit.

curve fitting and allowed the fixing of the levels of the *endo* and *exo* products and transition states in the energy profile relative to those of the starting materials (Fig. 1). The binding constants at 60 °C for substrates and products were also converted to free energies to give the energy levels for the bound species. Finally the rates for the unimolecular reverse reaction for each bound adduct (k_{-1} (*exo*) and k_{-1} (*endo*)) within the trimer cavity were measured by NMR spectroscopy as described in the experimental section. These rates provide the activation energies for reaching the bound transition states from the bound Diels–Alder adducts.[11] The resulting complete free energy profile for the reaction at 60 °C is shown in Figure 1.

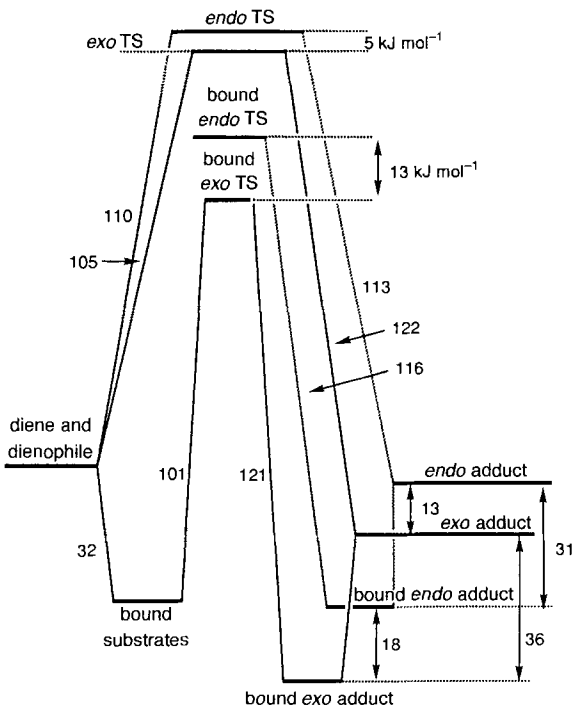

Fig. 1. Free-energy profiles for the Diels–Alder reaction at 60 °C in $C_2H_2Cl_4$ solution. TS = transition state.

The profile identifies three sources of the *exo* selectivity in the trimer-accelerated reaction: 1) the *endo* adduct is less stable thermodynamically by about 13 kJ mol^{-1}; 2) since trimer **1** binds the *endo* adduct less strongly, the *endo* complex is 18 kJ mol^{-1} less favorable than the *exo* complex; 3) the trimer slows the reverse reaction of the *endo* adduct by threefold (Table 1), showing that the *endo* transition state is less well recognized by the trimer than the *endo* adduct. By contrast, the reverse reaction of the *exo* adduct is not slowed by trimer: the *exo* transition state is as well recognized as the *exo* adduct.

These three factors combine such that the *endo* transition state within the trimer cavity is some 13 kJ mol^{-1} higher in energy than the *exo* transition state, giving a predicted difference of more than 100-fold in the forward rates for formation of the two adducts inside the cavity. This prediction is consistent with our inability to detect *endo* product. The energies of the bound transition states derived by this indirect route correspond to an increase in the activation energy for the forward *endo* reaction from 110 to 114 kJ mol^{-1} and a decrease in activation energy for the *exo* reaction from 105 to 101 kJ mol^{-1}.[11] The decreased activation energy for the forward *exo* reaction inside the cavity corresponds to an effective molarity[12] of at least 4 M; the reaction is accelerated by a positive templating effect.[13] It appears therefore that the macroscopic acceleration observed is partly the result of concentrating the diene and dienophile within the same cavity, and partly the result of a reduced activation energy once the starting compounds are bound. In contrast, the larger activation energy (Table 1) of the forward *endo* reaction within the cavity corresponds to an effective molarity within the cavity of 0.2 M. Since this effective molarity is greater than the concentration of the free substrates, a macroscopic acceleration of the forward *endo* reaction is predicted by virtue of the high concentration of substrate pairs in the cavity. However, it cannot be observed experimentally because the *exo* reaction is so dominant.

One consequence of these energetics is that the trimer effectively encourages conversion of the *endo* adduct to its *exo* isomer: the reverse reaction is marginally slowed, but as soon as the (very dilute) diene and dienophile are created, they bind within the cavity and react to form *exo* adduct. Thus, a 0.9 mM solution of *endo* adduct in the absence of trimer is converted over a period of hours to a largely dissociated diene–dienophile pair, while in the presence of trimer it is converted instead into roughly 55% *exo* adduct in 100 hours.

Trimer **1** represents an important step in the development of enzyme mimics, because its major role is in recognition and orientation events that are decoupled from the reaction itself: one should be able to bring together a wide range of different reactive pairs simply by changing the substituents on the amine ligand. The ability of **1** to catalyze acyl transfer reactions has been described elsewhere.[6] Furthermore, rational changes in synthetic design should allow systematic study of the importance of such factors as host flexibility and quality of fit in supramolecular catalysis.

Experimental Procedure

Binding constants were measured by UV/Vis spectroscopy as described previously [3]. Forward and reverse reaction rates of the control reactions (in the absence of **1**) were determined from NMR spectra of reaction mixtures. Rates of reactions in the presence of trimer **1** were measured by removing aliquots (0.5 mL) of reaction mixture, quenching by addition of several drops of 1:1 trifluoroacetic acid/CD_3OD (to remove the zinc ion from **1**), and then neutralizing by addition of solid potassium carbonate before transfer to an NMR tube for spectroscopic assay. All rate constants were derived by following the reaction to completion and by obtaining the best-fit computer simulation of the kinetics over the whole reaction curve.

exo Adduct **4**: 4-(3-Furyl)pyridine hydrochloride (80 mg, 0.44 mmol) [14] was added to a solution of 4-(maleimidomethyl)pyridine (80 mg, 0.43 mmol) in distilled toluene (10 mL). The suspension was stirred with potassium carbonate for 2 h at room temperature and filtered. The resulting solution of **2** and **3** was flushed with argon and heated at 60 °C in the dark for 5 d. The crystals of *exo* adduct that formed were then collected by filtration. Yield: 65 mg (41%) ^{1}H NMR (250 MHz, $CDCl_3$): δ = 3.02 (d, J = 8 Hz, 1H), 3.08 (d, J = 8 Hz, 1H), 4.68 (s, 2H), 5.47 (d, J = 3 Hz, 1H), 5.65 (s, 1H), 6.92 (d, J = 3 Hz, 1H), 7.19 (d, J = 6 Hz, 2H), 7.27 (d, J = 6 Hz, 2H), 8.55 (d, J = 6 Hz, 2H), 8.66 (d, J = 6 Hz, 2H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 41.5, 47.5, 48.8, 81.3, 82.7, 119.7, 122.4, 133.1, 150.3, 150.8, 175.0, 175.2. Anal. calcd for $C_{14}H_{15}N_3O_3$: C 68.46, H 4.54, N 12.61. Found: C 68.37, H 4.57, N 12.62. Neither the mass spectrum nor melting point could be obtained owing to rapid reverse Diels-Alder reaction on ionization or heating.

endo Adduct **5**: An identical reaction mixture to that above was kept at room temperature in the dark for 10 d. White crystals of **4** were removed by filtration, and **5** was separated from the filtrate by preparative thin-layer chromatography (7% methanol in chloroform). Yield: 5 mg (3%) ^{1}H NMR (250 MHz, $CDCl_3$): δ = 3.75 (m, 2H), 4.29 (s, 2H), 5.43 (m, 1H), 5.62 (m, 1H), 6.22 (s, 1H), 6.84 (d, J = 6 Hz, 2H), 6.94 (d, J = 6 Hz, 2H), 8.27 (d, J = 6 Hz, 2H), 8.52 (d, J = 6 Hz, 2H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 41.1, 46.3, 47.4, 80.2, 81.7, 120.0, 123.5, 130.8, 149.8, 150.1. Neither the mass spectrum nor melting point could be obtained owing to rapid reverse Diels-Alder reaction on ionization or heating.

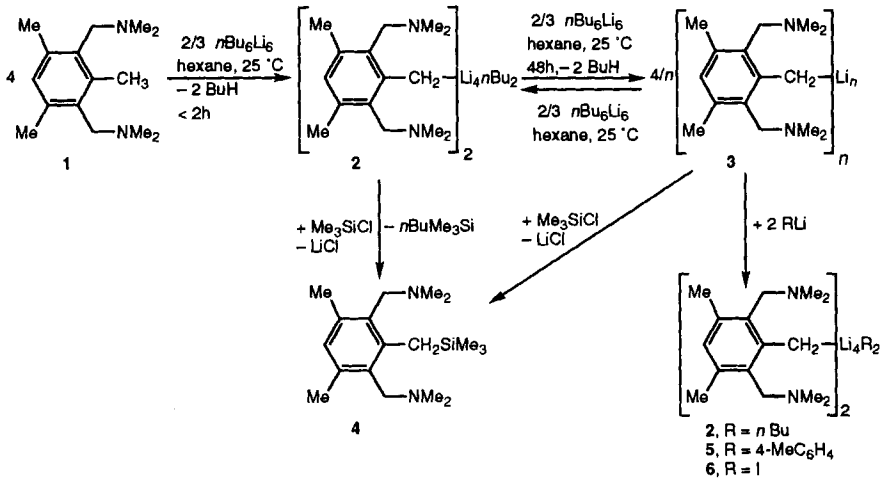
The Formation of a Mixed Organolithium Aggregate $Li_4R_2nBu_2$ during the Heteroatom-Assisted Lithiation of 1,3-Bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (R = 2,6-$(CH_2NMe_2)_2$-3,5-$Me_2C_6HCH_2$)

Peter Wijkens, Ernout M. van Koten, Maurits D. Janssen, Johann T. B. H. Jastrzebski, Anthony L. Spek, and Gerard van Koten*

Dedicated to Professor Ekkehard Lindner on the occasion of his 60th birthday

In the course of our studies into the organometallic chemistry of the potentially tridentate monoanionic 2,6-bis(dimethylaminomethyl)phenyl ligand, compounds having special properties and reactivities were obtained:[1, 2] 1) metals stabilized in unusual oxidation states,[3] 2) stabilized reactive intermediates,[4] and 3) species showing catalytic activity.[5] Such organometallic compounds have related structures in which two five-membered M-C-C-C-N chelate rings share a common M–C bond.



In order to fine-tune the metal environment, we decided to investigate the properties of compounds in which the two five-membered chelate rings are extended to six-membered ones having an M-C-C unit in common. Heteroatom-assisted lithiation is, especially when the heteroatom belongs to a tertiary amino group, a valuable reaction for the synthesis of heteroatom-containing organolithium compounds, and usually provides products of high purity with excellent yield.[6, 7] We therefore started our investigations with the attempted metalation of 1,3-bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (**1**) at the 2-methyl group.

The lithiation of **1** with *n*BuLi in a 1:1 molar ratio at room temperature afforded a white, crystalline precipitate within two hours. According to its ^{1}H NMR spectrum this precipitate appeared to be a unique aggregate **2** of the parent lithiated ligand and unreacted *n*BuLi in a 1:1 ratio (Scheme 1).[8] Compound **2** was characterized by elemental analysis, ^{1}H, ^{13}C, and ^{6}Li NMR spectroscopy, and an X-ray crystal structure determination.[9]

Prolonged reaction times (two days) afforded a yellow compound **3**, tentatively assigned the structure of the pure lithiated ligand. Its insolubility in both apolar and polar solvents hampered characterization of **3**. Alternatively, **3** could be prepared in high yield within two hours by the reaction of **1** with *t*BuLi in a 1:1 molar ratio (see *Experimental Procedure*). According to the ^{1}H NMR and mass spectra (see *Experimental Procedure*), reaction of both **2** and **3** with D_2O afforded exclusively the α-monodeuteriobenzyl derivative; this indicated that quantitative regioselective lithiation at the 2-methyl group had occurred. This was furthermore confirmed by the exclusive formation of the α-trimethylsilylbenzyl derivative **4** from the reaction of both **2** and **3** with Me_3SiCl (Scheme 1). Moreover, reaction of **2** with Me_3SiCl afforded the α-trimethylsilylbenzyl derivative and *n*$BuMe_3Si$ in a 1:1 molar ratio, while the same reaction of **3** afforded only trace amounts (< 1%) of *n*$BuMe_3Si$. That **2** may

Scheme 1.

be regarded as an intermediate in the heteroatom-assisted lithiation of **1** to give **3** became evident from the initially surprising observation that reaction of pure **3** with one equivalent of *n*BuLi led to selective re-formation of **2**.

An X-ray crystal structure determination of **2** revealed an overall structural geometry based on a central, almost regular Li_4 tetrahedron.[9] Two of the four Li_3 faces of the Li_4 tetrahedron are each bound to an anionic tridentate ligand ($C\widehat{N}_2$) through the benzylic carbon atom in a four-center two-electron (4c–2e) interaction (C–Li 2.319(7) Å, mean value). The two butyl groups are likewise 4c–2e-bound through the α-carbon atom (C–Li 2.215(7) Å, mean value) to the other two Li_3 faces (Fig. 1).[10] Coordinative saturation for each lithium atom is achieved by intramolecular coordination of the four nitrogen atoms (N–Li 2.079(7) Å, mean value), two from each of the heteroatom-containing ligands. The two tridentate anionic ligands may be arranged in two different ways at the faces of the Li_4 tetrahedron, and two enantiomeric aggregates thus exist. As a consequence of the crystal space-group symmetry, both are present in the unit cell.

The bonding of the benzylic group to the Li_3 face is slightly asymmetric, as is reflected by the three different C–Li distances (2.204(6), 2.348(7), and 2.407(7) Å). However, there seems to be no significant interaction between the aromatic C1 atom attached to C_α and one of the Li atoms (shortest C1–Li distance 2.782 Å). This conclusion seems to be corroborated by the angle of 113° between the C1–C7 bond and the center of the plane defined by Li1, Li2, and Li4. This points to a tetrahedral geometry around the benzylic carbon atom. These structural features of **2** are rather surprising since numerous X-ray crystal structure determinations have shown that aggregated benzyllithium compounds have planar benzyl ligands in which both the benzylic C_α and the aromatic C(*ipso*) atoms interact with lithium, as in $[PhCH_2Li(N(CH_2CH_2)_3N)_2]_n$[11] and $[PhCH_2Li(Et_2O)]_n$.[12] Only in monomeric $[PhCH_2Li(tmeda)(thf)]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine)[13] and $[PhCH(SPh)Li(thf)_3]$[14] is the benzylic group η^1-bound.

The overall structural geometry of **2** is closely related to that found for other tetranuclear alkyl- and aryllithium aggregates:[15] each of the organic groups is 4c–2e-bound to a Li_3 face of the central Li_4 tetrahedron; the fourth coordination site of each lithium atom is occupied by either an intramolecularly coordinating substituent (i.e., a well-positioned solvent molecule)[16, 17] or an additional donor molecule.[18, 19]

The ^1H, ^{13}C, and ^6Li NMR spectra of **2**, recorded in solution ([D_8]toluene) and at low temperature (– 30 °C), are consistent with a structure in solution analogous to that found in the solid state. Furthermore, the molecular weight of 587 measured by cryoscopy in benzene agrees with this tetranuclear aggregation state (calcd 608). Below –10 °C the ^1H NMR spectrum of **2** shows four resonances for the two NMe_2 groups, two AB patterns for the two CH_2N groups, and two resonances for the two Me substituents; the H4 resonance is, on the other hand, a singlet (Table 1). These results indicate the lack of a symmetry plane perpendicular to the plane of the aryl ring that also contains C(benzyl)–C4 as well as the lack of a symmetry plane containing the aryl ring. Accordingly, the CH_2NMe_2 substituents are diastereotopic as are the methyl groups in each NMe_2 group. This diastereotopicity also indicates that the N–Li coordination is nonfluxional on the NMR timescale at this temperature. A similar conclusion can be drawn from ^{13}C NMR data obtained at –20 °C. Moreover, the ^6Li NMR spectrum at –20 °C shows two distinct resonances at $\delta = 1.36$ and 1.44, respectively, in a 1:1 intensity ratio; this indicates the presence of two magnetically inequivalent lithium atoms in the Li_4 tetrahedron (the two benzylic ligands and the two butyl groups are enantiotopic as a result of twofold axial symmetry).

At higher temperatures (20 °C) a process becomes operative on the NMR timescale that generates a virtual symmetry plane perpendicular to the plane of the aryl ring; in

4	25	2.31	2.11	3.35	20.7	44.9	57.9	19.3 [d]

[a] $^2J(HH) = 12$ Hz. [b] X = Li, the line width of 80 Hz, due to coupling of three lithium atoms with carbon, corresponds to an average $^1J(^{13}C^7Li)$ of about 9 Hz. [c] X = D, $^1J(CD) = 19$ Hz. [d] X = SiMe$_3$.

the ^1H NMR spectrum there is one AB pattern, two NMe resonances, and one Ar–CH$_3$ resonance. A possible explanation might be a process involving the pairwise exchange of coordinating nitrogen atoms. Finally, at elevated temperatures (above 100 °C) there is also coalescence of the AB pattern and the two NMe resonances coalesce to single lines. The ^6Li NMR spectrum shows a single resonance; this indicates that the Li atoms have become equivalent. These observations are probably explained by process involving fast scrambling of the organic groups over the Li$_3$ faces of the Li$_4$ tetrahedron (alternatively interaggregate exchange may occur). Similar process have been proposed for other tetranuclear organolithium compounds in which the organic group contains one heteroatom substituent.[16, 17]

Previously we suggested a possible mechanism for the heteroatom-assisted lithiation of substituted *N,N*-dimethylbenzylamines with *n*BuLi that involves the successive replacement of *n*Bu groups on the Li$_3$ faces of the solvated Li$_4$(*n*Bu)$_4$ aggregate. The first step was the anchoring of the substrate through its heteroatom to a vertex of the Li$_4$ tetrahedron.[20] Based on chemical evidence Li$_4$(*n*Bu)$_2$(C$_6$H$_4$-2-CH$_2$NMe$_2$)$_2$ was proposed to be a stable intermediate in the lithiation reaction of C$_6$H$_5$CH$_2$NMe$_2$ with *n*BuLi.[21, 22] The isolation of **2** provides additional evidence for the mechanism outlined above. The conversion of **2** to **3** proceeds much slower than that of **1** to **2**, since, in order to anchor the substrate, the reaction beyond **2** requires cleavage of the intramolecular Li–N bond.

This reasoning points the way for the rational construction of mixed organolithium clusters by design of organic ligands, that is to say, the two benzylic diamine anions in **2** stabilize a dicationic Li$_4$ tetrahedron $[(\overset{\frown}{C}\overset{\frown}{N}_2)_2Li_4]^{2+}$ that can bind two monodentate anions R$^-$. The selective synthesis of the $[(\overset{\frown}{C}\overset{\frown}{N}_2)_2Li_4X_2]$ aggregates with X = *n*Bu (**2**), or *p*Tolyl (**5**), or halide (**6**) (Scheme 1 and *Experimental Procedure*) is proof of the potential of this method. Recent examples of this exciting area in organolithium chemistry is the selective synthesis of RLi$_2$X aggregates in which R is the pentadentate monoanionic organic group [C$_6$H$_3$-2,6-(CH$_2$N(Me)CH$_2$CH$_2$NMe$_2$)$_2$]$^-$.[23]

Owing to the presence of two different organic groups in **2**, this material is obviously not well suited as a starting material for the synthesis of other organometallic compounds, and it has already been shown that its reaction with Me$_3$SiCl affords two products. For the synthesis of organometallic compounds containing the [1,3-bis(dimethylaminomethyl)-4,6-dimethylphenyl)methyl tridentate monoanionic ligand, compound **6** (which may be regarded as a soluble modification of **3**) seems to be a better choice. This topic will be the subject of a forthcoming study.

Experimental Procedure

2: A hexane solution (16 mL) of 1.6 M *n*BuLi (25.6 mmol) was added at room temperature to a solution (30 mL) of **1** [24] in hexane. After 1 h the clear yellow solution was concentrated to ca. 20 mL. After 2 h pale yellow crystals were formed. These were isolated by centrifugation, washed with pentane, and dried in vacuo to afford **2** (2.56 g, 70% yield). Relevant ^1H and ^{13}C NMR data are given in Table 1 [26]. Reaction of **2** with Me$_3$SiCl afforded **4** and BuMe$_3$Si in a 1:1 molar ratio according to ^1H and ^{13}C NMR, and GCMS analysis.

3: A pentane solution (6.2 mL) of 1.5 M *t*BuLi (9.3 mmol) was added at −50 °C to a solution (20 mL) of **1** in pentane. The reaction mixture was stirred at room temperature for 1 h, during which time a yellow solid material was formed. This solid material was isolated by centrifugation, washed with pentane, and dried in vacuo to afford **3** (1.92 g, 87% yield). Reaction of a suspension of **3** in D_2O afforded, according to ^1H and ^{13}C NMR, and GCMS analysis, exclusively 1,3-bis-(dimethylaminomethyl)-4,6-dimethyl-2-monodeuteriomethylbenzene. Reaction of a suspension of **3** with Me$_3$SiCl afforded exclusively **4**.

Reaction of a suspension of **3** in benzene or diethyl ether with *n*BuLi, 4-MePhLi, and LiI (1:1 molar ratio) afforded **2**, **5**, and **6**, respectively. All compounds were characterized by elemental analysis, and ^1H and ^{13}C NMR spectroscopy. Relevant ^1H and ^{13}C NMR data are given in Table 1 [26].

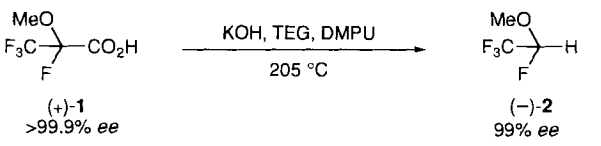
Carbon–Carbon Bond Cleavage with Inversion of Configuration: Conversion of (*R*)-(+)-1-Methoxytetrafluoropropionic Acid to (*S*)-(−)-1,2,2,2-Tetrafluoroethyl Methyl Ether

Keith Ramig,* Linda Brockunier,
Patrice W. Rafalko, and Leonid A. Rozov



Dedicated to Professor Theodore Cohen on the occasion of his 65th birthday

Asymmetric synthesis of pharmaceuticals is of increasing interest, because in many cases only one enantiomer of a chiral drug may be effective. In the field of inhalational anesthetics differences in the pharmacological profiles of enantiomers have been noted.[1] However, access to these small, highly fluorinated compounds in optically active form has been limited owing to the scarcity of suitable synthetic methods.[2] Enantiomeric separation of some of these compounds on a preparative scale has only recently been accomplished.[3]

A recent report[4] has detailed the asymmetric synthesis of 1,2,2,2-tetrafluoroethyl methyl ether (**2**),[5] an intermediate in the synthesis of the anesthetic compounds 1,2,2,2-tetrafluoroethyl difluoromethyl ether (desflurane, Suprane, **6**),[6] and 1,2,2,2-tetrafluoroethyl chlorofluoromethyl ether.[7] The key reaction was stereospecific decarboxylation of enantiomerically pure 1-methoxytetrafluoropropionic acid (**1**),[8] yielding ether **2** with 99% enantiomeric excess (*ee*) (Scheme 1). Important data lacking in that paper were the absolute configurations of the starting material and the product. We wish to report that we have determined the absolute configurations of both acid **1** and ether **2**. This data, which will establish the stereochemical direction of C–C bond cleavage, is important if these types of reactions are to become viable in asymmetric synthesis.

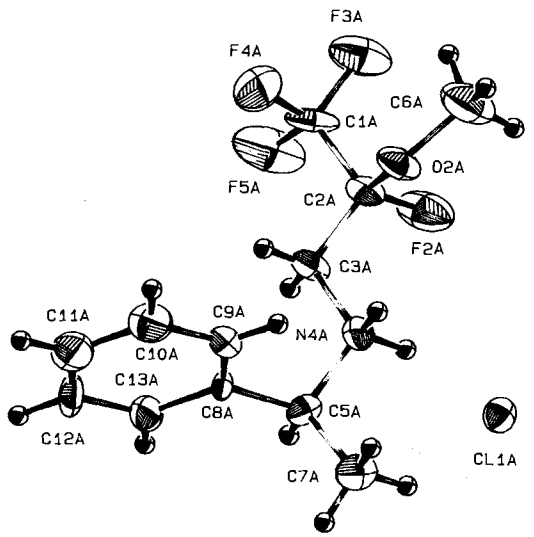
Scheme 1. Decarboxylation of acid **1** [4]. TEG = triethylene glycol, DMPU = dimethylpropylene urea = 1,3-dimethyl-3,4,5,6-tetrahydro-1*H*-2-pyrimidinone.

The absolute configuration of acid **1** is established by an X-ray crystallographic structure determination of a derivative. Amide (+)-**3** (>99.9% diastereomeric excess),[4] an intermediate in the optical resolution of acid (±)-**1**, is treated sequentially with $BH_3 \cdot THF$ complex[9] and ethereal HCl, affording amine salt (+)-**4**[10] (Scheme 2). The X-ray crystal structure[11]

Scheme 2. Establishment of the absolute configuration of acid **1**.

(Fig. 1) shows that the chiral fluorine-bearing carbon atom has the (*R*) configuration. Thus, it is established that acid **1** has the (*R*)-(+) configuration.



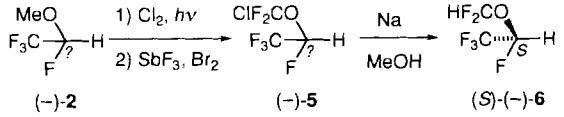


Fig. 1. ORTEP drawing of one of the two (*R*)-(+)-**4** molecules [11] in the asymmetric unit.

Establishment of the absolute configuration of ether **2** relies upon its conversion to a compound of known absolute configuration (Scheme 3). Trichlorination of the methoxy group of ether (−)-**2**[4] with Cl_2/incandescent light followed by difluorination with SbF_3/Br_2[12] gives chloroether (−)-**5** (bp 22–24 °C, $[\alpha]_D^{25} = -33$ ($c = 1$ in $CHCl_3$)). Chloroether (−)-**5** is converted to the anesthetic (−)-desflurane ((−)-**6**) by the action of Na in MeOH. According to ^1H and ^{19}F NMR analyses, the reaction results in a 1.5:1 mixture of chloroether **5** and desflurane. Chiral

(−)-**2** (−)-**5** (*S*)-(−)-**6**

Scheme 3. Establishment of the absolute configuration of ether **2**.

capillary GC analysis at 35 °C on a Chiraldex G-TA column (ASTEC, Whippany, NJ, USA) shows that the anesthetic **6** produced from the reaction is the levorotatory isomer, based on its longer retention time.[13] Because it is known[14] that the absolute configuration of (−)-**6** is (*S*), it is now certain that the absolute configuration of ether (−)-**2** is also (*S*).

The above data indicate that acid **1** undergoes highly stereospecific C–C bond cleavage, producing ether **2** with 99.5% inversion of configuration at the chiral carbon atom. This result is surprising, considering that in acyclic systems certain decarboxylations[15] and such related C–C bond breaking processes as the cleavage of tertiary alcohols[16] and Haller–Bauer cleavage[17] in most cases exhibit retention of configuration in the product, sometimes as high as 98%. The reaction is less selective in other solvents. In the present case, the very high level of inversion of configuration may be due to the highly electronegative α substituents of acid **1**. These, through hydrogen bonding, may cause the quenching proton of triethylene glycol to be in the required position opposite the carboxyl leaving group, assuming decarboxylation and quenching of the resultant organopotassium intermediate occur heterolytically; a concerted mechanism is also possible.

We have shown that under relatively harsh conditions an enantiomerically pure acyclic carboxylic acid can be decarboxylated to give a product with nearly complete inversion of configuration. This result is especially significant considering that carboxylic acids are known to produce products with a medium to high degree of configurational retention or racemization when subjected to much less drastic conditions.[15] To our knowledge, this is the most stereospecific C–C bond cleavage ever seen in an acyclic system. Future reports from this laboratory will describe use of this reaction in the synthesis of optically active anesthetics as well as new mechanistic data which will clarify the basic concept of configurational retention versus inversion in these systems.

[10] All new compounds provided satisfactory spectral data and correct combustion analyses.

[11] Single crystals of amine (*R*)-(+)-**4** were grown by slow evaporation from a solution of 12% v/v water in acetone. In the crystal structure determination the asymmetric unit contains two crystallographically independent molecules exhibiting similar configurational and geometric parameters. Representative molecule A is depicted in Figure 1. All bond lengths and bond angles are as expected. $M_r = 301.71$, monoclinic, space group $P2_1$, $a = 11.140(6)$, $b = 17.275(5)$, $c = 7.290(4)$ Å, $\beta = 90.19(5)°$, $V = 1403(2)$ Å^3, $Z = 4$, $\rho_{calc} = 1.43$ g cm^{-3}, $\mu = 28.28$ cm^{-1}. Data were collected on a colorless crystal measuring $0.25 \times 0.25 \times 0.10$ mm at $T = -160$ °C with a Rigaku AFC5S diffractometer; $\omega/2\theta$ scans with a scan speed of 8–32°/min in ω and a scan width of $(1.47 + 0.30 \tan\theta)°$ using graphite-monochromated $Cu_{K\alpha}$ radiation. Lattice parameters were determined by least squares using 25 reflections with $37.3° < 2\theta < 77.2°$. Three standards monitored every 150 reflections indicated no significant decay. A full set of Friedel mates was collected totaling 3918 reflections ($\sin\theta_{max}/\lambda = 0.56$ Å^{-1}; $0 \le h \le 13$, $0 \le k \le 19$, $-8 \le l \le 8$), 3535 of which were unique with merging $R = 0.055$. (The Friedel mates were not merged.) The structure was solved using MITHRIL and refined (P. W. Rafalko, R. I. Fryer, L. V. Kudzma, *Acta Crystallogr. Sect. C* **1993**, *49*, 116, and references therein) using 2706 reflections with $I > 3.00\sigma(I)$. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were assigned calculated positions and temperature factors (H–C = 0.95 Å; $B_{eq}(H) = 1.2\,B_{eq}$ (C or N)). The final R and R_w values $R^R = 0.086$ and $R_w^R = 0.116$, respectively, with GOF = 2.64. The Hamilton R-test (D. Rogers, *Acta Crystallogr. Sect. A* **1981**, *37*, 734) confirms that the absolute configuration of amine (*R*)-(+)-**4** is as shown. Both data for stereoisomers (*R*)-(+)-**4** and (*S*)-(−)-**4** were fully refined: $R^S/R^R \sim R_w^S/R_w^R = 1.07$ ($R^S = 0.093$, $R_w^S = 0.124$, GOF = 2.82 for (*S*)-(−)-**4**. Calculated $\alpha < 10^{-10}$ for $N = 2364$ establishes the validity of the assignment. Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ (UK), on quoting the full journal citation.

Investigations into the Targeted Design of Solids: Hydrothermal Synthesis and Structures of One-, Two-, and Three-Dimensional Phases of the Oxovanadium–Organodiphosphonate System**

Victoria Soghomonian, Qin Chen, Robert C. Haushalter,* and Jon Zubieta*

The recent expansion of the chemistry of the metal organophosphonate systems[1–3] reflects their practical applications as catalysts, hosts in intercalation compounds, and protonic conductors.[4–7] Vanadyl organophosphonates such as $[VO(RPO_3)] \cdot x H_2O$[8–11] and $[(VO)_2\{(O_3P)_2CH_2\}] \cdot 4H_2O$,[10] possess structurally well-defined internal void spaces

[**] The work at Syracuse was supported by the National Science Foundation (Grant CHE 9318824).

and coordination sites which allow such materials to intercalate alcohols by coordination of the substrate molecule to the vanadium sites of the V-P-O layer. When combined with readily modified organic substituents, the thermal stability and reactivity of transition metal oxide moieties, and the interplay of hydrophilic and hydrophobic domains, such substrate-specific recognition and incipient coordinative unsaturation of the vanadium sites offers an approach to the design of highly selective oxidation catalysts.[12–14] We have sought to expand the chemistry of the V-O-RPO_3^{2-} system by the introduction of various templates as structure-directing units, a methodology which results in a dramatic expansion of the range of materials (with respect to structure and composition) of the analogous oxovanadium phosphate phases.[15–18] Encouraged by our success in introducing progressively more radical modifications in the layered structures of V-O-RPO_3^{2-} phases by exploitation of appropriate templates,[19–21] we have turned our attention to the oxovanadium diphosphonate system, V-O-$[O_3P(CH_2)_nPO_3]^{4-}$, where "engineering" of the material could be accomplished both by introduction of different templates and by changes in the length of the diphosphonate space group R. Pursuing this strategy, one-, two- and pillared two- or three-dimensional phases, **1**, **2**, and **3** respectively, have been synthesized and structurally characterized.

$[H_2N(CH_2CH_2)_2NH_2][(VO)(O_3P(CH_2)PO_3)]$ **1**

$[H_3N(CH_2)_2NH_3][(VO)(O_3P(CH_2)_2PO_3)]$ **2**

$[H_3N(CH_2)_2NH_3][(VO)_4(OH)_2(H_2O)_2\{O_3P(CH_2)_3PO_3\}_2]\cdot 4H_2O$ **3**

The materials **1**–**3** were prepared by hydrothermal synthesis.[22–24] By employing temperatures in the 150 °C to 250 °C range under autogenous pressures, self-assembly from simple molecular precursors of metastable phases which retain the bond relationships between most of the constituent atoms may be accomplished. A variety of precursors may be introduced since all precursors are soluble under the conditions of the synthesis. Furthermore, a variety of templating cations may be employed to direct the organization of the solid and to induce crystallization, since templates of appropriate size or geometry may be selected from the reaction mixture to fill the crystal vacancies. In this way, compounds **1**–**3** were prepared from mixtures of VCl_4, H_2O, the appropriate diphosphonates, and templates at 200 °C for periods of 50–96 h. The IR spectra of each of the materials exhibited a band in the 968 to 985 cm^{-1} range assigned to ν(V=O) and several bands in the 1000 to 1200 cm^{-1} region characteristic of the (PO_3) group.

As shown in Figure 1, the structure of **1**[25] consists of infinite puckered chains of $[(VO)(O_3P(CH_2)PO_3)]^{2-}$ units with piperazinium ions occupying the interstrand regions. The V^{IV} sites exhibit square pyramidal coordination geometry with the apical position occupied by a terminal oxygen atom and the four equatorial positions defined by phosphonate oxygen atoms, two from each of two diphosphonato ligands. Each diphosphonate group symmetrically bridges two vanadium centers, and each PO_3 unit of the ligand retains a pendant (P–O) group. While pendant (P–OH) groups are more common in organophosphonate coordination chemistry, the uncoordinated (P=O) group has been demonstrated in the structure of $[nBu_4N]_2[V_2O_4(RPO_3)_2]$.[2] The structure of this (P–O) moiety in **1** receives contributions from the multiply bonded (P=O) form, as suggested by the relatively short P–O distance of 1.518(6) Å, and more significantly from the charge interaction [$-PO^- \cdots {}^+HN-$] with the cation in **1** as indicated by O···H distances in the 2.1–2.5 Å range. This diphosphonate coordination mode contrasts with that of the layered solid $[(VO)_2(O_3P(CH_2)PO_3)(H_2O)_4]$ wherein all phosphonate oxygen donors are coordinated to metal centers. The unusual chain-puckering in **1** is attributed to the long-range axial interactions between adjacent (VO) sites which cause folding of the one-dimensional strands through an alternating short–long (V=O···V=O···V=O) zigzag motif. This structural feature is also observed in the structure of the V-P-O plane of $[(VO)(O_3PC_6H_5)(H_2O)]$. Valence sum calculations[26] confirm that vanadium is in the +IV oxidation state.

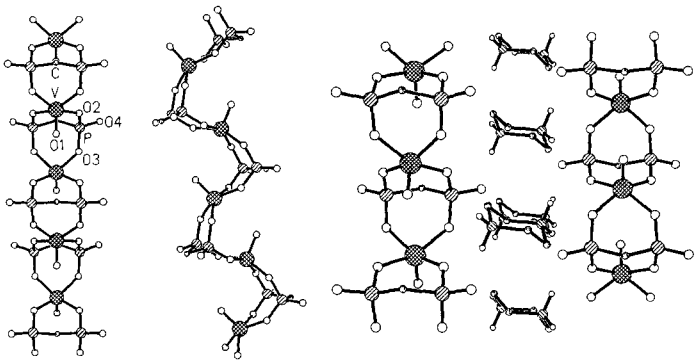

Fig. 1. Two views of the $[(VO)(O_3PCH_2PO_3)]_n^{2n-}$ chains of **1**. Middle: View of the zigzag pattern adopted as a result of folding of (V=O) groups into the vacant coordination site of the neighboring vanadyl unit. Left: View of the chain showing the atom-labeling scheme, which is also applicable in all subsequent figures: V atoms are crosshatched, P atoms are lined bottom left to top right, O atoms are open circles, and C atoms are lightly shaded small circles. Right: A view of neighboring $[(VO)(O_3PCH_2PO_3)]_n^{2n-}$ chains and the intervening piperazinium ions.

The structure of **2**[27] consists of layers of square pyramidally surrounded V^{IV} sites; the pyramids corner-sharing with diphosphonate tetrahedra to produce $[(VO)(O_3PCH_2CH_2PO_3)]_n^{2n-}$ layers. The ethylenediammonium ions occupy the interlamellar regions (Fig. 2). In addition to the apical oxygen atom, each vanadium(IV) site is bonded in the equatorial positions to four diphosphonate oxygen donors, one from each of four diphosphonate groups. Hence, each diphosphonato ligand bridges four vanadium centers in a monodentate fashion through two oxygen donors of each (PO_3) unit. In a fashion akin to that in **1**, each PO_3 group exhibits a pendant (P–O) group, which projects into the interlamellar space, as do the vanadyl oxygen atoms. Again, the structure exhibits hydrogen bonding between the pendant group and the organic cations. In comparison to the prototypical layered structures $[(VO)(O_3PC_6H_5)(H_2O)]$[9] and $[(VO)_2\{(O_3PCH_2PO_3)\}(H_2O)_4]$,[10] and V-O-$RPO_3^{2-}$ layer of **2** exhibits a more open net as a consequence of the presence of 14-membered (V-O-P-C-C-P-O)$_2$ rings (see Fig. 4b). The layer also exhibits eight-membered (V-O-P-O-V-O-P-O-) rings, char-

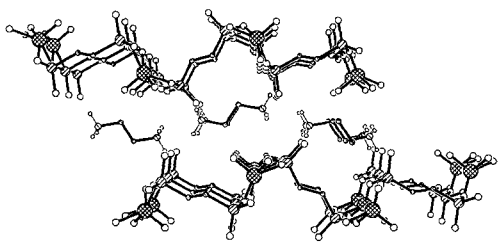

Fig. 2. The structure of **2** viewed along the crystallographic a axis, illustrating the interlamellar location of the organic cations.

acteristic of both molecular and solid-phase structures of the V-O-RPO_3^{2-} system.

The dramatic structural variations attendant to expansion of the phosphonate tether group are evident in the "pillared" structure adopted by **3** (Fig. 3). The structure of **3**[28] may be described in terms of inorganic V-P-O layers joined covalently

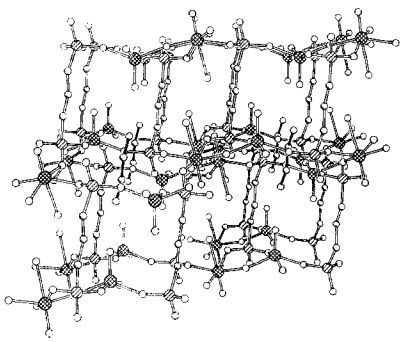

Fig. 3. A view of the three-dimensional V-O-P-C framework adopted by **3**, highlighting the positions of the organic cations which penetrate the inorganic V-O-P layers. Dotted circles are N atoms.

by the trimethylene bridges of the diphosphonate groups. Since the covalently linked framework includes the ligand carbon framework, the solid may alternatively be described as a three-dimensional V-P-O-C framwork with ethylenediammonium cations occupying the channels parallel to the crystallographic *a* axis. There are two distinct vanadium(IV) environments (see Fig. 4c): the V1 site is square pyramidal, surrounded by an apical oxygen atom, three oxygen donors of PO_3 groups and an oxygen atom of a bridging hydroxy group, while the V2 site is distorted octahedral, surrounded by an apical oxygen atom, three oxygen donors of PO_3 groups, the oxygen atom of a bridging hydroxy group, and an oxygen atom of a terminal aquo ligand. The binuclear $[V^{IV}_2O_2(OH)]$ unit provides an unusual structural motif within the V-P-O layers. The diphosphonato ligands span adjacent layers such that one of the PO_3 groups symmetrically bridges the V^{IV} sites of a $[V_2O_2(OH)]$ unit and coordinates through the remaining oxygen donor to the V2 site of an adjacent binuclear unit, while the second (PO_3) group bonds to two V1 sites and one V2 site of three proximal $[V_2O_2(OH)]$ units from a neighboring layer. In contrast to the structures of **1** and **2**, all the oxygen donors of the diphosphonato ligand in **3** coordinate to metal centers.

An unusual feature of the V-O-RPO_3^{2-} system is the range of connectivity patterns which are beginning to emerge for vanadium polyhedra and phosphonate tetrahedra within the V-P-O layers. As shown in Figure 4a, $[(VO)(O_3PC_6H_5)(H_2O)]$ exhibits vanadium octahedra corner-sharing through short–long V–O interactions into infinite chains, while $[(VO)\{(O_3P)_2CH_2\}(H_2O)_4]$ contains isolated (VO_6) octahedra, that is, no V-O-V bonding. While the structure of **2** resembles the latter with respect to the absence of V-O-V bonds, the vanadium sites are square pyramidal and as noted previously the details of the polyhedral connectivity are quite distinct. The V-P-O structure of **3** is unique in presenting $[V_2O_2(OH)]$ binuclear units with both octahedral and square-pyramidal vanadium sites. While the structure of $(Et_4N)[(VO)_3(OH)(H_2O)(O_3PEt)_3]\cdot H_2O$[21] also displays the $[V_2O_2(OH)]$ motif, the detailed connectivity within the plane is quite distinct from that of **3**.

The preparation of compounds **1**–**3** illustrates the power of hydrothermal synthesis, since in this way compounds can be formed by "self-assembly" from molecular precursors of metastable phases not accessible through conventional high-temperature solid-state techniques. While "designed" synthesis in the sense of predictability of product identity has yet to be achieved, it is clear that the combination of hydrothermal synthesis methods, appropriate adjustment of organic spacers in the ligand component, and suitable templates for framework organization allows modification both of framework dimensionality, and of V-P-O layer separation, and isolation of a range of phase compositions of dramatic structural variability limited only by the flexibility of polyhedral connectivity of the component moieties. Modification of the length of the organic buttress of the diphosphonato ligand should allow the engineering of materials with specific interlayer spacings and hence tailored microporosities.[4, 29]

Experimental Procedure

1: A mixture of VCl_4, methylenediphosphonic acid, piperazine, and water in the mole ratio 1:1:1.93:945 was heated at 200 °C and autogenous pressure for 50 h in a 23 mL Teflon-lined Parr acid digestion bomb (50% fill volume). Green crystals of **1** were isolated in 80% yield. IR (KBr pellet) $\tilde{\nu}$[cm^{-1}] = 3024 (w), 2958 (w), 2758 (m), 2626 (n), 1621 (m), 1505 (m), 1449 (m), 1156 (s), 1084 (s), 1029 (vs), 968 (s), 907 (w), 785 (s), 630 (m), 475 (w). Anal. calcd. for $C_5H_{14}N_2O_7P_2V$: C 18.3; H 4.28; N 8.56; found: C 18.3; H 4.39; N 8.55.

2: A mixture of VCl_4, ethylenediphosphonic acid, ethylenediamine, and water in the mole ratio 1:3.11:5.1:1890 was heated at 200 °C and autogenous pressure for 96 h in a quartz glass tube. Green crystals of **2** were collected in 90% yield. IR (KBr pellet) $\tilde{\nu}$[cm^{-1}] = 3448 (w), 2925 (m), 1181 (w), 1109 (s), 1076 (s), 1037 (sh), 1014 (vs), 975 (s), 775 (m), 546 (m), 463 (w). Anal. calcd. for $C_4H_{14}N_2O_7P_2V$: C 15.2; H 4.44; N 8.89; found: C 14.9; H 4.14; N 8.67.

3: A mixture of VCl_4, propylenediphosphonic acid, ethylenediamine, piperazine, and H_2O in the mole ratio 1:1.47:4.8:945 was heated at 200 °C and autogenous pressure for 80 h in a quartz glass tube. Blue crystals of **3** were isolated in 40% yield along with $[H_2N(CH_2CH_2)_2NH_2][(VO)_2(HO_3PCH_2CH_2CH_2PO_3)_2]$ (**4**), a layered material whose properties will be discussed elsewhere. While the piperazine template does not appear in the product **3**, it is necessary for the isolation of crystals suitable for X-ray crystallography. In the absence of piperazine, compound **3** was obtained

Dimensional Reduction of $Re_6Se_8Cl_2$: Sheets, Chains, and Discrete Clusters Composed of Chloride-Terminated $[Re_6Q_8]^{2+}$ (Q = S, Se) Cores**

Jeffrey R. Long, Andrew S. Williamson, and Richard H. Holm*

Lack of access to certain transition metal halide and chalcohalide clusters through self-assembly methods has enkindled interest in cluster excision, a low-temperature procedure in which the desired cluster is removed intact in molecular form from its covalently bound environment within an extended solid framework.[1] As demonstrated for the *n*-dimensional phases $Re_6Se_{4+n}Cl_{10-2n}$ ($n = 1 - 3$),[2] the effective use of current excision methodology is largely contingent upon the clusters being loosely bound in one or two dimensions.[3] This, however, is not always the case, and many clusters exist in a three-dimensional and/or more tightly bound framework. Our recent efforts have therefore focused on the development of a general high-temperature technique for producing frameworks of reduced connectivity, in hope of thereby gaining entry to a wealth of formerly inaccessible cluster chemistry. Herein, we describe such a technique, and demonstrate its efficacy by application to the $Re_6Se_8Cl_2$ parent structure.

The premise underlying our approach is exemplified in Figure 1, which illustrates the stepwise deconstruction of a rudimentary three-dimensional cluster framework. The initial structure consists of $[M_mQ_q]$ cluster cores linked in three dimensions by bridging anions X. Successive incorporation of additional equivalents of X reduces the overall dimensionality of the framework by terminating intercluster bridges, producing structures containing sheets, chains and, finally, discrete clusters. To preserve the original cluster electron count, each X added is accompanied by a charge-compensating cation A, which resides external to the framework (i.e., between sheets, chains, or isolated clusters). The scheme presented in Figure 1 is not necessarily intended to imply a specific reaction pathway (although it may do so in some cases), but rather to provide a formalism with which new lower dimensional compounds may be derived from existing structures. Thus, this process of *dimensional reduction*, when applied to a known parent phase, serves as a means of formulating synthetic targets with structures amenable to excision or direct dissolution, ultimately affording the desired cluster in molecular form. Substitution of single metal centers M for the $[M_mQ_q]$ cores in Figure 1 creates an analogous formalism for metal–anion frameworks, useful in relating covalent structures throughout the solid state.[4]

Many of the more intractable cluster frameworks are partially or entirely linked by bonding interactions directly between cores, rather than through some intermediate bridging ligand, as in Figure 1.[1] The two-dimensional framework in $Re_6Se_8Cl_2$ ($\triangleq [Re_6Se^i_4Se^{i-a}_{4/2}]Se^{a-i}_{4/2}Cl^a_2$)[5] provides such an example. Its structure[6] (Fig. 2) is built up from electron-precise, face-capped octahedral $[Re_6Se_8]^{2+}$ cluster cores, each with two attendant terminal chlorides at *trans* rhenium apices and four

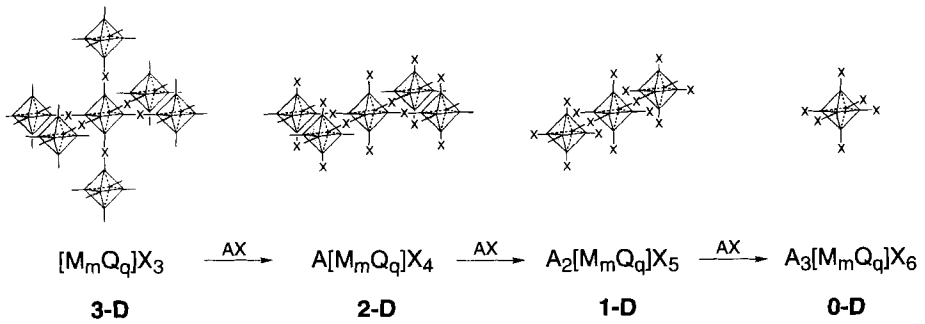

Fig. 1. Dimensional reduction of a simple three-dimensional cluster framework, $[M_mQ_q]X_3$. Anions X bridging cluster cores $[M_mQ_q]$ (arbitrarily represented by shaded octahedra) are rendered terminal through the incorporation of additional equivalents of X, reducing the overall dimensionality of the structure. Cations A (not shown) are simultaneously introduced to balance the negative charge accrued by the framework.

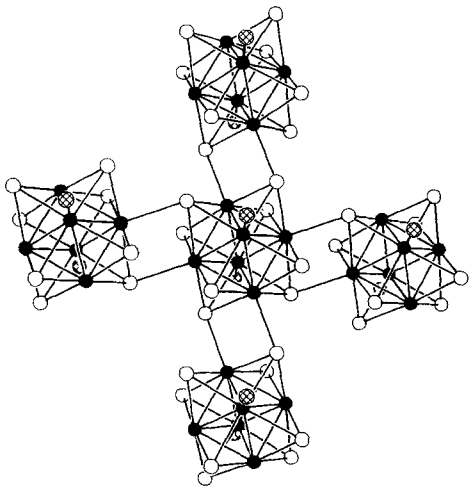

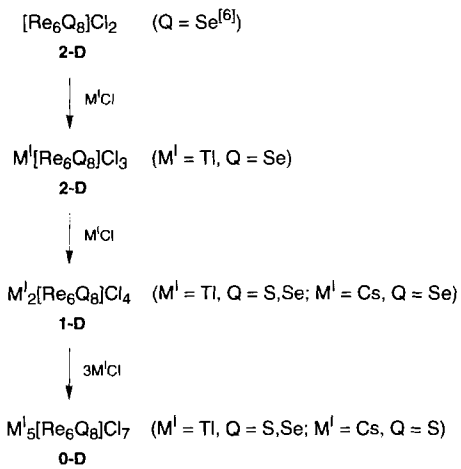

Fig. 2. Local cluster environment in the $Re_6Se_8Cl_2$ parent structure; its sheetlike cluster framework extends within the plane of the page. Black, white and cross-hatched spheres represent Re, Se, and Cl atoms, respectively. Selected mean interatomic distances [Å] and angles [°]: Re–Re 2.64(2), non-rhomb Re–Se^i 2.52(1), Re–Se^a 2.62(2), Re–Cl 2.38(1), Re-Re-Re 60.0(5); within Re_2Se_2 rhombs Re–Se 2.62(1), Re–Re 3.43(2) [6].

rhombic Re_2Se_2 interactions linking neighboring cores. The rigidity inherent in these Re_2Se_2 rhombs lends itself to the overall framework, rendering the chloride-terminated sheets impervious to excision. In view of the multitude of solids exhibiting $[Re_6Q_8]^{2+}$ (Q = S, Se) cluster cores,[1] and the lack of any corresponding species in solution, the $Re_6Se_8Cl_2$ structure was chosen as a prototype for testing the validity of the dimensional reduction approach. Seven new phases containing this core motif were synthesized and structurally characterized by single-crystal X-ray methods.[7] Their relations to the $Re_6Se_8Cl_2$ parent phase[8] through extent of M^ICl (M^I = Cs, Tl)[9] uptake are presented in Scheme 1.

The first step in Scheme 1 proceeds with the incorporation of one equivalent of TlCl to yield $TlRe_6Se_8Cl_3$ ($\triangleq$ $Tl[Re_6Se^i_5Se^{i-a}_{3/2}]Se^{a-i}_{3/2}Cl^a_3$). Here the overall dimensionality of the cluster framework has not been reduced; however, the rigidity of the sheets has relaxed substantially. Figure 3 shows the structure and local surroundings of the $[Re_6Se_8]^{2+}$ cores in the new two-dimensional phase. Each core now has three associated terminal chlorides (*fac* arrangement) and three rhombic Re_2Se_2 interactions with neighboring cores. As in $Re_6Se_8Cl_2$, the clusters achieve an ideal configuration of 24 metal-based electrons corresponding to twelve Re–Re bonds, and consequently display no significant distortion away from a perfectly regular Re_6 octahedron (an observation which holds for the entire series of compounds listed in Scheme 1). Similarly, the sole core irregularity, an approximate 0.1 Å lengthening in those Re–Se bonds integral to the Re_2Se_2 rhombs, is retained in $TlRe_6Se_8Cl_3$, as are the other core interatomic distances and angles. Although it contains one fewer linkage per cluster, the sheetlike framework of $TlRe_6Se_8Cl_3$ is slightly more complicated than that of $Re_6Se_8Cl_2$. While the lower two Re_2Se_2 rhombs in Figure 3 are perpendicular to the plane of the page, the upper one is situated within the plane. The choice of atom Se(7) over Se(4) in forging an intercore bond effectively destroys

Scheme 1. Dimensional reduction of the $Re_6Se_8Cl_2$ parent structure.

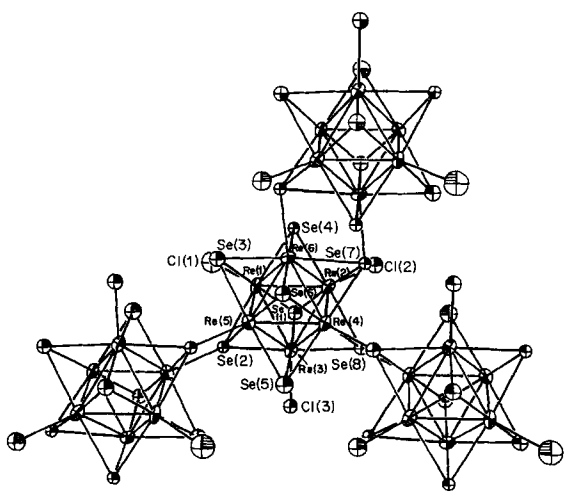

Fig. 3. Local cluster environment in the structure of two-dimensional $TlRe_6Se_8Cl_3$ (70% probability ellipsoids). Inversion centers are situated in the middle of each Re_2Se_2 rhomb; lower two rhombs are perpendicular to the plane of the page. Selected interatomic distances [Å] and angles [°]: mean Re–Re 2.64(2), Re(4)–Se(8) 2.63(2), Re(5)–Se(2) 2.62(2), Re(6)–Se(7) 2.67(2), mean of other Re–Se^i 2.51(2), mean Re–Se^a 2.62(2), mean Re–Cl 2.39(5), mean Re–Re–Re 60.0(5) and 90.0(4), mean Re–Re–Cl 135(2), mean Re–Se^i–R 63(1), mean Se–Re–Cl 91(2); within Re_2Se_2 rhombs mean values are Re–Se 2.63(2), Re–Re 3.41(3), Re–Se–Re 81.0(3), Se–Re–Se 99.0(3).

a potential threefold rotational axis running through atoms Se(1) and Se(6), preempting the simpler alternative structure in favor of a more densely packed, but corrugated sheet. The thallium cations sandwiched between these $[Re_6Se_8Cl_3]^-$ sheets interact with the exposed chlorine and selenium atoms on their surfaces.[10]

Incorporation of one more equivalent of TlCl gives rise to $Tl_2Re_6Se_8Cl_4$ ($\hat{=} Tl_2[Re_6Se^i_6Se^{i-a}_{2/2}]Se^{a-i}_{2/2}Cl^a_4$), wherein the dimensionality of the cluster framework has now been reduced by one. In this phase, neighboring $[Re_6Se_8]^{2+}$ cores are linked by Re_2Se_2 rhombs at *trans* rhenium apices to form a one-dimensional chain (Fig. 4). The chains are sheathed with terminal

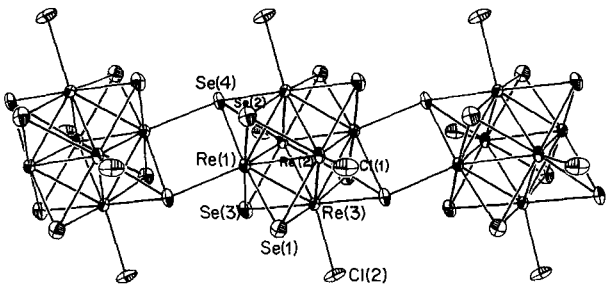

Fig. 4. Local cluster environment in the structure of one-dimensional $Tl_2Re_6Se_8Cl_4$ (70% probability ellipsoids). Inversion centers are located at the center of each cluster and each Re_2Se_2 rhomb. Selected interatomic distances [Å] and angles [°]: mean Re–Re 2.63(2), Re(1)–Se(4) 2.635(5), mean of other Re–Se^i 2.510(5), Re–Se^a 2.600(7), mean Re–Cl 2.413(2), mean Re-Re-Re 60.0(5) and 90.0(5), mean Re-Re-Cl 135.2(7), mean Re-Se^i-Re 63.0(8), mean Se-Re-Cl 92.2(6); within Re_2Se_2 rhombs mean Re–Se 2.62(2), Re–Re 3.407, Re-Se-Re 81.3(2), Se-Re-Se 98.7(2).

chlorides, which ligate the remaining four rhenium atoms of each cluster core. $Cs_2Re_6Se_8Cl_4$ contains virtually identical cluster chains, with only a slight increase in interchain separations due to the larger intermediate Cs cations. For both structures, the bond lengths and angles within clusters and rhombs do not significantly deviate from the corresponding parameters in $Re_6Se_8Cl_2$. Another closely related phase, $Tl_2Re_6S_8Cl_4$, features $[Re_6S_8]^{2+}$ cores linked to form an analogous chain structure. Here, the shorter Re–S bonds induce a contraction in the Re_2S_2 rhombs (mean interatomic distances [Å] and angles [°]: Re–S 2.52(3), Re–Re 3.24(2), Re-S-Re 80.2(2), S-Re-S 99.8(2)), drawing cluster cores within chains closer together. In other regards, the clusters differ unremarkably from those of $Cs_5Re_6S_8Cl_7$ described below. Interestingly, none of these phases assumes the isomeric two-dimensional cluster framework of Figure 1 (X = Cl), as adopted by $Re_6Se_6Cl_6$ ($\hat{=} [Re_6Se^i_6Cl^i_2]Cl^a_2Cl^{a-a}_{4/2}$).[11] Very likely, this is a result of the electrostatics involved in accommodating two large cations per cluster unit.

The terminus in the dimensional reduction of $Re_6Se_8Cl_2$ is attained with the incorporation of five total equivalents of TlCl to form zero-dimensional $Tl_5Re_6Se_8Cl_7$ (or, more precisely, $Tl_4[Re_6Se_8Cl_6] \cdot TlCl$). The discrete $[Re_6Se_8Cl_6]^{4-}$ clusters in this phase accomplish our immediate goal of breaking down the two-dimensional framework of $Re_6Se_8Cl_2$. Once again, the geometry of the clusters in the parent phase is preserved, barring those effects which arise from the presence of core-linking Re_2Se_2 rhombs. Exchange[12] of an alkali metal for Tl in this structure should provide the cluster in soluble form, however, such experiments await a more efficient synthesis of $Tl_5Re_6Se_8Cl_7$. Attempts at preparing a cesium-substituted analogue, invariably resulted in formation of large quantities of Cs_2ReCl_6, among other phases. In direct contrast, the parallel phases $Tl_5Re_6S_8Cl_7$ and $Cs_5Re_6S_8Cl_7$, containing unprecedented $[Re_6S_8Cl_6]^{4-}$ clusters (Fig. 5), are both produced very near quantitatively.[13] A comparison of the $[Re_6Se_8]^{2+}$ and $[Re_6S_8]^{2+}$ cores, reveals that the expected differences due to the shorter Re–S bonds are accompanied by a subtle isotropic con-

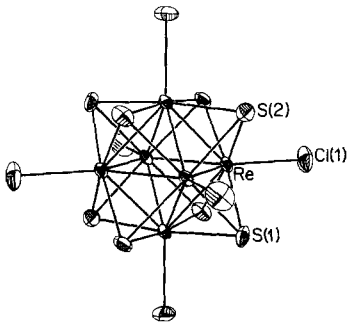

Fig. 5. Structure of the discrete $[Re_6S_8Cl_6]^{4-}$ cluster in $Cs_5Re_6S_8Cl_7$ (70% probability ellipsoids). The cluster resides on a $\bar{3}$ symmetry site, with atom S(2) on the threefold rotation axis. Selected interatomic distances [Å] and angles [°]: mean Re–Re 2.597(3), mean Re–S 2.399(3), Re–Cl 2.42(1), Re-Re-Re 60.0(1) (mean) and 90.0(1), mean Re-Re-Cl 135(1), mean Re-S-Re 65.5(1), mean S-Re-Cl 93.4(9).

traction of the Re_6 octahedron. $Cs_5Re_6S_8Cl_7$ readily dissolves in acidic media to afford a bright yellow solution, the chemical properties of which are currently under investigation. Preliminary X-ray studies confirm retention of the hexanuclear rhenium cores recovered from these solutions.

Experimental Procedure

Stoichiometric 0.500 g mixtures of Re (– 325 mesh, Cerac), Q (S: –100 mesh, Aldrich; Se: –325 mesh, Strem), $ReCl_5$ (– 40 mesh, Cerac), and M^ICl (TlCl: Strem; CsCl: Baker, dried for two days at 200 °C) were intimately ground in a pure dinitrogen atmosphere, and sealed in fused silica ampules (id × od × l = 7 × 10 × 120 mm) under vacuum. Reactions were carried out at 900 °C for 7000 min, cooled at 0.2 °C per min to about 500 °C, and air-quenched. Product identity and purity was confirmed by comparison of the observed X-ray powder diffraction (Scintag XDS-2000, $Cu_{K\alpha}$ radiation) pattern with calculated patterns generated from single-crystal results. Samples exhibiting large crystal faces were analyzed (EMPA) with a Cameca MBX electron microprobe employing a Tracor Northern TN-1310 wavelength-dispersive spectrometer.

$TlRe_6Se_8Cl_3$ (EMPA: $Tl_{0.95(1)}Re_{6.00(4)}Se_{8.31(7)}Cl_{2.90(8)}$) forms as black hexagonal prisms which are not single crystals, but rather consist of a large number of slightly misfit stacked plates. With considerable difficulty, a razor blade was employed in slicing a single plate off of one of these stacks for X-ray analysis. Reactions targeting $Tl_2Re_6Se_8Cl_4$ (small black parallelpipeds) and $Tl_5Re_6Se_8Cl_7$ (EMPA: $Tl_{4.70(6)}Re_{6.00(5)}Se_{8.2(1)}Cl_{6.80(6)}$; large, irregular red blocks) gave very low yields (typically 5 and 10 mg of mechanically sorted crystals, respectively), the major products being $TlRe_6Se_8Cl_3$ and TlCl. Attempts at improving these yields by varying reaction conditions or including transport agents were not successful. Red $Tl_2Re_6S_8Cl_4$ and black $Cs_2Re_6Se_8Cl_4$ both crystallize in densely packed clumps of thin needles. $Tl_5Re_6S_8Cl_7$ (EMPA: $Tl_{4.7(2)}Re_{6.00(7)}S_{7.93(8)}Cl_{6.8(1)}$) and $Cs_5Re_6S_8Cl_7$ (EMPA: $Cs_{5.10(6)}Re_{6.01(1)}S_{7.88(6)}Cl_{6.75(6)}$) occur as thick hexagonal plates, of respective orange-red and yellow-orange color. The latter phase dissolves in dilute $HCl_{(aq)}$ and EtOH/$HCl_{(aq)}$ to yield a bright yellow solution.

Data were collected at 223 K (295 K for $Tl_2Re_6Se_8Cl_4$) on a Nicolet P3f diffractometer employing graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Structures were solved by direct methods with the aid of difference Fourier maps, and refined ($F_0 > 6\sigma F_0$) with successive full-matrix least-squares cycles (SHELXTL PLUS). All of the compounds absorb X-rays heavily, and an empirical correction (XEMP) based on azimuthal Ψ-scans was applied to each data set. For the rhombohedral crystals, this correction proved adequate when combined with collection of excess data used to average equivalent reflection intensities. However, the lack of (non-Friedel) equivalent data for triclinic crystals led to remanent absorption effects; as a result, the Se and Cl atoms in $TlRe_6Se_8Cl_3$ and two of the S atoms in $Tl_2Re_6S_8Cl_4$ could not be refined anisotropically. The structure of $Cs_2Re_6Se_8Cl_4$ was solved, but would not refine satisfactorily. An analytical absorption correction (six crystal faces were indexed as {100}, {010} and {001}) was successfully applied to $Tl_2Re_6Se_8Cl_4$. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58636.

[8] Alternatively, the three-dimensional $Re_6S_8Cl_2$ ($\triangleq [Re_6S_6^{i-a}]S_{2/2}^{a-i}Cl_{4/2}^{a-a}$) structure may serve as a parent for the $[Re_6S_8]^{2+}$ core-containing phases: C. Fischer, S. Fiechter, H. Tributsch, G. Reck, B. Schultz, *Ber. Bunsenges. Phys. Chem.* **1992**, *96*, 1652.

[9] In general, smaller monocations M^I were found to be considerably less effective.

[10] The M^I cations in all of the seven new phases display complex coordination environments involving both Q and Cl atoms.

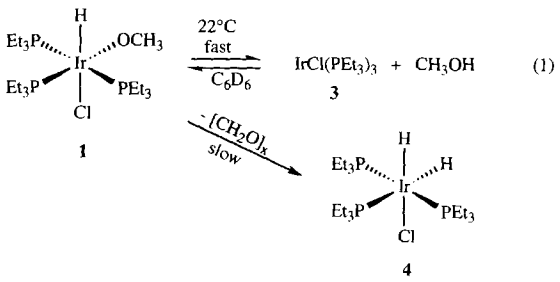
Direct Observation of O–H Reductive Elimination from Ir^{III} Complexes**



Ofer Blum and David Milstein*

Hydrido(hydroxo) and -(alkoxo) complexes are postulated as intermediates in various transition metal mediated catalytic transformations.[1] Formation of O–H bonds by reductive elimination from such complexes is suggested as the product-forming step in several reactions, such as the hydrogenation of CO to methanol,[2] hydrogen transfer reactions,[1e] and alcohol homologation.[1f] O–H bond formation by reductive elimination is rarely observed, and was so far found to require ligand addition,[1c, 3] UV irradiation,[3a] or oxidation.[4] In other examples, the H–M–OR (R = H, alkyl or aryl) species was generated in situ but was not observed.[2, 5] In all these cases, O–H bond formation was not rate determining. Here we report the reversible, unassisted reductive elimination of water and methanol from *mer-cis*-$[HIr(OR)Cl(PR'_3)_3]$ (R = H, Me; R' = Me, Et), which takes place without prior ligand dissociation. The results of this study lead to the conclusion that for hydrido(alkoxo) complexes, O–H reductive elimination is preferred over β-hydride elimination.

The compounds **1** and **2** are prepared by oxidative addition of

mer-cis-$[HIr(OR)Cl(PEt_3)_3]$ **1**, R = CH_3; **2**, R = H

methanol or water to $[IrCl(PEt_3)_3]$ (**3**)[6] at −30 °C.[7, 8] Both **1** and **2** undergo HOR reductive elimination in pure benzene at room temperature, generating **3**. Fast equilibrium between **1** and **3** is observed (Scheme 1) at 22 °C in a 9.36 mM solution of

Scheme 1. Reactions of **1**.

3 in C_6D_6 containing methanol ($c_{CH_3OH} = 223$ mM). Concomitantly, slow, irreversible β-hydride elimination from **1** generates the complex **4**[9] and decreases the concentrations of **1** and **3** (Scheme 1). Nevertheless, the ratio of these concentrations remains unaffected. The same c_1/c_3 ratio was obtained when starting with a 9.36 mM solution of **1** under otherwise identical conditions.[10] This corroborates the establishment of a fast equilibrium between **3** and **1**, and that the O–H reductive elimination from **1** is substantially faster than the β-H elimination.

As expected, the reductive elimination process (Scheme 1) is entropically driven ($\Delta S^0 = 67(4)$ cal K^{-1} mol^{-1}) (Fig. 1).[11]

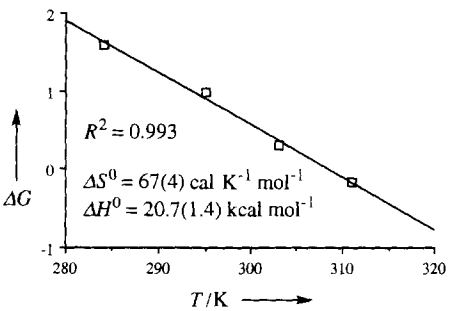


Fig. 1. The temperature dependence of ΔG [kcal mol^{-1}] of the O–H reductive elimination from **1**.

From the value of the reaction enthalpy ($\Delta H^0 = 20.7(1.4)$ kcal mol^{-1}) it is possible to estimate the sum of the Ir–H and Ir–OCH_3 bond energies D of **1** as 125 kcal mol^{-1}.[12] Based on previously determined D(Ir–H) values,[13] the Ir–H bond strength in **1** is estimated to be between 57 and

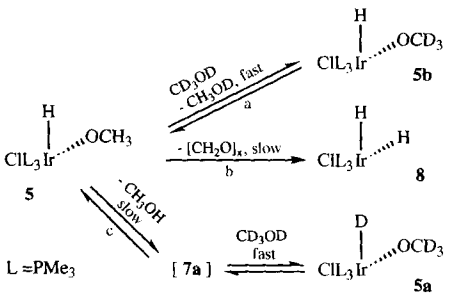
64 kcal mol^{-1} resulting in $D(\mathrm{Ir-OCH_3}) \approx 68-61$ kcal mol^{-1}. To our knowledge, this is the first experimentally determined bond strength for the bond between an alkoxo group and a late transition metal.[14] The observation that $D(\mathrm{M-H}) \sim D(\mathrm{M-OCH_3})$ is in agreement with the relative M–X bond strengths (X = anionic ligand) reported by Bryndza, Bercaw and coworkers.[14]



The PMe_3 complexes **5** and **6**[15] were prepared in a similar manner to **1** and **2** from **7**[16] and methanol or water, respectively. Interestingly, only **5** and **6** (but not the Ir^{I} complex **7a**[17]) are present after completion of the oxidative addition under the conditions mentioned above, indicating strong dependence of the equilibrium in Scheme 1 on the phosphane ligand size.[18]

mer-cis-[HIr(OR)Cl(PMe$_3$)$_3$] **5**, R = CH$_3$; **6**, R = H

[(C$_8$H$_{14}$)IrCl(PMe$_3$)$_3$] **7**

[IrCl(PMe$_3$)$_3$] **7a**

The addition of CD_3OD (2.24 M) to a solution of **5** (32.1 mM) in C_6D_6 at 22 °C gives rise to three competing reactions (Scheme 2, a–c). The fast anionic ligand exchange (a) has

Scheme 2. Reactions of **5**.

a pseudo first order rate constant ($k_2c_{CD_3OD}$) of 7.85×10^{-4} s^{-1}.[19] The rate constant of the β-hydride elimination to give **8** (b) (in CH_3OH and not CD_3OD under otherwise the same conditions) is 3.28×10^{-5} s^{-1}.[20] The rate-determining reductive elimination[21] step in reaction c has a rate constant of 1.22×10^{-4} s^{-1},[22] about 3.7 times faster than the β-hydride elimination. Reaction c takes place (albeit slowly) also under conditions in which the β-hydride elimination from **5** is not observed (at −30 °C or in the presence of lower methanol concentration (89.2 mM)).[9] The hydrido(hydroxo) complex **6** also undergoes Ir–H to Ir–D exchange (in D_2O/THF).

The rate of the oxidative addition to **3** in Scheme 1 was not influenced by the addition of a tenfold excess of triethylphosphane. Similarly, the rate of methanol oxidative addition to **7a** was not affected by a fifteenfold excess of LiCl.[23] These results indicate that the O–H reductive elimination from **1**, **2**, **5**, and **6** proceeds without prior chloride or phosphane dissociation.[25]

Surprisingly, the cation in **9** does not undergo exchange of Ir–H in D_2O/THF, and **10** is stable towards thermal reductive elimination at 70 °C.[4] This result contradicts the expectations that reductive elimination is facilitated by lower electron density[26] or by higher steric hindrance.[18] (The cationic complexes in **9** and **10** are less electron-rich than the neutral complexes **6** and **5**, respectively, and the PMe_3 ligand is bulkier than the chloro ligand). It is possible that the chloro ligand in **5** and **6** stabilizes the pentacoordinate transition state of the reductive elimination by π donation. The effect of π donation on pentacoordinate d^6 iridium complexes was recently discussed.[9, 27] We are currently trying to clarify this point.

cis-[HIr(OH)(PMe$_3$)$_4$]PF$_6$ **9**

cis-[HIr(OCH$_3$)(PMe$_3$)$_4$]PF$_6$ **10**

In conclusion, this study demonstrates that formation of alcohols (and water) by O–H reductive elimination is feasible and can compete favorably with β-H elimination. This supports proposals of O–H bond formation as the product-forming step in industrially important processes such as CO hydrogenation[1d] and alcohol homologation.[1f, 2]

[8] **2**: IR (nujol): $\tilde{\nu} = 3463$ (m, OH), 2184 cm^{-1} (m, IrH). The complex is highly hygroscopic. ^{1}H NMR (400 MHz, C_6D_6, 22 °C, referenced to the residual solvent peak): $\delta = 2.10$ (m (13 lines), J(apparent) = 3.6 Hz, 6H; 2P(C(*H*)HCH$_3$)$_3$), 1.73 (m (13 lines), J(apparent) = 3.6 Hz, 6H; 2P(C(H)*H*CH$_3$)$_3$), 1.61 (apparent quintet, $^2J^d$(H,P) = $^3J^q$(H,H) = 8.0 Hz, 6H; P(C*H*$_2$CH$_3$)$_3$), 1.09 (m (apparent quintet), J(apparent) = 7.4 Hz, 18H; 2P(C(H)HC*H*$_3$)$_3$), 0.89 (dt, $^3J^d$(H,P) = 14.7 Hz, $^3J^t$(H,H) = 7.5 Hz, 9H; P(CH$_2$C*H*$_3$)$_3$), −2.07 (d, $^3J^d$(H,P,*trans*) = 5.5 Hz, 1H; IrO*H*), −21.72 (dt, $^2J^d$(H,P,*cis*) = 17.6 Hz, $^2J^t$(H,P,*cis*) = 15.3 Hz, 1H; Ir*H*). ^{31}P{^{1}H} NMR (C_6D_6 referenced to external 85% solution of H_3PO_4 in D_2O): $\delta = -17.4$ (t, ^2J(P,P,*cis*) = 15 Hz, 1P), −8.0 (d, ^2J(P,P,*cis*) = 15 Hz, 2P). Crystals of **2** suitable for low-temperature X-ray examination were obtained by slow evaporation of a 1/1 benzene/pentane solution. A detailed discussion of the interesting features of this structure will be given elsewhere.

[9] **4** and **8** are fully characterized and the β-H elimination from **1** and **5** is discussed in detail: O. Blum, D. Milstein, *J. Am. Chem. Soc.* submitted.

[10] The ratio of concentrations of **1** and **3** under the specified conditions is 1.203 ± 0.05, starting from pure **3**. The starting solution of pure **1** provided a ratio of 1.20 ± 0.09.

[11] The value of ΔS^0 seems high. A typical value of only 30 cal K^{-1} mol^{-1} is dictated by translational entropy upon formation of two molecules from one.

It is possible that loss of the relatively strong hydrogen bond between methanol and the methoxo ligand of **1** (which is expected to be much stronger than between two methanol molecules) accounts for the additional ΔS^0 release. We thank the referee for bringing this point to our attention.

[12] $\Delta H^0 + D(H-OCH_3) \approx D(Ir-H) + D(Ir-OCH_3)$. $D(H-OCH_3) = 104.4 \pm 1$ kcal mol^{-1}: L. Batt, R. D. McCulloch, *Int. J. Chem. Kinet.* **1976**, *8*, 491. For a discussion concerning such calculations see footnote 34 in ref. [3b].

[13] D(Ir–H) values of 57 to 64 kcal mol^{-1} have been reported for iridium phosphane complexes with phosphanes of a cone angle larger than 125°: J. A. Martinho-Simões, J. L. Beauchamp, *Chem. Rev.* **1990**, *90*, 629.

[14] Relative M–X bond strengths (X^- = anionic ligand as H^-, CH_3^-, MeO^-, Cl^- etc.) were experimentally determined for [Cp*(PMe_3)$_2$RuX] and for [{Ph$_2$P(CH$_2$)$_2$PPh$_2$}MePtX]: H. E. Bryndza, L. K. Fong, R. A. Paciello, W. Tam, J. E. Bercaw, *J. Am. Chem. Soc.* **1987**, *109*, 1444. Ferris, *ibid.* **1992**, *114*, 91.

[15] **5**: IR (neat): $\tilde{\nu}$ = 2165 (s, IrH), 1077 cm^{-1} (s, CO). Upon exposure to air, the CO peak disappears immediately and a broad OH signal, centered around 3400 cm^{-1} appears. ^{1}H NMR (400 MHz, C_6D_6, 22 °C, referenced to the residual solvent peak): δ = 4.09 (d, $^4J^d$(H,P,*trans*) = 5.6 Hz, 3H; OCH_3) 1.40 (t, J(apparent)(H,P) = 3.6 Hz, 18H; 2P(CH_3)$_3$), 1.13 (d, ^2J(H,P) = 10.5 Hz, 9H; P(CH_3)$_3$), −21.56 (dt, $^2J^d$(H,P) = 19.2, $^2J'$(H,P) = 14.7 Hz; 1H; Ir*H*). ^{1}H{^{31}P} NMR (C_6D_6): δ = 4.09 (s, 3H), 1.40 (s, 18H), 1.13 (s, 9H), −21.56 (s, 1H). ^{31}P{^{1}H} NMR (C_6D_6, referenced to external 85% solution of H_3PO_4 in D_2O): δ = −30.9 (d, ^2J(P,P,*cis*) = 18.5 Hz, 2P), −50.6 (t, ^2J(P,P,*cis*) = 18.5 Hz, 1P). ^{13}C{^{1}H} NMR (C_6D_6, referenced to the solvent peak): δ = 65.3 (br.s; OCH_3), 21.2 (d, ^1J(C,P) = 37 Hz; P(CH_3)$_3$), 16.2 (t, ^{virt}J(C,P) = 18 Hz; 2P(CH_3)$_3$). **6**: ^{1}H NMR (400 MHz, C_6D_6, 22 °C, referenced to the residual solvent peak): δ = 1.36 (t, J(apparent)(H,P) = 3.6 Hz, 18H; 2P(CH_3)$_3$), 1.19 (d, ^2J(H,P) = 9.6 Hz, 9H; P(CH_3)$_3$), −2.15 (d, ^3J(H,P,*trans*) = 5.8 Hz, 1H; IrOH), −21.73 (dt, $^2J^d$(H,P,*cis*) = 17.7, $^2J'$(H,P,*cis*) = 16.8 Hz, 1H; Ir*H*). ^{31}P{^{1}H} NMR (C_6D_6, referenced to the solvent peak): δ = −33.0 (d, ^2J(H,P,*cis*) = 18 Hz, 2P), −49.3 (t, ^2J(H,P,*cis*) = 18 Hz, 1P).

[16] T. Herskovitz, *Inorg. Synth.* **1982**, *21*, 99.

[17] We found that **7** is completely dissociated into **7a** and cyclooctene at room temperature in C_6D_6.

[18] a) W. D. Jones, V. L. Kuykendall, *Inorg. Chem.* **1991**, *30*, 2615; b) P. L. Kuch, R. S. Tobias, *J. Organomet. Chem.* **1976**, *122*, 429.

[19] The second order rate constant is 3.50×10^{-4} M^{-1} s^{-1}. This reaction was discussed in detail in ref. [9] and in references therein.

[20] As the exchange reaction is fast, practically only **5b** is available for the β-hydride elimination. Yet, since deuterium substitution α to the oxygen atom is not expected to influence the reductive elimination rate by much, the comparison to **5** is relevant.

[21] A mechanism involving H/D exchange with C_6D_6 is unlikely since **5** is unreactive in neat C_6D_6, and since also in [H_8]THF reaction c in Scheme 2 yields only **5a**.

[22] In CD_3OD the observed rate constant for the disappearance of the IrH signal in ^{1}H NMR spectrum is the simple sum of the first order rate constants of the reductive elimination to **7a** and the β-H elimination to **8**. The rate constant of reaction b in Scheme 2 was obtained by following the disappearance of the overlapping signals of the aliphatic protons of **5** and **5b**.

[23] *mer-cis*-[HIrCl$_3$(PMe_3)$_3$] [24] is obtained. Yet, since the presence of LiCl does not change the oxidative addition rate, it has the same rate-determining step as the methanol oxidative addition in absence of LiCl.

[24] A. A. Zlota, F. Frolow, D. Milstein, *J. Chem. Soc. Chem. Commun.* **1989**, 1826.

[25] These rule out reversible, non-rate-determining phosphane or chloride dissociation, followed by O–H reductive elimination. Experiments reported in ref. [9] exclude also mechanisms involving rate-determining initial dissociation of phosphane or chloride. Repeating reaction b in Scheme 2 in presence of [D_6]PMe_3 brought to no incorporation of labeled phosphane into **8**. As reaction c in Scheme 2 is faster and reversible under the conditions applied, this result indicates that any phosphane dissociation from **5** must be very slow, and not on the reaction pathway. Chloride heterolysis from **5** is on the pathway of reaction b in Scheme 2, and is methanol catalyzed. As a minimum amount of methanol is necessary to solvate the basic methoxo ligand (and possibly to participate in relatively strong hydrogen bonding with it), a methanol concentration threshold was observed for this reaction. The equilibrium in Scheme 1 and the reaction c in Scheme 2 are not catalyzed by methanol, implying that rate-determining chloride dissociation is not on the O–H reductive elimination pathway.

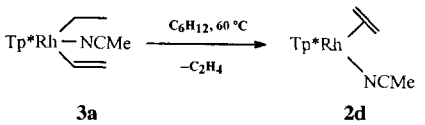
Does the Facile Inter- and Intramolecular C–H Bond Activation by Tp*–Rh Complexes Proceed via Rh^I or Rh^{III} Intermediates?**

Pedro J. Pérez, Manuel L. Poveda, and Ernesto Carmona*

The majority of C–H activation processes in arenes that are induced by Rh or Ir complexes of cyclopentadienyl or related ligands involve low-valent, electron-rich Rh^I or Ir^I centers as the reactive intermediates.[1, 2] Recent work from our laboratory[3] and from Bergman's group[4] has shown that more electrophilic Ir^{III} species are able to promote C–H activation under very mild conditions. In our case, as in a similar example reported by Graham et al.[5] the use of a hard, N-donor ligand, the tris(3,5-dimethylpyrazol-1-yl)hydroborate (Tp*), which is in addition known to enforce sixfold coordination,[6] contributes to the stabilization of the Ir^{III} oxidation state and drives, for example, the conversion of [Tp*Ir(C_2H_4)$_2$] into the thermodynamically more stable hydridovinyl Ir^{III} isomer [Tp*Ir(H)(CH=CH_2)(C_2H_4)].[7] We have now prepared the Rh analogue [Tp*Rh(C_2H_4)$_2$] (**1**) and would like to report preliminary studies which reveal intriguing and unexpected reactivity patterns in the thermal C–H activation.

Following Trofimenko's synthesis[8] of the unsubstituted Tp analogue, complex **1** was prepared in approximately 70% yield by reacting KTp* with [{RhCl(C_2H_4)$_2$}$_2$]. In solution **1** was found to be a highly fluxional molecule that exhibited an interesting behavior towards Lewis bases: Treatment of solutions of **1** in benzene at 20 °C with the soft donors CO, PMe_3, or *t*BuNC resulted in fast extrusion of one of the molecules of C_2H_4 and formation of the adducts **2** (Scheme 1).[9] However, under the

Scheme 1. Reactions of **1** with Lewis bases.



same conditions, the harder N-bases NCMe and C_5H_5N(py) produced the Rh^{III} complexes **3**, which contain ethyl and vinyl fragments derived from the original ethylene ligands. In com-

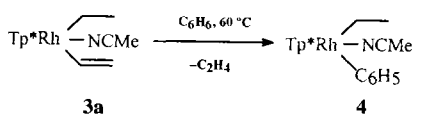
pound **3a** the coordinated NCMe ligand was substituted rapidly at 20 °C by $NCCD_3$ or PMe_3.

A more important observation was that **3a** in a cyclohexane solution maintained at 60 °C for 8 h, reverted to the Rh^I adduct **2d** [Eq. (a)]. Similarly, the CO complex **2a** was formed when the

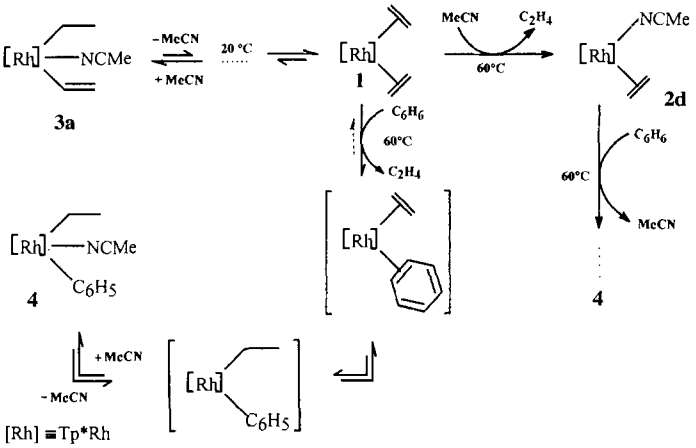
3a **2d** (a)



Rh^{III} derivative **3a** was stirred at 20 °C under an atmosphere of carbon monoxide. To account for this behavior, we propose that the bis(ethylene)–Rh^I complex **1** is in equilibrium with undetectable, although kinetically accessible, amounts of the hydridovinyl Rh^{III} isomer **A**, and that the ethylvinyl intermediate **B** is also attainable from **A** at room temperature (Scheme 2). The

Scheme 2. Proposed mechanism for the reactions in the system **1**, **2**, and **3**.

reactions of **1** with the soft donors proceed through the Rh^I route. This route seems to be kinetically disfavored for the harder donors at room temperature, and the corresponding reactions go to completion by the alternative, competitive Rh^{III} pathway. Since the aforementioned reactivity of **3a** suggests that intermediate **B** can also be reached from the Rh^{III} adduct, our results indicate that, at 60 °C, acetonitrile is able to enter the Rh^I pathway and displace one of the C_2H_4 ligands in **1** to afford the Rh^I adduct **2d**, which is obviously the thermodynamic product of the reaction of **1** with NCMe.



The lability of the acetonitrile ligand in **3a** makes this complex an ideal candidate for promoting intermolecular C–H bond activation reactions. When a benzene solution of **3a** was heated at 60 °C for 8 h, a smooth reaction ensued that furnished the ethylphenyl derivative **4** in almost quantitative yield [Eq. (b)]. With C_6D_6, $[D_{10}]$-**4** was obtained (i.e., the product

3a **4** (b)

was fully deuterated in both the phenyl and the ethyl fragments). The similarity between the starting material and the final product, together with the observation that free MeCN slows down this reaction, may suggest a mechanism involving the Rh^{III} intermediate **B** as the active species (see Scheme 2).

However, GC-MS analysis of the gas evolved in the reaction with C_6D_6 reveals the ethylene produced has normal isotopic composition, and this clearly contradicts the above proposal (see below). Since, as already shown, the bis(ethylene) complex **1** is accessible from **3a** under the reaction conditions, we propose that C_6H_6 activation occurs in an η^2-benzene species[10] resulting from the substitution of C_2H_4 by C_6H_6 in compound **1** (Scheme 3). The proposed reversibility for the C_6H_6 coordina-

Scheme 3. C–H activation with **3a**.

tion and activation steps is supported by the fact that identical products were obtained from the reactions of both **1** and **4** with a large excess of C_2H_4 at 60 °C (the η^4-butadiene complex [Tp*Rh(η^4-C_4H_6)] and two minor species, which have so far not been completely characterized). The mechanism provides a reasonable explanation for the formation of $[D_{10}]$-**4** in C_6D_6. It seems that, under the conditions used for the C_6H_6 activation reaction, the back transformation of the η^2-benzene adduct into **1** (Scheme 3) does not occur to a measurable extent. This explains the fact that only C_2H_4 was detected when C_6D_6 was used. Interestingly, complex **2d** also yielded **4** when heated in C_6H_6, but the conversion rate is lower than that of **3a**; therefore, **2d** cannot be an intermediate in the activation of C_6H_6 by **3a**.

In conclusion, we have demonstrated that: a) Apparently simple, straightforward reactions of the olefin complex **1** can proceed either with C_2H_4 replacement by the donor, in other words, with substitution at the Rh^I–C_2H_4 complex, or via an unsaturated Rh(H)(C_2H_3) species, that is to say, via a Rh^{III} hydridovinyl isomer. Such behavior is, to our knowledge, unprecedented. b) Despite the availability of the Rh^{III} unsaturated intermediates in this system, only Rh^I species seem to be directly involved in the activation of benzene. The implication for Rh^{III} compounds in this kind of reaction must await the design of appropriate model systems.

Experimental Procedure

1: A solution of $[\{RhCl(C_2H_4)_2\}_2]$ (0.79 g, 2 mmol) in THF (50 mL) was cooled to −30 °C and treated with KTp* (1.35 g, 4 mmol). The mixture was stirred for 4 h and volatiles were then removed under reduced pressure at −20 °C (overheating must be avoided up to this stage). The residue was dissolved in CH_2Cl_2/Et_2O (1/1, 40 mL) and filtered through Celite. The resulting yellow-orange solution was evaporated to dryness to give 1.5 g of complex **1** (80% yield). This product must be stored below 0 °C. ^1H NMR (500 MHz, C_6D_6, 25 °C): δ = 5.61 (s, 3H, $H_{arom.}$), 2.59 (d, 8H, $2C_2H_4$, J(H,Rh) = 2 Hz), 2.43 (s, 9H, 3Me), 2.16 (s, 9H, 3*C*-Me); $^{13}C\{^1H\}$ NMR (125 MHz, C_6D_6, 25 °C): δ = 150.4 (3*C*-Me), 143.4 (3*C*-Me), 107.1 ($3C_{arom.}$-H), 47.1 (d, $2C_2H_4$, J(C,Rh) = 12 Hz), 14.4 (3C-*Me*), 12.5 (3C-*Me*).

3a: Upon dissolving complex **1** (0.6 g, 1.3 mmol) in acetonitrile (20 mL) an off-white solution was rapidly formed. After the solution had been stirred for 15 min, it was concentrated until cloudy and cooled overnight at −20 °C. Complex **3a** was

obtained as white crystals in 75% yield. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 8.36, 6.02, 5.40 (m, 3H, Rh-CH$_A$=CH$_M$H$_X$, J(A,X) = 17, J(A,M) = 9, J(M,X) = 2, J(A,Rh) = 3, J(X,Rh) = 1, J(M,Rh) = 2 Hz), 5.83, 5.76, 5.61 (s, 3H, H$_{arom.}$), 2.80 (m, 1H, CH$_3$CH*H*), 2.70 (m, 1H, CH$_3$C*H*H), 2.55, 2.43, 2.39, 2.27, 2.26, 2.16 (s, 18H, 6Me), 1.09 (t, 3H, C*H*$_3$CH$_2$, J(H,H) = 7.5 Hz), 0.69 (s, 3H, NCMe); ^{13}C{^{1}H} NMR (125 MHz, C_6D_6, 25 °C): δ = 158.8 (d, CH$_2$=*C*H-Rh, J(C,Rh) = 30 Hz), 151.8, 149.1, 149.0, 143.3, 142.6, 142.2 (6*C*-Me), 118.2 (d, N*C*Me, J(C,Rh) = 12 Hz), 117.7 (*C*H$_2$=CHRh), 107.5, 106.0, 105.7 (3$C_{arom.}$-H), 16.8, 14.1, 13.7, 13.1, 13.0, 12.3, 12.1 (6Me and *C*H$_3$CH$_2$), 10.0 (d, CH$_3$*C*H$_2$, J(C,Rh) = 25 Hz), −0.4 (NC*Me*).

4: A solution of **3a** (0.2 g, 0.4 mmol) in benzene was heated at 60 °C for 8 h. Complex **4** was isolated as a white powder in 80% yield upon removing all volatiles under reduced pressure. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 7.64 (d), 7.42 (t), 7.13 (d), 7.09 (d), 6.94 (t) (5H, C$_6$H$_5$, J(H,H) = 7 Hz), 5.86, 5.77, 5.61 (s, 3H), 2.96 (m, 1H, CH$_3$CH*H*), 2.70 (m, 1H, CH$_3$C*H*H), 2.44, 2.29, 2.28, 2.20, 1.86, 1.69 (s, 18H, 6Me), 1.06 (t, 3H, C*H*$_3$CH$_2$, J(H,H) = 7.5 Hz), 0.51 (s, 3H, NCMe); ^{13}C{^{1}H} NMR (125 MHz, C_6D_6, 25 °C): δ = 159.0 (d, C$_q$Rh, J(C,Rh) = 30 Hz), 152.1, 149.0, 148.9, 143.2, 142.8, 142.0 (6*C*-Me), 140.6, 137.8, 126.0, 125.5, 121.2 (C$_6$H$_5$), 118.4 (d, N*C*Me, J(C,Rh) = 8 Hz), 107.8, 106.0, 105.9 (3$C_{arom.}$-H), 16.9, 14.0, 13.5, 13.2, 13.1, 12.4, 12.2 (6*C*-*Me* and *C*H$_3$CH$_2$), 11.7 (d, CH$_3$*C*H$_2$, J(C,Rh) = 25 Hz), 0.8 (NC*Me*).

LaI: An Unprecedented Binary Rare Earth Metal Monohalide with a NiAs-Type Structure**

James D. Martin and John D. Corbett*

For more than 30 years, considerable effort has been devoted to the discovery and characterization of binary halides M_aX_b rare earth metals in low oxidation states. Dihalide phases with X = Cl, Br, and I are known for a majority of the rare earth metals. These exhibit saltlike characteristics except for the metallic diiodides of La, Ce, Pr, Gd, and Sc. Other reduced halides M_2X_3 and M_2X_5 seem to be more limited and elusive.[1] Nevertheless, the quest for binary monohalides of the rare earth metals has witnessed a tumultuous history. Numerous reports of supposed binary rare earth monohalides,[2] in which the heavy atom arrangement is the same as in the truly binary phases ZrCl and ZrBr,[3] were later shown to be MXH_n phases ($\approx 0.67 \leq n \leq 1$) stabilized by hydrogen atoms in the tetrahedral interstices between the double layers.[4, 5] As a result, it has been generally concluded that binary monohalide phases of these elements do not exist. But if a monohalide were to exist, chemical experience would predict that the larger, more polarizable iodide should provide the most stable compound either as a conventional salt or, more likely, as a metallic phase like LaI_2.[6]

We report here the first example of a truly binary rare earth metal monohalide, LaI, discovered during our explorations of very reduced lanthanum/iodine/transition metal systems. This unprecedented monohalide is also the first to adopt the NiAs-type structure, as depicted in the [110] projection in Figure 1. Here La occupies all octahedral interstices (site 2*a*; 0, 0, 0) between the hexagonal closes-packed (hcp) iodide layers (2*c*; 1/3, 2/3, 1/4) in the hexagonal space group $P6_3/mmc$.[7] Furthermore, LaI exhibits by far the largest c/a ratio (2.47) of any known compound with a NiAs-type structure. This compares with $c/a = 1.63$ for closest packing of spheres and the previous maximum c/a ratio of 1.93 for TiS, which had been considered anomalously large.[8] The elongation of the c axis is a consequence of an optimization of La–La bonding within the (002) planes under the constraints of reasonable La–I interactions and closed-shell repulsions between iodine ions. The I-La-I angles for I atoms related by the 3 and $\bar{3}$ symmetry operations are 72.50(1) and 107.50(1)°, respectively. The I···I distance (sixfold) of 3.93 Å is a little less than those reported for rare earth metal iodides with cluster or chain structures (3.96 and 3.97 Å in $Y_6I_7C_2$ and $Sc_7I_{12}C$ are the shortest[9]). But the repulsion is offset by an equal number of bonding La–La interactions also at 3.93 Å. This corresponds to a Pauling metallic bond order of 0.128 (× 6), whereas the La–La distance of 4.86 Å along c corresponds to one of 0.004 (× 2). The two observed La–La distances are far different from those predicted for an ideal hcp NiAs-type structure with the same La–I distances namely, 4.7 and 3.8 Å, respectively. The La–I distances of 3.3227(2) Å are 0.09 Å larger than the estimated sum of the radii of the six-coordinate atoms,[10] but close to the 3.35 Å distances reported for LaI_2 ($MoSi_2$-type, eight-coordinate).[11] The NiAs structure is distinctive in its relative flexibility compared with higher symmetry or layered structures and can, as seen, accommodate enhanced metal–metal interactions even in the presence of relatively large anions.[8]

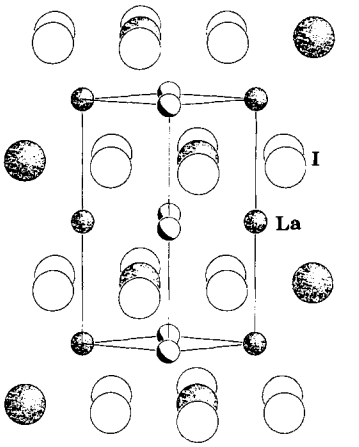

Fig. 1. [110] view of LaI (NiAs-type structure, La: ○, I: ○). The atoms in the [110] section are shaded, while atoms in two additional layers both in front and back are white.

LaI is obtained by reduction of sublimed LaI_3 by La metal (Ames Lab, 99.8 atom% total, 0.07 atom% H) at 750 °C for several weeks in a welded niobium tube that is in turn sealed within a well-baked, evacuated fused silica jacket. Reactions of

[**] The authors gratefully acknowledge Prof. M.-H. Whangbo and Dr. E. Canadell for helpful discussions and Dr. Ming Xu for magnetic susceptibility measurements. This research was supported by the National Science Foundation, Solid-State Chemistry (grant DMR-9207361), and was carried out in the facilities of the Ames Laboratory of the U.S. Department of Energy.

binary mixtures with the components in the desired stoichiometry are incomplete and yield a mixture of LaI (≈40%), LaI_2, and La after ten weeks in which the iodides completely cover the metal surfaces. Only LaI_2 has been observed from reactions run at or above 800 °C, implying that the stability range of LaI has been exceeded. LaI that is free of other iodides according to Guinier patterns has been obtained from the same type of reactions with a onefold excess of La. These reaction mixtures also contained Mn or Cr, but these do not yield iodide phases under these conditions and appear to be completely superfluous. Several large single crystals from a reaction with Mn were found to contain only La and I in a 1:1 ratio according to results of scanning electron microscopy with energy dispersive spectroscopy. In the slow reactions that yield LaI from LaI_2 and La, transport appears to be the rate-limiting factor, probably because of low LaI_3(g) pressure above LaI_2(s). Preliminary experiments have not yet revealed similar monoiodide phases for other rare earth elements (Pr, Nd, Gd); however, appropriate reaction conditions may yield positive results. LaI has a metallic appearance with a silver to light gold reflectance and is typically found coating the surface of the metal. It can be readily distinguished from the layered LaI_2 by the latter's violet-purple reflectance and ready cleavage.

The long reaction times, enhanced yields from lanthanum-rich reactions, and the low apparent decomposition temperature are somewhat reminiscent of the earliest reports of numerous rare earth monohalides that later proved to be halide hydrides MXH_n.[2, 4, 5] In those cases hydrogen initially came from adventitious sources, for example from metals prepared by decomposition of MH_2 or from H_2O from the walls of insufficiently baked fused silica reaction jackets. Traces of water in the reaction mixture normally led to an MOI by-product, but LaOI has been notably absent from our reactions. To clarify further the possibility of hydrogen in LaI, several reactions of LaI_3, LaH_2, and La were run at 750 °C for three to four weeks. The reaction with an overall La:I:H mole ratio of 1:1:1 yielded the desired iridescent green phase in 95% yield (plus an unknown black powder). Thus the bona fide $LaIH_n$ ($n \approx 1$) adopts the expected layered ZrCl-type structure for the heavy atoms ($a = 4.2063(4)$, $c = 31.947(7)$ Å). This product was sealed in a Nb container and heated for 9 h at 770 °C in dynamic high vacuum, whereupon ≈40% decomposed to LaI (plus traces of LaOI and LaI_2). That the new LaI must contain very little hydrogen, if any, was confirmed by a similar synthesis reaction with a La:I:H mole ratio of 1:1:0.25, which yielded 45–55% $LaIH_n$, 35–40% LaI, 5–10% LaI_2 (presumably because of incomplete reaction), and ≈5% LaOI. Virtually no hydrogen remains for LaI if the limiting hydride content of $LaIH_n$ is near $n = 0.6$, as reported elsewhere.[12] The overall results are not characteristic of an undetected ternary interstitial atom at significant levels, but very small amounts of hydrogen may never be ruled out.

Actually the NiAs-type structure itself affords strong evidence that interstitial hydrogen atoms cannot be important. Unlike the close-packed, double metal layers in the ZrCl- and ZrBr-type frameworks, where the hydrogen atoms in MXH_n occupy tetrahedral cavities within condensed trigonal antiprisms of M atoms,[5, 12] the NiAs structure type with a trigonal-prismatic arrangement of metal atoms affords no plausible cavities for hydrogen. The heavy atoms in recently described dihalides such as $LaBr_2D_{0.9}$ adopt MoS_2-like layered structures such that a trigonal prism of halogen atoms surrounds each metal atom.[13] This affords each hydrogen atom a trigonal-planar site (c) in the metal layer (b) with no adjacent halogen atoms [Ab(c)A]. In contrast, each hydrogen atom in the equivalent site in an NiAs structure [Ab(c)C] would have three La atoms at a reasonable distance of 2.27 Å, but one coaxial iodine atom only 2.42 Å away. If the hydrogen atom is displaced 0.53 Å from the iodine atom, the I···H distances to all four neighboring iodine atoms would be 2.96 Å. Nonetheless, this is still quite short compared with either the estimated sum of crystal radii (3.16 Å) or, better, the distances derived from the shortest D···Br separations found in this sort of structure, namely in $Th_6Br_{15}D_7$[14] and Zr_2Br_2D (3.13 and 3.18 Å, respectively),[15] when corrected for the 0.24 Å difference in radii of the halogens. Such a cavity with three La and also four close I neighbors does not appear at all suitable for binding hydrogen atoms.

Like the MI_2 phases, LaI is expected to exhibit metallic properties. While sufficient quantities of single-phase LaI have not yet been synthesized for reliable measurements, two-probe conductivity measurements on a single crystal (using La contacts) indicated virtually only contact resistance in the best directions with appreciably higher resistance in others. Magnetic susceptibility measurements from 6 to 300 K on a single-phase sample (by X-ray diffraction) showed a Pauli paramagnetism of 2.0×10^{-4} emu mol^{-1} after core corrections.

Extended Hückel tight-binding (EHTB) band calculations[16] have been carried out to ascertain more about the electronic structure of LaI. The dispersion relations of the d-block bands are shown in Figure 2. The calculated Fermi surface of the

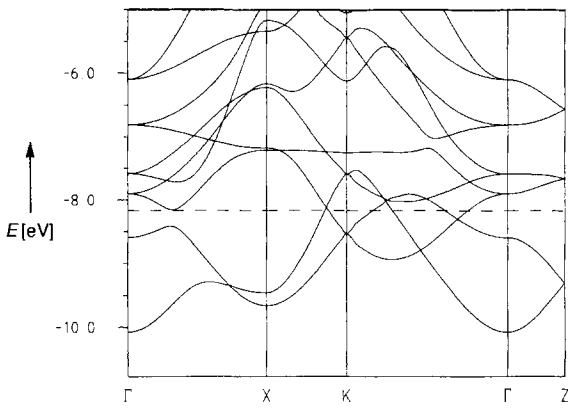

Fig. 2. The La d-block bands in LaI according to EHTB band calculations; the Fermi level is marked by a dashed line. The iodine valence band lies below −12.0 eV. X = $a^*/2$, 0, 0; K = $a^*/3$, $b^*/3$, 0; Z = 0, 0, $c^*/2$. (Parameters from E. Canadell, M.-H. Whangbo, *Inorg. Chem.* **1994**, *33*, 287.)

three-dimensional structure with the large c/a ratio is strongly anisotropic and best described as six warped cylinders oriented along the c^* direction with hole and electron pockets at c^* and $c^*/2$, respectively. (Cross sections of the calculated Fermi surface at 0.1 intervals along 0, 0, c^* are included in the supplementary material). Because of symmetry the two electron surfaces are degenerate at $c^*/2$. Thus, the warped cylinder is closed by the electron pocket. Strongly anisotropic conductivity characteristics are expected. Strong La–La bonding within the *a*, *b* plane is responsible for the extensive mixing of the bands perpendicular to c^* derived from the "t_{2g}-like" d orbitals. This along with poor La–La bonding along *c* creates the strongly anisotropic Fermi surface in spite of the symmetry-required degeneracy which closes the surface along c^*.

Because of the *k*-vector dependent mixing of t_{2g}-like bands, LaI cannot be considered a version of the 1T-MX_2 (CdI_2-type) layered structures in which diverse patterns of metal clustering are driven by charge density waves.[17] The absence of any

superstructure at room temperature has been confirmed by Weissenberg photographs of the *hk*0 and *hk*1 layers, and there is no sign of a transition in the magnetic data >6 K.

[7] Crystal structure analysis of LaI: Lattice constants, $a = 3.9297(4)$, $c = 9.710(1)$ Å were obtained from Guinier powder patterns ($\lambda = 1.540562$ Å), $V = 129.86(4)$ Å^3, $Z = 2$, hexagonal space group $P6_3/mmc$ (no. 194). Data were collected on a Rigaku AFC6 diffractometer at 22 °C with monochromated $Mo_{K\alpha}$ radiation ($h,k,\pm l$). The structure was solved by direct methods (SHELXS). The residuals were $R(F) = 0.028$, $R_w = 0.029$ for 49 independent reflections ($2\theta < 50°$, $I > 3\sigma(I)$) and 7 variables. The platelike crystal habit ($0.05 \times 0.15 \times 0.6$ mm) caused significant absorption problems ($\mu = 278.9$ cm^{-1})($R = 0.054$) which were corrected by the DIFABS method (N. Walker, D. Stuart, *Acta Crystallogr. Sect. A* **1983**, *39*, 158; transmission range 0.581–1.175). This removed the anisotropy in thermal parameters of both atoms and the corresponding "ghost peaks" (3.0–2.1 e Å^{-3}) in the difference Fourier map. An inverse NiAs structure can clearly be ruled out, since it gave a poorer refinement and disparate temperature factors (B-values). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-58 680.

Molecular Recognition at an Interface: Binding of Monolayer-Anchored Ferrocenyl Groups by an Amphiphilic Calixarene Host**

Litao Zhang, Luis A. Godínez, Tianbao Lu, George W. Gokel, and Angel E. Kaifer*

Self-assembly of alkanethiols on gold surfaces constitutes one the most useful methods for the preparation of supported monolayers exhibiting a high degree of molecular organization.[1] The preparation of similar monolayers incorporating molecular recognition sites is of fundamental as well as practical importance. However, the literature contains only a few reports of binding phenomena in supported monolayer systems.[2] We demonstrate here that ferrocenyl groups covalently attached to a supported alkanethiol monolayer can be complexed effectively by an amphiphilic receptor in the contacting aqueous solution. The major finding of this work is that the receptor must have substantial amphiphilic character in order to bind the guest residues anchored to the monolayer assembly.

Coassembly of the thiolated ferrocene derivative **1** with an alkanethiol yields mixed monolayers in which, by selecting the length of the alkanethiol chain, one can easily vary the degree of accessibility of the ferrocenyl groups to the contacting solution.[3] Exposure of a gold bead electrode to an ethanolic solution containing 0.25 mM **1** and 0.75 mM decanethiol ($C_{10}H_{21}SH$) resulted in the coassembly of a monolayer in which the ferrocenyl groups protrude from the hydrophobic core. The voltammetric response of this supported monolayer in 1.0 M $HClO_4$ (Fig. 1) is characterized by the reversible oxidation of the surface-confined ferrocenyl groups ($Fc \rightleftharpoons Fc^+ + e^-$). The formal oxidation potential measured from the cyclic voltammogram was +0.51 V vs a sodium chloride saturated calomel electrode (SSCE), and the potential difference between the anodic and cathodic peak potentials (ΔE_p) was typically smaller than 10 mV at scan rates of 0.5 V s^{-1} or less. The surface coverage of ferrocenyl groups, as determined from the integration of the anodic wave, was 1.2×10^{-10} mol cm^{-2}, while the maximum coverage obtained in our experiments from self-assembly of pure **1** (no alkanethiol) was 4.3×10^{-10} mol cm^{-2}. All these electrochemical parameters are in agreement with published values for this and similar ferrocenyl-containing, self-assembled monolayer systems.[4]

1

We have recently reported that the sulfonated calix[6]arene **2** is an excellent host for several ferrocene derivatives in aqueous media.[5] Thus, we were interested in probing the interactions of monolayer-anchored ferrocenyl groups with this host. However, we could not find any evidence for binding, as the E° value for the oxidation of the ferrocenyl groups in the monolayer did not change appreciably when the contacting solution contained

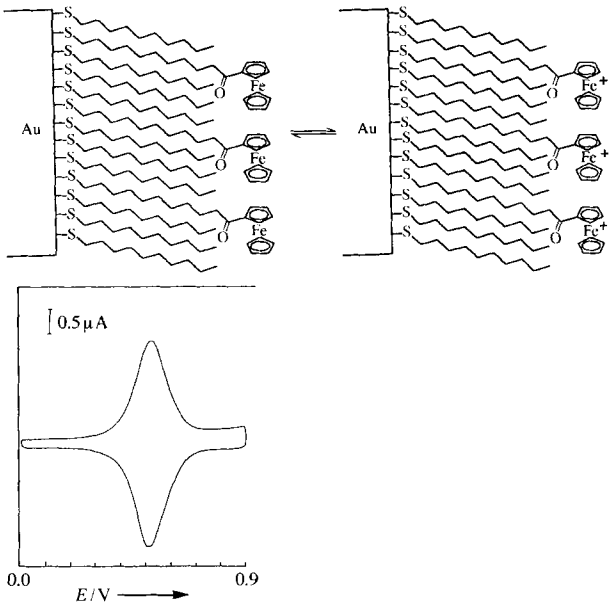

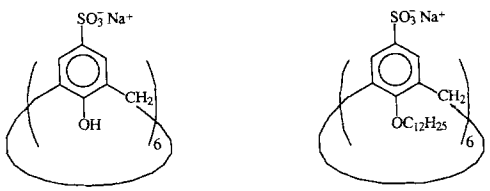

Fig. 1. Voltammetric response of a mixed monolayer formed by the coassembly of **1** and $C_{10}H_{21}SH$ on a gold bead electrode. The voltammogram was recorded with the monolayer-modified electrode immersed in 1.0 M $HClO_4$. Initial potential: 0.0 V vs SSCE; scan rate: 0.5 $V s^{-1}$.

the calixarene host, even at concentrations as high as 1–2 mM. This highly charged, anionic host must be strongly solvated by water molecules,[6] which seems to prevent its effective approach to the ferrocenyl groups residing in the monolayer/solution interface.

Thus we turned our attention to an amphiphilic analogue of **2**, the dodecyl derivative **3**, which is prepared by O-alkylation of

2 **3**

the parent calixarene.[7] Very low concentrations of **3** have a profound effect on the voltammetric response of the $C_{10}H_{21}SH$/**1** monolayer. For instance, in the presence of 0.4 μM **3** the anodic peak for ferrocene oxidation splits into two well-resolved peaks (Fig. 2 top). The first one remains at approximately the same potential as that observed in the absence of **3**, while the second one is shifted in the positive direction by about 90 mV. The latter peak increases with the concentration of **3** at the expense of the original peak. In the presence of 2 μM **3**, only the calixarene-induced peak is observed. We thus assign this new redox couple to the oxidation of the monolayer-anchored ferrocenyl groups complexed by the amphiphilic calixarene hosts. Figure 2 bottom shows a comparison of the initial (no **3** added) and final (in the presence of 2.0 μM **3**) voltammetric responses. Further additions of **3** do not affect the voltammetric response of the monolayer.

Potential cycling of a gold electrode derivatized with a $C_{10}H_{21}SH$/**1** monolayer results in a gradual loss of ferrocene coverage due to the slow decomposition of the oxidized ferrocenyl sites.[8] This decomposition reaction is responsible for the decreased peak currents observed in the presence of 2 μM **3** (see Fig. 2 bottom), as this voltammogram was recorded after several additions of calixarene and several potential cycles to monitor their effects. As a control experiment, a gold electrode derivatized with a $C_{10}H_{21}SH$/**1** monolayer was submitted to prolonged potential cycling between 0.0 and 0.9 V vs SSCE in a 1.0 M $HClO_4$ solution (no calixarene). As expected, the currents associated with the ferrocene redox couple continuously decreased with cycling time, but the oxidation potential remained unaffected at 0.51 V vs SSCE. Therefore, the changes in oxidation potential observed upon addition of calixarene are due to changes in ferrocene's microenvironment, not to variations in the surface density of ferrocenyl sites in the monolayer.

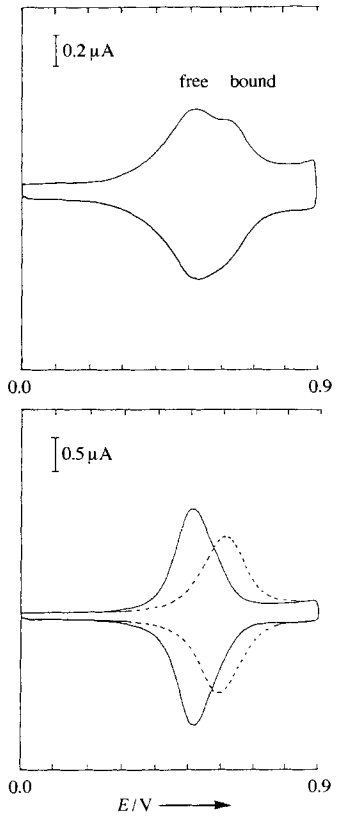

Fig. 2. Top: Voltammetric response of a mixed monolayer prepared like that in Figure 1 in the presence of **3** (0.4 μM) in the contacting solution. Bottom: Comparison of the voltammograms obtained in the absence (continuous line) and in the presence (dotted lined) of **3** (2.0 μM) in the contacting solution. All other conditions were as those used in Figure 1.

Recently, Craeger et al. have shown that the presence of long-chain alcohols in the solution phase causes substantial anodic shifts in the oxidation potential of monolayer-anchored ferrocenyl residues.[9] They interpreted these findings as the result of aggregation of the long-chain alcohol at the monolayer/solution interface which increases the hydrophobic character of the ferrocene microenvironment, thus favoring the reduced neutral form over the oxidized cationic form and shifting the oxidation potential to more positive values. Our results with **3** cannot be explained simply by the aggregation of the amphiphilic calixarene at the monolayer/solution interface because of two key experimental findings: 1) The presence of **3** in the solution causes the split of the ferrocene redox couple into two couples that can be clearly assigned to the oxidation of free and bound ferrocenyl sites. 2) The splitting of the ferrocene redox couple is only detected in the concentration range 0.05–2 μM **3**. At higher concentrations of **3** the voltammetric behavior remains constant, indicating that all the monolayer ferrocenyl groups are bound so that further additions of host have no effect in the observed E° value. These observations are fully consistent with the proposed interfacial binding of the ferrocenyl sites by the amphiphilic calixarene host. We performed several control experiments exposing $C_{10}H_{21}SH$/**1** monolayers to solutions contain-

ing increasing concentrations of amphiphiles having only one alkyl chain. The results are shown in Figure 3. In agreement with Craeger's observations with long-chain alcohols,[9] both amphiphiles surveyed (dodecyl sulfate and dodecyltrimethylammonium) caused anodic shifts in the oxidation potential of the monolayer-anchored ferrocenyl groups. However, the redox couple never splits, and the magnitude of the observed potential shifts was smaller than the saturation shift observed with **3**. These findings, as well as the insensitivity of the E° shifts to the amphiphile's positive or negative charge, are consistent with the aggregation of the amphiphiles on the monolayer/solution interface. The differences between these data and those obtained with the amphiphilic calixarene clearly suggest a more specific mechanism for the interaction between the ferrocene groups and these host molecules.

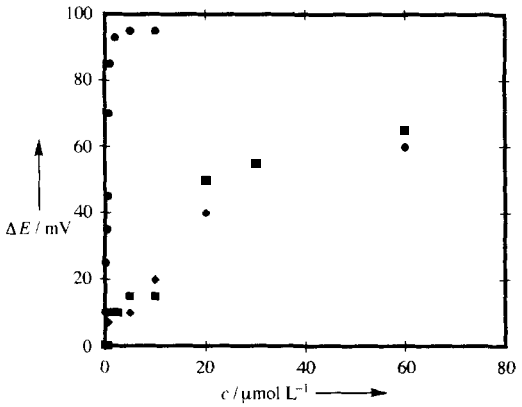

Fig. 3. Oxidation potential shift of the monolayer-anchored ferrocenyl groups induced by the addition of micromolar solutions of **3** (●), sodium dodecyl sulfate (■), and dodecyltrimethylammonium bromide (◆).

The calixarene-induced E° shift of +90 mV is very similar to that observed in solution for the binding of ferrocene derivatives by β-cyclodextrin.[10] This value contrasts with the larger negative shifts observed for the binding of ferrocene derivatives by compound **2** in solution.[5] In the latter case, the calixarene acts as an anionic host. In this work, host **3** probably interacts with the ferrocenyl group primarily by including it "octopus-like" in its aliphatic "tentacles" (Fig. 4). The change in the microenvironment of the ferrocenyl groups upon binding by **3** is thus close to that suffered upon inclusion by cyclodextrin in solution experiments, which explains the similarity in the observed oxidation potentials shifts.

Coassembly of **1** and octadecanethiol ($C_{18}H_{37}SH$) leads to a monolayer in which the formal oxidation potential of the ferrocenyl groups is quite insensitive to the presence of host **3** in the

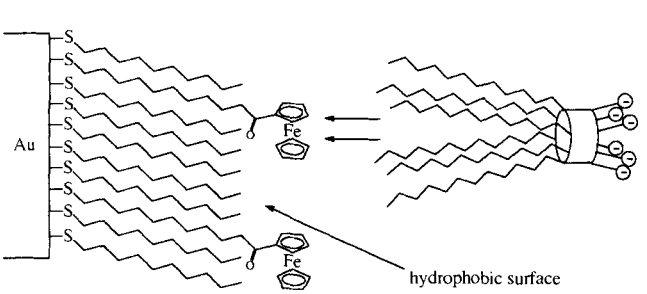

Fig. 4. Schematic representation of the proposed mode of interaction between the monolayer-anchored ferrocenyl groups and the amphiphilic calixarene host **3**.

containing monolayer. In this case, the alkanethiol's chains are long enough to surround the ferrocenyl sites in the hydrophobic core of the monolayer, preventing their interaction with the calixarene host in the contacting solution. Therefore, the location of the ferrocenyl groups in the monolayer assembly plays an important role in their binding by amphiphilic hosts.

In summary, we provide evidence in this work for the complexation of monolayer-anchored ferrocenyl groups at an interface by the sparingly water-soluble, amphiphilic calixarene host **3**. The binding was detected electrochemically from the profound effects that very low concentrations (0.05 - 2.0 μM) of the host exert on the voltammetric response of the ferrocenyl sites at the interface. The parent calixarene **2** lacks the amphiphilic character that seems to be necessary to show effective receptor properties in interfacial environments. The results reported here combined with recently published data[11] establish calixarene **3** as a versatile interfacial host.

Experimental Procedure

Thiol **1** was synthesized according to a reported procedure [4a]. The calixarene hosts were prepared as their corresponding salts (Na_8-**2** and Na_6-**3**) according to the methods described by Shinkai and co-workers [7]. Sodium dodecyl sulfate and dodecyltrimethylammonium bromide were obtained from Fluka and Kodak, respectively, and used without further purification. Gold wire (99.999%) was purchased from Johnson Matthey. All other chemicals and solvents were of the best commercial grade available. Distilled water was further purified by passage through a Barnstead Nanopure four-cartridge system.

The gold bead working electrodes were made as reported elsewhere [12]. The geometric and true surface areas of these electrodes were measured by published methods [12]. The voltammetric response of these electrodes was checked in 1.0 M $HClO_4$. Flat background responses in the potential range 0.0 to +0.90 V vs SSCE were commonly found. Otherwise, the electrode was discarded.

For monolayer preparation the gold bead electrode was immersed overnight in deoxygenated ethanolic solutions containing mixtures of **1** and the appropriate alkanethiol. The total concentration of thiol was always maintained at 1.0 mM. Before the cyclic voltammetric experiments, the gold bead electrode was rinsed with copious amounts of pure ethanol and then purified water. Cyclic voltammetry (single compartment cell, Pt flag counter electrode, homemade SSCE) was performed with the monolayer-covered gold bead working electrode immersed in 1.0 M $HClO_4$ (cell volume 10 mL). As required by the binding studies, the hosts were introduced to this solution by addition of microliter aliquots by syringe from appropriate stock solutions.

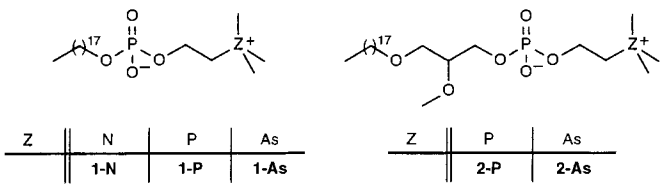
Synthesis, Antitumor Activity, and Tolerability of Phospholipids Containing Nitrogen Homologues**

Jurij Stekar,* Gerhard Nössner, Bernhard Kutscher, Jürgen Engel, and Peter Hilgard

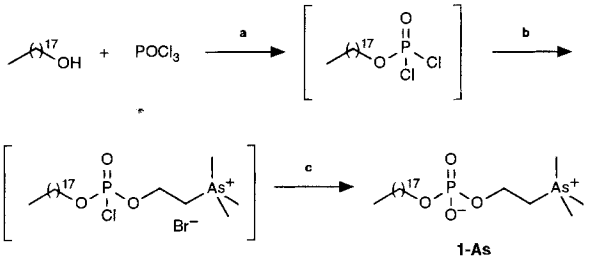
Edelfosine (2-*O*-methyl-1-*O*-octadecyl-*rac*-glyceryl-3-phosphocholine, **2-N**) and miltefosine (hexadecylphosphocholine) are prototypes of new antineoplastically active phospholipids that have been already used clinically. However, oral administration of these drugs to cancer patients was seriously hampered

miltefosine



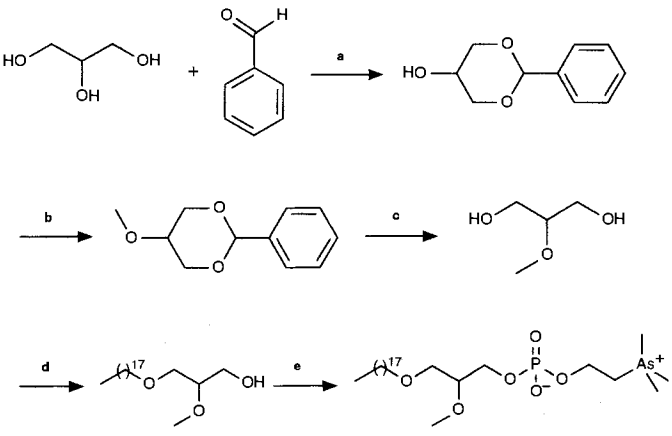
edelfosine 2-N

by side effects in the digestive tract (nausea, vomiting, diarrhea, loss of body weight).[1] Corresponding animal experiments led us to assume that during the metabolism of these phospholipids, choline esters are formed which imitate the effects of the parasympathetic nervous system on the intestine; such compounds might be responsible at least in part for the symptoms observed in patients and animals. This hypothesis has been supported by the finding that a heterocyclic phospholipid in which choline is replaced by *N*-(2-hydroxyethyl)-*N*-methylpiperidine is tolerated much better.[2]



In our search for new phospholipids with better tolerability and higher cytostatic activity, special attention was given to the fact that phosphonium and arsonium homologues of choline esters (e.g. of acetylcholine) exert a considerably weaker parasympathomimetic action than the choline esters themselves.[3] Furthermore, it was recently recognized that large amounts of arsonium compounds are ingested with sea food (lobsters, crabs, and clams contain up to 80 ppm arsenic; As content of sea water is only 0.003 ppm!) mainly in the form of just slightly toxic compounds such as arsonium betaine and arsonium choline.[4, 5] Based on these findings, it seemed possible that replacement of N in choline with As or P would lead to better tolerable but still chemotherapeutically active phospholipids. Accordingly, the biological effects of the new analogues (Scheme 1) synthesized to test this working hypothesis were compared to those of the parent compounds **1-N** (octadecylphosphocholine) and **2-N**. The analogues are derived from the parent compounds by exchange of the central atom of the onium complex while maintaining the hydrophobic octadecyl and octadecylglyceryl residues, respectively. We report here on the syntheses and first results of biological tests with these novel derivatives.

The parent compounds **1-N** and **2-N** were prepared as described previously.[6, 7] In the synthesis of [2-(trimethylarsonio)ethyl]-*n*-octadecylphosphate (**1-As**) (Scheme 1), phosphoryl



Scheme 1. General formulas and abbreviations for the homologous phospholipids.

chloride was treated with *n*-octadecanol. The resulting *n*-octadecylphosphoric dichloride was not isolated but treated directly with 2-hydroxyethyltrimethylarsonium bromide (prepared from trimethylarsane and bromoethanol according to Irgolic et al.[8]). The phosphoric diester chloride that formed was hydrolyzed to yield **1-As** as an inner salt (Scheme 2). The homologous compound **1-P** was prepared analogously from *n*-octadecanol, $POCl_3$, and 2-hydroxyethyltrimethylphosphonium bromide (yield 24%).

Scheme 2. Synthesis of **1-As**. a) $CHCl_3$/pyridine/0 °C; b) $HO(CH_2)_2As^+(CH_3)_3Br^-$/pyridine/0 °C → 20 °C; c) 10% HCl/purification with ion exchange resin (Amberlite MB3, ethanol)/digestion with acetone; total yield 43%.

In the synthesis of 2-*O*-methyl-1-*O*-octadecyl-*rac*-glyceryl-3-phosphoarsonium choline (**2-As**), methylation of 1,3-benzylideneglycerol with dimethyl sulfate was followed by cleavage of the benzylidene residue and alkylation with methyl octadecylsulfonate to provide 2-*O*-methyl-1-*O*-octadecyl-*rac*-glycerol. Subsequent phosphorylation with $POCl_3$, reaction of the intermediate with arsonium choline bromide, and hydrolysis of the resulting diester led to **2-As** (Scheme 3). The phosphonium ana-

[a] The chemical shifts are relative to external tetramethylsilane (TMS). All spectra were recorded at 25 C and 500 µHz on a Bruker AMX-500 spectrometer. Abbreviations: s singlet, d doublet, t triplet, q quartet, quin quintet. Number of protons in parentheses determined by signal integration. Correct elemental analyses.

As evident from Table 2, the novel phospholipids are less toxic for mice than the two cholinephospholipids **1-N** and **2-N**. This is particularly noteworthy since arsenic compounds are generally quite poisonous. These results indicate that the toxicity of the phospholipids containing hydrophobic regions of the same structure is determined solely by the atomic number of the Group 5 element that is the central atom in the hydrophilic onium complex.

Table 2. Acute oral toxicity (LD_{50} p.o. [a], mmol kg^{-1}) of **1-N**, **2-N**, and the corresponding phosphonium and arsonium phospholipids in mice.

Hydrophobic region	Onium group Me_3N	LD_{50}	Me_3P	LD_{50}	Me_3As	LD_{50}
octadecyl	**1-N**	0.8	**1-P**	1.8 [b]	**1-As**	2.0 [c]
2-*O*-methyl-1-*O*-octadecylglyceryl	**2-N**	0.8	**2-P**	1.8 [b]	**2-As**	1.7 [b]

[a] The acute oral LD_{50} value is the dose per kilogram body weight that results in the death of 50% of the animals (solutions or suspensions are introduced to the stomach by means of a stomach tube). The LD_{50} value serves as a measure of the toxicity of a given compound; a higher value thus indicates lower toxicity. To determine the LD_{50} value, each of four equidistant logarithmic doses were applied to ten mice, and the results were evaluated by using logit analysis. [b] $P < 0.05$ vs LD_{50} of the corresponding N-containing phospholipid. [c] $P = 0.001$ vs LD_{50} of **1-N**.

The comparatively low acute toxicity of **1-P** and **1-As** is not accompanied by reduced cytotoxicity in vitro, as quantified by EC_{90} values. Although the EC_{90} values suggest that the two alkylphospholipids have slightly higher cytotoxic activity, the differences relative to **1-N** are not statistically significant (Table 3). The results of the comparative in vitro examination of the two glycerophospholipids on DS cancer cells were similar (**2-N**: $EC_{90} = 5.5$ µmol L^{-1}; **2-As**: $EC_{90} = 4.8$ µmol L^{-1}).

Table 3. Cytotoxicity of three homologous phospholipids on cell lines L1210, KB, and DS (soft-agar tumor stem-cell assay according to Salmon et al. [11]).

Phospholipid	EC_{90} [a] [µmol L^{-1}] L 1210 cells	KB cells	DS cells
1-N	7.3 ± 1.6	6.4 ± 3.1	7.3 ± 1.9
1-P	6.6 ± 2.9	6.2 ± 3.1	[b]
1-As	5.8 ± 0.6	6.4 ± 0.9	6.2 ± 2.1

[a] The EC_{90} value is the concentration that kills 90% of the treated cells, in other words, only 10% of the cultivated cells survive phospholipid application; the means are given ± s ($n = 6$). The lower the EC_{90} value, the stronger the cytotoxic activity. No significant difference to the corresponding EC_{90} values of **1-N**; ΔEC_{90} for **1-N** and **1-As** in L1210 cells is only marginally significant ($0.10 > P > 0.05$; two-tailed t-test). [b] Not tested.

Experiments on rats bearing DMBA-induced carcinoma[12] show that the arsonium and phosphonium phospholipids have distinctly better tolerability than the corresponding choline compounds. This is illustrated by a comparison between **1-As** and miltefosine (**1-N** is not suitable for clinical applications because of its high toxicity). As can be seen in Figure 1a, when

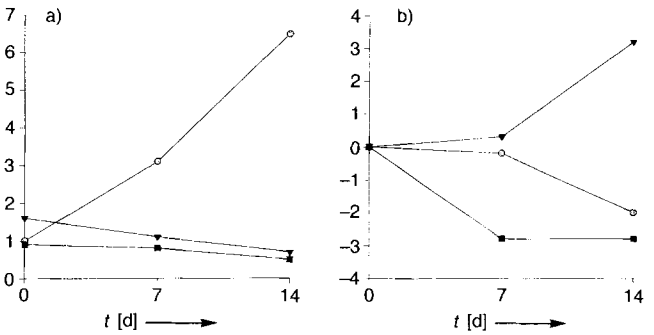

Fig. 1. a) Decrease in the weight of DMBA-induced tumors as a consequence of oral treatment with four doses (given on days 0, 3, 7, 10) of miltefosine (■, 4×68.1 mg per kg body weight) or **1-As** (▼, 4×68.1 mg per kg body weight), as well as tumor growth in untreated animals (●, control). The differences in the intensity of tumor regression between the groups treated with miltefosine and **1-As** are not statistically significant (multivariate rank test according to Koziol). Each of the three test groups consisted of seven rats. The median tumor weight in grams is plotted on the ordinate. b) Comparison of the tolerability of miltefosine and **1-As** based on the change in the mean net body weight in the test groups. The observed differences between the means are statistically significant on day 14 ($P < 0.05$; two-tailed t-test). The decrease in net body weight in the control group is attributed to the toxic effects of the tumor. Each of the three test groups consisted of seven rats. The mean of the change in net body weight in % is plotted on the ordinate. For the assignment of the curves see Fig. 1a.

four oral doses of 68.1 mg of miltefosine per kg body weight (4×167 µmol kg^{-1}) were applied, clear regression of the tumors (to about 56% of the weight registered on day 0) was observed on day 14. However, the general condition of the animals had also deteriorated (3% loss of net body weight (body weight minus tumor weight) on day 14, Fig. 1b). Four applications of 68.1 mg of **1-As** per kg body weight (4×137 µmol kg^{-1}) resulted

in slightly stronger tumor shrinkage on day 14 (to about 45% of the value registered at the start of the experiment, Fig. 1a), although the molar dose amounted to only 82% of that of miltefosine. In contrast to studies with miltefosine, the animals showed a clear-cut gain in net body weight on day 14 (3%, Fig. 1b). Even when $4 \times 100\ mg\,kg^{-1}$ ($4 \times 201.4\ \mu mol\,kg^{-1}$) of **1-As** was administered, an increase (1% on day 14) rather than reduction of the net body weight was registered. At the same time the tumors shrank to 20% of their starting weight (results not shown graphically). The difference between these results and the corresponding data from the experiment with $4 \times 68.1\ mg\,kg^{-1}$ miltefosine was significant both with respect to the net body weight and regression of the tumors (P (probability) < 0.05). Thus, due to its better tolerability, **1-As** could be administered in higher doses which led to a further improvement of the antitumoral effect (i.e. the therapeutic range was increased relative to that of miltefosine). Similar results were obtained also with the other novel analogoues.

In the present experiments we have demonstrated that the new compounds have comparable antineoplastic activity to that of the N-containing parent phospholipids in vitro and in rats bearing DMBA-induced tumors. For a definitive evaluation of cancer-inhibiting potency, further comparative experiments and dose–response curves are necessary. We have also shown that **1-As** is better tolerated by rats than miltefosine. This finding supports the previously mentioned hypothesis. The superiority of arsonium phospholipids over the N-containing parent compounds is due to their broader therapeutic range. Accordingly, by appropriately changing the structure of the molecule, it is possible to mitigate the side effects (e.g. loss of the net body weight) of phospholipids without diminishing their antineoplastic efficacy. This suggests that the (still unknown) mechanism of the anticancer activity may be different from that responsible for the side effects of this new class of anticancer agents.

The weaker parasympathomimetic activity of the arsonium and phosphonium analogues relative to that of acetylcholine[3] was ascribed to the fact that the P and As atoms have greater covalent radii than N atoms. As a result, the corresponding onium complexes are larger.[3] The same explanation might also account for the better tolerability of phosphonium and arsonium phospholipids.

To our knowledge no cancer-inhibiting arsonium derivatives have been prepared so far. Some As^{III} compounds exhibit antineoplastic activity;[9, 10] however, they are much more toxic than the tetracoordinate arsenic containing phospholipids described here. Progress in the synthesis of further biologically active phospholipid derivatives will be described in the near future.

Addenda

The authors of the communication "Unequivocal Partitioning of Crystal Structures, Exemplified by Intermetallic Phases Containing Aluminum" by R. Nesper et al. (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 2073–2076) would like to make the following addenda:

1. Qualitative and quantitative interpretations of ELF have already been given by A. Savin (A. Savin, H.-J. Flad, J. Flad, H. Preuss, H. G. von Schnering, *Angew. Chem.* **1992**, *104*, 185; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 185; A. Savin, P. Kohout, H. G. von Schnering, *Intern. Conf. Inorg. Chem.* Stuttgart, **1993**).
2. In a recent publication by B. Silvi and A. Savin (*Nature*, **1994**, *371*, 683 and cf. D. L. Cooper, *ibid.* **1994**, *371*, 651) there are also attempts at a new interpretation of chemical bonding by means of ELF.
3. A series of hitherto unpublished works by Kohout, Savin, and von Schnering concerning quantifications of ELF, partly on ionic radii and ionic volumes, were performed at the same time as our investigations on the Wirkungsbereiche.
4. We explicitly would like to thank Dr. A. Savin for helpful advice regarding the interpretation of ELF and his support concerning calculations of ELF.

D. A. Dougherty and S. J. Jacobs, authors of the communication "Combination of Superexchange and Spin-Polarization Mechanisms Leads to a Novel Hydrocarbon Tetraradical with a High-Spin Ground State" (*Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1104–1106), would like to make the following addendum to their work: This work was supported by the National Science Foundation, to whom we are grateful.

Djerassi's Park

The Bourbaki Gambit. By *C. Djerassi.* The University of Georgia Press, Athens (USA), 1994. 230pp., hardcover $ 19.95.—ISBN 0-8203-1652-0

Chemists often complain about their poor public image. Instead of praise or thanks for their achievements they are almost exclusively accused of heinous deeds. Well, a public image, that precarious and ephemeral notion, is influenced by many things, not only by reports of catastrophes, the toxin of the week, or the destruction of the environment. Self-presentation is also important, whether it be in television, film, or aesthetic literature. Compared with doctors and lawyers, the number of chemists who have given up their original career or who write as a hobby is vanishingly small. How Elias Canetti scornfully turned his back on his chemistry studies can be read in "Fackel im Ohr", and what happens when a nonchemist recruits his heroes from our ranks is evident in Heinrich Mann's "Untertan". That Carl Djerassi, after an extremely successful career as organic chemist with hundreds of scientific publications and several chemistry books to his name, has defected from this literature to what he terms Science-in-fiction is just as remarkable as it is welcome from the above-mentioned considerations.

What is Science-in-fiction? On the one hand a genre that enables the link between science and literature to be used to bring scientific knowledge and normally unseen details of the life and career of a scientist to a wider public. On the other hand this concept embodies the claim to provide a "high proportion of truth and fiction", that is, a particular quality of accuracy and credibility, which even the author finds an exacting demand.

In the first book of a planned trilogy, "Cantor's Dilemma", the themes were trust and ambition, truth and fraud in science. Besides the yearning of scientists to be recognized by their peers, "The Bourbaki Gambit" tackles, in particular, the problems that confront aging natural scientists in a society possessed by the idea of perpetual youth. Such a natural scientist is Max Weiss, Professor of Biochemistry at Princeton University, who was manoevered by the skillful tactics of the dean into early retirement. Deeply vexed he decides to take vengeance on the scientific establishment in order to prove that researchers at his age not only can, but are ideally suited to achieve outstanding results. He formulates the plan to work with other like-minded scientists under a pseudonym, just like the group of French mathematicians which has really existed since 1934 under the name Nicolas Bourbaki. The first he can win over to his "Bourbaki concept" is the Innsbruck professor Sepp Krzilska, who has just retired and is particularly piqued that the day after his retirement every one of his nameplates had been removed from the institute. Then there is the Japanese Hiroshi Nishimura of the University of Tokyo, which has a particularly low retirement age limit. At sixty he already has to face retirement in the near future. The author uses his participation to provide the reader with an at times quite protracted discourse on the Japanese scientific establishment. Although Mr. Nishimura actually wants to devote himself to lyric poetry, he is enthusiastic about the Bourbaki idea. As the fourth, and the only scientist not immediately faced with retirement, is the Professor of Mathematical Biophysics, Charlea Cherith Conway, called C_3 by the narrator. Together they form a "biochemical Bourbaki" and name themselves "Diana Skordylis". Although she does not belong to the Bourbaki group in the strictest sense, the list would be incomplete without the historian Diana Doyle-Ditmus, whom the narrator nicknames D_3 (for the first person narrator, these abbreviations are munemonics, which in addition have "something so comfortingly chemical" about them). Max Weiss meets her through her grandchild, Jocelyn Powers, one of his students who is later involved in the project as a post-graduate.

As the notion takes shape, the problems begin to arise: What fields should be covered in the first place, who should have a casting vote in controversial decisions, what topic should take precedence? The intention should, of course, remain largely secret—besides, none of the members have stood at the lab bench for decades. For that reason alone, the topics for consideration must be mainly theoretical. Furthermore, since the four come from different fields of biochemistry and microbiology, it soon becomes clear that a common topic is lacking. Initially, therefore, extensions and corrections of old papers are chosen for publication. Above all, the development of a universally valid theory of epigenetics and the application of catalytic antibodies are discussed as other research areas; incidentally, the latter theme is explained in lucid terms, even for nonscientists. Then one day Sepp Krzilska has the contagious idea, namely the polymerase chain reaction, which was last year acknowledged with the Nobel prize for chemistry. This reaction actually has nothing to do with Carl Djerassi nor with the Bourbaki concept (the true circumstances of its discovery are at least equally spectacular and are described by their discoverer K. B. Mullis in a fascinating article in *Scientific American*). Nevertheless, the theme is eminently suitable for the story—the genial simplicity of PCR enables the novel to present an amazingly in-depth and yet extremely understandable account of the scientific implications. In this way Djerassi succeeds in bringing this important new biochemical development, which has already been widely applied, to a broad circle of readers. In addition the fictional discovery is so spectacular that the plot reaches a climax shortly thereafter. At first the conceit

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

of researchers is evident. This does not really apply to Hiroshi, whose chief interest anyway is his lyric poetry. Also for Charlea the project is interesting for another reason, namely to explore the limits of the possible. Max is in a somewhat different position, since he is beginning to gather ideas for a later date in order to publish them independently. The crucial stumbling block, however, is Sepp Krzilska, who considers the whole discovery his idea. For him it is a matter of utmost importance, and at all events he wishes to publish under his own name. An additional problem is that the fictional Diana Skordylis is increasingly dragged into the limelight of the scientific public—at first she escapes, pleading "personal circumstances"—until the award of the renowned Levenson Prize exposes the whole affair.

What makes this book a particular pleasure to read is the excellent detailed knowledge of the author. It makes the tale so realistic that it could, in principle, happen at any time (or perhaps has happened somewhere already?). The showplaces of the plot—whether they be the annual conference of the National Academy of Sciences, the Virgin Islands, the Isle of Capri, or the Villa Malaparte—are described with a remarkable precision. In addition, topical themes such as the position of women in the natural sciences are also discussed. Furthermore, the story of the love affair between two septuagenarians is charming.

If one expects to be informed and/or entertained by literature, whatever the genre, this tale by Djerassi from the world of chemistry and biochemistry does both. What more can one hope for? Give us the third volume of the series (i.e. make it a veritable PCR, a *p*oetry *c*hain *r*eaction), which is rumored to appear next year and certainly will extend Djerassi's (science) park by another colorful sector, as soon as possible.

Amorphous Inorganic Materials and Glasses. By *A. Feltz*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 440 pp., hardcover DM 198.00.—ISBN 3-527-28421-4/1-56081-212-5

Almost ten years after the publication of the original German edition of this now well-established standard work on the amorphous state of matter, the author and publishers have set out through this English translation to bring it to a wider international readership. Its format and size are largely unchanged, but the style of production is more up-to-date and the new two-column layout emphasizes the author's concise and informative style of writing, and leads the reader in a clear way through the great wealth of data that the book contains.

However, when one begins to examine the contents in detail it becomes evident, if one has not already realized this, that it is essentially just a one-to-one translation of the German version. The list of contents (9 pp.) has exactly the same length and exactly the same unclear structure as its predecessor. It could undoubtedly have been made more useful and informative by putting less emphasis on the fine detail of the less important topics and instead highlighting the main topics. The subject index (11 pp.) is only slightly longer than in the original version and consequently does not contain much more information.

After a brief introduction the second chapter is entitled "The Amorphous and Vitreous State of Inorganic Materials", and deals with the conditions needed for preparing glasses and amorphous solids, the thermodynamic description of the glassy state, and the types of phase transformations that can occur in such systems. In the section on the characterization of the structures of noncrystalline materials the main approaches discussed are the various diffraction methods (X-rays, electrons, and neutrons) and spectroscopic methods (IR, Raman, NMR, UV, Mössbauer, and EXAFS spectroscopies). In the section on the electronic states in noncrystalline solids the author develops theoretical models for describing the phenomenon of electrical conduction in amorphous substances.

The third and longest chapter, "Amorphous and Glass-Forming Substances", begins with elements and alloys, including metallic glasses and amorphous nonmetals ranging from boron to arsenic and antimony. Other glass-forming systems are then discussed, beginning with the various binary compounds and moving on to the ternary chalcogenide systems.

Chapter 4, "Electrical Conductivity and Optical Properties of Glasses and Amorphous Solids", describes these phenomena in detail, covering aspects such as the mechanism of charge transport and photoinduced structural changes in glasses.

The publication of a translation of a ten-year-old book prompts one to ask whether the subject matter remains up-to-date, since even in the field of amorphous materials, research has not stood still during the last decade. The first four chapters have been updated only by briefly outlining the latest developments at the ends of the chapters. Chapter 5, "Applications", is much better in this respect, as it has undergone a considerably more thorough revision. The topics discussed include the latest trends and developments in applications of the semiconducting properties of certain glasses and amorphous films, the use of optical glasses for IR transmission, and information storage based on the structural changes that take place in glasses.

The aspects to be criticized, as in the case of the contents list already mentioned, relate only to the formal presentation. Thus, the bibliographies are, as in the German version, collected together at the ends of the chapters. As a result of this, especially for references that extend across chapters, the corresponding citation in the text can only be found by a time-consuming search through the book or by consulting the not very clear list of contents followed by much flipping of pages. Also the old consecutive numbering system based on the German text has been retained, so that new citations that have been inserted into the text have been assigned numbers that break the original numbering scheme. On the other hand the figures, which have only undergone slight changes, are clear and are a great help to understanding many of the points mentioned in the text.

The information has been assembled with great care, involving an enormous amount of work and attention to detail. This is especially evident in the literature references, of which there are over 2000; their number does not fully reflect the vast amount of individual data, as many of these relate to monographs and review articles. The wealth of information is impressive, and could only be presented in this form through the author's precise and economical style. However, the desire to cover all the results and theories on the amorphous state within a limited space has unfortunately meant that some aspects, such as the sol–gel process or solid-state NMR spectroscopy, could only be treated briefly. The reader who would like to learn more about such topics will certainly be disappointed at first glance on opening this book. But on examining it more carefully he or she will find that the literature references open up access to the whole range of the subject. In any case, everyone interested in obtaining a comprehensive overview of the subject will find this book indispensable. It is to be

Methods of Immunological Analysis. VCH Verlagsgesellschaft, Weinheim/ VCH Publishers, New York, 1993. **Vol. 1: Fundamentals.** Edited by *R. F. Masseyeff, W. H. Albert* and *N. A. Staines.* 715 pp., hardcover DM 410.00, $ 265.00.—ISBN 3-527-27906-7/0-89573-902-X; **Vol. 2: Samples and Reagents.** Edited by *W. H. Albert* and *N. A. Staines.* 591 pp., hardcover DM 410.00, $ 265.00.—ISBN 3-527-27907-5/0-89573-903-8; **Vol. 3: Cells and Tissues.** Edited by *R. F. Masseyeff, W. H. Albert* and *N. A. Staines.* 603 pp., hardcover DM 410.00, $ 265.00.—ISBN 3-527-27908-3/0-89573-904-6

This is a very comprehensive work with an excellent arrangement of the contents. In view of the rapid developments occurring in immunochemistry, this three-volume set appears at just the right time. In Volume 1 the basic concepts of immunological analysis are explained, and the most important and well-established methods are described in detail. The chapter entitled "Molecular Basis of Antigen–Antibody Reactions" is especially good, giving a concise but thoroughly comprehensive account of the state of knowledge up to the beginning of 1991. As well as structural aspects of antigen–antibody reactions, the kinetics and thermodynamics of such reactions are discussed in detail. Another important quantity in relation to antigen–antibody reactions is the cross-reactivity, which is discussed using the example of the steroid ring skeleton. This chapter ends with a very nice contribution on "Factors Modulating Antigenicity". The chapters on "Methods Using Labeled Reagents" and "Labels and their Measurement" give an up-to-date survey of important reagents (tracers) and the methods for detecting them. These chapters are indispensable for choosing a suitable detection system. The discussion here is soundly based and thorough, and includes structural formulas.

Volume 2 describes the preparation and characterization of reagents used in immunological analysis. As well as explaining the theory of the methods, the chapters include practical advice on carrying them out and suggestions for overcoming problems, showing that the authors have much experience in everyday laboratory practice. Sections 4.1 to 4.5, devoted entirely to antibodies, deserve a special mention. With over 280 pages these are practically a book in themselves, containing detailed treatments of the advantages and disadvantages of polyclonal and monoclonal antibodies, the modification of antibodies, and antibodies with special properties, e.g. catalytic antibodies. Chapter 5 is concerned with chemical coupling and derivatization methods, which are indispensable for applications in immunochemistry. The various methods are described in a clear and easily understandable way, with selected examples of laboratory procedures based on different chemical approaches. However, some of the most elegant coupling methods that have been reported in the literature are not mentioned. Also the importance of immunoaffinity columns and the methods for preparing them are not given enough emphasis.

Volume 3 gives a comprehensive overview of immunological methods for the analysis of cells and tissues. In addition considerable space is devoted to cell preparation and cell culture, which are very important as preliminaries to the analysis of cells and tissues. The first 90 pages contain very detailed descriptions of the isolation of cells and tissues, which even relatively inexperienced users should be capable of following without difficulty. The main emphasis is on human cell systems, but adequate attention is also given to experimental animal and plant systems. Some basic principles of cell culture for the types of cell systems mentioned above are then explained, with careful distinctions according to the different systems. The chapter on "Methods of Phenotype Analysis" (over 180 pp.) is especially useful, covering all aspects of immunocytochemistry from general principles to detailed laboratory methods, often giving several alternatives and including references. Everyone acquainted with such methods knows that it is necessary to vary a large number of experimental parameters to arrive at conditions giving the best results. Surprisingly, some important new detection methods based on immunohistochemical and, most notably, immunofluorescence techniques, which are also capable of yielding quantitative information at the single cell level (e.g. through the distribution of damage in DNA), are not covered. This is an area which should definitely be included in the next edition.

To sum up, this is a work that will be of value throughout the field of immunological analysis. It includes a wealth of references covering the period up to the beginning of 1991, and thus serves as a guide to the original literature. This series of volumes will be essential for every laboratory concerned with immunochemistry.

Atom Economy—A Challenge for Organic Synthesis: Homogeneous Catalysis Leads the Way

Barry M. Trost*

Enhancing the efficiency of the synthesis of complex organic products constitutes one of the most exciting challenges to the synthetic chemist. Increasing the catalogue of reactions that are simple additions or that minimize waste production is the necessary first step. Transition metal complexes, which can be tunable both electronically and sterically by varying the metal and/or ligands, are a focal point for such invention. Except for catalytic hydrogenation, such methods have been rare in complex synthesis and virtually unknown for C–C bond formation until the advent of cross-coupling reactions. These complexes may orchestrate a variety of C–C bond-forming processes, important for creation of the basic skeleton of the organic structure. Their ability to insert into C–H bonds primes a number of different types of additions to relatively nonpolar π-electron systems. Besides imparting selectivity, they make feasible reactions that uncatalyzed were previously unknown. The ability of these complexes to preorganize π-electron systems serves as the basis both of simple additions usually accompanied by subsequent hydrogen shifts and of cycloadditions. The ability to generate "reactive" intermediates under mild conditions also provides prospects for new types of C–C bond-forming reactions. While the examples reveal a diverse array of successes, the opportunities for new invention are vast and largely untapped.

Keywords: carbon–carbon coupling · catalysis · cycloadditions · synthetic methods

1. Introduction

The goal of reducing simultaneously the depletion of raw materials and the generation of waste has taken on new urgency for the chemical community as society places increasing emphasis on environmental concerns. Thus, production of the myriad of substances that are required to serve the needs of society, stretching from the worlds of materials science to health care, must address synthetic efficiency not only in terms of selectivity (chemo-, regio-, diastereo-, and enantioselectivity) but increasingly in terms of atom economy, that is, in terms of maximizing the number of atoms of all raw materials that end up in the product.[1] The ideal chemical reaction is not only selective but is also just a simple addition (either inter- or intramolecular) in which any other reactant is required only in catalytic amounts.

The producers of commodity chemicals have recognized the importance of these issues. Though many existing processes do not meet these objectives, they are mainly rather old technologies. "Newer" processes represented by hydroformylation,[2] Ziegler–Natta polymerization,[3] and hydrocyanation[4] are spectacular illustrations of how practical and important processes that possess these characteristics are. On the other hand, such issues have not been emphasized for production of smaller volume chemicals. Clearly, a high priority goal of any chemical production is an environmentally benign design.

With the increasing sophistication of the types of substances that we must produce to meet society's needs, this task is quite daunting. In many instances, the synthesis of such compounds by any means in an economically viable way is a major accomplishment; to do so with atom economy as well is an almost untenable proposition. Part of the problem lies in the lack of some type of selectivity for processes that meet this definition. For example, apart from catalytic hydrogenation, the Diels–Alder reaction comes closest to representing the ideal chemical reaction in terms of atom economy and chemo-, regio-, and diastereoselectivity.[5] However, achievement of enantioselectivity in a catalytic sense is a major challenge and a subject of intense activity.[6] In most instances, the failure arises from the lack of atom economy. In a practical sense, while we should strive for the ideal in which all reactions are simple additions, we cannot expect to always achieve the ideal. When reactions are of the form A + B → C + D where C is the desired product, the by-product D should be as small and innocuous as possible. Catalysis by transition metal complexes has a major role to play in addressing the issue of atom economy—both from the point of view of improving existing processes and, most importantly, from discovering new ones. This review will focus on the formation of C–C bonds by homogeneous catalysis in complex organ-

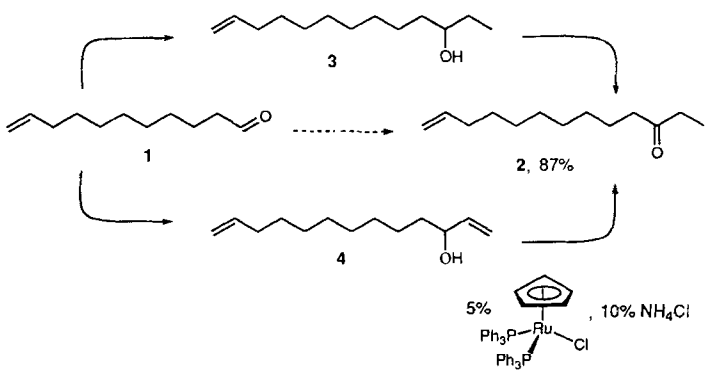
ic synthesis. Thus, polymerization methods, although extremely important, are outside its scope. Several well established transition metal catalyzed reactions represented by carbonylation are well appreciated and well reviewed; as a result, they are not covered by this overview.



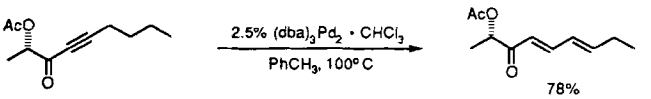
2. Prototropic Rearrangements

The ability of transition metal complexes to make and break C–H bonds forms the basis of many catalytic processes beyond the obvious catalytic hydrogenation. Olefin isomerizations[7] may involve insertion into an allylic C–H bond (Scheme 1),

Scheme 1.

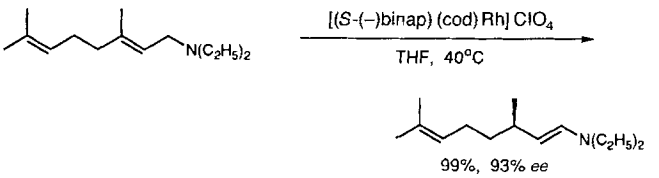
which has been proposed for a ruthenium catalyzed intramolecular redox reaction of an allylic alcohol (Scheme 2, **4** → **2**).[8] While many metal complexes effect olefin isomerizations, their lack of chemoselectivity render them useless with substrates like **4**. This example illustrates the potential such methodology offers in terms of atom economy. Whereas the "normal" conversion of aldehyde **1** to **2** would employ two steps involving stoichiometric organometallic reagents to form **3** followed by

Scheme 2.



adjustment of the oxidation level with some stoichiometric oxidant, this reaction supplants the latter with a simple prototropic isomerization. While **4** may be formed from **1** by use of a stoichiometric vinyl organometallic reagent, it may also be formed by catalytic additions of acetylene[9] followed by hydrogen thereby transforming aldehyde **1** into ketone **2** with excellent atom economy.

Isomerizations by C–H insertion take advantage of the stability of π-allyl metal complexes. However, such pathways are not always feasible. An alternative mechanism invokes a metal hydride addition followed by a β-elimination (Scheme 3).

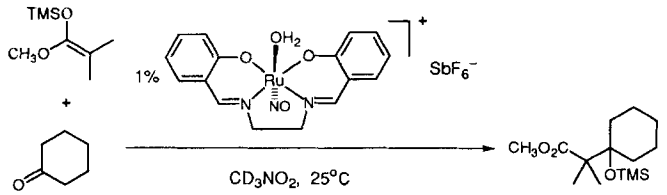


Scheme 3.

This pathway permits isomerizations of alkynes to dienes (Scheme 4), which are geometrically precluded from reacting by a π-allyl mechanism.[10, 11] In addition to palladium complexes, those of iridium,[11] ruthenium,[12] and rhodium[13] also catalyze similar reactions.

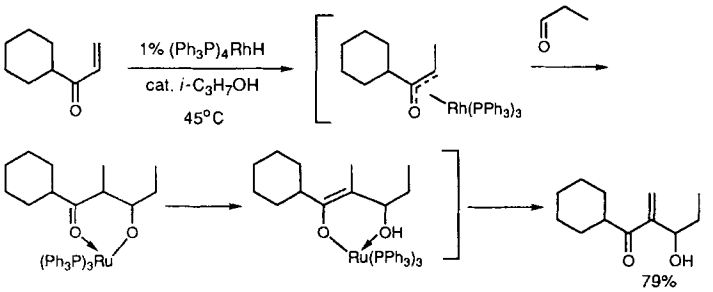
Scheme 4. dba = dibenzylidene acetone.

The analogous isomerization of *N*,*N*-diethylgeranylamine with chiral rhodium complexes (Scheme 5) to produce natural citronellal after hydrolysis of the enamine[14, 15] serves as the key step in the synthesis of the side chain of α-tocopherol[16] and a commercial synthesis of menthol.[17]



Scheme 5. cod = cyclooctadiene, binap = 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl.

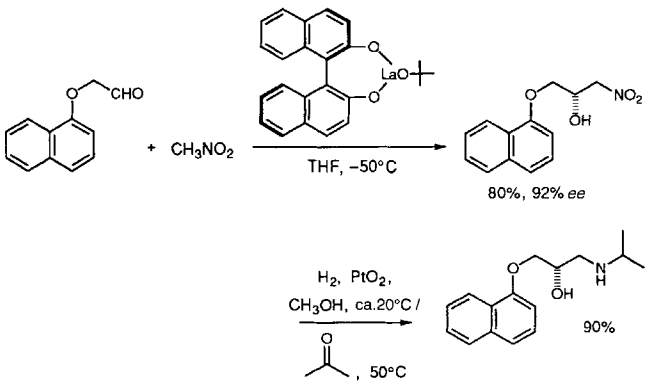
Born in Philadelphia, Pennsylvania in 1941, where he obtained his BA (1962) at the University of Pennsylvania, Barry M. Trost completed his Ph. D degree in Chemistry at the Massachusetts Institute of Technology in 1965 under Professor Herbert O. House. He moved immediately to the University of Wisconsin where he was promoted to Professor of Chemistry in 1969 and subsequently became Vilas Research Professor in 1982. He joined the faculty at Stanford as Professor of Chemistry in 1987 and became Professor of Humanities and Sciences in 1990. In addition, he has been visiting professor in Germany (Marburg, Hamburg, Munich), France (Universities of Paris VI and Paris South), Italy (University of Pisa), Denmark (Copenhagen) and Spain (University of Barcelona). In 1994 he was presented with an honorary doctorate from the Université Claude-Bernard (Lyon I), France. He has garnered numerous awards for both teaching and research, the most recent being the Roger Adams Award of the ACS (1995) and was elected a member of the U. S. National Academy of Sciences (1980) and a fellow of the American Academy of Sciences (1982).



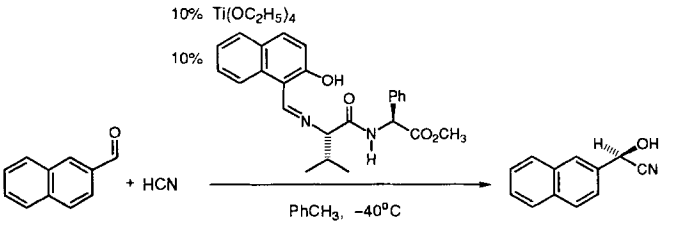
3. Intermolecular Prototropic and Related Additions

The aldol and related addition reactions to the carbonyl group of aldehydes and ketones normally entails use of Brønsted bases or acids, most commonly in stoichiometric amounts. Performing such reactions with transition metal catalysts offers two advantages beyond the avoidance of stoichiometric reagents: 1) more neutral reaction conditions that can enhance chemoselectivity and 2) prospects for asymmetric induction. The enol silyl ether version of the aldol addition may be effectively catalyzed by a ruthenium catalyst (Scheme 6) and

Scheme 6.



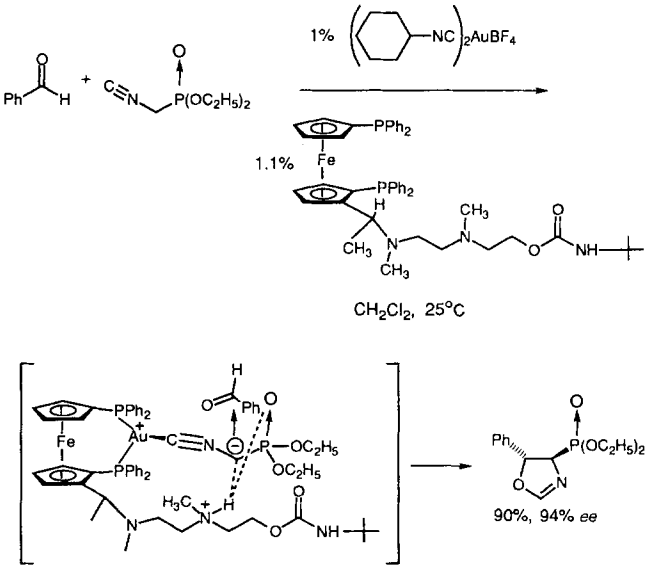
proceeds to > 90% completion in less than 3 minutes. The ruthenium center may be considered to enhance the electrophilicity of the carbonyl partner by coordination; that is, it functions as a Lewis acid.[18] However, mechanistic diversity of transition metal catalyzed reactions permits unorthodox types of aldol reactions. As illustrated in Scheme 7, formation of an enolate by



Scheme 7.

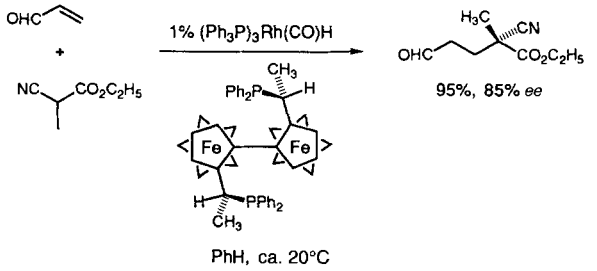
hydrometalation of an enone sets the stage for a net aldol reaction of unsaturated ketones as the aldol donor partner—a role they cannot play in simple acid or base catalyzed chemistry.[19]

The promise that such transition metal catalyzed versions may proceed with good enantioselectivity is beginning to be fulfilled. The addition of nitromethane to aldehydes (the Henry reaction) proceeds with good asymmetric induction on use of a catalytic lanthanide base.[20] A simple synthesis of (*S*)-(−)-propranolol utilizes this reaction (Scheme 8).[21] In another variation a titanium complex serves as the equivalent of a chiral Lewis acid in promoting cyanohydrin formation (Scheme 9).[22]



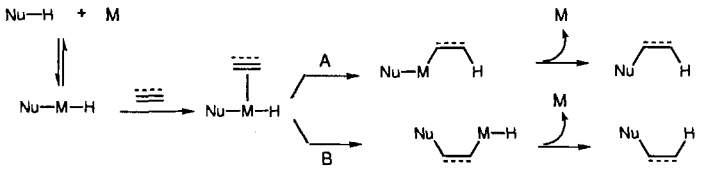
Scheme 8.

Scheme 9.



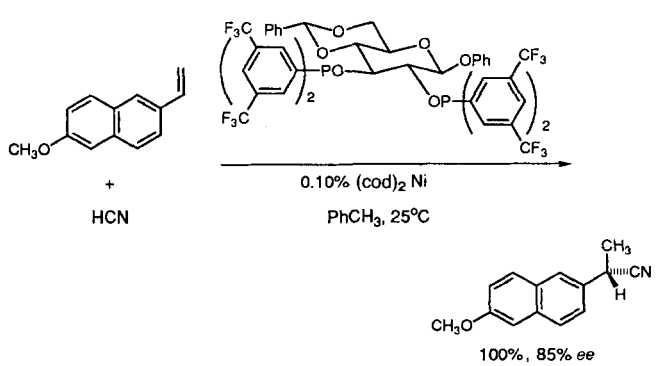
The gold and silver catalyzed aldol addition of isonitriles proceeds with high asymmetric induction in the presence of a chiral ligand. An asymmetric synthesis of α-amino acids ensues on use of α-isocyanocarboxylates.[23] Phosphorus analogues derive from use of α-isocyanophosphonates (Scheme 10).[24]

Scheme 10.



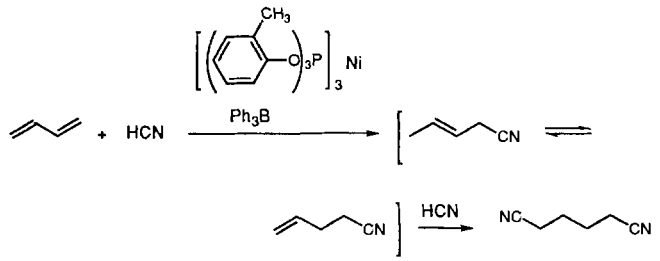
The ability of the isonitrile to coordinate to gold or silver provides the activation of the isonitrile—promoting deprotonation and addition to the carbonyl group.

This same type of activation serves as the basis of the metal catalyzed Michael addition of nitriles in which coordination of the nitrogen of the nitrile initiates the events leading to addition.[25] The asymmetric addition of ethyl α-cyanopropionate to prop-2-enal highlights the utility of this metal catalyzed version of the Michael reaction (Scheme 11).[26]



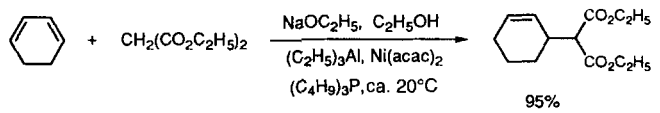
Scheme 11.

Using a transition metal to activate a pronucleophile for addition reactions creates a new level of reactivity that is not present with main group elements, namely the ability to add to nonpolarized unsaturated systems. The important facile processes of hydrometalation and carbametalation, characteristic of the transition elements, initiate additions of a C–H bond across double and triple bonds as formalized in Scheme 12.



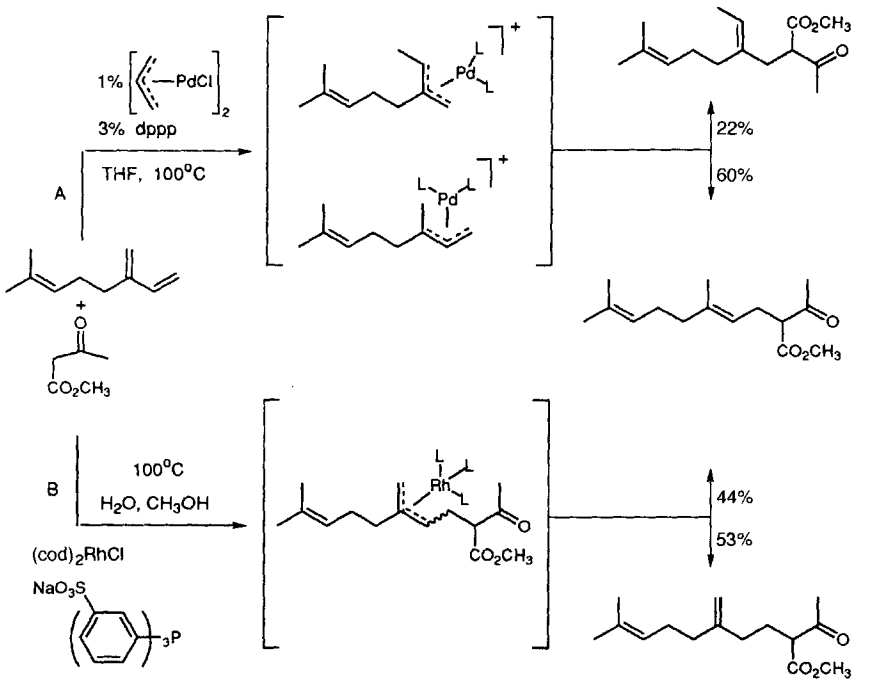
Scheme 12. Formal representation of the hydrometalation A and carbametalation B as routes to the addition of C–H bonds to nonpolar double and triple bonds.

The nickel catalyzed hydrocyanation of olefins[4, 27] is initiated by a hydrometalation (Scheme 12, path A), which may proceed with high asymmetric induction in the presence of a chiral ligand (Scheme 13).[28] The *cis* nature of the addition[29] suggested by (Scheme 12) leads to *E* isomers of substituted acrylonitriles by hydrocyanation of 1-alkynes.[30] Dienes are excellent acceptors, since the intermediate is a π-allylnickel complex.[4, 31] Combining hydrocyanation with olefin isomerization led to a commercially viable synthesis of adiponitrile (Scheme 14).[4, 32]

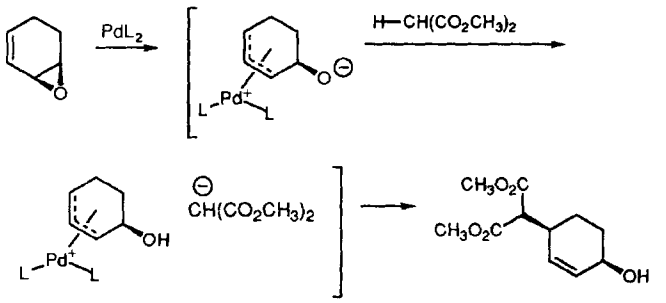


Scheme 13.

Scheme 14.



Nickel complexes also catalyze the addition of active methylene compounds like malonic esters and β-ketoesters to cyclic dienes (Scheme 15),[31] which presumably proceed by a similar mechanism (Scheme 12, path A). Extrapolation to acyclic dienes is normally plagued by diene oligomerization, itself an important and interesting process (see Scheme 31). With palladium catalysis such oligomerizations may be suppressed relative to simple additions by use of bidentate ligands (Scheme 16A).[33] With an unsymmetrical diene like myrcene, the two feasibile regioisomeric π-allylpalladium complexes yield two regioisomeric products, although one predominates. The major regioisomer isolated in 60% yield serves as a commercially important intermediate in the synthesis of vitamins A and E.



Scheme 15. acac = acetylacetonate.

Switching the catalyst may change the mechanism. Indeed, a rhodium complex catalyzes the same addition by a carbametalation (Scheme 12, path B) to produce a different mixture that results from lack of regioselectivity in the proton transfer step (Scheme 16B).[34] This latter route becomes commercially viable since both products can be taken on to pseudoionone, the key intermediate on the route to vitamins A and E.

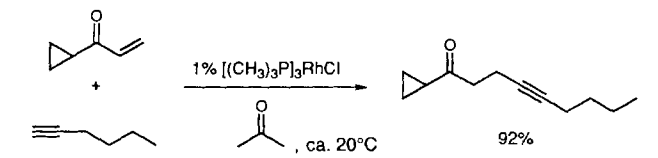
A related but mechanistically different process is the palladium catalyzed addition of pronucleophiles to vinyl epoxides (Scheme 17). In this reaction, ionization of the epoxide by palladium creates the base to deprotonate the pronucleophile, setting the stage for the normal nucleophilic attack on a π-allyl complex.[35] The stereochemistry always involves formation of the new C–C bond on the same face of the π system from which the leaving group departed, regardless of regiochemistry. The regiochemistry normally involves attack at the allylic terminus distal to oxygen as depicted. This process differs from the simple base

Scheme 16. dppp = 1,3-bis(diphenylphosphino)propane.

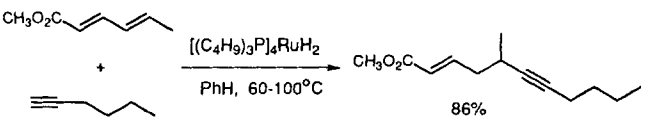
Scheme 17.

promoted nucleophilic ring opening of the epoxide in both regio- and diastereoselectivity.

The ability of transition metals to insert readily into acetylenic C–H bonds, as represented formally in Scheme 18,



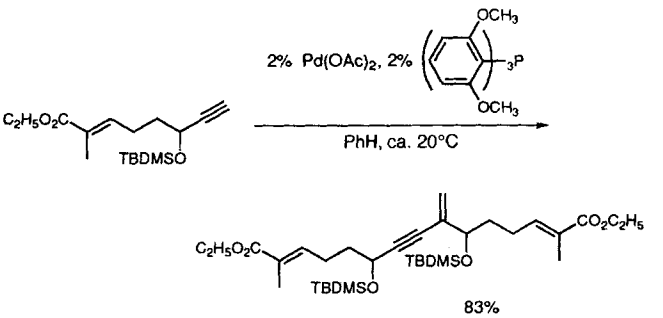
Scheme 18.



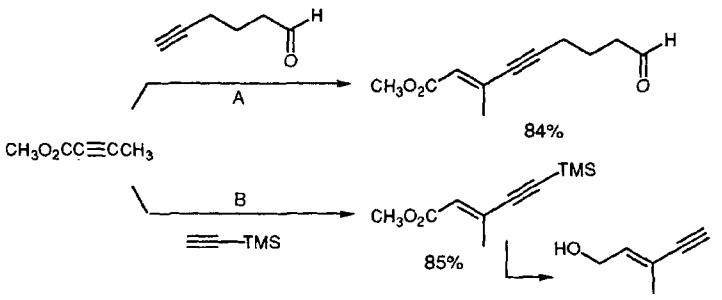
derives both from the acidity of this proton and the excellent coordinating ability of the acetylenic linkage. Thus, a 1-alkyne may function similarly to HCN and active methylene compounds as summarized in Scheme 12.

Rhodium [36] and ruthenium (Schemes 19 and 20)[37] complexes catalyze the addition of terminal alkynes to activated olefins and dienes. Appropriate deuterium labeling experiments demonstrate that with dienes the reaction proceeds by a clean *cis*-1,2-addition. The low conversions of the rhodium catalyzed reaction diminish its utility in spite of the high yields.

The addition to unactivated multiple bonds is complicated by the normally dominant self-addition. For example, with a palladium catalyst the dimerization proceeds well, even in the pres-

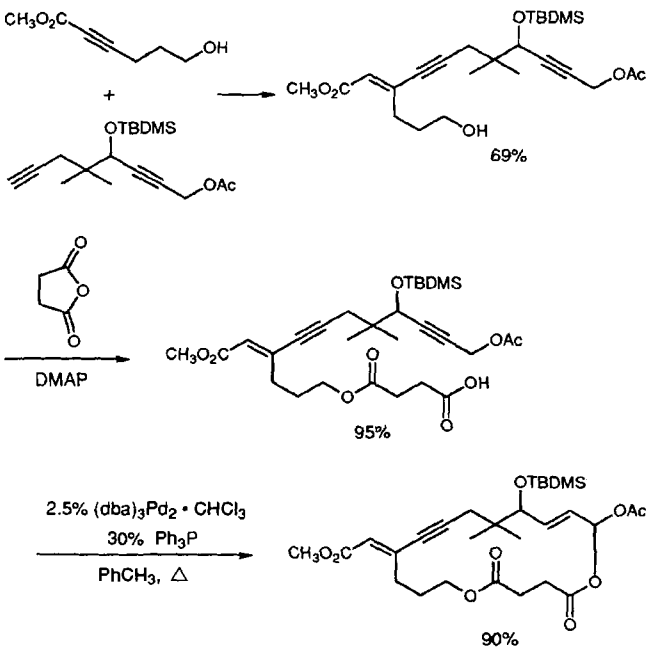


Scheme 19.



Scheme 20.

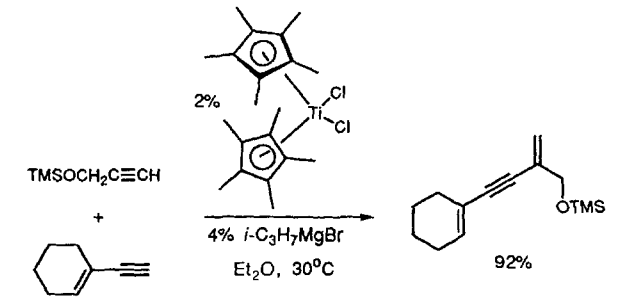
ence of an activated olefin (Scheme 21).[38] On the other hand, an activated 1-alkyne completely intercepts the organopalladium intermediate in a highly chemoselective fashion. For ex-



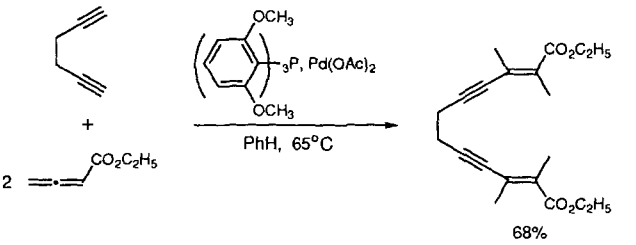
Scheme 21. TBDMS = *tert*-butyldimethylsilyl.

ample, the unsymmetrical cross-coupling occurs even in the presence of an unprotected aldehyde (Scheme 22, path A).[39] The adduct of methyl butynoate and trimethylsilylacetylene (Scheme 22, path B)[40] may be readily transformed into an

Scheme 22. The reaction conditions for A and B are the same as given in Scheme 20. TMS = trimethylsilyl.



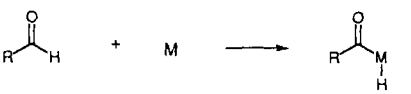
important building block for Vitamin A synthesis.[41] Scheme 23 illustrates the use of this reaction as a key step in constructing an acyclic carboxylic acid that ultimately undergoes a palladium catalyzed lactonization by cycloisomeriza-



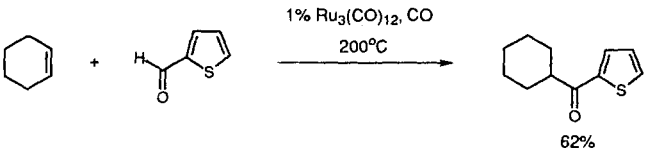
Scheme 23. Conditions for the first step as given in Scheme 20.

tion.[42] Thus, a relatively complicated eighteen-membered macrodiolide arises from two alkyne building blocks by a simple series of inter- and intramolecular additions. A most remarkable selectivity has occurred with a titanium(II) catalyst that promotes the coupling of an unsaturated terminal alkyne as the donor and a saturated terminal alkyne as the acceptor (Scheme 24).[43] Allenes serve as effective acceptors for terminal alkynes, and novel oligo(enyne)s may result (Scheme 25).[44]

Extension of these concepts to other additions depends upon the ability of the transition metal to undergo the C–H insertion.

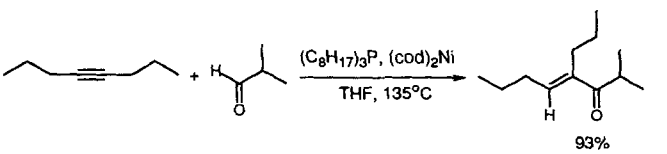


Scheme 24.



Scheme 25.

The ability of transition metals to decarbonylate aldehydes via an acyl metal hydride intermediate (Scheme 26) suggests the

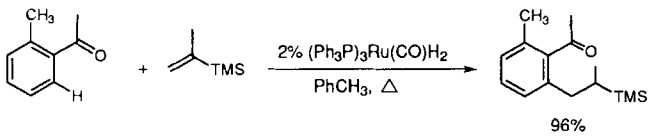


Scheme 26.

prospect of trapping that intermediate as in Scheme 12. Whereas capture with a simple olefin proceeds in only modest yields with a ruthenium complex (Scheme 27),[45] capture by a 1-alkyne occurs in good yields with a nickel catalyst

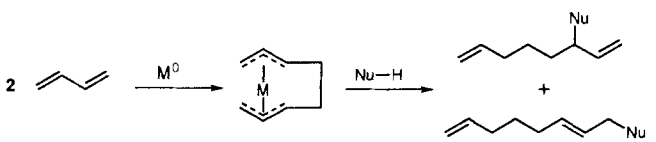
Scheme 27.

(Scheme 28).[46] Substrates containing sulfur are compatibile with homogeneously catalyzed reactions, which contrasts with their role as poisons for many heterogeneously catalyzed processes. The *E* geometry of the product in Scheme 28 is consistent with a *cis* addition.

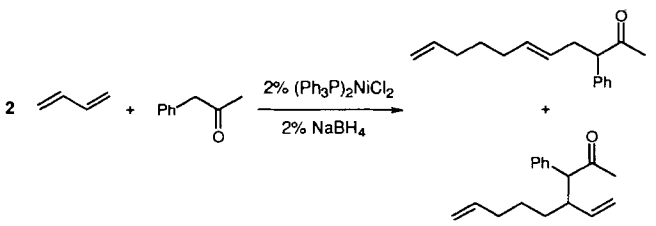


Scheme 28.

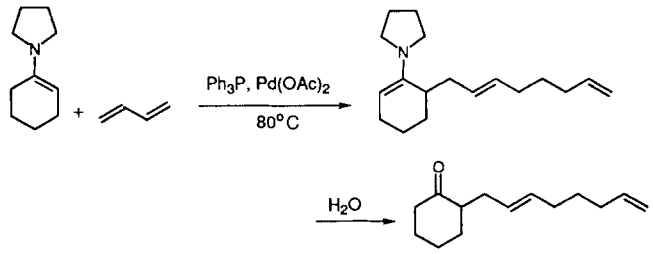
Precoordination provides an important kinetic path for many transition metal catalyzed reactions, one of which is *ortho*-metalation (Scheme 29). On use of a ruthenium catalyst which becomes coordinatively unsaturated by loss of hydrogen to promote *ortho*-metalation, aryl ketones add to unhindered olefins, especially vinylsilanes.[47] The example of Scheme 30 reveals the kinetic preference for insertion into a sp^2 C–H bond over a sp^3 C–H bond, in spite of the greater stabilization by conjugation of the benzylic organometallic intermediate that would have formed in the latter case and its lower bond energy.



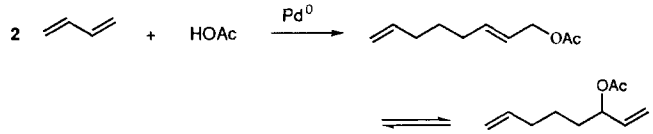
Scheme 29. CG = coordinating group.



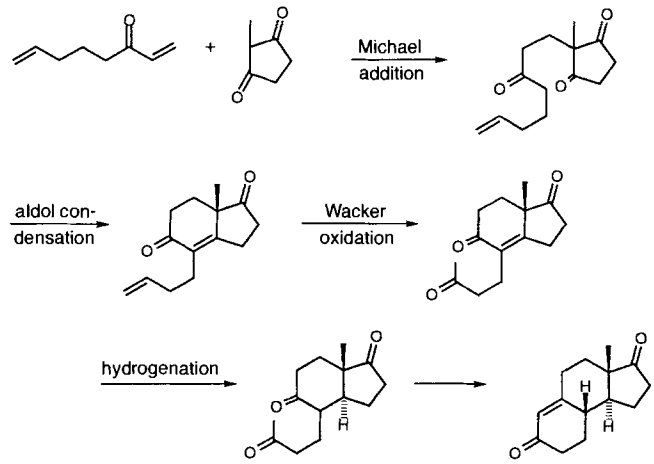
Scheme 30.



The reactions of simple dienes in additions are frequently complicated by self-oligomerization or telomerization. Such reactions are believed to involve bis(allyl)metal complexes as intermediates, which react with pronucleophiles to give regioisomeric addition products (Scheme 31). Although many metals including Co, Ir, Rh, and Ru promote such reactions, most work centers on Ni[48] and Pd.[49] For example, a Ni^0 catalyst generated in situ from triphenylphosphane and nickel chloride in the presence of sodium borohydride gave an 85:15 mixture of the 2:1 adducts of butadiene and phenylacetone depicted in Scheme 32 (telomers) to the 1:1 adducts.[50] Of the 2:1 adducts, the linear to branched telomer ratio is 8.4:1. Better selectivity for the telomeric products is obtained from the palladium catalyzed reaction (Scheme 33).[51] The adduct of acetic acid (Scheme 34) has proved to be particularly useful for the synthesis of natural products. For example, the linear adduct which may obtained in 88% yield and 28:1 regioselectivity [catalyst (o-$C_7H_7O)_3P$, $Pd(OAc)_2$][52] served as a useful intermediate for the synthesis of the fragrance ingredient muscone[53] and the macrolide diplodialide.[54] The branched product is a convenient source of octa-1,7-dien-3-one, which by a simple sequence is converted into a useful steroid intermediate (Scheme 35).[55]

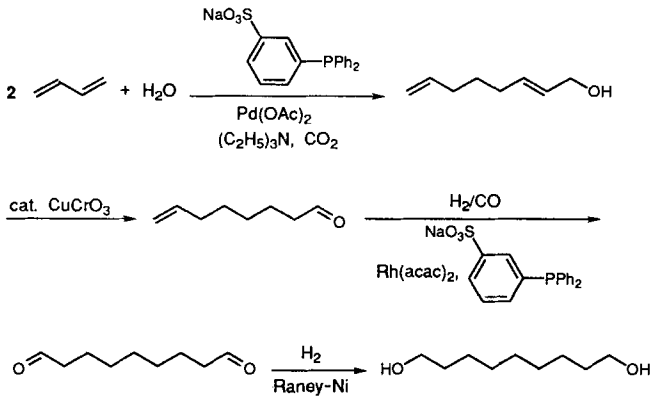


Scheme 31.

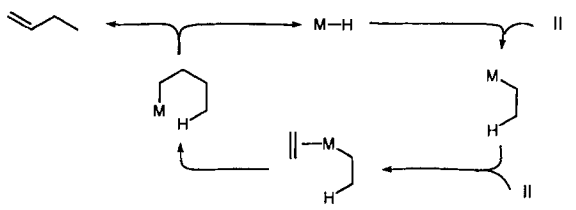


Scheme 32.

Scheme 33.

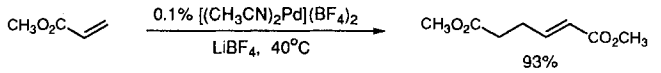


Scheme 34.



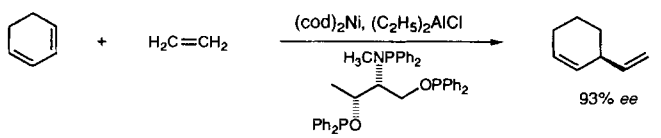
Scheme 35.

Since all the reactions are either simple additions or involve only water as a by-product, this strategy becomes rather atom economical. The commercial synthesis of 1,9-nonanediol (Scheme 36) that combines a prototropic addition and isomerization of the telomer 2,7-octadien-1-ol with hydroformylation and hydrogenation is an ideal synthetic strategy for this commercial target.[56]



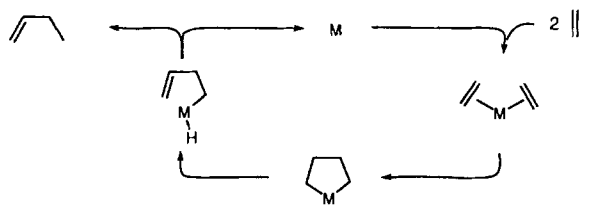
Scheme 36.

The employment of nonacidic reaction partners for additions to π-electron systems requires initiation by a metal hydride (Scheme 37). The dimerization of olefins by complexes of the



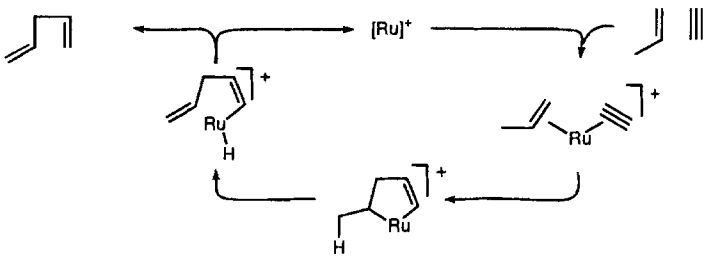
Scheme 37.

later transition metal complexes illustrates this approach. Whereas nickel is normally the preferred catalyst with nonfunctionalized olefins, a "naked" Pd^{2+} catalyst is recommended for the dimerization of methyl acrylate (Scheme 38).[57] Cross-cou-



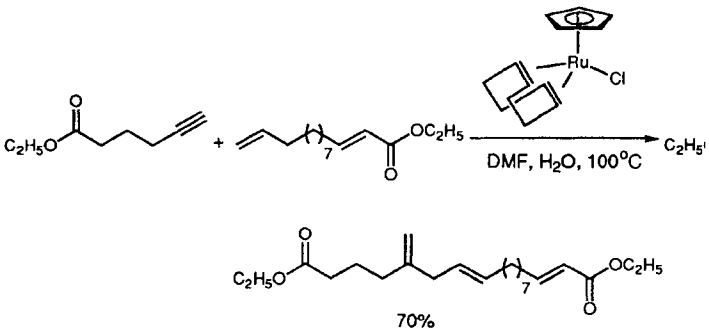
Scheme 38.

pling can occur between simple olefins (e.g. ethylene) and olefins activated either by strain (e.g. norbornene)[58] or electronic factors (e.g. styrene).[59] Alternatively, a diene is an excellent partner for hydrovinylation for which the advantage of transition metal catalysis for asymmetric induction may be exploited (Scheme 39).[60]



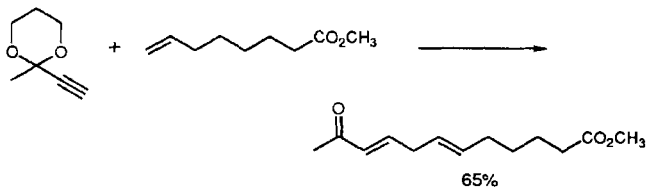
Scheme 39.

An alternative mechanism to that in Scheme 37 invokes a metallacycle (Scheme 40). This pathway requires a geometrically difficult β-hydride elimination in the metallacyclopentane, because the dihedral angle between the C–M and β C–H bonds



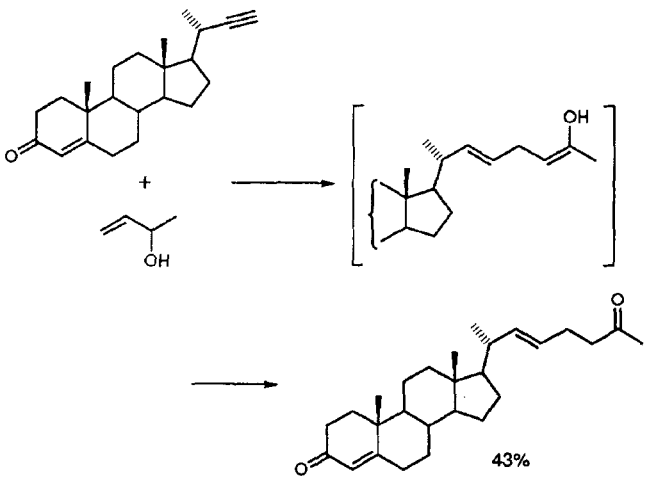
Scheme 40.

cannot readily become 0° as required for such eliminations.[61] On the other hand, such a mechanism seems to operate in a ruthenium catalyzed addition, which obviates the above problem by an elimination exocyclic to the ring according to Scheme 41. Thus, heating an internal or terminal alkyne with

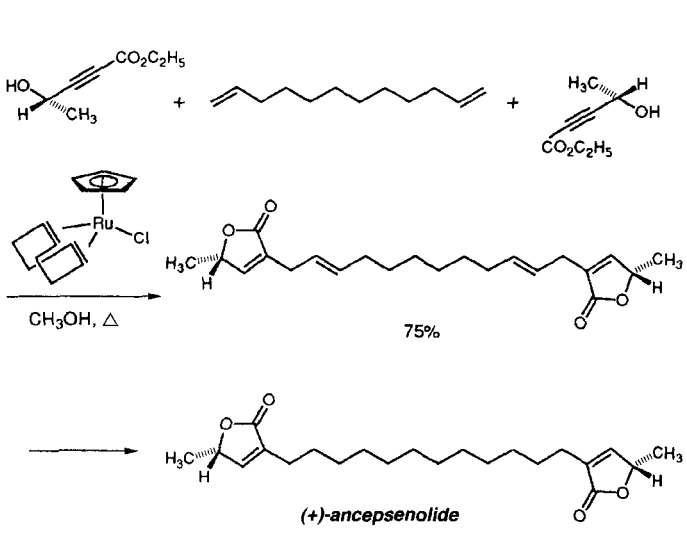


Scheme 41.

a monosubstituted olefin in the presence of a ruthenium complex gives rise to the equivalent of a highly selective Alder ene type reaction (Scheme 42).[62] The high chemoselectivity is exhibited by its compatibility with most functional groups (esters,

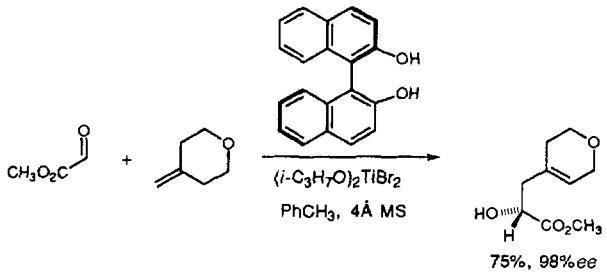


Scheme 42. DMF = dimethylformamide.



ketones, alcohols, ketals etc.): the "activated" olefin, that is, the conjugated ester, would normally be thought to be the site of reaction. The regioselective preference for formation of the "branched" product changes upon introduction of steric hindrance at the propargylic position (Scheme 43). A similar preference for the "linear" product also results from employment of an allyl alcohol in which the initial product, an enol, tautomerizes to give the γ,δ-unsaturated ketone (Scheme 44).[63] Employing a γ-hydroxybutynoate as the acetylenic partner (Scheme 45) leads to a surprising regioselectivity in which the alkylation occurs at the position α to the carbonyl group, a contra-elec-

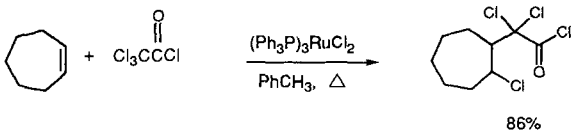
Scheme 43. Reaction conditions as in Scheme 39.



Scheme 44. Reaction conditions as in Scheme 39.

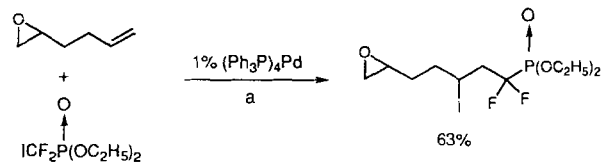
Scheme 45.

tronic orientation with respect to the normal preference in an Alder ene reaction. The *Z* juxtaposition of the hydroxy and ester groups leads to spontaneous lactonization with the expulsion of ethanol under the reaction conditions and thus to a facile synthesis of α-alkylated-γ-butyrolactones. A short route to the acetogenin (+)-ancepsenolide employs a double ruthenium catalyzed addition and establishes the absolute configuration of this natural product (Scheme 45).[64] The regioselectivity is consistent with the metallacycle intermediate proposed in (Scheme 40) in which 1) steric hindrance is minimized and 2) substituents that may coordinate to ruthenium are preferentially proximal to the metal.



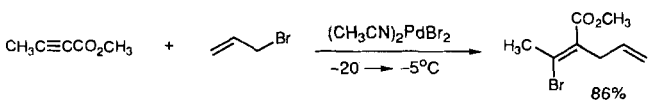
When the enophile is replaced by a carbonyl group, the reaction corresponds to the oxaene reaction. Such reactions have been catalyzed by standard Lewis acids including those of the early transition elements. Chiral titanium complexes as catalysts in these reactions have afforded high enantiomeric excess in selected cases (Scheme 46).[65]

Scheme 46. MS = Molecular sieves.



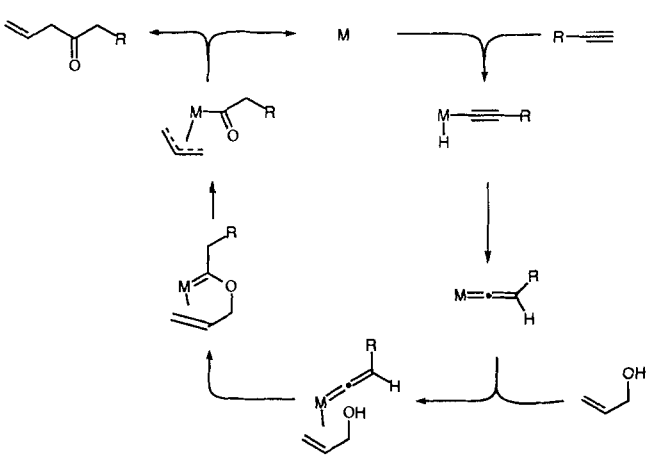
4. Intermolecular Heterotropic Additions

Halotropic additions of polyhalides to olefins have been catalyzed by ruthenium (Scheme 47)[66] and palladium



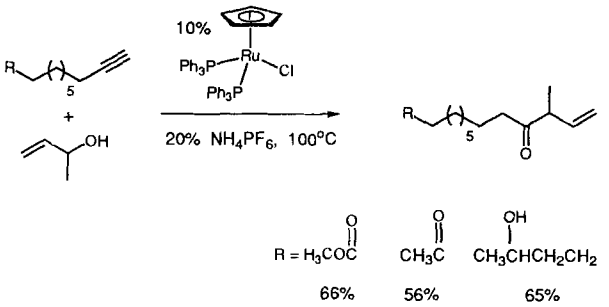
Scheme 47.

(Scheme 48).[67] Such reactions have characteristics very similar to those of radical reactions. The role of the metal may be mainly to serve as an electron shunt. On the other hand, the *cis*



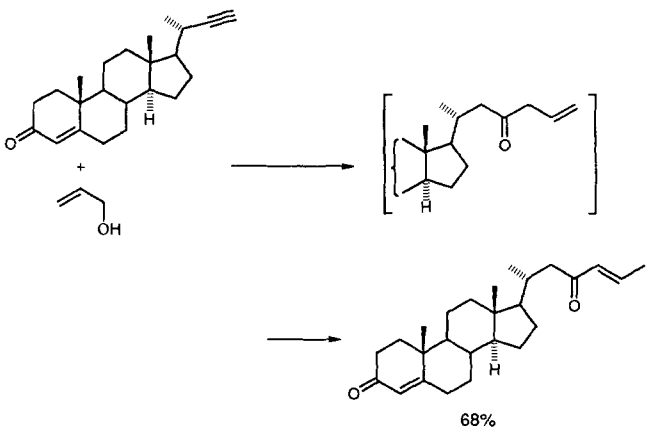
Scheme 48. a: Neat, at room temperature.

addition of allyl chlorides and bromides to alkynes (Scheme 49) appears to involve a halopalladation followed by carbametalation and dehalopalladation, in accord with the observed regioselectivity.[68]



Scheme 49. The reaction was performed without solvent.

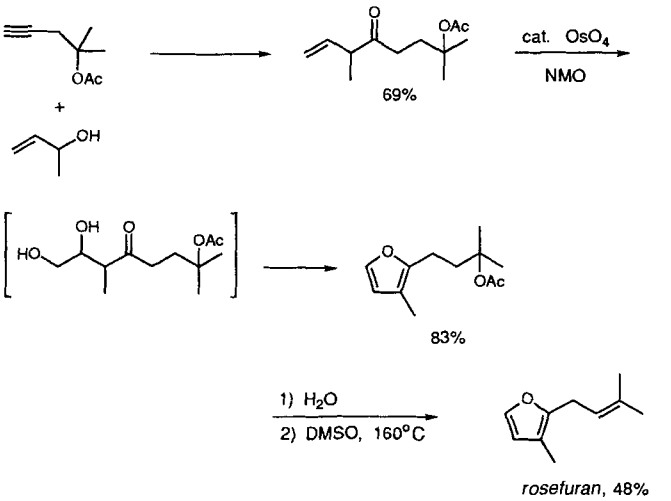
Novel transition metal complexes offer a particularly promising approach to new reactions involving heterotropic shifts. The ease of formation of vinylidene complexes from terminal alkynes suggested the catalytic cycle outlined in Scheme 50. Use of



Scheme 50.

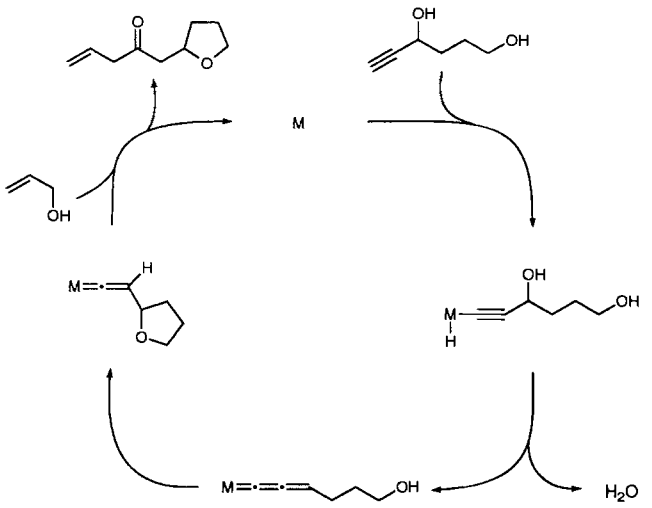
an allyl alcohol as the second component promotes a normally sluggish nucleophilic addition by precoordination. The resultant 1-metalla-3-oxa-1,5-hexadiene undergoes a metalla-Claisen rearrangement to set the stage for reductive elimination to form a β,γ-unsaturated ketone. The net result is the conversion of a terminal alkyne and an allyl alcohol into the simple adduct, and involves an oxytropic rearrangement. This process is realized with a ruthenium catalyst in a reaction that exhibited excellent chemo- and regioselectivity (Scheme 51).[69, 70] The dramatic

Scheme 51.



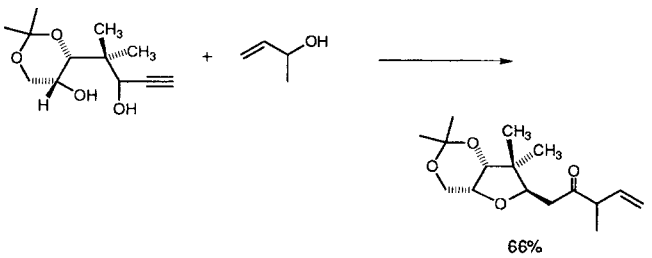
effect of the ligands on the course of the reaction can be seen by comparing Schemes 44 and 52. This latter example illustrates the utility of this methodology for the construction of functionalized steroid side chains such as that of the ganoderic acids, which function as ACE inhibitors.[71] By introducing phosphanes ligated to ruthenium, the pathway switches completely from the metallacycle pathway, which requires coordinative unsaturation, to the vinylidene pathway, which requires an electron-rich ruthenium center. The phosphanes both block coordination sites and enhance the electron-richness of the metal. Thus, from the same two reaction partners, addition may result

Scheme 52. Reaction conditions as in Scheme 48.



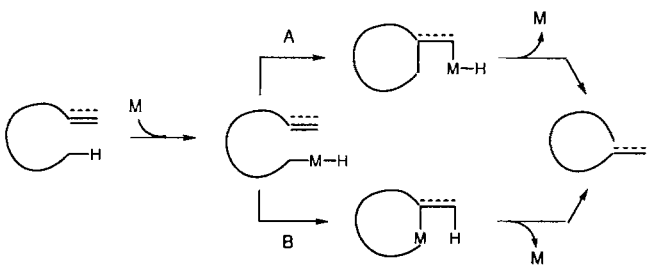
in a γ,δ-unsaturated ketone with no oxytropic rearrangement[63] or a β,γ-unsaturated ketone with oxytropic rearrangement.[69, 71]

The β,γ-unsaturated ketones also function as convenient furan precursors displaying atom economy. The synthesis of rosefuran (Scheme 53) exemplifies this methodology in which the recyclability of the *N*-methylmorpholine-*N*-oxide and acetic acid enables this sequence to be performed with only water as a by-product.[72]



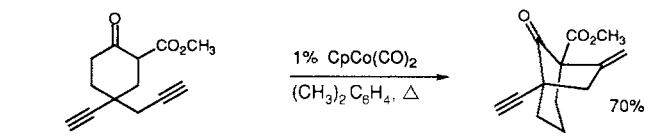
Scheme 53. Reaction conditions for the first step as in Scheme 48. DMSO = dimethylsulfoxide, NMO = *N*-methylmorpholine-*N*-oxide.

If the alkyne partner is a propargylic alcohol, the initial acetylide metal intermediate may undergo dehydration rather than protonation to form an allenylidene complex. Scheme 54 outlines a cyclization accompanying reconstitutive addition in which the only by-product is water.[73] In a model study which culminated in the synthesis of the spiroketal unit of the phosphatase inhibitor calyculin A, an alkyne derived from (*R*)-pantolactone condensed with 1-buten-3-ol to give the highly functionalized tetrahydrofuran unit with exclusive 2,5-*trans* configuration (Scheme 55).[74]



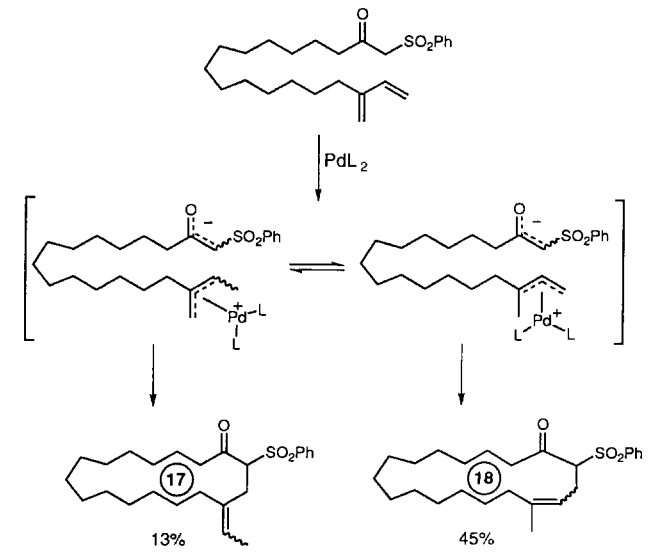
Scheme 54.

Scheme 55. Reaction conditions as in Scheme 48.



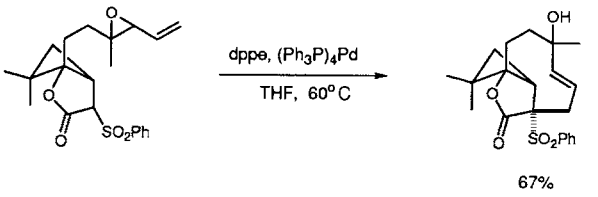
5. Prototropic and Related Cycloisomerizations

When the reactions described in Sections 2–4 are performed intramolecularly, the reaction constitutes a cyclization by isomerization as illustrated in Scheme 56 for a proton shift. Con-



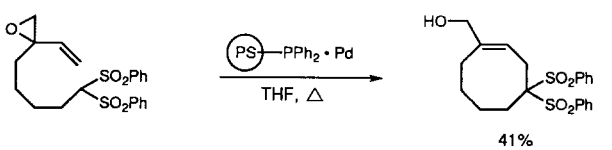
Scheme 56.

sidering the potential in this approach to cyclization, there are relatively few examples. For highly acidic compounds like β-keto esters, a cobalt complex effects addition to an alkyne (Scheme 57), presumably by a mechanism resembling path A in Scheme 56.[75] Additions of similar pronucleophiles to dienes occur with a palladium catalyst (Scheme 58).[76] This process probably involves initial hydropalladation to form π-allylpalladium intermediates (Scheme 56, path B), which undergo cy-



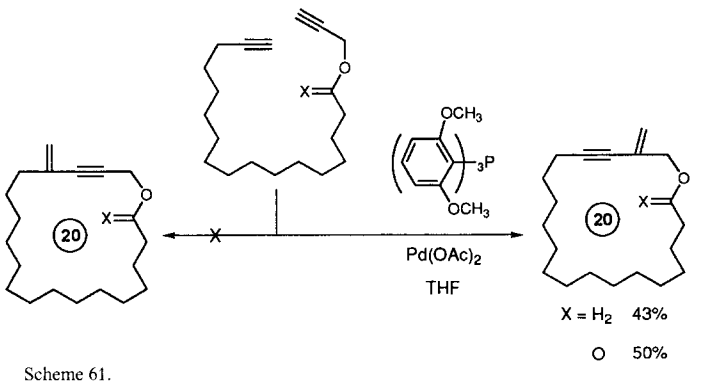
Scheme 57.

Scheme 58.



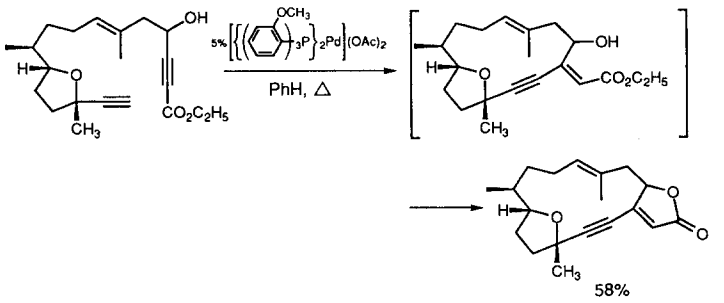
clization. The formation of macrocycles by this process is noteworthy. Initiating the cycloisomerization by deprotonation of the pronucleophile by the initial adduct between the Pd^0 catalyst and the vinyl epoxide has proven a powerful approach to macrocyclizations even for the formation of medium-sized rings.[77, 78] This reaction is a key step in the synthesis of punctaporonin B (Scheme 59).[79] With a polymeric catalyst cycliza-

Scheme 59. dppe = bis(diphenylphosphino)ethane.



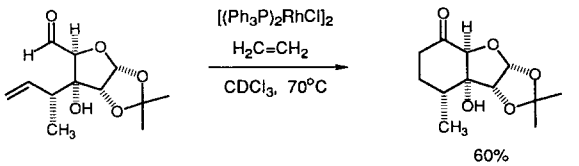
tions to medium as well as large rings can be performed at 0.5 M substrate concentration (Scheme 60).[80]

The ease of insertion of Pd^0 into acetylenic C–H bonds permits macrocyclizations also by a mechanism analogous to path



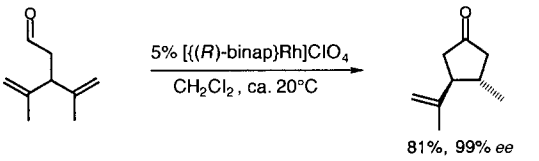
Scheme 60. PS = polystyrene.

B in Scheme 56. In the example of Scheme 61, although cyclization could occur in either direction, it is completely chemoselective: the acetylenic linkage proximal to the electronegative substituent serves as the acceptor.[81] In this reaction an activated



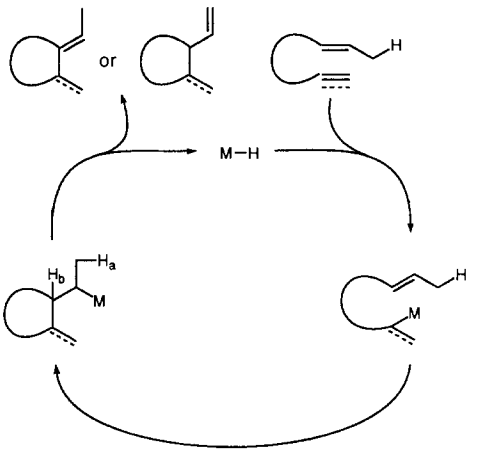
Scheme 61.

alkyne as in Scheme 62 results in cycloisomerization and concomitant butenolide formation.[82] This macrocyclization serves as a key step in a projected synthesis of the cembranoid pachiclavulanolide.



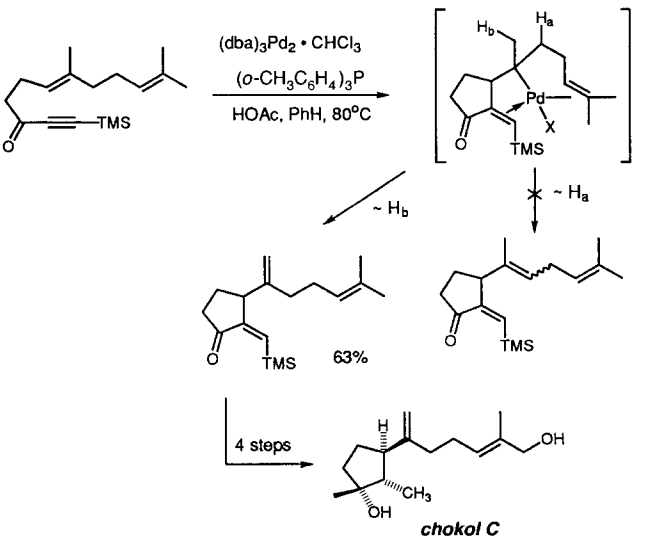
Scheme 62.

If the ability to insert into an aldehydic C–H bond (Scheme 26) is applied to intramolecular additions to unsaturated C–C bonds (intramolecular version of Scheme 12), the result is a novel cycloalkanone synthesis.[83] Although the formation of cyclopentanones proceeds most readily, cyclohexanones may also form (Scheme 63).[84] Excellent asymmetric induction may be observed (Scheme 64).[85]



Scheme 63.

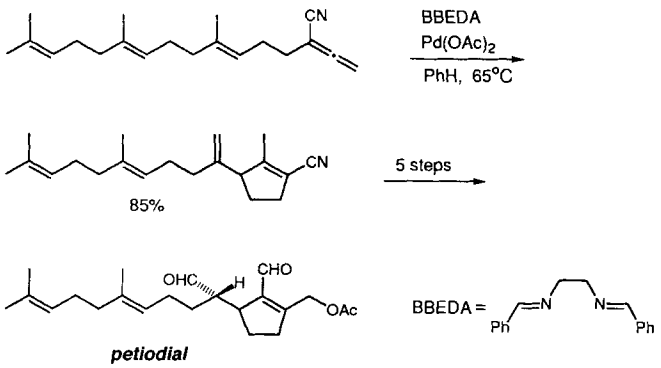
Initiating the reaction by hydrometalation and terminating the sequence by β-elimination (Scheme 65) opens a variant on Scheme 56 for cyclization that is a transition metal analogue of the intramolecular Alder ene reaction.[86] A further feature



Scheme 64.

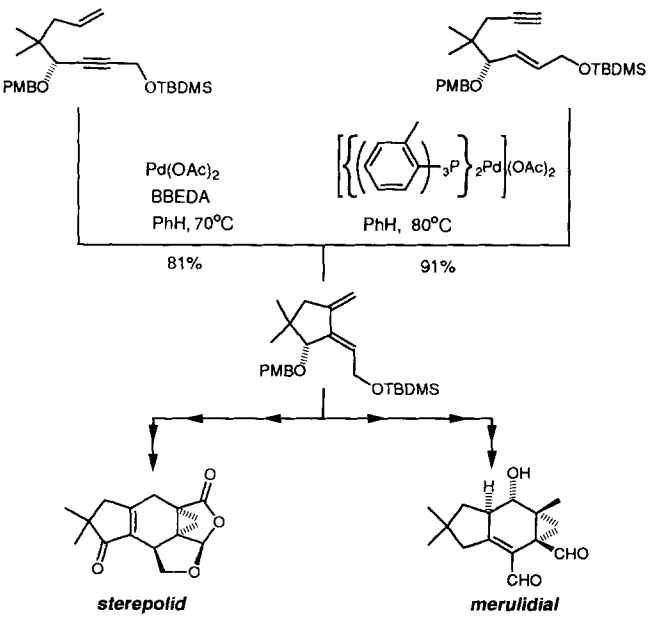
Scheme 65.

of this process is the ability to direct regioselectivity.[87] For example, cycloisomerization of the enyne of Scheme 66 may produce two Alder ene type products. Thermal reactions of analogous substrates generally favor migration of H_a. A hydri-



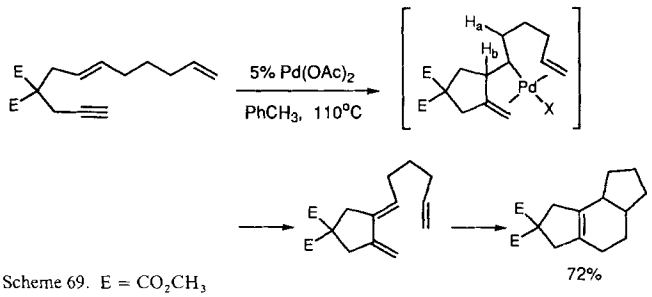
Scheme 66.

dopalladium catalyst, generated in situ from palladium (0) and acetic acid, yields the compound produced exclusively by migration of H_b.[88] This unorthodox regioselectivity derives from coordination of the remote double bond to palladium, thereby fixing the geometry of C–H_a to disfavor its β-elimination. The resultant product is easily converted into the cyclopentanoid antifungal agent chokol C. The total synthesis requires only



seven steps from commercially available geranyl bromide and *N*,*N*-dimethylacetamide. Syntheses of dendrobine[89] and picrotoxinin[90] utilized this cycloisomerization as a key step.

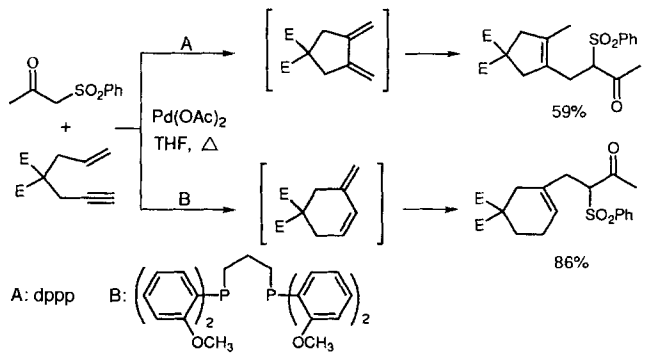
Replacing an alkyne by an allene may also lead to successful Alder ene type cyclizations. A synthesis of the marine antibiotic petiodial involves such a tranformation to create the properly substituted cyclopentenyl ring (Scheme 67).[91] A nickel-chromium catalyst supported on polystyrene[92] appears to be more general for cyclizations of enallenes.[93]



Scheme 67.

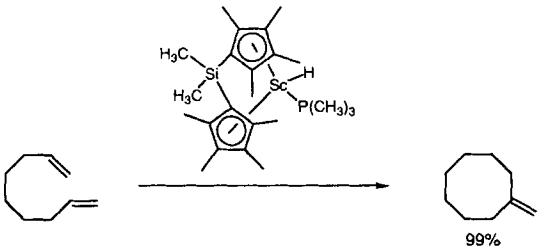
A major benefit of this type of transition metal catalyzed reation is the prospect of performing reactions not possible under thermal conditions. In Scheme 65 it is seen that the Alder ene type product derives from β-elimination of H_a in the primary cyclized product. Elimination of H_b to produce the synthetically versatile 1,3-dienes cannot be achieved thermally, but it can be envisioned to occur in this metal catalyzed version. Indeed, such a reaction proceeds in excellent yield[94, 95] and served as the key to a general strategy for the synthesis of the isolactaranes represented by sterepolide[96] and merulidial[97] (Scheme 68). The regioselectivity of the cycloisomerization of the enyne with the terminal triple bond reveals the effect of

Scheme 68. PMB = *para*-methoxybenzyl.



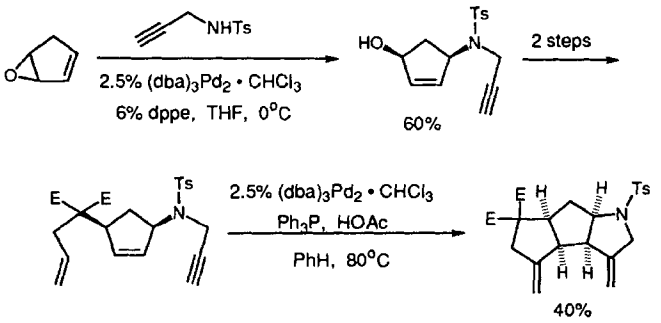
substitution at the allylic position: an alcohol or its derivative functions as a regiochemical control element directing the β-elimination to favor the 1,3-diene.[95, 98] The importance of this cycloisomerization stems from the ability of the 1,3-dienes to function in a second atom economical process, the Diels–Alder reaction. Tethering of remote substituents also favors 1,3-diene formation. Thus, cycloisomerization may be followed by cycloaddition to fold an acyclic polyenyne into a polycycle (Scheme 69).[94] While elimination of neither H_a nor H_b is particularly geometrically favorable, the C–H_b bond can

Scheme 69. E = CO_2CH_3



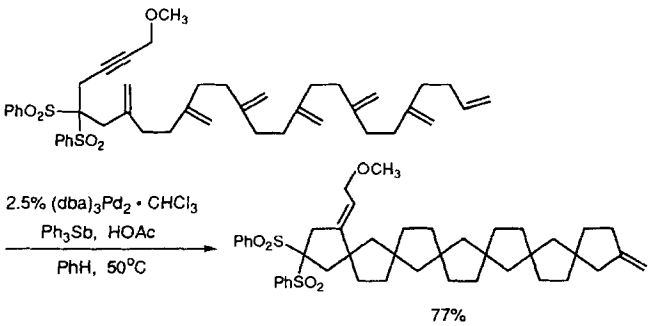
more nearly approach the requisite orientation and, being allylic, is weaker—two factors that favor formation of the 1,3-diene. The remote double bond then functions as the dienophile to form the tricycle. Similar reactions have also been catalyzed by a nickel–chromium complex, preferably supported on polystyrene.

The formation of 1,3-dienes by cycloisomerizations sets the stage for metal catalyzed additions of pronucleophiles as in Scheme 15 and path A in Scheme 16a. Since palladium can catalyze each step separately, finding the right ligand allows the steps to proceed successively in a one-pot reaction (Scheme 70).[99] Surprisingly, changing the ligand completely



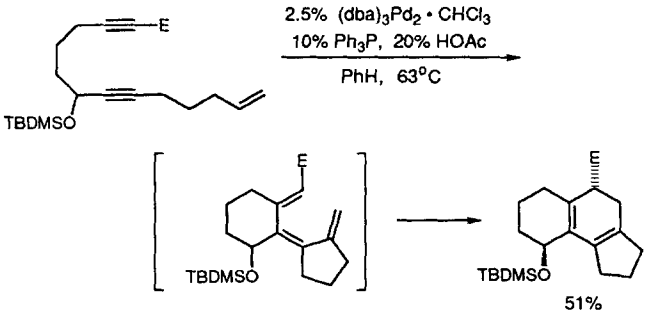
Scheme 70. The ligands for the routes A and B are listed separately. E = CO_2CH_3.

changes the regioselectivity of the initial cyclization from five- (Path A) to six-membered (Path B) ring formation. Path B normally is not observed in the simple cycloisomerizations. A scandium hydride catalyzes the cycloisomerization of α,ω-dienes by a similar mechanism.[100] Remarkably, medium and large rings form readily (Scheme 71), although the catalyst cannot tolerate Lewis basic sites. Other metals including palladium,[101] rhodium,[101] and nickel[102] are reported to cycloisomerize α,ω-dienes with varying success.



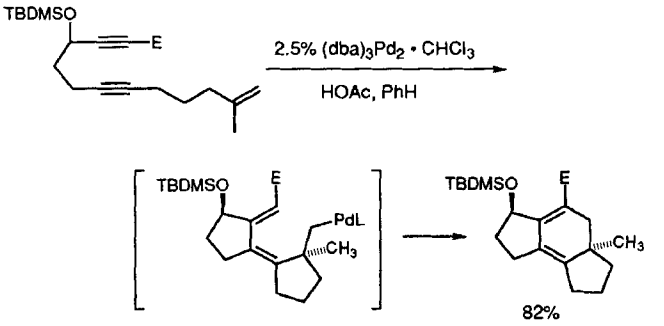
Scheme 71.

Another prospect for invention is the interception of the initial monocycle of Scheme 65 by further unsaturated functional groups. Construction of quinanes and heteroquinanes involves capture by an additional double bond system (Scheme 72) in a



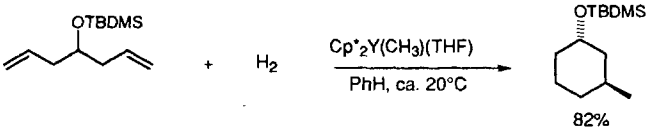
Scheme 72. Ts = *para*-tolylsulfonyl, E = CO_2CH_3.

sequence initiated by a palladium catalyzed addition of a vinyl epoxide and a pronucleophile.[103] The juxtaposition of the unsaturated bonds determines the nature of the ring system that will be created, as illustrated for a linear azatriquinane synthesis in Scheme 72. The number of rings that can be created equals the number of double plus triple bonds minus one. Thus, zipping up the heptaenyne in Scheme 73 with a palladium catalyst creates a heptaspirane that resembles a molecular rope.[104]



Scheme 73.

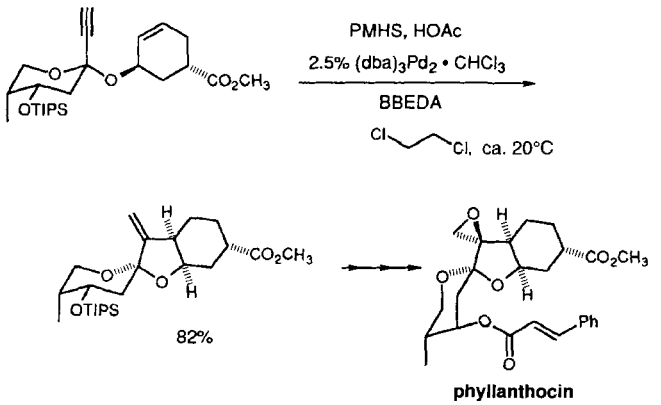
Replacing the internal double bond by another triple bond provides a novel strategy for the synthesis of 1,3,5-hexatrienes (Scheme 74). These intermediates further cycloisomerize by a rotoselective disrotation to form a single diastereomeric tricycle. Preclusion of the final β-elimination does not stop cyclization, since the intermediate with a terminal palladium moiety



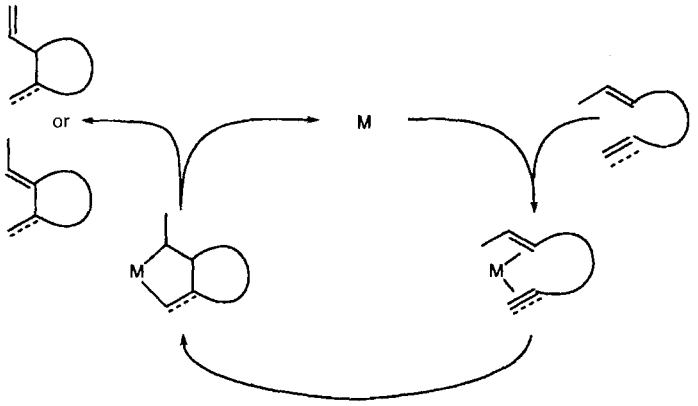
Scheme 74. E = CO_2CH_3.

may bite back on itself to produce a tricycle similar to that derived from electrocyclization of a hexatriene (Scheme 75). Other mechanisms also explain this efficient tricyclization.

Scheme 75.



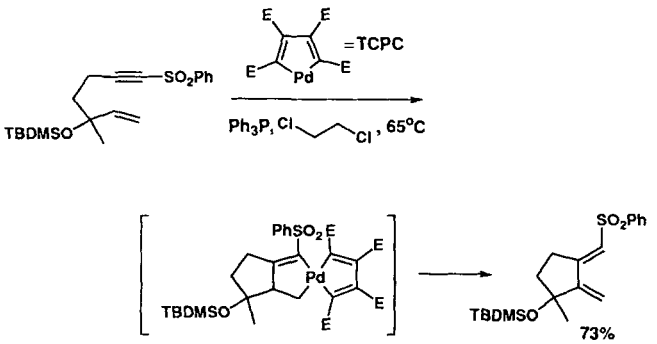
Another opportunity for innovation envisions interception of the C–M bond of the initial monocycle of Scheme 65 by an external trap such as hydrogen to effect a reductive cyclization. Indeed, an yttrium hydride formed in situ permits an atom economical addition of hydrogen with concomittant cyclization, which dominates over simple reduction with appropriate substrates (Scheme 76).[105] A more general but less atom econom-



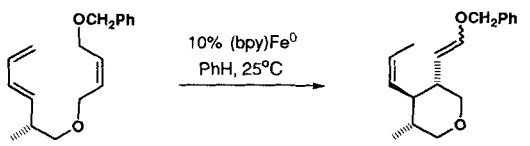
Scheme 76. Cp*.

ical reductive cyclization employs a proton and a hydride source as an equivalent of molecular hydrogen.[106] This palladium catalyzed reductive cyclization of an enyne served as a key step in a synthesis of the clinically useful phyllanthocin (Scheme 77).[107]

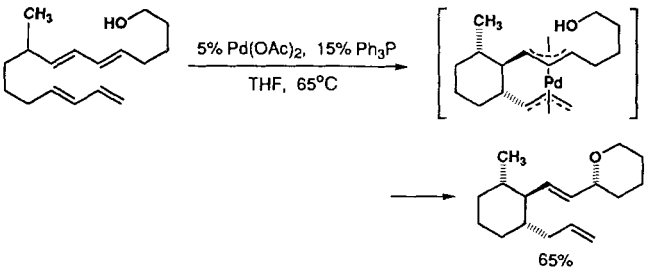
An alternative mechanism for cycloisomerization recognizes the chelating potential of α,ω-unsaturation (Scheme 78). In fact, some of the palladium catalyzed cyclizations of Schemes 66–69, 72–75, and 77 may proceed through such a pathway.[86b, 94] Use of "tetramethoxycarbonylpalladacyclopentadiene" (TCPC) as catalyst for such cycloisomerizations is



Scheme 77. PMHS = polymethylhydrosiloxane. TIPS = triisopropylsilyl.

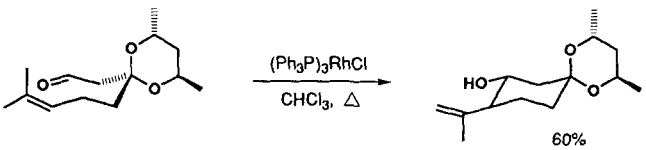


Scheme 78.

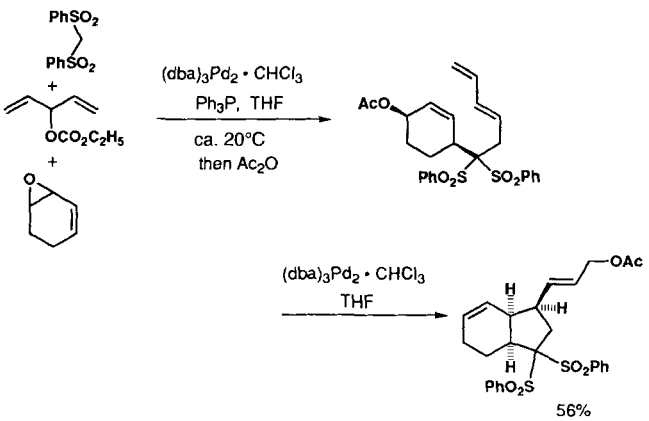


be lieved to involve such a pathway (Scheme 79).[108] The iron(0) catalyzed Alder ene type process (Scheme 80) appears to involve such a mechanism.[109] The intramolecular analogue of the diene telomerization reaction (Scheme 31)[110] also invokes a similar concept (Scheme 81) via a bis(π-allyl)palladium intermediate.

Scheme 79. E = CO_2CH_3.

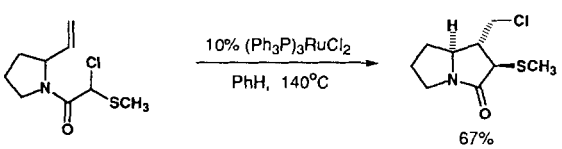


Scheme 80. bpy = bipyridine.



Scheme 81.

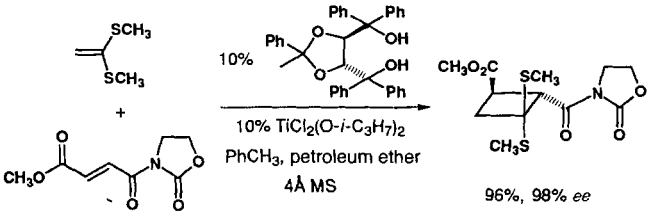
Replacment of an olefin by a carbonyl group leads to an oxaene reaction. While typical Lewis acids normally catalyze this reaction, such cycloisomerizations have also been reported with Wilkinson's catalyst (Scheme 82), although the mechanism of this catalysis is obscure.[111, 112]



Scheme 82.

Cycloisomerizations can also involve heterotropic rearrangements. An oxytropic cyclization involving π-allylpalladium intermediates proceeds stereospecifically to the bicycle with an *endo*-oriented side chain (Scheme 83).[113] The ruthenium

Scheme 83.

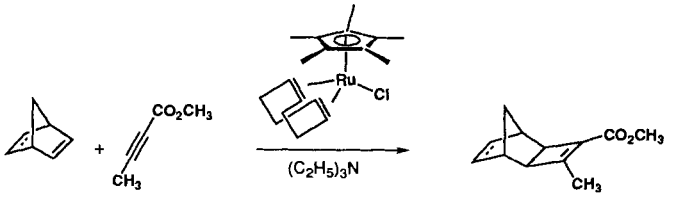


catalyzed halotropic addition occurs intramolecularly (Scheme 84).[114] This reaction may be extendable to form medium and large rings.[115]

Scheme 84. Only the major product is shown.

6. Cycloadditions

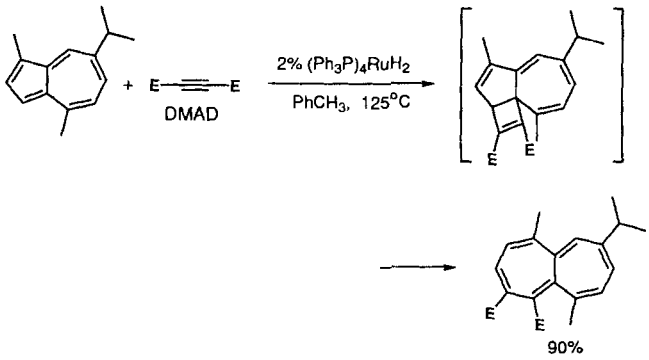
The fastest way to increase molecular complexity is to form more than one bond at a time as in cycloadditions. Orbital symmetry reveals that Hückel-like (4n + 2) transition states are favored whereas 4n transition states are forbidden in a geometrically favorable suprafacial conformation. However, metal catalysis may succeed in both cases since it opens a plethora of mechanistic possibilities beyond the concerted cycloaddition. The orbital-symmetry-forbidden [2 + 2] suprafacial cycloaddition is catalyzed by early transition metals which seem to function as Lewis acids. Chiral cyclobutanes (Scheme 85) and cyclobutenes form with excellent enantioselectivity.[116]



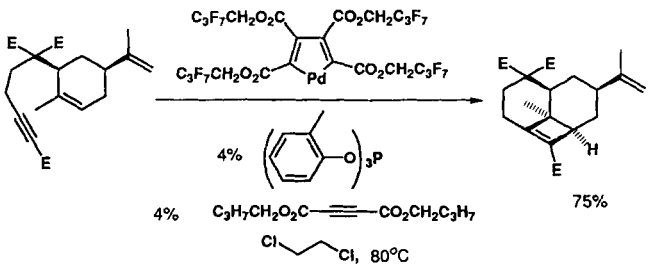
Scheme 85.

A more promising strategy involves reductive elimination of metallacyclopentenes that may form from alkynes and alkenes (Scheme 86). Such an intermediate has been invoked in the

Scheme 86.



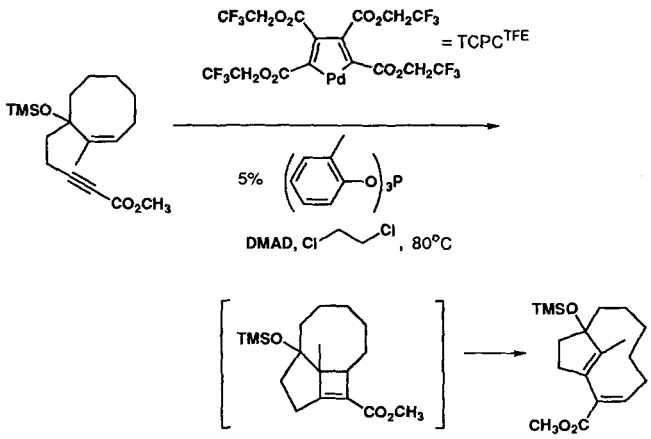
ruthenium catalyzed Alder ene reaction (Scheme 41). With a strained alkene partner such as norbornene or norbornadiene, such a [2 + 2] cycloaddition occurs in the presence of a coordinatively unsaturated ruthenium complex (Scheme 87).[117] In



Scheme 87. The yield is 79% relative to norbornene and 87% relative to norbornadiene.

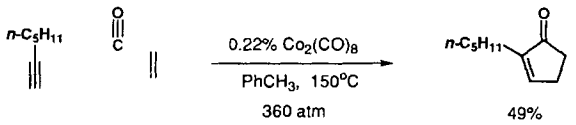
contrast to other diene reaction partners (vide infra), norbornadiene undergoes only [2 + 2] cycloaddition. Other catalysts have been reported to behave similarly.[118] This reaction expanded an azulene into a heptalene with dimethyl acetylenedicarboxylate (DMAD) (Scheme 88).[119]

Palladacyclopentadienes promote [2 + 2] cycloadditions of enynes (Scheme 89).[120] The resulting cyclobutenes undergo



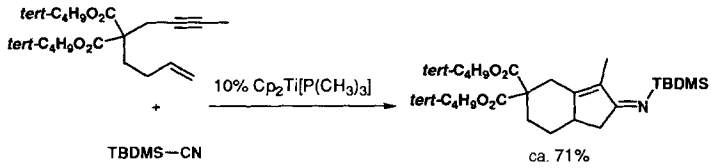
Scheme 88. E = CO_2CH_3.

Scheme 89.



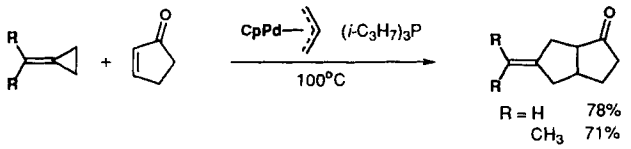
thermal conrotatory ring opening to form 1,3-dienes. Shortening the tether connecting the double and triple bonds of the substrate from four to three atoms lowers the temperature for ring opening so much that only the enyne metathesis product is observed (Scheme 90).[121] The presence of bicyclic structures like those depicted in Scheme 90 in many natural products makes this simple approach for their creation very attractive.

Scheme 90.



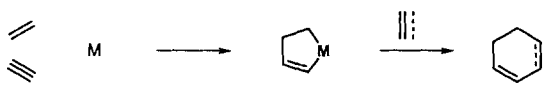
Intercepting the metallacyclopentene by carbon monoxide creates the structurally important cyclopentenones. Surrogates for CO such as isonitriles react analogously. With dicobalt octacarbonyl as the complex, this addition is known as the Pauson–Khand reaction and is an important synthesis of cyclopentenones.[122] Unfortunately, the reaction generally requires a stoichiometric amount of the cobalt complex, although a recent

example has illustrated the potential for a catalytic process (Scheme 91).[123] An analogous process catalytic in a titanium complex traps the cyclopentene with a silylisonitrile generated in



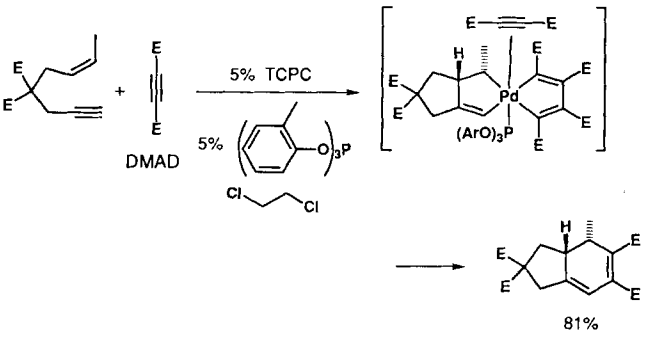
Scheme 91.

situ by isomerization of a silylcyanide (Scheme 92).[124] Ni^0 effects a similar reaction, which, however, requires a stoichiometric amount of the "catalyst."[125] These sequences constitute a [2 + 2 + 1] approach for five-membered ring construction.



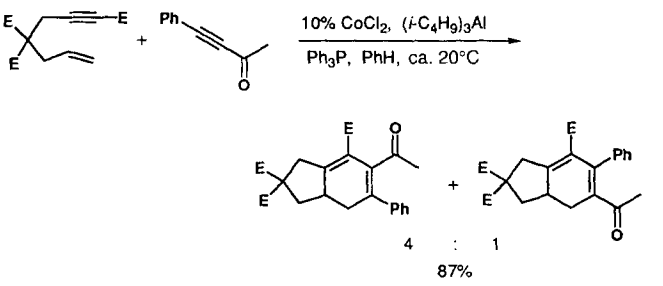
Scheme 92.

A [3 + 2] cycloaddition also generates five-membered rings. A cooligomerization of methylenecyclopropane with electron-deficient or strained alkenes produces methylenecyclopentanes even with substituted substrates (Scheme 93).[126] Whether the reaction involves ring opening to a trimethylenemethane complex or direct oligomerization through a metallacycle has not been elucidated.



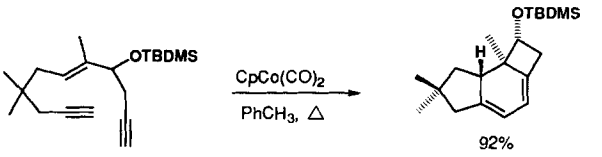
Scheme 93.

Intercepting the metallacycle of Scheme 86 with a two-carbon trap generates six-membered rings in a formal [2 + 2 + 2] type of cycloaddition (Scheme 94). Cycloisomerization of enynes

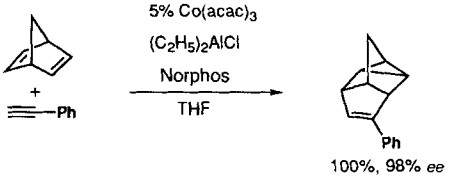


Scheme 94.

with TCPC in the presence of excess dimethyl acetylenedicarboxylate leads to the bicyclic derivative formed by trapping the purported palladacyclopentene intermediate (Scheme 95).[108] A low-valent cobalt complex generated in situ extends this reaction to monoactivated alkynes (Scheme 96),[127] whereas tethering all three unsaturated bonds permits [2 + 2 + 2] cycloaddi-

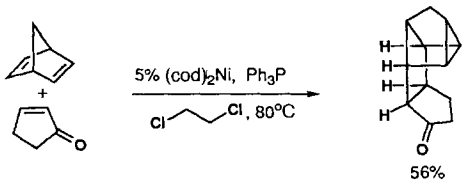


Scheme 95.



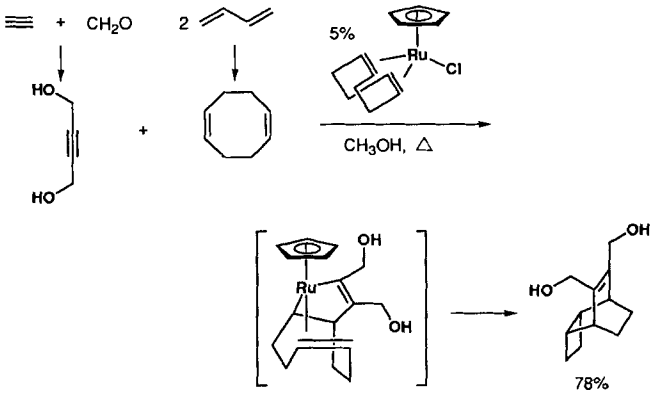
Scheme 96.

tion even without activating groups (Scheme 97),[128] although a stoichiometric amount of the cobalt "catalyst" is required because the product is strongly coordinated to cobalt.



Scheme 97.

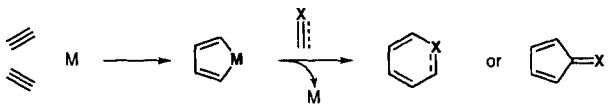
Norbornadiene undergoes [2 + 2 + 2] cycloadditions (homo-Diels–Alder reactions) with alkynes in the presence of a cobalt catalyst.[129] Since norbornadiene functions as a bidentate ligand to direct the initial cobaltacycle to the *endo* face, deltacyclenes (Scheme 98) rather than cyclobutenes (Scheme 87)[130]



Scheme 98. Norphos = 5,6-bis(diphenylphosphino)norbornene.

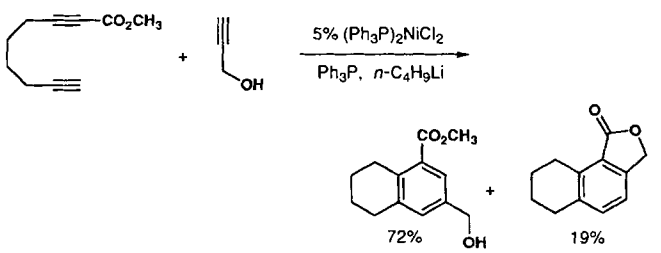
result. As illustrated, placing the metal in a chiral ligand environment may impart high enantioselectivity. Using a nickel catalyst enables enones to be used as the "homodienophile" (Scheme 99),[131] which suggests that the course of reaction in Scheme 94 may be applicable to metallacyclopentanes. 1,5-Cy-

Scheme 99.



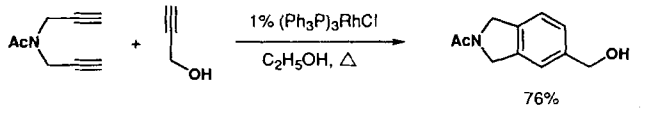
clooctadiene participates efficiently in [2 + 2 + 2] cycloadditions (bis-homo-Diels–Alder reaction) with alkynes in the presence of a ruthenium catalyst in which a ruthenacyclopentene may be postulated as an intermediate (Scheme 100).[132] The

Scheme 100.



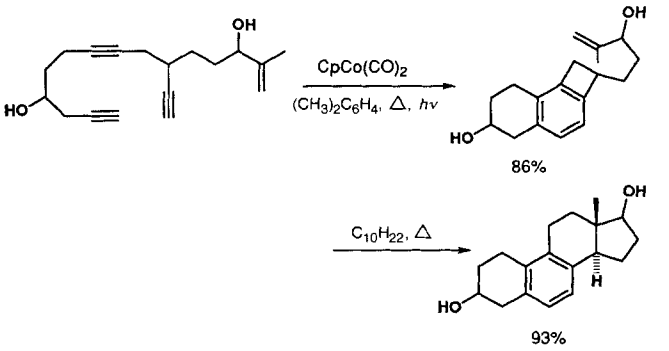
atom efficiency of this process for construction of the energy-rich tricycle becomes evident when it is realized that both reaction partners are synthesized by simple addition reactions. Thus, by a series of three additions, acetylene, formaldehyde (or other aldehydes or ketones), and butadiene combine to form the tricyclo[4.2.2.$0^{2,5}$]dec-7-enes. All other are used catalytically.

The formation of metallacyclopentadienes (Scheme 101) appears to be even more facile than that of metallacyclopentenes.

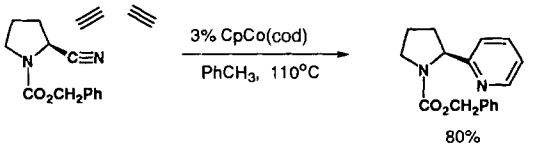


Scheme 101.

The classical example is the construction of benzenoid arenes by cotrimerization of alkynes.[133] Many metals catalyze this process, but nickel (Scheme 102),[134] rhodium (Scheme 103),[135]

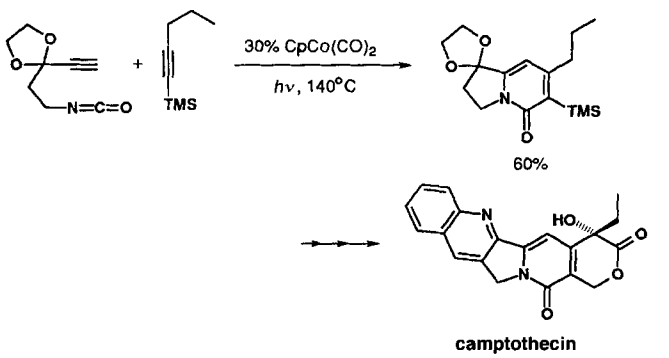


Scheme 102.



Scheme 103.

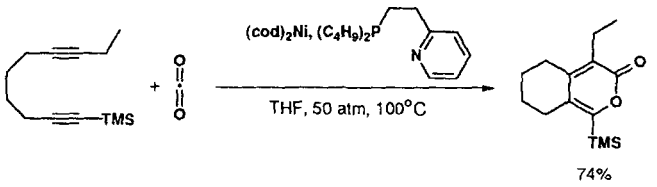
and especially cobalt (Scheme 104)[136] have proven particularly effective. In contrast to the reaction in Scheme 97, the cobalt dissociates easily from the arene, and the reaction is truly cata-



Scheme 104.

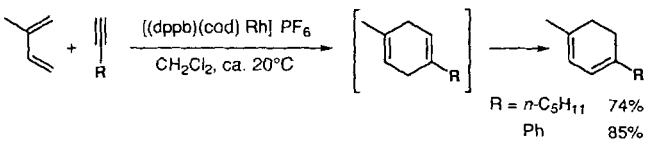
lytic in cobalt. This example illustrates the strain that may be incorporated into the cycloaddition product, which is released in a subsequent thermal electrocyclic reaction to set the stage for a final [4 + 2] thermal cycloaddition. Thus, by a series of simple cycloisomerizations, an acyclic precursor is folded into the entire steroid skeleton. Replacing an alkyne by the isoelectronic nitrile leads to a very efficient pyridine synthesis (Scheme 105).[137, 138] Cumulative unsaturation represented by

Scheme 105.



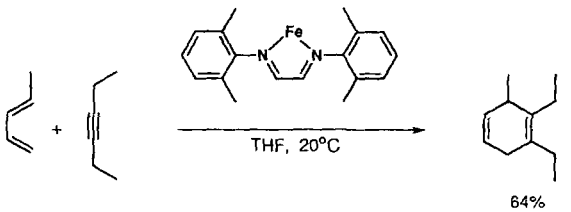
an isocyanate effectively captures the cobaltacyclopentadiene (Scheme 106)—an important step for the synthesis of the antitumor agent camptothecin.[139] Alkenes also function as effective

Scheme 106.



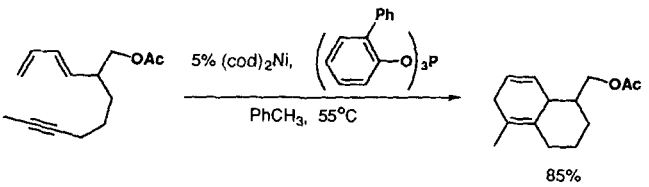
traps. Since the resultant cyclohexadienes coordinate extremely well to cobalt, normally stoichiometric amounts of the "catalyst" are required in such cases. Niobium complexes also initiate [2 + 2 + 2] cycloadditions of alkynes.[140]

With carbon monoxide, capture of the metallacyclopentadiene normally generates the cyclopentadienone rather than pyran derivatives. However, since cyclopentadienones are excellent ligands, the products are normally metal complexes, and thus the reactions require stoichiometric amounts of the metal.[141] On the other hand, carbon dioxide participates in a [2 + 2 + 2] type cycloaddition under the influence of a nickel catalyst (Scheme 107).[142] Aldehydes may function in similar fashion to produce pyrans.[143]



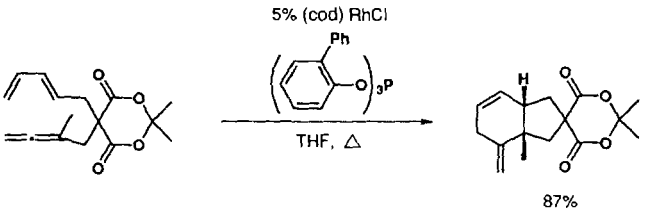
Scheme 107.

Precoordination onto a transition metal promotes [4 + 2] cycloadditions that might not occur thermally or occur only at unacceptably high temperatures. On use of a coordinatively unsaturated electrophilic rhodium complex, dienes react with unactivated alkynes (Scheme 108) to give the adduct in which

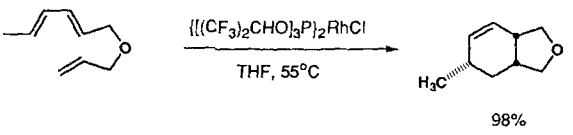


Scheme 108. dppb = 1,4-bis(diphenylphosphino)butane

isomerization of the double bonds to the thermodynamically more stable conjugated isomer accompanies cycloaddition.[144] With an iron(0) complex, catalysis of the cycloaddition occurs without isomerization of the double bonds (Scheme 109).[145]

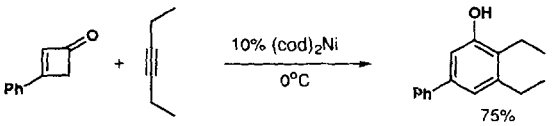


Scheme 109.

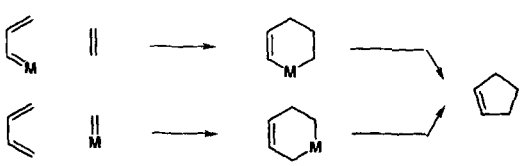


While the "para" type product dominates, other isomers also form. Tethering the partners overcomes the regioselectivity problem, and catalysis may be accomplished both with rhodium[146] and nickel (Scheme 110)[147] complexes. Rhodium catalysts enable both allenes (Scheme 111)[148] and simple olefins (Scheme 112)[148] to serve as "dienophiles." The ability of transition metals to promote ring opening of strained rings has led

Scheme 110.

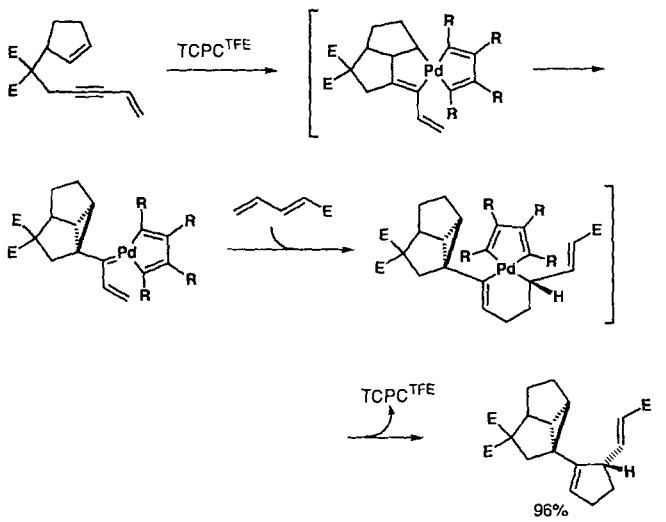


Scheme 111.



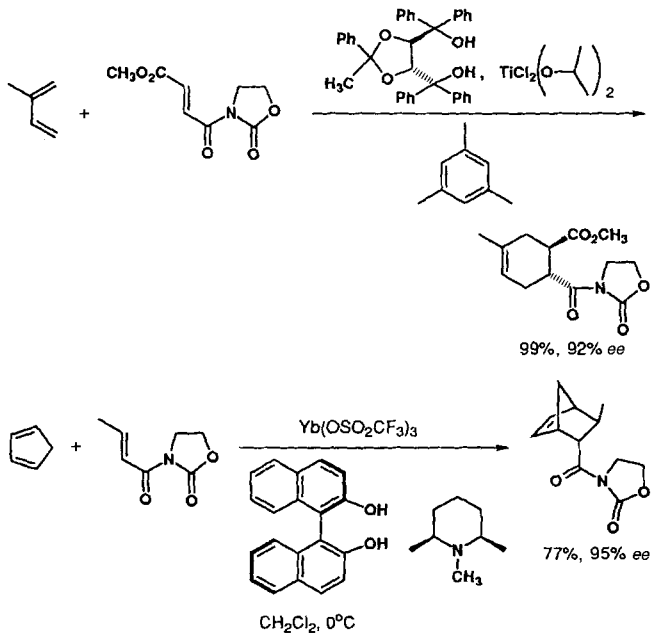
Scheme 112.

to a novel Diels–Alder type cycloaddition of cyclobutenones with alkynes, presumably involving a vinylketene coordinated to the metal as the diene partner (Scheme 113).[149] Unsymmetrical alkynes show no regioselectivity.



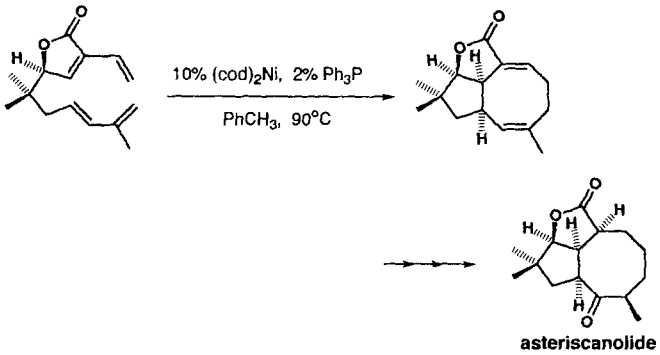
Scheme 113.

A new type of approach for cycloaddition proposes the use of a metalladiene or metallaenophile as reaction partner (Scheme 114). Although such carbenes normally participate in [2 + 2] cycloadditions leading to metathesis type products, the potential for creation of unusual ring systems not directly accessible by Diels–Alder reactions, such as cyclopentenes, make the search for such processes highly worthwhile. In the first example of a metalladiene participating in a cycloaddition, the vinylcar-



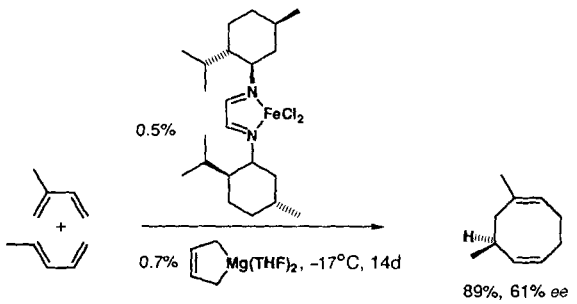
Scheme 114.

bene is generated in situ by a cycloisomerization of an enyne as in Scheme 115.[150] Trapping of the palladadiene intermediate requires a diene or enyne and proceeds with high regio- and diatereoselectivity.[151] Thus, simple metal catalyzed isomerization and addition convert simple building blocks into complex polycycles with high atom economy.



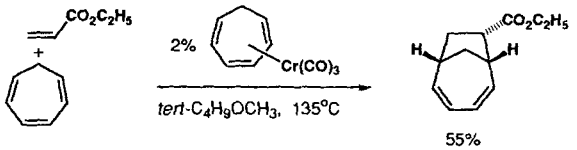
Scheme 115. E = CO_2CH_3, R = $CO_2CH_2CF_3$.

A more traditional catalysis of the Diels–Alder reaction utilizes the transition metal as a Lewis acid. These catalysts offer the advantage of imparting enantioselectivity as exemplified by titanium[152] and lanthanide (Scheme 116)[153] catalysts.



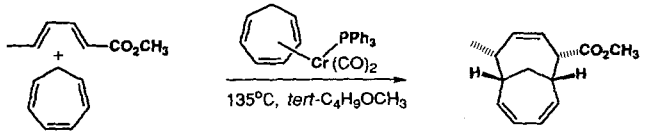
Scheme 116.

Higher order cycloadditions are also promoted by transition metals. The [4 + 4] cycloaddition to cyclooctanes catalyzed by nickel controls regioselectivity by tethering the two groups.[154–156] An effective synthesis of (+)-asteriscanolide highlights the practicality of this cycloaddition (Scheme 117).[157] While intermolecular homocoupling of dienes also



Scheme 117.

may be achieved with the nickel catalyst, an iron catalyst has effected selective cross-coupling of two different dienes asymmetrically (Scheme 118).[158] An alternative paradigm for eight-



Scheme 118.

membered ring construction is [6 + 2] cycloadditions. On use of a chromium catalyst, cycloheptatriene (Scheme 119) and its heterocyclic variants form cycloadducts with typical dieno-

Scheme 119.

philes.[159] This reaction has been extended to [6 + 4] cycloadditions, which, however, proceed much slower (only 36% complete after 18 h, Scheme 120). Many further prospects for metal assisted cycloadditions not achievable otherwise abound.

Scheme 120.

7. Conclusion

The tremendous strides in organic synthesis in the last several decades have engendered the feeling that no target is too complex to tackle by synthesis. However, such notions founder if the practicality is questioned. It is not adequate only to complete a synthesis; the effectiveness of the route is critical. Improving the ability to design molecular structures more efficiently stems largely from enhancements in the selectivity of available reactions and reagents. Increasingly, transition metal catalyzed reactions are proving their value for such goals. No reaction better exemplifies this point than the transition metal catalyzed cross-coupling. However, in solving such problems of selectivity, the issue of atom economy is normally neglected. The scale-up of a complex synthesis from the research laboratory to the plant cannot ignore this fundamental question. This issue has long been recognized by the commodity chemical industry for obvious reasons. Only recently has the subject become an issue for the synthesis of smaller volume products. As the legitimate concerns of society for wise use of our limited resources with minimal environmental risk grow, the ability to produce the chemicals needed to improve the human condition will hinge on the inventfulness of chemists to design more efficient syntheses.

As a start, the repertoire of reactions that are highly atom economical must increase. The prospects for invention are vast. Clearly, the molecular gymnastics—even acrobatics—for organic molecules that transition metals direct represent promising opportunities for new invention.

Several themes become evident. Many reactive intermediates do not participate usefully in synthetic reactions either because of the harshness of the conditions required to generate them or because their high reactivity makes their trapping impractical. The ability of transition metals to create such "reactive" intermediates under mild conditions promotes specific further reactions with a selectivity tunable by the ligand environment. Precoordination imparts both selectivity and kinetic reactivity to otherwise unselective or unreactive systems. One additional benefit that emerges from this last concept addresses chemical safety. By imparting chemical reactivity only during the synthesis, the chemicals to be handled and/or stored can be more benign.

The reactions described herein represent only a beginning towards achieving these objectives. Clearly, the vastness of the territory to be explored assures exciting opportunities for generations. We still require "functional groups" to assist selective activation for new bond formation. An ideal for which we should strive is the elimination of such a requirement when the functional groups are absent from the ultimate target. We have barely begun to broach such a strategy, which today seems unattainable. Undoubtedly, such pessimism will fade as new breakthroughs emerge, especially those emanating from the domain of transition metal catalysis.

I am thankful for the many coworkers who have contributed both intellectually and experimentally to our program and who have been identified in the references. The National Science Foundation and the National Institutes of Health through the General Medical Science Institute have provided the financial support for our work.

Digitalis Research in Berlin–Buch—Retrospective and Perspective Views**

Kurt R. H. Repke,* Rudolf Megges, Jürgen Weiland, and Rudolf Schön

"The following remarks consist partially of matter of fact, and partially of opinion. The former will be permanent; the latter must vary with the detection of error, or the improvement of knowledge. I hazard them with diffidence, and hope they will be examined with candour." These declarations, which stem from the famous book "An Account of the Foxglove and some of its Medical Uses" by physician William Withering in 1785 in which he introduced preparations from digitalis leaves in the therapy of dropsy (cardiac failure), are cited here by the senior author because of his awareness of the difficulties in presenting a balanced report on his life-long research project on the further development of digitalis. His decision to devote himself to digitalis research originated at the bedside, when as a physician he experienced the grim final stages of cardiac failure in which no real help for the patients is possible. Unfortunately, his research project did not fit into the research program decreed by the Ministry of Science of the German Democratic Republic, so that he was ordered to stop the digitalis project in favor of biomembrane studies. Fortunately, he got round the ban simply by labeling the digitalis-like acting steroids as probes for the cell membrane-located Na^+/K^+-transporting ATPase which he had just recognized as the digitalis target (receptor) enzyme. These and other ventures by the authors are collated here for the first time. The aim of this review is to foster straightforward research for solving a major challenge: the development of steroidal drugs for the prevention and cure of cardiac failure.

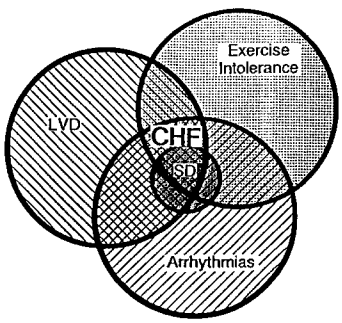
Keywords: digitalis · drug design · medicinal chemistry · pharmaceuticals · steroids

1. Introduction: The Challenge of Digitalis Research

The challenge of digitalis research derives from the need for new drugs for the prevention of cardiac failure and the successful treatment of the failing heart. Specifically, the need follows from: the prevalence and mortality of heart failure in developed countries; the fact that the cardiac drugs available are clearly inadequate to restore health or even to minimize discomfort and disability; and the condition that previous research efforts to provide drugs satisfying the above requirements have widely failed. Selected facets of the latter studies were previously reviewed by the authors of this review.[1, 2]

1.1. The Underlying Medical Demand

The incidence and prevalence of congestive heart failure have increased in recent years,[3] and as the average age of the population increases, it is expected to continue to increase. The prognosis after first diagnosis is grim; less than half of the patients survive more than five years.[4] The survival rate depends on several variables, essentially defined in Figure 1.



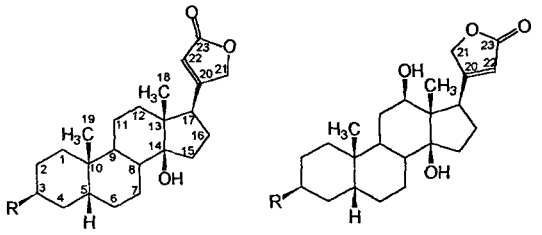


Fig. 1. Clinical manifestations of myocardial disease. The Scheme shows the possible coincidences of left ventricular dysfunction (LVD), exercise intolerance, and ventricular arrhythmias as the most common manifestations of the failing heart syndrome. Clinical heart failure (CHF) corresponds to the coexistence of LVD and exercise intolerance. Sudden death (SD) occurs in patients with arrhythmias and predominantly in those with LVD and CHF (from ref. [5]).

The therapeutic value of preparations from Digitalis plants was discovered by Withering more than 200 years ago.[6] Digitoxin (**1**) and digoxin (**2**) (Fig. 2), the predominant active materials, still belong today to the drugs most common-

[**] Definitions and abbreviations: Digitalis: generic term to cover all steroids which act cardiotonic by inhibiting Na^+/K^+-ATPase by occupancy of its digitalis recognition matrix and binding cleft; Na^+/K^+-ATPase, the Na^+/K^+-transporting adenosine triphosphate phosphohydrolase (EC 3.6.1.37), residing in the plasma membrane of all mammalian cells, which effects the conversion of scalar phosphoryl energy of ATP into vectorial electrochemical energy; for the molecular mechanism see K. R. H. Repke, R. Schön, *Biol. Rev.* **1992**, *67*, 31–78; *Biochim. Biophys. Acta* **1992**, *1154*, 1–16.

1 2

Fig. 2. Structural formulae of digitoxin (**1**) and digoxin (**2**) (R = tridigitoxosyloxy). Compound **1** is shown in 14/22-conformation and **2** in 14/21-conformation in which the C22 proton or the C21 protons, respectively, are localized opposite to the C14β-OH group. High potency is preserved in conformationally semi-rigid cardenolide derivatives in which the butenolide C21 protons, due to bulky substituents at the C22 atom (cf. Fig. 9), are forced into a potential energy well near C14β-OH. Hence, the 14/21-conformer appears to be the receptor-bound conformer [7]. Note the *cis*-junction of the rings C and D of the steroid framework is not achieved in the biosynthetic pathways of humans and animals (except for a few toads) (cf. Sections 2.5 and 2.6).

ly prescribed for the treatment of cardiac failure.[3, 8] In 1930, the famous heart specialist Wenckebach[9] concluded: "Digitalis treatment is one of the most important and serious duties of the general physician; it demands a great deal of skill, power of observation, keen interest, and experience. A long life is too short to learn enough about this wonderful drug." More recently, however, considerable controversy has arisen about the role and value of digitalis in treating patients with cardiac failure.[3] The open question at present, is that one cannot draw any conclusions about the effects of digitalis on survival.[10] Physicians are looking forward to additional first-line agents that are relatively safe and that can be used as monotherapy to improve the quality of life, retard progression of the disease, and prevent sudden death.[4, 11] One may expect in the coming years that every effort must and will be made to develop new compounds that will not only beneficially affect the hemodynamic and functional impairment of patients with cardiac failure, but will also hopefully contribute to reaching an achievable goal, namely, the prevention of the clinical manifestation of cardiac insufficiency.[4, 11]

1.2. Paradise Postponed

During the last decade many new drugs have been developed and tested on patients with heart failure at a rate of one new agent every month. An overview of the more interesting agents and their putative major mechanisms has been presented in a detailed, but balanced way by G. Grupp.[12] Phosphodiesterase inhibitors such as amrinone and milrinone seemed to hold great promise, but finally yielded disappointing results. In contrast to the digitalis compounds such cardiotonic drugs lose their effectiveness when they are needed most, that is in severe heart failure.[13] Moreover, reports on increased mortality[14-16] have dampened the initial enthusiasm for the use of phosphodiesterase inhibitors: "paradise postponed".[17] The return on the huge investment of money, time, manpower, and resources to develop an orally administrable inotropic drug to supplement or replace digitalis compounds has generally been disappointing. This has had a devastating effect on the further development of this class of non-digitalis inotropic drugs.[18]

Only digitalis, diuretics, and inhibitors of the angiotensin-converting enzyme each fulfill some of the criteria of a first-line agent in the treatment of chronic heart failure. However, none of these drugs satisfies all of the desired characteristics, and none can optimally manage the heart failure state when used alone.[19] Unfortunately, converting enzyme inhibitors and diuretics have the tendency to impair renal function, while digitalis compounds tend to improve renal function. However, digitalis intoxication has continued to be one of the most prevalent adverse drug reactions encountered in clinical practice due to the narrow margin between the therapeutic and toxic doses and the marked variations in individual sensitivity.[20] Nevertheless, there has been little decline in the use of digitalis over the last five years, indicating that the mentioned newer agents for the treatment of cardiac failure have not replaced the widespread use of digitalis.[3]

1.3. Apparent Causes for the Previous Lack of Success

The search for cardiotonic steroids with an increased therapeutic range by modification of the structures of known digitalis

Kurt R. H. Repke, born in 1919, obtained his medical doctor's degree in 1945. Between 1945 and 1950 he trained in various medical disciplines at hospitals in Hamburg and Potsdam as well as, under Professor Gerhardt Katsch, at the Clinic for Internal Medicine of the University in Greifswald. To acquire a profound understanding of the pharmacological and biochemical foundations of drug therapy, he worked and habilitated under Paul Wels at the Institute of Pharmacology of the University in Greifswald (1950–1955), and subsequently until 1963 under Professor Karl Lohmann at the Institute of Biochemistry of the Academy of Sciences in Berlin–Buch. He followed Lohmann as the director of this institute (1964–1971) and then headed the Biomembrane Section of the newly formed Central Institute of Molecular Biology of the Academy (1971–1984). Since he has been an emeritus professor he has pursued with full vigor his research aims which include in addition to digitalis research the elucidation of the complex mechanism of the interconversion of the scalar phosphoryl energy of ATP into the vectorial energy of cation gradients through biomembranes. Professor Repke has been a member of the Deutsche Akademie der Naturforscher Leopoldina and a honorary member of the Cardiac Muscle Society of USA. He devotes his leisure time to the study of Goethe's genius.

compounds appeared unsuccessful for several decades. This has been interpreted as probably reflecting an already insuperably high degree of structural optimization in the therapeutically used natural compounds of herbal origin.[21] However, the lack of progress might have followed from conceptual limitations or experimental weaknesses in the research endeavors.

The synthetic modifications were based on equating the natural compounds with lead structures. Specifically, the derivatizations were focussed on the side chain at C17 in **1** and **2**, erroneously taken to be the pharmacophoric lead structure.[22-25] The activity of the derivatives was primarily evaluated in animal model systems. They allow the measurement of inotropic and toxic effects, but not the discrimination between the diverse molecular mechanisms underlying the observed effects (cf. Section 2.4). Such observations preclude the derivation of self-consistent structure–activity relationships, as emerges from pertinent reviews.[24-26] Thus, the initially untargeted strategy for the chemical modification necessarily resembled a "molecular roulette". However, for a rational approach to the development of drugs, an understanding of the effect-triggering interaction between active agent and receptor on the molecular level is needed, as emphasized by Ariëns in 1976.[27] He felt that basic research into physiological and biochemical processes would become the cornerstone for new drug development in the near future.

1.4. The Early Illusion and the Present Realities

As reviewed by Parascandola[28] very early some attempts were made to relate the pharmacological action of organic compounds to their structure while structural organic chemistry was still in its infancy. Nevertheless, Brown and Fraser began their promising work in 1869 with the following declaration of faith: "There can be no reasonable doubt that a relation exists between the physiological action of a substance and its chemical composition." In 1877, Brunton even speculated that physicians would soon be able to predict the pharmacological action of any compound from its constitution. This early hope turned out to be an illusion that still applies. Consequently, in 1992 Kuntz[29] stated that we cannot design drugs with a specific mode of action and acceptable biological properties from first principles. What we can reliably expect is to be able to design competitive enzyme inhibitors, and to begin the long process of drug development from such a sensible starting point.[29]

The cornerstone of the newest strategy for design of novel drugs has been proclaimed to be the accurate knowledge of the three-dimensional structure of the potential target proteins, which are complexed with a great variety of ligands (inhibitors) in their recognition and triggering place.[29-33] As stated by the staff of a specialist drug design company in 1991[32]—knowledge of the three-dimensional structure of pharmacologically significant receptor-ligand complexes at the level of resolution achieved by X-ray crystallography has the potential for profoundly influencing and speeding the discovery and development of lead compounds. Since the desolvation of ligand and protein in their going from free to bound form are not considered in this procedure, it has been easier to discover various novel lead compounds by satisfying the evident nonpolar and electrostatic requirements for binding to the catalytic center of a target enzyme than it has been to elaborate these lead structures into potent inhibitors with a small number of iterations.[32] The superiority of that "direct" strategy, as described for the discovery of drugs, over existing methods remains to be investigated.[32]

Despite impressive advances in X-ray crystallography of macromolecules, availability of high-quality crystals remains the major limiting factor in the exploitation of this technique. Otherwise, modeling based on the knowledge of homologous proteins is now generally held to provide an insufficiently stable base for rational drug design.[33] In addition, for the majority of protein sequences with little significant homology to known structures, the problem of predicting secondary and tertiary structures[34] accurately enough for drug design applications is felt to be still insurmountable.[33]

As the "direct" strategy in drug design has been mostly not applicable, "indirect" routes based on the analysis of structure–activity relationships have more generally been pursued. These routes had to be followed also in digitalis research (cf. ref. [1, 2, 35–71]). As long as neither the site nor the mechanism of digitalis action were known, we had to discover by "untargeted" strategy the target enzyme (receptor) to clear the path to the targeted strategy (see Sections 2.1 and 2.2). The ensuing multistage development (cf. ref. [72]) of digitalis research in Berlin–Buch led to the targeted strategy, comprising the following stages: the Na^+/K^+-ATPase was identified as the digitalis target (receptor) enzyme and its role in controlling cardiac contractility was derived (Section 2.2); the "microscopic" digitalis mechanism of Na^+/K^+-ATPase inhibition was clarified (Section 2.3); the capabilities and limitations of biological and molecular screening test systems were evaluated (Section 2.4); the lead structures for digitalis-like action were discovered in the course of an extended "chemical hunt"[1, 2, 35-71] (Sections 2.5 and 3); the mystery surrounding the chemical identity of the putative endogenous digitalis was attributed to the lack of specificity of the various analytical procedures applied (Section 2.6). Based on the achieved insights, some facets of the most recent developments of the research will be delineated in Section 3.

2. The Stages of Digitalis Research

Over thirty years, digitalis research has been stimulated by mutual supplement and criticism of the research groups in Sydney and Berlin–Buch. Although both studying the digitalis problem, their research efforts differed in many ways due to different experiences and preferences as well as different methodological and conceptional approaches. The work in Sydney has focussed on the isolation and structure determination of natural substances and, above all, the synthesis of digitalis analogues by substitution of the lactone group at C17 by different open side chains or/and substitution of the sugar component at C3 by different ester groups as well as the determination of the inotropic activity of the compounds on surviving preparations from the cardiac muscle of the guinea-pig. The voluminous results of the Australian groups were comprehensively published by Wright in 1960;[73] Thorp and Cobbin in

1967;[74] Thomas, Boutagy, and Gelbart in 1974;[75] Thomas, Gray, and Andrews in 1990[24] and Thomas in 1991.[25] Thus, their brilliant contributions will not be reviewed here for the sake of brevity, too.

2.1. The Role of Biotransformation

The metabolic transformation of digitalis glycosides (reviewed in refs. [76, 77]) can sometimes render the interpretations of biological potency data in terms of structure–activity relationships more difficult. This becomes evident from the following examples. When orally applied, lanatoside C undergoes deglucosylation and deacetylation by microorganisms in the intestinal tract before the glycoside becomes absorbed in the form of digoxin (**2**).[78–80] Lanatoside C is thus a prodrug. Pentaacetylgitoxin requires deacetylation to 16-acetylgitoxin by microbial and animal hydrolases before it becomes effective; it presents thus an example of drug latentiation.[81–83]

As illustrated in Figure 3, digitoxin (**1**) and digoxin (**2**) undergo, by cleavage of the tridigitoxoside chains, a slow, stepwise degradation to the aglycones which are rapidly inactivated by epimerization and conjugation of the released hydroxy group at C3.[84–90] Taking into account the locus and speed of biotransformation on the one hand and the biological activities of the metabolites on the other (cf. Fig. 3), the following conclusions can be drawn: As a rule, the ultimately active agents are not formed by biotransformation. The biotransformations are rather detoxification reactions.[76, 77] Due to its slow removal, the sugar side chain prolongs the half time of the active molecules in the animal body.[84, 85, 93] However, the large variations in acute potency

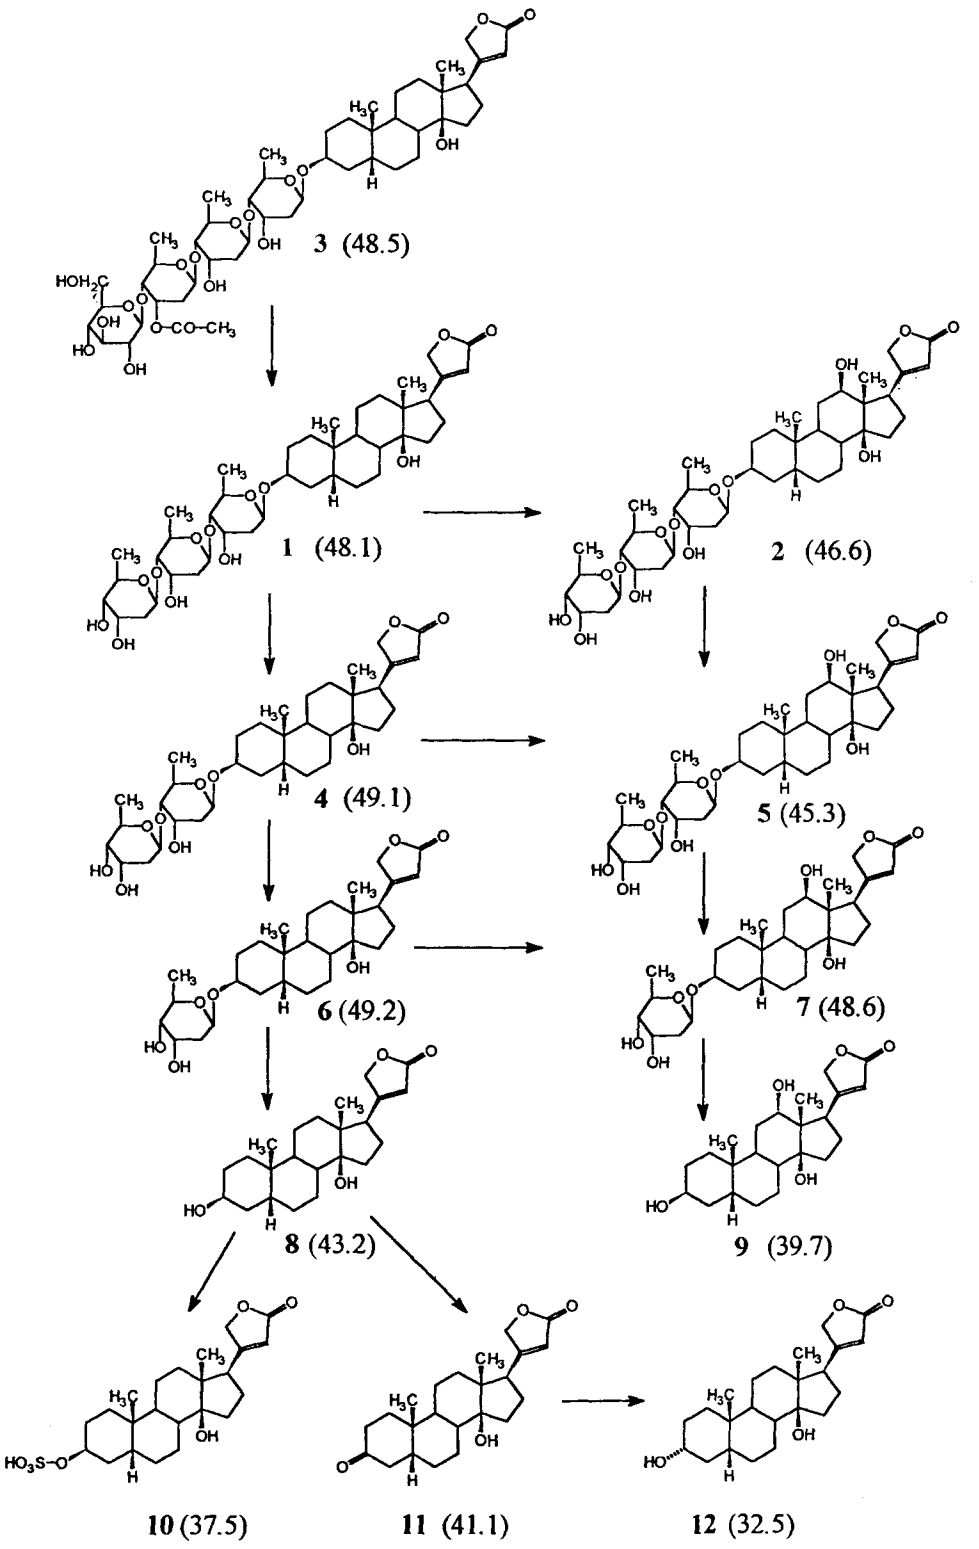

Fig. 3. Biotransformation of lanatoside A (**3**) in the animal body. The deacetylation and deglucosylation (**3** → **1**) are effected by microbial enzymes in the intestinal tract, allowing absorption of **1** [78–80]. Then, liver enzymes bring about C12β-hydroxylation (**1** → **2**), stepwise separation of the three digitoxose residues (**1** → **8**; **2** → **9**), conjugation with sulfuric acid (**8** → **10**) or epimerization of C3β-OH (**8** → **12**) [84–90]. The latter two reactions are the decisive detoxification steps as the drop in the Gibbs energy of interaction with the receptor enzyme (given below the formulae in parentheses, expressed in $-$kJ mol^{-1}) indicates. Scrutiny of the $\Delta G^{0\prime}$ values suggests that the sugar side chain for the most part remains outside the digitalis recognition matrix and binding cleft of the receptor and that the sugar residue next to the steroid nucleus lies at the mouth of the receptor cleft. If so, the lactone function is positioned at the bottom of the cleft such that the cleft length amounts to about 1.88 nm [91, 92].

shown by digitalis glycosides of different constitution and configuration cannot be explained by differences in the biotransformation.[76, 77, 93–96]

The 12β-hydroxylation of digitoxin (**1**) to form digoxin (**2**)[97] is no prerequisite of cardiotonic action;[97] as indicated in Figure 3, it rather involves a small loss of potency. The double bond in the butenolide side chain can be hydrogenated by microorganisms in the intestinal tract.[76, 77, 79] Since this appears to be irreversible in the animal tissues, the lactone residue cannot serve as hydrogen carrier in the intermediary metabolism[76] as suggested earlier. The double bond orients the H-binding acceptor oxygen atoms of the butenolide towards the H-donating amino acid residues of the recognition matrix of Na^+/K^+-ATPase involved in long-range attraction and high potency binding[2] (cf. Fig. 9). Moreover, the double bond is important for stabilizing the lactone side chain against hydrolysis at physiological pH which is accompanied by loss of potency.[98]

2.2. The Target Enzyme and Its Role in Controlling Contractility

The results of our studies on the metabolic fate of digitalis compounds led us to the inviting conclusion that the question as to the biochemical mechanism of digitalis action is not related to the biotransformation of the herbal compounds in the mammalian body, but that this question appears to coincide with the question as to the nature and function of the digitalis receptor.[76] This conception appeared in 1961 rather daring as it emerges from a look back at a symposium on enzymes and drug action held at that time.[99] When asked to comment on receptor models, R. J. P. Williams replied that he understood the word "receptor" as a synonym for lack of knowledge, and Chain added to not believe that the enzyme approach is the right way to discover new drugs nor to understand in a general way the mode of action of drugs.

Nevertheless, our group wanted to test whether the Na^+/K^+-ATPase, only just shown to be inhibited by the digitalis glycoside ouabain,[100] exhibits the characteristics to potentially serve as the digitalis target (receptor) enzyme. To this end, we extensively compared the many conditions under which digitalis compounds act on contractility, Na^+/K^+ transport, and Na^+/K^+-ATPase activity. At each level, correlations were demonstrated for all 20 characteristics of digitalis action examined, for example locus of action, species differences of digitalis sensitivity, structure–activity relationships, ionic antagonism and synergism, cation requirements for action, time course for development of effects, dependence on specific functional states, and range of effective digitalis concentrations.[76, 101–104] Since the early sixties, our findings and conclusions have been confirmed and extended in several ways by various research groups.[105–113] At long last, after decades of controversy, a consensus has emerged that the inotropic effects of digitalis compounds result from binding to and inhibition of Na^+/K^+-ATPase as stated by T. W. Smith in 1988.[20] Okita et al. reported in 1990 that, in accordance with its receptor function, digoxin (**2**), administered therapeutically in the clinical setting, inhibits the Na^+/K^+ pump in the human heart.[114]

The Na^+/K^+-ATPase is the biochemical machinery in the Na^+/K^+ pump which maintains the normally high intracellular concentration of K^+ ions and low intracellular concentration of Na^+ ions in cardiac muscle and other excitable cells. As deduced by Repke in 1964,[115] the actual Na^+ concentration regulates indirectly the Ca^{2+} concentration in cell interior which has been known to be the final regulator of cardiac contractility. More specifically, the integrating assessment of the then available experimental data on the relationship between the contractility of the cardiac muscle cell and the flows of K^+, Na^+, and Ca^+ ions across the cell membrane led him to the hypothesis that a transient increase of the intracellular Na^+ concentration, resulting from the digitalis-produced reduction of the Na^+/K^+ pumping capacity of the cell by inhibition of a portion of the Na^+/K^+-ATPase total, plays the primary role in the control of cardiac force.[115, 116] The indicated interrelationship has often been questioned, but in 1985 it was finally fully corroborated in using Na^+-selective microelectrodes. Lee[117] established the essential role of the increase in the intracellular Na^+ activity for the action of digitalis at low and high concentrations. Specifically, he showed that digitalis produces a parallel increase in Na^+ activity and contractile force, and that these parameters remain closely correlated during the positive inotropic effect. The increase of the chemical activity of Na^+ ions leads, via the Na^+/Ca^{2+} exchanger, to an increase of the chemical activity of the Ca^{2+} ions through enhanced Ca^{2+} influx into and reduced Ca^{2+} efflux from the cardiac muscle cell as reviewed elsewhere.[1]

2.3. The "Microscopic" Mechanism of Na^+/K^+-ATPase Inhibition

In 1953, Wilbrandt et al.[118] accounted for the strong dependence of the cardiac action of digitalis compounds on contraction frequency with the hypothesis that these steroidal agents interfere with cation transmembrane flows occurring during excitation and recovery. This suggestion was based on the knowledge that other steroids, especially corticosteroids, play an important role, possibly as cation carriers (Fig. 4), in cation

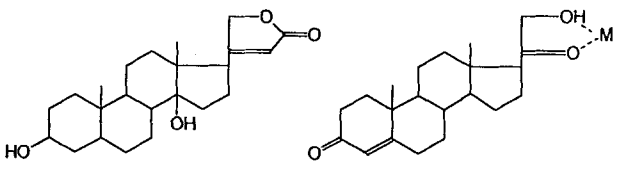

Fig. 4. Assumed structural analogy between a strong inhibitor of Na^+/K^+ transport (digitoxigenin; left) and a presupposed chelate formed between 11-deoxycorticosterone and an alkali metal cation (M; right). On this basis, the action of digitalis compounds was suggested by Wilbrandt [119] to be caused by competitive antagonism towards cation-laden corticosteroids which were thought to be complexed with Na^+/K^+-transporting ATPase and to serve as cation carriers across the membrane of the cell (from ref. [119]).

transport. In support of the above hypothesis, Wilbrandt[120] reported that corticosteroids antagonize the inhibitory action of cardiotonic steroids on cellular Na^+/K^+ transport. Consequently, Wilbrandt[121] considered the possibility that the digitalis effect may be on a corticosteroid-carrier part of Na^+/K^+-ATPase rather than on the enzyme protein. However, our group[122] showed that corticosteroids do not attenuate a digi-

talis-induced Na^+/K^+-ATPase inhibition, and the observations appeared to exclude a direct, functionally antagonistic competition between corticosteroids and cardiotonic steroids for binding to a common site on that enzyme. The antagonistic action of corticosteroids and cardiotonic steroids found by Wilbrandt and Weiss[123] for intact cells appears to be based on the induction of biosynthetic increases of the number of Na^+/K^+-ATPase molecules[124] compensating for the portion of digitalis-inhibited enzyme molecules.

The inhibitory effect of digitalis compounds on Na^+/K^+-ATPase activity arises from their interaction with the recognition part and effect-triggering binding site on the enzyme protein which we have further characterized by the following findings. Large excesses of ATP over digitalis with respect to the concentration do not antagonize digitalis binding to the enzyme.[125] There is a competitive K^+ effect on digitalis binding under certain conditions, but, as shown by us,[125] its molecular basis is not competition for a common binding site on the enzyme, but competition for the ATP- or digitalis-binding enzyme conformation. Using definitions given by Monod et al.,[126] digitalis compounds are thus noncompetitive, heterotropically acting allosteric inhibitors which produce the transition from an active to an inactive conformational state of enzyme protein. More specifically, a common denominator of the inhibitory action of digitalis compounds has been shown by our group[127] to be a large gain in entropy in the enzyme protein associated with a loss of high ATP affinity to the catalytic center.

The search for the proper locality of the digitalis recognition and binding protein matrix has intensively been approached by several groups through elucidation of the connection between distinctions in digitalis affinity (ouabain taken as a prototype) and those in the primary structure of Na^+/K^+-ATPase (Fig. 5). However, with increasing knowledge all hitherto published proposals (see review in ref. [2]) have turned out to be untenable. As we shortly shall show elsewhere, the digitalis binding cleft is formed by two membrane-penetrating peptide sequences (H1 in Fig. 5) which through their association bring about the interplay between the two catalytic α subunits in the diprotomeric holoenzyme $(\alpha\beta)_2$ such that, by intercalation of a digitalis molecule, the catalytic cycle becomes interrupted.

2.4. The Comparison of Biological and Molecular Screening Test Systems

The most suitable method for the quantitative determination of the positive-inotropic (cardiotonic) effect of a cardioactive compound is the assessment of its influence on the isometric contraction curve measured in isolated cardiac muscle preparations from some animal species. However, to obtain reliable data for the comparison of the inotropic potency of the various cardioactive compounds, it is essential to perform the experiments under identical conditions.[131] Because of the variety of test conditions used, it is not easy or is even impossible to integrate in terms of structure–activity relationships the numerical values reported in the literature.[132, 133] A comprehensive survey of the structure–activity relationships found in guinea-pig cardiac preparations under identical conditions has recently been presented by R. Thomas et al.[24]

Important for the realization of the message of this review is the understanding that there are two basic possibilities for misinterpretation of observations with animal model systems. First, all inhibitors of the Na^+/K^+ transport system irrespective of their microscopic inhibitory mechanism (see below) produce positive inotropic effects if they do not additionally affect other biochemical systems which preclude the manifestation of the inotropic action.[110] Second, some inhibitors of Na^+/K^+ transport, even when effective through occupancy of the digitalis binding cleft, can fail to produce a positive inotropic action when they additionally affect biochemical systems which preclude the manifestation of their inotropic faculty. Prominent examples for both cases were diagnosed[2] by successive use of the "macroscopic" and "microscopic" test systems characterized below.

The macroscopic screening with Na^+/K^+-ATPase proved to be an only initially useful test. It restricts itself to the assessment

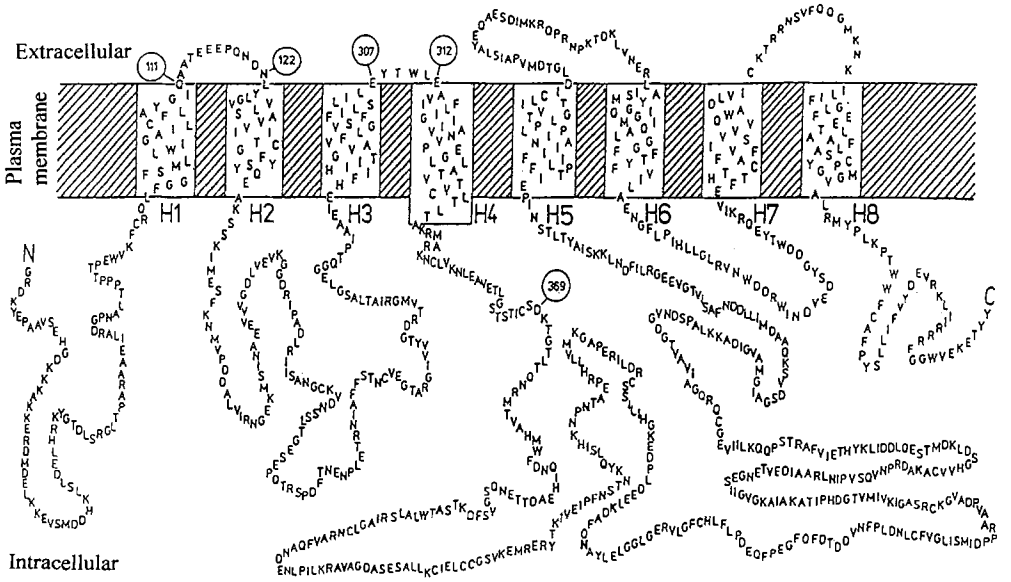

Fig. 5. Schematic representation of the primary structure and spatial organization of the catalytic subunit of Na^+/K^+-ATPase. The amino acid chain penetrates the membrane of the cell eight times. The membrane crossing sequences H1–H4 carry the extracellularly disposed H1–H2 junction (Q111–N122) and H3–H4 junction (E307–E312) which were supposed to interplay in building the digitalis recognition and binding matrix [2]. The H4 stretch directly mediates the communication of the matrix with the phosphorylatable aspartyl residue D369 in the catalytic center of the enzyme. The scheme shown here is a combination of the figures in refs. [128 129].

of the apparent Gibbs energy change ($\Delta G^{0\prime}$) in the formation of the equilibrium complex of an inhibitor with the enzyme under standardized conditions; the experimental details were published elsewhere by us.[92, 134, 135] The availability of the $\Delta G^{0\prime}$ values allowed us to apply the extrathermodynamic approach to the quantitative analysis of structure–activity relationships.[92, 134, 135] This procedure clearly requires that a uniform macroscopic and microscopic mechanism underlies the observed inhibitory effectiveness. However, fulfilment of this prerequisite cannot be derived from studies on the inhibition of Na^+/K^+-ATPase (or Na^+/K^+ transport): therefore the investigation is named a macroscopic screening test. Specifically, many inhibitory-active ligands of any structure (cf. ref. [136]) can interrupt the catalytic cycle of Na^+/K^+-ATPase by binding to quite different binding sites than those occupied by digitalis compounds (Fig. 6). Hence, agents which inhibit the enzyme system through a digitalis-unlike microscopic mechanism will necessarily lead to a null hypothesis concerning structure–activity relationships.

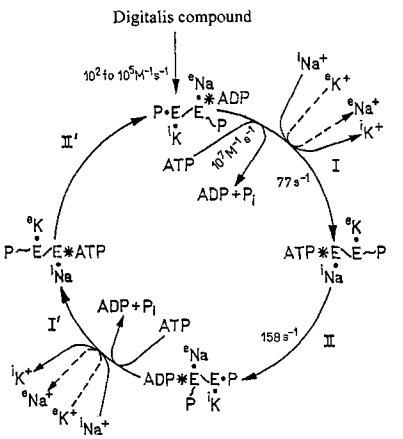

Fig. 6. Reaction and function scheme of Na^+/K^+-ATPase. Noteworthy are the large differences in the association rate constants for the formation of the inhibitory complex between various digitalis compounds and the phosphorylated enzyme intermediate on the one hand, and for the formation of the productive complex between ATP and the same intermediate on the other, during maximum activity of the enzyme. The letters E denote the two catalytic subunits, and the superscripts indicate the locations of the Na^+ or K^+ ions on the intracellular (i) or extracellular (e) side of the enzyme or the cell, respectively. Compared with the diffusional rate constant of slowly diffusing reactants (10^9 M^{-1}s^{-1}), the digitalis association rate constants were found to be 4 - 7 orders of magnitude smaller [127], but similar to the isomerization constant known to characterize the protein conformation change in enzyme–substrate interactions ranging from 10^2–10^4 s^{-1}. The duration of the half-cycle at 37 °C is 6–7 ms (from ref. [137]).

The microscopic screening is based on our experience[66, 130] that the competent occupancy of the digitalis binding cleft by an inhibitor of Na^+/K^+-ATPase, no matter of structure, and hence its quality as a mechanistically digitalis-like compound is proved by its capacity to promote the synthesis of the energy-rich carboxyphosphate–phosphoenzyme from orthophosphate in presence of Mg^{2+} ions. Microscopic screening has therefore been proven as a final test for selecting or rejecting compounds for uncovering the pharmacophoric lead structure in bimolecular recognition studies.[66, 130]

As well-known, man is in many respects a unique species. Therefore it is not really surprising that for the receptor–effector parameters, there are considerable distinctions between the isoforms of Na^+/K^+-ATPase from man and other species.[104, 127, 134, 138] Fortunately, the Na^+/K^+-ATPase preparations from human tissues, suitable for the use in the above molecular test systems, can easily be made.[92, 134] The times are over, in which a surviving heart cut out of a decapitated man had to be used to study the action of digitoxin on human cardiac muscle.[139]

2.5. The Chemical Hunt for the Discovery of Lead Structures and the Functional Classification of the Other Structural Components in Digitalis-Like Acting Inhibitors

The lead structure in complex biologically active compounds is defined as that structural component which shows the minimal, specific recognition requirements and is still able to evoke the biological effect of interest although its potency may be weak.[140, 141] The discovery of the lead structure has been regarded as an essential step in reducing the gamble in drug design.[142] In fact, the development of a novel drug can demand the synthesis of 10000–20000 new compounds and cost more than 200 million German Marks.[143] Also in case of cardiac glycosides such as digitoxin (**1**) or digoxin (**2**) (Fig. 1) the detection of their lead structure proved to be difficult. Digitalis compounds are noncompetitive, heterotropically acting allosteric inhibitors of Na^+/K^+-ATPase as deduced in Section 2.3. This means that they bear no resemblance to the substrate ATP and thus do not provide a sensible starting point in the search for the lead structure. This appears to explain why it took until 1985 before our group detected the proper lead component in cardiac glycosides.[91, 92] Our systematic screening of about seven hundred essentially congeneric digitalis derivatives has been made possible through the donation of numerous rare compounds by many eminent chemists such as K. Meyer, G. R. Pettit, T. Reichstein, D. Satoh, F. Sondheimer, C. Tamm, R. Tschesche, K. Wiesner, and W. W. Zorbach to name but a few. The given rich fund has been supplemented in our laboratory by targeted partial synthesis of steroid derivatives not available from herbal sources.[35–68] The structure of the compounds and the pertinent test data have fully been presented in references [1, 2].

Thus, we have travelled a long distance down the road that has led us to the functional apportionment of the three structural components of ordinary digitalis compounds. As concisely substantiated in Figure 7, the steroid skeleton, 5β,14β-androstane-3β,14-diol (**16**), is the inherently active lead structure in the natural cardiac glycosides. The removal of the hydroxyl group at C3β only lessens the potency slightly and the replacement of C14β-OH by C14β-NH_2 can even considerably increase the inhibitory effect.[2] Hence, the basic lead structure is 5β,14β-androstane (cf. Figs. 7 and 10). The C3β-O and C17β side chains, when separated from the steroid skeleton, are without intrinsic inhibitory action of their own; however, when linked with the steroid lead, the C3β-O and C17β side chains contribute moderately or powerfully, respectively, to the integral interaction energy. This is summarized below.

The tridigitoxoside chain of digitoxin (**1**) and digoxin (**2**) can more than isoenergetically be replaced by several monosides as exemplified in Figure 8. The butenolide substituent of **1** and **2**

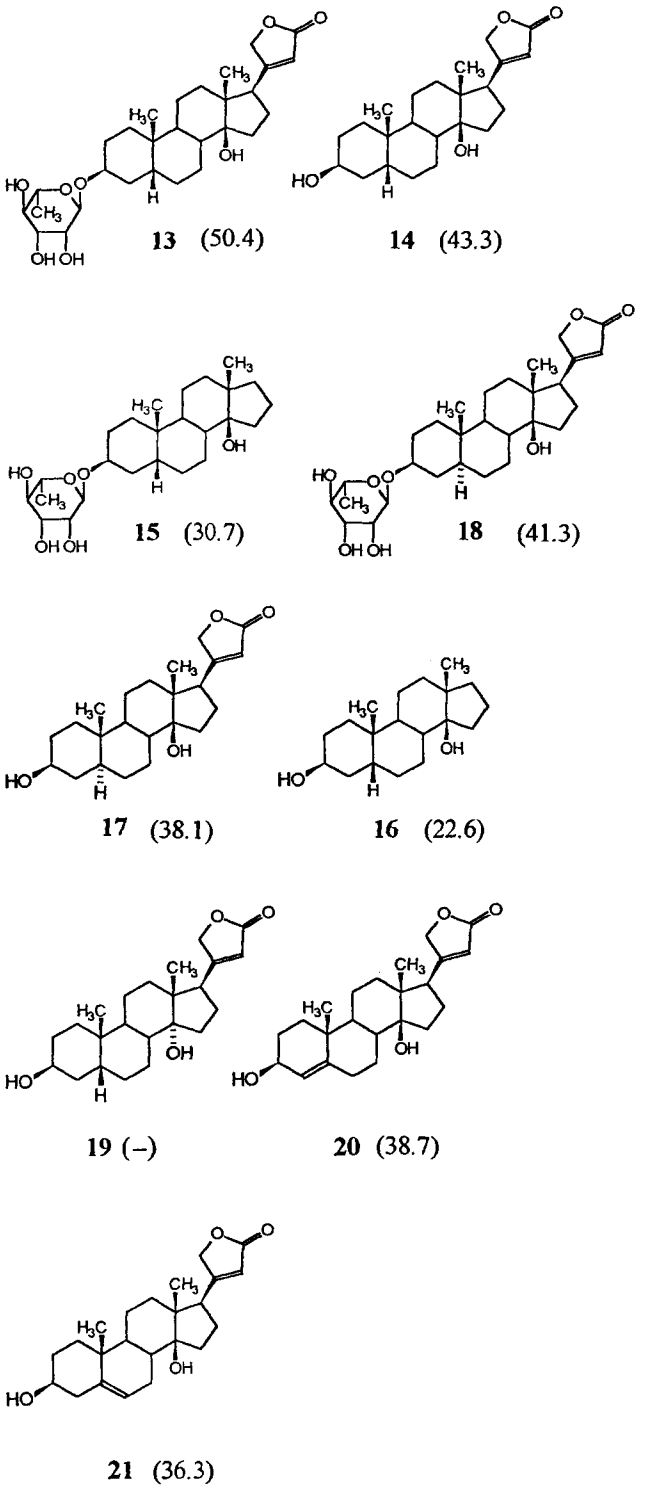

Fig. 7. The impact of stripping the side chains of 3β-*O*-(α-L-rhamnosyl)-digitoxigenin (**13**) (**13** → **14**, **13** → **15**, **13** → **16**) reveals their distinct contributions to the integral Gibbs energy of interaction with Na^+/K^+-ATPase from human cardiac muscle [91, 92]. While the sugar and lactone residues are devoid of inhibitory effect on their own, the steroid skeleton **16** exhibits an intrinsic potency not different from unity [130] and acts thus as the lead structure in the digitalis glycosides [91, 92, 130]. Conversion of the A/B-*cis*- into the A/B-*trans*-ring junction (**14** → **17**) reduces the potency of the aglycon and also diminishes the strengthening of the inhibitory efficacy by glycosidation (cf. **14** → **13** with **17** → **18**). However, conversion of the C/D-*cis*- into the C/D-*trans*-ring junction (**14** → **19**) annuls the potency of the precursor compound. A comparison of the Gibbs interaction energies of the aglycons **14**, **17**, **20**, and **21** shows that **14** with a strongly bent, essentially inflexible steroid skeleton fits best into the digitalis binding cleft. The numbers in parentheses indicate the $\Delta G^{0\prime}$ values in $-kJ\,mol^{-1}$; **19** is inactive.

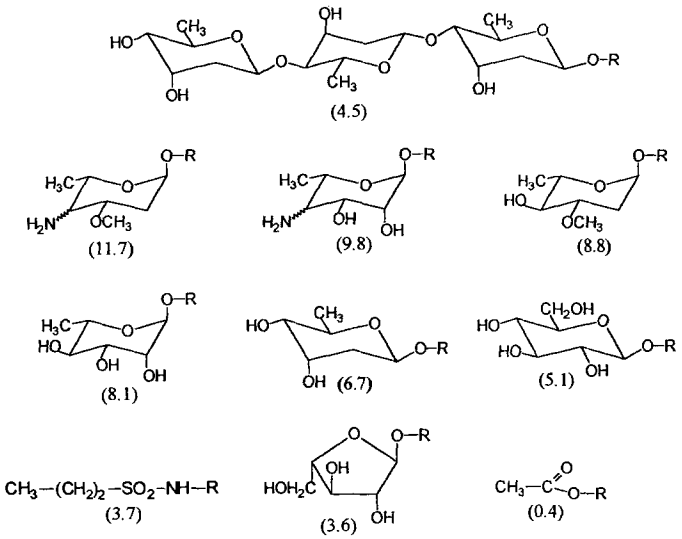

Fig. 8. Differences in the increments of Gibbs energy of the interaction between Na^+/K^+-ATPase from human cardiac muscle and digitoxigenin (**14**) produced by introduction of various substituents at C3β-OH [2]. The conformational flexibility of the sugar residues, arising from the two degrees of rotational freedom about the glycoside bonds, can help to account for the finding that both β-D- and α-L-sugars with C1 or 1C conformation, respectively, increase the interaction energy. In addition, the amino acid sequences involved in forming the sugar binding subsite may have some conformational adaptability. The numbers in parentheses indicate the $\delta\Delta G^{0\prime}$ values in $-kJ\,mol^{-1}$.

also can isoenergetically or even more than isoenergetically be replaced by several heterocycles shown in Figure 9. Attempts have been made to utilize our complete data for the derivation of the chemotopography of the digitalis recognition matrix and binding cleft in the Na^+/K^+-ATPase protein as a step in the rational design of new inotropic steroids.[2]

As shown in Figure 7, the powerful inhibitor digitoxigenin **14** loses its potency already by conversion of the C/D-*cis* ring junction into the C/D-*trans* junction (**14** → **19**). The latter geometry is common in the endogenous hormonal steroids. Due to this early experience, C/D-*trans* steroids were regarded by us as irrelevant in considerations of the relationship between structure and inhibitory potency, although we had found some compounds without lactone substituent at C17β as active or even more active than their C/D-*cis* relatives[92] (cf. the $\Delta G^{0\prime}$ values for **16** and **23** in Figures 7 and 10).

As pointed out by Marshall and Cramer recently,[144] attempts to correlate biological activity with the structure of a compound often have had limited success unless the study has confined itself to congeneric series. However, the inclusion of structurally diverse molecules, interacting at the same receptor site, promises more basic solutions to the problem of structure–activity relationships, which may lead to the development of novel therapeutic agents.[144] Hence, we resumed and systematically extended our studies with C/D-*trans* steroids of hormonal type.

Fundamental for this endeavor was our detection that in the macroscopic and microscopic screening tests (cf. Section 2.4) some progestins such as megestrol acetate (**25**) and chlormadinol acetate (**26**) proved to be effective inhibitors of Na^+/K^+-ATPase (Fig. 10) operating through a digitalis-like microscopic mechanism, that is, competent occupancy of the digitalis binding cleft.[66] Linkage of C3β-OH with a monosaccharide either

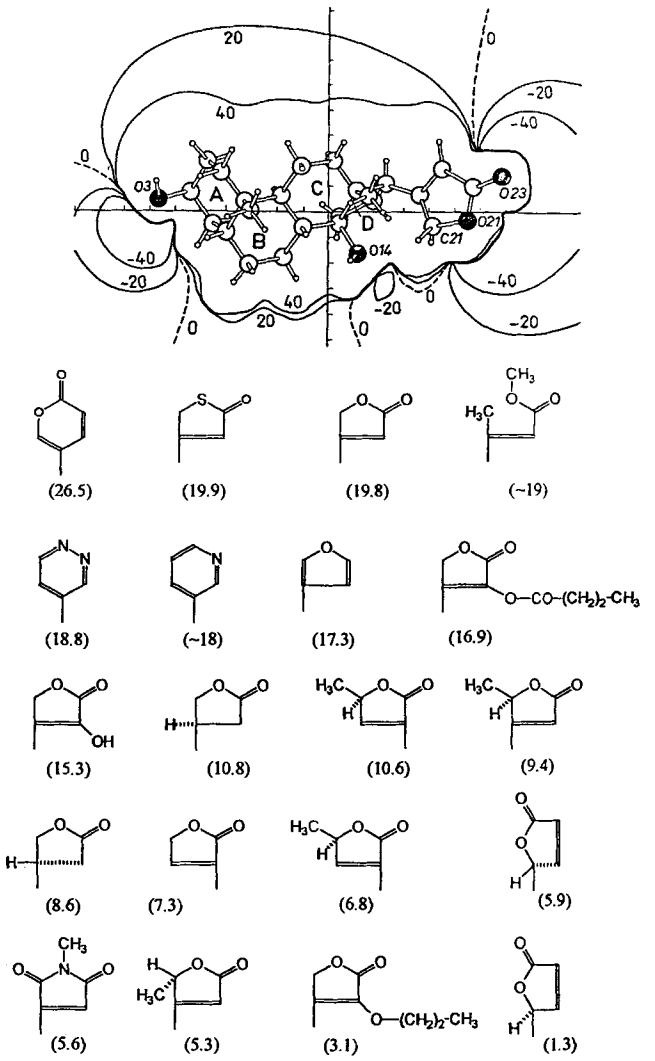

Fig. 9. The kinetic role and energetic contribution of substituents at C17β of 5β,14β-androstane-3β,14-diol in the interaction of the inhibitors with Na^+/K^+-ATPase from human cardiac muscle. The grossly dipolar distribution of the molecular electrostatic potential field in the outer space of digitoxigenin (**14**) shown in the upper part of the figure (from ref. [91]), appears to control the long- and medium-range attraction of the molecule in forming the diffusion complex and to promote the pull of the aglycon, with the lactone ring ahead, into the receptor binding cleft [91, 92]. The formation of the inhibitory complex appears to involve hydrogen bonds between the electron-rich oxygen, sulfur, or nitrogen atoms in the different side chains on the one hand and H-donating amino acid side chains in the pertinent receptor binding subsite on the other. A perusal of the very different contributions of the C17β-substituents to the interaction energy reveals that the sizes of the measured integrals result from an intricate superposition of both attractive and repelling electronic and steric components of their partial structures [1, 2]. The numbers in parentheses indicate the $\delta\Delta G^{0\prime}$ values in $-kJ\,mol^{-1}$.

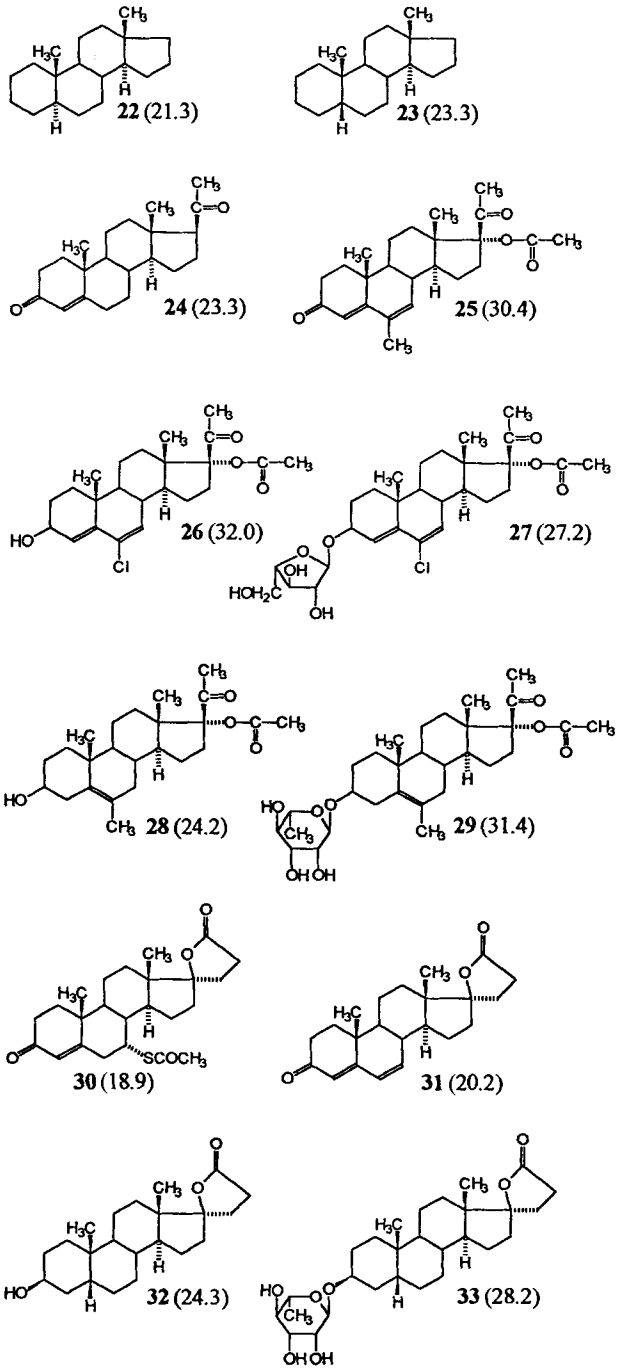

Fig. 10. The Gibbs energy of interaction between Na^+/K^+-ATPase from human cardiac muscle and digitalis-like acting C/D-*trans* steroids of hormonal type: impact of changes in configuration and substitution [2, 64–66, 145]. Applying the definition cited in Section 2.5 [141, 142], the lead structure in these steroids is 5β-androstane when occupying the digitalis binding cleft. The numbers in parentheses give the $\Delta G^{0\prime}$ values in $-kJ\,mol^{-1}$.

decreases (**26** → **27**) or increases (**28** → **29**) the inhibitory potency. This roughly parallels the response of some C/D-*cis* steroids (cf. **17** → **18** with **14** → **13** in Fig. 7). The mentioned differential impact of glycosidation reflects the unwieldy or fitting spatial disposition of the sugar side chain in the sugar subsite of the digitalis binding cleft that is guided by the geometry of the A/B ring junction.[65]

Most remarkably, glycosidation of chlormadinol acetate **26** → **27** transformed its negative-inotropic action[146] into a surprisingly continual, positive-inotropic action.[64] The effects of **27** on cardiac contractility and other circulatory parameters in cats are more favorable than those of digitoxin (**1**). The possibility that this functional distinction is related to the C/D-*trans* or C/D-*cis* ring junction in the two inotropic agents still needs to be verified. The way to the answer of this question will be addressed in Section 3. Here, the primary, most important conclusion from our studies with **27** is that the C/D-*cis* ring junction, known to occur in steroids of some plants and toads only, is—contrary to the present dogma—not an indispensable requirement for cardiotonic action; likewise animal hormone steroids with a C/D-*trans* ring junction can have the capability

of eliciting digitalis-like, positive inotropic actions.[64] The prerequisite for the realization of this potential has been recognized to be the elimination of the hormonal potency by steroid glycosidation which prevents interaction with the intracellularly located hormone receptors.[64] A further potential case for such connection will be considered in Section 3.

2.6. The Mystery of Endogenous Digitalis

Our interest in the exploration of C/D-*trans* steroids of hormone type with regard to possible digitalis-like actions has also been stimulated by their potential relation to endogenous digitalis. The methodical search for its nature was pioneered by Szent-Györgyi[147] who reported in 1953 that normal blood serum contains substances which exert a digitalis-like action. Among 22 steroids probed, deoxycorticosterone and progesterone were found to share with serum and cardiac glycosides the action on the contractility of the heart. Their potency, however, was too low to account for the serum activity. In the above context, Szent-Györgyi reasoned that "the digitalis glycosides are no drugs at all: they are substitutes for a missing screw in our machinery, which had a cardinal role in one of the most basic physiological regulations".

More recently, the search for endogenous digitalis was fuelled by the discovery of endorphins, the endogenous ligands of the opiate receptor. Thus, it became tempting to conclude that a parallel situation might apply to an endogenous analogue of digitalis. This conception appears to be supported by the fact that a specific digitalis-binding site exists on the Na^+/K^+-ATPase of all animal species.

For theoretical and practical reasons, the search for endogenous digitalis has become a challenge to many people in medical and basic research as well as in the pharmaceutical industry. As reviewed by Goto et al.[148] and Hamlyn and Manunta,[149] numerous affirmative reports have provided circumstantial and substantial evidence for the occurrence of endogenous inhibitors of Na^+/K^+-ATPase, but the clarification of their chemical identity has remained elusive. Many candidates for an endogenous digitalis-like factor have been proposed on the basis of the application of nine criteria.[148] However, all underlying assays say little or nothing about the precise binding site of the candidates and the microscopic mechanism of observed effects. The most suitable criterion for classifying a substance or an isolate as digitalis-like acting is by proving its occupancy of the digitalis binding matrix[66, 130] as evidenced by the microscopic test technique (cf. Section 2.4). However, it has hitherto been utilized in one study only.[150] Therein, the well-characterized hypothalamic inhibitor of Na^+/K^+-ATPase has shown, unlike digitalis, a negative response in the microscopic assay. Apparently, some physiological inhibitors of Na^+/K^+-ATPase exist in the animal body which have not necessarily a structural relationship to digitalis compounds.[151]

The reports by Hamlyn et al.[152] and Goto et al.[153] that some Na^+/K^+-ATPase inhibitors isolated from various sources appeared to be identical with ouabain or digoxin were, in fact, most compelling. The serious problem with the acceptance of their identity is that a biosynthetic pathway for such C/D-*cis* steroids, as exists in some rare plants and toads, is unknown in mammals. Our doubt about the identity of the endogenous inhibitor of the Na^+/K^+-ATPase with ouabain has most recently been reinforced.[154] In this context, we are tempted to speculate that some C/D-*trans* hormone steroids, such as the progestins listed in Section 2.5, could serve as models for the chemical nature of endogenous digitalis.[66]

3. The Most Recent Development Stage: Data-Directed Optimization of the Lead Steroid

The major limiting factor of the maximum digitalis dose which can be administered in the treatment of cardiac failure, is the development of ventricular arrhythmias. An essential element contributing to the origin of arrhythmogenic action of cardiac glycosides is cerebral neuroexcitation.[155] The importance of neural digitalis actions follows from the various functions of Na^+/K^+-ATPase in neural tissues.[156] Thus, inhibition of neural Na^+/K^+-ATPase by digitalis compounds plays the causal role in triggering both the therapeutically useful and detrimental, initially neural actions of digitalis.[157] Hence, a promising way to increase the ratio of doses for the therapeutic and toxic digitalis effects appears to be the design of digitalis derivatives with exceptionally different affinities for the isoforms of Na^+/K^+-ATPase in cardiac muscle and brain cells.[1, 2]

An initiating comparison of Na^+/K^+-ATPase preparations from human cardiac muscle and brain cortex with regard to their affinity to 76 C/D-*cis* steroids revealed on average a 1.5-fold lower affinity to the cerebral enzyme preparation.[134] The C/D-*trans* compound **27** showed a 3.2-fold lower affinity to the same enzyme preparation.[64] This possibly explains why **27** did not evoke arrhythmias in cats as observed with **2**.[64] However, both enzyme preparations apparently consisted of a mixture of three Na^+/K^+-ATPase isoforms[158] of unknown individual affinities. The clearcut decision about the relative affinities of C/D-*cis* and C/D-*trans* steroids to particular isoenzymes from cardiac muscle and neural cells requires studies with the isolated isoforms not available as yet. In the light of the knowledge that the steroid skeleton serves as the pharmacophoric lead structure not only for Na^+/K^+-ATPases from human tissues but also from animal tissues of widely differing digitalis affinity,[2, 104, 134] it appears almost certain to suppose that a proportion of Na^+/K^+-ATPase isoforms in human contractile and neural cells differs in the chemotopography of the steroid binding subsite in the digitalis binding cleft.

Our endeavor to clarify the possible suitability of C/D-*trans* hormone steroids as parent structures for the design of novel cardiac drugs has most recently centred on the aldosterone antagonists spironolactone (**30**) and canrenone (**31**) (see Fig. 10). Our interest in these spirosteroids was raised by reports from clinicians and general practitioners that these C/D-*trans* steroids exert a direct positive-inotropic action in the treatment of patients with severe congestive heart failure.[159–164] However, the spirosteroids have been fully effective only in combination therapy with a diuretic, an inhibitor of the angiotensin-activating enzyme or/and digoxin. Hence, the mechanism of the remarkably beneficial cardiac action of the aldosterone antagonists has remained not well understood.[163, 164] For that reason, the unexpected cardiotonic aspects of their action has

been analyzed by us; it turned out to be one of the rare cases of "clinical feedback".

Our analysis of the interaction of **30** and **31** with human Na^+/K^+-ATPase preparations in the macroscopic and microscopic test system (cf. Section 2.4) uncovered that both spirosteroids are digitalis-like acting inhibitors of the receptor enzyme. Their low inhibitory potency (cf. their $\Delta G^{0\prime}$ values shown in Fig. 10 with those of digitoxin (**1**) or digoxin (**2**) given in Fig. 3) accounts for the need of the mentioned combination therapy. Derived from our experience on the impact of glycosidation on the potency of various progesterone derivatives[64, 65] we succeeded in increasing the efficacy of **31** twenty-fold by glycosidation **31** → **33**.[145] The potency of **33** is even somewhat higher than that of **27** which we had shown to exert a favorable positive-inotropic action in cats.[64] Of course, additional studies with **33** and compounds of this type will have to be performed to establish their pharmacological profile and to select those derivatives not with top potency, but with the largest therapeutic dosage range. The experience with the pharmacological profile of **27**[64] gives reasons for the expectation that the adverse hormonal reactions of the aldosterone antagonists[165–167] are reduced or eliminated by their glycosidation, when their interaction with the hormone receptors can be prevented. The probe on the generality of the postulated interrelationships and the further structural and functional optimization of aldosterone antagonists may be studied by exploiting the innovative potential invested in the more comprehensive insight in those problems which is derivable from our studies with C/D-*cis* steroids[1, 2] (cf. Figs. 7–9).

4. Summary and Prospect

The article starts by outlining the reasons why cardiotonic steroids constitute a long-standing and still continuing research challenge, and by disclosing the motivation of the senior author to engage himself in this demanding field 30 years ago. This is followed by detailing the stages and levels of digitalis research in which the authors have extensively been involved, and by outlining the most recent developmental stage opened by their discoveries. The article reveals that even the elementary stages of drug research as treated here are a multifaceted and intricate domain which at last should include pharmacological and clinical feedback "loops" to test the limits of chemical and biochemical patterns of thought suggested by the initiating work of the authors. Any major development as envisaged here is necessarily a long haul and involves extensive investment of resources in the pursuit of the designated concept, the therapeutic merit of which can be judged only at the end of the road (cf. ref. [168]).

The most recent work has been supported by grants from the Deutsche Forschungsgemeinschaft (Re 878/1–4) and the Fonds der Chemischen Industrie.

Chemical Engineering Dynamics

Modelling with PC Simulation

1994. XX, 701 pages with 430 figures.
Hardcover. DM 276.-/
öS 2153.-/ sFr. 256.-.
ISBN 3-527-28577-6

In this book, the reader is guided through the complex study of dynamic chemical engineering systems by the unique combination of a simplified presentation of the fundamental theory (Part 1) and direct hands-on computer experimentation with the provision of 85 accompanying computer-based simulation examples (Part 2) supplied on diskette.

The ISIM digital simulation language is very simple to use and its powerful interactive nature enables the readers to create their own simulations, based on their own specific problems. This powerful dynamic ISIM software is ready to run on any DOS personal computer.

The treatment employed in this book is well tried and tested, based on over 20 years experience in teaching an international post-experience course. Whether for the teacher, the student, the chemist or engineer, this book serves as the key to a greater understanding of chemical engineering dynamics through the fun and enjoyment of active learning.

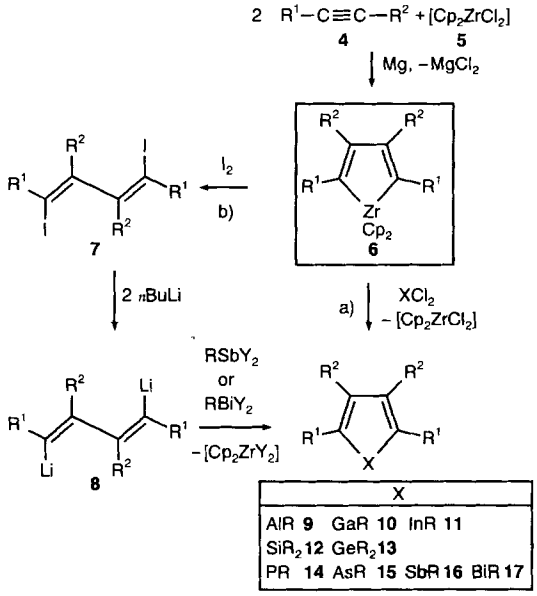
Five-Membered Aromatic and Antiaromatic Rings with Gallium, Germanium, and Bismuth Centers: A Short March through the Periodic Table

Hansjörg Grützmacher*

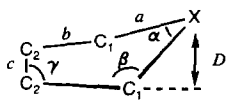
The concepts of aromaticity and anti-aromaticity are troublesome,[1] as can also be clearly seen from the examples described here of five-membered 4π and 6π heterocycles XC_4R_4 (4π: X = CR^+, BR, AlR, GaR, InR; 6π: CR^-, SiR^-, GeR^-, N^-, NR, P^-, PR, O, S, Se, etc.). These heterocycles therefore enjoy the attention of many research groups as objects for the study of bonding theory and because of their rich heterocyclic chemistry. At any rate the simple count of π electrons in a ring framework is no sufficient criterion for aromaticity or anti-aromaticity. A concept of Dauben, Jr., for establishing a criterion for aromaticity has now been taken up and extended by Kutzelnigg et al.[1a] and Schleyer et al.[2] An increased magnetic susceptibility Λ of a cyclic π-elcctron system is calculated as the difference ($\chi_M - \chi'_M$) between the susceptibility χ_M of the cycle with *delocalized* electrons and the susceptibility χ'_M with localized electrons. For an aromatic ring Λ is negative (diamagnetic), for an antiaromatic ring positive (paramagnetic).[1b] The susceptibility χ_M is, in principle, also experimentally determinable, while χ' is calculated from increments. The research group of Schleyer can show with a wide range of five-membered rings that the Dauben concept is compatible with aromatic stabilization energies and the geometries of the rings. A planar ring framework and bonds that are to a large extent equal in length indicate delocalization of the electrons, that is, the aromatic character. On the other hand a folded ring framework for 6π heterocycles and, in any case, alternating bond lengths point to localization of the electrons in antiaromatic compounds. The following series along which the aromaticity decreases and the anti-aromaticity increases can be set up: $C_5H_5^- > HNC_4H_4 > SC_4H_4 > OC_4H_4 > HSiC_4H_4^- > HPC_4H_4 > HAlC_4H_4 > HBC_4H_4 > HSiC_4H_4^+ > C_5H_5^+$. The calculations of the gas-phase structure of the silacyclopentadiene anion $HSiC_4H_4^-$ (**1a**) of the 6π aromatic rings will be highlighted here.

The calculation of the structure of this molecule, which had already been undertaken by Gordon et al.,[3] and Damewood, Jr., has now been repeated by Goldfuss and Schleyer with an extended basis set (RMP2(fc)/6-31 + G**).[5] According to these calculations, **1a** has a folded C_s-symmetrical structure [Σ°(Si) = 321.6°] with slightly different C–C lengths (b = 1.399, c = 1.433 Å) and Si–C lengths that are shortened relative to Si–C single bonds (a = 1.847 Å). Calculated to be only 3.8 kcal mol^{-1} more energetic, the planar structure **1b** with C_{2v} symmetry (which corresponds to the transition state for the inversion at the Si center) shows, in addition, a distinctly shortened Si–C bond (1.793 Å) and virtually equal C–C lengths (1.422, 1.414 Å). The new calculations also demonstrate that the stability of silacyclopentadiene anions **1** have previously been substantially underestimated (about 51% of the calculated aromatic stabilization energy of Cp^-). Interestingly, for the solvent-free ion pair silacyclopentadienyllithium (**2**) a structure has been determined



1a C_s **1b** C_{2v} **2**

that approximates even more closely the planar molecular geometry of **1b**.[5] An η^5-coordinated "inverse" lithium silanide with an only slightly pyramidalized silicon center [Σ° = 340.2°, a = 1.823, b = 1.420, c = 1.424 Å] as global minimum resulted from a RMP2/6-31G** calculation. Already 80% of the aromatic stabilization energy calculated for LiCp can be assigned to this molecule.



Of the antiaromatic rings, $C_5H_5^+$ (**3**) is particularly interesting as counterpart to $C_5H_5^-$. A laborious ab initio study of the Erlangen group[6] gives the remarkable result that this cation has a planar molecular structure (D_{5h}) with a triplet ground state, and not, as the anticipated according to the Jahn–Teller theorem for a cyclic anti-aromatic π electron system, a molecular structure distorted towards C_{2v} symmetry with a singlet ground state. As early as 1973, Saunders, Breslow et al. could generate the cation $C_5H_5^+$ (**3**) from C_5H_5Br and SbF_5 at low temperatures and prove its triplet state by ESR spectroscopy.[7]

Not only the theoreticians, but also experimentalists refined their methods. The preparation of heterocyclopentadiene was considerably facilitated in particular by a synthetic route developed by Fagan and Nugent,[8] in which two equivalents of an alkyne (**4**) was coupled with [Cp_2ZrCl_2] (**5**) in the presence of magnesium to form zirconacyclopentadienes **6**. Metallacycle **6**

reacts with halides according to route a) to form heterocyclopentadienes such as **9**–**15**. Ashe III et al. chose for the synthesis of stibole and bismole derivatives **16** and **17** (X = SbR, BiR; cf. Table 1), a roundabout route b) via a 1,4-diiodobutadiene (**7**) and a 1,4-dilitiobutadiene (**8**) prepared from it by halogen/metal exchange.[9] Cowley et al. also used the Fagan–Nugent synthesis for the preparation of a galla- and an indacyclopentadiene (**10** and **11**, respectively).[10] A single-crystal X-ray structure analysis was possible on **10**. Selected distances and angles (Scheme 1) are listed in Table 1 together with those of other 4π and 6π heterocycles. These compounds extend the neutral class

Scheme 1.

Table 1. Selected structural parameters (see Scheme 1) of some XC_4H_4 heterocycles [21]. The exact description of the substituents are to be found in the cited original references.

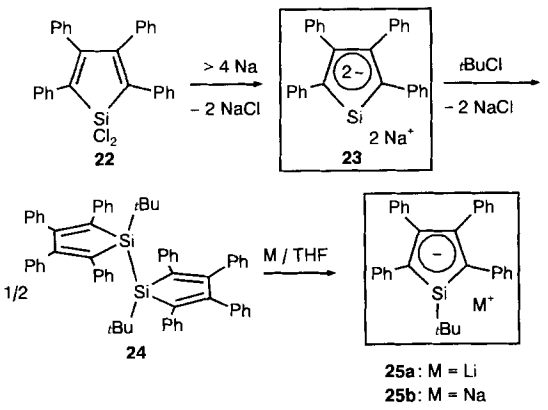
[a] Et_2O adduct; Al–O 1.91 Å.

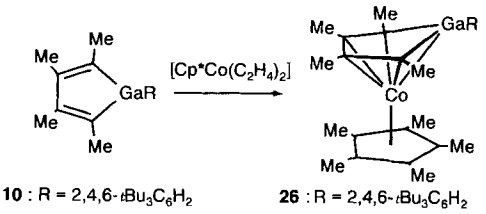
of five-membered 4π heterocycles obtained by the isovalent electronic replacement of CR^+ by BR, AlR, GaR, or InR. Of these, some deeply colored boroles, RBC_4R_4, have been known the longest, although no structure determination has yet been successful.[11] However, an aluminacyclopentadiene (**9**) could also be structurally characterized as diethyl ether adduct by Krüger, Sekutowski et al. in 1977.[12]

The heteroatom built into the ring frameworks of **9**–**11** forces the heterocycles into C_{2v} symmetry. The rings **9**–**11** are in the singlet state, and the delocalization of the electrons over the ring framework, which is anticipated for an anti-aromatic π system,[2] is lifted. In **9** and **10** the experimetally determined C–C distances *b* (1.31–1.36 Å) and *c* (1.52 Å) are therefore distinctly different. The planarity of the five-membered rings **9** and **10** is remarkable (deviation *D* of the aluminum center in **9** is only 0.04 Å).

The five-membered rings with 6π-electron systems are best exemplified by the cyclopentadienide ion $C_5H_5^-$ (Cp^-), whose planar molecular structure with D_{5h} symmetry has been experimentally determined in uncomplexed form, for instance in the compounds $[(Me_3P)_4(NO)MeRe]^+Cp^-$[13] or $[Cp_2Ta(\mu\text{-}CH_2)_2Pd(Me_2PCH_2CH_2PMe_2]^+Cp^-$.[13b] The length of the C–C bonds (*a*, *b*, and *c*) is about 1.40 Å.[13a] In contrast the C–C bonds *b* (1.32–1.34 Å) and *c* (1.42–1.56 Å) in the phospholes **14**, arsoles **15**, stiboles **16**, and bismoles **17** are very different in length and confirm the localization of the electrons (weak aromatic character).[14] In addition, the rings **14**–**17** containing an element of the third to sixth period are no longer planar (D = 0.21–0.08 Å). For steric reasons the deviation is most pronounced in the phospholes.



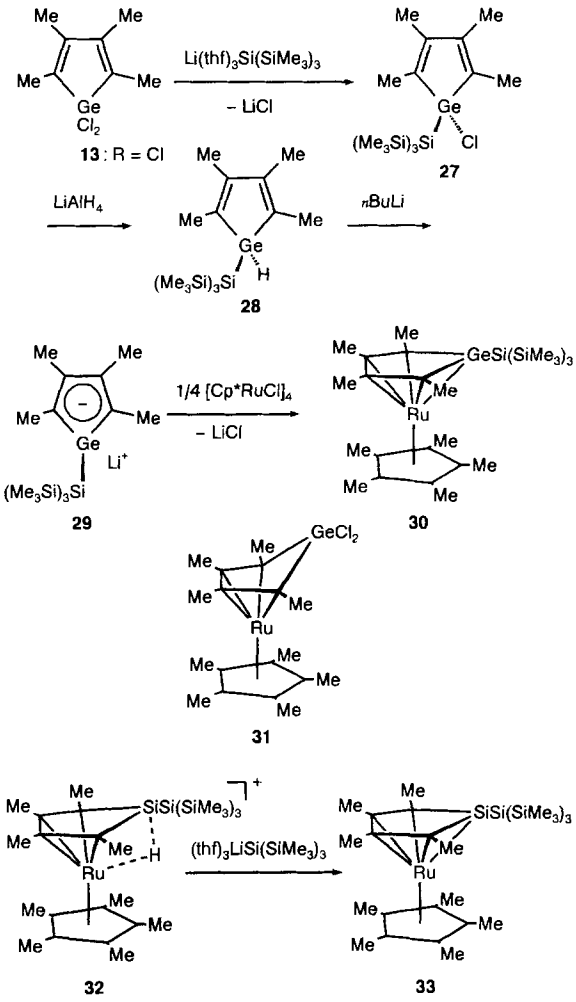
The anions $XC_4H_4^-$ **18**–**21** (X = P, As, Sb, Bi) with lithium ions as counterions can be prepared from suitable pnictogen



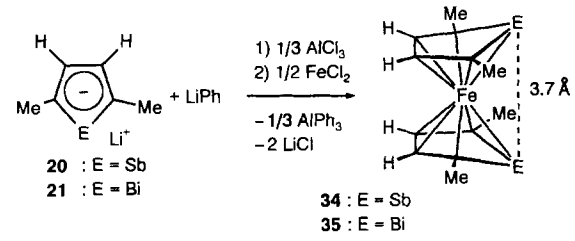
cyclopentadienes. To date only the structural analysis of lithium phospholide $Li(PC_4Me_4)$ (**18**) has been achieved.[15] In **18**, besides relatively long Li–C distances (2.40 Å), almost equal C–C distances *b* (1.40 Å) and *c* (1.42 Å) were found; thus **18** can be assigned an increased aromatic character relative to the neutral phosphole **14** [cf. $HSiC_4H_4^-$ (**1a**) and $LiHSiC_4H_4$ (**2**)].

Despite intensive experimentation[16] no sila-, germa-, stanna-, or plumbacyclopentadienide analogous to Cp^- has previously been able to be characterized. Boudjouk et al. recently presented an efficient synthesis of the sterically demanding substituted lithium and sodium silacyclopentadienide (**25a**, **b**).[17] The anion is prepared via the pyrophoric dianion **23** that W.-C. Joo et al. isolated as red-brown solid and characterized by ^1H and ^{13}C NMR spectroscopy.[18] Also **25a** and **b** could be characterized only by NMR spectra. The resonance signal of the ^{29}Si nucleus was detected at relatively low field [δ = 25.1 (Li counterion, THF); δ = 26.1 (Na counterion, THF)] The authors therefore anticipate a delocalization of the negative charge over the C_4Si ring and a planarization of the coordination geometry at the silicon atom, which was supported by IGLO calculations of the chemical shift of the ^{29}Si nucleus in **2**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0296 $ 10.00+.25/0



The heterocyclopentadienes and -dienides presented here are suitable as complex ligands. They bind in an η^5 fashion to metal complex fragments like the classical cyclopentadienyl ligand. For example, the complex **26** synthesized by Cowley et al. can



be readily constructed from the substitutionally labile complex $[Cp^*Co(C_2H_4)_2]$ ($Cp^* = C_5Me_5$) and the isolated 4π heterocycle **10** (R = 2,4,6-$tBu_3C_6H_2$).[10] Alternatively, a heterocyclopentadienide like the stibolide **20** or the bismolide **21** can be generated in solution and coupled with a metal halide. The syntheses of **30**[19] and **33**[20] performed by Tilley et al. deserve particular attention in the light of the vain attempts (until recently) to detect unambiguously an η^5-coordinated germa- or silacyclopentadienide in a complex. The synthesis of **30** is achieved by coupling the germacyclopentadienide **29**, prepared in solution, with $[(Cp^*RuCl)_4]$. In contrast, the analogous silacyclopentadienyl complex **33** is obtained by deprotonation of the complex cation **32** with a bent Ru-H-Si bond, because the synthesis of the silacyclopentadienide analogous to **29**, $C_4Me_4SiSi(SiMe_3)_3^-$ failed. The compounds **30** and **32** could be structurally characterized. A planar five-membered C_4Ge or C_4Si ring is observed, and the bulky $Si(SiMe_3)_3$ substituent is hardly twisted out of this plane [12.9° (**30**) and 19.0° (**32**)]. The different lengths of the C–C distances *b* (1.39 Å) and *c* (1.46 Å) in **32** clearly show that the extent of the delocalization of the electrons in **32** is less than that of **30** ($b = 1.40$, $c = 1.41$ Å). The preparation of a pure sample of **33** and its structural characterization has not yet been achieved. The spectroscopic data, in particular the downfield shift of the ^{29}Si NMR resonance signal on deprotonation of **32** ($\delta(^{29}Si) = -27.1$) to **33** ($\delta(^{29}Si) = -7.3$), leave no doubt about the existence of **33**.

Just as remarkable are the sandwich compounds **34** and **35** synthesized by Ashe III et al., in which an unusual ecliptical arrangement of the five-membered rings is observed.[9a, b] The

special arrangement invites speculation about a (binding?) interaction between the antimony and bismuth centers. In the complexes **26** and **30**–**35** in which the heteroatoms of the five-

membered rings are incorporated into the π bonding, a fundamental equalizing of the C–C bond lengths *b* and *c* accompanying a planarization of the ring framework is observed relative to the uncomplexed or η^4-bound heterocycles. Thus, the deviation *D* of the germanium center is 0.97 Å in **31**, but only 0.02 Å in **30**.[19]

In hardly any other branch of chemistry has such a systematic, experimental investigation of the changes in properties of one class of compounds been undertaken by deliberate substitution of a molecular unit by chemical elements from a wide range in the periodic table. By means of the heterocyclopentadienes and

-dienides presented here and their complex compounds, the remarkable validity of experimental concepts, but also of bonding principles can be convincingly tested. Perhaps still open questions, for instance into the interesting structures of silacyclopentadienyl salts like **2** and related compounds or into the dependence of their structures on the counterion, can also be answered by experiment in the near future.

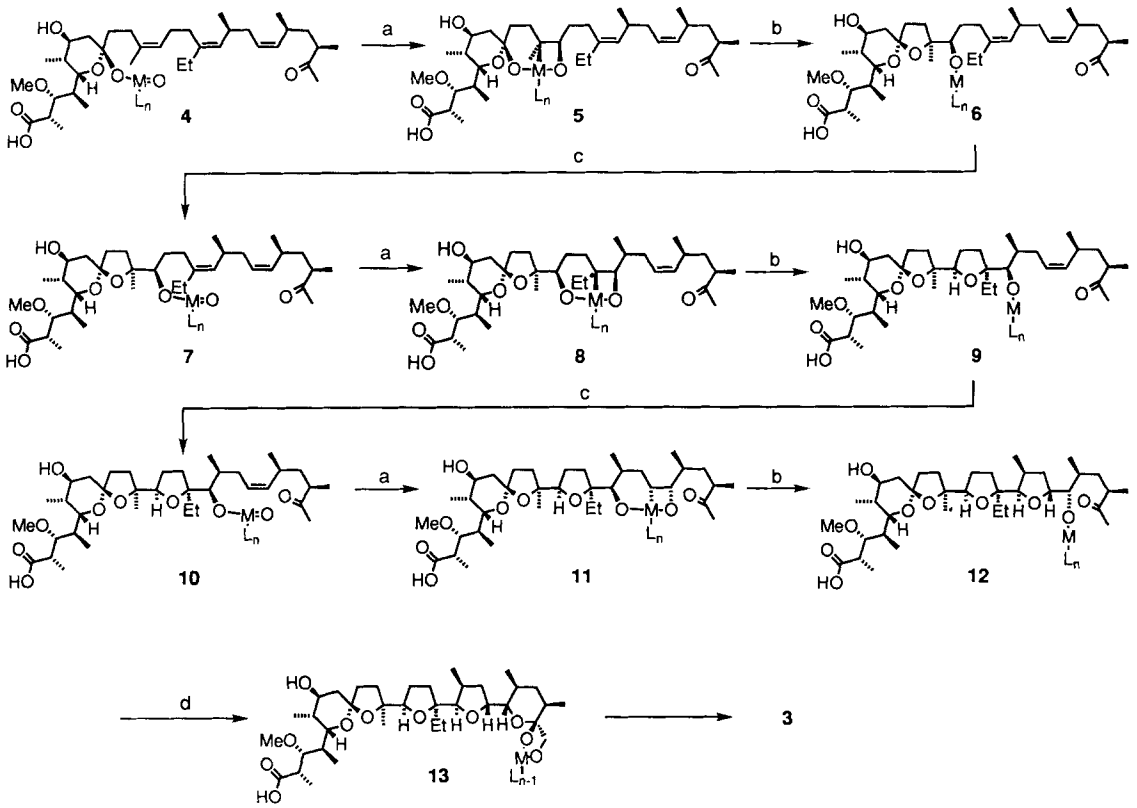
Oxidative Polycyclization versus the "Polyepoxide Cascade": New Pathways in Polyether (Bio)synthesis?

Ulrich Koert*



In 1983, Cane et al. postulated that polyether biosynthesis takes place as a two-step process. The first of these steps was proposed to be the enzymatic polyepoxidation of an acyclic hydroxypolyene precursor, and the second comprised a cascade of intramolecular epoxide ring openings with formation of the polyether framework.[1] For monensin A (**3**), for example, this is shown in the following scheme (Scheme 1): the (*E*,*E*,*E*)-triene **1** is transformed biosynthetically into the tris-epoxide **2**, which reacts further in a cascade of epoxide ring openings to yield the natural product **3**.[2]

This biosynthetic scheme gained rapid acceptance, above all because of the elegance of the second step, the "polyepoxide cascade". Polyepoxide cascades of the type **2** → **3** were reproduced in the laboratory[3] and used as key steps in the synthesis of polyethers.[4] The first step in the Cane–Celmer–Westley hypothesis, the stereoselective polyepoxidation, was subject to far less attention, even though it may be regarded as a weak point in the hypothesis. In feeding studies with *Streptomyces cinnamonensis*, no conversion of the (*E*,*E*,*E*)-triene **1** to monensin A (**3**) could be detected.[5] Earlier labeling studies had shown merely that the oxygen atoms in the two tetrahydrofuran rings

Scheme 1. The Cane–Celmer–Westley hypothesis for the biosynthesis of monensin A (**3**); a) stereoselective polyepoxidation; b) polyepoxide cascade; it is assumed that the OH group at C(26) is also introduced during the epoxidation step.

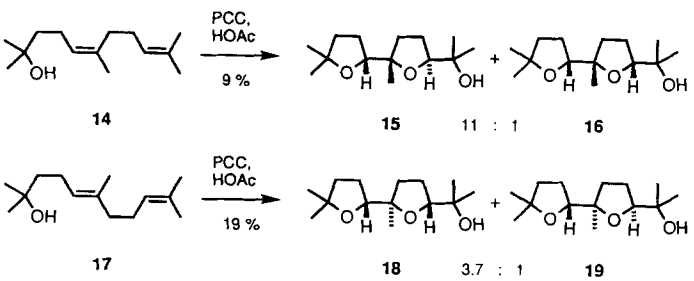
Telefax: Int. code + (6421)/288917



Scheme 2. Townsend–Basak–McDonald hypothesis for the biosynthesis of monensin A (**3**); a) [2 + 2] cycloaddition; b) reductive elimination of the metal with formation of the tetrahydrofuran ring; c) reoxidation of the metal; d) hemiacetal formation and oxidative introduction of the OH group at C(26).

(O-7,8) and in the tetrahydropyran hemiacetal (O-9) were derived from molecular oxygen, and it was unclear whether these were incorporated into the polyether framework by epoxidation or by another oxidation process.[2] Although the second step of the Cane–Celmer–Westley hypothesis, the polyepoxide cascade, is compelling, the initial, polyepoxidation step is still not sufficiently proven experimentally, and hence the entire hypothesis is uncertain.

In a recent publication, McDonald and Towne[6] extended studies of Townsend and Basak,[7] and presented an alternative model to the Cane–Celmer–Westley hypothesis: *syn*-oxidative polycyclization. The Townsend–Basak–McDonald hypothesis for the biosynthesis of monensin A (**3**) is depicted in Scheme 2.

The starting point is the alkoxy-bound oxo metal derivative of a (*Z*,*Z*,*Z*)-triene **4**. Intramolecular [2 + 2] cycloaddition affords a metallaoxetane **5**,[8] and the first tetrahydrofuran ring is then closed by reductive elimination of the metal to form compound **6**. An oxidation step from **6** to **7** activates the alkoxy-bound metal for the next [2 + 2] cycloaddition (**7** → **8**). Reductive elimination of the metal with closure of the second tetrahydrofuran ring leads to compound **9**. The third tetrahydrofuran ring of monensin A is closed in a further, analogous oxidative cyclization sequence (**9** → **10** → **11** → **12**). From compound **12** the natural product **3** can be obtained via the intermediate **13**. The stereochemical course of the oxidative cyclization should be emphasized: because a [2 + 2] cycloaddition is involved, the two oxygen atoms are added to the double bond in *syn* configuration. In order to construct the correct stereochemistry for the polyether framework of monensin A (**3**), the Townsend–Basak–McDonald hypothesis therefore postulates a (*Z*,*Z*,*Z*)-triene of type **4** as a biosynthetic precursor.

Using more simple systems, McDonald and Towne were able to demonstrate that pyridinium chlorochromate (PCC) is a suitable reagent for carrying out *syn*-oxidative polycyclization (Scheme 3).[6] Thus, transformation of the (*Z*)-hydroxydiene **14** yielded the bis-tetrahydrofurans **15** and **16**. Starting with the (*E*)-hydroxydiene **17**, the bis-tetrahydrofurans **18** and **19** were obtained.

Scheme 3. Model reactions of the Townsend–Basak–McDonald hypothesis.

The formation of **15** and **16** from the (*Z*)-diene and of **18** and **19** from the (*E*)-diene support the assumption of a *syn*-oxidative mechanism. The authors present conformational analysis arguments to explain the preferred formation of the *trans*-tetrahydrofurans **15** and **18**.[6]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0299 $ 10.00+.25/0

The low yields attained for the reactions shown in Scheme 3 call into doubt the usefulness of the *syn*-oxidative polycyclization under the published conditions for preparative purposes. However, the palette of possible oxidation reagents is by no means exhausted. Valuable ideas for a solution of the problem may come from the work of Kennedy et al. with Re_2O_7 as an oxidizing agent for oxidative olefin cyclizations.[9]

A fully satisfying answer to the question of the biosynthesis of polyether compounds such as monensin A (**3**) cannot be given form the results described here. However, it is clear that the new Townsend–Basak–McDonald hypothesis has gained ground on the older Cane–Celmer–Westley hypothesis. A key experiment to test the Townsend–Basak–McDonald hypothesis will be the use of labeled (*Z*,*Z*,*Z*)-trienes of type **4** in feeding experiments with *Streptomyces cinnamonensis*.

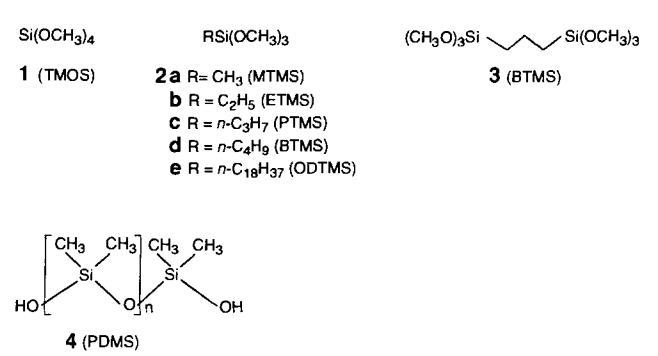
Efficient Heterogeneous Biocatalysts by Entrapment of Lipases in Hydrophobic Sol–Gel Materials



Manfred T. Reetz,* Albin Zonta, and Jörg Simpelkamp

Lipases are amongst the most widely used enzymes in organic chemistry.[1] In aqueous emulsions, they catalyze the chemo-, regio-, and stereospecific hydrolysis of esters, and when suspended in organic solvents[2] they catalyze the reverse reaction, effecting selective esterification.[1] In order to increase the activity and stability of lipases and at the same time to facilitate their recovery, many studies on the immobilization of lipases have been carried out.[3–5] We report here on the entrapment of lipases in hydrophobic sol–gel materials, which results in the formation of highly active, stable and reusable heterogenous biocatalysts.[6]

Following the procedures described earlier for the entrapment of biomolecules in silica gel (SiO_2) using the sol–gel process,[7, 8] tetramethoxysilane (TMOS) **1** was hydrolyzed in the presence of various lipases (e.g. from *Ps. cepacia*, Amano PS). Classical sol–gel processes of this type are acid or base catalyzed; hydrolysis and condensation of TMOS lead to nanometer-sized sol particles which then cross-link to form insoluble amorphous SiO_2 gels.[8] Unfortunately, the immobilized lipases that were produced by this method displayed extremely low activities. For example, relative activities of only 5% were obtained in the esterification of lauric acid (**A**) (0.05 M) with *n*-octanol (**B**) (0.1 M) in isooctane to give octyl laurate (**C**). In this test reaction that was used in all of the following studies, the relative activity x is defined as v(immobilized enzyme)/v(commercial enzyme), where v is the initial rate of the reaction (in μmol(h mg lipase)$^{-1}$).

Since lipases are interphase-active enzymes with hydrophobic domains, they can form ionic as well as hydrophobic interactions with other molecules.[9] For this reason, we speculated that alkyl-modified silica gels[10] with hydrophobic character, produced from silanes of the type $RSi(OCH_3)_3$, might be more suitable host matrices for lipases. In preliminary experiments, we therefore immobilized the lipase from *Ps. cepacia* (Amano PS) in a sol–gel process using $CH_3Si(OCH_3)_3$ (MTMS) (**2a**) or mixtures of TMOS (**1**) and MTMS (**2a**). NaF was used as the catalyst.[11] Figure 1 shows the dependence of the activity on the "methyl content" of the gel. In a mixed gel with 50% MTMS, the relative activity was still only 30%. Further increases in the MTMS content caused the relative activity to rise dramatically, reaching 1300% for a pure MTMS gel.

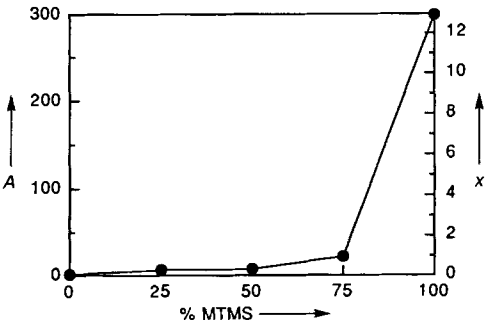


Fig. 1. Dependence of the activity A [μmol(h mg lipase)$^{-1}$] of immobilized *Ps. cepacia* lipase in TMOS/MTMS mixed gels on the gel composition. For the definition of the relative activity x see the text.

Taking a constant $TMOS/RSi(OCH_3)_3$ ratio of 1/1 and varying the R group of the silane, the relative activity sharply rises in the order $CH_3 < C_2H_5 < n\text{-}C_3H_7 < n\text{-}C_4H_9$. In contrast, a further increase in the size of the R group and the associated rise in the lipophilicity by use of *n*-octyl or *n*-octadecyl groups causes only a small additional increase in activity (Fig. 2).

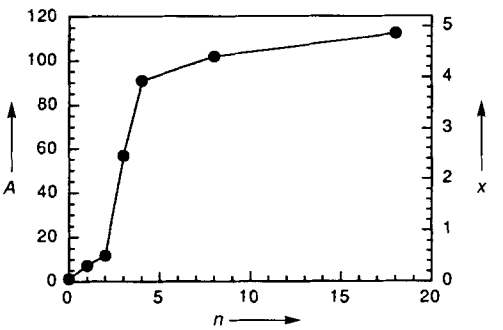

Fig. 2. Influence of the chain length of R on the activity of immobilized *Ps. cepacia* lipase in gels of the type $TMOS/RSi(OMe)_3$ (1/1). n = number of C atoms in R.

Kaiser-Wilhelm-Platz 1, D-45470 Mülheim an der Ruhr (Germany)
Telefax: Int. code + (208)306-2985

The results summarized in Figures 1 and 2 clearly show that the silane component is an important parameter for optimizing the enzymatic activity. We therefore investigated the commercially available silanes **3** and **4**, $n = 5-9$ as gel precursors in combination with TMOS and several lipases.[12] In all cases gel materials were obtained with excellent activities. Up to 93% of the protein was immobilized.

The representative results given in Figure 3 indicate that there is no general recipe for an optimal gel matrix, although in many cases TMOS/PTMS (1/5) gels turned out to be particularly well suited. An increase in activity by a factor of 5 and more (relative to the commercial powders) was achieved with many entrapped lipases. With the lipase SP 523 (Novo) the factor is even 88.

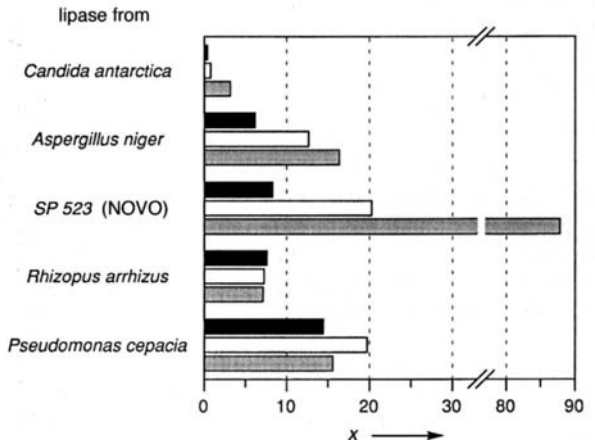

Fig. 3. Relative activity x of immobilized lipases in three different gel materials. Solid: MTMS; outlined: MTMS/PDMS (6/1); shaded: PTMS/TMOS (5/1).

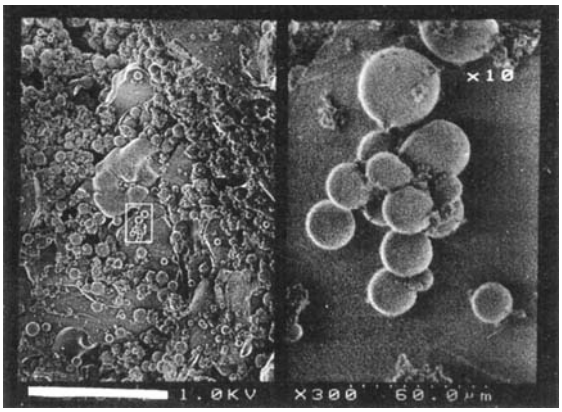
The long-term stability of the entrapped lipases is remarkably high. The test reaction was performed over 30 days in batch reactions, in which the solid catalyst was filtered off after 22 h, washed, and then reused.[13] The activity decreased typically by 15–20% after the first two to three cycles and then remained constant at 80–85% of the initial activity, for example, for Amano PS lipase in pure MTMS or MTMS/PDMS (6/1) gels. In contrast, the same lipase *adsorbed* on a pure MTMS gel lost more than 75% of its initial activity after only eight reaction cycles. Probably only a small fraction of the lipase (15–20%) is adsorbed or only weakly stabilized in the sol–gel process and is hence more easily deactivated or lost.

The morphology of the sol–gel immobilizates was examined by scanning electron microscopy (SEM).[14] Figure 4 shows a typical scanning electron micrograph of a lipase-containing MTMS gel containing amorphous regions as well as spherical particles.

What are the reasons for the increased relative enzyme activities? Since the comparisons are based on suspensions in organic solvents, the primary cause is probably the fine distribution and therefore increased accessibility of the enzyme. It can also be speculated that the hydrophobic groups R in the sol–gel matrix are involved in stabilizing and activating interactions with the hydrophobic domains of the lipases. The observed "alkyl effect" could also be intrinsic during the formation of the gel, possibly by a smaller damaging effect to the enzyme by the hydrophobic silane monomers. An increase in activity caused by a local rise in substrate concentration in the hydrophobic matrix is also conceivable.[5] A favorable influence of possible hydrophobic interactions in the immobilization of lipases on other supports, albeit with much smaller increases in activity, has been described previously.[4]



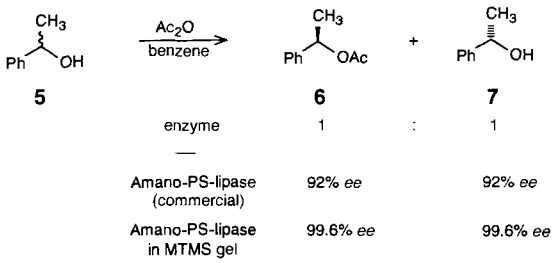


Fig. 4. Scanning electron micrograph of an immobilized lipase (*Ps. cepacia* lipase in MTMS gel). Right: 10x magnification of the area marked on the left. The length of the white bar corresponds to 60 µm.

The first attempts at application of the heterogeneous biocatalysts were carried out in the kinetic resolution of 1-phenylethanol (**5**)[15] using Amano PS lipase in a MTMS gel. The commercial enzyme preparation resulted in 92% *ee*,[16] whereas the same amount of entrapped lipase produced the enantiomerically pure products **6** and **7** (*ee* > 99%).

5		**6**		**7**
	enzyme	1	:	1
	—			
	Amano-PS-lipase (commercial)	92% *ee*		92% *ee*
	Amano-PS-lipase in MTMS gel	99.6% *ee*		99.6% *ee*

The method described herein leads to immobilized lipases with excellent activity and stability. The resulting biocatalysts are easy to reuse[13] and should also be suitable for application in continuous processes. A particular advantage is that by varying a range of parameters[17] it is possible to generate tailor-made gels for each lipase.[6]

[11] The lipase was dissolved in water or buffer, centrifuged to remove undissolved solids, and mixed with aqueous solutions of polyvinyl alcohol and sodium fluoride. The silanes were then added in the order of increasing reactivity. The reaction mixture was thoroughly mixed and shaken until gelation occurred (ca. 1 min). The gels thus obtained were allowed to stand in sealed vessels for 24 h, dried for 3 days at 37 °C, washed with water, acetone, and pentane, dried and ground into a powder.

[12] We thank Novo Nordisk A/S (Denmark) for a sample of SP 523 (NOVO) and Amano Enzyme Europe Ltd. (England) for PS lipase.

[13] Whereas the commercial enzyme powder combined with the water produced from the reaction and formed a viscous residue which was difficult to separate, the sol-gel immobilized lipase could be recycled without any difficulty.

[14] We thank Dr. B. Tesche (Fritz Haber Institut, Berlin) for the scanning electron micrographs.

[15] D. Bianchi, P. Cesti, E. Battistel, *J. Org. Chem.* **1988**, *53*, 5531.

[16] According to Cesti et.al. [15] the reaction resulted in 95% *ee*. However, it is known that the enantioselectivity of enzyme-catalyzed reactions can vary for different batchesm of enzyme.

[17] The influence of other parameters, for example the use of additives, the stoichiometry water/silane, the amount of catalyst, and the use of other silane monomers are presently under investigation in our group.

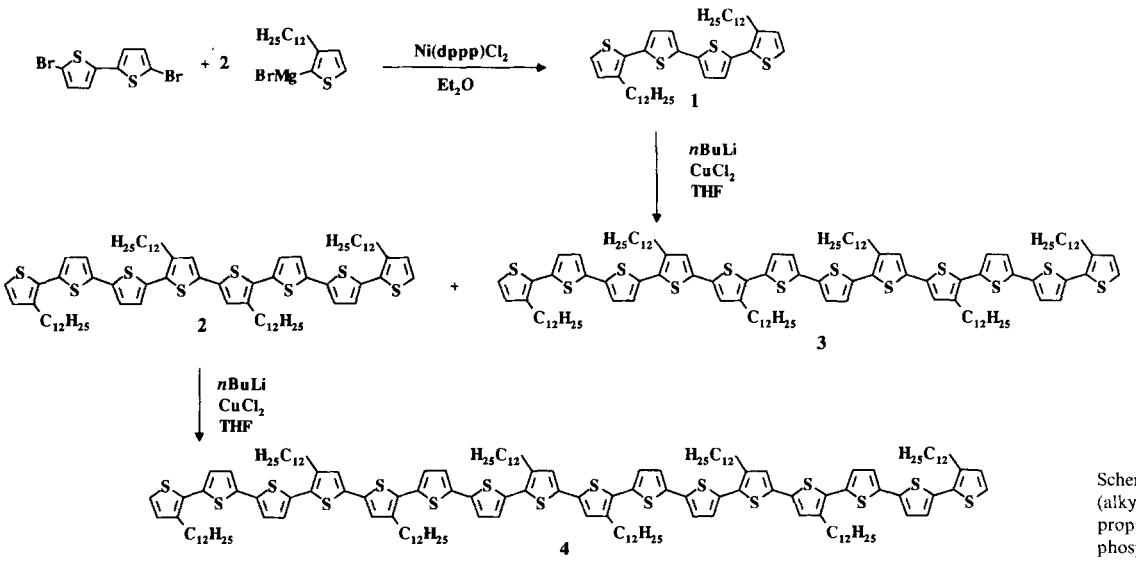
Oligothiophenes—Yet Longer? Synthesis, Characterization, and Scanning Tunneling Microscopy Images of Homologous, Isomerically Pure Oligo(alkylthiophene)s**

Peter Bäuerle,* Thomas Fischer, Bernd Bidlingmeier, Andreas Stabel, and Jürgen P. Rabe*

The synthesis of structurally defined conjugated oligomers with dimensions on the nanometer scale have recently awakened interest not only because of the possibility of investigating transport behavior along the "molecular wire". Interestingly, the lengths of the molecules achieved so far in the series of oligo(tetraethynylethene)s,[1] up to 50 Å, oligo(thienylenethynylene)s,[2] up to 100 Å, and oligo(phenylenethynylene)s,[3] up to 128 Å, have reached the size of the smallest achievable structural dimensions of lithographic nanostructures.[4] Although members of the first series can be charged, preferably by reduction, and are suitable as molecular conductors owing to delocalization, these properties have not yet been established for oligomers linked by alkyne units.

α-Conjugated oligothiophenes are defined model compounds for electrically conducting polythiophenes. Because of their easily oxidized π-electron systems, they exhibit conductivities of up to 20 $S cm^{-1}$, values comparable to those of the corresponding polymers.[5] The correlation between the chain length of oligothiophenes and their electronic properties have already been investigated.[6] The properties of an organic semiconductor are also influenced, however, by the spatial arrangement of the molecules in the solid material.[7] Garnier et al.[7, 8] and Ostoja et al.[9] demonstrated that by improving the molecular order in thin layers of sexithiophene derivatives on silicon, they were able to increase the conductivity and simultaneously improve the mobility of the charge carrier improved. For the transfer of charge from chain to chain (interchain hopping), not only the distance separating the conjugated π-electron systems of the molecules but also their spatial overlap appear to be decisive.[7] The images of poly(3-alkylthiophene)s obtained by high-resolution scanning tunneling microscopy (STM) and atomic force microscopy (AFM) have not been convincing up to now. As Chang and Bard have shown,[10] details in the images recorded by Lacaze et al.[11] of the polymers on graphite cannot readily be distinguished from defects in the graphite structure and assigned to clearly defined molecules. Kamrava et al.[12] used STM to record images of an electrochemically prepared polythiophene film, partially oxidized with $FeCl_4^-$; however, they obtained a resolution of only 5–10 nm. Similarly, AFM investigations did not yield images with molecular resolution.[13]

We report here on the synthesis of a homologous series of isomerically pure α-linked oligo(alkylthiophene)s **1**–**4**. According to calculations, sedecithiophene **4**, the longest known and clearly characterized oligothiophene, should be 64 Å long when extended. Previously, oligo(alkylthiophene)s up to a dodecamer were known,[14] and it is only recently that a pentadecamer has been described.[15] Because of their improved solubility in organic solvents, the new oligothiophenes **1**–**4** can be successfully purified and their physical properties, even those of the longer homologues, were determined in solution. In this way the structure–property relationships can be extended to chain lengths that were previously unobtainable. In addition it was possible to obtain the first STM images of physisorbed two-dimensional (2D) crystalline layers of homologues **1**–**4** with submolecular resolution.



The synthesis of the new oligo(alkylthiophene)s **1**–**4** is shown in Scheme 1. 3,3‴-Didodecylquaterthiophene **1** was obtained in 75% yield by the nickel-catalyzed coupling of two equivalents of the Grignard reagent prepared from 2-bromododecylthiophene[16] with 5,5′-dibromo-2,2′-bithiophene. After the analogous Grignard coupling of an appropriate monobrominated quaterthiophene failed, the conversion of **1** to higher homologues was carried out by oxidative dimerization of the lithiated compound with $CuCl_2$.[17] It had to be taken into account that because of exchange reactions the lithiation of oligothiophenes generally leads to a mixture of mono- and dilithiated products,[17b, 18] and that the yields drop rapidly as the size of the coupling components increases.[19] Thus, the reaction of **1** with equimolar amounts of *n*-butyllithium and $CuCl_2$ yielded as

Universität Stuttgart) for the temperature-dependent spectroelectrochemical measurements.

Scheme 1. Syntheses of oligo(alkylthiophene)s **1**–**4**; dppp = propane-1,2-diylbis(diphenylphosphane).

expected a mixture of starting material, tetradodecyloctithiophene **2**, hexadodecyldodecithiophene **3**, and other higher molecular weight products. Owing to their good solubility, **2** and **3** could be obtained in analytically pure form in yields of 30 and 8%, respectively, by repeated chromatography (purity according to HPLC >99%). Compound **2** was coupled with $BuLi/CuCl_2$ in an analogous manner to give the corresponding octadodecylsedecithiophene, which is the longest known oligothiophene to date (yield of pure material 19%; purity according to HPLC >99%).

The physical properties of the new oligo(alkylthiophene)s **1**–**4** are listed in Table 1. Compounds **1**–**4** are very stable materials; their melting points increase with increasing chain length

Table 1. Physical properties of the substituted oligothiophenes **1**–**4**.

[a] 10^{-5} M in CH_2Cl_2. [b] 10^{-4} M in dichloroethane, Pt disk electrode ($\varnothing$ = 1 mm), 200 mVs^{-1}, 0.1 M tetrabutylammonium hexafluorophosphate, 40 °C, oxidation potentials E_{pa} vs Fc/Fc^+.

but lie markedly below those of the unsubstituted oligothiophenes.[20] The alkyl side chains lead to increased steric interactions between the conjugated backbones and thus reduce π–π interactions between the molecules in the solid state. In addition the solubility in organic solvents is raised by the presence of the side chains, such that all the homologues are soluble in hexane, aromatic, and chlorinated hydrocarbons and could be fully characterized.

Absorption spectroscop of **1**–**4** showed that not only the energy of the longest wavelength π–π^* transition but also the transition probability increased with increasing chain length (Fig. 1). While a good correlation was found between the absorption energy and the reciprocal of the chain length for other oligothiophene series up to a chain length of eight,[6] the relationship in the series **1**–**4** is not linear (Fig. 2). As a result of the steric influence of the alkyl side chains, the alkyl-substituted thiophene rings in the longer homologues are twisted and the π-conjugated chain appears to deviate increasingly from linearity such that the absorption maxima of **3** and **4** are shifted to higher energies than expected.

Oligothiophenes are ideal model compounds for the charge carriers responsible for the transport of charge in polymers with

conjugated π-electron systems. The stable radical cations and dications as well the corresponding anionic species generated specifically from longer oligothiophenes can be regarded as models for polarons and bipolarons.[21] In this context a temperature-dependent reversible dimerization equilibrium of oligothiophene radical cations was studied in detail.[22] The diamagnetic dimeric cations exhibit properties that were previously ascribed to bipolarons, and can therefore be evoked in an alternative description of the mechanism of charge transport in electrically conductive polymers.

The redox properties of **1**–**4**, which were determined by cyclic voltammetry in several solvents, are therefore of special interest. As expected, the first oxidation potential E_{pa} is shifted cathodically with increasing chain length, which is equivalent to a better stabilization of the positive charge in the radical cation (Table 1). The oxidation potentials of **4** ($E_{pa} = 0.12$ V vs ferrocene(Fc)/Fc^+) and **3** ($E_{pa} = 0.19$ V vs Fc/Fc^+) are clearly more negative than those of polythiophene and poly(alkylthiophene)s ($E_{pa} = 0.3$–0.35 V vs Fc/Fc^+).[6b, 23] This indicates that the longer oligomers, in particular, clearly exceed the average chain length of the parent π-conjugated polythiophenes, which typically lie at 8–10 properly linked monomer units. Initial spectroelectrochemical investigations of the radical cations of the new oligomers indicate, in agreement with data from end-capped oligothiophenes,[22b] that the tendency to dimerize increases strongly with increasing chain length. Whereas the monomeric and the dimeric radical cations are in equilbrium at approximately −40 °C for tetramer **1**, equivalent portions of each species are formed at ≈30 °C for octamer **2**, at ≈65–70 °C for dodecamer **3**, and even at >80 °C for hexamer **4**.

In multisweep experiments thin films of controlled thickness of all the homologues could be deposited on the working electrode. The first oxidation potentials of these films with $E_{pa} = -0.11$ to -0.13 V vs Fc/Fc^+ are once again at considerably lower potentials than those of the oligothiophenes **1**–**4**, and indicate the presence of fairly well-defined higher oligomerization products whose characterization is still in progress.

The structures of the oligothiophene films were characterized by the investigation of physisorbed monomolecular layers of **1**–**4** on graphite by STM. Two-dimensional crystals of the two longest compounds, **3** and **4**, which were independent of the concentration of the solution, could be examined, though only during the first half hour after deposition. The mobility and instability of the domain boundaries were found to be very high. We deduce from this that in the case of the longest oligomer **4** in particular, thermodynamic equilibrium had not yet been achieved. 3D crystallization may possibly begin after a longer period, and a macroscopic film is formed on the surface, which inhibits STM imaging because of the low bulk conductivity of the undoped oligothiophene.

Figure 3 shows STM images of 2D crystals of the oligomers **1**–**4** on graphite and the corresponding molecular models. In analogy to earlier work on alkyl(oligothiophenes)[24, 25] we assign the bright areas to the aromatic thiophene skeletons and the darker regions in between to the alkyl chains. The 2D crystals of the four oligothiophenes are based on a common packing pattern in which the molecules are stacked along the length of a lamella. In all four cases the lamellae are separated by roughly 2.2 nm (measured perpendicular to the major axis of the molecule). The degree of overlap between two neighboring thiophene chains in a lamella decreases with increasing chain length. The interpretation of the STM results for **1**–**4** indicates a linearly extended π-electron system in which twisting of the thiophene rings relative to one another is possible. The models in Figure 3 should be understood as schematic representations of a system

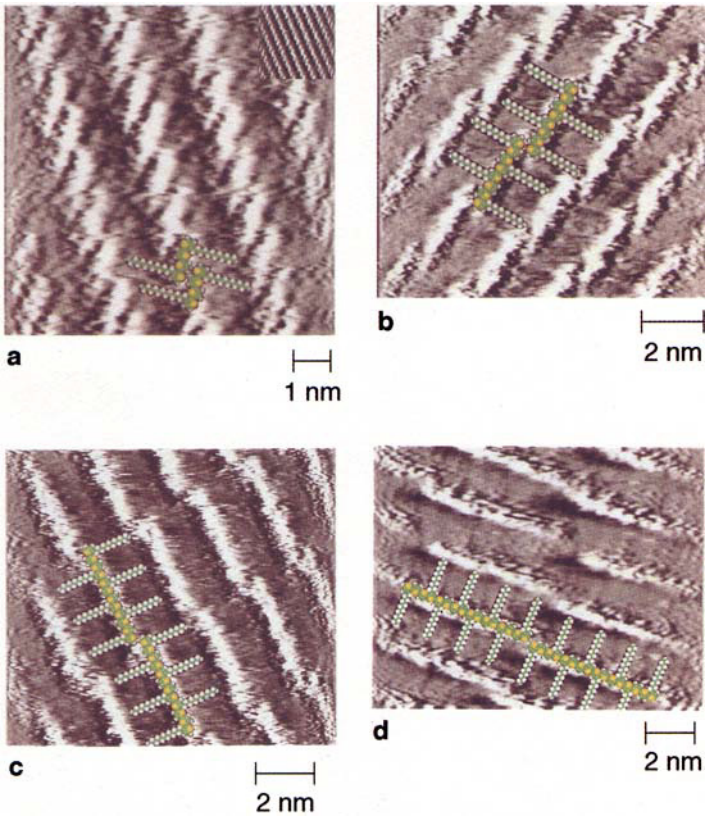

Fig 3. STM images of 2D crystals on HOPG. a) **1**, tunnel potential $U_T = 0.5$ V, tunnel current $I_T = 2.0$ nA; insert upper right: enlarged section; b) **2**, $U_T = 0.4$ V, $I_T = 1$ nA; c) **3**, $U_T = 0.4$ V, $I_T = 0.5$ nA; d) $U_T = 0.5$ V, $I_T = 3$ nA.

subject to rapid configurational molecular dynamics, which at present cannot be resolved on the timescale of STM experiments. For example, the alkyl chains are not found in the all-*trans* conformation shown in the simplified model, but dynamically occupy all of the surface available. By comparison with STM images recorded under conditions in which the graphite surface makes the dominant contribution to the tunnel current I_T and thus to the image,[25] it was established that the alkyl chains are oriented in equilibrium parallel to one of the crystal axes of the graphite. A lamella of adjacent rows of oligothiophenes is shown schematically in Figure 4a. The overlap length defined here Δ of the conjugated aromatic backbone of the thiophenes can be calculated by means of Equation (a), where l is the molecular length, r the distance between two molecules in the direction of the lamella, and ϕ the angle between the lamella direction and the major axis of the molecule.

$$\Delta = l - r \cdot \cos\phi \qquad \text{(a)}$$

The corresponding data for **1**–**4** are given in Table 2. The overlap length Δ and the number of thiophene units n have a linear relationship (Fig. 4b). As expected, Δ depends primarily on the substitution pattern of the oligothiophenes. Thus, for example, the Δ value for 4′,3′′′′-didodecylsexithiophene[25] cannot be predicted on the basis of the slope of the graph in Figure 4b. Comparison with nonregioselectively substituted analogues shows that the thiophene skeleton must be alkylated regioselectively for accurate determination of the overlap length, since the separation δr between the adjacent thiophene skeletons can otherwise vary by up to 30%.[25]

3	4.35±0.05	8±2	4.8±0.02	0.44±0.05
4	6.1±0.05	5±2	6.4±0.02	0.32±0.05

The synthesis of the soluble oligothiophenes **1**–**4**, which are stable at various oxidation levels, provides the first homologous series of conjugated, easily oxidized molecules with nanometric dimensions, whose conjugation length exceeds that of the previously known oligo- and polythiophenes. Because of the defined geometric and electronic structures and the satisfactory characterizability of oligothiophenes **1**–**4**, the structure–property relationships deduced clearly show longer oligothiophenes may deviate from the linear behavior determined for shorter chains, since the degree of conjugation approaches a limiting value with increasing chain length. The general tendency of the radical cations of the longer chain oligothiophenes to dimerize emphasizes the model character of these compounds with respect to charge carriers and transport phenomena in molecules with conjugated chains and is a further indication of such species in electrically conducting polymers.

In addition, the first STM images of a homologous series of oligomers were recorded. Based on the high-resolution images of isomerically pure oligothiophenes, the relationship between the overlap length of two adjacent thiophene skeletons and the length of the oligothiophene backbone could be determined. Above all, this unexpected supramolecular arrangement of the longer oligomers, in which the molecules are lined up almost ideally for coupling at the α positions, can explain the formation of extremely long molecular wires in electrochemically prepared thin films.

Experimental Procedure

To a solution of 0.35 mmol of the oligothiophene in 20 mL of absolute THF was added dropwise 0.22 mL of a 1.6 M solution of *n*-butyllithium in hexane. A suspension of 0.35 mmol of copper(II) chloride in 8 mL absolute THF was then added. After 4 h the reaction mixture was hydrolyzed with ice water, acidified, and extracted with dichloromethane. The organic phase was neutralized, washed with water, and dried over $MgSO_4$. Oligothiophene **2** was purified several times by chromatography on silica gel eluting with hexane/dichloromethane; **3** and **4** were purified by chromatography on nitrophenol-modified silica gel eluting with hexane/toluene.

1: orange-yellow crystals, m.p. 59–60 °C; ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.15 (d, 2H; H^1-5, H^4-5), 7.10 (d, 2H; H^2-4, H^3-3), 7.00 (d, 2H; H^2-3, H^3-4), 6.92 (d, 2H; H^1-4, H^4-4), 2.77 (t, 4H; α-CH_2), 1.64 (m, 4H; β-CH_2), 1.24 (m, 36H; CH_2), 0.87 (t, 6H; CH_3); UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [L mol^{-1} cm^{-1}]) = 251 [12100], 379 [26600]. Elemental analysis: calcd C 72.01, H 8.76, S 19.22; found C 72.12, H 8.81, S 19.99.

(The assignment of the H-atoms to the rings is not indicated here by primes but by the number of the appropriate ring as a superscript e.g. H^4 for H'''.)

2: red crystals, m.p. 73–74 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.17 (d, 2H; H^1-5, H^8-5), 7.12 (d, 4H), 7.03 (d, 2H), 7.02 (d, 2H), 7.00 (s, 2H; H^4-4, H^5-3), 6.93 (d, 2H; H^1-4, H^8-4), 2.76 (m, 8H; α-CH_2), 1.65 (m, 8H, β-CH_2), 1.25 (m, 72H; CH_2), 0.87 (m, 12H; CH_3); UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [L mol^{-1} cm^{-1}]) = 255 [15900], 439 [59700]. Elemental analysis: calcd C 72.13, H 8.63, S 19.26; found C 71.98, H 8.54, S 19.05.

3: small red plates, m.p. 86–87 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.18 (d, 2H; H^1-5, H^{12}-5), 7.14 (d, 2H), 7.13 (d, 4H), 7.05 (d, 2H), 7.03 (d, 2H), 7.02 (d, 2H), 7.00 (s, 4H; H^4-4, H^5-3, H^8-4, H^9-3), 6.94 (d, 2H; H^1-4, H^{12}-4), 2.77 (m, 12H; α-CH_2), 1.65 (m, 12H; β-CH_2), 1.26 (m, 108H; CH_2), 0.87 (m, 18H; CH_3); UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [L mol^{-1} cm^{-1}]) = 255 (27300), 456 (93300). Elemental analysis: calcd C 72.16, H 8.58, S 19.26; found C 72.39, H 8.62, S 19.02.

4: violet microcrystals, m.p. 90–91 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.18 (d, 2H; H^1-5, H^{16}-5), 7.14 (d, 4H), 7.13 (d, 4H), 7.05 (d, 4H), 7.04 (d, 2H), 7.03 (d, 2H), 7.01 (s, 6H; H^4-4, H^5-3, H^8-4, H^9-3, H^{12}-4, H^{13}-3), 6.94 (d, 2H; H^1-4, H^{16}-4), 2.77 (m, 16H; α-CH_2), 1.67 (m, 16H; β-CH_2), 1.26 (m, 144H; CH_2), 0.87 (t, 24H; CH_3); UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [L mol^{-1} cm^{-1}]) = 259 (48400), 464 (138400). Elemental analysis: calcd C 72.18, H 8.55, S 19.27; found C 71.69, H 8.55, S 19.38.

Saturated solutions of **1**–**4** in trichlorobenzene (Aldrich, >99%) were applied to the basal surface of highly oriented pyrolytic graphite (HOPG, Grade ZYB Advanced Ceramics, Cleveland, OH) with a Pasteur pipette. The tunnel tips were etched electrochemically (2 N KOH + 6 N NaCN; Pt/Ir (80/20) wire). Adsorption occurred after a waiting period which was different for each oligomer (ca. 30 min for **1**, 20 min for **2** and about 2–3 min for **3** and **4**). In some cases 2D crystallization was induced by a potential pulse applied between the substrate and the tip (100 ns, 4 V). The images were made with equipment built by us [26]. The STM images were made in current mode (constant height mode) under ambient conditions (scan rate 0.3 Hz per image, positive tip voltage) recorded on videotape, and then digitized. The STM images (Fig. 3) were not digitally processed later. The brightness correlates with the current.

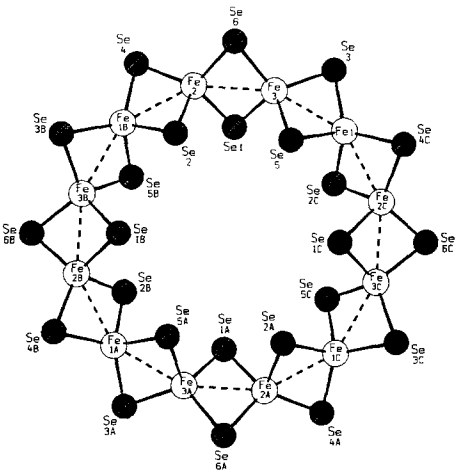
New Selenolato-Bridged Clusters of Iron and Nickel; the Structures of $[Fe_{12}(SePh)_{24}]$ and $[Na_2(POPh_3)_6][Ni_{20}Se_{12}(SeMe)_{10}]$**

Dieter Fenske* and Andreas Fischer



Dedicated to Professor Dr. Gerhard Fritz on the occasion of his 75th birthday

The reactions of phosphane complexes of transition metal halides with $E(SiMe_3)_2$ (E = S, Se, and Te) lead to a great number of multinuclear clusters, whose frameworks contain sections from the structures of binary chalcogenides, which are surrounded by a protecting shell of PR_3 ligands (R = organic group).[1] We have now investigated whether $PhSeSiMe_3$ and NaSeMe can also be used for the synthesis of these types of clusters.

As an example, we found that the Fe_{12} cluster **1** is formed almost quantitatively in the reaction of $FeCl_3$ with PPh_3 and $PhSeSiMe_3$ [Eq. (a)]. In THF and toluene at room temperature, only amorphous powder is obtained, some of which is pyrophoric. In contrast, **1** crystallizes in the form of shiny black needles within 12 h when a suspension of $FeCl_3$ and PPh_3 in dichloroethane is carefully covered with a layer of $PhSeSiMe_3$. Compound **1** decomposes readily on warming in organic solvents releasing elemental selenium. The IR spectrum of **1** contains the characteristic bands of the PhSe group, but further structural information cannot be extracted. An X-ray crystal structure analysis was carried out on **1** to determine the molecular structure.[2] Depending on the conditions of crystallization, crystals containing varying amounts of dichloroethane are formed. $\mathbf{1}\cdot 4C_2H_4Cl_2$ crystallizes in the tetragonal space group $P\bar{4}2_1c$, and $\mathbf{1}\cdot 5C_2H_4Cl_2$ in the orthorhombic space group $Pmmn$; however, this has practically no influence on the bonding parameters of **1**.

$$FeCl_3 \xrightarrow{PPh_3 + PhSeSiMe_3} \underset{\mathbf{1}}{[Fe_{12}(SePh)_{24}]} \qquad (a)$$

Figure 1 shows that a cyclic Fe_{12} cluster is present in **1** which has $\bar{4}$ symmetry in the tetragonal cell. Each Fe atom is surrounded by four Se atoms of the μ_2-SePh ligands in a distorted tetrahedral fashion. As a result, edge-sharing Se_4 tetrahedra connect to form a ring. The Fe atoms are located in the centers of the Se_4 tetrahedra (Se···Se 360–428 pm). The principle of bridging

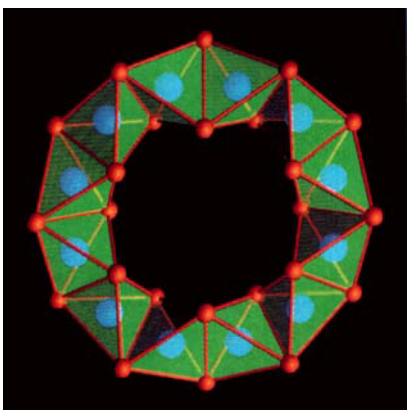


Fig. 1. Top: Ball-and-stick model of **1** (without Ph groups); bottom: polyhedron model of the edge-bridged Se_4 tetrahedra (Fe: blue; Se: orange). Selected distances [±0.2 pm]: Se1-Fe2 242.0, Se1-Fe3 244.6, Se2-Fe2 243.5, Se2-Fe1 243.6, Se3-Fe1 244.8, Se3-Fe3 245.0, Se4-Fe2 243.8, Se4-Fe1 246.6, Se5-Fe3 243.4, Se5-Fe1 244.8, Se6-Fe2 243.4, Se6-Fe3 244.1, Se-C 192–197.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 195) and the Fonds der Chemischen Industrie.

chalcogen polyhedra is found in the structures of many ternary chalcogenides. In contrast to **1**, vertex-sharing and edge-sharing E_4 tetrahedra (E = chalcogen) are observed to form dimeric and trimeric units, or even infinite chains in these compounds.[3]

The shortest Fe–Fe distances in **1** are 286.7–290.1 pm. They are thus comparable to the distances in $[Fe_2(SEt)_6]^{2-}$ (Fe–Fe: 297.8 pm) and $Ba_9(Fe_2S_4)_8$ (Fe–Fe: 275.1–286.8 pm),[3,4] as well as those in $[Fe_3S_4(SEt)_4]^{3-}$ (Fe–Fe: 271.4 pm), and $[Na_2Fe_{18}Se_{30}]^{8-}$ and $[Na_9Fe_{20}S_{38}]^{9-}$ (Fe–Fe: 272–289 pm).[5,6]

As in **1**, a ring-shaped cluster is also found in $[Na_2Fe_{18}S_{30}]^{8-}$ which is formed by the connection of S_4 tetrahedra having Fe atoms at their centers. In addition, two Fe_2S units are located at the center of the cluster. These four Fe atoms carry the charge + 2; the remaining 14 Fe atoms occur as Fe^{3+} ions.

In contrast to this, **1** contains iron centers only in the formal oxidation state + 2 (d^6 configuration). Preliminary results from the Mössbauer spectra indicate the presence of Fe^{2+} ions in tetrahedral environments. Obviously, considerable interactions between the Fe^{2+} ions must be considered.[7] This is possibly one explanation for the fact that a magnetic moment of μ_{eff} = 1.51 μB/Fe (at 293 K) was found. In this context, it must be mentioned that investigations have already been performed on ring-shaped iron clusters containing oxygen ligands.[8] The magnetic properties of $[\{Fe(OMe)_2(O_2CCH_2Cl)\}_{10}]$, a compound with octahedrally coordinated Fe^{3+} ions bridged by OMe and O_2CCH_2Cl ligands, are well understood.[8] Just as in **1**, antiferromagnetic coupling between the Fe^{3+} ions is observed (Fe–Fe: 302.8 pm).[8]

A space-filling model of **1** (Fig. 2) clearly shows that the Fe_{12} cluster ring is effectively shielded by the Ph groups bonded to the Se atoms. The Ph groups are arranged in an alternating fashion above and below the Fe_{12} cluster plane. The entire molecule has a diameter of about 12 Å.

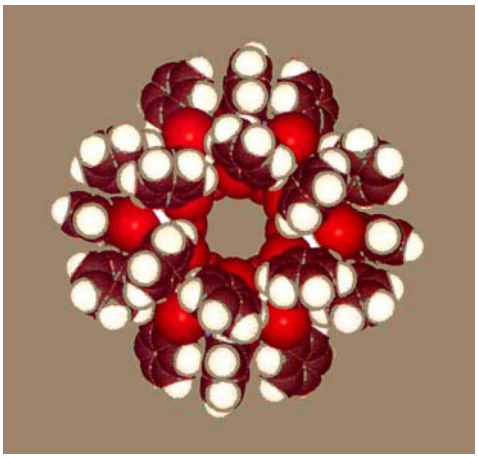

Fig. 2. Space-filling model of **1** (Fe: blue; Se: red; C: black; H: white). The Fe atoms are barely visible.

A further possibility for the synthesis of metal clusters with bridging chalcogen ligands is the reaction of metal halides with NaSR.[5,6,9,10] For example, the reaction of $NiCl_2$ with NaSMe (in the presence of Me_4NCl) leads to the complex $(Me_4N)_2[Ni_3(\mu_3\text{-}S)(\mu_2\text{-}SMe)_3]$.[11] On the other hand, if $[NiCl_2(PPh_3)_2]$ is treated with NaSeMe, black crystals of **2** are obtained in a yield of about 10% [Eq. (b)]. Cluster **2** is formed as a side product in a reaction that has not yet been clarified. The main products of the reaction are NiS and as yet unidentified cluster complexes.

$$[NiCl_2(PPh_3)_2] + NaSeMe \rightarrow \underset{\mathbf{2}}{[Na_2(POPh_3)_6][Ni_{20}Se_{12}(SeMe)_{10}]} \quad (b)$$

Product **2** is an ionic compound consisting of a $[Na_2(POPh_3)_6]^{2+}$ ion and a $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ ion. Two Na^+ ions are found in the centrosymmetrical cation (Fig. 3), each of which is coordinated by the O atoms of the $POPh_3$ ligands in a distorted tetrahedral fashion. The oxygen atoms O3 and O2, which are bonded to P1 and P2, respectively, are about 10 pm closer to Na1 than O1 is (Na1–O1: 227.4; Na1–O2: 218.4; Na1–O3: 216.5 pm). $POPh_3$ is obviously necessary for the formation of this cation; it arises possibly from the reaction of PPh_3 with the solvent or with oxygen.

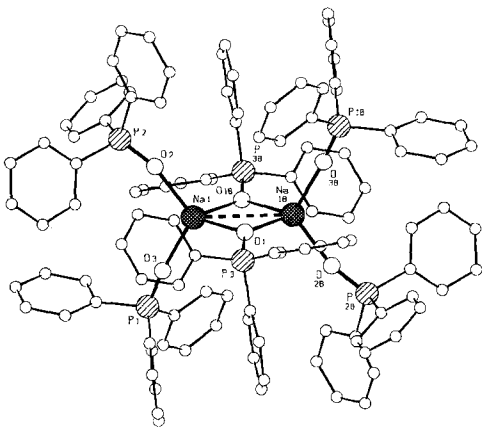

Fig. 3. The structure of the $[Na_2(POPh_3)_6]^{2+}$ ion in **2** (H atoms not shown). Selected distances [± 0.9 pm] and angles [± 0.2°]: Na1-O1 227.4, Na1B-O1 231.5, Na1-O2 218.4, Na1-O3 216.5, Na1 ··· Na1B 333.1, P1-O3 147.9, P2-O2 150.1, P3-O1 149.1; Na1-O1-P3 126.4 (134.3), O2-Na1-O3 115.4, O2-Na1-O1 108.3 (120.5), O3-Na1-O1 110.1 (112.0).

A certain structural relationship can be recognized between the structure of the $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ ion with $\bar{1}$ symmetry (Fig. 4) and that of the (as yet) largest nickel chalcogenide cluster $[Ni_{34}Se_{22}(PPh_3)_{10}]$.[12]

A pentagonal antiprism of Ni atoms (Ni1–Ni5 and atoms at inverted sites) makes up the central unit in the cluster anion of

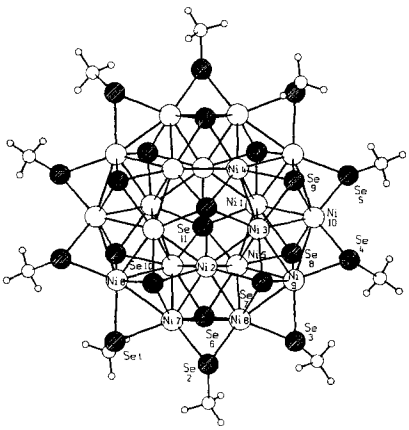

Fig. 4. The structure of the $[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ ion in **2**. Selected distances [±0.3 pm]: Ni1-Ni2 248.2, Ni1-Ni5 248.2, Ni2-Ni3 246.2, Ni3-Ni4 248.9, Ni4-Ni5 245.5, Ni6-Ni7 258.9, Ni7-Ni8 257.1, Ni8-Ni9 254.3, Ni9-Ni10 256.3, Ni6-Ni10 259.8, Se11-Ni 235.6–239.1, (μ_4-Se)-Ni 233.9–239.0, (μ_2-Se)-Ni 233.6–238.2.

2; the Ni–Ni distances (in the pentagonal ring) lie between 245.5 and 248.9 pm. In contrast, the Ni–Ni distances between the pentagonal layers are on average more than 260 pm, and the remaining Ni–Ni distances lie between these values. In the anion of **2** μ_5-Se (Se11, Se11'), μ_4-Se (Se6–Se10), and μ_2-SeMe (Se1–Se5) ligands are present. This shows that the cluster is formed as a result of a complex reaction which takes place partially by cleavage of the Se–C bonds.

Just as in $[Ni_{34}Se_{22}(PPh_3)_{10}]$, two μ_5-Se ligands (Se11) in the anion of **2** cap the top and bottom Ni_5 rings. The remaining Se atoms act as μ_4 ligands, whereas the SeMe groups are μ_2 bridging. As a result of this arrangement, one Ni_2 unit is located over each triangular face of the pentagonal antiprism. These Ni_2 units, together with the μ_4-Se bridging atom and the Ni atoms of the triangular face, give rise to octahedra consisting of five Ni atoms and one Se atom (e.g. Ni1, Ni3, Ni4, Ni6, Ni10, Se9). Thus the cluster can be described as a ring made up of face-sharing Ni_5Se octahedra, in which the Se atoms are arranged in an alternating fashion above and below the ring planes. The outer Ni_{10} ring (Ni6–Ni10 and atoms at inverted sites) is additionally bridged by ten μ_2-SeMe groups and thus sterically saturated. The Ni atoms Ni6–Ni10 are each coordinated by two $SeMe^-$ and two Se^{2-} ligands in a distorted tetrahedral fashion. In contrast, the Ni atoms of the pentagonal antiprism are coordinated by three Se^{2-} ligands.

$[Ni_{20}Se_{12}(SeMe)_{10}]^{2-}$ contains a Ni_{20}^{32+} cluster; the Ni atoms thus have the formal oxidation number 1.6. Mixed-valent states are well known for nickel. For example, the Ni atoms in $[Ni_{34}Se_{22}(PPh_3)_{10}]$ have a formal oxidation number of 1.7, and those in $[Ni_8S(SC_4H_9)_9]^-$ of 1.25.[12, 13] A simple description of the bonding situation in the cluster anion is not possible, as an assignment of Ni–Ni bonds is only possible when arbitrary assumptions are made. We have already had similar difficulties with other chalcogenidonickel cluster complexes.[1] This in mind, it is not surprising that the 18 electron rule and topological rules are not complied with.[14]

Experimental Procedure

1: $FeCl_3$ (0.16 g, 1 mmol) and PPh_3 (0.26 g, 1 mmol) were suspended in dichloroethane (80 mL). Solid undissolved material remained at the bottom of the red solution. The solution was then carefully covered with a layer of $PhSeSiMe_3$ (1 mL, 4 mmol). The solution became colorless at the phase boundary, and a white precipitate was observed. In the course of the following 24 h, the solution turned first dark green and then dark brown. Long dark needles of **1** started to grow on the walls of the reaction vessel along the diffusion boundary. Yield 90%. In contrast, when PPh_3 (0.52 g, 2 mmol) and $PhSeSiMe_3$ (1 mL, 4 mmol) were added to $FeCl_2$ (0.24 g, 2 mmol) in a heterogeneous reaction, in addition to **1**, a pyrophoric residue was also obtained, which was presumably elemental iron.

2: $[NiCl_2(PPh_3)_2]$ (4.44 g, 6.7 mmol) and NaSeMe (2.8 g, 23.9 mmol) were suspended in THF (100 mL) and stirred for several minutes. The suspension turned dark red. After a reaction time of several weeks, a powder was formed containing NaCl and other diverse products. In addition, triclinic crystals of **2** were obtained in the form of black lozenges.

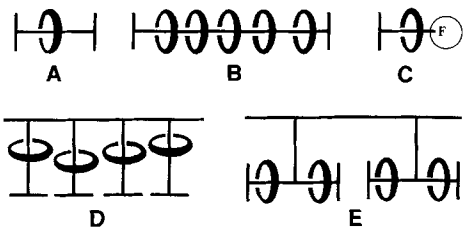
Side-Chain Polyrotaxanes with a Tandem Structure Based on Cyclodextrins and a Polymethacrylate Main Chain**



Markus Born and Helmut Ritter*

The chemistry of the rotaxanes has moved out of the area of low molecular weight compounds (Scheme 1, A) in the direction of polymeric structures, in which the linear "thread" molecules pass through a number of crown ethers or cyclodextrins.[1, 2] Recently we extended this group of main-chain polyrotaxanes[3–5] (Scheme 1, B) with a new class of side-chain polyrotaxanes (Scheme 1, D) based on polymethacrylate, polysulfone, and polyether ketone main chains.[6–8]

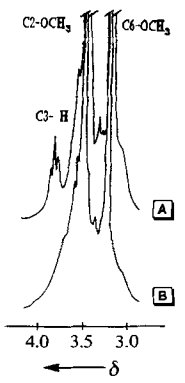
Scheme 1. Rotaxane structures. A = low molecular weight rotaxane; B = main-chain polyrotaxane; C = semirotaxane; D = side-chain polyrotaxane; E = tandem polyrotaxane.

We report here on the synthesis of new tandem polyrotaxanes, in which each branched polymeric side chain has a noncovalently bound cyclodextrin at either end of the side chain (Scheme 1, E). These polymers not only have remarkable structures, but they may also provide fundamental insight for the development of new materials with chiral components which may be useful, for example in the area of chromatography.

Radical copolymerization of 5-[(11-methacryloylamino)-undecanoylamino]isoisophthaloylbis(12-azadodecanoic acid) (**1**) and methyl methacrylate in a ratio of 1:4.1 yielded **2** (Scheme 2). The free acid groups of copolymer **2** were then condensed with the free amino groups of semirotaxane **3a**, which was prepared from 2,6-*O*-dimethyl-*β*-cyclodextrin and 4-amino-*N*-[4-(triphenylmethyl)phenyl]butanamide (**3**). The optically active tandem polyrotaxane **4a** resulted ($[\alpha]_D^{22} = +72.5$ ($CHCl_3$, $c = 10\,g\,L^{-1}$)). The relatively stable semirotaxane[6] **3a** used is similar to a low molecular weight rotaxane that has only one bulky end group and one reactive group (Scheme 1, A, C). In order to characterize **4a**, model polymer **4b**, which has the same structure but without cyclodextrin rings, was prepared analogously.

In the ^1H NMR spectra of **4a** the signals are significantly broadened and shifted relative to those in the spectra of **4b**. The signals of **4a** at $\delta = 7.41-7.43$ corresponding to the anilide segment in 2,6-position ($H_\alpha/H_{\alpha'}$ in Scheme 2) are markedly broadened and shifted downfield by roughly $\Delta\delta = 0.05$, whereas the remaining signals for the triphenylmethyl groups are almost unchanged. The signals of H_a, H_b, and H_c of the isophthaloyl components in **4a** are also broadened. This indicates that the cyclodextrins move readily along the aliphatic side chains at room temperature. In contrast, at $-10\,°C$ the rings are located preferentially near the anilide end groups, according to NMR spectra. The signals of the central isophthaloyl residue are now identical with the corresponding signals of **4a**, and are thus unaffected by the rings at low temperatures.



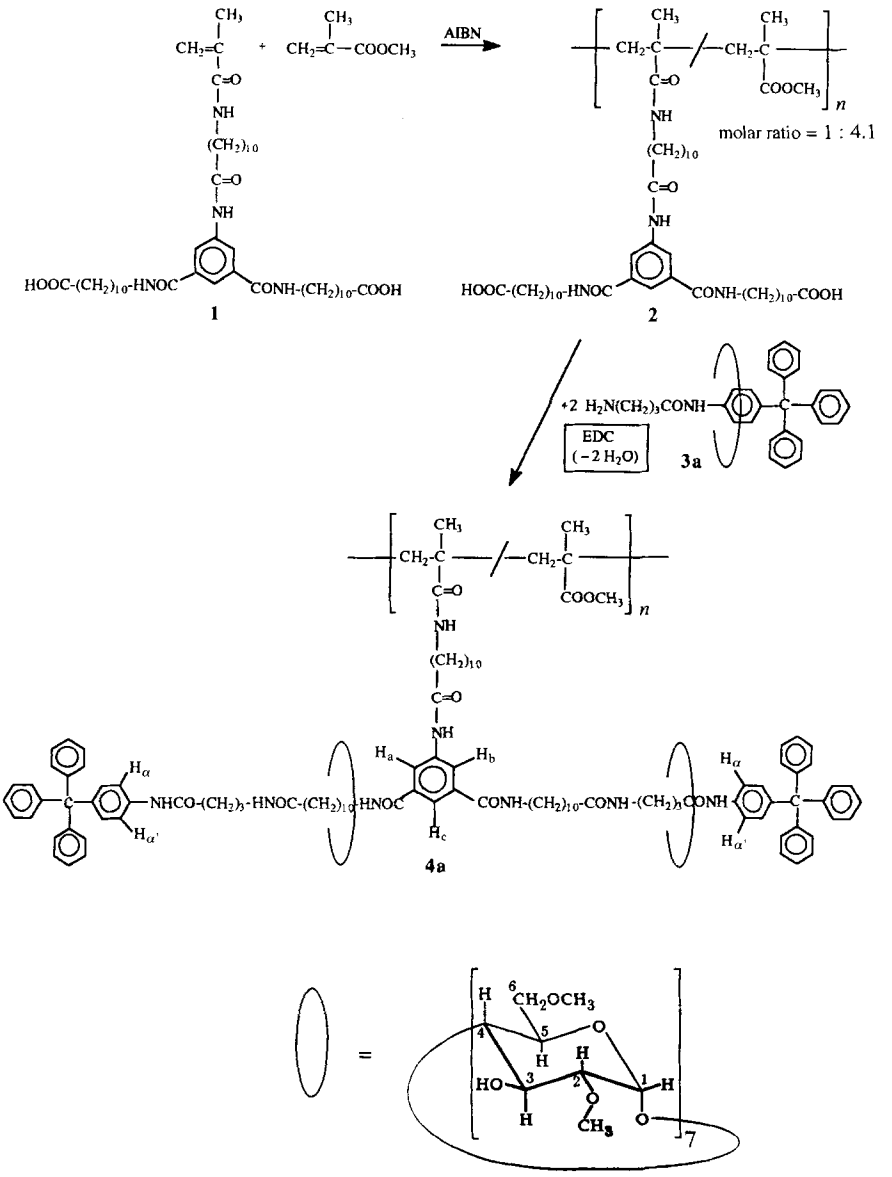


Fig. 1. Sections of the ^1H NMR spectra (250 MHz, $CDCl_3$) near the signals of the C3 protons of the cyclodextrins of a mixture of **4b** and cyclodextrin (A) and **4b** (B). (The signals of the methyl ether protons are cut off for clarity).

As expected, not only do the cyclodextrin rings affect the proton signals of the guests, but also inversely, the guests significantly influence a few signals of the rings. For example, in **4a** the signal of the proton at C3 pointing into the interior of the cage has a marked upfield shift, which is not seen for a simple mixture of **4b** and "free" cyclodextrin (Fig. 1). The original signals of the C3 protons are all shifted in the spectrum of **4a**. This, along with the results of thin-layer chromatography (TLC), indicates that free cyclodextrins are not found with polymer **4a**. Moreover, elemental analysis (see Experimental Procedure, analysis of **4a** and the cyclodextrin-free model compound **4b**) proves that close to all of the side chains are occupied according the proposed structure (Scheme 2).

The cyclodextrin rings of the tandem polyrotaxane **4a** were removed directly by acid glycolysis to give the model polymer **4b**, according to NMR spectroscopy. The characteristic signals of the α,α' protons shift gradually as evident in Figure 2.

Scheme 2. Synthesis of tandem polyrotaxane **4a**. AIBN = α,α'-azodiisobutyronitrile. EDC = *N'*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0310 $ 10.00+.25/0

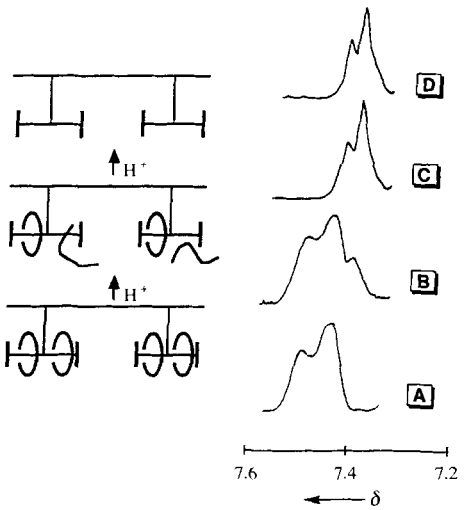

Fig. 2. Progression of the cleavage of cyclodextrin from **4a** in trifluoroacetic acid monitored by ^{1}H NMR. A: **4a**; B: **4a** after 7 h; C: **4a** after 60 h; D: **4b**.

Measurements by differential scanning calorimetry indicated that the glass transition temperature of **4a** is roughly 19 °C higher than that of **4a** (**4a**: 120 °C; **4b**: 101 °C). Apparently the bulky cyclodextrin rings reduce the mobility of the polymer segments.

Experimental Procedure

(11-Methacrylolylamino)undecanamido-1,3-phenylenedicarboxylic acid: A solution of (11-methacryloylamino)undecanecarboxylic acid [9] (6.50 g, 0.02 mol) in THF (30 mL) was treated with triethylamine (2.34 g, 0.02 mol). The resulting solution was cooled to −15 °C, and ethyl chloroformate (2.60 g, 0.02 mol) was added dropwise. After 1 h silylated 5-aminoisophthalic acid (0.02 mol) was added to the suspension, and the reaction mixture was then stirred at room temperature for 2 d.

Silylation: 5-aminoisophthalic acid (4.32 g, 0.02 mol) was suspended in $CHCl_3$ (25 mL) and treated with trimethylchlorosilane (7.60 g, 0.07 mol). Triethylamine (7.08 g, 0.07 mol) was added carefully dropwise. The reaction mixture was then heated at reflux for 3 h. In the workup the solvent was removed and the residue suspended in 200 mL of 2 N HCl. The resulting solid was removed by filtration and washed with water until the rinses were neutral. Yield: 9.04 g (87%).

^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 1.13–1.74 (m, 16H), 1.83 (s, 3H), 2.29–2.35 (t, 2H), 3.03–3.11 (m, 2H), 5.27 (s, H), 5.60 (s, 1H), 8.14 (s, 1H), 8.44 (s, 2H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3300–3600 (OH, NH), 3000–3100 (=C-H), 1655 (amide I), 1535 (amide II); Elemental analysis: calcd. for $C_{23}H_{32}N_2O_6$: C 63.87%, H 7.46%, N 6.48%; found C 63.66%, H 7.33%, N 6.41%.

1: An analogous reaction to that above with the mixed anhydride of (11-methacrylamino)undecanamido-1,3-phenyldicarboxylic acid, two equivalents of 11-aminoundecanoic acid, and four equivalents of trimethylchlorosilane and triethylamine provided **1** in 72% yield.

^{1}H NMR (250 MHz, CD$_3$OD): δ = 1.19–1.73 (m, 48H), 1.92 (s, 3H), 2.27–2.33 (t, 4H), 2.36–2.43 (t, 2H), 3.18–3.24 (t, 2H), 3.34–3.39 (t, 4H), 5.34 (s, 1H), 5.66 (s, 1H), 7.93 (s, 1H), 8.13 (s, 2H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3300–3600 (OH, NH), 3000-3100 (=C-H), 2860, 2930 (CH$_2$ valence), 1715 (C=O), 1600 (C=C), 1640–1655 (amide I), 1530–1550 (amide II); Elemental analysis: calcd. for $C_{45}H_{74}N_4O_8$: C 67.63%, H 9.33%, N 7.017%; found C 67.72%, H 9.37%, N 7.16%.

2: Compound **1** (3.34 g, 4.2 mmol) was dissolved in THF (15 mL), and then methyl methacrylate (2.21 mL, 21 mmol), dodecanethiol (0.16 g, 3 mol%), and AIBN (0.13 g, 3 mol%) were added. The mixture was allowed to polymerize at 60 °C for 4 d under N_2. The solution was then added dropwise to acetone (100 mL) and filtered. The solid product was dried at 60 °C ($\eta_{sp}c^{-1}$ = 27 mL g^{-1}; $c = 1.0 \times 10^{-3}$ g mL^{-1}; THF; 25 °C).

^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 0.73–2.04 (m, 73.5H), 2.14–2.20 (t, 4H), 2.27–2.31 (t, 2H), 2.97–3.07 (m, 2H), 3.22–3.25 (m, 4H), 3.54 (s, 12.3H), 7.89 (s, 1H), 8.12 (s, 2H). The composition ratio of the copolymer was determined to be 1:4.1 from the integration of the signals of the protons adjacent to the carboxylic acid groups at δ = 2.14–2.20 and the ester protons of methyl methacrylate at δ = 3.54. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3300–3600 (OH, NH), 3000–3100 (=C-H), 2860, 2930 (CH$_2$ valence), 1715–1725 (C=O, acid, ester), 1630–1655 (amide I), 1530–1555 (amide II); Elemental analysis: found C 65.04%, H 8.89%, N 4.63% calcd. for $(C_{45}H_{74}N_4O_8)_1/(C_5H_8O_2)_{4.1}$: C 64.83%, H 8.97%, N 4.51%.

4a: Compound **2** (1.45 g, 1.2 mmol) was dissolved in a mixture of THF (15 mL) and water (5 mL). Then **3a** (4.90 g; contains 1.09 g (2.6 mmol) of **3b**) was added. The solution was cooled to 0 °C and treated with EDC (0.50 g, 2.6 mmol). The reaction mixture was allowed to stir at room temperature for 4 d, then added dropwise to water. The resulting solid was removed by filtration and dried for several days under vacuum over silica gel (η_{spec}/c = 22 mL/g; $c = 1.0 \times 10^{-3}$ g mL^{-1}; THF; 25 °C).

^{1}H NMR (250 MHz, $CDCl_3$): δ = 0.72–2.00 (m, 73.5H), 2.10–2.17 (m, 4H), 2.24–2.51 (m, 6H), 2.67–2.73 (br., 4H), 7.13–7.25 (m, 34H), 7.46–7.51 (br., α-H, α′-H), 7.91–8.34 (br., H$_a$, H$_b$, H$_c$) cyclodextrin signals: δ = 3.39 (s, C6-OCH$_3$), 3.63 (s, C2-OCH$_3$) 4.98–5.07 (m, C1-H, C3-OH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3300–3600 (OH-cyclodextrin, NH), 2840–2930 (CH, CH$_2$ valence), 1725 (C=O, ester) 1635–1670 (amide I), 1520–1555 (amide II); Elemental analysis: found C 59.72%, H 8.00%, N 2.58%; calcd. for $(C_{215}H_{322}N_8O_{78})_1/(C_5H_8O_2)_{4.1}$: C 60.47%, H 7.75%, N 2.40%.

4b: An analogous procedure was used as that for **4a** except that **3b** (1.09 g, 2.6 mmol) was the starting material η_{spec}/c = 27 mL g^{-1}; $c = 1.0 \times 10^{-3}$ g mL^{-1}; THF; 25 °C).

^{1}H NMR (250 MHz, $CDCl_3$): δ = 0.72–2.04 (m, 73.5H), 2.12–216 (m, 4H), 2.24–2.55 (m, 6H), 2.65–2.73 (br., 4H), 2.97–3.06 (br., 2H), 3.25–3.49 (m, 10H), 3.59 (s, 12.3H of MMA ester protons), 7.14–7.25 (m, 34H), 7.41–7.43 (d, α-H, α′-H), 8.01 (s, 1H); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3280–3400 (NH), 3000–3100 (=C-H), 2860, 2920 (CH$_2$ valence), 1725 (C=O, ester), 1630–1655 (amide I), 1530–1555 (amide II); Elemental analysis: found C 72.95%, H 8.02%, N 5.28%; calcd. for $(C_{103}H_{126}N_8O_8)_1/(C_5H_8O_2)_{4.1}$ C 73.63%, H 7.94%, N 5.56%.

Structures of UV-B Induced Sunscreen Pigments of the Scots Pine (*Pinus sylvestris* L.)**

Tim P. Jungblut, Jörg-P. Schnitzler, Werner Heller,* Norbert Hertkorn, Jörg W. Metzger, Wilfried Szymczak, and Heinrich Sandermann, Jr.

Owing to increased global UV-B radiation, a consequence of ozone destruction in the stratosphere,[1] living beings need effective protection mechanisms for survival.[2, 3] Most experiments investigating the effect of UV-B radiation have been carried out on cultivated plants,[4] whilst only a few have been performed on trees.[5] Here we report on the structure of sunscreen pigments formed in Scots pine seedlings (*Pinus sylvestris* L.) specifically as a reaction to UV-B irradiation.[6, 7]

Analysis of methanolic extracts of needles from UV-B treated pine seedlings by reversed-phase high-performance liquid chromatography (RP-HPLC) showed that compound **1** in particular was strongly induced in cotyledons, and compound **2** in primary needles (**1** from less than 0.1 to about 0.9 μmol per g fresh weight, and **2** from 0.8 to 2.4 μmol per g fresh weight).[6] Figure 1 shows a typical HPLC elution profile of a methanolic extract from cotyledons after four days of UV-B treatment.

Compounds **1** and **2** were purified and isolated by countercurrent chromatography (MLCCC), gel chromatography on Sephadex LH-20, and preparative RP-HPLC. Their structures were determined by UV and ^{1}H NMR spectroscopy (2D ^{1}H-^{1}H COSY and NOESY), modern techniques in mass spectrometry (TOF-SIMS, electrospray MS in combination with MS/MS), as well as selective chemical degradation. According to these results, **1** is 3″,6″-di-*O*-(*para*-coumaroyl)isoquercitrin, and **2** is 3″,6″-di-*O*-(*para*-coumaroyl)astragalin. These two metabolites belong to a group of diacylated flavonol monoglycosides which have seldom been discussed until now. Compound **1** has already been described; however, there was some uncertainty in the substitution pattern on the sugar moiety.[8] Compound **2** was isolated and characterized for the first time here.

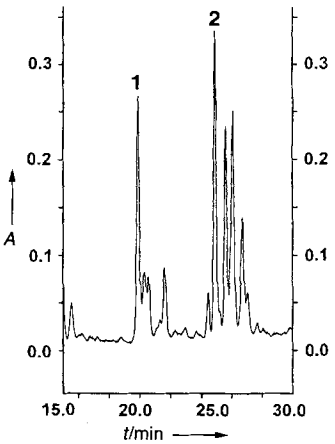

Fig. 1. RP-HPLC trace of a methanolic extract of cotyledons (compound **1** induced) from Scots pine seedlings after four days of UV-B irradiation; detection at 280 nm. t = retention time, A = absorbance in arbitrary units.

The results of the ^{1}H NMR spectroscopic investigations of **1** and **2** are summarized in Table 1. The molecular framework was determined by ^{1}H NMR and 2D ^{1}H-^{1}H COSY NMR spectroscopy. The unequivocal assignment of the aromatic protons was confirmed by NOESY experiments and by comparison with spectra of monoacylated compounds obtained by solvolysis. Selective decoupling experiments enabled unambiguous assignment of the sugar protons and showed the acylation at positions 3″ and 6″.

Structural data obtained from the ^{1}H NMR spectra were confirmed by mass spectrometric measurements. An initial molecular weight determination by time-of-flight secondary ion mass

Table 1 ^{1}H NMR [a], ES-MS, and MS/MS data [b].

1: ^{1}H NMR (400 MHz, CD_3OD (δ = 3.30), 310 K): δ = 8.55 (H, s; OH-7), 7.68 (H, d, ^3J = 15.9 Hz; H-7‴), 7.58 (2H, m; H-2′, H-6′), 7.47 (2H, AA′, ^3J = 8.6 Hz; H-2‴, H-6‴), 7.43 (H, d, ^3J = 15.9 Hz; H-7⁗), 7.33 (2H, AA′, ^3J = 8.6 Hz; H-2⁗, H-6⁗), 6.85 (5H, m (d and 2BB′); H-5′, H-3‴, H-5‴, H-3⁗, H-5⁗), 6.41 (H, d, ^3J = 15.9 Hz; H-8‴), 6.20 (H, d, ^4J = 2.0 Hz; H-8), 6.12 (H, d, ^3J = 15.9 Hz; H-8⁗), 6.06 (H, d, ^4J = 2.0 Hz; H-6), 5.31 (H, d, ^3J = 7.6 Hz; H-1″), 5.13 (H, t, ^3J = 7.9 Hz; H-3″), 4.33 (H, dd, ^2J = 11.8, ^3J = 1.5 Hz; H-6″A), 4.22 (H, dd, ^2J = 11.8, ^3J = 5.9 Hz; H-6″B), 3.73 (H, dd, ^3J = 7.9, ^3J = 9.4 Hz; H-2″), 3.55 (2H, m; H-4″, H-5″); ES-MS: *m/z*: 757 $[M + H]^+$, 455 $[Gl]^+$, 303 $[Agl + 2H]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; ES-MS/MS: daughter ions of *m/z* 757 $[M + H]^+$: *m/z*: 611 $[M - pC + 2H]^+$, 455 $[Gl]^+$, 303 $[Agl + 2H]^+$, 291 $[Gl - pCOH]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; daughter ions of *m/z*: 455 $[Gl]^+$: *m/z*: 291 $[Gl - pCOH]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; parent ions of *m/z*: 303 $[Agl + 2H]^+$: *m/z*: 757 $[M + H]^+$, 611 $[M - pC + 2H]^+$; parent ions of *m/z*: 291 $[Gl - pCOH]^+$: *m/z*: 757 $[M + H]^+$, 455 $[Gl]^+$; parent ions of *m/z* 147 $[pC]^+$: *m/z*: 757 $[M + H]^+$, 611 $[M - pC + 2H]^+$, 455 $[Gl]^+$, 291 $[Gl - pCOH]^+$; neutral loss of 308 *u* $[Gl - pC]$: *m/z*: 611 $[M - pC + 2H]^+$, 455 $[Gl]^+$.

2: ^{1}H NMR (400 MHz, CD_3CN (δ = 1.93), 310 K): δ = 12.26 (H, s; OH-5), 8.40 (H, s; OH-7), 8.04 (2H, AA′, ^3J = 9.0 Hz; H-2′, H-6′), 7.71 (H, d, ^3J = 16.0 Hz; H-7‴), 7.53 (2H, AA′, ^3J = 8.6 Hz; H-2‴, H-6‴), 7.46 (H, d, ^3J = 16.0 Hz; H-7⁗), 7.39 (2H, AA′, ^3J = 8.9 Hz; H-2⁗, H-6⁗), 6.86 (6H, m (3BB′); H-3′, H-5′, H-3‴, H-5‴, H-3⁗, H-5⁗), 6.41 (H, d, ^4J = 2.1 Hz; H-8), 6.40 (H, d, ^3J = 16.0 Hz; H-8⁗), 6.21 (H, d, ^4J = 2.1 Hz; H-6), 6.14 (H, d, ^3J = 16.0 Hz; H-8‴), 5.28 (H, d, ^3J = 7.9 Hz; H-1″), 5.08 (H, t, ^3J = 9.4 Hz; H-3″), 4.24 (H, dd, ^2J = 11.9, ^3J = 1.6 Hz; H-6″A), 4.19 (H, dd, ^2J = 11.9, ^3J = 5.9 Hz; H-6″B), 3.65 (H, dd, ^3J = 7.9, ^3J = 9.4 Hz; H-2″), 3.58 (2H, m; H-4″, H-5″); ES-MS: *m/z*: 741 $[M + H]^+$, 455 $[Gl]^+$, 287 $[Agl + 2H]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; ES-MS/MS: daughter ions of *m/z* 741 $[M + H]^+$: *m/z*: 595 $[M - pC + 2H]^+$, 455 $[Gl]^+$, 291 $[Gl - pCOH]^+$, 287 $[Agl + 2H]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; daughter ions of *m/z* 455 $[Gl]^+$: *m/z*: 291 $[Gl - pCOH]^+$, 165 $[pCOH + H]^+$, 147 $[pC]^+$; parent ions of *m/z* 287 $[Agl + 2H]^+$: *m/z*: 741 $[M + H]^+$; parent ions of *m/z* 291 $[Gl - pCOH]^+$: *m/z*: 741 $[M + H]^+$, 455 $[Gl]^+$; parent ions of *m/z* 147 $[pC]^+$: *m/z*: 741 $[M + H]^+$, 455 $[Gl]^+$, 291 $[Gl - pCOH]^+$; neutral loss of 308 *u* $[Gl - pC]$: *m/z*: 455 $[Gl]^+$.

[**] This work was supported by the Fonds der Chemischen Industrie, and by the Deutsche Forschungsgemeinschaft (SFB 323, C-3 Metzger). We thank Dipl.-Phys. M. Köfferlein and Dr. H. Seidlitz (GSF-Arbeitsgruppe Expositionskammern) for recording UV-B radiation during the experiments, and Dr. A. Marston and Prof. Dr. K. Hostettmann (Université de Lausanne, Switzerland) for instruction in advanced techniques in countercurrent chromatography.

spectrometry (TOF-SIMS) was in agreement with the postulated structures.[9] In the negative-ion mode, the base peaks for **1** and **2** at *m/z* 301 and 285, respectively, correspond to the aglycone ions. The quasi molecular ions $[M - H]^-$ at *m/z* 755 and 739 were also observed. Here, the method was used for the first time for analysis of secondary plant substances. Further important structural information was obtained from electrospray MS and MS/MS investigations, after collision-induced dissociation of the protonated molecular ions in a triple quadrupole mass spectrometer (see Table 1). Recently this technique was successfully applied to the analysis of anthocyanins and betacyanins.[10]

In addition to the physicochemical methods mentioned, the following solvolytic degradation reactions were used in the structure determination:

a) Alkaline hydrolysis with NaOH: The products were analyzed directly from the reaction mixture by RP-HPLC and were identified, by co-chromatography and by comparison of the diode array UV spectra with those of authentic samples, as *para*-coumaric acid and isoquercitrin (for **1**), and *para*-coumaric acid and astragalin (for **2**) (molar ratio 2:1 in each case). This confirmed the spectroscopic data, since ester bonds are preferentially cleaved under alkaline conditions.

b) Methanolysis: Continuous degradation of **1** and **2** was observed during the recording of ^{1}H NMR spectra in CD_3OD, indicated by new signals growing in intensity at the expense of the original ones. Analysis of both samples by RP-HPLC showed that two new products had been formed. They were isolated and characterized by UV and ^{1}H NMR spectroscopy as well as by ES mass spectrometry. Apparently transesterification of the diacylated compounds **1** and **2** with the solvent (methanol or perdeuteromethanol) gave rise to the corresponding 6″-monoacyl compounds 6″-*O*-(*para*-coumaroyl)isoquercitrin (**3**) and 6″-*O*-(*para*-coumaroyl)astragalin (tilirosid, **4**), as well as coumaric acid methyl ester and perdeuteromethyl ester.

Compounds **1** and **2** have very similar UV spectra. The maximum of the main absorption band at 315 nm lies right in the region of 290–320 nm expected for effective UV-B absorption. The extinction coefficient was determined in each case as $\varepsilon_{max} = 50\,300$. Thus these compounds offer optimal physiological protection against UV-B radiation. Figure 2 shows the UV spectra of compounds **1**, **3**, and **5** (= **3** with H instead of *para*-coumaroyl at 6″-O).

The absorption behavior of the monoacylated and diacylated metabolites is, as expected, qualitatively similar, but differs quantitatively. The ratios of the absorbances at 315 nm, the absorption maximum for flavonol monoglucosides acylated with coumaric acid, and at 350 nm, the maximum for non-acylated flavonol monoglucosides, are 2.44 (**1**) and 2.33 (**2**) for the diacylated compounds, whereas for the monoacylated compounds the ratios are 1.57 (**3**) and 1.61 (**4**). These values indicate that the

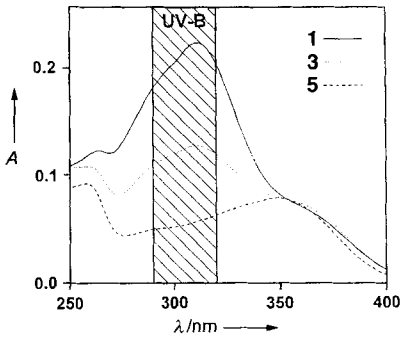

Fig. 2. UV spectra of quercetin derivatives: dicoumaroyl- (**1**), monocoumaroyl- (**3**), and non-acylated quercetin-3-glucoside (**5**) in acetonitrile (normalized to the absorption maximum of the non-acylated flavonol glucoside at 350 nm). The UV spectra of the corresponding kaempferol derivatives (**2**, **4**, and **4** with H instead of *para*-coumaroyl at 6″-O) were very similar; for this reason they are not shown.

irradiation-induced diacylated metabolites exhibit better protection against UV-B radiation than monoacylated compounds at the same molarity.

Respective analyses of enzymatically prepared epidermal tissue[11] and whole needles showed that up to 94% of the diacylated compounds are situated in the epidermis of the pine needle. It can be concluded from this result that the compounds under investigation are compartmented in the epidermis. The absorption behavior at 300 nm of the soluble and the cell wall bound fractions showed that about 80% of the absorption can be attributed to the soluble, and only 20% to the cell wall bound compounds.[12] Thus the soluble diacylated flavonol monoglucosides investigated here provide optimal protection for deeplying tissue against potentially damaging UV-B radiation.

Experimental Procedure

Needles from Scots pine seedlings were homogenized at liquid-nitrogen temperature in a microdismembrator II (Braun, Melsungen, Germany), and extracted in 1.0 mL methanol per 100 mg homogenate for 1 h in the dark at room temperature. After 10 min of centrifugation at 16000 *g* and 4 °C, the supernatant was removed and stored at −80 °C, or analyzed by RP-HPLC using a Beckman HPLC Gold system (Beckman, München, Germany; Nova-Pak (4 μm), 3.9 mm × 300 mm, Waters, Eschborn, Germany). The elution was performed with a gradient of 30–45% acetonitrile in water with 0.1% (w/v) ammonium formate in 2%(v/v) formic acid over 25 min at a flow rate of 1 mL min^{-1}. The elution was monitored with a UV/Vis spectrophotometer (diode array detector 136, Beckman).

The ES-MS measurements were performed with a Sciex API III triple quadrupole mass spectrometer equipped with an ionspray ion source (Sciex, Thornhill, Ontario, Canada). The ES voltage was 4.9 kV and the orifice voltage between 80 and 100 V. Collision-induced dissociation (CID) spectra (daughter ion, parent ion, and neutral loss scans) were obtained with argon as collision gas at a density of 2×10^{14} to 5×10^{14} atoms per cm^2 and a collision energy of 30 to 50 eV. For the ES-MS experiments solutions of the purified substances in acetonitrile were injected directly into the electrospray interface and measured in the positive-ion mode. Addition of ammonium acetate favored formation of $[M + H]^+$ ions and simultaneously suppressed formation of other adduct ions $[M + X]^+$ (X = Na, K). The sample solutions (1 μg mL^{-1}) were injected into the ES interface with a medical syringe infusion pump (Model 22, Harvard Apparatus, South Natik, USA) and a 100 μL microsyringe (Hamilton, Reno, Nevada, USA) at a constant rate of 5 μL min^{-1}.

For the preparation of samples for TOF-SIMS measurements [9] (in negative-ion mode) 35 μg cm^{-2} nitrocellulose (dissolved in acetone) was sprayed onto a polished stainless steel plate with an electrospray setup. The sample was dissolved in *tert*-butyl alcohol (1 μg mL^{-1}), and 1 μL of this was added dropwise to the nitrocellulose. For the ionization, the samples were bombarded with a pulsed 30 keV SF_5^+ beam (3 nA, pulse length 5 ns) at an effective angle of incidence of 42°. The flight length was 60 cm. A transient recorder [13] recorded the complete time-of-flight spectrum for each primary pulse (< 10 primary particles per pulse).

Degradation reactions: a) Alkaline hydrolysis with NaOH: About 20 μg of **1** or **2**, dissolved in methanol, was heated with 100 μL of 0.5% aqueous NaOH for 20 min in a heating block (Liebisch, Bielefeld, Germany) at 45 °C. The reaction mixture was then neutralized with 1 N HCl (pH meter, pH 521, WTW, Weilheim, Germany), and

the resulting reaction products were analyzed by RP-HPLC immediately. b) Methanolysis: Solutions of compounds **1** and **2** in pure methanol were allowed to stand for four weeks, and two new products formed; the reaction was followed by RP-HPLC.

Self-Assembled Helicates of Zinc and Cadmium Cyanides, $[M_x(CN)_{2x+1}]^-$, $x \leq 27$**

Ian Dance,* Phillip Dean, and Keith Fisher

Metal cyanide compounds, long known in the solid and solution phases, are virtually unknown in the pristine conditions of the gas phase.[1] We report here the formation of a series of gaseous zinc and cadmium cyanide anions of general formula $[M_x(CN)_{2x+1}]^-$ for x up to 27. Density functional (DF) theory and force-field (FF) calculations indicate that these ions have regular helical structures.

We recently found that solid CuCN and AgCN under laser ablation at 1064 nm form two series of ions, $[M_x(CN)_{x-1}]^+$ and $[M_x(CN)_{x+1}]^-$ ($x \leq 5$, M = Cu or Ag), with evidence for the formation of the neutral molecules $[M_x(CN)_{2x}]^0$, $x \leq 5$.[1a] We concluded that the ions $[M_x(CN)_{x-1}]^+$ and $[M_x(CN)_{x+1}]^-$ have completely linear structures with alternating M and CN groups on the basis of 1) the observed addition of two molecules of NH_3, H_2S, or CO to the cations $[M_x(CN)_{x-1}]^+$, 2) the observed association of the anions $[Ag_x(CN)_{x+1}]^-$ with one or two Na^+ ions, and 3) density functional optimizations of the molecular structures.

The negative ions formed by similar laser ablation of $Zn(CN)_2$ and $Cd(CN)_2$ have the compositions $[M_x(CN)_{2x+1}]^-$ for x up to 27 and possibly higher. In the mass spectrum for the product mixture from $Cd(CN)_2$ (Fig. 1) signals for members of the series for $x < 8$ are almost nonexistent, while the most abundant ions are in the region $15 \leq x \leq 23$. The spectrum of the $[Zn_x(CN)_{2x+1}]^-$ ions is similar, with more pronounced intensities at $x = 15$, 17, 19, and with the ions $3 \leq x \leq 8$ apparent.

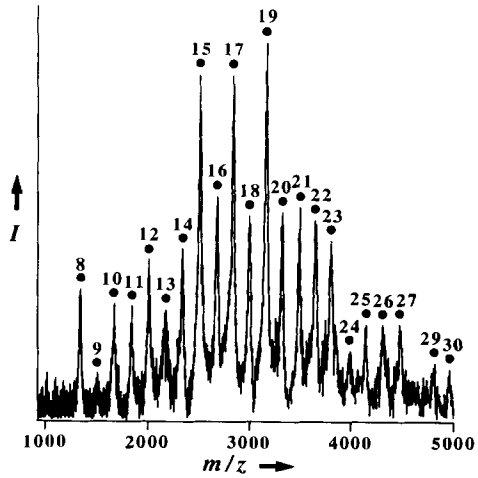

Fig. 1. Mass spectrum of ions $[Cd_x(CN)_{2x+1}]^-$ formed by laser ablation of solid $Cd(CN)_2$; laser power ca. 12000 MWcm^{-2}, $\lambda = 1064$ nm. Values of x are marked above the peaks.

What are the structures of these ions? We seek the structural principle for the continuous series $[M_x(CN)_{2x+1}]^-$, in which the zinc and cadmium cyanides are presumably isostructural. We expect that the structural motif should maximize the cluster density, as is achieved with anisotropic structures in the Cu/Ag series. There are two reasons why the $[M_x(CN)_{2x+1}]^-$ ions are unlikely to be fragments of the diamondoid crystal structures of $Zn(CN)_2$ and $Cd(CN)_2$. Firstly, the $M(CN)_2$ lattices have inherently low density, with long linear M-CN-M connections, compensated by the occurrence of interpenetrating unconnected diamondoid lattices,[2] or lattice filling with solvent.[3–5] Secondly, fragments excised to maintain consistent acceptable coordination at all metal atoms do not provide the observed continuous series of compositions.

In order to approach the structures of the observed ions, we first determined the relevant structural principles, using DF methods[7] to explore the structures of smaller members of the series (Fig. 2). For both $[Zn_2(CN)_5]^-$ and $[Zn_3(CN)_7]^-$ the isomer with the linear Zn-CN-Zn bridges, trigonal-planar coordination at Zn, and linear Zn-CN termini is clearly the most stable. The optimization sequence similarly indicates that CN bridges other than linear M-CN-M are less favorable, a conclusion consistent with the computational results for copper and silver cyanide complexes, and with the crystal structures of other $Zn(CN)_2$ and $Cd(CN)_2$ derivatives.[3–6, 8]

D. is grateful to the University of Western Ontario for sabbatical leave, and to the National Sciences and Engineering Research Council of Canada for providing partial travel funds.

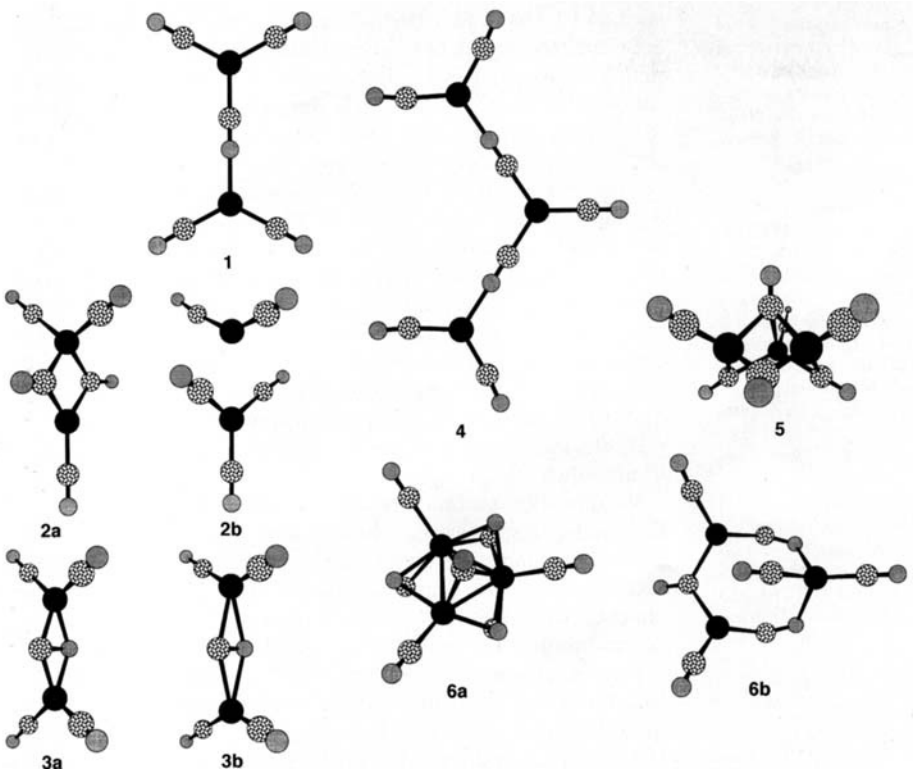

Fig. 2. Structures of zinc cyanides optimized by DF methods (● = Zn, ◎ = C, ○ = N). a) $[Zn_2(CN)_5]^-$: relative to the most stable structure **1**, the energies for **2b** and **3b** are + 80 and + 118 kJ mol^{-1}, respectively. The optimization of **2a** with (μ-CN)$_2$ to **2b** involved separation of the bridges and approach to a linear (140°) NC-Zn-CN arrangment and a trigonal-planar (116, 122°) [Zn(CN)$_3$] arrangement. The optimization of **3a** with (μ,η^2-CN) to **3b** involved elongation of the bridge and approach to two linear (140°) NC-Zn-CN units. b) $[Zn_3(CN)_7]^-$: relative to the most stable structure **4**, the energies for **5** and **6b** are + 110 and + 230 kJ mol^{-1}. The optimization of **6a**, with (μ,η^2-CN)$_3$(μ_3-CN), to **6b** involved substantial rearrangement of the bridges to more stable parallel arrays with secondary interactions.

Structure element **4** provides the clue to the structural principle that generates the series, namely the helical structure type illustrated in Figure 3 for $[Zn_{27}(CN)_{55}]^-$. In this structure the primary coordination of each zinc atom is nominally trigonal planar, the coordinated CN units are either linear bridging or linear terminal, and the helix is stabilized by secondary interactions between Zn atoms and bridging C and N atoms of the contiguous strand. These stabilizing interactions require a nonintegral number n of Zn(CN)$_2$ units per turn; reasonable geometries result from $n = 4.67$ and 5.67 (as in Fig. 3). The helical structure type maintains linear M-CN-M bridges, has the same coordination for all metal atoms, provides for a continuous series $[M_x(CN)_{2x+1}]^-$, and accounts for the enhanced stability for larger values of x through the increased opportunities for interstrand interactions.

We have evaluated the stabilities and geometries of the helical structures by DF and FF methods. The structures of $[Zn_9(CN)_{19}]^-$ with $n = 4.67$ and 5.67 optimized by DF[7] are stable helices with normal bond lengths; the secondary interactions between contiguous strands correspond to Zn–CN distances of 3.65 to 3.85 Å. These geometry optimizations also reveal that the terminal CN ligands peripheral to the helix are not perpendicular to the helix axis, but inclined slightly towards an adjacent strand of the helix as a consequence of coulombic attractions between $CN^{\delta-}$ and $Zn^{\delta+}$. The helical ions with $x > 9$ were modeled by FF methods, using bond lengths, bond angles, and atomic partial charges from the DF calculations.[9] These calculations confirm the stability of the helices with $n = 4.67$ and 5.67, reproduce the interstrand distances found in the DF calculations, and yield the characteristic inclinations of the terminal CN groups. The FF methods can be applied to all of the observed ions; the structure shown in Figure 3 was also optimized by this method.

All of these results support the stability of the helical structure type, which accounts for the continuous series of observed ions in the mass spectra, and for the lesser abundance of the zinc cyanide ions and absence of the cadmium cyanide ions with $x < 8$, which do not benefit from the stabilizing interstrand interactions. Alternative structural motifs such as graphitic arrays of M-CN-M linkages or M_x polyhedra with linear CN bridges along edges predict stoichiometries and mass spectra different from our observations. The helix is supramolecular and dependent on nonbonded interactions.

Finally, what are the prospects for crystallization of these structures, or, by extension, the infinite uncharged helix? Crystallization of zinc and cadmium cyanides from polar and protic noncoordinating solvents has always yielded inclusion lattices without helical motifs.[3–6] However, crystallization from nonpolar aprotic solvent systems (or cocrystallizing media) should enhance the influences of the intrahelix electrostatic interactions.

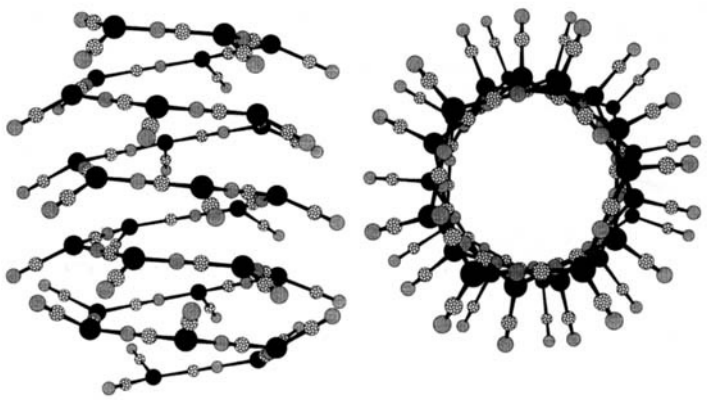

Fig. 3. Side view (left) and top view (right) of the optimized helical structure of $[Zn_{27}(CN)_{55}]^-$ with 5.67 Zn(CN)$_2$ units per turn.

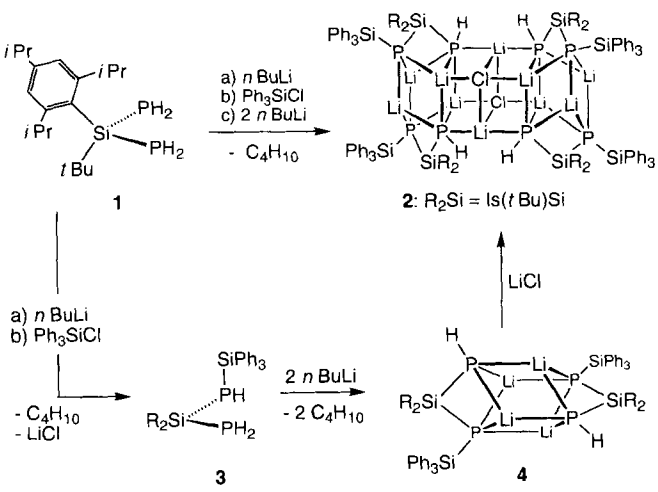
Novel Alkali Metal Phosphanide Aggregates**

Matthias Driess,* Gottfried Huttner, Norbert Knopf, Hans Pritzkow, and Laszlo Zsolnai

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

Lithium phosphanides of the type $LiPR_2$ (R = H, alkyl, aryl, triorganosilyl) are key reagents in organophosphorus synthesis. They are capable of aggregation (cluster formation) and like the homologous amides often have two-dimensional, ladderlike structures **A**.[1] Nevertheless, polymeric chains **B**[2] and helical strands **C**[3] have also been observed. These structural differences and the degree of oligomerization *x* (x > 2) are based primarily on the spatial requirements of the substituents and the ratio of the number of lithium to donor solvent centers. This is, for example, confirmed very well by systematic investigations of the $LiP(SiMe_3)_2$/donor solvent system.[4]



The aggregation of $(R_3Si)_2PM$ compounds (M = alkali metal) according to the "ladder structure" principle (**A**) led to the question of whether the highly functionalized molecular bis- and tris(alkali metal phosphanidyl)silanes of the type $[R_2Si(PR^1M)_2]$ (**D**) and $[RSi(PR^1M)_3]$ (**E**) organize according to the same building principle to give three-dimensional, closed aggregates. Furthermore, it should be studied whether mixed aggregates also exist and under which conditions (type of solvation, nature and number of metal centers) a closed arrangement of the cluster is possible; however, compounds of the type **D** and **E** were hitherto unknown.

We report here on the first lithium compounds of type **D** and **E** (**4** and **7**, respectively), which indeed have closed "dimeric" cluster structures; furthermore, we have isolated the mixed aggregate **2** from dimeric **D** and $(LiCl)_2$. In addition, we describe the dimeric sodium tris(phosphanide) **8** (type **E**), which is solvated by two molecules of toluene; **8** has an open polyhedron structure.

Colorless crystals of the dimeric bis(lithium phosphanidyl)silane **4** form in 87% yield in a one-pot reaction in toluene starting from the silylphosphane **3** with bulky substituents (prepared from **1**[5] by monosilylation with Ph_3SiCl) and two equivalents of *n*BuLi.

The composition of **4** is confirmed by correct C,H,P elemental analyses and cryoscopic measurements. The latter gave a degree of association *x* of about two for solutions in benzene (concentration range 0.018 to 0.033 M); because of the low solubility of **4**, *x* could not be measured at higher concentrations. It is not possible to determine the constitution of **4** based on its ^{31}P and ^{7}Li NMR spectra,[6] since only broad signals are observed at 25 °C, and below −35 °C the solubility is not sufficient to obtain high-resolution spectra. So far we have been unable to obtain single crystals of **4** or a derivative ($SiMe_3$ or $SiiPr_3$ groups on phosphorus)[7] for an X-ray crystal structure analysis. In an attempt to grow suitable crystals of **4** from the LiCl-containing crude product in hot toluene, we observed that **4** reacts with LiCl. This reaction leads to colorless rhombuses of the unusual, sparingly soluble aggregate **2** (55% yield), the structure of which was determined by X-ray diffraction[8] (Fig. 1).

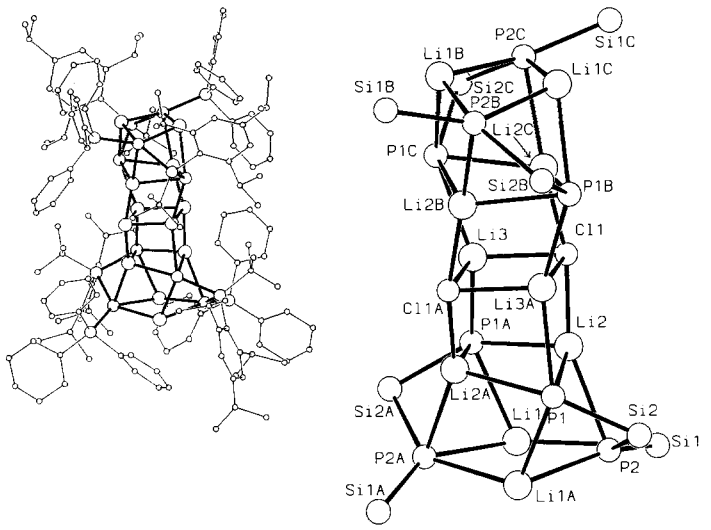
[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG Schwerpunktprogramm "Polyeder") and the Fonds der Chemischen Industrie.



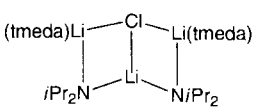


Fig. 1. Left: Crystal structure of **2**; right: framework of **2** shown without the organic groups. Selected distances [Å] and angles [°]: Cl1-Li3 2.20(3), Cl1-Li2 2.17(3), Li3-P1a 2.20(3), Li1-P 2.55–2.67(3), P1-Si2 2.237(6), P2-Si1 2.203(7), P2-Si2 2.252(6); Li2-Cl1-Li3 89.1(10), Li3-Cl1-Li3a 77(2), Cl1-Li3-Cl1a 103(2), Li1a-P1-Li2a 71.7(9), Li2-P1-Li2a 67.9(13), Si1-P2-Si2 129.0(3), Si1-P2-Li1a 146.9(7), Si2-P2-Li1a 83.1(6).

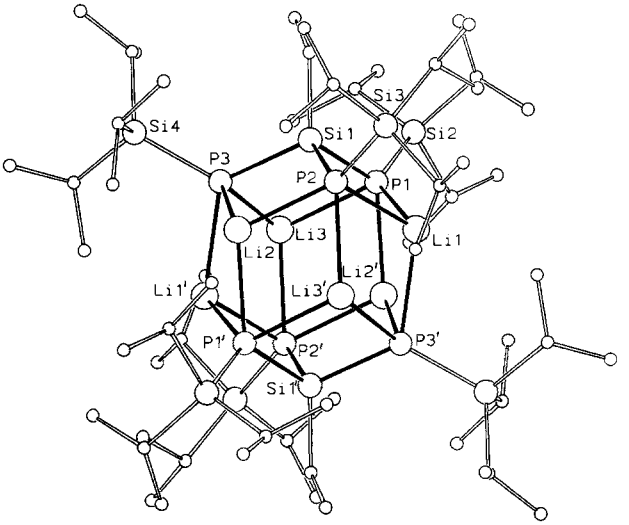
Compound **2** is a "dimer of dimers": two cluster molecules of **4** are linked to each other through a "middle deck" of $(LiCl)_2$. The phosphorus atoms are five- and six-coordinate, whereas the lithium centers have a distorted tetrahedral environment. The chlorine centers in the $(LiCl)_2$ middle deck are quasi-trigonal bipyramidally coordinated. Particularly noteworthy is the finding that the Li1 centers are each η^2 coordinated to a phenyl group of the $SiPh_3$ substituents. These interactions and the steric demand of the $SiPh_3$ group are probably responsible for the fact that no higher aggregation (attachment of LiCl and **4**) occurs. The Si–P (2.203(7)–2.252(6) Å) and Li–P distances (2.20(3) and 2.55–2.67(3) Å) lie in the normal range for lithium phosphanides. The Li–Cl distances are 2.20(3) (in the $(LiCl)_2$ ring) and 2.17(3) Å ("exocyclic" Li–Cl bonds) and are thus significantly shorter than in the lithium diisopropyllithium amide (LDA)–LiCl aggregate **5** (2.364–2.448(3) Å), in which the LiCl–"monomer" is complexed by two LDA units.[9]

5

The first lithium and sodium tris(phosphanides) **7** and **8**, respectively, form as colorless crystals by metalation of ethyl tris(triisopropylsilylphosphino)silane (**6**) with *n*BuLi and *n*BuNa, respectively, in toluene at −30 °C. Compound **6** is readily accessible from $EtSi(PH_2)_3$[10] in a one-pot reaction by lithiation with LDA in the mole ratio 1:3 in THF at −80 °C and subsequent reaction with three equivalents $iPr_3Si-OSO_2CF_3$. The trilithium derivative $EtSi(PHLi)_3$ decomposes above −30 °C, that is compounds of this type are stabilized substantially by the replacement of the H atoms at phosphorus by silyl groups.

Owing to the poor solubility of **7** and **8** in aliphatic and aromatic solvents it has so far not been possible to determine their structures in solution. Crystal structure analyses[8] revealed that in both cases dimeric aggregates with different topologies exist.

Whereas the donor-solvent-free **7** contains a $Si_2P_6Li_6$ framework in the form of a distorted rhombic dodecahedron (Fig. 2),



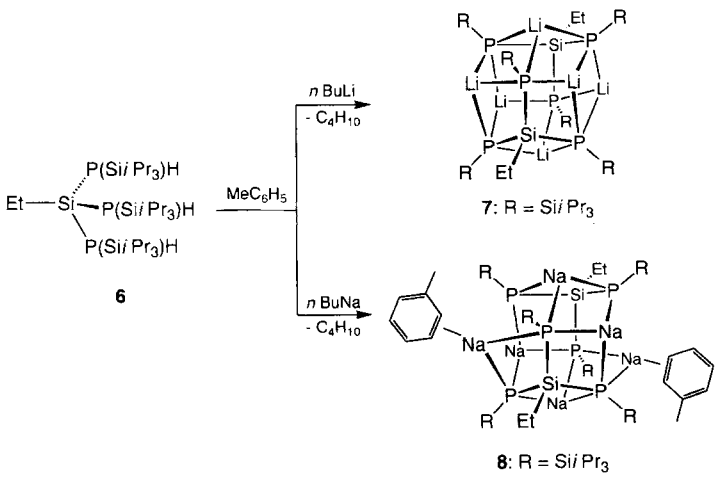


Fig. 2. Crystal structure of **7**. Selected distances [Å] and angles [°]: Li1-P1 2.464(5), Li1-P2 2.507(5), Li1-P3' 2.562(5), Li2-P2 2.449(5), Li2-P3 2.511(5), Li2-P1' 2.525(5), Li3-P3 2.452(5), Li3-P1 2.528(5), Li3-P2' 2.554(5), P1-Si2 2.236(1), P1-Si1 2.275(2), P2-Si1 2.271(2), P2-Si3 2.226(2); Si1-P1-Si2 123.89(6), Li1-P1-Si2 137.06(12), Li1-P1-Si1 81.71(13), Si1-P2-Si3 119.83(6), Li2-P2-Si3 140.38(13), Li2-P2-Si1 80.03(12), Si1-P3-Si4 120.95(6), Li3-P3-Si4 143.60(12), Li3-P3-Si1 83.48(13), P1-Si1-P3 103.36(7), P2-Si1-P3 106.66(5), P1-Si1-P2 104.62(6).

8, which is solvated with two molecules of toluene, has a $Si_2P_6Na_6$ framework with an open polyhedron structure (Fig. 3), although both compounds were prepared under the same reaction conditions. Compounds **7** and **8** have a center of symmetry. The structure of **8** can be described in a simplified way as a distorted drumlike $Si_2P_6Na_4$ framework, in which the atoms P1 and P3 (and P1′ and P3′) are bridged by the Na2 (Na2′) center. These Na bridging centers are each solvated with one molecule of toluene, which is surprisingly η^2 coordinated.

The structure of **7** is in accord with that of the homologous dimeric tris(lithioarsino)germane **9**[11] and that of the corresponding tris(lithioamino)silane.[12] The electronic saturation of the Li centers in **7** and **9** results from Li–P and Li–As multicenter bonding, respectively, as well as by Li-H-C interactions of adjacent methyl groups of the $SiiPr_3$ groups. The five-coordi-

$[\{t\text{BuGe}[\text{As}(\text{SiiPr}_3)\text{Li}]_3\}_2]$ **9**

nate P atoms reveal a distorted tetragonal-pyramidal coordination; the Li–P distances are 2.449–2.562(5) Å, that is they correspond with those in lithium disilylphosphanides.[3,4]

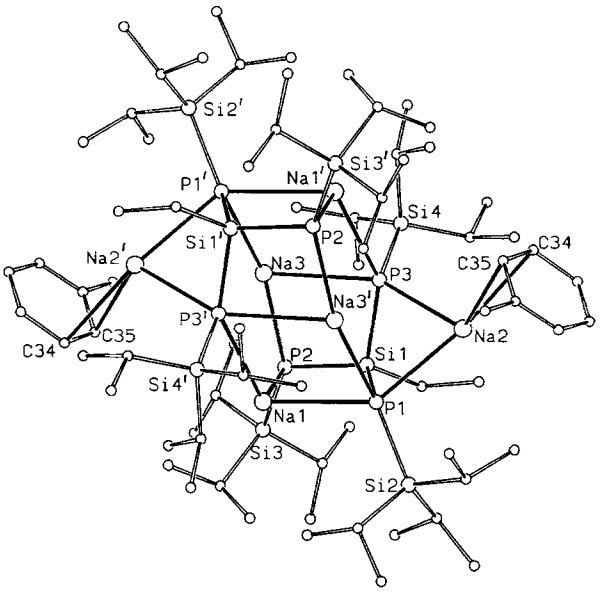

Fig. 3. Crystal structure of **8**. Selected distances [Å] and angles [°]: Na1-P1 2.878(2), Na1-P2 2.805(2), Na1-P3' 3.012(2), Na2-P1 2.858(2), Na2-P3 2.840(2), Na3-P1' 2.823(2), Na3-P2 2.778(2), Na3-P3 2.935(2), Na3-P3' 3.357(2), Si1-P 2.249–2.290(2), *i*PrSi-P 2.226–2.239(1), Na-Na 3.359–3.889(3); Si1-P1-Si2 122.48(5), Si1-P2-Si3 120.86(5), Si1-P3-Si4 113.87(5), P1-Si1-P2 116.20(5), P1-Si1-P3 95.04(6), P2-Si1-P3 105.69(6).

The structure of **8** results from the opening of two Na–P edges in the hypothetical $Si_2P_6Na_6$ rhombic dodecahedron by two molecules of toluene as donor. Toluene is known to be a relatively weak donor to alkali metal centers. Therefore why does **8** prefer an open polyhedron structure to the rhombic dodecahedral structure? The reason for this lies primarily in the differences in the sizes of lithium and sodium: the hypothetical $Si_2P_6Na_6$ rhombic dodecahedral framework has a pronounced ring strain, owing to the large differences between the Si1–P and Na–P distances (ca. 2.2 Å vs. 2.8 Å) and the restrictive, tripodal geometry of the SiP_3 increment, which is predestined to lead to an opening of the polyhedron. In contrast, the corresponding differences in the distances in **7** (2.236–2.275(2) Å vs. 2.449–2.562(5) Å) and in **9**[11] (Ge–As: 2.442–2.448(2) Å vs. Li–As: 2.52(2)–2.62(1) Å) are obviously such that these compounds are also generated in the donor-solvent-free form in ethereal solvents. The three unequivalent kinds of Na in **8** are coordinatively unsaturated because of the particularly bulky ligand spheres: With the exception of Na2, the Na centers are bound to three P atoms and have close contacts with H atoms of methine and methyl groups (Na-H-C interactions, Na–H distances: 2.44–2.54 Å) of adjacent $SiPr_3$ groups; in contrast, the Na2 center achieves its electronic stabilization primarily by bonding to two P and two toluene-C atoms. The Na–C distances are 2.882(5) and 2.968(5) Å. Similar Na–C distances were found in other complexes with π coordination of Na centers to arene ligands.[13]

At present we are testing whether molecular alkali metal oligophosphanides such as **4**, **7**, and **8** can be extended to give host lattices.

Experimental Procedure

2: **4** (780 mg, 0.65 mmol) in boiling toluene (ca. 50 mL) was treated with an excess of freshly prepared, anhydrous LiCl. After filtration (warm, GIV frit) to remove LiCl, the clear solution was concentrated to about 10 mL and crystallized at 0 °C. In this way **2** was isolated in a monocrystalline form. Yield: 430 mg (0.17 mmol, 55%)

4: A solution of **1** (2.33 g, 6.58 mmol) in toluene (50 mL) was lithiated with one equivalent *n*BuLi at −30 °C; the clear yellow solution was allowed to warm to room temperature and treated with a solution of Ph_3SiCl (1.93 g, 6.58 mmol) in toluene. The LiCl formed was filtered (GIV frit) off and the resulting clear solution was treated with two equivalents of *n*BuLi. Thereafter, the pale yellow solution was warmed to about 60 °C for 2 h to complete the conversion. Subsequently the solvent was removed in vacuum and the solid residue was washed with hexane (3 × 20 mL). Recrystallization afforded colorless, analytically pure **4**. Yield: 3.57 g (2.86 mmol, 87%).

6: $EtSi(PH_2)_3$ (0.51 g, 3.3 mmol) in THF (10 mL) was treated with LDA (10 mmol; freshly prepared from $HNiPr_2$ (1 g) and *n*BuLi (4 mL, 2.5 M solution in hexane) in THF (10 mL)) at −80 °C. After 1 h iPr_3SiOTf (3 g, 10 mmol) dissolved in THF (5 mL) was added to this solution and the mixture was allowed to warm to room temperature. The solvent was then removed under vacuum (10^{-2} Torr) and the residue was taken up in hexane (50 mL), filtered (to remove LiOTf), and the solvent was again removed. Yield: 1.8 g (2.8 mmol, 85%) of a colorless, viscous oil. ^{31}P NMR: $\delta = -236.0$ (d, $^1J(P,H) = 200$ Hz); ^{29}Si NMR: $\delta = 22.0$ (d, $SiPr_3$, $^1J(Si,P) = 42$ Hz), 9.5 (q, SiEt, $^1J(Si,P) = 66$ Hz); EI MS (70 eV): *m/z* (%): 624 (6) $[M^+]$, 581 (14) $[M^+ - iPr]$, 467 (34) $[M^+ - SiPr_3]$, 435 (100) $[M^+ - PHSiPr_3]$.

7: **6** (1 g, 1.6 mmol) was dissolved in toluene (50 mL) and treated with *n*BuLi (1.9 mL, 2.5 M solution in hexane) at −20 °C. After 8 h at room temperature the resulting suspension was heated (ca. 50 °C) until the solution cleared. Subsequent gradual cooling to room temperature afforded **7** as colorless crystals. Yield: 0.9 g (1.4 mmol, 88%).

8: **6** (1 g, 1.6 mmol) dissolved in toluene (10 mL) was added to a suspension of *n*BuNa (0.38 g, 4.8 mmol) in toluene (40 mL) at −20 °C and the mixture was stirred for 8 h at room temperature. The resulting suspension was heated until the solution cleared. Slow cooling to room temperature afforded colorless crystals. Yield 1 g (1.4 mmol, 88%).

Reactions of 1,1′-Ferrocenediylbis{chloro-[(1,2,5,6-η)-1,5-cyclooctadiene]}diplatinum with Triarylphosphane and Molecular Oxygen**

Toshiya Yoshida, Shigeaki Tanaka, Tomohiro Adachi, Toshikatsu Yoshida, Kiyotaka Onitsuka, and Kenkichi Sonogashira*

In the chemistry of transition metal complexes containing metallocenes, intramolecular metal–metal interactions involving the metal atom of the metallocene have become one of the most interesting topics in recent years.[1] As part of our studies of ferrocenyl transition metal complexes[2] we have investigated the reactivities of the 1,1′-ferrocenediyldiplatinum complexes $[\{C_5H_4Pt(cod)X\}_2Fe]$ (X = Cl, Br; cod = cyclooctadiene) (**1**).[3] These complexes react with two mole equivalents of PAr_3 (Ar = Ph, p-$CH_3OC_6H_4$) and oxygen to give the novel paramagnetic μ-hydroxo complexes **2**. We wish to report here the chemistry of these and related complexes.

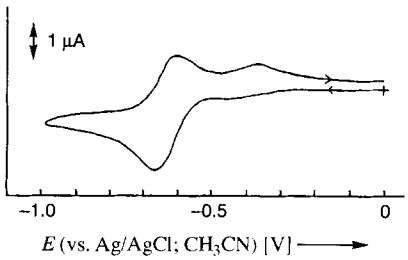
The μ-hydroxo-1,1′-ferrocenediyldiplatinum complexes **2** were prepared in yields of 46 to 62% as air-stable green crystals by ligand exchange reaction of the corresponding 1,1′-ferrocenediyldiplatinum complexes **1**, in which each Pt atom has a cyclooctadiene ligand, with two equivalents of PAr_3 in CH_2Cl_2 in the presence of molecular oxygen at room temperature for 6 h [Eq. (1)].[4]

(1)

1a X = Cl
1b X = Br

2a X = Cl, Ar = Ph
2b X = Br, Ar = Ph
2c X = Cl, Ar = p-$C_6H_4OCH_3$
2d X = Br, Ar = p-$C_6H_4OCH_3$

The IR spectrum of complex **2a** shows an absorption at 3440 cm^{-1} due to the stretching of the OH group.[5] In the ^1H NMR spectrum of **2a** the characteristic broad signal of the μ-OH unit appears at much higher field ($\delta = -23.5$) than those of other μ-hydroxo complexes,[6] and disappeared upon addition of a few drops of D_2O. The broad signals attributed to the cyclopentadienyl protons are observed at $\delta = 36.6$ and 26.6 owing to the paramagnetism of the ferrocenediyl group,[7] which was confirmed by the detection of a paramagnetic resonance in the ESR spectrum of **2a**. The cyclic voltammogram of **2a** in CH_2Cl_2 shows a reversible reduction peak ($E_{1/2} = -0.62$ V) ascribed to the reduction of Fe^{III} to Fe^{II} accompanied by decomposition to give an unknown product ($E_a = -0.37$ V) (Fig. 1). In an effort to obtain information about the origin of the μ-hydroxo group, we carried out several experiments. Treatment of **1a** with one equivalent of triphenylphosphane per platinum atom in thoroughly degassed and anhydrous solution did not



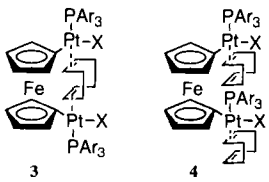


Fig. 1. Cyclic voltammogram of **2a** (10^{-3} M in CH_2Cl_2); scan rate 100 mVs^{-1}, supporting electrolyte tetrabutylammonium hexafluorophosphate (10^{-1} M), working electrode Pt disk (2 mm diameter).

lead the formation of **2a**. ^1H and ^{31}P NMR spectra of this reaction mixture indicated the presence of reactive diamagnetic intermediates such as **3** and **4**. Complex **2a** was not obtained when H_2O was added to this system, but it was generated by the introduction of dry air. These results suggest that the reactive intermediate is easily oxidized by molecular oxygen. Thus, we believe that the oxygen atom of complex **2** arises from O_2, though we have no indications of the origin of the hydrogen atom of the μ-hydroxo group.

A single-crystal X-ray structure analysis of **2c**[8] confirms the presence of an OH group bridging the two platinum atoms in a bent fashion. The unit cell contains two independent molecules with essentially the same structure, one of which is shown in Figure 2. The coordination around each platinum atom is square

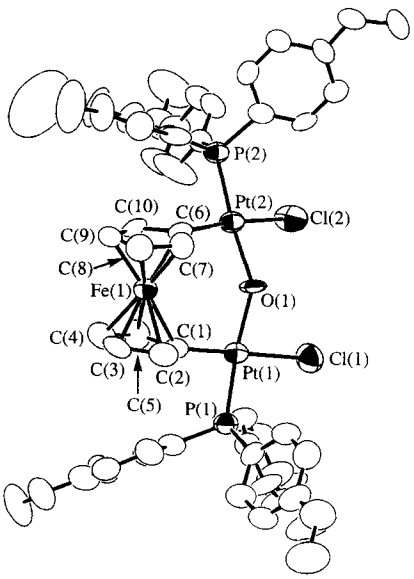

Fig. 2. Crystal structure of **2a**. Selected bond lengths [Å] and angles [°]: Pt(1)–Cl(1) 2.390(5), Pt(1)–P(1) 2.224(5), Pt(1)–O(1) 2.127(9), Pt(1)–C(1) 2.00(2), Pt(2)–Cl(2) 2.386(5), Pt(2)–P(2) 2.241(5), Pt(2)–O(1) 2.13(1), Pt(2)–C(6) 2.01(2); Cl(1)-Pt(1)-O(1) 83.5(3), P(1)-Pt(1)- O(1) 172.6(3), O(1)-Pt(1)-C(1) 93.0(5), Cl(2)-Pt(2)-O(1) 82.7(3), P(2)-Pt(2)-O(1) 177.3(3), O(1)-Pt(2)-C(6) 91.2(6), Pt(1)-O(1)- Pt(2) 138.9(5).

planar, and the dihedral angle between the two Pt coordination plane is 146.9°. These planes form dihedral angles of 87.1 and 63.8° with the adjacent cyclopentadienyl ligands. The roughly equal Pt–O bond lengths (2.127(9) and 2.13(1) Å) are longer

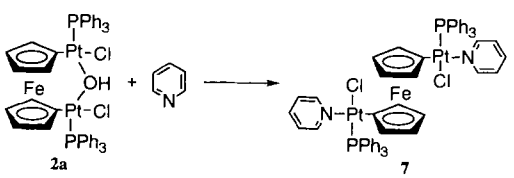
than that of $[NBu_4][\{Pt(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (2.07(2) Å)[9] but agree with the average value found in $[\{Pt(PEt_3)_2(\mu\text{-}OH)\}_2]$ (2.130 Å).[10] The Pt-O-Pt angle of 138.9(5)° is significantly larger than those of the other μ-hydroxodiplatinum complexes (92(2)–101.4(6)°).[9, 10] The Pt–C bond lengths of 2.00(2) and 2.01(2) Å are within the range expected for a normal Pt–C bond in a σ-ferrocenylplatinum complex.[11] The Pt–Fe distances of 3.728(3) and 3.725(3) Å and the Pt–Pt distance of 3.990(2) Å indicate the absence of any direct M–M interaction. The separation of 3.49(1) Å between the oxygen atom and the iron atom does not reflect any bonding interaction. The ferrocenediyl group has a staggered conformation, and the dihedral angle between the two cyclopentadienyl ligands is 8.5°.

The reaction of **2a** with CO (30 kg cm^{-2}) in dichloromethane at room temperature gave the brown-red solid **5a**. Although we were not able to purify **5a**, its structure was assigned based on IR and ^{1}H NMR spectra. Subsequent treatment of **5a** with excess tri(*n*-butyl)phosphane led to the formation of stable orange crystals of **6a** [Eq. (2)]. In the IR spectrum of **6a** a CO stretching

2a X=Cl
2b X=Br



5a X=Cl
5b X=Br

6a X=Cl
6b X=Br

(2)

band at 1600 cm^{-1} indicates that CO inserted into the Pt–C bonds of **2a**. ^{1}H and ^{13}C NMR spectra reveal that the two cyclopentadienyl ligands are equivalent, and the *trans* arrangement of the Pt moieties is supported by a singlet in the ^{31}P NMR spectrum and the ^2J(P,C) coupling of the CO signal in the ^{13}C NMR spectrum. These data are consistent with the structure of **6a** which is produced by the insertion of one molecule of CO into each Pt–C bond of **2a**. The analogous reaction of **2b** gave insertion product **6b**.

When complex **2a** was treated with pyridine, the red complex **7** was isolated [Eq. (3)]. The structure of **7** determined by X-ray

2a **7**

(3)

crystallography is shown in Figure 3.[8] Apparently pyridine has cleaved the hydroxo bridge in **2a** following reduction of the complex; the pyridine ligand at each platinum atom is *trans* to the cyclopentadienyl ligand. The fate of the bridging hydroxo group is not known. The Pt atoms have the expected square-planar coordination with Pt–C σ bonds to the 1,1′-ferrocenediyl moieties and coordination to PPh_3, pyridine, and Cl ligands. The 1,1′-ferrocenediyl group adopts an eclipsed conformation with the Pt planes in a transoid orientation, which minimizes steric interaction across the ferrocene molecule. The tilt angle between the two cyclopentadienyl rings is 1.6°. The bond lengths and angles lie in the expected range.

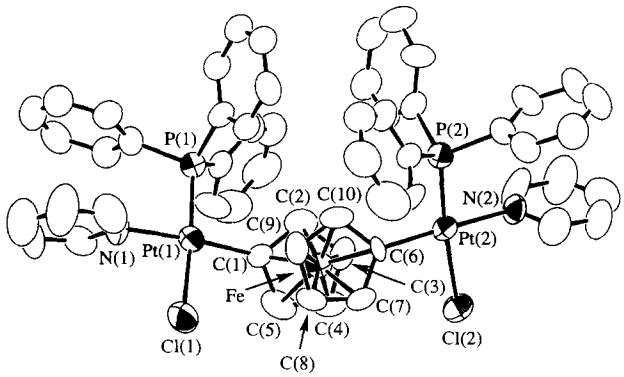


Fig. 3. Crystal structure of **7**. Selected bond lengths [Å]: Pt(1)–C(1) 2.02(1), Pt(1)–Cl(1) 2.362(4), Pt(1)–P(1) 2.216(4), Pt(1)–N(1) 2.15(1), Pt(2)–C(6) 2.03(1), Pt(2)–Cl(2) 2.361(4), Pt(2)–P(2) 2.208(4), Pt(2)–N(2) 2.15(1).

In conclusion, we have synthesized a novel paramagnetic μ-hydroxo 1,1′-ferrocenediyldiplatinum complex **2**, in which the 1,1′-ferrocenediyl group functions not only as a bridging ligand fixing the two platinum atoms at an appropriate distance but also as an electron pool. Complexes **2** are reduced by CO and pyridine to give diamagnetic complexes **6** and **7**, respectively. We are now exploring further reactions of these complexes.

Experimental Procedure

2a: To a solution of **1a** (101 mg, 0.117 mmol) in CH_2Cl_2 (20 mL) was added PPh_3 (63 mg, 0.240 mmol). The reaction mixture was stirred at room temperature for 6 h, during which time the color gradually turned from red to green. After removal of the solvent, the green residue was dissolved in 1,2-dichloroethane. Slow evaporation of this solution provided green crystals of complex **2a** (100 mg, 62%). M.p. 235–240 °C (decomp); IR (Nujol): $\tilde{\nu}$ = 3440 cm^{-1} (OH); ^{1}H NMR (CD_2Cl_2): δ = 36.56 (br, 4H; C_5H_4), 26.59 (br, 4H; C_5H_4), 12.80 (br, 12H; Ph), 10.89 (br, 12H; Ph), 10.15 (br, 6H; Ph), −23.49 (br, 1H; OH); ^{31}P NMR (CD_2Cl_2, PPh_3): δ = −84.88 (s); MS (FAB): *m/z*: 1168 $[M - OH]^+$; UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon \times 10^{-2}$) = 774 (6.05), 637 (4.03), 406 nm (27.0).

6a: A solution of **2a** (48 mg, 0.0347 mmol) in 10 mL of CH_2Cl_2 was placed in a 100 mL autoclave, which was then charged with CO (30 kg cm^{-2}). The reaction mixture was allowed to stand for 24 h at room temperature. Then tri(*n*-butyl)phosphane (70 mL, 0.281 mmol) was added and the solution stirred for 4 h at room temperature. The solvent was removed, and the residue was purified by column chromatography on silica gel (15 mm × 100 mm) with $CHCl_3$ as eluent. Recrystallization from hexane gave orange crystals of **6a** (19 mg, 37%). M.p. 131–132 °C; IR (KBr): $\tilde{\nu}$ = 1600 cm^{-1} (CO); ^{1}H NMR ($CDCl_3$): δ = 4.61 (s, 4H; C_5H_4), 4.23 (s, 4H; C_5H_4), 1.83 (br, 12H; CH_2), 1.67 (br, 12H; CH_2), 1.49–1.39 (m, 48H; CH_2), 0.92 (t, J = 7.3 Hz, 36H; CH_3). ^{13}C NMR ($CDCl_3$): δ = 213.62 (t, ^2J(P,C) = 5.3 Hz; CO); 97.92 (t, ^3J(P,C) = 4.2 Hz; C_5H_4 *ipso*), 70.54, 69.49 (C_5H_4), 25.97, 24.23, 21.72, 13.81 (PBu_3); ^{31}P NMR ($CDCl_3$, PPh_3): δ = 11.72 (J(Pt,P) = 3034 Hz).

7: A solution of **2a** (35 mg, 0.0295 mmol) in 10 mL of pyridine was stirred for 48 h at room temperature. The green solution gradually turned orange, and then a red orange precipitate (35 mg, 90%) was obtained. M.p. 237–241 °C (decomp).

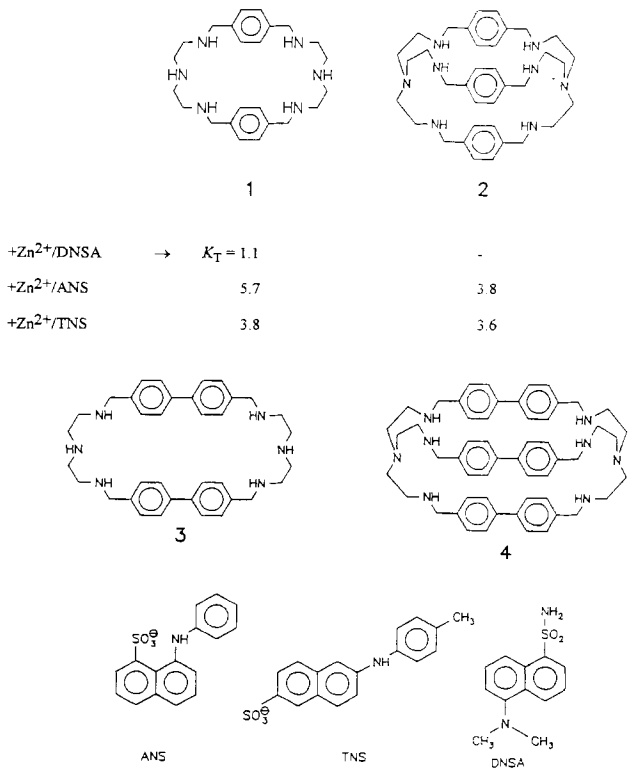
Complexes from Polyazacyclophanes, Fluorescence Indicators, and Metal Cations—An Example of Allosterism through Ring Contraction**



Ralf Baldes and Hans-Jörg Schneider*

Synthetic host–guest systems can be relatively easily designed to have a receptor containing several conformationally strongly coupled binding sites that may also bind organic substrates.[1] We report here on ternary complexes in which the cavity for a lipophilic guest molecule is fitted spacially by *contraction* of the hollow space, which is initiated by the binding of metal cations.

Molecular mechanics simulations (force-field CHARMm[3]) of polyazacyclophanes **1** and **2** (Scheme 1)—obtained by published procedures[2]—indicate an almost spherical shape with a wide cavity in the absence of complexing metal cations (Fig. 1a). When metal ions, for example zinc ions, are bound to the ethylene diamine moieties, the cavities become smaller and more strongly anisotropic (Fig. 1b), thus allowing an optimal enclosure of guest molecules of the naphthalene type (Scheme 2, Fig. 1c). The potential energy necessary for the formation of the smaller cavity is provided by the high stability constants[4] of metal complexes of the corresponding polyamine ligands. Unfortunately, the complexes of the new derivatives of **1** and **2** with biphenyl instead of benzene moieties (**3** and **4**, Scheme 1) are too insoluble in water, and we can only discuss here the allosteric properties of the well-known[2] polyazacyclophanes **1** and **2**. Because of the low solubility of these systems, the complexation reactions could not be monitered by NMR spectroscopy. However, using fluorescence spectroscopy and suitable indicators[5] (ANS (8-anilinonaphthalene-1-sulfonic acid), TNS (6-*p*-toluidino)-2-naphthalenesulfonic acid), DNSA (5-dimethylaminonaphthalene-2-sulfonic acid), Scheme 1), the expected cooperative effects could be quantified. At the same time this presented new possibilities for the detection of, for example, zinc ions in aqueous solution.

Scheme 1. Structures of the host ligands L and guest molecules G (fluorescence indicators) and their equilibrium constants (in units of 10^{-3} M^{-1}; water, 25 °C) for the ternary complex L·G·Zn^{2+}.

The addition of a solution of **1** (5×10^{-3} M, at pH 7.0 present as $\mathbf{1} \times 4H^+$) with $ZnCl_2$ (5×10^{-3} M) to a solution of the fluorescent dye DNSA (10^{-5} M) in water at pH 7.0 led to a considerable increase in the fluorescence emission F; from the saturation curve (Fig. 2) a constant $K_T = 1.1 \times 10^3$ M^{-1} with a scattering of about 8% could be calculated for the formation of the ternary complex L·G·M (**1**·DNSA·Zn^{2+}) from a nonlinear fitting

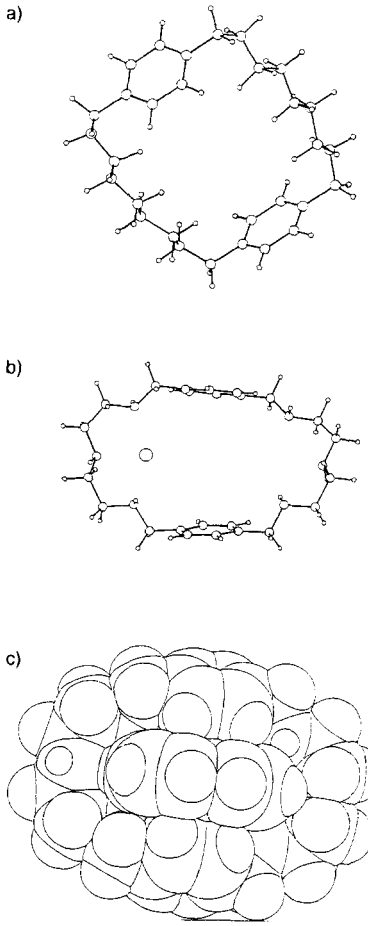

Fig. 1. Force-field-optimized (CHARMm [3]) structure of a) host **1** without a metal ion, b) **1** with a zinc ion, c) the complex of **1**·ANS·Zn^{2+} as space-filling model—the enclosed naphthalene ring is visible in the cavity.

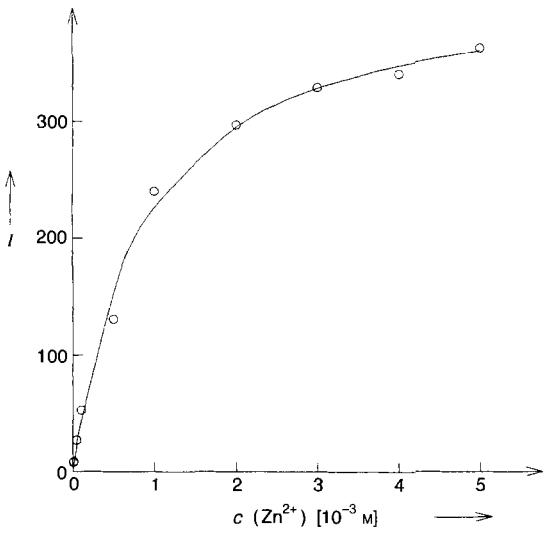
on the basis of a 1:1 model. When only **1** was added, the increase of F was, at most, 4% compared to the effect obtained from the formation of the ternary complex; nevertheless, this was taken into account in the calculation on the basis of linear calibration curves ($r > 0.99$), along with the slight decrease in the concentration of DNSA during the titration. Control experiments showed that both Zn^{2+} and **1** alone have a negligible effect on the F values of DNSA, which implies that the complexation of DNSA in the absence of the metal ion acting as an allosteric effector is immeasurably small. On the basis of the increase in F from **1** and DNSA alone, which hardly exceeds the statistical error, the maximum value of the formation constant of the binary complex in the absence of metal ions can be estimated to be below $K_B = 5-10\,M^{-1}$. Thus, the value of the relative constant of the ternary complex of at least $K_{rel} = K_T/K_B = 10^2$ demonstrates a greater level of cooperation than in many other synthetic systems.[1] A distinctly smaller value is usually found for allosteric proteins.[6]



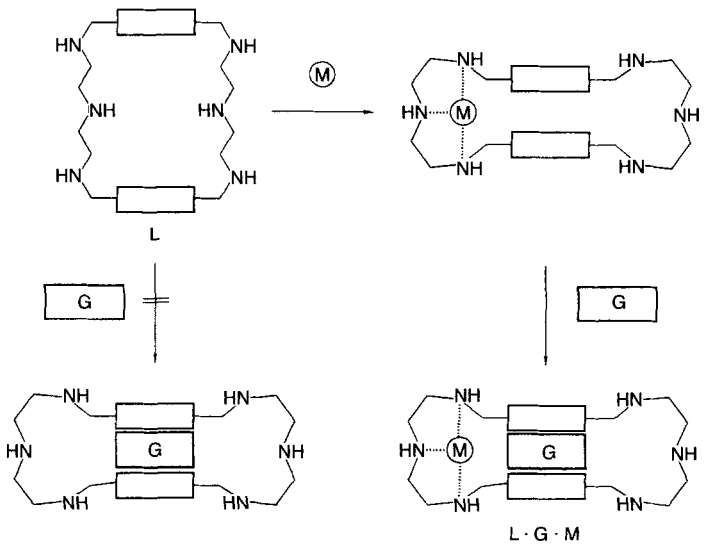


Fig. 2. Complex titration of DNSA (10^{-5} M) with a 1:1 mixture of **1** and $ZnCl_2$ (both 5×10^{-3} M; water, 25 °C, pH 7.0); fluorescence intensity in relative units; experimental values (corrected, see text) and nonlinear fitting for a 1:1 complex (continuous line).

All the host molecules L investigated have binding sites for two metal ions M. Indeed, a UV/vis titration with $CuSO_4$ indicates a composition M_2L, in particular for the more strongly binding tricyclic **2** (Fig. 3). However, not only the complex titration discussed above, but also a separate experiment (Fig. 4) indicated that a ternary complex with *one* metal ion is the dominant species. The simultaneous binding of an organic substrate in the ternary complex leading to a deformation of the second metal binding site is in agreement with molecular mechanics simulations, which indicate the instability of the corresponding

Scheme 2. Principle of the formation of ternary complexes through contraction of the metal-free macrocycle L after addition of metal cations M.

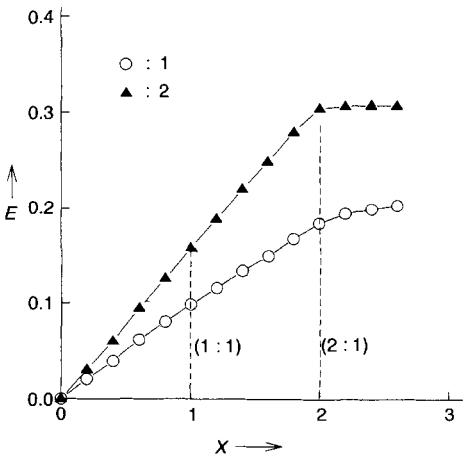

Fig. 3. Dependence of the UV/vis-extinction on the molar ratio X of Cu^{2+} to ligand; this shows a 2:1 (M_2L) stoichiometry for the complexes of Cu^{2+} with **1** and **2**; extinction at 620 nm (for **1**, $\varepsilon = 91.9\,L\,mol^{-1}\,cm^{-1}$) or at 860 nm (for **2**, $\varepsilon = 154\,mol^{-1}\,cm^{-1}$).

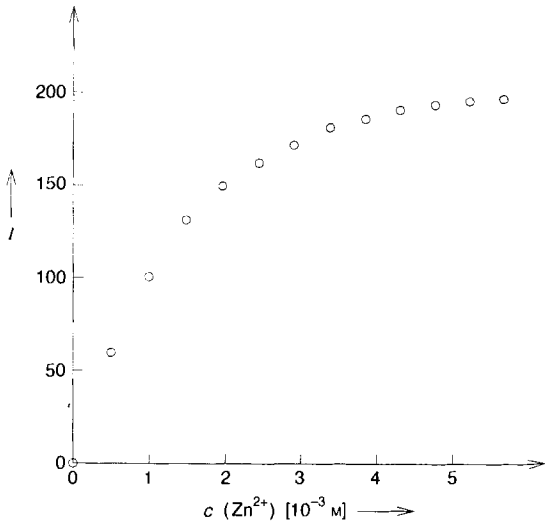

Fig. 4. Dependence of the fluorescence intensity of a mixture of DNSA (5×10^{-6} M) and **1** (5×10^{-3} M) on the $ZnCl_2$ concentration; shows the 1:1:1 (L · M · G) stoichiometry of the ternary complexes (for further information see the legend of Fig. 2).

L · G · 2 M (**1** · DNSA · $2Zn^{2+}$) complex. In this respect, the system described above is positively cooperative with regard to the ternary complex, but it is negatively cooperative with regard to a theoretical quaternary complex L · G · M_2 (**1** · DNSA · $2Zn^{2+}$).

The anionic substituents of the indicators ANS and TNS should lead to a further increase in the level of cooperation. Whilst the ternary complex with the electoneutral DNSA can only benefit from solvophobic and/or van der Waals binding forces in the allosteric closure of the lipophilic pocket, ionized substrates such as ANS and TNS can call on additional electrostatic energy in the sense of a cocomplexation. Indeed, the corresponding constants, which, as for DNSA, were obtained from the saturation curves after correction by linear calibration curves, show a four- to sixfold increase in the formation constants of the ternary complexes (Scheme 1); the cooperativities with ANS and TNS increase to at least $K_{rel} = 10^3$. (Problems of solubility limited the measurement to the determination of the constants for **3** and **4** shown in Scheme 1.)

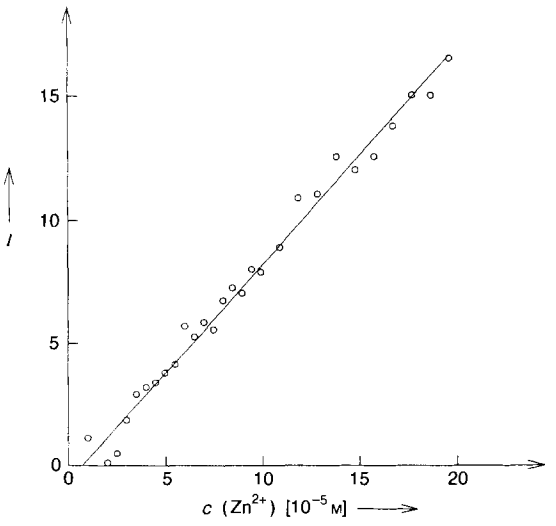

Fig. 5. Dependence of the fluorescence intensity of a mixture of $ZnCl_2$, DNSA (5×10^{-2} M) and **1** (5×10^{-3} M) on the $ZnCl_2$ concentration (maximum 2×10^{-4} M) (for further information see the legend of Fig. 2).

A possible application of the ternary complexes lies in the exploitation of the high sensitivity of fluoresence spectroscopic methods for the determination of the concentration of metal ions. Figure 5 shows that the concentration of Zn^{2+} in the region of 10^{-6} to 10^{-4} M is directly proportional to the fluorescence intensity.

Designed conformational coupling in synthetic complexes between heterotopic binding sites should allow the development of allosteric systems with potential technical and biological/medicinal applications. These systems can have considerably greater cooperativity than that possible in biopolymers.

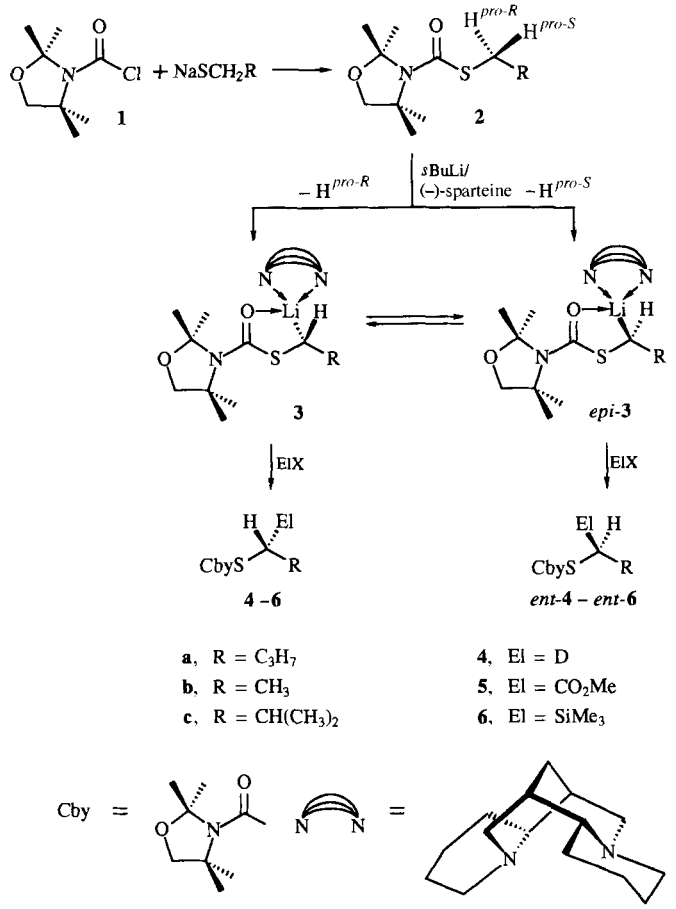
Preparation and Detection of Enantiomerically Enriched and Configurationally Stable α-Thioalkyllithium Compounds

Bernd Kaiser and Dieter Hoppe*



Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

Chiral α-alkylthioalkyllithium compounds are, in contrast to their α-alkoxy analogues, configurationally instable even at −80 °C.[1] The causes and mechanisms of the configurational conversions have been thoroughly investigated.[2] For example, using racemic 1-arylthioalkyllithium compounds, Hoffmann et al.[1f] showed that sterically demanding aryl groups on the sulfur atom raise the barrier to configurational inversion and that the

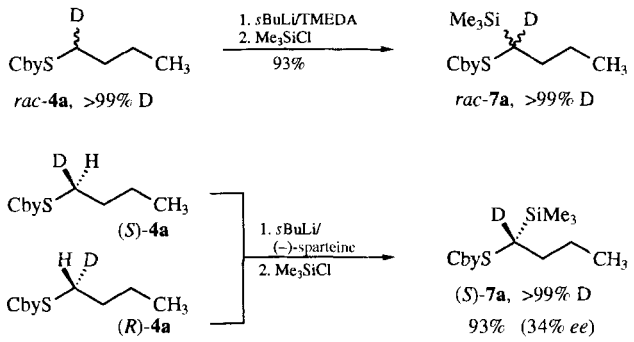
torsion about the C–S bond is rate determining. Enantiomerically enriched α-thioalkyllithium compounds, whose chirality is determined solely by the stereogenic carbanionic center, have never been prepared to the best of our knowledge. We now report a method for forming enantiomerically enriched, configurationally labile ion pairs, and the synthesis of a configurationally stable α-thioalkyllithium compound. As we have shown,[3] several alkyl carbamates (**2** with O instead of S) can be lithiated under the influence of the chiral additive (−)-sparteine with effective differentiation between the enantiotopic protons *pro-S*-H and *pro-R*-H; the complexes (**3** with O instead of S) are configurationally stable, and electrophilic substitution leads to products (**4** with O instead of S) with retention of configuration

and enantiomeric excesses of ≥95% *ee*.[3e] The corresponding *S*-alkylthiocarbamates **2** formed from 1,3-oxazolidine-3-carbonyl chloride (**1**)[4] and sodium thiolates[5] were deprotonated under the same conditions in diethyl ether and trapped with various electrophiles to give the substitution products **4**–**6** (Table 1).[6, 7] The enantiomeric excesses were between 40 and 60% *ee* and are almost totally independent of the electrophile used.

Two explanations for the comparatively small enantiomeric excesses are possible: 1) The diastereomeric ion pairs **3** and *epi*-**3** are configurationally labile; they exist in equilibrium and their ratio is thermodynamically defined.[8] 2) **3** and *epi*-**3** are configurationally stable under the reaction conditions, but the chiral reagent cannot differentiate sufficiently between the enantiotopic protons of the starting compounds **2**.



To investigate these possible explanations, we made use of the extremely high kinetic H/D isotope effect, which was recently

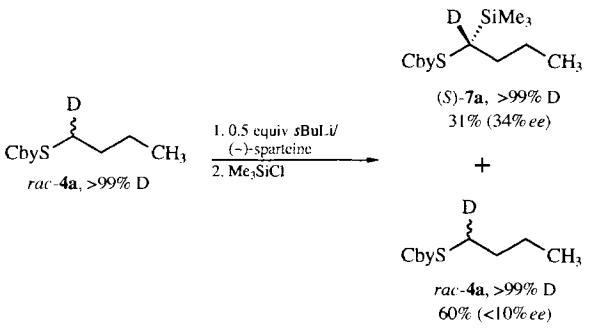
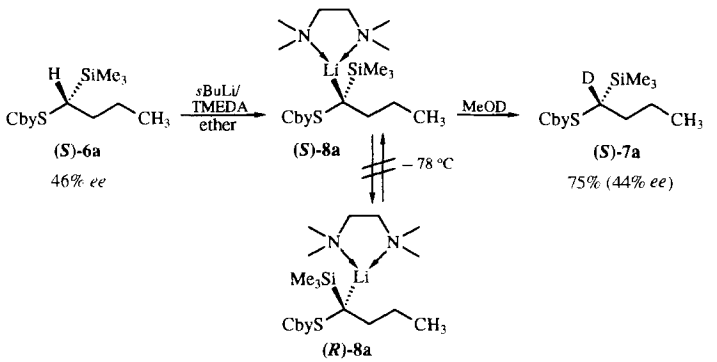
demonstrated for the deprotonation of similar compounds.[9] In a control experiment, less than 1% D was lost during the deprotonation of *rac*-**4a** with *s*BuLi/*N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine (TMEDA) under "achiral conditions" and subsequent silylation to give *rac*-**7a**;[10] this corresponds to an isotope effect $k_H/k_D \geq 100$. In an analogous experiment with the chiral complexing agent (−)-sparteine, (*S*)-**7a** was formed in 93% yield with a deuterium content of >99% of the theoretical



value, and in 34% *ee*. Because of the enantiomeric excess, the first explanation appears to be correct; that is, the reaction proceeds via an intermediate lithiated species that is configurationally labile even at −78 °C. Similar equilibrations have been confirmed for the lithium/(−)-sparteine complexes of primary allyl[8a, b] and benzyl anions.[8c] We attribute the reduced configurational stability of **3**, in comparison to its O analogues, to a reduced rigidity of the chelate complex, which in turn is due to a better stabilization of the negative charge by the sulfur atom,[11] as well as the longer bond length in the sulfur compound (C–S ca. 180 pm, C–O ca. 140 pm).[12] In addition, the good yield indicates that the enantiotopic differentiation in the deprotonation of carbamate **4a** is insufficient. If the chiral base could efficiently differentiate between the enantiotopic protons, (*R*)-**4a**, which contains a proton topologically equivalent to the *pro-S*-H in **2a**, would react more rapidly under kinetic racemic resolution.



To estimate the relative rates of hydrogen abstraction from the enantiotopic positions, racemate **4a** was deprotonated in the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0324 $ 10.00+.25/0

presence of only 0.5 equivalents of chiral base, and the carbanions formed in this way were trapped with chlorotrimethylsilane. In the starting material isolated at the end of the experiment (60%) the enantiomer ratio (*R*)-**4a**:(*S*)-**4a** was determined to be 45:55 by ^{1}H NMR spectroscopy;[14] the removal of the *pro-S* proton in **2** is thus only slightly preferred.

Since the lithiated primary thiocarbamates of type **3** are not configurationally stable in ether at −78 °C, we thought that a more sterically demanding group at the carbanionic center might lead to higher configurational stability. Thus, (*S*)-**6a** (46% *ee*) was deprotonated with *s*BuLi/TMEDA under the conditions described above, left at −78 °C for 2.5 h, and the ion pair thus formed trapped with [D$_1$]methanol. The α-deuterated silane (*S*)-**7a** was obtained with 44% *ee*.[15] Even though the-

negative charge on the carbanion is stabilized by the trimethylsilyl group, synthetically useful configurational stability was observed. Thus, the formation of a configurationally stable, enantiomerically enriched α-thioalkyllithium compound has been achieved for the first time.

Experimental Procedure

To a solution of (−)-sparteine (352 mg, 1.5 mmol) or TMEDA (174 mg, 1.5 mmol) in 10 mL of ether cooled to −78 °C was added dropwise 1.25 mmol of an approximately 1.4 M solution of *sec*-butyllithium in isopentane/cyclohexane. The reaction mixture was stirred for 10 min at −78 °C, then 1.0 mmol of the carbamate (**2a-c**, **4a**, **6a**) was slowly added dropwise and the solution stirred for a further 2.5 h. Finally, 3.0 mmol of the desired electrophile was added by syringe and the mixture stirred a further 4 h at −78 °C. The workup consisted of pouring the solution into a mixture of 20 mL of 2 N HCl and 20 mL of ether. The product was purified in the usual fashion. The resulting carboxylic acids were treated with diazomethane to provide the methyl esters **5a-c**.

[Fe(2,4,6-*t*Bu$_3$C$_6$H$_2$)$_2$], a Monomeric Diaryl Complex with Two-Coordinate Iron(II)**

Hardy Müller, Wolfgang Seidel,* and Helmar Görls

Homoleptic organo transition metal compounds with low coordination numbers are rare. This is especially true for neutral complexes of the type [MR$_n$] ($n < 4$) which are expected to exhibit interesting chemical properties based on their coordinatively unsaturated character. To date tetramesityldiiron[1] serves as the only example of a structurally characterized neutral

iron(II) complex with organic ligands. In this complex the metal atom is three-coordinate; the same coordination number is found in the analogous Co(II) complex[2a] and in $[\{Mn(mes)_2\}_3]$ (mes = 2,4,6-$Me_3C_6H_2$).[2b] Even though two-coordinate iron(II) species are rare, Power et al. were able to show that they can be prepared by employing bulky amido ligands such as $[N(SiMePh_2)_2]^-$, $[N(SiMe_2Ph)_2]^-$, and $(NmesBmes_2)^-$.[3] In the crystal, these compounds have a N-Fe-N bond angle of approximately 170°. For the vaporizable iron(II) amide $[Fe\{N(SiMe_3)_2\}_2]$ in the gas phase, the two-coordinate nature of the central metal and a N-Fe-N bond angle of 180° was confirmed by electron diffraction studies.[4] Furthermore, Power et al. recently also reported the synthesis and characterization of thiolato complexes with two-coordinate iron(II).[5]

We therefore decided to investigate whether monomeric two-coordinate iron complexes of type $[FeR_2]$ could be obtained by the use of aryl ligands with bulkier substituents than those found in the three-coordinate tetramesityldiiron $[\{Fe(mes)(\mu\text{-mes})\}_2]$. We applied 2,4,6-$iPr_3C_6H_2$ (trip), 2,4,6-$Ph_3C_6H_2$ (triph), and 2,4,6-$tBu_3C_6H_2$ (mes*) as aryl ligands.

The corresponding compounds were synthesized analogously to the preparation of tetramesityldiiron; stoichiometric amounts (1:2) of $[FeBr_2(thf)_2]$ (**1**) and Grignard reagent were allowed to react in tetrahydrofuran, after that the magnesium halides were precipitated by addition of dioxan. The reaction with (trip)MgBr afforded a brown, crystalline substance of composition **2**. This compound is a dimer and structurally similar to tetramesityldiiron.[6]

$[\{Fe(trip)(\mu\text{-trip})\}_2]$ **2**

In contrast, treatment of the iron halide with (triph)MgBr does not afford the corresponding diaryliron complex. Instead, a colorless precipitate forms which presumably is an adduct of the reactants. No change in the nature of this precipitate is observed upon treatment with dioxan.

A similar colorless, fine-crystalline precipitate of the composition **3** is initially obtained when **1** is treated with two equivalents of (mes*)MgBr in tetrahydrofuran [Eq. (a)]. Addition of dioxan, followed by removal of the solvent and extraction of the residue with *n*-pentane yielded an air- and moisture-sensitive yellow product **4** [Eq. (b)]. Its magnetic moment of 4.77 μ_B at room

$$2\,[FeBr_2(thf)_2] + 4\,(mes^*)MgBr \xrightarrow{THF} [Fe_2Mg_3Br_6(mes^*)_4(thf)_2] + MgBr_2 \quad (a)$$
(**1**) (**3**)

$$[Fe_2Mg_3Br_6(mes^*)_4(thf)_2] \xrightarrow{THF/dioxan} 2\,[Fe(mes^*)_2] + 3\,MgBr_2(dioxan)_2 \quad (b)$$
(**3**) (**4**)

temperature is appropriate for an iron(II) high-spin complex. Notably, $[\{Fe(mes)(\mu\text{-mes})\}_2]$ and **2** show a markedly smaller magnetic moment.

The homoleptic diaryliron(II) compounds prepared dissolve readily in apolar solvents. The increase in size of the substituents on the aryl ligands has a decisive influence on the reactivity. The adduct formation with nitrogen bases and concurrent cleavage of the respective dimer has been reported for **2**[6] and $[\{Fe(mes)(\mu\text{-mes})\}_2]$;[7] however, no such reaction is observed for **4**. Moreover, whereas tetramesityldiiron rapidly undergoes an insertion reaction with isocyanate or CO,[8] the same reaction occurs at a much slower rate with **4**. Complex **4** is thermally surprisingly stable (decomposition occurs at 179 °C); this is a result of the steric shielding of the central atom, which in turn kinetically disfavors the decomposition reaction.

Single crystals of **4** suitable for an X-ray structure analysis were obtained from *n*-heptane.[9] The crystal structure analysis of **4** shows the presence of two-coordinate iron(II) centers in the C_2-symmetric molecules (Fig. 1). The Fe–C1 distance (2.051(5) Å)

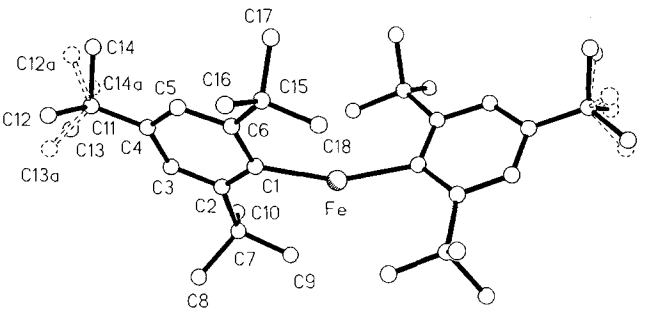

Fig. 1. Molecular structure of **4** in the crystal; selected bond lengths [Å] and angles [°]: Fe-C1 2.051(5), C1-C2 1.426(7), C1-C6 1.413(7), C2-C3 1.400(7), C3-C4 1.376(7), C4-C5 1.388(7), C5-C6 1.389(7), Fe···C18 2.822(8), Fe···C9 2.744(6), Fe···H9b 2.16#, Fe···H18c 2.33(1)#; C1-Fe-C1A 158.9(3), Fe-C1-C2 119.4(4), Fe-C1-C6 122.7(3), C1-C2-C7 124.3(4), C1-C6-C15 122.9(4), C1-C2-C3 120.2(5), C2-C3-C4 123.2(5), C3-C4-C5 116.2(5), C4-C5-C6 123.2(5), C1-C6-C5 120.8(4). Distances marked with a # were calculated based on the covalent radius of the hydrogen atom.

is comparable with the terminal Fe–C distances in tetramesityldiiron and those in **2**. The C1-Fe-C1A bond angle of 158.9(3)° is about 11° smaller than the corresponding angles in the aforementioned amides and about 17° smaller than that in $[Cu(mes^*)SMe_2]$[10] which serves as the only known compound of a 3d element with a (mes*) group. The neutral dialkylmanganese compound $[Mn\{C(SiMe_3)_3\}_2]$[11] in which the manganese(II) center is two-coordinate has a linear structure with an Mn–C bond length of 2.102 Å. The bent geometry at the iron center in **4** is most likely a result of packing effects; intermolecular interactions can be excluded. Larger deviations from a linear arrangement of ligands have also been reported for two-coordinate phosphane complexes of type $[M(PR_3)_2]$ (e.g. M = Pd, R = *c*-C_6H_{11}).[12]

An Fe···H distance of 2.1–2.3 Å can be calculated from the Fe···C9 and Fe···C18 distances of 2.744(6) Å and 2.822(8) Å, respectively. However, no evidence of agostic interactions in **4** was apparent from the IR spectrum (between 2700 and 2350 cm^{-1}) or from ^1H NMR investigations. The ^1H NMR spectrum in $[D_8]$toluene shows three paramagnetically shifted signals which are assigned to protons of the *para*- and *ortho*-*t*Bu groups and to aromatic protons. No splitting of these signals is observed even at temperatures as low as −80 °C; similar results have also been reported for thiolatoiron(II) complexes[5] and trimesitylrhodium.[13]

Experimental Procedure

All reactions were carried out under anaerobic and anhydrous conditions.

4: A solution of (mes*)MgBr (34.2 mmol, 103.5 mL) in THF was added dropwise over a period of 2.5 h to a stirred suspension of **1** (6.15 g, 17.08 mmol) in THF (30 mL). Stirring was continued for an additional 1.5 h, whereupon 1,4-dioxan (12 mL) in THF (15 mL) was slowly added to precipitate the $MgBr_2(dioxan)_2$. After 15 h the solution was evaporated to dryness and the residue was treated with *n*-pentane. After one hour the magnesium salts were collected on a filter and washed with the filtrate so to completely extract the products. The filtrate was then reduced in volume to about 30–40 mL. Crystallization was accomplished by cooling to −30 °C, and agitating the filtrate until the yellow compound started to crystallize. After 48 h the product was collected by filtration. Crystals suitable for a X-ray structure analysis were obtained upon cooling a saturated solution (*n*-heptane; 50 °C) to room temperature. Yield: 5.9 g (63%).

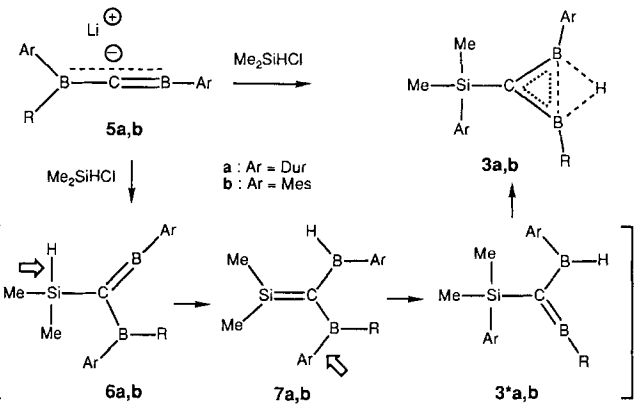
Compounds with Planar Tetracoordinate Boron Atoms: Anti van't Hoff/Le Bel Geometries without Metal Centers**

Matthias Menzel, Dirk Steiner, Heinz-Jürgen Winkler, Dieter Schweikart, Sigrid Mehle, Stefan Fau, Gernot Frenking, Werner Massa, and Armin Berndt*

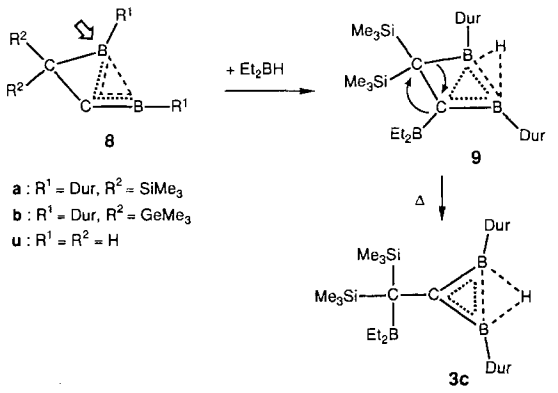


Dedicated to Prof. Paul von Ragué Schleyer on the occasion of his 65th birthday

Numerous compounds **1**[3, 4] and **2**[5] have anti van't Hoff/Le Bel geometries[1, 2] with planar tetracoordinate carbon atoms; all of them contain at least one metal atom (M = Ti, Zr, Hf...; E = H, B), and most contain even two (E = Al, Ga, Zr...) (Scheme 1). We show here by crystal structure analyses that compounds **3a** and **3c** contain planar tetracoordinate boron atoms. Compounds **3** and **4**[6] are examples of compounds having anti van't Hoff/Le Bel geometries *without* metal centers.

Scheme 1. **1**, **2**: M = Ti, Zr, Hf...; **1**: X = +, Cl, Br, CH_3; **2**: X = H, Cl, CH_3, C≡CR; E = B, Al, Ga, Zr...; **4**: R = 2,3,5,6-Me_4C_6H.

The H-bridged borylmethyleneboranes **3a, b** are obtained from the reaction of borylborataalkynes **5a, b**[6] with chlorodimethylsilane at 25 °C (Scheme 2). In these reactions a hydrogen atom is transferred from a silicon atom to a boron atom, and an



Scheme 2. R = $CH(SiMe_3)_2$; Dur = 2,3,5,6-Me_4C_6H; Mes = 2,4,6-$Me_3C_6H_2$.

aryl group from a boron atom to a silicon atom. Primary products are probably silylmethyleneboranes **6a, b**, which then give the diborylsilaethenes **7a, b** by means of a 1,3 shift of the hydrogen atom from the tetracoordinate silicon atom to the dicoordinate boron atom. The 1,3 shift of the aryl group from the boron atom with the bis(trimethylsilyl)methyl substituent R to the tricoordinate silicon atom formally leads to the classical borylmethyleneboranes **3*a, b**, which have the β-agostic[6] structure **3a, b**. Compound **3c** is formed by melting **9** (150 °C),[7] which in turn is accessible from **8a**[6] and diethylborane. In the reaction giving **3c** two boron atoms connected to the carbon atom framework change places—possibly by a double 1,2 rearrangement (Scheme 3). The respective substituents migrate together with the boron atoms.

Figure 1 shows the X-ray crystal structures of **3a** and **3c**;[8] the corresponding constitution of **3b** is deduced from the similarity of its NMR data to that of the framework atoms of **3a** and **3c** (Table 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. In this paper the unsubstituted parent compounds are denoted with the letter u, all classical structures with a star, and all α- or β-agostic structures with the subscript α or β.

Scheme 3.

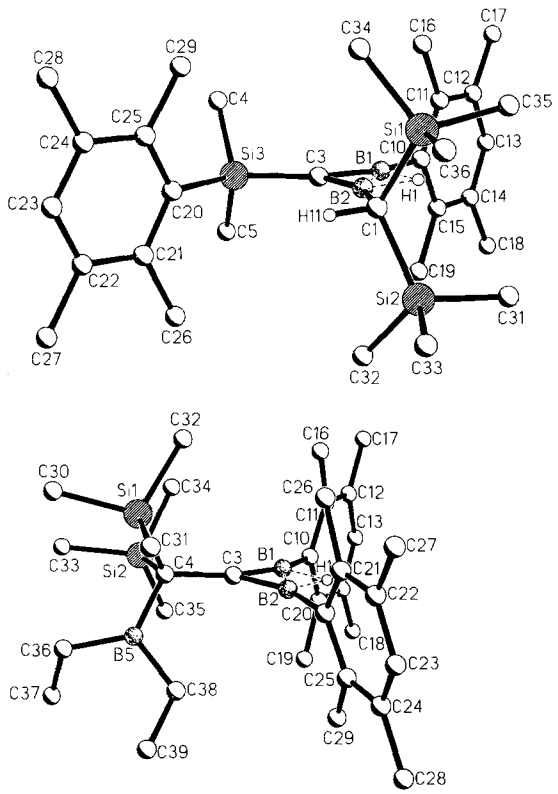

Fig. 1. Crystal structures of **3a** (top) and **3c** (bottom). Selected distances [pm] and angles [°] supplementary to the data in Table 2: **3a**: B1-C10 156.4(4), B2-C1 155.0(4), C3-Si3 183.5(2); B1-C3-B2 74.9(2), B1-B2-C3 52.3(2), C3-B1-C10 149.3(2), C3-B2-C1 150.4(2), B1-C3-Si3 142.1(2), B2-C3-Si3 142.8(2); C10-B1-B2-C1 −1.6(10), C10-B1-B2-C3 −178.1(6). **3c**: B1-C10 156.7(4), B2-C20 157.3(4), C3-C4 151.8(3); B1-C3-B2 73.1(2), B1-B2-C3 53.3(2), C3-B1-C10 154.3(2), C3-B2-C20 152.9(2), B1-C3-C4 143.2(2), B2-C3-C4 143.6(2); C10-B1-B2-C20 −2.9(8), C10-B1-C3-C4 1.4(7).

In Table 2 the distances in the CB_2H framework of **3a** and **3c** are compared with those calculated for the unsubstituted $\mathbf{3u}_\beta$.[2, 9, 10] The scattering of the B—H distances is within the bounds of the fundamentally low precision of H atom positions determined by X-ray diffraction. In **3a** and **3c** both boron atoms lie in the best fit plane of their four neighboring atoms with deviations of 0.6(3) and 2.8(3) pm for **3a** and 1.5(3) and 1.6(3) pm for **3c**. In **4**[6] this deviation is 0.4(3) pm for B2. The boron atoms in **3a** and **3c**, and the B2 atom in **4**, are thus planar tetracoordinate.

Table 1. Some physical data for compounds **3a–c** and **9**.

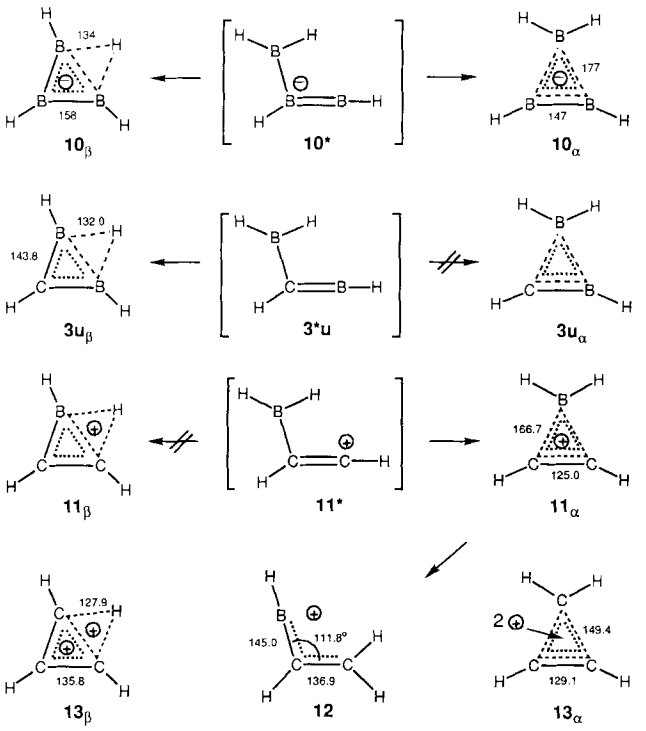
3a: colorless crystals, m.p. 174 °C, yield: 74%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 0.09$ (s, 18H, $SiMe_3$), 0.52 (s, 6H, $SiMe_2$), 0.95 (d, $^3J(H,H) = 5.2$ Hz, 1H, CH(B)), 2.12, 2.18, 2.23, 2.29 (each s, 24H, *o*- and *m*-CH_3), 6.94, 6.97 (each s, each 1H, *p*-H), 7.36 (br. s, 1H, BHB); – ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): $\delta = 1.3$ (q, 6C, $SiMe_3$), 4.8 (q, 2C, $SiMe_2$), 9.0 (br. d, $^1J(C,H) = 107.9$ Hz, 1C, CH(B)), 20.0, 20.1, 20.7, 21.2 (each q, 8C, *o*- and *m*-CH_3), 130.4 (br. s, 1C, CB_2), 131.4, 132.1 (each d, each 1C, *p*-C), 134.4 (br. s, 1C, *i*-C(B)), 133.1, 133.3, 136.2, 140.0 (each s, 8C, *o*- and *m*-C), 137.8 (s, 1C, *i*-C(Si)); – ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 29$

3b: colorless oil, yield: 70%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 0.33$ (s, 18H, $SiMe_3$), 0.77 (s, 6H, $SiMe_2$), 1.21 (d, $^3J(H,H) = 4.9$ Hz, 1H, CH(B)), 2.47, 2.52, 2.58, 2.65 (each s, 18H, *o*- and *p*-CH_3), 7.00, 7.07 (each s, each 2H, *m*-H), 7.53 (br. s, 1H, BHB); – ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 1.5$ (q, 6C, $SiMe_3$), 5.0 (q, 2C, $SiMe_2$), 9.6 (br. d, $^1J(C,H) = 105.7$ Hz, 1C, CH(B)), 20.9, 21.2, 23.1, 24.9 (each q, 6C, *o*- and *p*-CH_3), 127.4, 128.8 (each d, each 2C, *m*-C), 130.6 (br. s, 1C, *i*-C(B)), 133.3 (s, 1C, *i*-C(Si)) 138.0, 138.3 (each s, each 1C, *p*-C) 141.1, 143.9 (each s, each 2C, *o*-C); – ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 29$

3c: colorless crystals, m.p. 157 °C (decomp.), yield: 98%. – ^{1}H NMR (500 MHz, $CDCl_3$, −30 °C): $\delta = 0.03$ (s, 18H, $Si(CH_3)_3$), 0.95 (t, 6H, CH_2CH_3), 1.25 (q, 4H, CH_2CH_3), 2.20, 2.24 (each s, each 12H, *o*- and *m*-CH_3), 6.95 (s, 2H, *p*-H), 7.83 (br. s, 1H, BHB); – ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): $\delta = 2.4$ (q, 6C, $Si(CH_3)_3$), 9.1 (q, 2C, CH_2CH_3), 19.4 (br. t, 2C, CH_2CH_3), 20.0, 21.0 (each q, each 4C, *o*- and *m*-CH_3), 43.2 (s, 1C, CSi_2), 131.3 (d, 2C, *p*-C), 133.3, 136.1 (each s, each 4C, *o*- and *m*-C), 135.1 (br. s, 2C, *i*-C), 144.2 (br. s, 1C, CB_2); – ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 24, 82$

9: colorless solid, m.p. 148 °C (decomp.), yield: 81%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = -0.08, 0.26$ (each s, each 9H, $Si(CH_3)_3$), 1.14 (t, 6H, CH_2CH_3), 1.48 (q, 4H, CH_2CH_3), 1.96 (br.), 2.24, 2.29 (br.), 2.33, 2.45 (br.), 2.59 (each s, together 24H, *o*- and *m*-CH_3), 4.43 (br. s, 1H, BHB), 7.02, 7.12 (each s, each 1H, *p*-H); – ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 1.2$, 1.6 (each q, each 3C, $Si(CH_3)_3$), 9.5 (q, 2C, CH_2CH_3), 19.3 (br. t, 2C, CH_2CH_3), 20.2, 20.3, 21.1 (each q, together 8 °C, *o*- and *m*-CH_3), 28.8 (s, 1C, CSi_2), 86.2 (br. s, 1C, CB_2), 131.7, 134.7 (each d, each 1C, *p*-C), 132.6, 133.1, 137.0, 139.3, 140.0 (each s, together 8 °C, *o*- and *m*-C), 133.4, 133.6 (each br. s, each 1C, *i*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 5, 50, 80$

The three-center/two-electron (3c2e) bonds B—H—B in **3a–c** and B—B—B in **4** correspond to the 3c2e bonds M—H—C in **1** and M—E—C in **2**, respectively (Scheme 1). Planar tetracoordinate boron atoms are also present in the recently calculated structures $\mathbf{10}_\beta$ and $\mathbf{10}_\alpha$;[12] $\mathbf{10}_\beta$ is isoelectronic with $\mathbf{3u}_\beta$, and $\mathbf{10}_\alpha$ can be regarded as boryldiboranide(3) **10*** with a strong α-agostic[13, 14] interaction.



In order to determine the importance of the electronegativity for planar tetracoordinate boron atoms, we carried out MP2/6-31G* calculations on the β-borylvinyl cation **11***, which is isoelectronic with **3*u** and **10***.[15] Instead of finding the β-agostic bridged $\mathbf{11}_\beta$, which corresponds to $\mathbf{10}_\beta$ and $\mathbf{3u}_\beta$, $\mathbf{11}_\alpha$ corresponding to $\mathbf{10}_\alpha$ is found to be a minimum-energy structure; the boron atom of $\mathbf{11}_\alpha$ is planar tetracoordinate as a result of a strong α-agostic interaction. However, structure $\mathbf{11}_\alpha$ is 13.8 kcal mol^{-1} higher in energy than the classical 1-boraallyl cation **12**: the marked electron deficiency at the C^+ center in **11*** leads to the transfer of a hydride ion, that is, to a rearrangement—the extreme case[6] of an agostic interaction.[16]

Dications $\mathbf{13}_\alpha$ and $\mathbf{13}_\beta$ with planar tetracoordinate C atoms, isoelectronic with $\mathbf{3u}_\beta$, $\mathbf{10}_\beta$, and $\mathbf{11}_\beta$, and $\mathbf{10}_\alpha$ and $\mathbf{11}_\alpha$, respectively,

Table 2. Experimentally determined (**3a**, **3c**) and calculated [q][a] ($\mathbf{3u}_\beta$) distances in the CB_2H frameworks.

	3a	3c	$3u_\beta$
B1-B2	175.1(4)	173.5(4)	170.9
B1-C3	143.5(4)	145.4(4)	143.8
B2-C3	144.4(4)	146.2(4)	143.8
B1-H	128(2)	125(2)	132.0
B2-H	131(2)	124(2)	132.0

[a] MP2/6-31G* level.

are 14.4 and 14.6 kcal mol^{-1} higher in energy than the planar allene dication.[17]

The formation of compounds with anti van't Hoff/Le Bel geometries thus requires electropositive elements: in addition to metals, boron is also suitable.

[4] In the literature compounds of type **1** are not explicitly included with those having planar tetracoordinate C atoms. However, their C–H β-agostic interaction corresponds to the C–E β-agostic interactions in **2**: the β-C–M distances—considered a criterion for the fourth coordination of the β-C atom—in **1** are only slightly longer than those in **2**.

[7] The constitution of **9** ensues from the similarity of the chemical shifts of its framework atoms with those of known nonclassical 1,2-diboretanes: D. Steiner, C. Balzereit, H. J. Winkler, N. Stamatis, M. Hofmann, P. von R. Schleyer, W. Massa, A. Berndt, *Angew. Chem.* **1994**, *106*, 2391–2394; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 2303–2306.

[8] Crystal structure determinations: Colorless crystals of **3a** and **3c** were examined on a four-circle diffractometer (CAD4, Enraf-Nonius) at −60 and 25 °C, respectively, with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). **3a**: ($C_{30}H_{52}B_2Si_3$) crystal dimensions $0.4 \times 0.3 \times 0.3$ mm^3, monoclinic, space group $P2_1/n$, $Z = 4$, $a = 927.2(2)$, $b = 2792.9(6)$, $c = 1329.5(3)$ pm, $\beta = 105.16(3)°$, $V_{EZ} = 3323.0 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.037$ g cm^{-3}; in total, 4370 reflections were measured with ω scans in the range up to $2\theta = 110°$; all 4162 independent reflections were used for the further calculation after LP correction (LP = Lorentz Polarization); no absorption correction ($\mu = 14.1$ cm^{-1}). The structure was solved by direct methods and refined against the F_o^2 data with full matrix. Most of the H atoms, in particular that bonded to the boron atoms, could be localized from difference Fourier syntheses, the positions of the rest were calculated. The H1 atom bonded to B1 and B2 could be freely refined with an isotropic temperature factor. The standard deviations of the site parameters of between 2.2 and 2.4 pm and the low temperature factor ($U = 0.046(6) \times 10^{-20}$ m^2 [= Å^2]) unequivocally indicate the good reliability of localization. All other H atoms were included riding on their bonding partners in groups with common isotropic temperature factors. Anisotropic temperature factors were used for all heavier atoms. The result was $wR_2 = 0.1112$, corresponding to $R = 0.0406$ for 3482 reflections $> 4\sigma(F_o)$, the maximum residual electron density was 0.29 e Å^{-3}. **3c**: ($C_{32}H_{56}B_2Si_2$) crystal dimensions $0.6 \times 0.3 \times 0.3$ mm^3, triclinic, space group $P\bar{1}$, $Z = 2$, $a = 885.3(2)$, $b = 1189.1(2)$, $c = 1605.4(3)$ pm, $\alpha = 93.41(3)°$, $\beta = 96.07(3)°$, $\gamma = 92.89(3)°$, $V_{EZ} = 1674.8 \times 10^{-30}$ m^3, $\rho_{calcd} = 1.048$ g cm^{-3}; in total, 4476 reflections were measured with ω scans in the range up to $2\theta = 110°$; all 4142 independent reflections were used for the further calculation after LP correction; no absorption correction ($\mu = 10.7$ cm^{-1}). The structure solution and refinement as carried out for **3a** led to $wR_2 = 0.1479$. $R = 0.049$ for 3686 reflections $> 4\sigma(F_o)$; the maximum residual electron density was 0.38 e Å^{-3}. Analogous to **3a**, the H1 atom in this case was also clearly localized (standard deviations of the site parameters 1.8–2.4 pm; $U = 0.040(6) \times 10^{-20}$ m^2 [= Å^2]). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-58730.

[10] Our own calculations for CB_2H_4 show [11] that **3u$_\beta$** is not only an energy minimum ($i = 0$), but also the global minimum on the potential energy surface. The energetically next highest lying isomer, the B-borylmethyleneborane $H_2C{=}B{-}BH_2$ (C_{2v}), is 30.6 kcal mol^{-1} (MP4/6-311G(2df,2pd)//MP2/6-31G(d)) less stable. The deep potential minimum of **3u$_\beta$** is also given by the calculated vibrational frequency for the out-of-plane mode of the bridging H atom, which is rather high at 504.7 cm^{-1} (MP2/6-31G(d)). The parent framework **3u$_\beta$** is thus energetically very stable according to the calculations.

[13] Bühl et al. recently recognized a planar tetracoordinate boron atom in the α-agostic distorted borylmethyleneborane **8u** (Scheme 3) [14]. In **8b** [6] the tetracoordinate boron atom lies 6.8 pm outside the plane of best fit of its four neighbors. Its bond to the duryl substituent is bent by 6.4° with respect to the plane of the framework atoms, probably owing to steric reasons.

[15] The geometries were optimized to the MP2/6-31G* level with the program GAUSSIAN 92: Gaussian 92, Revision A, M. J. Frisch, G. W. Trucks, H. Head-Gordon, P. M. W. Gill, M. W. Wond, J. B. Foresman, H. B. Schlegel, K. Raghavachari, M. A. Robb, J. S. Binkley, C. Gonzalez, R. Martin, D. J. Fox, D. J. DeFrees, J. Baker, J. J. P. Stewart, J. A. Pople, Gaussian, Inc. Pittsburgh, PA, **1992**.

[16] Structure **11$_\beta$**, in which the bridging H atom is 121.4 pm from the boron atom and 170.3 pm from the C atom (C–C 127.6, C–B 153.9 pm), is the transition state for the 1,2-H rearrangement **11$_\alpha$** → **12**. The activation barrier at the MP2/6-31G* + ZPE level is 3.7 kcal mol^{-1}.

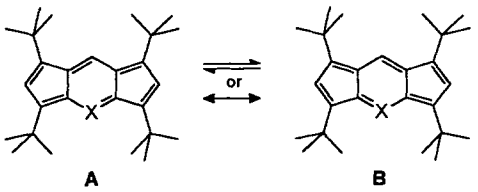
1,3,5,7-Tetra-*tert*-butyl-4-aza- and 1,3,5,7-Tetra-*tert*-butyl-4-phospha-*s*-indacene**

Teodor Silviu Balaban, Stefan Schardt, Volker Sturm, and Klaus Hafner*

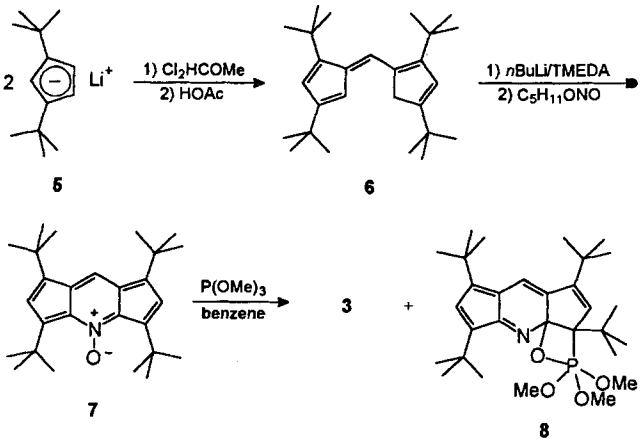
Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

s-Indacene (**1**),[1] a tricyclic, nonalternating [4n]π system, has been the subject of repeated theoretical and experimental investigations. Formally, **1** may be regarded as a [12]annulene perturbed by two σ bonds, and can therefore be considered as an antiaromatic compound. According to calculations carried out previously for **1**,[2-4] a ground state structure with localized double bonds and the C_{2h}-symmetrical π-bonding was suggested for isomers **1A** and **1B**.



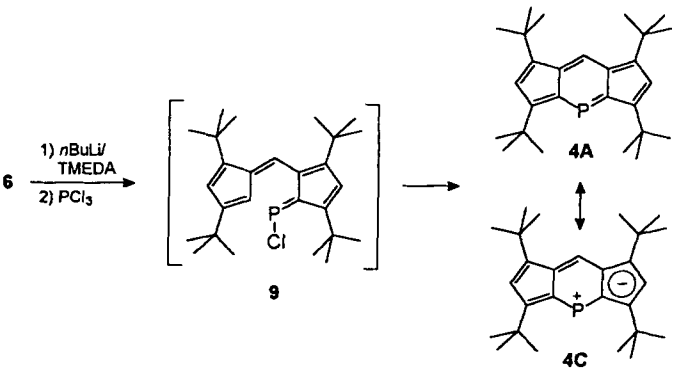
1: R=H
2: R=*t*Bu

In contrast to **1**, which could not be isolated, the kinetically stabilized 1,3,5,7-tetra-*tert*-butyl-*s*-indacene **2** has been found to be a stable compound. The D_{2h} structure with equidistant bond lengths established for **2** by an X-ray structure analysis[5,6] was attributed to an unusually strong electronic influence of the *tert*-butyl groups.[7] On the other hand, according to recent quantum chemical calculations by Koch et al.,[8] **1** is also expected to exist in the ground state as a delocalized π system with a D_{2h} structure. The limited stability of **1** is a consequence of the considerable singlet-diradical character of the *s*-indacene system.



Only a few investigations of hetero-*s*-indacenes have been carried out so far. Owing to the electronically stabilizing substituents, the donor-substituted 1,3,5,7-tetrakis(diethylamino)-2,6-diaza-*s*-indacene synthesized by Gompper et al.[9] is not suitable for obtaining information about the influence of the nitrogen atoms on the π perimeter. The introduction of one nitrogen atom or a different heteroatom into the fully conjugated *s*-indacene system has not been described hitherto. Herein we report on the syntheses of 1,3,5,7-tetra-*tert*-butyl-4-aza-*s*-indacene (**3**) and its phospha-analogue (**4**) as well as on their bonding in comparison to that of the carbocycle **2**.

For the synthesis of **3**, (*E*)-1,3-di-*tert*-butyl-5-(2,4-di-*tert*-butylcyclopenta-1,3-dienylmethylidene)cyclopenta-1,3-diene (**6**) was prepared by reaction of lithium 1,3-di-*tert*-butylcyclopentadienide (**5**) with half an equivalent of 1,1-dichloromethyl methyl ether.[10-12] This could be transformed by deprotonation with



3: X=N
4: X=P

n-butyllithium in the presence of TMEDA and subsequent treatment with isoamyl nitrite into 1,3,5,7-tetra-*tert*-butyl-4-aza-*s*-indacene-*N*-oxide (**7**), which was obtained in 42% yield as a dark blue, fine crystalline powder (m.p. 261-263 °C (decomp.)).[13] Deoxygenation of **7** to give the 4-aza-*s*-indacene **3** was achieved with trimethyl phosphite in boiling benzene. This afforded the tricycle **3** in 75% yield as an extremely unstable, dark red solid (m.p. 136-138 °C (decomp.)). In addition to **3**, small amounts of the 1,2λ^5-oxaphosphetane **8** (bordeaux red plates, m.p. 181 °C, 17% yield) were isolated, whose structure was established by an X-ray structure analysis.[14]

In analogy to the synthesis of **7**, the pentafulvene **6** was deprotonated (*n*BuLi/TMEDA) and subsequently treated with phosphorus trichloride at −50 °C to give rise to the 1,3,5,7-tetra-*tert*-butyl-4-phospha-*s*-indacene **4**, which could be isolated as blue-black crystals with a metallic luster (m.p. 221-222 °C (decomp.), 75% yield). At room temperature **4** may be stored for several weeks under an inert atmosphere, and is only poorly soluble in organic solvents giving intense dark blue solutions. In the synthesis of **4**, the 6-phosphapentafulvene derivative **9**[15] may be

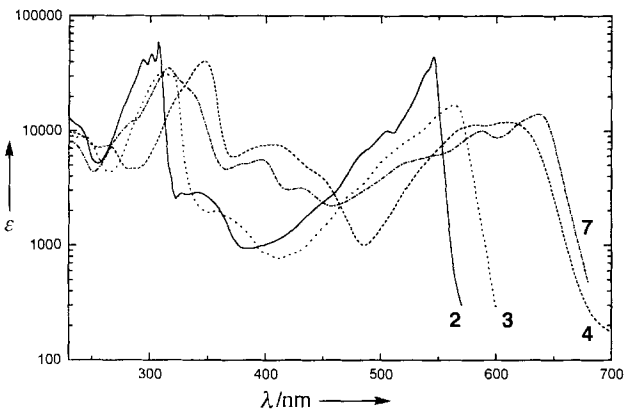
an intermediate, whose 12π-electrocyclization and subsequent hydrogen chloride elimination generate the heterocycle **4**.

The spectroscopic data of the azaindacene **3** (see below) suggest only a slight perturbation of the electronic structure by the introduction of the nitrogen atom into the 4-position of the 12π perimeter of **2**. A potential loss of symmetry through localized double bonds is not observed. The 300 MHz ^{1}H NMR spectrum shows, in addition to two singlets for the *tert*-butyl groups, a common singlet for 2-H and 6-H, as well as one for 8-H. In the ^{1}H broadband decoupled ^{13}C NMR spectrum, six singlets are observed for the eleven ring carbon atoms. These data may be interpreted on the assumption of a C_{2v}-symmetric structure with π-electron delocalization and equivalent bond lengths, as well as a rapid bond shift of the localized π-bonding isomers **3A** and **3B**. A ^{13}C NMR spectrum in [D$_8$]THF recorded at 173 K shows no splitting of the signals by "freezing" a possible π-bond shift. The proton resonances of the azaindacene **3** experience a downfield shift of $\Delta\delta = 0.1$ for the 2-, 6-, and 8-H, compared with those of **2**. This small difference in chemical shift indicates the similarity between the electronic structures of both compounds.

The NMR spectra of the phosphaindacene **4** likewise show no signal splitting due to double bond localization, neither at room temperature nor at 173 K. The resonances in the ^{1}H NMR spectrum ($\Delta\delta = 0.25$ for 2-H and 6-H and 0.37 for 8-H) display a distinctly stronger downfield shift than those of **2**. The ^{1}H broadband decoupled ^{31}P NMR spectrum of **4** with a singlet at $\delta = 258.6$,[16] indicates a comparatively strong deshielded phosphorus nucleus. This could be attributed to an appreciable contribution of dipolar resonance structures with a formal positive charge at the phosphorus atom, for example **4C**. An X-ray structure analysis of **4** did not furnish any reliable data regarding bond lengths and angles owing to statistical disorder of the molecules in the crystal.[14]

The UV/Vis spectrum of **3** in dichloromethane shows an absorption maximum at $\lambda_{max} = 314$ nm with resolved vibrational fine structure and a further maximum at 564 nm (Fig. 1). In



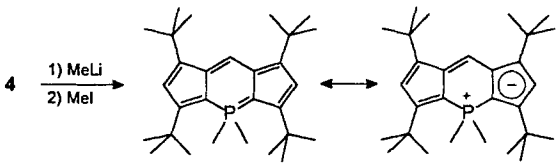


Fig. 1. UV/Vis spectra of the *s*-indacenes **2** and **3** in *n*-hexane, as well as those of **4** and **7** in CH_2Cl_2.

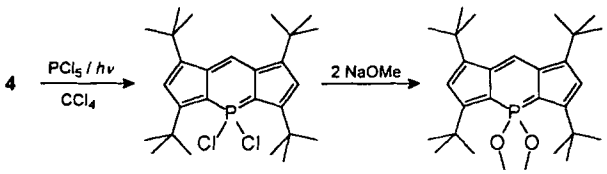
comparison with the carbocyclic *s*-indacene **2**, the absorption bands of the 4-aza-indacene **3** are shifted bathochromically by 10–15 nm with a very similar fine structure. However, the extinction coefficients of the heterocycle **3** are comparable to those of the parent system **2**. The UV/Vis absorptions of the phosphaindacene **4** ($\lambda_{max} = 346$, 582, and 610 nm) show a bathochromic shift of more than 30 nm relative to those of **2** (Fig. 1). The fact that these absorptions are shifted more bathochromically than those of the azaindacene **3** may be, presumably, attributed to a resonance structure of type **4C**.



The reaction of the phosphaindacene **4** with methyllithium, followed by addition of methyl iodide led to 1,3,5,7-tetra-*tert*-butyl-4,4-dimethyl-4λ^5-phospha-*s*-indacene (**10**), which was obtained as stable red needles (58% yield, sublimes ≥ 310 °C).

10A **10C**

In an analogy to λ^5-phosphinines,[17] the cyclic π-conjugation is partially perturbed by the formally pentavalent phosphorus. The resulting decrease of the paramagnetic ring current effect leads to downfield shifts of $\Delta\delta = 0.59$ for 2-H and 6-H and 0.75 for 8-H in the ^{1}H NMR spectrum of **10**, relative to that of the λ^3-phosphaindacene **4**. The ^{31}P resonance of **10** at $\delta = -16.7$ is in the range of usual values as expected for cyclic conjugated phosphorus ylides and suggests a substantial contribution of the resonance stabilized betaine structure of type **10C** to the ground state of the λ^5-phospha-*s*-indacene **10**.

Upon irradiation (300 W, Osram Concentra), **4** reacts with phosphorus pentachloride under radical addition of one mole equivalent of chlorine at the phosphorus atom to give 1,3,5,7-tetra-*tert*-butyl-4,4-dichloro-4λ^5-phospha-*s*-indacene (**11**) (43% yield, pale green needles, sublimes ≥235 °C). Double nucleophilic substitution in the 4-position of **11** with sodium methoxide affords the 4,4-dimethoxy derivative **12** (48% yield, black

11 **12**

crystals, m.p. 228–229 °C, soluble in organic solvents leading to an emerald green coloration).

Some spectroscopic data for the compounds **2**–**4**, **7**, **8**, and **10**–**12** [18].

2 [5]: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.18$ (s, 36 H; 1-, 3-, 5-, 7-*t*Bu), 5.29 (s, 2 H; 2-, 6-H), 6.90 (s, 2 H; 4-, 8-H); ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta = 31.2$ (C(CH_3)$_3$), 34.0 (*C*(CH_3)$_3$), 124.9 (C-2, C-6 or C-4, C-8), 129.1 (C-2, C-6 or C-4, C-8), 132.0 (C-3a, C-4a, C-7a, C-8a), 164.3 (C-1, C-3, C-5, C-7); UV/Vis (*n*-hexane): λ_{max} (lg ε) = 224 (4.10), 234 (4.03) (sh), 278 (4.23) (sh), 284 (4.37) (sh), 289 (4.48) (sh), 294 (4.61), 301 (4.66), 307 (4.77), 330 (3.45) (sh), 340 (3.48), 451 (3.41) (sh), 486 (3.83) (sh), 500 (3.96) (sh), 505 (4.01), 519 (4.11) (sh), 527 (4.26) (sh), 539 (4.51) (sh), 545 nm (4.64)

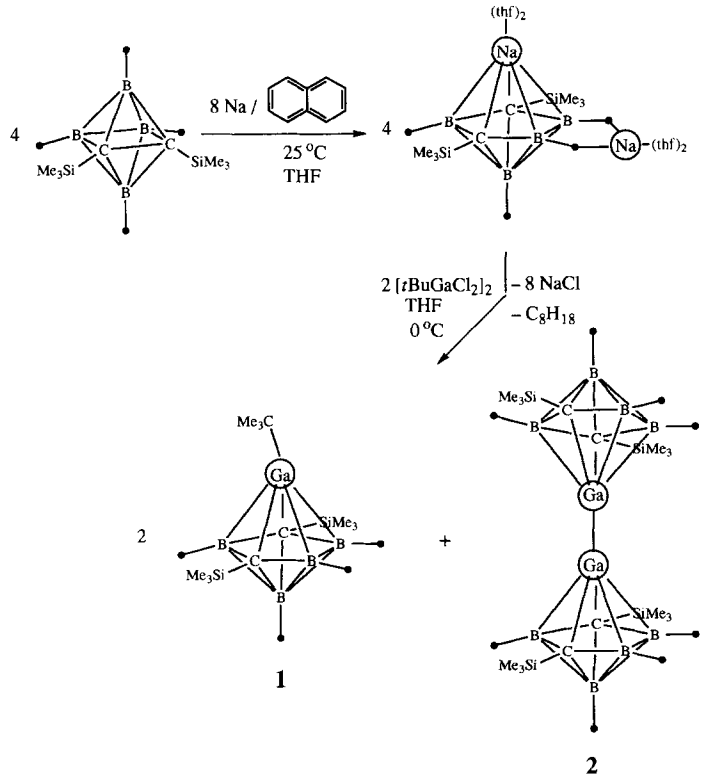
Surprising Formation of a Carborane-Substituted Digallane**

Anil K. Saxena, Hongming Zhang, John A. Maguire, Narayan S. Hosmane,* and Alan H. Cowley*



Dedicated to Professor M. Frederick Hawthorne on the occasion of his 65th birthday

Classical inorganic compounds with Ga–Ga bonds such as Ga_2Br_3[1] have been known for several years. However, organometallic derivatives with Ga–Ga bonds are of newer vintage,[2] and structurally characterized examples are restricted to the Ga^I and Ga^{II} compounds [GaC(SiMe$_3$)$_3$]$_4$[3] and Ga_2R_4 (R = (Me$_3$Si)$_2$CH,[4] 2,4,6-iPr$_3$C$_6$H$_2$,[5] and 2,4,6-(CF$_3$)$_3$C$_6$H$_2$[6]). We report a new class of compound in which the Ga–Ga bond is supported by 2,4-dicarba-*nido*-hexaborate(2$^-$) carborane ligands.

The reaction of one equivalent of [Ga(tBu)Cl$_2$]$_2$ with two equivalents of the disodium compound of *closo-exo*-5,6-Na(thf)$_2$-1-Na(thf)$_2$-2,4-(SiMe$_3$)$_2$-2,4-$C_2B_4H_4$[7] afforded a mixture of two products, **1** and **2** (Scheme 1), which were separated by fractional distillation and sublimation. Compound **1** is an air- and moisture-sensitive colorless oil for which the overall

Scheme 1. • = H.

composition $C_{12}H_{31}B_4GaSi_2$ was established on the basis of elemental analysis and high-resolution mass spectrometry.[8] The ^{1}H, ^{13}C, and ^{11}B NMR spectra for **1** are very similar to those of the structurally characterized "carbons adjacent" isomer, *closo*-(*t*Bu)Ga-2,3-(SiMe$_3$)$_2$-2,3-$C_2B_4H_4$,[9] hence a *closo* structure with an η^5 attachment of the Ga*t*Bu moiety to the carborane cage can also be proposed in this case.

Compound **2** is an air- and moisture-sensitive solid with an empirical composition $(Me_3SiC)_2(BH)_4Ga$. The ^{11}B NMR spectrum of **2**[8] indicated the presence of three basal boron atoms and one apical boron atom. These observations, together with the detection of basal carbon atoms in the ^{13}C NMR spectrum and trimethylsilyl groups in the ^{1}H NMR spectrum, imply the presence of intact Me_3Si-substituted C_2B_3 moieties. It is significant that no peaks corresponding to *t*Bu groups were evident in either the ^{13}C or ^{1}H NMR spectra of **2**. In the EI high-resolution mass spectrum, the peak corresponding to the dimer at m/z = 574.1765 was accompanied by a cluster of other peaks with the appropriate isotopic intensities. Other prominent clusters of peaks corresponded to [dimer − Me]$^+$ and [monomer].$^+$ There was no mass spectrometric evidence for gallium hydride entities; moreover, no IR absorptions or Raman bands were detected in the Ga–H stretching region.

Confirmation of the structure of **2** was provided by X-ray crystallography.[10] The crystalline state comprises discrete dimeric molecules (Fig. 1) and there are no unusually short intermolecular contacts. In accord with the spectroscopic data, there are no indications of Ga–H bonds and the Ga–Ga distance in **2** (2.340(2) Å) is more than 0.2 Å shorter than the formally nonbonded Ga···Ga distances in the hydride-bridged species Ga_2H_6 (2.580(2) Å)[11] and $Me_2Ga(\mu\text{-}H)_2GaMe_2$ (2.610(5) Å).[12] The Ga–Ga distance in **2** is also shorter than those in the digallanes $Ga_2\{CH(SiMe_3)_2\}_4$ (2.541(1) Å),[4] Ga_2(2,4,6-*i*Pr$_3$C$_6$H$_2$)$_4$ (2.513(3) Å)[5] and Ga_2(2,4,6-(CF$_3$)$_3$C$_6$H$_2$)$_4$ (2.479(1) Å).[6] Interestingly, within experimental error, however, the Ga–Ga distance in **2** is equal to that in the anion radical $[Ga_2(2,4,6\text{-}iPr_3C_6H_2)_4]^{\cdot -}$ (2.343(2) Å)[5] and together they represent the shortest Ga–Ga distances known. Modeling studies[13] reveal that the steric protection of the Ga–Ga bond in **2** is significantly less than that in previous digallanes. It is therefore possible that the bond length in **2** corresponds to that of a "normal" Ga–Ga single bond in an organometallic compound.[14]

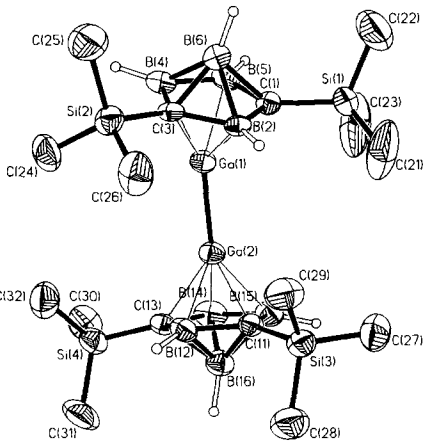

Fig. 1. Crystal structure of **2** showing the atom numbering scheme. The silyl-H atoms are omitted for clarity. Pertinent distances [Å] and angles [ ]: Ga(1)-Ga(2) 2.340(2), Ga(1)-Cnt(1) 1.679, Ga(1)-C(1) 2.164(8), Ga(1)-B(2) 2.232(11), Ga(1)-C(3) 2.146(10), Ga(1)-B(4) 2.145(11), Ga(1)-B(5) 2.125(10), Ga(2)-Cnt(2) 1.679, Ga(2)-C(11) 2.171(7), Ga(2)-B(12) 2.241(10), Ga(2)-C(13) 2.160(8), Ga(2)-B(14) 2.136(15), Ga(2)-B(15) 2.136(11); Cnt(1)-Ga(1)-Ga(2) 159.6, Cnt(2)-Ga(2)-Ga(1) 164.4. Cnt = center of the C_2B_3 ring.

When the disodium precursor was replaced by the corresponding dilithium species in Scheme 1, the *closo*-gallacarborane **1** was produced exclusively without the elimination of the *t*Bu group,[15] indicating that the reaction of the dilithium compound with $[Ga(t\text{Bu})Cl_2]_2$ involves a straightforward ligand replacement process to give **1**. While the mechanism for the formation of **2** is not known, the dependence of the reaction on the nature of the alkali metal in the carborane precursor indicates that **2** is probably not the result of a simple elimination of *t*Bu groups during the isolation of **1** by vacuum distillation. In principle, one would expect that such an elimination would favor the formation of a hydride-bridged species, such as $[(\text{carborane})Ga(\mu\text{-}H)]_2$, rather than **2**. However the absence of any evidence for Ga–H containing species with either the dilithium or the disodium compound tends to argue against extensive decomposition of **1** during the isolation process. Interestingly, we were not able to isolate **2** from the reaction of the dicarba-*nido*-hexaborate(2$^-$) ion with $Ga_2Cl_4 \cdot 2$dioxane or $GaCl_3$.

Finally, we note that the attachment of each Ga atom to the respective C_2B_3 carborane face is "slip distorted" in the sense that the Ga(1)–B(2) and Ga(2)–B(12) distances are about 0.1 Å longer than the other distances between the Ga atoms and the corresponding C_2B_3 moiety. The rotational orientation of the two C_2B_3 faces is such that the C(13)-Ga(2)-Ga(1)-C(3) dihedral angle is 58.3°.

Experimental Procedure

A sample of *closo-exo*-5,6-Na(thf)$_2$-1-Na(thf)$_2$-2,4-(SiMe$_3$)$_2$-2,4-$C_2B_4H_4$ (8.04 mmol) [7] was allowed to react for 4 h with anhydrous [*t*BuGaCl$_2$]$_2$ (1.59 g, 4.02 mmol) in dry THF (25 mL) at 0 °C, during which time the solution turned to pale yellow and some gray solid started to precipitate. At this point, the solvent and C_8H_{18} (spectroscopically identified but not measured) were removed from the heterogeneous product mixture resulting in a gray semi-solid. This residue was then subjected to a sequential fractional distillation/sublimation procedure. A colorless

oily liquid, later identified as **1**, was collected at 80–85 °C at 1.3 kPa pressure in a detachable U-trap held at 0 °C (1.02 g, 2.96 mmol, 37%). After further heating of the gray residue at 110–120 °C in vacuo, a colorless transparent crystalline solid, identified as **2**, sublimed out of the reaction flask and was collected in a second detachable U-trap at 0 °C (the side arms of both the reaction flask and the U-trap were maintained at about 100 °C with heating tape during the sublimation). The yield of highly air- and moisture-sensitive **2** was 13% (0.308 g, 0.536 mmol). Compound **2** (m.p. 48–49 °C) is soluble in both polar and nonpolar organic solvents. The gray residue that remained in the flask after the second sublimation was found to be insoluble in polar and nonpolar organic solvents and was discarded.

The Cope Rearrangement Transition Structure Is Not Diradicaloid, but Is It Aromatic?**

Haijun Jiao and Paul von Ragué Schleyer*

Any problem that has generated nearly a half century of controversy is not solved easily. What is the "precise mechanism" of the parent, degenerate Cope rearrangement of 1,5-hexadiene (**1**) (Scheme 1)?[1–4] Does the favored pathway with chairlike

Scheme 1. The stepwise and synchronous mechanisms of the Cope rearrangement. Transition structures with chair and boat conformations are possible.

transition structures follow a stepwise mechanism via a C_{2h}-symmetrical intermediate **3** (**3a**) and two equivalent C_2-symmetrical transition structures, **2** and **2'**, or is this a synchronous, fully concerted process in which the C_{2h}-symmetrical structure **3a** describes the only transition structure? What is the mechanism of the alternative route via boatlike transition structures, which are roughly 11 kcal mol^{-1} higher in energy?[4b] Do the transition states or intermediates have "diyl" character, in other words "diradicaloid" (singlet diradical) character, or are they better described as "delocalized" or "aromatic"?

Using experimental reference data which later proved to be inaccurate, Doering et al. estimated in 1971 that the hypothetical 1,4-cyclohexanediyl (**4**) was 33.7 kcal mol^{-1} higher in energy than 1,5-hexadiene (**1**).[4a] This value was essentially identical with the measured activation enthalpy of 33.5 ± 0.5 kcal mol^{-1} for the favored Cope pathway via chairlike transition structures.[4a] When the latest group enthalpy increments by Cohen and Benson are used,[4f] 1,4-cyclohexanediyl (**4**) appears to be 42 kcal mol^{-1} higher in energy than **1**. Hence, the likelihood of a diradicaloid mechanism is sharply diminished, and "the archetypal Cope rearrangement" is "restored securely to the land of concert."[4g] The dissociation of **1** into two allyl radicals (**5**) also is not competitive, since it is endothermic by 59.7 kcal mol^{-1}.[4c] Thus, our best estimates of the "energy of concert"[3c] are now 26.2 kcal mol^{-1} (based on **5**) and roughly 9 kcal mol^{-1} (based on **4**).

Likewise, the long-held assumption that only multireference ab initio treatments, which are capable of describing concerted and diradical transition states equally well, could provide unbiased calculations on the Cope rearrangement, was not confirmed.[2a–d] However, analysis of the CAS-MCSCF wavefunc-

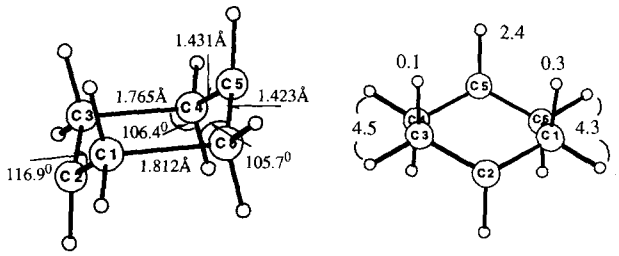
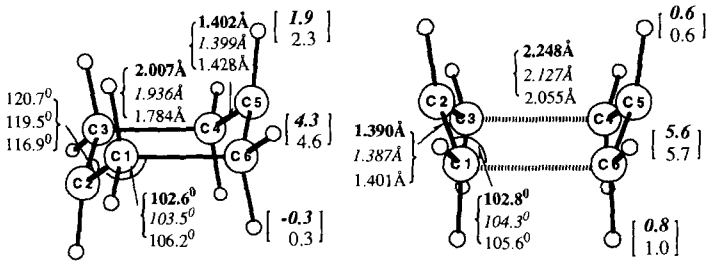
[**] This work was supported by the Fonds der Chemischen Industrie, the Convex Computer Corporation, the Deutsche Forschungsgemeinschaft, and the Volkswagen-Stiftung. We also thank Prof. W. Kutzelnigg and Prof. W. T. Borden for helpful suggestions, and the Shanxi Normal University (the People's Republic of China) for a scholarship (to H. J.).

tion revealed "that the chair transition structure has little diradical character."[2c, d] In their most recent CASPT2N study Borden et al. found the degenerate Cope rearrangement of 1,5-hexadiene (**1**) to be synchronous.[2f] A delocalized, rather than a diyl structure best describes transition structure **3**. Unlike earlier theoretical results (e.g. at CASSCF/6-31G*),[2d] the most recent computations, including our own, show that single-determinant theory with electron correlation (e.g. MP4SDTQ/6-31G*) yield results in excellent agreement with experiment, both in terms of the energies and the kinetic isotope effects.[2i]



Hence, the mechanism of the parent Cope rearrangement is not "diradicaloid", but is it "aromatic"? To provide an answer, we have computed the magnetic properties of **1**–**4**. Several pericyclic reactions,[5] including the degenerate Cope rearrangement of semibullvalene,[5a,f] have already been examined in this manner. The shape of the potential energy surface (PES) around the C_{2h}-symmetrical structure **3a** varies with the theoretical level. Even though the PES is quite flat, we now find that this does not have any important consequence on the computed magnetic properties. Thus, there is no basic difference in the electronic structure of the transition structures for the synchronous (C_{2h}) and stepwise (C_2) mechanisms.

We employed frequency computations[6, 7] at three different *ab initio* levels with electron correlation (MP2(fc)/6-31G*, CID/6-31G*, and density functional theory (DFT)) to characterize the potential energy surfaces.[6b–d] DFT optimizations (Becke3LYP/6-311 + G*) employed Becke's three-parameter exchange functional with the correlation functional of Lee, Yang, and Parr, which includes both local and nonlocal DFT terms.[6b–d] While the "boat" pathway only has a single transition structure (**3a**) with one imaginary frequency (531 $i\,cm^{-1}$ (MP2), 809 $i\,cm^{-1}$ (CID), 499 $i\,cm^{-1}$ (Becke3LYP)), the nature of the "chair" pathway changed from level to level.



At MP2/6-31G* the C_{2h}-symmetrical form **3a** (Fig. 1, cf. Table 1) corresponds to a *minimum* (the lowest frequency was 109 cm^{-1}). The related transition structure **2** (C_2) (note the

[a] This work. [b] In ref. 33 there.

closely related geometries of **2** and **3a**, Fig. 1) is characterized by one imaginary frequency (-143 cm^{-1}) but has almost exactly the same energy as **3a** (33.4 kcal mol^{-1}). The single-point energies at MP4SDTQ/6-31G* and at QCISD(T)/6-31G*, computed using the MP2/6-31G*-optimized geometries, also were nearly the same (within 0.2 kcal mol^{-1}, see Table 2). However, MP2 calculations tend to *overestimate* the effects of electron delocalization, for example the resonance energy of benzene.[7c] The same also may be true of CASPT2N calculations, which use second-order perturbation theory to obtain the dynamic correlation energy for all the electrons, starting from a CASSCF reference wave function.[2f]

Indeed, reoptimization at the levels CID/6-31G*, CISD/6-31G*, and Becke3LYP/6-311 + G* gave geometries for **3a** that were less compact than those at the MP2/6-31G* and CASPT2N levels (Table 1, Fig. 1). Moreover, **3a** was a *transition structure* with one large imaginary frequency both at CID/6-31G* (784 $i\,cm^{-1}$) and at Becke3LYP (579 $i\,cm^{-1}$).

Geometries: The starting compound 1,5-hexadiene (**1**) corresponds to a minimum (no imaginary frequencies at MP2, CID, and Becke3LYP) in the C_{2h}-symmetrical conformation; the geometries are all nearly the same (Fig. 1). Except for the value of 1.428 Å obtained with MP2, the C–C bond lengths of the allyl moieties in **3a** (C_{2h}) and in **3b** (C_{2v}) (Table 1) are all close to the allyl[5g] and benzene values (ca. 1.395 Å).[5a, b] The more critical C1 ··· C6 separations between the allyl units in **3b** (C_{2v}) and especially in **3a** (C_{2h}) are unusually sensitive to changes in the theoretical level (Table 1).[2j] The distances from MP2/6-31G*, MP4SDTQ/6-31G*, QCISD(T)/6-31G* calculations are shorter, but at the other levels the distances are more consistent with the approximately 2.08 Å separation in **3a** reported by Houk et al.[2i] in a recent theoretical analysis of the experimental kinetic isotope effects. The C1 ··· C6 separations in **3b** appear to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0335 $ 10.00+.25/0

be about 0.2 Å longer than in **3a**. These C–C distances are typical for bond formation or cleavage in many computed aromatic transition structures for pericyclic reactions.[2e]

Although useful for our analysis of the energies (see above) and magnetic properties, the MP2(fc)/6-31G* and CASPT2N geometries appear to be too compact. The chairlike MP2(fc)/6-31G* transition structure **2** with reduced C_2 symmetry (Fig. 1) may be an artifact. In **2**, the forming C1–C6 bond is 1.812 Å long, whereas the breaking C3–C4 bond is 1.765 Å long. The average value, 1.788 Å, is nearly the same as that in the symmetric intermediate **3a** at the same level of theory (1.784 Å).

Energies: The relative energies computed at various high theoretical levels are summarized in Table 2. These, along with the calculated thermal energies, give the activation enthalpies $\Delta H^{\neq}$ (500 K) which can be compared with the experimental data. Note that **2** and **3a** have nearly the same energy when the MP2(fc)/6-31G* geometries are employed (where the latter structure corresponds to a minimum).

Table 2. The calculated relative electronic energies E_{rel} and the activation enthalpies $\Delta H^{\neq}$ (both in kcal mol^{-1}, computed to 500 K) for the parent Cope rearrangement compared with the measured values.

[a] MP2(fc)/6-31G* frequencies were employed. [b] CID/6-31G* frequencies were employed. [c] Ref. [2f]; CASSCF/6-31G* frequencies were employed.

The computed activation enthalpies for the chair pathway is nearly the same as that measured for 1,6-dideutero-1,5-hexadiene (33.3 ± 0.5 kcal mol^{-1})[4a] (Table 2). Moreover, the calculated activation entropies of −9.4 and −6.2 cal mol^{-1} K^{-1} for **3a** and **3b** are close to the measured values (−13.8 ± 1 and −3.0 ± 3.6 cal mol^{-1} K^{-1}, respectively, for the deuterated isomers).[4a, b, 9a, b] The calculated activation energy for the C_{2v}-symmetric transition structure **3b** is 7–12 kcal mol^{-1} higher in energy than that for the C_{2h}-symmetric structure **3a** (Table 2); the experimental estimate is 11 ± 3 kcal mol^{-1}. The energy difference between **1** and two allylic radicals **5** is 57.5 kcal mol^{-1} at QCISD(T)/6-31G*//CISD/6-31G* + E_{th} (CID/6-31G*, 500 K), which agrees well with experiment (59.7 kcal mol^{-1}),[4c] but the Becke3LYP value is too low. The CASPT2N level of Borden et al.[2f] (see Table 2) also performs well.

Magnetic Properties: Chemical shifts as well as magnetic susceptibilities and anisotropies were computed using the IGLO[8] method employing both the MP2/6-31G* and the CISD/6-31G* geometries. These calculated magnetic properties show pronounced ring current effects which characterize the aromaticity of pericyclic transition structures.[5] The ^{1}H nuclei are shielded (and deshielded), and the magnetic susceptibilities and anisotropies of the transition states are exalted, just as in benzenoid and other aromatic molecules (Table 3).[10–14]

The ^{1}H NMR shifts (Fig. 1) from IGLO/II calculations using both the MP2 and CISD geometries differ dramatically from values for normal polyenes such as compound **1**. In **3a** and **3b** the signals of the axial (inner) hydrogen atoms are all shifted upfield (δ = −0.3 to 2.4) relative to the corresponding signals of **1**, whereas the signals of the equatorial hydron atoms are shifted *downfield* (δ = 4.3–5.7). Note that the individual CH_2 hydrogens have the same chemical shifts in **1**, but show large differences ($\Delta\delta$ = 4.0 to 4.8) in **3a** and **3b**.

For **3a** the calculated magnetic susceptibility exaltations relative to that of 1,5-hexadiene (**1**) are −16.4 (MP2 geometry) and −19.9 (CISD geometry), and only a little less, −16.2 (MP2 geometry) for the asynchronous transition structure (**2**). The exaltation is −17.4 (CISD geometry) for the boat transition structure **3b**. Thus **2**, **3a**, and **3b** are aromatic, with larger exaltations than benzene (−13.7 experimentally,[11a] −13.4 based on IGLO/II calculations[14h]). Comparisons with values computed for other electrocyclic transition structures are summarized in Table 3, along with the measured and calculated activation energies and the energies of concert.

The calculated magnetic susceptibility anisotropies for **3a** (−55.0) and for **3b** (−56.6) are larger than that for **1** (−17.9) using the CISD geometries, and are comparable to that of benzene (−62.9). The value of the magnetic susceptibility an-

Table 3. Calculated (E_a) and measured activation energies (E_a, exp.), energies of concert (E_{con}) (all in kcal mol^{-1}) as well as the magnetic susceptibility exaltations (Λ/ 10^{-6} cm^3 mol^{-1}) for a selection of pericyclic reactions.

isotropy of transition structure **2** for the stepwise reaction (− 47.8) is essentially identical with that of **3a** (− 47.9) when the MP2 geometries are used for both. Hence, all the magnetic criteria agree that **2** and **3a** do not differ significantly in their electronic character.

Conclusions: The geometries and energies determined by ab initio methods, as well as the IGLO analysis of the magnetic properties, show that the parent Cope rearrangement of 1,5-hexadiene occurs through a concerted, synchronous mechanism via an *aromatic* transition structure **3a**. This is a general feature of the pericyclic reactions we have studied in this context (Table 3). There appears to be no relationship between the energies of concert or the activation energies and the magnetic susceptibility exaltations (which are in the range of the benzene value, −13.7). The cyclic electron delocalization, which is responsible for the ring current effects, also stabilizes the transition structures, but is only one of the contributing factors governing the reactivity and mechanistic pathway.

Aromaticity and Antiaromaticity in Five-Membered C_4H_4X Ring Systems: "Classical" and "Magnetic" Concepts May Not Be "Orthogonal"**

Paul von Ragué Schleyer,* Peter K. Freeman, Haijun Jiao, and Bernd Goldfuss

Despite the fundamental importance of aromaticity and antiaromaticity in chemistry,[1, 2] no generally acceptable definitions have been established.[1] Instead, aromaticity is discussed in terms of various criteria: energetic, structural, and magnetic. Aromatic stabilization energies (ASEs) have been deduced from experimental measurements, but as the needed reference thermochemical data often are not available, recourse has been made to theoretical data.[3, 4] Bond length analyses[5–7] are based on experimental (for example, from X-ray analyses) or

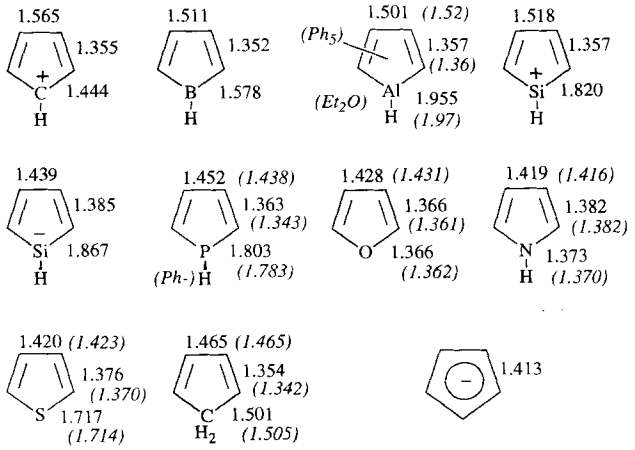
Goldfuss), the Convex Computer Corporation, the Deutsche Forschungsgemeinschaft, and the Stiftung Volkswagenwerk, as well as the National Institute of Environmental Health Sciences (Grant ES00040). We also thank Prof. Dr. W. Kutzelnigg for helpful suggestions, Prof. Dr. A. R. Katritzky for constructively critical discussions, and the Shanxi Normal University (the People's Republic of China) for a scholarship to H. Jiao.

theoretical[3, 4] structures. The C–C bond lengths in aromatic systems tend to be very similar, and the other bond lengths adjust accordingly. Aromatic compounds exhibit exalted diamagnetic susceptibilities[1, 8–11] as well as magnetic susceptibility anisotropies.[9] The external protons are deshielded (in the larger annulenes, internal protons are shielded),[1, 6c–h, 10] but not only ring currents cause these effects.

To what extent are these criteria related? Katritzky et al.'s[6a] "principle component analysis" of data sets for five- and six-membered heterocycles concluded that "the 'classical' and 'magnetic' concepts of aromaticity are almost completely orthogonal" and that "there are at least two types of aromaticity". Although Katritzky's analysis was based on a large number of common aromatic systems, the magnetic properties encompassed only a narrow range—in view of the likely experimental uncertainties, perhaps too limited a range for a definitive assessment. The present study helps dispel Katritzky's pessimistic conclusion by demonstrating that *linear relationships exist among the energetic, geometric, and magnetic criteria of aromaticity, and that these relationships even extend to antiaromatic systems.*

We have now examined a comprehensive set of five-membered C_4H_4X ring systems. Theoretical computations enable 4π electron antiaromatic (X = CH^+ (singlet), SiH^+, BH, and AlH) as well as 6π electron aromatic compounds (X = CH_2, PH, SiH^-, O, S, NH, and CH^-) to be included, so we employ a uniform set of good quality theoretical data to analyze systems with a much wider range of properties than Katritzky et al.[6a] As magnetic susceptibilities depend on ring size,[11] we have chosen the set of five-membered heterocycles because their shape is nearly uniform. The geometries (MP2(fc)/6-31G* level)[12, 13] and energies (with MP2(fc)/6-31G* zero point energy corrections) have been computed at reasonably high ab initio levels (with the GAUSSIAN 92 program[13]). For molecules of this type, MP2 geometries can be expected to be quite accurate.[14] Indeed, the optimized geometries for X = O, S, NH, and CH_2, as well as PH and AlH, are in excellent agreement with the experimental values (given in italics in parenthesis in Fig. 1).[15]



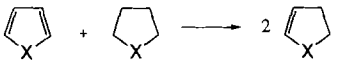


Fig. 1. The lengths of the C_4H_4X ring bonds at MP2(fc)/6-31G* level (experimental values are given in italics in parentheses).

IGLO calculations employing the MP2/6-31G* geometries and the basis set II (IGLO/II//MP2/6-31G*)[16] [9s5p(51111/2111) augmented by one set of d functions, $\eta = 1$, for carbon and 5s (311) augmented by one set of p functions, $\eta = 0.7$, for hydrogen; basis sets for other elements are given in Ref. [16] provided the magnetic susceptibilities and their anisotropies. These magnetic properties depend on the area of the ring,[11] but this should be nearly equal for the five-membered systems employed here. The homodesmotic reaction [Eq. (a)] was used to evaluate

(a)

the ASEs. Because the reference compounds all were computed in their most stable conformations, strain effects should be canceled to a large extent. Furthermore, the reference monoenes are conjugated, so Equation (a) gives the ASE associated with cyclic delocalization (positive energies denote the stabilization for aromatic compounds) or with cyclic localization (negative energies denote the destabilization of antiaromatic systems).

The magnetic susceptibility exaltation [Λ, Eq. (b)] is defined as the difference between the IGLO magnetic susceptibility for C_4H_4X (χ_M) and the value estimated for the hypothetical system without cyclic electron delocalization ($\chi_{M'}$). The latter is based

$$\Lambda = \chi_M - \chi_{M'} \quad \text{(b)}$$

on the group increments (for example, for CH and X) that we have determined by IGLO computations on appropriate model compounds. These magnetic susceptibility group increments (to be reported in a full paper) vary hardly at all with structure (that is, acyclic or cyclic). The exaltations Λ are negative (diamagnetic) for the aromatic compounds, but positive (paramagnetic) for the antiaromatic cases (Table 1).

Table 1. The calculated magnetic susceptibility exaltations Λ, magnetic susceptibility anisotropies χ_{anis} [10^{-6} cm^3 mol^{-1}], homodesmotic stabilization/destabilization energies ASE [kcal mol^{-1}], and the Julg parameters A for C_4H_4X rings.

X [a]	Symmetry	Λ [b]	χ_{anis}	ASE [b]	A
CH^+	C_{2v}	32.6	58.1	−56.7	−0.084
SiH^+	C_{2v}	13.2	−0.8	−24.1	0.346
BH	C_{2v}	12.8	−5.6	−19.3	0.354
AlH	C_{2v}	11.2	−11.4	−6.8	0.476
CH_2	C_{2v}	−2.4 (−6.5 [8b, c])	−31.0	3.7 (2.4 [10d])	0.684
PH	C_s	−3.3	−35.2	7.0	0.795
SiH^-	C_s	−7.7	−41.5	13.8	0.926
O	C_{2v}	−9.1 (−8.9 [6a])	−36.2	19.8	0.900
S	C_{2v}	−10.0 (−13.0 [6a])	−46.4	22.4	0.951
NH	C_{2v}	−12.1 (−10.4 [6a])	−41.8	25.5	0.967
CH^-	D_{5h}	−17.2	−45.8	28.8	1.000

[a] All species correspond to minima at MP2(fc)/6-31G* (no imaginary frequencies). [b] Experimental estimate in parentheses.

Table 1 also summarizes the aromatic stabilization energies [ASEs, Eq. (a)], the magnetic susceptibility exaltation Λ, the magnetic susceptibility anisotropies χ_{anis}, and the Julg parameter A [based on Eq. (c)],[5] a geometric criterion that has proved useful for quantitative comparisons of such heterocyclic molecules.[5] The χ_{anis} values do show a definite trend towards more negative values for the more aromatic systems, but may be less generally useful as a quantitative aromaticity criterion.

The Julg parameter A[5] defines the degree of aromaticity in terms of the deviations of the individual C–C bond lengths (r_i) from the mean carbon–carbon bond length (r). In Equation (c),

$$A = 1 - (225/n)\,\Sigma\,(1 - r_i/r)^2 \quad \text{(c)}$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0338 $ 10.00+.25/0

n represents the number of C–C bonds (three in the C_4H_4X systems). $A = 1$ for benzene (D_{6h}) and the cyclopentadienyl ion (D_{5h}), that is, for the fully delocalized, highest symmetric systems. The empirical factor 225 provides an aromaticity scale in which $A = 0$ for the Kekulé form of benzene (assuming 1.33 and 1.52 Å C–C lengths).

A plot of the calculated magnetic susceptibility exaltations Λ versus ASE (Fig. 2) reveals a remarkable linear correlation that extends from the highly antiaromatic singlet cyclopentadienyl

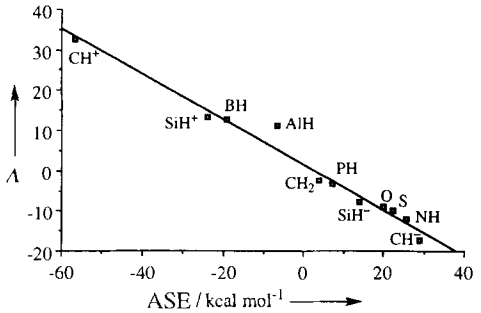

Fig. 2. Plot of the magnetic susceptibility exaltations Λ versus ASE for C_4H_4X rings. The correlation coefficient of the regression line ($y = 1.45 - 0.56\,x$) is $c = 0.99$.

cation to the highly aromatic cyclopentadienyl anion. The cyclopentadienyl anion (D_{5h}) contains π electrons that are fully delocalized ($A = 1$) and has the largest stabilization energy (ASE = +28.8 kcal mol^{-1}) as well as the most negative (diamagnetic) susceptibility exaltation ($\Lambda = -17.2$). In contrast, the singlet cyclopentadienyl cation (C_{2v}),[17] which is close in energy to the triplet ground state, has the largest destabilization energy (ASE = − 56.7 kcal mol^{-1}), the most positive (paramagnetic) exaltation ($\Lambda = +32.6$), and the smallest Julg parameter ($A = -0.084$).

The quantitative analysis of bond length is equally striking. The Julg parameter A correlates very well both with the stabilization/destabilization energy ASE (Fig. 3a, $c = 0.99$) and with

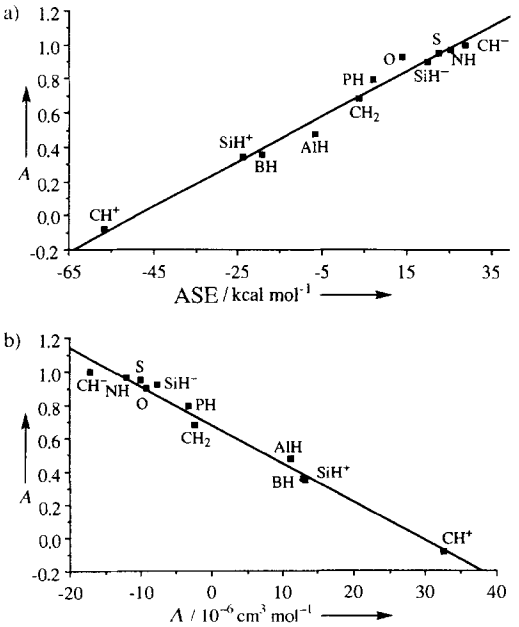

Fig. 3. Plot of Julg parameters A versus ASE (a) and versus magnetic susceptibility exaltations Λ (b). The correlation coefficients for the regression lines ($y = 0.65 + 0.01\,x$ (a); $y = 0.68 - 0.02\,x$ (b)) are both $c = 0.99$.

the magnetic susceptibility exaltation Λ (Fig. 3b, $c = 0.99$). Equal or nearly equal bond lengths in the ring (which are the average of typical single and double bond values) are an important characteristic of aromatic molecules.[1, 10] In contrast, antiaromatic molecules exhibit strong bond-length alternation.[1, 11b] Table 2 summarizes the typical single and double

Table 2. Typical lengths of C_{sp^2}–X single and double bonds and their average values in Å (at MP2(fc)/6-31G*).

C–X [a]		C=X		Average
C–C	1.504	C=C	1.339 [a]	1.421
C–C$^-$	1.418	C=C	1.375 [a]	1.396
C–C$^+$	1.422	C=C	1.367 [a]	1.394

[a] Based on divinyl derivatives X(HC=CH$_2$)$_2$. [b] Average values from open-chain polyenes, see Refs. [10b–e]. [c] Based on (H$_3$C)$_2$C=X. [d] From *trans*-H$_3$C–X=CH–CH$_3$ derivatives. [e] From *trans*-CH$_3$–SiH=CH–CH$_3$.

bond lengths as well as their average values, which may be compared with the optimized values for C_4H_4X given in Figure 1.

For the antiaromatic systems (X = CH$^+$ (singlet), BH, AlH, SiH$^+$) with C_{2v} symmetry, the C–C double bond lengths of 1.352–1.357 Å resemble those in polyenes (1.350 Å).[10b–e] On the other hand, the conjugated C–C single bond lengths are longer than those in polyenes (about 1.450 Å in *trans*-butadiene,[10e] 1,3-pentadiene,[10d] 1,3,5-heptatriene,[10b] and 1,3,5,7-octatetraene[10c]). In the singlet cyclopentadienyl cation (C_{2v} symmetry), the two C–C single bond lengths of 1.565 Å are 0.04 longer than those in cyclohexane (1.526 Å at MP2 level). Pronounced bond-length alternation is a typical antiaromatic feature. The C_{sp^2}–X bond lengths also are longer than the average values of typical single and double C_{sp^2}–X bonds, or may even be close to the single-bond lengths (Table 2). Thus, energetic, magnetic, and geometric criteria also characterize antiaromatic compounds.

Table 1 and Figure 2 show that the stabilization energies ASEs and the diamagnetic susceptibility exaltations of cyclopentadiene (X = CH$_2$) and phosphole (X = PH) are the smallest among the aromatic systems. In addition, The C=C and C–C bond lengths are rather normal. The possible aromaticity of cyclopentadiene (through the 2π hyperconjugative contribution of the CH$_2$ group)[9a, 10d, 11a] and especially of phosphole[18, 19] ("Despite their pyramidal structure, phospholes are 'aromatic' systems")[19b] have been debated. At best, these are "borderline" aromatics. This conclusion agrees with the results of other more recent analyses of the energy of phosphole,[18] which supersede earlier, low-level calculations.[19]

Like phosphole (X = PH), the isoelectronic silacyclopentadienyl anion (X = SiH$^-$) is another pyramidal five-membered ring heterocycle with (at least formally) 6π electrons. Our higher level results do not agree with the earlier theoretical conclusion[20] that the "silacyclopentadienyl anion has only weak aromatic character." "Moderate" would be a better description.[21] The Julg parameter is quite large ($A = 0.926$), and the ASE (13.8 kcal mol^{-1}) as well as the diamagnetic susceptibility exal-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0339 $ 10.00+.25/0

tation ($\Lambda = -7.7$) are about half the values for the cyclopentadienyl anion (Table 1).

The relative aromaticity of furan (X = O), thiophene (X = S), and pyrrole (X = NH) has been much discussed.[3] All have planar, C_{2v} symmetries, and their C–C "double" and "single" bond lengths are very similar and almost equal to the average distances given in Table 2. The C_{sp^2}–X bond lengths also are close to the average of single and double bond lengths. The diamagnetic exaltations, ASEs, and Λ values in Table 1 (plotted in Figures 2 and 3) give the same aromaticity order: pyrrole > thiophene > furan.

In conclusion, aromaticity and antiaromaticity are well characterized by a combination of geometric, energetic, and magnetic criteria. These criteria correlate quantitatively for the five-membered ring systems. Aromatic compounds are stabilized energetically and exhibit diamagnetic susceptibility exaltations Λ and negative anisotropies; bond-length equalization is apparent. In contrast, antiaromatic systems are destabilized; the single and double bonds are localized. The magnetic susceptibilities and anisotropies of antiaromatic systems are more positive due to paramagnetic ring-current effects. Cyclopentadiene is a borderline arene at best, but phosphole and the silacyclopentadienyl anion show increasing aromatic character. The pyrrole > thiophene > furan aromaticity order is established firmly, and the cyclopentadienyl anion is the "most aromatic" five-membered ring system.

Topochemical Aspects of the Formation of Networks in Layered Langmuir–Blodgett (LB) Assemblies**

Michael Seufert, Matthias Schaub, Gerhard Wenz, and Gerhard Wegner*

Reactions in layered assemblies of organic molecules as obtained by the Langmuir–Blodgett (LB) technique are frequently of topochemical nature,[1–6] that is the course of the reaction and the direction in which the product is formed are completely controlled by the packing of the starting material in the lattice.[3, 6] The monolayers of which LB assemblies are composed, extend in the x,y plane; the assembly direction defines the z axis

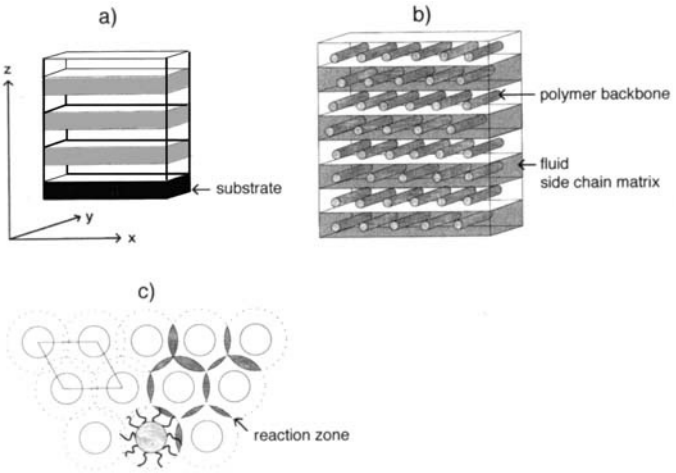
[**] This work was carried out as part of the project "Ultrathin Layers" supported by the MATFO-program of the German Ministry of Research and Technology (BMFT).

(Fig. 1a). All the reactions occurring in such systems can be characterized by a "dimensionality", where "dimensionality of the reaction" should be differentiated from "product dimensionality". The latter refers to the spatial structure of the product, that is for example whether a linear macromolecule or a two- or three-dimensional network is the reaction product. In contrast the dimensionality of the reaction describes the tensorial character of the reaction.



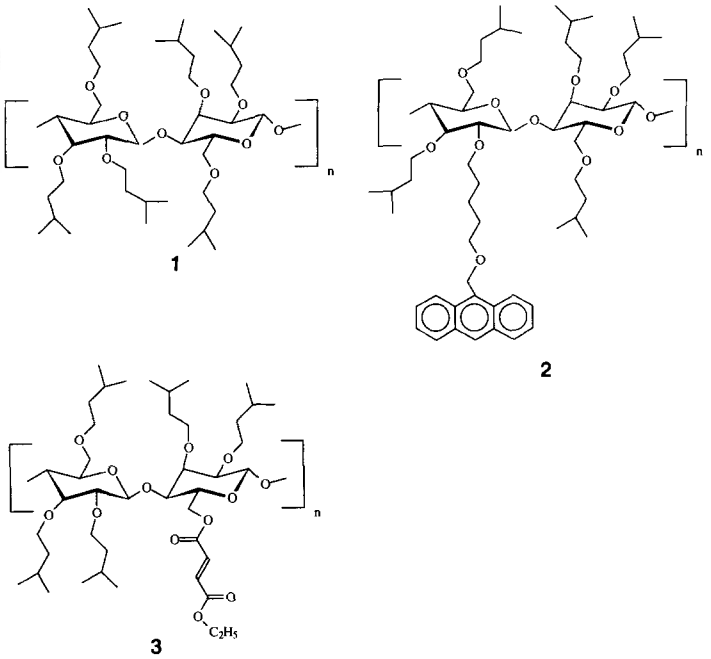


Fig. 1. a) General architecture of a LB layered assemblies. b) Layered assembly composed of "hairy rod" macromolecules [11–13]. c) Definition of the reaction zones relevant for intermolecular reactions. The schematic representation shows the hexagonally dense packing; other packing symmetries, for example a monoclinic packing of the macromolecules, would not affect the principal conclusions drawn from the model.

The polymerization of amphiphilic monomers within LB-layered assemblies is a reaction that proceeds in one direction and gives polymeric chains as one-dimensional products. The topochemical polymerization of amphiphilic dialkynes serves as an example.[6, 8] Other monomers, for example acrylates, give one-dimensional products as well, however, the polymerization within the layer plane does not occur with topochemical control of the chain direction. Thus, the reaction is pseudo one-dimensional. The lack of topochemical control leads to a decrease in "reaction-dimensionality" as compared to "product-dimensionality".[5]

Reactions with zero-dimensionality, that is a type of reaction which takes place at the site of individual molecules only, are exemplified by *cis-trans* isomerizations. The formation of a well-defined three-dimensional network starting from a LB-layered assembly has been described—to the best of our knowledge—only once, namely in the photochemical crosslinking of co-poly(glutamate)s which contained cinnamoyl groups in the side chains.[7] Work dedicated at the construction of purely two-dimensional networks[9] in LB-assemblies remained inconclusive, since additional reactions in the third dimension—the *z* direction—could not be excluded.[10] Two-dimensional networks should, however, be simply obtained by the same reactions as ordinarily used for formation of three-dimensional networks, if the reaction partners are kept far enough apart along the *z* direction that crosslinking remains limited to the *x,y* plane; thus, a matrix isolation of the reactive layers is attempted.

In the following, layered assemblies of cellulose derivatives are investigated, which may be regarded as copolymers composed of anhydroglucose units randomly substituted by ether and ester groups. They conform to the type of polymers characterized by a rigid backbone decorated by flexible side groups ("hairy rod macromolecules"). Layered LB assemblies obtainable from such molecules are well investigated.[11–13] We used isopentylcellulose (**1**) with a degree of substitution (DS) of 2.9, [5-(9-anthrylmethoxy)pentyl]isopentyl cellulose (**2**)(DS = 2.8 with respect to the isopentyl and 0.1 with respect to the anthryl residues) and a partially modified polymer containing fumarate residues (**3**) (DS = 2.5 with respect to the isopentyl and 0.25 with respect to fumarate residues). The average degree of polymerization P_n of the cellulose derivatives was 87.

The anthryl residues undergo a $4_\pi + 4_\pi$ cycloaddition[14] when irradiated which leads to a network. The reaction can be monitored by the decrease in the anthracene absorption at 250 nm. The reaction in the *z* direction is prevented by embedding single layers of **2** between layers of **1**. Figure 2a shows the

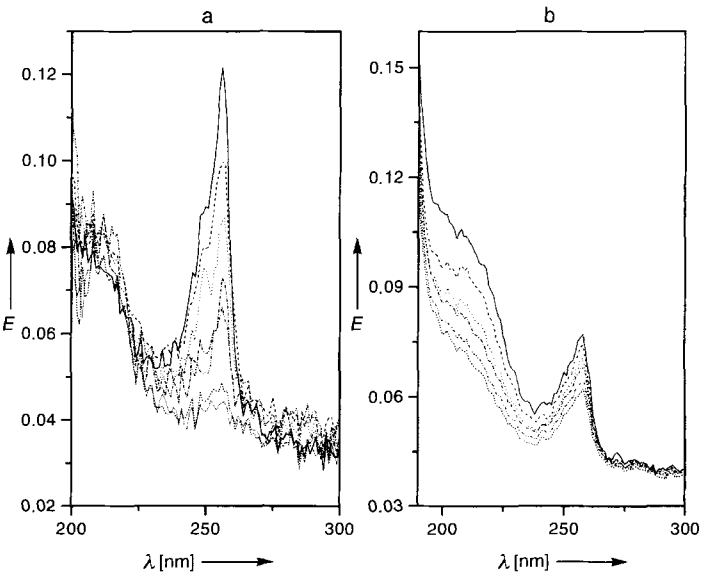

Fig. 2. a) UV spectra of a $(\mathbf{112})_{30}$ layered assembly depending on irradiation time: unirradiated, 30, 60, 120, 240, 480, 960s. b) UV spectra of a $(\mathbf{111123})_{15}$ layered assembly without annealing and after annealing for 10, 25, 50, 120, and 270 min.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0341 $ 10.00+.25/0

UV spectra of such a layered assembly consisting of 30 periodically repeated (**112**) layers as a function of the irradiation time. The intensity of the anthracene absorption decreases with increasing time of irradiation. The lack of reaction partners in the z direction restricts the reactivity of the anthryl groups to the x,y plane. This results in the formation of a two-dimensional network. Since the self-diffusion coefficient of the macromolecules is unmeasurably small in the layered assemblies,[11, 13] a photoreaction involving lateral diffusion of the macromolecules can be excluded. Annealing of the assembly (120 °C, 7 h in the dark) did not give rise to changes of the optical spectra.

A further strategy to create two-dimensional products involves selective cross-linking of adjacent layers. This reaction, which ought to proceed one-dimensionally in the z direction, nevertheless results in a two-dimensional network, as can be seen in Figure 1c. Reactions occurring in the x,y plane must be prevented here. This requires appropriate functionalization of adjacent layers as exemplified by a thermally induced $2_\pi + 4_\pi$ Diels–Alder reaction.[15] The reaction partners here are **2** and **3**. In order to demonstrate that a reaction in the x,y plane does not occur, single layers of **2** and **3** were each separated by two layers of **1**, that is a periodic structure of 11 such packages were assembled on a quartz substrate. If this $(\mathbf{112113})_{11}$ sample was annealed at 120–150 °C for more than five hours, no reaction occurred. If however, an analogous layered assembly was prepared in which, adjacent layers of **2** and **3** were each embedded between four layers of **1**, a substantial decrease of the intensity of the anthracene absorption band was observed when the sample was annealed at the same temperature (c.f. Fig. 2b). The only difference to the control experiment was the sequence of layers and, thus, the changes observed in the UV spectra can only be a consequence of a chemical reaction of **2** and **3** across the interface of adjacent layers.

X-ray reflectivity measurements[13, 16, 17] allow the monitoring of the overall thickness of the assembly described by $(\mathbf{111123})_{16}$ before and after the reaction. The "Kiessig-fringes" shown in Figure 3 that result from interference of X-rays reflected from the air/polymer and polymer/glass surface have been evaluated to give the data summarized in Table 1. The layered assembly exhibits a thickness of $D = 817$ Å immediately after preparation; it shrinks by about 3% to 790 Å in the course of the reaction. The periodic order of the single layers of the cellulose derivatives does not give rise to a Bragg reflection since the electron density fluctuation between backbone and side chain matrix is too small.[18] The double bonds of the fumarate residues in the freshly prepared sample, however, offer the possibility of achieving a contrast, by reaction with osmium tetraoxide. A Bragg reflection for a periodicity of 51.3 Å is observed in agreement with the sample architecture after it had been exposed to this reagent. Once the sample had been thermally crosslinked this Bragg reflection could not be produced because of the concentration of double bonds to be reacted with OsO_4 was too small.

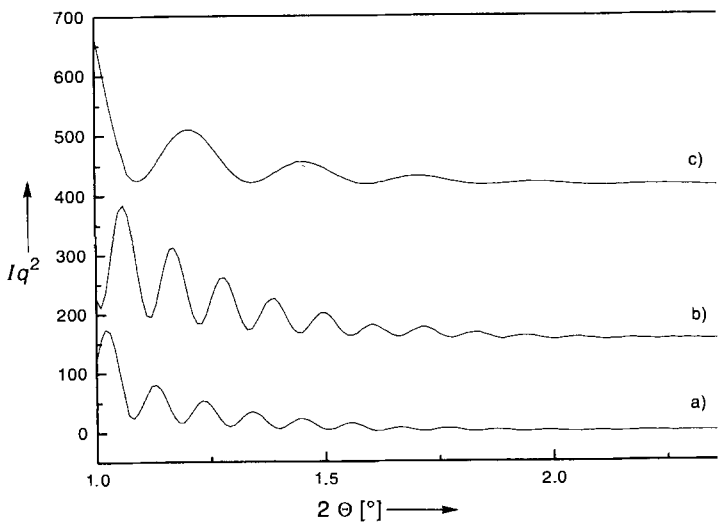

Fig. 3. X-ray reflection curve of a $(\mathbf{111123})_{16}$ layered assembly on glass: a) After preparation, b) after annealing (540 min, 150 °C), c) after extraction with toluene. I_{q^2} ($q = 2\theta/\lambda$) in arbitrary units.

Table 1. Dimensions of the layered assemblies $(\mathbf{111123})_N$ before and after thermally induced crosslinking.

Sample status	D [Å] [a]	d [Å] [b]	N [b]	d' [Å] [b]
as prepared	817	51.06	6	8.51
after annealing	790	49.38	6	8.23
after extraction	346.5	21.66	2	10.83

[a] Thickness of the layered assembly. [b] Thickness of periodic pattern of the assembly composed of N such repeat units; d' is the average thickness of a single monolayer.

The stability of the two-dimensional network obtained by Diels–Alder reaction was checked by washing the whole sample with chloroform or toluene, both good solvents for uncrosslinked cellulose derivatives. The UV transmission spectra of the layered assembly did not change, indicating that the number of chromophores per unit area remained constant. The corresponding X-ray reflectivity measurements showed, however, that the total thickness was drastically reduced to 346.5 Å, a reasonable value under the assumption that all layers consisting of **1** had been dissolved.

The thermally induced crosslinking of adjacent layers as a consequence of the chosen layer architecture is clearly a one-dimensional reaction proceeding along the z direction. However, the network obtained as the reaction product is two-dimensional. Since the dimensionality of product and reaction differ, the reaction may also be defined as pseudo two-dimensional. The dissolution of the interlayers composed of **1** serve as an additional means of manipulating the supramolecular architecture of the assembly along z. The formation of bonds between the reactive groups of adjacent macromolecules is restricted to the zones of overlap between the shells of the substituent groups surrounding each rodlike backbone. The situation is outlined in Figure 1c for a hexagonal dense packing of cylinders as the model of the architecture.

Although the reactions discussed here are not of topochemical nature in the strict sense of definition, they help to stabilize the periodic packing of the macromolecules. Futher work is necessary to establish the size of the zones of overlap and the restrictions in distance over which bimolecular reactions may occur within the limits of the architecture of such layered assemblies.

Experimental Procedure

1: Cellulose acetate (10 g) (DS = 2.34, $P_n = 150$) dissolved in dimethyl sulfoxide was treated with 3-methyl bromide (174 g) and NaOH (46 g) at room temperature for 8 days. The product was then poured into water (1.5 L) and extracted with CH_2Cl_2. The organic phase was concentrated and the residue precipitated from methanol. Yield (after drying in vacuo): 9.21 g (66%). $C_{20.5}H_{39}O_5$ (365.53). ^{1}H NMR (1,1,2,2-tetrachloro[D_2]ethane, 80 °C): $\delta = 4.3$ (d, 1H), 3.7–2.9 (m, 12H), 1.63 (s, 3H), 1.44 (m, 6H), 0.87 (s, 17H); DS (NMR) = 2.9. Membrane osmosis in toluene: $M_n = 32000\ \mathrm{g\,mol^{-1}}$.

5-(9-Anthrylmethoxy)1-bromopentane: NaH (3.6 g of an 80% suspension in mineral oil) was added to a solution of 9-anthrylmethanol (5 g) in anhydrous THF

(80 mL). The suspension was added dropwise to a mixture of 1,5-dibromopentane (55.2 g) in THF (80 mL) at 60 °C. The mixture was stirred under reflux for 20 h, it was then poured into water and the product was extracted with CH_2Cl_2. After workup and chromatographic purification (in toluene/ethyl acetate, 10/1, over silica) the yield was 6.7 g (78%). ^{1}H NMR ($CDCl_3$): δ = 8.31 (s, 1H), 8.22 (d, 2H), 7.88 (d, 2H), 7.35 (m, 4H), 5.31 (s, 2H), 3.5 (t, 2H), 3.19 (t, 2H), 1.64 (m, 2H), 1.49 (m, 2H), 1.31 (m, 2H).

2: Synthesis as described for **1**; the two bromides were added as a mixture. Components: cellulose acetate (0.5 g), NaOH (2.76 g), 3-methylbutyl bromide (10.1 g), 5-(9-anthrylmethoxy)1-bromopentane (0.715 g). Yield: 0.3 g (41.5%). ^{1}H NMR ([D_8]toluene, 100 °C) δ = 8.34 (d, 2H), 8.12 (s, 1H), 7.72 (d, 2H), 7.32 (m, 2H), 7.21 (m, 2H), 5.31 (d, 1H), 4.58 (d, 1H), 4.02 (m, 2H), 3.86–3.64 (m, 4H), 3.57 (m, 3H), 3.37 (m, 2H), 3.13 (t, 1H), 1.75 (m, 1H), 1.54 (m, 1H), 1.27 (m, 3H), 0.93 (m, 1H); $DS_{isopentyl}$ (NMR) = 2.8; $DS_{anthryl}$ (NMR) = 0.1.

3: **1** (0.91 g) (DS = 2.6) and monoethyl fumarate (0.15 g) were dissolved in THF (10 mL) (distilled over Na/K alloy). *para*-Dimethylaminopyridine (0.5 mg) and dicyclohexylcarbodiimide (0.21 g) dissolved in CH_2Cl_2 (5 mL) were added at 0 °C; the mixture was stirred at 0 °C for 4h and for an additional 12 h at 25 °C; workup procedure was as described for **1**. Yield: 0.761 g (71%). $C_{20.05}H_{36.6}O_{5.75}$ (369.71). ^{1}H NMR (1,1,2,2,-tetrachloro[D_2]ethane, 80 °C): δ = 6.85 (s, 0.5H), 4.5–2.9 (M, 12H), 1.8–1.1 (m, 9H), 0.9 (s, 15H); $DS_{isopentyl}$ (NMR) = 2.5; $DS_{fumarate}$ (NMR) = 0.25.

Preparation of the LB layers: for the quartz and glass substrates and for the characterization of the layered assemblies see ref. [19]. All substances were spread on the water surface (20 °C) as solutions of substance (5 mg) in chloroform (10 mL). With each down- and upstroke one monolayer of **1**, **2**, and **3** was transferred (dipping speed is 1 cm min^{-1}) and the transfer ratio was 1 ± 5%.—Transfer pressure: **1**: 14.5, **2**: 15.5, **3**: 16.5 m Nm^{-1}. Crosslinking: A Hg high-pressure lamp (Osram HBO 100W/2) was used for irradiation equipped with a quartz diffuser and an edge filter WG 360 at a sample distance of 30 cm.

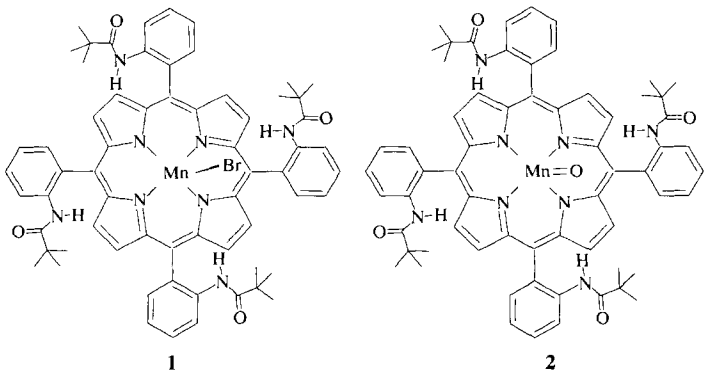
Characterization of an Oxo(porphyrinato)manganese(IV) Complex by X-ray Absorption Spectroscopy**

Khadija Ayougou, Eckard Bill, John M. Charnock, C. David Garner,* Dominique Mandon, Alfred X. Trautwein,* Raymond Weiss,* and Heiner Winkler



Two oxo(porphyrinato)manganese(IV) complexes generated by NaOCl or NaOBr oxidation of (porphyrinato)manganese(III) complexes have been isolated and shown to be capable of transferring an oxygen atom to styrene and triphenylphosphane.[1] Extended X-ray absorption fine structure (EXAFS) studies of these derivatives are compatible with a monomeric six-coordinate manganese(IV) porphyrin with a well defined Mn–O bond distance of 1.84 ± 0.02 Å and a water molecule as sixth ligand.[1] Formation of oxo(porphyrinato)manganese(IV) species by the reaction of (porphyrinato)manganese(III) complexes with potassium peroxycarbonate has also been reported.[2] Preliminary X-ray absorption spectroscopic (XAS) studies of the corresponding picket-fence porphyrin derivative have indicated a short Mn–X distance of 1.67 ± 0.03 Å, compatible with the presence of an Mn^{IV}=O group.[2]

Five- and six-coordinate, high-spin oxo(porphyrinato)manganese(IV) derivatives have also been obtained by peroxy acid or electrochemical oxidation of (porphyrinato)manganese(III) derivatives.[3–5] The presence of an Mn^{IV}=O moiety in these species was identified by assignment of the Mn–O stretching mode from a combination of FTIR and resonance Raman (rR) spectroscopy. However, EXAFS studies failed to demonstrate the presence of a short Mn–O bond distance.[3] To ascertain the presence of a Mn^{IV}=O moiety in the species obtained by reaction of picket-fence bromo(porphyrinato)manganese(III) with potassium peroxycarbonate and obtain more information on the Mn–O bond distance in this compound, we have reinvestigated this species by XAS. Herein we report the results of these studies.

The samples studied were prepared as 4 mM solutions by reaction at −70 °C of bromo-*meso*-tetra(α,α,α,α-pivalamidophenyl-porphyrinato)manganese(III) [$Mn^{III}Br(T_{piv}PP)$] (**1**; UV/VIS (THF): $\lambda_{max}(\varepsilon)$ = 361(66), 380(53), 475(117), 525(8), 581.5(13), 616.5(10) nm; Fig. 1) with a very large excess (10^3:1) of a THF/DMF solution of potassium superoxide KO_2 as 222-cryptate (222 = Kryptofix Hexaoxadiazabicyclohexacosane), saturated with carbon dioxide, as described previously.[12] At −70 °C the UV/Vis spectrum of the manganese species (**2**) in these samples showed bands at $\lambda_{max}(\varepsilon)$ = 436.5(196) and 555.0(20) nm (Fig. 1); monitoring of the reaction by UV/Vis spectroscopy indicated that a fast and complete conversion of the manganese(III) precursor into **2** requires the use of a large excess of $K(222)O_2/CO_2$.

This large excess prevented the observation of a clean EPR spectrum for **2**. Thus, the X-band EPR spectrum of such a sample at 4.2 K in frozen THF/DMF solution contained a very strong signal at a g value close to 2 and a very weak signal at a g value close to 4. The EPR spectrum of a THF/DMF solution

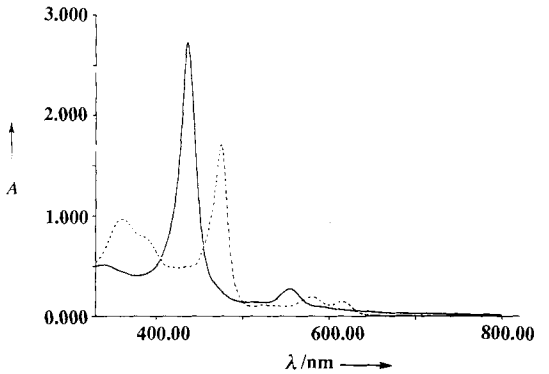

Fig. 1. UV/Vis spectra of **1** in THF (broken line) and **2** (solid line) in THF/DMF with a large excess (10^3:1) of $K(222)O_2/CO_2$.

containing only the oxidizing agent $K(222)O_2/CO_2$ demonstrated that the strong signal at $g \approx 2$ derives from this reagent. The weaker line at $g \approx 4$ is compatible with oxidation of the Mn^{III} complex **1** to a high-spin ($S = 3/2$) Mn^{IV} species, since high spin d^3 Mn^{IV} complexes in which the zero-field splitting parameter D is large exhibit EPR spectra with $g \approx 4$ and $g \approx 2$ signals.[6] These signals, which are masked by the intense signal of the oxidizing agent, can be made visible upon slow addition of only a small excess (5:1) of oxidizing reagent to **1**. Such a sample yields the spectrum depicted in Figure 2, leaving the majority of manganese in its EPR-silent trivalent state.

Samples of **2**, prepared with a large excess of the oxidizing agent (10^3:1), were transfered to aluminum cells with Mylar windows and frozen at 77 K. The manganese K-edge XAS was recorded at the SERC Daresbury Laboratory Synchroton Radiation Source, operating at 2 GeV with an average beam current of 150 mA. The sample cell was mounted on a liquid nitrogen cooled cold-finger cryostat. Data were collected in fluorescence mode on station 8.1 equipped with a double crystal Si(220) focusing monochromator and a prefocusing mirror. The second crystal was detuned to reject 30% of the beam to minimize harmonic contamination. Fluorescence was recorded with a 13-element Canberra solid-state detector. Two samples were measured; 16 scans were run for the first and 9 for the second. Individual scans showed no systematic variation, and each set of scans was summed and the two profiles compared; as the two

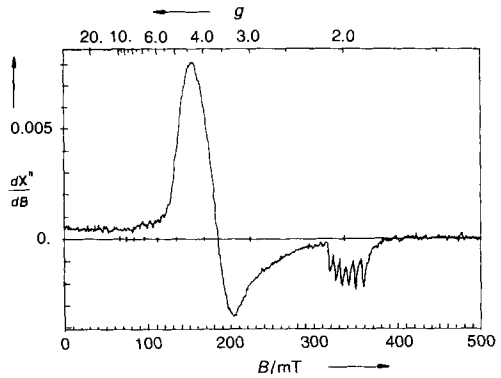

Fig. 2. EPR spectrum of the manganese compound obtained after reaction of **1** with a small excess (5:1) of $K(222)O_2/CO_2$. Microwave frequency 9.417 GHz, $T = 10$ K, microwave power 200 μW, modulation amplitude 1 mT.

spectra were identical in all features, all 25 scans were summed to give the final spectrum.

The background-substracted data (see Figure 3) showed a distinct pre-edge feature some 10 eV lower in energy than the edge. Transition metal–oxo and –nitrido complexes often exhibit an intense pre-edge transition.[7, 8] It is noted that the pre-edge peak of **2** is significantly weaker than the corresponding feature for $[Mn^{V}N(T(4\text{-}CH_3OP)P]$[8] (Fig. 3; T(4-$CH_3$OP)P = dianion of tetra(*p*-methoxyphenyl)porphyrin), $[Cr^{IV}O(TPP)]$, and $[Cr^{V}N(TPP)]$[9] (TPP = dianion of tetraphenylporphyrin). However, Fe^{IV}=O systems manifest a weak pre-edge transition, and this lack of intensity has been rationalized on the basis of a relatively long Fe–O bond (>1.6 Å).[9, 10] This argument is consistent with the data reported herein (vide infra).

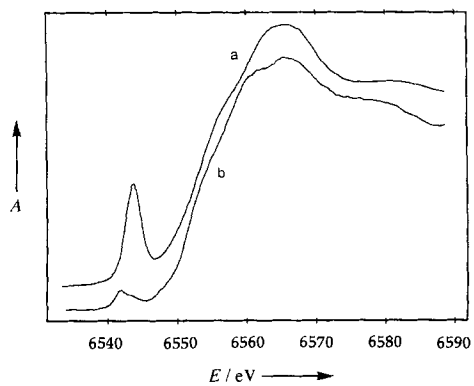

Fig. 3. Comparison of the manganese K pre-edge and edge peaks of $[Mn^{V}N(T(4\text{-}CH_3OP)P)]$ (a) and **2** (b).

The K-edge shift of manganese was measured relative to manganese metal foil. The edge position was selected as the maximum of the first derivative: +12.2 eV for **2**, +13.6 eV for $[Mn^{V}N(T(4\text{-}CH_3OP)P)]$,[8] +10.3 eV for β- and γ-$[Mn^{III}O(OH)]$,[11] and +8.3 eV for $[Mn^{II}SO_4]$. This is consistent with an oxidation state of IV for the manganese center present in **2**.

The isolated EXAFS was analyzed over the range $3 \leq k \leq 13$ Å^{-1} with EXCURV 90 and 92[12] by employing curved wave theory.[13–15] Phase shifts were calculated ab initio within these programs, from Xα-potentials and ground state, and their reliability checked by analysis of the manganese K-edge EXAFS recorded for $[Mn^{IV}(OCH_3)_2(TPP)]$,[6] and $[Mn^{V}N(T(4\text{-}CH_3OP)P)]$.[8] The metal–ligand distances of the

inner coordination spheres of these complexes were reproduced to within 0.03 Å of the corresponding crystallographic values. The EXAFS data were simulated by initially setting up a coordination environment comprising the axial ligands (or ligand) and a planar porphyrin ring with typical internal dimensions,[6, 8, 16–19] then varying the metal-backscatter distances (r), the Debye-Waller parameters ($2\sigma^2$), and E_0 until the best fit to the experimental EXAFS was achieved. The inclusion of multiple scattering from the atoms of the porphyrin ring was required to achieve a good fit at low k values. For $[Mn^{IV}(OCH_3)_2(TPP)]$ the metal was placed in the porphyrin plane,[6] but for $[Mn^{V}N(T(4\text{-}CH_3OP)P)]$ it was located 0.388 Å out of the plane.[8]

The number of independent parameters in these fits was reduced by fixing the coordination number and constraining the distances and Debye Waller factors for the pairs of pyrrole carbons at about 3 Å, and also for those at about 4.2 Å, to be the same. A similar approach was adopted in the simulations of the EXAFS of **2** (Fig. 4). In addition to the porphyrin ring, a

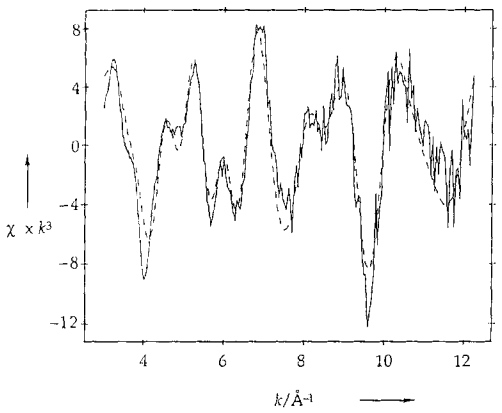

Fig. 4. EXAFS (solid line) and theoretical fit (broken line) of **2**.

light atom, assumed to be oxygen, at about 1.70 Å was required to reproduce the low r feature seen in the Fourier transform of the EXAFS (Fig. 5), and its inclusion improved the residual R factor[20] from 51.2 to 39.0. The number of independent parameters in the final fit was 14:6 pairs of r and $2\sigma^2$ (see Table 2), E_0, and the displacement of the manganese from the porphyrin plane. The possibility of a sixth ligand at the Mn^{IV} center in **2** at about 2.1 Å was investigated, but this was not

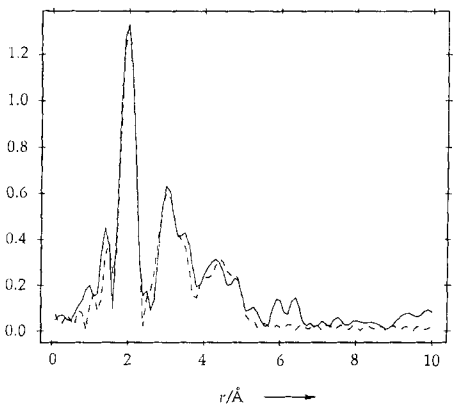

Fig. 5. Fourier transforms of the EXAFS of **2** (solid line) and theoretical fit (broken line).

justified by the improvement of the residual. Therefore, the Mn^{IV} center in **2** is considered to be five-coordinate (Table 1), and accordingly, the final simulations of the EXAFS data (Table 2 and Figs. 3 and 4) involved treatment of the multiple scattering of the porphyrin coordinated with the metal 0.5 Å out of the plane of this ligand.[16–18] The final metal–ligand distances obtained (Table 2) were Mn–O 1.69 ± 0.03 for Mn–O and 2.00 ± 0.03 Å for Mn–N.

Table 1. Coordination number (CN), spin state, and M–O bond lengths observed in oxometalloporphyrins [16–19, 22], dimethoxo(tetraphenylporphyrinato)-manganese(IV) [6], and in a macrocyclic tetraamidato-oxomanganese(V) complex. [21]

Porphyrin	CN	Spin S	M–O distance [Å]	Method	Ref.
$[Ti^{IV}O(OEP)]$	5	0	1.613(5)	X-ray	16
$[V^{IV}O(OEP)]$	5	1/2	1.620(2)	X-ray	17
$[Cr^{IV}O(TPP)]$	5	0	1.572(6)	X-ray	18
$[Mn^{IV}O(T_{piv}PP)]$	5	3/2	1.69 ± 0.03	EXAFS	this study
$[Fe^{IV}O(THF)(T_{piv}PP)]$	6	1	1.604(19)	X-ray	19
$[Fe^{IV}O(1\text{-}Melm)(TPP)]$	6	1	1.64 ± 0.03	EXAFS	22
$[Mn^{IV}(OCH_3)_2TPP]$	6	3/2	1.829(2)	X-ray	6
$[Mn^{V}O(\eta^4\text{-}L)][Et_4N]$	5	0	1.555(4)	X-ray	21

Table 2. Interpretation of EXAFS data (Mn K edge) for **2**.

Atom	CN [a]	r [Å] [b]	$2\sigma^2$ [Å^2]
O	1	1.69 [c]	0.005
N	4	2.00 [c]	0.003
C [d]	8	3.00	0.003
C [e]	4	3.35	0.011
C [d]	8	4.17	0.013
C [f]	4	4.82	0.026

[a] Coordination number, fixed at value shown. [b] Mn–atom distance. [c] Estimated uncertainty ±0.03 Å. [d] Pyrrole carbons. [e] *meso*-Carbon atoms. [f] α-Carbon atoms of pivalamidophenyl substituents.

Thus, the results of this XAS study are consistent with the postulated five-coordinate oxo-manganese(IV) derivative **2** produced by oxidation of $[Mn^{III}Br(T_{piv}PP)]$, in which the Mn–O bond lengths is 1.69 ± 0.03 Å. This value is in agreement with the results of the preliminary investigation,[2] and slightly shorter than the 1.84 ± 0.02 Å distance reported for the manganese porphyrin with a water molecule as a sixth ligand.[1] Furthermore, Table 1 compares the bond distances found in the oxo(porphyrinato)metal compounds that have been characterized to date with the Mn–O distances found in the non-oxo dimethoxo(porphyrinato)manganese(IV) complex.[6] The relatively weak pre-edge feature (Fig. 3) for the Mn^{IV}=O species **2** is consistent with a relatively long Mn–O bond, based on the arguments presented previously for Cr=O, Cr=N and Fe=O species.[9] The lengthening of the Mn^{IV}=O bond in **2** relative to the bond lengths in low-spin Cr^{IV}=O and Fe^{IV}=O porphyrin complexes is most probably related to the high-spin nature of this compound and, as shown by Spiro et al.,[4] to the special stability and low polarizability of the half-filled t_{2g}^3 subshell. Furthermore, an anionic macrocyclic tetraamidato–oxomanganese(V) complex has been characterized recently by X-ray crystallography.[21] The Mn=O length of 1.555(4) Å found in this five-coordinate, low-spin (S = 0), manganese(V) derivative is, as expected, shorter than the 1.69 Å found in **2**.

The high reactivity of the oxo(porphyrinato)manganese(IV) complexes towards olefins and saturated hydrocarbons is probably also related to the high-spin nature of these species.[2–4]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0345 $ 10.00+.25/0

The higher stability of the picket-fence porphyrin derivatives relative to those obtained with other porphyrins (H_2TPP, H_2TPFPP, H_2TMP[2, 3, 5]) indicates that the oxo group of the Mn=O moiety of **2** probably lies in the hydrophobic cavity formed by the four pivalamide pickets of this porphyrin.

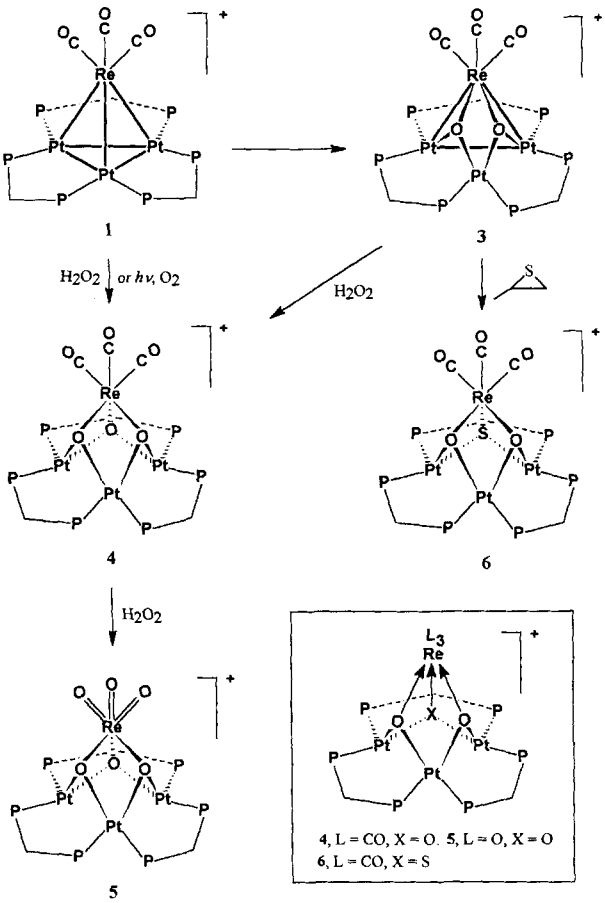
Models for Bimetallic Catalysts: Multiple Oxidation States in Pt_3Re Cluster Cations**

Leijun Hao, Jianliang Xiao, Jagadese J. Vittal, and Richard J. Puddephatt*

Binding between oxo ligands and the small metal clusters present in the important oxide-supported bimetallic Pt–Re catalysts may occur at the metal-support interface and also during oxidation–reduction cycles.[1] However, knowledge of how oxygen interacts with the metal clusters is limited due to the difficulties in characterizing the heterogeneous materials. There are also few related metal oxo clusters to act as model compounds.[2, 3] The oxidation of **1** (dppm = $Ph_2PCH_2PPh_2$) with Me_3NO or oxygen to give the clusters **2** and **3**, respectively, was reported earlier.[4] Here we show that further oxidation of **3** to give the novel clusters **4**–**6** is possible (Scheme 1). The oxidation of **1** to **4**, **5**, or **6** leads to an increase in cluster electron count by

$[Pt_3\{Re(CO)_3\}(\mu\text{-dppm})_3]^+$ **1** $[Pt_3\{Re(CO)_3\}(\mu_3\text{-O})(\mu\text{-dppm})_3]^+$ **2**



$[Pt_3\{Re(CO)_3\}(\mu_3\text{-O})_2(\mu\text{-dppm})_3]^+$ **3** $[Pt_3\{Re(CO)_3\}(\mu_3\text{-O})_3(\mu\text{-dppm})_3]^+$ **4**

$[Pt_3\{ReO_3\}(\mu_3\text{-O})_3(\mu\text{-dppm})_3]^+$ **5**

$[Pt_3\{Re(CO)_3\}(\mu_3\text{-O})_2(\mu_3\text{-S})(\mu\text{-dppm})_3]^+$ **6**

12 electrons (from 54 to 66 electrons) and the formation of **5** from **1** involves a 12-electron oxidation (from Pt_3Re^+ to Pt_3Re^{13+}) without cluster fragmentation. Such multielectron processes appear to be unprecedented in cluster chemistry.

The trioxo cluster **4** could be prepared either by the thermal reaction of **1** with hydrogen peroxide or the photochemical reaction of **1** with oxygen. In both cases, NMR monitoring showed that the reaction proceeded via the intermediacy of the dioxo cluster **3** (Scheme 1) and, as predicted on this basis, reaction of

Scheme 1.

cluster **3** with H_2O_2 led to addition of a third oxo ligand giving **4** in high yield. The analogous dioxo(thio) cluster **6** was obtained by sulfur atom addition in the reaction of cluster **3** with propene sulfide. Finally, the hexaoxo cluster **5** was obtained by further oxidation of **4** with H_2O_2; cluster **5** has low solubility in acetone and so precipitates as it is formed. The $Re(=O)_3$ frag-

[**] This work was supported by the Natural Sciences and Engineering Research Council (Canada).

ment present in **5** is also present in $[Pt_3(ReO_3)(\mu\text{-dppm})_3]^+$, which was obtained by the high-temperature reaction of **1** or **3** with O_2.[5] The oxidation of Re–CO groups to Re=O groups finds precedent in the oxidation of $[(\eta^5\text{-}C_5Me_5)Re(CO)_3]$ to $[(\eta^5\text{-}C_5Me_5)ReO_3]$ in reaction with H_2O_2 or $O_2/h\nu$.[6] For the Pt_3Re clusters **1** and **3**, oxidation by oxygen atom addition evidently takes place first at the Pt–Re bonds; the $Re(CO)_3$ to $Re(=O)_3$ transformation has a higher activation energy.

Complexes **4** and **5** each give a single resonance in the ^{31}P NMR spectrum due to the phosphorus atoms and two resonances in the ^1H NMR spectrum due to the methylene protons of the dppm ligands, indicating a structure with C_{3v} symmetry. The magnitudes of the coupling constants $^1J(Pt,P)$ (3401 Hz for **4**, 3561 Hz for **5**) are greater than for the precursor **1** (2411 Hz), as expected since the phosphorus atoms are *trans* to the oxygen atoms rather than to the metal–metal bonds. The IR spectrum of **4** contains ν(CO) bands at 1987 and 1856 cm^{-1}, whose positions are close in energy to those in **1**–**3**;[4] the spectrum of **5** contains ν(Re=O) bands at 937 and 900 cm^{-1}, comparable to those observed in $[Pt_3(ReO_3)(\mu\text{-dppm})_3]^+$ (935 and 893 cm^{-1})[5] and $[(\eta^5\text{-}C_5Me_5)ReO_3]$ (909 and 878 cm^{-1}).[6]

The cluster **6** is C_2 symmetric and, as expected, the ^{31}P NMR spectrum exhibited three resonances due to the dppm ligands, with $^1J(Pt,P)$ values of 3388 and 3283 Hz (P atoms *trans* to oxygen atoms) and 3190 Hz (P atoms *trans* to the sulfur atom). The IR spectrum contains ν(CO) bands at 1989, 1865, and 1856 cm^{-1}. The structure of **6**, as the $[PF_6]^-$ salt, was confirmed crystallographically (Fig. 1).[7] Table 1 summarizes the changes

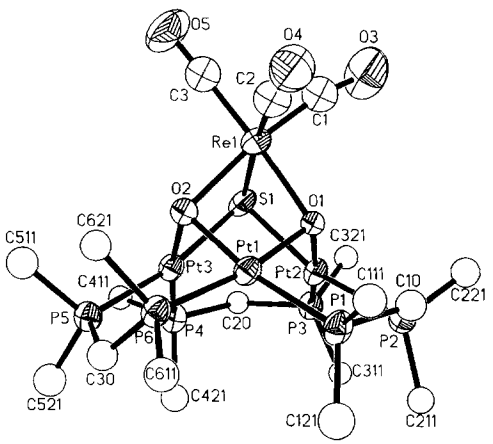

Fig. 1. A view of the structure of the cluster cation **6**. Only the *ipso* carbon atoms of the phenyl groups are shown for clarity.

in Pt–Pt and Pt–Re distances in **1**, **3**, and **6** as two oxo (**3**) and two oxo and one thio ligand (**6**), respectively, are added to cap the Pt_2Re faces of cluster **1**. It is immediately apparent that because of additional chalcogenido ligands all metal–metal separations increase in this series of clusters, and that complex **6** contains no metal–metal bonds.

Table 1. Comparison of the metal–metal distances in **1**, **3**, and **6**.

	1	**3**	**6**
Pt1-Pt2	2.611(1)	2.826(1)	3.254(2)
Pt1-Pt3	2.593(1)	3.094(1)	3.157(2)
Pt2-Pt3	2.608(1)	3.081(1)	3.143(2)
Pt1-Re	2.684(1)	2.843(1)	3.132(2)
Pt2-Re	2.649(1)	2.854(1)	3.378(2)
Pt3-Re	2.685(1)	3.228(1)	3.465(2)

Cluster **1** is intensely red-black and the color appears to be associated with the metal–metal bonds, while the clusters **4**–**6** are yellow or white, consistent with the absence of metal–metal bonds in all cases. The cluster electron count increases from 54 in **1** to 66 in each of **4**–**6** (each μ_3-O or μ_3-S ligand contributes four electrons, each terminal CO or O contributes two electrons). The additional 12 electrons in **4**–**6** cause the cleavage of all metal–metal bonds. Hence the $Pt_3Re(\mu_3\text{-}X)_3$ framework established for **6** is a model for the series **4**–**6** (X = O, S). A valence-bond representation of the bonding in **4**–**6** is shown in the inset in Scheme 1. Thus the metal centers in **4** and **6** are considered as octahedrally surrounded Re^I ions and square-planar surrounded Pt^{II} ions (PtP_2O_2 or PtP_2OS coordination); the sum of the oxidation states of the metal atoms increases from +1 in **1** to +7 in **4** and **6**. The platinum coordination is the same in **5**, but the rhenium is oxidized to Re^{VII} with octahedral ReO_6 coordination and the sum of oxidation states of the metal centers is now +13. We know of no cluster complexes containing this type of rhenium coordination but related mononuclear complexes are known.[8] For example, the complexes $[LReO_3]^+$ (L = 1,4,7-triazacyclononane, 1,4,7-trithiacyclononane) are related to **5** if the Pt_3O_3 ring is considered as a tridentate pseudo-crown ether ligand.[8] The high oxidation state of rhenium in **5** is shown by the Re ($4f_{7/2}$) binding energy of 45.6 eV in the X-ray photoelectron spectroscopy (XPS), only slightly lower than in Re_2O_7 (46.7 eV).[9]

The use of polyhedral skeletal electron theory to predict the extent of metal–metal bonding is central to the systematic study of cluster complexes. Previously, the effect of a 12-electron increase in cluster electron count could only be studied by using structurally similar clusters of different metals. A well-known example is found in the clusters $[Cp_4Fe_4(CO)_4]$ (60 electrons, six M–M bonds) and $[Cp_4Co_4S_4]$ (72 electrons, no M–M bonds).[10] The clusters **1** (54 electrons) and **4**–**6** (66 electrons) provide a particularly good example because all are based on the Pt_3Re core and because the intermediate 58- and 62-electron clusters are also known.[4] Similarly, the ability to increase the sum of the oxidation states of the metal atoms in the cluster **1** by six (**1** → **4**, **1** → **6**) or by 12 (**1** → **5**), while maintaining the cluster integrity is unprecedented.[11] There is a close analogy between the structure of the $Re(CO)_3(\mu\text{-}O)_3$ unit in **4** and that proposed for rhenium carbonyl complexes bound to oxide supports. The chemistry of **4** gives credence to the theory that oxophilic rhenium centers are present at the oxide support/bimetallic alloy interface in supported Pt–Re catalysts.[1, 12]

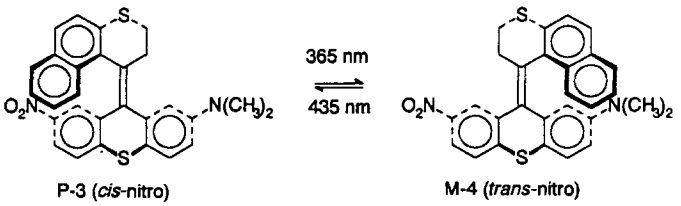
A Highly Stereoselective Optical Switching Process Based on Donor–Acceptor Substituted Dissymmetric Alkenes**

Wolter F. Jager, Johannes C. de Jong, Ben de Lange, Nina P. M. Huck, Auke Meetsma, and Ben L. Feringa*

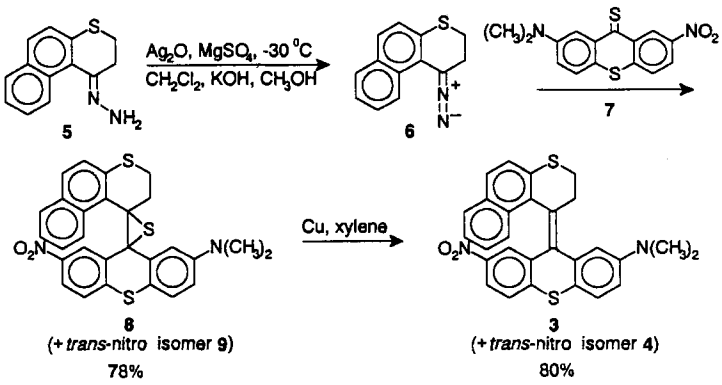
The development of organic materials for optical data storage and molecular optical devices requires components whose physical properties can be modulated by light.[1] For a few bistable molecular systems based on photocyclization reactions impressive results have been obtained.[2] So far the bistable molecules are detected primarily by UV/Vis spectroscopy (photochromism),[1, 2] although detection based on changes in other properties such as refractive index[3] and conductivity[4] is also successfully employed.



The first chiroptical molecular switch, based on the bistability of the helical *cis* and *trans* thioxanthenes **1** and **2**, was reported by our group.[5] These pseudoenantiomers[6] interconvert stereospecifically M-*cis* ⇌ P-*trans*; in other words the *cis*–*trans* isomerization of **1** and **2** is accompanied by a reversal of helicity. For these compounds a difference in the relative proportion of the two photostationary states of only 4% was reached (irradiation with $\lambda = 300$ nm: 64% M-*cis*, 36% P-*trans*; irradiation with $\lambda = 250$ nm: 68% M-*cis*, 32% P-*trans*), whereas 10% racemization (M-*cis* → P-*cis*; P-*trans* → M-*trans*) was observed after 20 switching cycles.[5]

We describe here a remarkably selective switching process based on the intrinsic chirality of donor–acceptor substituted

1 : X = CH_2, R^1 = CH_3, R^2 = OCH_3, R^3 = H
2 : X = CH_2, R^1 = CH_3, R^2 = H, R^3 = OCH_3
3 : X = S, R^1 = H, R^2 = NO_2, R^3 = N $(CH_3)_2$
4 : X = S, R^1 = H, R^2 = N $(CH_3)_2$, R^3 = NO_2



dissymmetric *cis* and *trans* **3** and **4**, respectively (Scheme 1). The absorption maxima of these compounds are red-shifted relative to those of **1** and **2**, allowing the switching process to take place in the visible. Moreover, increased thermal and photochemical stability towards racemization was obtained by the introduction of a sulfur atom at the 1-position.

Scheme 1. Chiroptical molecular switch based on the photoisomerization of P-**3** and M-**4**.

The photochemical isomerization P-**3** (*cis*-nitro) ⇌ M-**4** (*trans*-nitro) (Scheme 1) is detected by chiroptical techniques. Major advantages over other photochromic systems are: a) a more discriminative detection technique, since unlike UV spectra, circular dichroism (CD) and optical rotatory dispersion (ORD) spectra of both molecular forms P-**3** (*cis*-nitro) and M-**4** (*trans*-nitro) can reverse sign and are roughly mirror images; b) photochemical isomerization during readout[1] (fatigue) can be excluded by using ORD techniques employing a wavelength outside the absorption region.

The formation of the central double bond is the key step in the synthesis of **3** and **4** outlined in Scheme 2. Hydrazone **5** was

Scheme 2.

oxidized to the corresponding diazo compound **6** (Ag_2O, CH_2Cl_2, −30 °C), and subsequent 1,3-dipolar cycloaddition[7] with thioketone **7** was followed by extrusion of N_2 to provide the episulfides **8** (*cis*-nitro) and **9** (*trans*-nitro). The episulfides were desulfurized by reduction with copper powder to afford

isomers **3** and **4** in a 60:40 ratio. The red *cis*-nitro isomer **3** (m.p. 212 °C) and the yellow *trans*-nitro isomer **4** (m.p. 206 °C) were separated chromatographically.[8]

Recrystallization of **3** from ethanol afforded crystals suitable for X-ray analysis. The molecular structure of **3** is depicted in Figure 1.[9] The arrangement about the central double bond is

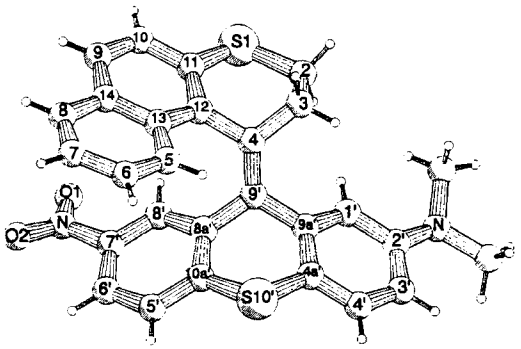

Fig. 1. X-ray crystal structure of **3** (PLUTO diagram).

nearly planar (dihedral angles 0.4–5.4°), and the bond length C4–C9′ has a normal value of 1.353 Å. The anti-folded helical structure, in which the top and bottom halves are tilted up and down, respectively, relative to the plane of the central double bond, and by which severe nonbonding interactions are avoided, is clearly shown. In **3** the nitroarene acceptor unit is located opposite the naphthalene moiety of the upper part of the molecule.

The enantiomers of **3** and **4** were resolved by chiral high-performance liquid chromatography (HPLC) with (+)-poly-(triphenylmethylmethacrylate) as a chiral stationary phase.[10] The configurations of all four stereoisomers M-**3**, P-**3**, M-**4**, and P-**4** were assigned by CD spectroscopy.[11] The enantiomers of **3** and **4** are perfectly stable under ambient conditions. The thermal racemization of P-**4** (*trans*-nitro) into M-**4** (*trans*-nitro), as determined by polarimetry at 85.0 and 90.0 °C, showed first-order kinetics with a barrier of 122.2 ± 0.5 kJ mol^{-1}. Introduction of a sulfur atom at the 1-position[12] increases the racemization barrier[13] by 12 kJ mol^{-1} relative to that of the carbon analogue **1**.[5] No thermal *cis*–*trans* isomerization (**3**⇌**4**) occurs. In contrast, a stereospecific photochemical *cis*–*trans* isomerization (P-**3**⇌M-**4**, λ = 300–435 nm, *n*-hexane) takes place readily and was monitored by CD, ^{1}H NMR spectroscopy, and HPLC analysis.

The UV/Vis spectra of **3** and **4** are clearly different (Fig. 2). Both compounds exhibit intense short-wavelength absorptions

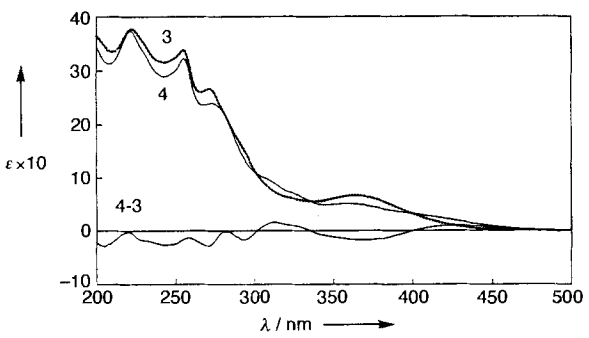

Fig. 2. UV spectra of **3** (dotted line) and **4** (solid line), and the difference spectrum (*n*-hexane).

at 220, 255, and 275 nm (ε = 25000–40000) and less intense long-wavelength absorptions. For **3** (*cis*-nitro) a well-defined absorption at 366 nm (ε = 7500) is observed, while **4** (*trans*-nitro) has a much broader, low-intensity absorption at 360 nm (ε = 5300). The CD spectra of P-**3** (*cis*-nitro) and M-**4** (*trans*-nitro) (Fig. 3) are roughly mirror images at most wavelengths. This is in accordance with the "pseudoenantiomeric nature"[6] of P-**3** and M-**4**, in which the chiral properties are mainly determined by the opposite helical structure.

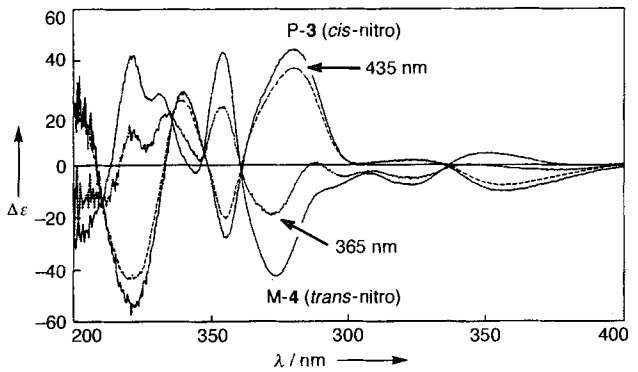

Fig. 3. CD spectra of M-**4**, P-**3**, and the photostationary states generated by irradiation at 365 and 435 nm (in *n*-hexane).

Irradiation of solutions of enantiomerically pure P-**3** (or M-**4**) in *n*-hexane at 300 and 350 nm for 10 s resulted in two distinct photostationary states. CD spectroscopy and chiral HPLC analysis revealed that at 300 nm the photostationary state was composed of 54% M-**4** (*trans*-nitro) and 46% P-**3** (*cis*-nitro), while the photostationary state at 350 nm was composed of 62% M-**4** (*trans*-nitro) and 38% P-**3** (*cis*-nitro). The P-**3**⇌M-**4** interconversion is perfectly reversible showing no trace of racemization after 60 switching cycles. The results of several irradiation experiments compiled in Table 1 show that the compositions of the photostationary states are strongly dependent on the solvents and wavelengths applied.[14]

Table 1. Composition of the mixture of diastereomers for the different photostationary states determined by irradiation of M-**4** in different solvents with light of different wavelengths.

Entry	Solvent	λ [nm]	Proportion of diastereomers [%]		(M-**4** vs P-**3**) [%]
1	*n*-hexane [a]	300	54 M-**4**	46 P-**3**	8
2	*n*-hexane [a, b]	350	62 M-**4**	38 P-**3**	24
3	cyclohexane [b]	350	62 M-**4**	38 P-**3**	24
4	toluene [b]	350	73 M-**4**	27 P-**3**	46
5	dioxane [b]	350	83 M-**4**	17 P-**3**	66
6	*n*-hexane [a]	313	50 M-**4**	50 P-**3**	0
7	*n*-hexane [a]	365	70 M-**4**	30 P-**3**	40
8	*n*-hexane [a]	405	53 M-**4**	47 P-**3**	6
9	*n*-hexane [a]	435	10 M-**4**	90 P-**3**	−80

[a] CD measurements. [b] HPLC analysis.

The extrema in the UV/Vis difference spectra of **3** and **4** (Fig. 2) at 314, 365, and 435 nm represent wavelengths at which after irradiation large differences in the composition of photostationary states can be expected.[15] Irradiation of either enantiomerically pure M-**4** (*trans*-nitro) or P-**3** (*cis*-nitro) at 365 nm results in a photostationary state composed of 70% M-**4** and 30% P-**3**. Alternating irradiation with 365 and 435 nm light results in a highly diastereoselective interconversion between

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0349 $ 10.00+.25/0

photostationary states with ratios of M-**4** and P-**3** of 70:30 and 10:90, respectively (Table 1, Fig. 3). The results demonstrate that the photochemical isomerization of both P-**3** and M-**4** is stereospecific and also shows high wavelength-dependent diastereoselectivity. At the same time the photochemical and thermal stability of **3** and **4** towards racemization has greatly improved.

Unlike other known potential optical memory systems[1-4] the key feature of the bistable molecules described here is that switching is accompanied by inversion of the chirality. These chiral compounds are suited as optical write-read-erase information storage systems.[1, 16] Photochemical writing in the visible and reading by chiroptical means either in the visible (ORD) or in the UV (CD) may be possible. Furthermore an Erasable Direct Read After Write (EDRAW) process might be executed by using for instance 365 nm light for reading and erasing (P-**3** $\rightleftharpoons$ M-**4** isomerization). The fact that the switching process occurs between photostationary states in which either of the pseudoenantiomers P-**3** or M-**4** are present in large excess makes this switch relatively insensitive towards racemization or degradation processes, since these processes will lower the CD signals of these states but will not change their signs. Studies on incorporating the highly selective chiral switchable molecules in polymeric films or depositing them on surfaces to develop macroscopic information storage devices are currently in progress.

Experimental Procedure

8 and **9**: A stirred solution of hydrazone **5** (350 mg, 1.53 mmol) in anhydrous CH_2Cl_2 (40 mL) was cooled to $-30\,^{\circ}C$, whereupon $MgSO_4$ (approximately 1 g), Ag_2O (530 mg, 230 mmol, 1.5 equiv), and a saturated solution of KOH in methanol (1.2 mL) were successively added. After 30 min the deep red solution was filtered into another ice-cooled flask, and the remaining residue was washed with cold CH_2Cl_2 (15 mL). To this clear solution was added thioketone **7** in small portions. Evolution of nitrogen was observed, and the deep red color slowly disappeared. The thioketone was added until the evolution of nitrogen had ceased; a total of 200 mg (0.63 mmol) was necessary. After 3 h of stirring and a standard workup, the red residue was purified by flash column chromatography (SiO_2, CH_2Cl_2/pentane 1/1, $R_f = 0.30$). The orange crystalline product consisted of isomers **8** and **9** (60:40). Yield: 255 mg, 78% (based on the amount of **7** added). HRMS calcd. 514.084, found 514.084; Elemental analysis calcd for $C_{28}H_{22}N_2O_2S_3$: C 65.34, H 4.31, S 18.69; found C 65.00, H 4.27, S 18.51.

8 (*cis*-nitro): ^{1}H NMR (200 MHz, TMS): $\delta = 2.40-2.70$ (m, 4H), 3.10 (s, 6H), 6.76 (dd, $J = 8.55$, 2.56 Hz, 1H), 6.97 (d, $J = 7.54$ Hz, 1H), 7.07 (d, $J = 8.97$ Hz, 1H), 7.20-7.55 (m, 7H), 7.86 (d, $J = 2.56$ Hz, 1H), 9.03 (d, $J = 7.69$ Hz, 1H).

9 (*trans*-nitro): ^{1}H NMR (200 MHz, TMS): $\delta = 2.17$ (s, 6H), 2.40-2.80 (m, 4H), 6.27 (m, 2H), 6.90 (d, $J = 8.98$ Hz, 1H), 7.02 (d, $J = 8.65$ Hz, 1H), 7.23-7.68 (m, 6H), 8.13 (dd, $J = 8.55$, 2.56 Hz, 1H), 8.89 (d, $J = 8.97$ Hz, 1H).

3 and **4**: The mixture of episulfides **8** and **9** (95 mg, 0.18 mmol) was desulfurized as described in ref. [11b]. The red solid obtained (71 mg, 0.14 mmol, 80%) consisted of the two isomers **3** and **4**, which were readily separated by flash column chromatography (SiO_2, CH_2Cl_2/hexane 1/1, $R_f = 0.57$ and 0.67).

3 (*cis*-nitro): m.p. 212.2-212.6 °C; ^{1}H NMR (200 MHz, $CDCl_3$, TMS): $\delta = 3.07$ (s, 6H), 4.21 (dd, $J = 7.58$, 2.55 Hz, 4H), 6.76 (dd, $J = 8.55$, 2.57 Hz, 1H), 6.95-7.21 (m, 4H), 7.29 (d, $J = 2.57$ Hz, 1H), 7.36-7.76 (m, 6H); HRMS calcd 482.110, found 482.112; UV (*n*-hexane, λ_{max} (ε)): 220.8 (36700) 254.9 (34500) 272.0 (27700) 365.2 (7500); CD (P isomer, *n*-hexane, $\lambda_{max}(\Delta\varepsilon)$): 221 (-57) 240 (28.3) 255.2 (-28) 281.4 (44) 356 (-10).

4 (*trans*-nitro): m.p. 205.8-206.1 °C; ^{1}H NMR (200 MHz, $CDCl_3$, TMS): $\delta = 2.30$ (s, 6H), 3.45-3.72 (m, 4H), 5.93 (d, $J = 2.56$ Hz, 1H), 6.26 (dd, $J = 8.76$, 2.78 Hz, 1H), 7.01-7.19 (m, 3H), 7.39 (d, $J = 8.4$ Hz, 1H), 7.48-7.69 (m, 4H), 8.15 (dd, $J = 8.55$, 2.56 Hz, 1H), 8.43 (d, $J = 2.14$ Hz, 1H); UV (*n*-hexane, λ_{max} (ε)): 221.7 (37700) 252.2 (33900) 273.0 (25500) 360.0 (5300); CD (P isomer, *n*-hexane, λ_{max} ($\Delta\varepsilon$)): 221 (-42) 226.6 (-26) 244 (3.3) 254.2 (-43.3) 274.2 (42.4) 323.2 (7.7) 348 (-4.6).

Irradiations of 2×10^{-5} M solutions of enantiomerically pure **3** and **4** were performed in cylindrical quartz cells. Low-pressure mercury lamps (28 × 1 cm; 8 W) were used for irradiations at 300 and 350 nm, and the irradiation time was 10 s. For irradiations at 313, 365, 405, and 435 nm a 200 W high-pressure mercury lamp equipped with interference filters was employed. Typical irradiation times for this setup were 20 to 30 min.

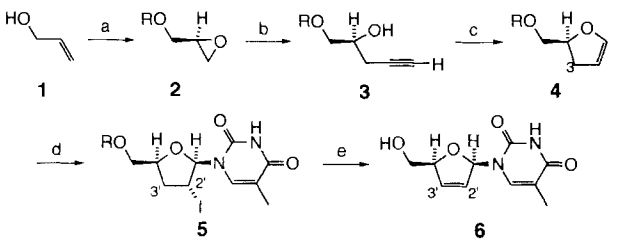
Asymmetric Syntheses of Stavudine (d4T) and Cordycepin by Cycloisomerization of Alkynyl Alcohols to Endocyclic Enol Ethers**

Frank E. McDonald* and Mark M. Gleason



Various deoxynucleosides[1] show potent antiviral activity, particularly against the human immunodeficiency virus (HIV), which is the causative agent for acquired immunodeficiency syndrome (AIDS). Stavudine (2′,3′-didehydro-3′-deoxythymidine; d4T) retains the high antiviral activity of 3′-azido-3′-deoxythymidine (AZT) while exhibiting significantly lower bone marrow toxicity and reduced inhibition of mitochondrial DNA synthesis.[2] Cordycepin (3′-deoxyadenosine) has been widely

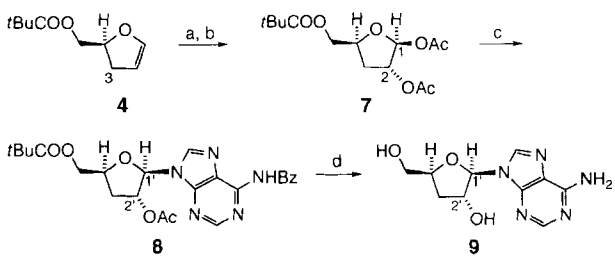
used as a probe for messenger RNA transcription and also exhibits antibiotic activity.[3] These compounds have been classically prepared by functional group manipulation of naturally occurring ribo- and 2'-deoxyribonucleosides or from carbohydrate precursors,[4] but more recently the synthesis of d4T has been reported from amino acid precursors.[5, 6] We envisioned that a shorter synthesis of deoxynucleosides might be obtained by molybdenum pentacarbonyl catalyzed cycloisomerization of acyclic alkynyl alcohols to endocyclic enol ethers.[7] Given the ready availability of chiral nonracemic alkynyl alcohols from achiral precursors[8, 9] as well as the demonstrated utility of endocyclic enol ethers in the synthesis of glycosides and nucleosides,[5, 10] we set out to establish the viability of the cycloisomerization strategy for asymmetric synthesis of deoxynucleosides.



The asymmetric synthesis of an appropriate five-carbon alkynyl alcohol precursor begins with the preparation of (*S*)-glycidyl pivaloate (**2**) by utilizing asymmetric epoxidation of allyl alcohol followed by in situ derivatization[8, 11] (Scheme 1).

Scheme 1. Synthesis of stavudine (d4T) by $Mo(CO)_5$-mediated cycloisomerization. R = *t*BuCO. a) 5% $Ti(O{i}Pr)_4$, 6% D-diisopropyl tartrate, $Me_2C(Ph)OOH$, 3Å molecular sieves, CH_2Cl_2, −20 °C; *t*BuCOCl, Et_3N (37%); b) LiC≡CH, $BF_3{\cdot}OEt_2$, THF, −78 → −20 °C (70%); c) 50 mol% $Mo(CO)_6$, 50 mol% Me_3NO, Et_3N, Et_2O (80%); d) I_2, *N*,*N*-bis(trimethylsilyl)thymine, CH_2Cl_2 (94%, 7:1 mixture); e) 60 equiv. NaOMe, MeOH (80%).

Addition of lithium acetylide to **2** is regioselective for the unsubstituted epoxide terminus, but careful control of reaction temperature and use of boron trifluoride–etherate[12] is critical to avoid ester group migration. Mosher ester analysis of the alkynyl alcohol product **3** indicates an enantiomeric excess of 89% (±1%, ^{1}H NMR). Cyclization of **3** upon reaction with molybdenum hexacarbonyl/trimethylamine *N*-oxide in the presence of triethylamine provides the isomeric dihydrofuran **4** in 80% isolated yield. Iodine-mediated introduction of thymine to **4** gives a 7:1 ratio (in favor of the iodonucleoside **5**) of *anti*-addition products in excellent yield. Iodonucleoside **5** is unstable to silica gel chromatography, and best overall yields are obtained by treating the crude product with a large excess of freshly prepared sodium methoxide, which accomplishes pivaloate methanolysis as well as bimolecular elimination[5] of HI to afford stavudine (**6**). Thus the asymmetric synthesis of stavudine has been achieved in five steps (longest linear sequence) from achiral allyl alcohol, instead of the previous eight steps in the synthesis from L-glutamic acid.[5]

We have explored other functionalization routes to deoxynucleosides from dihydrofuran **4**. For instance, osmium tetraoxide catalyzed dihydroxylation[13] of **4** proceeds predominantly from the face opposite to the acyloxymethyl side chain, and acylation of the crude diol provides a 13:4:3:1 mixture of diacetylated products favoring **7** (Scheme 2, Table 1). This mixture is subjected to Lewis acid catalyzed adenine glycosylation[14] to give a 9:1 mixture of stereoisomers favoring **8**. Methanolysis of acyl groups followed by purification on silica

Scheme 2. Synthesis of cordycepin. a) 1% OsO_4, *N*-methylmorpholine oxide (NMO), THF/*t*BuOH/H_2O (67%); b) Ac_2O, Et_3N, CH_2Cl_2 (90%, 13:4:3:1 mixture); c) N^7-benzoyl-N^4,N^7-bis(trimethylsilyl)adenine, $Me_3SiOSO_2CF_3$, $ClCH_2CH_2Cl$, 83 °C (65%); d) NaOMe, MeOH (42%).

[a] ^{1}H NMR spectra were recorded at 300 MHz and ^{13}C NMR spectra at 75 MHz.

gel affords complete separation of diastereomers to provide synthetic cordycepin (**9**).[3]

In conclusion, we have demonstrated an effective procedure for the preparation of the antiviral deoxynucleosides stavudine (**6**) and cordycepin (**9**), utilizing novel cyclization methodology as the missing link between readily available acyclic precursors and isomeric oxacyclic products. Since all the carbon atoms are derived from the simple achiral precursors allyl alcohol, acetylene, and the appropriate pyrimidine or purine bases, this methodology is well-suited for the preparation of enantiomeric

and diastereomeric analogs of these deoxynucleosides.[15] This synthetic route may also provide access to isotopically labeled nucleosides[16] for structural and pharmacological studies of nucleoside drugs as well as nucleotide polymers DNA and RNA.

Electron Transfer through DNA: Site-Specific Modification of Duplex DNA with Ruthenium Donors and Acceptors**

Thomas J. Meade* and Jon F. Kayyem

Long-range intramolecular electron transfer (ET) in protein–protein complexes and modified proteins takes place over appreciable distances at biologically significant rates.[1, 2] Experiments have confirmed its dependence on free energy and distance, as well as the importance of the reorganization of the ligand sphere and solvent environment.[3] Two factors that influence the rate of electron transfer that are far less understood in both inorganic and organic systems are the structure of the intervening medium and the orientation of the donor–acceptor unit.

A barrier to the further understanding of the factors that influence the mechanisms of long-range electron transfer is the development of an architecture capable of critically testing these properties. The unique ability of complementary single strands of DNA to hybridize into a rigid duplex of defined structure makes an oligonucleotide an attractive choice for use as a molecular template. This template can be modified with spectroscopically detectable and photochemically active redox centers at predetermined locations. Moreover, recent theoretical work suggests that the electronic coupling between donor and acceptor for modified DNA derivatives could display a remarkable dependence on nucleic acid sequence.[4]

In order to test these assumptions, we have devised a novel approach to prepare ruthenium-modified duplex DNA derivatives where the donor and acceptor are separated by any number of base pairs. The goal of this approach is to prepare a series of ruthenium-modified DNA derivatives in which 1) the ruthenium complexes are covalently and rigidly attached to a single site on the duplex, 2) the redox potential of each ruthenium complex can be varied independently, 3) the DNA duplex is unperturbed by the presence of the ruthenium complexes, and 4) the redox states of the donors and acceptors are spectroscopically distinguishable. This new synthetic procedure covalently attaches redox centers of varying potentials to a series of oligonucleotides each modified with a primary amino group at the 2′ position of the 5′-terminal ribose (Fig. 1). Intramolecular ET rates obtained from these rigidly attached redox centers should provide insight into the electronic coupling between donor and acceptor linked to DNA.

Our strategy for the preparation of these transition metal DNA derivatives involves a departure from previous work in which oligonucleotides have been modified with organic molecules and metal complexes at the terminal phosphates,[5–6] various heterocyclic bases,[7–11] and the ribose ring.[12–13] This new approach employs the synthesis of two sets of complementary strands (8–14 base pairs in length) of oligonucleotides modified with a terminal aminoribose[14] and subsequent covalent modification with redox-active ruthenium complexes. Unlike fluorescent DNA tags such as fluorescein isothiocyanate

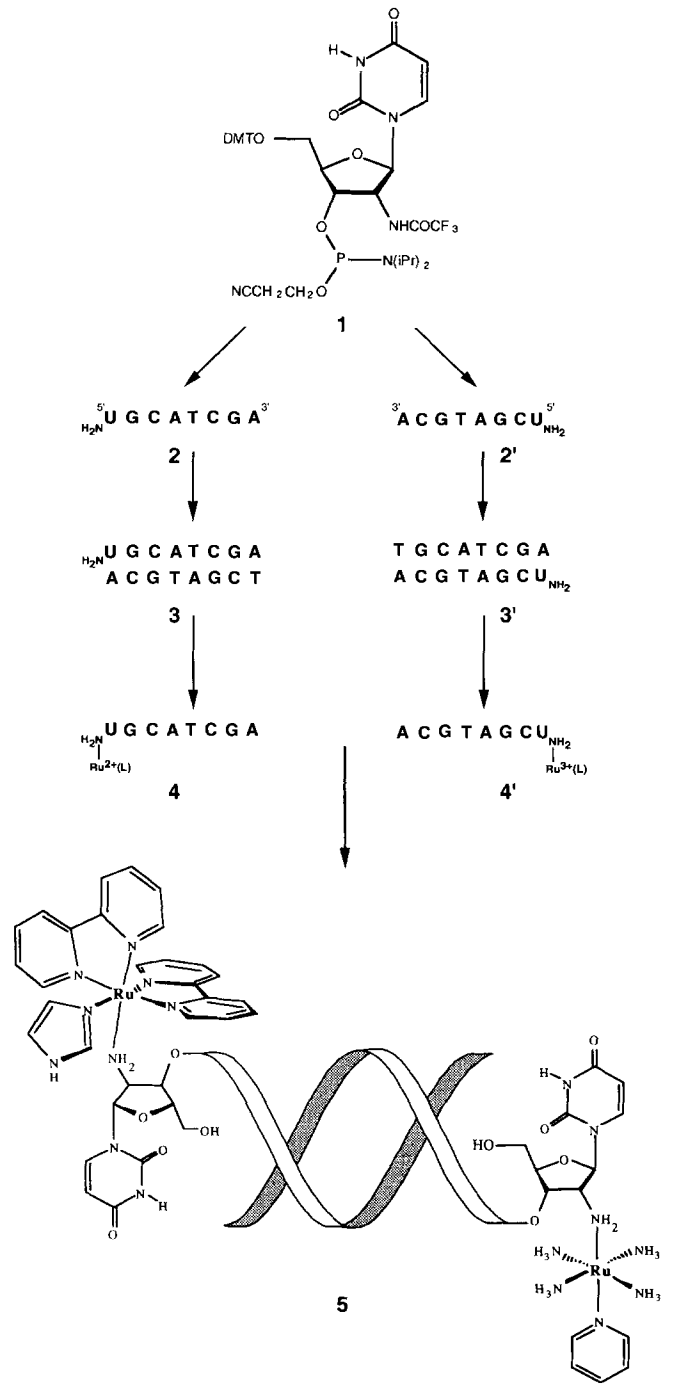

Fig. 1. Scheme for the preparation of duplex DNA labeled with donors and acceptors. The DMT-2′-*N*-trifluoroacetyl-protected phosphoroamidite (**1**) is incorporated into an oligodeoxyribonucleotide (**2**, **2′**) by automated solid-phase synthesis techniques and "protected" with a complementary strand (formation of **3**/**3′**). After reaction with a ruthenium complex, the complement is removed, and the modified oligonucleotide purified. The procedure is repeated and the strands annealed to yield **5**. Abbreviations U_{NH_2} = 2′-amino-2′-deoxyuridine; L = 2,2′-bipyridine, imidazole, pyridine, NH_3; DMT = dimethoxytrityl.

(FITC), the ruthenium complexes used in this work will react with the heterocyclic nitrogen atoms of the bases. Therefore, an unmodified complementary sequence is used as a large hydrogen-bonded blocking group to protect the sites on the bases that are susceptible to attack by the metal.[15] Under these conditions, the exposed primary 2′-amine at the 5′-terminal ribose position of the duplex DNA is readily modified with a variety of ruthenium complexes. In contrast, random ruthenium modification of the heterocyclic nitrogen centers is eliminated in some cases and substantially reduced in others.

A DMT-2′-*N*-trifluoroacetyl-protected phosphoroamidite (**1**) of 2′-amino-2′-deoxyuridine (U_{NH_2}) was prepared by variation of published procedures,[12] and oligodeoxyribonucleotides (**2**/**2′**) were assembled by standard solid-phase automated DNA synthesis techniques.[16] The 2′-amino-oligodeoxyribonucleotide **2** was annealed to the complementary sequence to form **3**. This U_{NH_2}-containing duplex was treated with $[Ru(bpy)_2CO_3]$, followed by imidazole in an inert atmosphere. The recovered duplex DNA was denatured in 7 M urea, and the ruthenium-modified oligonucleotide[17] was purified by using C-18 reversed-phase HPLC techniques (Fig. 2). This procedure was repeated with the complementary strand **2′** employing $[Ru(NH_3)_4(py)]^{2+}$ as the acceptor. Finally, the two ruthenium-modified oligonucleotides **4** and **4′** were annealed to give the desired duplex DNA **5** with a covalently bound donor and acceptor.

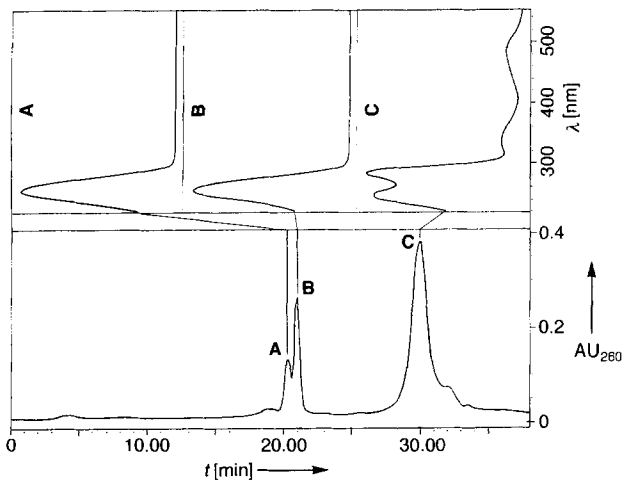

Fig. 2. HPLC analysis and UV/Vis spectra of duplex DNA following modification with ruthenium. Oligonucleotides were denatured in 7 M urea at 60 °C, injected onto a C-18 reversed-phase column, and eluted with a solvent mixture with a gradient of 2 to 40% CH_3CN in 7 M urea and 0.1 M triethylammonium acetate, pH 6.5. Peak A (25.4% CH_3CN) is unchanged amino-modified oligonucleotide (U_{NH_2}GCATCGA); peak B (27.7% CH_3CN) is the oligonucleotide complement of A (ACGTAGCT); peak C (38.8% CH_3CN) corresponds to Ru-modified A ($U_{NH_2Ru(bpy)_2}$(im)GCATCGA), where the absorption spectrum is consistent with the presence of a single $Ru(bpy)_2$(im)(U_{NH_2}) complex covalently bound to the oligonucleotide. Identities of peaks A, B, and C have been confirmed by coinjections of authentic samples and by enzymatic digestion (alkaline phosphatase, phosphodiesterase) followed by HPLC analysis of the nucleoside composition.

The new metal-modified oligonucleotides were characterized by fluorescent labeling, enzymatic digestion, and duplex-melting temperature studies. The aminoribose oligomers and their complements were treated with FITC under conditions that favor labeling of primary amines. As expected, only the 2′-amino-2′-deoxyribose site was labeled, which verified the presence of a primary amine on the DNA. Thermal denaturing and annealing experiments display similar melting temperatures for both ruthenium and aminoribose oligomers.[18] In addition, the amino-modified duplex DNA has been characterized by 2D NMR.[19] These data confirm that the donors and acceptors are covalently attached to the 2′-amino-2′-deoxyribose position and indicate that the DNA structure is unperturbed by the presence of the ruthenium complexes.

Kinetic measurements were performed by direct photoinduced and flash-quench techniques.[20] The rate of intramolecular electron transfer in the eight base-pair long duplex, modified with the acceptor $[Ru(bpy)_2(im)]^{3+}$ and the donor $[Ru(NH_3)_4(py)]^{2+}$, was determined to be $1.6(4) \times 10^6\ s^{-1}$ (metal–metal distance = 21 Å).[21] Since the driving force for this reaction ($-\Delta G^0 \approx 0.7$ eV) is well below the estimated reorganization energy ($\lambda \approx 0.9$ eV),[3, 20, 22] the activationless rate constant for electron transfer between ruthenium centers is expected to be roughly $2.5 \times 10^6\ s^{-1}$. Interestingly, this estimated k_{max} value is comparable to the k_{max} of one of the most efficient protein systems studied, His39-modified cytochrome c (Fe-to-Ru distance = 20.3 Å).[23]

Additional rates are required to determine the distance-dependent nature of this process, as well as to delineate the roles of base sequence and π-stacking in modulating the rates of long-range electron-transfer reactions through DNA.

[17] The yield of ruthenium-modified aminoribose duplex is typically 25–50% (see Fig. 2, peak C).
[18] Temperatures at which 50% of the DNA strands are dissociated (T_m) were determined by thermal denaturation and annealing in 0.9 M NaCl and 0.1 M Na phosphate buffer (pH 7) by means of a Hewlett Packard 8452A diode-array spectrophotometer with HP 89090A Peltier temperature-control accessory. Unmodified octamers as controls revealed a single helix-to-coil transition point and a T_m of 45 °C. The aminoribose oligomers showed a lower T_m of 40 °C. The ruthenium-modified oligomers, when hybridized to their unmodified complements, showed broad helix-to-coil transitions between 36 °C and 42 °C. All kinetic measurements were performed in the presence of 1 M Na^+ to insure that the modified oligonucleotides were annealed at ambient temperature (22 °C).

Structure and Bonding of Transition Metal Dihydrogen Complexes $[M(CO)_5(H_2)]$ (M = Cr, Mo, W)**

Stefan Dapprich and Gernot Frenking*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

Since the first synthesis of a stable dihydrogen complex, $[W(CO)_3(PR_3)_2(\eta^2\text{-}H_2)]$ (R = *c*-C_6H_{11} (Cy), *i*Pr) was reported by Kubas et al.[1] in 1984,[1a] many theoretical and experimental studies on the structures and properties of transition metal dihydrogen complexes have been published.[2] Although metal dihydrogen complexes play an important role as intermediates in catalytic hydrogenation reactions, relatively little is known about their geometries and bond strengths. The exact experimental determination of the equilibrium geometry of the L_nM-H_2 moiety is difficult, because the very low barrier for rotation about the $M-H_2$ axis even at very low temperatures yields a high degree of librational motion, which artificially shortens the H–H bond.[2, 3] Neutron diffraction studies of several complexes showed surprisingly similar H–H distances of 0.82 Å,[2–4] but recent experimental investigations of dihydrogen complexes reported H–H distances of >1 Å.[5]

Even more difficult than the geometry is the experimental determination of the $M-H_2$ bond energy. Ishikawa et al.[6a] estimated from studies of the lifetimes of several $[W(CO)_5L]$ complexes a W–L binding energy of >16 kcal mol^{-1} for $L = H_2$. The metal–ligand binding enthalpy of H_2 in $[W(CO)_3(PCy_3)_2(H_2)]$ was determined by Gonzalez et al.[6b] by using solution calorimetry as $\Delta H = 9.9$ kcal mol^{-1}. A quantum mechanical study of $[Cr(CO)_5(H_2)]$ by Pacchioni[7] gave a dissociation energy of 9.6 kcal mol^{-1} for H_2 dissociation. However, this value was derived from calculations only at the Hartree–Fock level of theory with partially optimized geometries.

The parent carbonyl complexes $[M(CO)_5(H_2)]$ are important for the study of $M-H_2$ bonding, because the unsubstituted molecules make it possible to analyze the metal–dihydrogen interactions in detail. The chromium analogue $[Cr(CO)_5(H_2)]$ is of particular interest, as it is a postulated intermediate in the water gas shift reaction.[8] The complexes $[M(CO)_5(H_2)]$ (M = Cr, Mo, W) have been characterized in noble gas matrices by IR spectroscopy,[9] but the equilibrium geometries and bond energies are not known. We have recently shown that the metal–ligand bond lengths calculated at the MP2 level of theory and the theoretically predicted first dissociation energies at the CCSD(T) level of theory using effective core potentials for the metals in complexes $[M(CO)_5L]$ (M = Mo, W; L = CO, CS) are in excellent agreement with experimental values, while the calculated Cr–L interatomic distances of $[Cr(CO)_5L]$ are slightly too short and the first dissociation energies too high.[10] Similar results have been obtained for $[M(CO)_5]$ (M = Fe, Ru, Os) and $[M(CO)_4]$ (M = Ni, Pd, Pt).[11] In this paper we report the theoretically predicted equilibrium geometries, vibrational frequencies, and metal–dihydrogen bond energies of $[M(CO)_5(H_2)]$ (M = Cr, Mo, W) obtained at the same theoreti-

[**] Theoretical Studies of Organometallic Compounds, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 10: ref. [11].

cal level as in the previous studies.[10, 11] We also report a detailed analysis of the metal–dihydrogen bonding interactions.

Figure 1 shows the optimized geometries of the $[M(CO)_5(H_2)]$ molecules. The complexes are pseudo-octahedral (C_{2v}), and the *cis* (equatorial) carbonyl ligands are bent slightly away from the H_2 ligand. The theoretically predicted H–H distances are between 0.791 Å (M = Mo) and 0.814 Å (M = Cr). These values are in agreement with the results of neutron diffraction studies

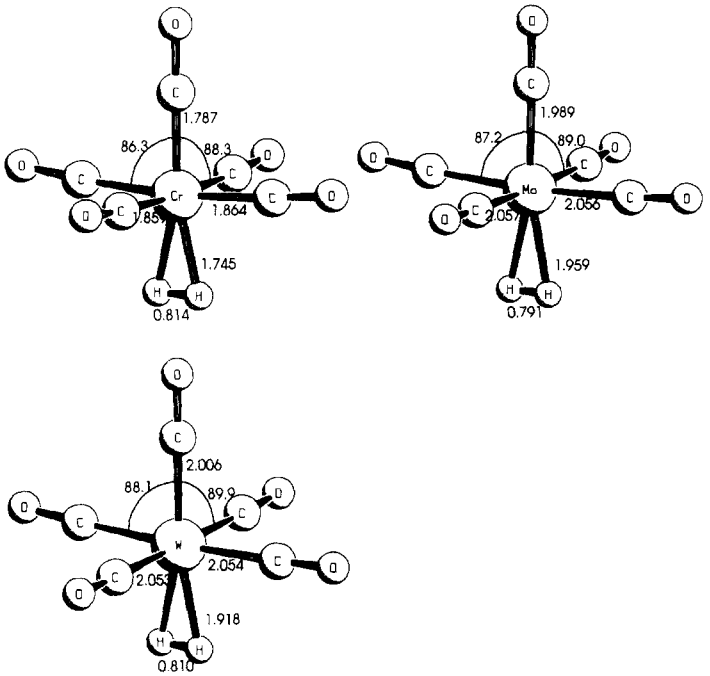

Fig. 1. Optimized geometries of $[M(CO)_5(H_2)]$ complexes at the MP2/II level. Bond lengths in Å, angles in degrees.

of several transition metal dihydrogen complexes, which show a H–H distance of roughly 0.82 Å despite widely varying ligand sets, central metal atoms, and charges.[3, 4] Also the predicted metal–hydrogen distances compare favorably with experimental results. The Mo–H bond length in $[Mo(CO)(H_2)(dppe)_2]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) is reported as 1.92 Å.[3] Since the dppe ligand (π acceptor) enforces the L_nM-H_2 bonding, the calculated Mo–H distance of 1.959 Å in $[Mo(CO)_5(H_2)]$ appears reasonable. The calculated W–H distance in $[W(CO)_5(H_2)]$ (1.918 Å) is in good agreement with the experimental value of the original Kubas complex $[W(CO)_3(PiPr_3)_2(H_2)]$, which has ben reported as 1.95 Å (X-ray) and 1.89 Å (neutron diffration).[1, 20] The Cr–H bond length of the chromium analogue $[Cr(CO)_3(PiPr_3)_2(H_2)]$ has recently been determined by X-ray analysis (1.70–1.80 Å).[21] The calculated value for the Cr–H distances in $[Cr(CO)_5(H_2)]$ is 1.745 Å (Fig. 1). The comparison of the theoretical and experimental results for $[M(CO)_6]$ indicates that the H–H and M–H distances should be quite accurate.

Figure 1 shows that the theoretically predicted equilibrium geometries of the $[M(CO)_5(H_2)]$ complexes have the H_2 ligands eclipsing equatorial carbonyl groups that are *trans* to each other. An eclipsed conformation is also found in other dihydrogen complexes[2, 3] and has been rationalized by MO arguments.[3] The four equatorial carbonyl groups are bent away from the H_2 ligand, which leads to a hybridization of the metal d orbitals towards H_2. The carbonyl ligands eclipsing the H_2 ligand are more strongly bent out of the equatorial plane, which yields stronger sd hybridization at the metal and stronger $M-H_2$ interactions in this conformation.

Table 1 shows the theoretically predicted bond dissociation energies D_e and D_0 for the $(CO)_5M-H_2$ bonds. The theoretical

Table 1. Dissociation energies D_e and D_0 [kcal mol^{-1}] and ν_{H-H} vibrational frequencies $\tilde{\nu}$[cm^{-1}] of $[M(CO)_5(H_2)]$ calculated with basis set II [a].

	Method	$[Cr(CO)_5(H_2)]$	$[Mo(CO)_5(H_2)]$	$[W(CO)_5(H_2)]$
D_e	CCSD(T)	19.8	16.1	19.8
D_0	CCSD(T)	15.9	12.8	16.3
D_0	exp.	15.0 ± 1.3 [c]	–	> 16 [d]
$\tilde{\nu}$	MP2	3363	3612	3338
$\tilde{\nu}$	exp. [b]	3030	3080	2711

[a] See ref. [12]. [b] See ref. [9]. [c] Ref. [29]. [d] Ref. [6a].

value $D_0 = 16.3$ kcal mol^{-1} for $[W(CO)_5(H_2)]$ is in agreement with the experimental estimate of > 16 kcal mol^{-1}.[6a] The theoretically predicted value is also supported by the experimental values for the W–L binding enthalpies of $[W(CO)_3(PCy_3)_2L]$. The measured values are $\Delta H = 9.9$ kcal mol^{-1} (L = H_2) and $\Delta H = 30.4$ kcal mol^{-1} (L = CO).[6b] The first CO dissociation energy of $[W(CO)_6]$ is calculated as $D_0 = 45.7$ kcal mol^{-1},[10a] the experimental value is 46.0 ± 2 kcal mol^{-1}.[22] Thus, the W–CO bond strength of $[W(CO)_6]$ is stronger than in $[W(CO)_3(PCy_3)_2L]$ by a factor of 1.5. This factor gives an estimated bond strength of approximately 15 kcal mol^{-1} for the $W-H_2$ bond in $[W(CO)_5(H_2)]$, which is in good agreement with the calculated value of 16.3 kcal mol^{-1}.

The calculations suggest that the tungsten complex has the strongest $(CO)_5M-H_2$ bond, in the chromium complex it is only slightly weaker, and in the molybdenum complex it is the weakest of all. After we had completed our theoretical studies the experimentally determined $(CO)_5Cr-H_2$ binding enthalpy was published by Weitz et al.[29] By using transient IR spectroscopy, they determined a gas-phase value of 15.0 ± 1.3 kcal mol^{-1}, which is in excellent agreement with our calculated value of 15.9 kcal mol^{-1}. The calculated binding enthalpies correlate with the properties of Group 6 dihydrogen complexes, which shows the order W ≈ Cr > Mo for the $M-H_2$ bond strengths.[21] Also, the thermal stability of $[Mo(CO)_5H_2]$ in liquid Xe is clearly lower than that of the W and Cr analogues.[9b] However, the results of our previous study of $[M(CO)_6]$ and $[M(CO)_5(CS)]$ complexes indicate that the calculated $Cr-H_2$ dissociation energy may be slightly too high.[10] This reasoning is supported by comparison of the calculated and experimental IR spectra of the three complexes. Because the vibrational frequencies are the only observables for which theoretical and experimental values of the $[M(CO)_5H_2]$ complexes are available, the comparison of the results is very helpful for judging the accuracy of the theoretical results.

The theoretical H–H stretching frequencies were calculated by using the harmonic approximation. The resulting values may be too high; however, the frequency *shift* within a class of compounds should be calculated correctly. The theoretically predicted frequency for $[W(CO)_5H_2]$ ($\tilde{\nu} = 3338$ cm^{-1}) is significantly higher than the experimental value of 2711 cm^{-1}.[9] Experimental studies show a higher frequency for the molybdenum analogue (3080 cm^{-1}).[9] The calculated value for $[Mo(CO)_5H_2]$ is 3612 cm^{-1}. Thus, theory and experiment agree that the H–H stretching frequency of the molybdenum complex is roughly 300 cm^{-1} higher than that of the tungsten complex.

This corresponds to the calculated higher $(CO)_5M-H_2$ bond energy of the tungsten complex relative to that of the molybdenum complex. The experimentally observed H–H stretching frequency of $[Cr(CO)_5H_2]$ (3030 cm^{-1})[9] is only slightly lower than the value for the Mo complex. The calculations predict that the H–H stretching frequency of $[Cr(CO)_5H_2]$ (3363 cm^{-1}) is similar to that of the tungsten complex. This also indicates that the calculated $(CO)_2Cr-H_2$ bond strength may be too high.

A hotly debated question concerns the nature of $M-H_2$ bonding in transition metal dihydrogen complexes. The barrier to rotation around the metal–H_2 axis indicates that $d(\pi) \rightarrow \sigma^*$ backbonding is important in these compounds.[3] Based on an analysis of the IR spectra of $[W(CO)_5H_2]$, it was also concluded that the dihydrogen ligand is a relatively strong π acceptor.[9c] IR studies of metal carbonyl complexes containing a dinitrogen or dihydrogen ligand suggest that these two ligands have similar bonding properties.[23] Previous theoretical studies indicate that both $H_2 \rightarrow M$ σ-bonding and $M \rightarrow H_2$ π-backbonding are important in stable complexes.[4b, 24] Very recently, Morris and Schlaf used the Mössbauer spectra of several iron complexes to probe the π-bonding of various ligands.[25] From the plot of isomer shift versus quadrupole splitting they concluded that "π-bonding in transition metal dihydrogen complexes is very significant, more so than for N_2 or CO complexes".[25]

We used the recently introduced[26] charge decomposition analysis (CDA) to probe the nature of the metal–dihydrogen interactions in $[M(CO)_5H_2]$ complexes. In the CDA method the canonical (or natural) molecular orbitals of the complex are expressed in terms of the MOs of appropriately chosen fragments. In the present case, the MOs of $[M(CO)_5H_2]$ are formed by a linear combination of the MOs of $M(CO)_5$ and H_2 in the geometry of $[M(CO)_5H_2]$. Charge donation d_i from H_2 to $M(CO)_5$ for each orbital is then given by Equation (a). Similarly, the back donation b_i from $M(CO)_5$ to H_2 is given by Equation (b). Finally, the repulsive polarization r_i between the occupied orbitals of $M(CO)_5$ and H_2 is given by Equation (c). In

$$d_i = \sum_{k}^{\text{occ, A}} \sum_{n}^{\text{vac, B}} m_i c_{ki} c_{ni} \langle \varphi_k | \varphi_n \rangle \quad \text{(a)}$$

$$b_i = \sum_{l}^{\text{occ, B}} \sum_{m}^{\text{vac, A}} m_i c_{li} c_{mi} \langle \varphi_l | \varphi_m \rangle \quad \text{(b)}$$

$$r_i = \sum_{k}^{\text{occ, A}} \sum_{m}^{\text{occ, B}} m_i c_{ki} c_{mi} \langle \varphi_k | \varphi_m \rangle \quad \text{(c)}$$

these equations the following symbols are used: $A = H_2$, $B = M(CO)_5$, m = occupation number (2.0 in case of canonical orbitals), c = fragment orbital coefficient, φ = fragment MO.

The sum of the orbital contributions d_i, b_i, and r_i gives the total amount of donation, back donation, and charge repulsion, respectively. It has been shown for several complexes of main group and transition metal elements that the calculated values of d_i, b_i, and r_i correlate very nicely with qualitative models of donor–acceptor interactions.[26]

Table 2 shows the calculated contributions of the donation, back donation, and charge repulsion at the MP2/6-31G(d,p) level of theory for $[M(CO)_5H_2]$, $[W(CO)_6]$, and $[W(CO)_5N_2]$. CDA suggests that CO is a strong σ donor and a slightly weaker π acceptor. N_2 is predicted by CDA to be a very poor σ donor and a moderate π acceptor. This is in agreement with the analysis of the Mössbauer spectra of dinitrogen complexes by Bancroft et al.[27] CDA indicates that H_2 has similar π-acceptor properties as N_2 (Table 2). However, the values in Table 2 suggest clearly that, unlike N_2, H_2 is a strong σ donor! The σ donation of H_2 in $[W(CO)_5H_2]$ (0.349 e) is significantly greater than the contribution from π-backbonding (0.129 e). The values for the Cr and Mo analogues are very similar. The negative sign of the contributions by the repulsive polarization indicates that electronic charge is depleted from the overlapping area of the occupied orbitals of the fragments. The depletion is quite large for CO and N_2, but less so for H_2. It should be noted that there is no direct correlation between the calculated CDA values and the relative bond strength of the ligands.

Table 2. Results of charge decomposition analysis of $[M(CO)_5L]$ complexes; donation d, back donation b, and repulsive polarization r were calculated at the MP2/II level.

M	L	d	b	r	D_0
Cr	H_2	0.393	0.143	−0.147	15.9 [a]
Mo	H_2	0.315	0.105	−0.117	12.8 [a]
W	H_2	0.349	0.129	−0.105	16.3 [a]
W	CO	0.315	0.233	−0.278	45.7 [b]
W	N_2	0.027	0.107	−0.252	24.8 [c]

[a] See Table 1. [b] See ref. [10a]. [c] See ref. [10b].

To investigate the electronic structure of the dihydrogen complexes further, we used the topological analysis of the electronic structure and its associated gradients and Laplacian.[28] Figure 2 shows the Laplacian of the electron density distribution of

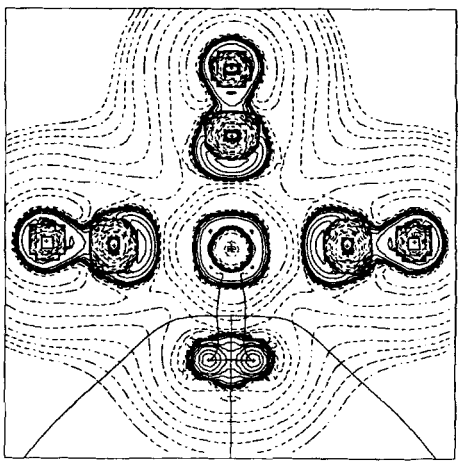

Fig. 2. Laplacian of the electron density distribution $\nabla^2\rho(r)$ of $[W(CO)_5(H_2)]$ at the MP2/II level. Dashed lines indicate charge depletion ($\nabla^2\rho(r) > 0$); solid lines indicate charge concentration ($\nabla^2\rho(r) < 0$). The solid lines connecting the atomic nuclei are the bond paths; the solid lines separating the atomic nuclei indicate the zero-flux surfaces in the molecular plane.

$[W(CO)_5(H_2)]$. Since the corresponding diagrams of the Cr and Mo analogues are very similar, they are not shown. The $M-H_2$ moiety has two distinct W–H bonds; there are two bond critical points for the W–H bonds, one for the H–H bond and one for the $M-H_2$ unit. The topology of the electronic structure of the $[M(CO)_5(H_2)]$ molecules indicates that the $M-H_2$ moiety has a cyclic structure and not a T-shaped form. The presence of a H–H bond critical point indicates that a true dihydrogen ligand exists, although there are two distinct metal–hydrogen bond paths.

[12] The geometries and harmonic vibrational frequencies were calculated at the MP2 [13] level using effective core potentials (ECPs) and a (441/2111/*N*1) split-valence basis set for the metals, which is derived from the (55/5/*N* + 1) minimal basis set optimized by Hay and Wadt [14] (*N* = 4, 3, 2 for Cr, Mo, and W, respectively). The $(n-1)s^2$ and $(n-1)p^6$ electrons are treated explicitly as part of the valence electrons. The ECPs are optimized from nonrelativistic atom calculations of Cr and relativistic calculations of Mo and W. A 6-31G(d,p) all-electron basis set is used for C, O, H [15]. The dissociation energies were determined by using coupled-cluster theory with singles and doubles and a noniterative estimate of triple substitutions (CCSD(T)) [16]. The calculations were carried out using the program packages TURBOMOLE [17], ACES II [18], and Gaussian 92 [19].

Searching Questions

Guardians of Science. Fairness and Reliability of Peer Review. By *H.-D. Daniel*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 118 pp., hardcover DM 78.00, $ 50.00.—ISBN 3-527-29041-9/1-56081-751-8

The subtitle "Fairness and Reliability of Peer Review" well describes what this book is about. The author, H.-D. Daniel, is one of Germany's leading experts in this area and is thus well qualified to examine this question. The data on which the study is based relate to the refereeing of one year's output of *Angewandte Chemie*. Manuscripts submitted for "Angewandte" are usually reviewed by two independent referees whose recommendations are then evaluated by the editor. To that extent the procedure is essentially the same as that normally applied to proposals submitted to the German Research Association (Deutsche Forschungsgemeinschaft, DFG), and thus the results are also relevant to the situation there. The author analyzes all the observations according to the rules of the art of statistics. He begins by trying to quantify the degree of agreement between the two specialist reviewers. If the recommendations are classified on a scale of 1 to 4, ranging from acceptance without change through two levels of revision to rejection, the statistical agreement seems surprisingly poor. However, if the recommendations are treated as being in agreement when they differ by only one point, the degree of consensus turns out to be satisfactory. To examine the "correctness" of decisions to reject, Daniel uses an interesting approach: he traces the fate of manuscripts that have been rejected and subsequently published elsewhere, and compares their frequency of citation with that of papers appearing in "Angewandte". As expected, the frequencies for the former are appreciably lower than those for the latter. Even Daniel does not know whether this might be simply because papers in "Angewandte" are generally cited more often (the journal has a high "impact factor"), and therefore one cannot conclude very much about the individual papers from this analysis. However, in the absence of any better approach this is certainly a useful piece of analysis. The book contains many other statistical analyses which are worth studying by everyone who is concerned with refereeing, either actively or passively, in other words every scientist engaged in research or university teaching.

There are two aspects to refereeing procedures. First there is the "correctness" of the decisions. As an insider I can confirm that, at least in the case of German referees, recommendations are made in good faith and to one's best ability. Secondly, however, there must be confidence within the scientific community that this is so. Since both the journals and the DFG preserve the anonymity of referees so far as possible (for very good reasons), great importance attaches to books and articles such as this which show, at least statistically, that the procedures are above reproach. However, I was somewhat surprised that Daniel gives no hint of recognition that, in the nature of things, every referee report must contain an element of subjectivity. All attempts to correct this by quantitative measures merely shift the problem to somewhere else. Daniel restricts himself to aspects that can be analyzed quantitatively. Thus he takes no account of the message that may be read "between the lines". We learn nothing here about the reviewer who writes a damning report but cannot bring himself to recommend rejection, nor about the one who gives a report that is intended to be favorable but qualifies it with sarcastic comments. In such cases the editor needs to be able to weigh up the situation and to know the peculiarities of his reviewers. I am disturbed by the many cases that are cited of manuscripts that were initially rejected (by a wide variety of journals, mostly well-known) but were later honored by Nobel prize awards. Unfortunately, refereeing systems probably suffer from a certain degree of conservatism, and have difficulty in dealing with anything which conflicts too much with current thinking—even when, as is usually the case, all those involved make great efforts to avoid this and value originality above all else.

In such an important matter as refereeing it is not surprising that there have already been many attempts at improving the system. One chapter lists every such proposal that I am aware of, and analyzes the experiences that have resulted from these in various places. For me personally this was the most interesting part of the book, showing as it does that there is probably no alternative to continuing with the present system. Here the ethical guidelines laid down by the American Chemical Society, which are reproduced in the book, deserve to be observed generally.

To complete this scholarly work Daniel includes a comprehensive bibliography of published work on the subject of refereeing together with extensive notes. The whole work is written in fluent English: 118 pages that are well worth reading.

Three-Dimensional Chemical Similarity Searching. By *C. Pepperrell*. Research Studies Press, Taunton, UK, 1994. XV, 304 pp., hardcover £ 57.50.—ISBN 0-86380-145-5

For well over a century chemists have relied on the two-dimensional structural formula for the display and communication of chemical information. This mode of representation of structure has certainly been the traditional mainstay for the

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

storage, manipulation, and retrieval of structural information in computerized systems. The *Chemical Abstracts* database alone comprises more than ten million such structures. The widespread and continuing use of the two-dimensional formula is, of course, a legacy of the past—it was bequeathed to us by pioneers such as Kekulé and Crum Brown who developed these formulas in the 1860s and then went on to show how they could be applied in the rationalization of chemical phenomena. Although this representation has served us well, the question now being raised is whether it has outlived its usefulness. Two-dimensional formulas are really quite unsuitable for computerized storage systems as the formulas need to be redrawn in the same format and orientation before structures can be compared. The comparing of structures and assessment of similarities has become very important during the past decade, following on from the realization that molecular similarity studies can be profitably exploited in the early stages of molecular design. The design of pharmaceutical drugs and agrochemicals in particular has benefited. In addition, a host of other modern chemical problems involve investigation of the stereochemistry or chirality of molecular species. It is thus hardly surprising that chemists are now beginning to take a serious look at the representation of chemical species by three-dimensional formulas.

The book reviewed here may be regarded as an important and innovative step in this direction. It comes from the information studies group at the University of Sheffield, arguably the world's leading group in the development of new approaches to the management of three-dimensional structural data. The author has chosen to focus on the techniques that may be used for searching three-dimensional structural databases, with special emphasis on similarity searching. After pointing out the limitations of two-dimensional searching, the author analyzes the role and effectiveness of four different three-dimensional similarity methods, namely the distance distribution method, the use of individual distances, atom mapping, and the maximal common substructure method. It is concluded that in overall terms the best of these is the atom mapping method, an approach based on a localized description of the three-dimensional environment of each atom in a molecule. When two molecules are to be compared, atoms with similar local environments are mapped on to each other, and the similarities between atoms so mapped are combined together to yield a global measure of the similarity of the two molecules. The rest of the book, including a 30-page appendix giving the results of sample calculations, is devoted to a discussion of the atom mapping method. Among other things, the author considers how the method may be optimized and made faster in practice, and describes a variety of elaborations that broaden its scope and applicability. In fact, with appropriate modifications, the method is applicable not only to relatively small molecules but also to the largest of macromolecules.

In presenting all this material in one volume the author has performed a very useful service to many different kinds of chemists. Structure-directed searching is now the most common type of query made to chemical structural databases and the demand is likely to grow considerably in the future. This work not only addresses the increasingly pressing problem of the storage and manipulation of three-dimensional data but also shows how similarity notions may be successfully incorporated into the searching of such data. Even though in its current form the method cannot cope with very large databases, it is certainly able to handle medium-sized databases containing up to 50000 structures. Moreover, research at present under way in several laboratories around the world will undoubtedly push up this limit substantially in the foreseeable future. The atom mapping method has many exciting potential applications and will feature in the design of molecular species for a variety of applications. The author is to be congratulated on bringing out such a useful and succinct guide to this rapidly evolving domain.

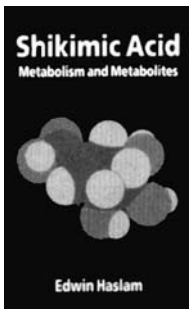
Dennis H. Rouvray
University of Georgia
Athens, GA (USA)

The World of Physical Chemistry. By *K. J. Laidler*. Oxford University Press, Oxford, 1993. 488 pp., hardcover £ 55.00.—ISBN 0-19-855597-0

The title of this book should really have been extended by adding the subtitle "A Historical Discourse". It contains a history of ideas in physical chemistry, from the beginnings when this classification did not yet exist, up to about the middle of the present century. To make for lighter reading the author intersperses the account with biographical notes about actors who have played important roles on this stage, although some of these have had little recognition. Some additional short biographies are collected together in an appendix, and there are plenty of literature references.

Three introductory chapters explain the background to the development of physical chemistry within the overall framework of the sciences, and discuss the nature of the problems that it addresses and the methods of working. The latter are illustrated by taking as examples two scientists with very different styles. H. Eyring and R. Norrish, and by outlining the development of the most important centers of physical chemistry research in England, Scotland, and North America. One chapter is concerned with the sources from which early physicochemical studies originated, and describes the beginnings of the journals that are now the leaders in this field. The heart of the book consists of the seven chapters outlining the development of the sub-disciplines of thermodynamics, the kinetic and statistical theory of matter, chemical spectroscopy, electrochemistry, chemical kinetics, colloid and interface chemistry, and quantum chemistry.

The author's treatment is firmly linked to the individual scientists and their contributions to the development of the subject. In the course of this he also mentions some little known facts. For example, I had not appreciated how wide-ranging was the work of D. L. Chapman, who not only contributed to the theory of the diffuse double layer by developing an early forerunner of the Debye-Hückel theory of electrolyte solutions, but also made important contributions to the understanding of reactions in the gas phase. Even more surprising is the reappraisal of the work of Agnes Pockel who, as a housewife in Braunschweig, carried out studies in her kitchen on the behavior of films of organic substances, the results of which were published thanks to the support of Lord Rayleigh. In her experiments she used an apparatus that already contained the essential elements of the Langmuir balance for measuring the surface tension of a film.



The reader will find that many recent developments are mentioned only very briefly or are even completely absent. However, to include all these would have made a larger book than was intended. The treatment is undoubtedly much colored by personal background, and an author from outside the English-speaking world would have given a different emphasis in many respects. However, that in itself adds to one's interest in reading this well-written book. In an age when the principles of physical chemistry are nearly always treated in a deductive way in textbooks, and the student is seldom told

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0360 $ 10.00+.25/0

about the historical development of the subject, a book of this kind is especially welcome. Without a knowledge of the historical background one's understanding of the nature and purposes of the discipline can only be superficial. Also the motivation for research gains an extra dimension when one is aware of the paths and the false trails involved in arriving at the present state of knowledge. The book should be in the library of every physical chemistry department, and is also highly recommended for inclusion in scientists' personal collections.

Heinz Gerischer
Fritz-Haber-Institut
der Max-Planck-Gesellschaft
Berlin (FRG)

Shikimic Acid. By *E. Haslam*. Wiley, Chichester, 1993. 387 pp., hardcover, £ 75.00.—ISBN 0-471-93999-4

Shikimic acid is the key to one of nature's most astonishing and multifaceted pathways, namely the aromatic metabolism developed in various organisms, mostly in plants, but also in microorganisms and fungi. The fact that the shikimate pathway does not exist (any longer) in mammals is the reason for the worldwide intensive research, as it raises the possibility of developing selective inhibitors for use as herbicides, antifungalagents, or antibacterial agents. One already successful example is the herbicide glyphosate, which acts as an inhibitor of one of the enzymes of the shikimate pathway (5-enoylpyruvylshikimate-3-phosphate synthase). The above book by Haslam achieves considerably more than dealing with this important aspect of the application of biosynthetic studies and reviewing the progress made in research on the shikimate biosynthetic pathway during the past twenty years (since his first book, *The Shikimate Pathway*, was published). The new results of studies on the shikimate pathway offer insights into intriguing questions of molecular evolution, reveal a gold mine of unusual enzymology, and include examples of important applications of the latest advances in synthetic organic chemistry.

The book is divided into five chapters, allowing the reader easy access to the different interesting facets of the shikimate pathway. In Chapter 1 a short introduction and overview is given. This includes interesting views on evolutionary aspects (metabolic costs, multifunctional enzymes, possible reasons why the shikimate pathway to aromatic compounds no longer exists in mammals) and on the development of the methodologies (genetic engineering, organic synthesis) used in this research. Chapter 2 deals with the chemistry (isolation, derivatization, and synthesis) of the starting molecules and of all intermediates of the common shikimate pathway, i.e. up to chorismic acid, the major branch point. Several approaches to the synthesis of important intermediates such as the title compound shikimic acid or chorismic acid are compared and evaluated. Chapter 3 provides information about the unique enzymes and the enzymology involved in the common shikimate pathway (up to chorismic acid), reflecting the immense knowledge gained in this field during the past twenty years. A section within this chapter focuses on the above mentioned 5-enoylpyruvylshikimate-3-phosphate synthase and its inhibitor glyphosate, the herbicidal component of the commercially important weedkiller "Roundup". The following two chapters are the longest and deal with all aspects of the stages beyond chorismic acid, such as the various further biosynthetic pathways, the products, the enzymes involved, etc. Chapter 4 focuses on generally occurring, so-called primary metabolites and their enzymes, in particular the five key enzymes initiating the major metabolic branches from chorismic acid (chorismate mutase, anthranilate synthase, *p*-hydroxybenzoate synthase, isochorismate synthase, and *p*-aminobenzoate synthase). The products thereby formed (the "primary metabolites") are obviously essential for the producing organisms: the aromatic amino acids (e.g. phenylalanine, tryptophan), the benzo- and naphthoisoprene quinones (e.g. ubiquinone, vitamin K), and the folate coenzymes. Other enzymes that are involved, and the metabolism into and of aromatic products, such as the lignin metabolism in plants and the aromatic amino acid metabolism in mammals, are also discussed. Chapter 5 deals with the so-called secondary metabolites, the more or less individually produced "chemicals" of a particular organism. The chapter begins with a brief discussion of the term "secondary metabolism", which although historically based and often didactically useful, is imprecisely defined and misleading. The treatment is subdivided into natural products from microorganisms and those from plants. These special branches occurring mostly in the late but sometimes in the early shikimate pathway of certain organisms lead to important natural products such as antibiotics, mycotoxins, alkaloids, and flavonoids. There is also an addendum listing literature published after the manuscript was finished. This is divided into the main areas of chemistry/synthesis, enzymology, and biosynthesis, and covers the most recent literature (up to 1993!).

Shikimic Acid is written in an engaging and easily understandable style. Occasional quotations (e.g. from the Bible, from Oscar Wilde, and especially from important early researchers in the field) and excursions into the history of several of the intermediates or products of the shikimate pathway, together with the author's remarkably wide grasp of the broad field of natural products chemistry, make it a pleasure to read. The different facets of the rapidly advancing field of natural products chemistry are presented so elegantly and absorbingly that it would be small-minded to recount the few structural or printing errors. It is a pity that the high price will prevent many students from buying this excellent text, a rare example where a detailed overview of an important field of bioorganic chemistry is successfully embedded in a very entertaining story. As a source of motivation and a resource for preparing lectures as well as a reference book, *Shikimic Acid* is a must for everybody involved in teaching and research in the broad field of natural products and biochemistry.

Shape in Chemistry. An Introduction to Molecular Shape and Topology. By *P. G. Mezey*. VCH Publishers, New York, 1993. XI, 224 pp., hardcover $ 75.00.—ISBN 0-89573-727-2

Shape is a concept of interest to a wide range of scientists. For instance, biologists map the shapes of microorganisms, geologists the shapes of rocks, and chemists the shapes of molecules. However, all use different measures, for there is no general agreement on how shape should be defined. Most chemists resort to the concept as and when it is needed, without ever trying to get to grips with it in any deep abstract sense. In this respect shape resembles a number of other chemical

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0303-0361 $ 10.00+.25/0

concepts—the examples of similarity and structure spring to mind—in that it is often used but never rigorously defined. This book focuses on molecular shape and in particular on measures to quantify it. In fact, over the past two centuries numerous contributions to the study of molecular shape have been made by a succession of distinguished scientists. Molecular shape first came of the fore when the founder of modern atomic theory, John Dalton, had a set of molecular models made for him in 1810. These were of the ball-and-stick variety still in use today, his idea being to display the shapes that simple molecules might assume. Other leading lights who worked on shape were Kekulé, who in the mid-1860s established the hexagonal shape of the benzene ring; van't Hoff and Le Bel, who in 1874 independently put forward the notion of the tetrahedral carbon atom; Fischer, who in 1894 proposed a lock and key model to illustrate the complementarity of a drug and its receptor; Pauling, who in the 1930s introduced the concept of hybridization to explain the shapes of many molecules; and Barton, who in 1950 coined the expression "conformational analysis" to describe his approach to the three-dimensional characterization of organic species. From about the 1950s a variety of shape descriptors began to appear: these ranged from the use of two-dimensional silhouettes by Amoore in the 1960s to the advocacy of shape topological indices by Kier in the 1980s. Over the past decade a plethora of exciting new ways of quantifying molecular shape—too numerous to go into here—have also been developed.

Unfortunately, precious little of this rich history of the evolution of shape concepts in chemistry is covered in Mezey's book. Indeed, this book contains only cursory references to some key problems that dominate the most recent work on molecular shape. A case in point is the controversy that has raged over the past dozen years on whether it is meaningful to assign shapes at all to objects that are as small and fuzzy as molecules. Quantum theoreticians such as Primas and Amann in Switzerland and Woolley in England have repeatedly pointed out that isolated molecules do not admit of a stable shape, and that the notion of shape can be introduced only via the Born–Oppenheimer approximation which effectively freezes the positions of the atomic nuclei. This fundamental question should surely have been addressed in this book, which claims that its principal objective is "to convince the reader that molecular shape is accessible to rigorous study". Another issue that I feel should have been explored is that of where to draw the line between micromolecular objects that clearly need to be discussed in terms of quantum theory and macromolecular objects such as large crystals that can be more conveniently discussed using classical mechanical language. Although Mezey emphasizes that molecular shape is a dynamic rather than a static property, and goes on to point out that much of our current thinking is based on the erroneous idea that the nuclei are fixed and so can be treated classically, he does not tell us when the classical approach might be valid, e.g. in the case of large molecules such as DNA. Nor does he discuss such novel topics as the treatment of crystals with oscillating shapes, the non-trivial problem of inferring three-dimensional structures from their two-dimensional projections, or the use of neural networks in the characterization of molecular shape.

Having outlined my criticisms of this book, I would now like to expand on its many virtues. First, a word or two about the author himself. Mezey is the most significant contributor to the discussion on molecular shape in the latter half of the twentieth century, and so it is appropriate and timely that he should write a book expaining his methods. He writes extremely well—even though English is not his mother tongue—and his ideas are always thought-provoking. Mezey has a tendency to clothe his ideas in mathematical language that is perhaps unfamiliar to many chemists. This sometimes makes his work rather challenging to the average chemist, though in the case of his book I feel he has risen to the occasion and produced a work of admirable clarity and one that is eminently readable. This book contains excellent accounts of the various methods he has developed for molecular shape analysis over the past two decades. Because Mezey believes that molecules are topological objects rather than geometric ones, he tends to make heavy use of algebraic topology. In his shape group methods for instance, which have been applied to molecular isodensity contours, electrostatic potentials, and van der Waals surfaces, the properties of the continuous functions characterizing the contours are captured by a family of algebraic shape groups. In an analogous fashion, his quantitative shape–activity relationships (QShAR) approach treats the geometric similarity of molecular species as a topological equivalence that can be quantified in terms of shape representations or shape descriptors. Both of these methods have the considerable advantages that they can be used on nonrigid molecules and that they lend themselves readily to computer processing. Moreover, it would appear that such methods are suited for molecular shape similarity and shape complementarity analysis in large families of molecules. As this will probably prove to be the case, Mezey's methods may well yield important and powerful new tools in the never-ending search for new drugs and in molecular design generally. It is this great promise of Mezey's work that makes the study of it so rewarding and this book so stimulating to read.

Vitamin B_{12}: How the Problem of Its Biosynthesis Was Solved

Francis Blanche, Beatrice Cameron, Joel Crouzet, Laurent Debussche, Denis Thibaut, Marc Vuilhorgne, Finian J. Leeper, and Alan R. Battersby*

Vitamin B_{12} is an essential vitamin for human health, and lack of it leads to pernicious anemia. This biological activity has attracted intense interest for some time; in addition, the complex architecture of the B_{12} molecule has fascinated chemists and biochemists since its discovery as the first natural organocobalt complex and the establishment of its structure by X-ray analysis. The organic ligand surrounding the cobalt displays many stereogenic centers along its periphery carrying reactive functional groups. This complexity led vitamin B_{12} to be rightly regarded as an extreme challenge to the synthetic chemist. Yet microorganisms achieve this synthesis in vivo with complete control of regio- and stereochemistry. How do they do it? This review tells the full remarkable story. Success in unraveling this biosynthetic puzzle resulted from a collaborative effort by biologists and chemists using the full range of methods available from their disciplines—from genetics at one end of the spectrum to synthesis and NMR spectroscopy at the other. This work can act as a guide for future research on the biosynthesis of yet more complex natural substances.

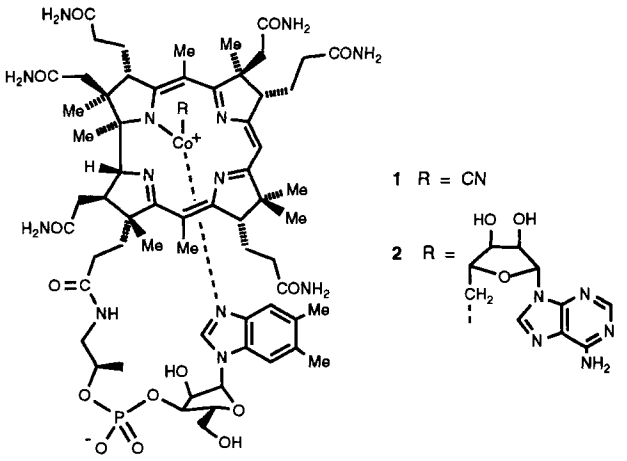
Keywords: bioorganic chemistry · biosynthesis · vitamin B_{12}

1. Introduction

1993 marked the end of an era for research on the biosynthesis of vitamin B_{12}, an essential vitamin that prevents pernicious anemia. Experiments carried out during roughly the previous 25 years had, by 1993, uncovered the complete pathway by which this remarkable cobalt-containing molecule is constructed in microorganisms. This is exciting because the problem of vitamin B_{12} biosynthesis had posed what is surely the greatest challenge in the biosynthetic arena. So much so, that it was known as the Mount Everest of biosynthetic problems. This mountain has now been climbed, fittingly on the 40th anniversary of Hillary and Tenzing's conquest of Everest itself. Progress up the mountain during the past 25 years initially showed steady progress during which critically important advances were made and solid bases were established. This phase was followed by a spectacular surge to the top during the past 10 years and especially during the last five.

The time is therefore ripe to write a review that sets a flag on the summit. Our aim is to relate how the latest surge was made by what was largely a European effort and to convey the excitement of a scientific chase full of surprises. We will emphasize at appropriate points in our account what in retrospect can be seen as the decisively important choices, techniques, and experimental approaches. Undoubtedly, the key choice was of the right B_{12}-producing organism for the experiments, and it will become clear why the one selected, *Pseudomonas denitrificans*, could not have been bettered. The decision to add the power of genetics and molecular biology to the array of approaches previously used for biosynthetic research was also of immense importance. But we must avoid giving the impression, which occasionally has currency, that when once the molecular biology is worked out, the rest is easy; far from it, as the reader will see. Huge difficulties still remained to be overcome at that stage, and the way through the maze depended heavily on the chromatographic techniques developed for the purification of proteins and water-soluble intermediates.

More details will be given of each of these key elements as the article unfolds, but the reader must be made aware at the outset of the scale of the B_{12} problem and what a broad sweep of interdisciplinary science was needed to solve it. That sweep extended from genetics and molecular biology, through protein chemistry and enzymology, and on to organic synthesis including radioactive and stable isotopic labeling with NMR spectroscopy as a marvellous final tool.



Before going further, it should be made clear that the B_{12} system, cyanocobalamin (**1**), is the form in which the vitamin is isolated for medicinal and commercial use; **1** and close derivatives with varying R groups are often called cobalamins. The

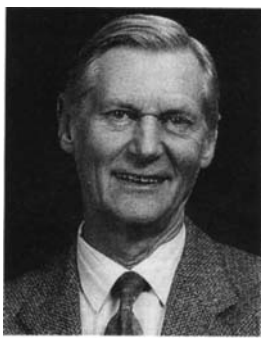
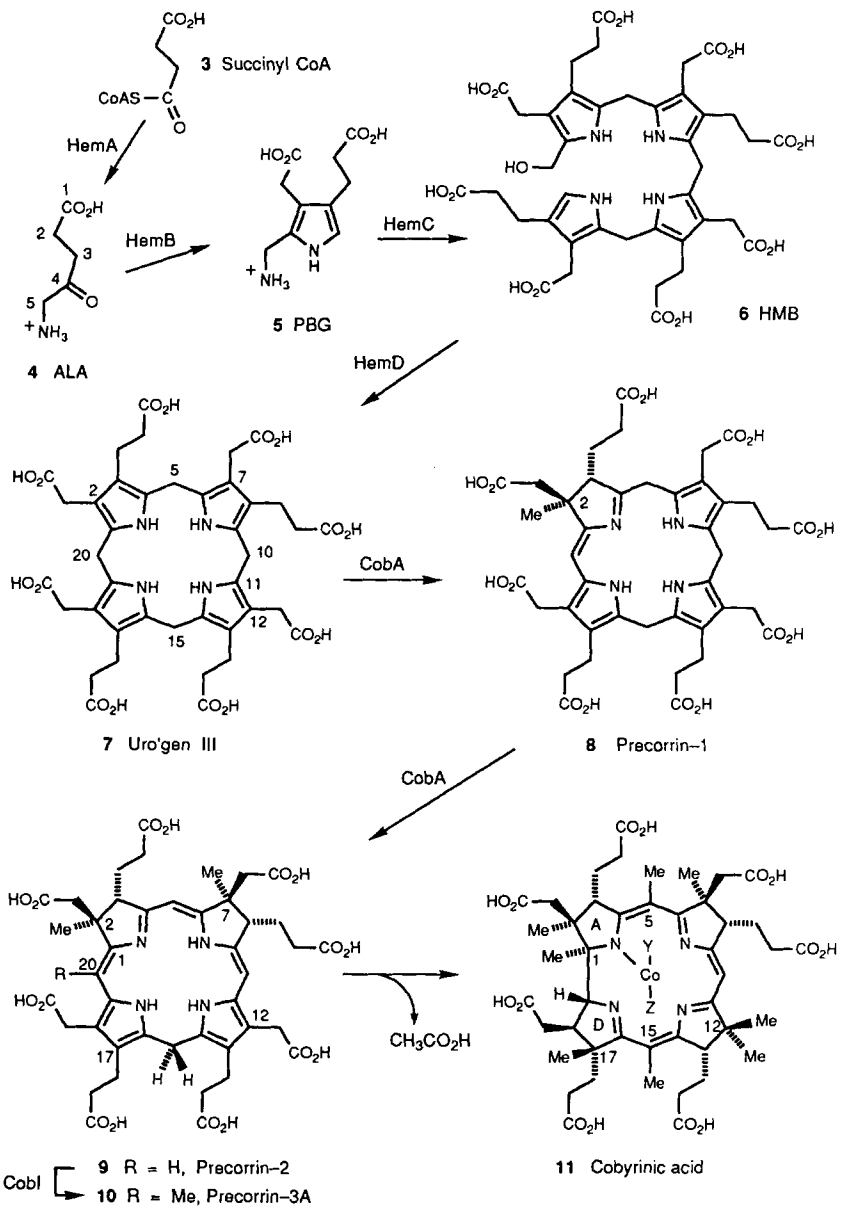
most important biologically active species is the coenzyme form, adenosylcobalamin (**2**) having an adenosyl residue in place of the cyano group of vitamin B_{12}. We will discuss later when and how this residue is added.



2. Laying the Foundations and Discovery of the First Three Unique B_{12} Intermediates



Vitamin B_{12} (**1**) belongs to a family of structurally related and biologically important pigments that also includes heme, the oxygen-carrying center of hemoglobin, and chlorophyll, which is responsible for photosynthesis. The biosynthetic pathway to all these "pigments of life" initially follows the same track starting from 5-aminolevulinic acid (ALA, **4**; Scheme 1) which, for *Pseudomonas*, is biosynthesized from succinyl CoA (**3**) and glycine[1] (as for animals, yeasts, and photosynthetic bacteria), whilst in plants and some other bacteria the starting material is glutamic acid. Two molecules of **4** are first condensed together to yield porphobilinogen (PBG, **5**), and then four molecules of PBG **5** are joined head-to-tail without rearrangement by the enzyme deaminase leading to hydroxymethylbilane (HMB, **6**).[2] Subsequently a fascinating ring closure and rearrangement process[2] catalyzed by cosynthetase generates uroporphyrinogen III (uro'gen III, **7**). This macrocycle is structurally modified in living systems to build heme and chlorophyll by a series of enzymic steps starting with decarboxylations and oxidation. This does not happen for B_{12} **1**; its pathway branches away from the others at uro'gen III **7**. In experiments with the bacterium *Propionibacterium shermanii* it was discovered that the diversion is initiated by C-methylation of **7** by methyl transfer from *S*-adenosylmethionine (SAM). These studies produced a rich harvest of biosynthetic information, but only those findings essential to understanding the main story of our article will be briefly given here. All the other results from this work are described in several reviews[3] which give complete literature references for this phase of the research.

Normally *Pr. shermanii* is grown on a medium containing cobalt. The cells can be disrupted to release a preparation of soluble proteins, which, together with the necessary cofactors, can be used to biosynthesize cobyrinic acid (**11**) from simpler precursors such as PBG **5** (Scheme 1). Notice the direct connection of ring A to ring D in **11**, a characteristic feature of the corrin ring system. Cobyrinic acid (**11**) is a late biosynthetic precursor of B_{12} **1** in *Pr. shermanii*, and it contains the fully constructed corrin macrocycle present in B_{12}. Presumably the biosynthesis does not go further in the broken-cell enzyme system, because the enzyme necessary for the next step beyond cobyrinic acid en route to B_{12} **1** is destroyed or lost from the soluble protein preparation or lacks its cofactor. It may be significant that the enzyme(s) responsible for the later amidations of carboxyl groups are reported to be unstable; also these enzymes in *Pr. shermanii* are known to transfer NH_2 from the amide group of glutamine.[4]

The discovery that the B_{12} biosynthetic pathway is diverted away from that for heme by C-methylation of uro'gen III **7** depended on an experiment that asked the question "What happens when *Pr. shermanii* cells are grown with strict exclusion of cobalt?" The striking answer was that now the cells did not biosynthesize cobyrinic acid (**11**), but three new substances appeared instead, which could be isolated either at their original oxidation level or as aromatic derivatives (by aerial dehydrogenation). A major effort was needed to establish the structures of all these compounds, and the findings allowed the next three intermediates beyond **7** to be set in place. Thus, uro'gen III **7** undergoes methylation first at C-2 to form precorrin-1[5] (**8**;

Alan R. Battersby is Emeritus Professor at the University of Cambridge (UK). He was born in 1925 in England and gained BSc and MSc degrees from the University of Manchester, a PhD from St. Andrews, and DSc and ScD degrees from Bristol and Cambridge, respectively. He has received many awards including the Karrer Medal (Switzerland), the Royal Medal (UK), the Roger Adams Medal (USA), the August-Wilhelm-von-Hofmann-Denkmünze (FRG), and the Wolf Prize (Israel). His interests are in the chemistry of living systems (especially vitamin B_{12} biosynthesis), music, camping, and fly fishing. – Dr. F. J. Leeper is a Lecturer at the University of Cambridge and Fellow of Emmanuel College; he has been a partner in the work on B_{12} since 1982. The research on vitamin B_{12} biosynthesis during the last ten years at the Rhone-Poulenc Rorer company has involved three groups. The group in biochemistry, led by Francis Blanche, with Laurent Debussche and Denis Thibaut, focuses on enzymology and purification of biosynthetic intermediates; Joel Crouzet, in collaboration with Beatrice Cameron, heads a group cloning bacterial targets and biosynthetic genes; Marc Vuilhorgne is in charge of structural analysis.

Scheme 1. Biosynthetic pathway from succinyl CoA (**3**) to precorrin-3A (**10**).

Scheme 1), which is further methylated at C-7 by the same methylase enzyme to form precorrin-2 (**9**). Then a second methylase introduces a third methyl group, and it was the first surprise of many to follow that the methylation site was C-20, leading to precorrin-3A (**10**). Importantly, precorrin-3A (**10**) was proved by unambiguous labeling experiments to be converted into cobyrinic acid (**11**) when it was incubated with the complete enzyme system prepared from normal *Pr. shermanii* cells grown on a cobalt-containing medium. So it is clear that exclusion of cobalt from growing *Pr. shermanii* cells interrupts the biosynthesis at precorrin-3A (**10**). A reasonable explanation is that in this organism, insertion of cobalt into the macrocycle occurs at or close to this stage. This hypothesis has been supported by recent studies based in one case on incorporation experiments with cobalt complexes of the aromatized derivatives of **9** and **10**,[6] and in the other by a novel application of triple isotopic pulse labeling (^{13}C, ^{14}C, ^{60}Co) using normal *Pr. shermanii* cells.[7]

Little is known at present about the enzymes of the B_{12} pathway in *Pr. shermanii*. Surely this will change over the coming years, for at present no enzyme has been purified and only the first methylase described above has even been enriched[8] (50-fold). More is known about the relevant enzymes in *Ps. denitrificans*, the organism on which we will focus in this review; for example, the two corresponding methylases responsible for converting uro'gen III **7** into precorrin-3A (**10**) are well characterized (see Section 11, Table 2).

Comparison of the structure of precorrin-3A (**10**) with that of cobyrinic acid (**11**) shows that, in addition to cobalt insertion, many more biosynthetic steps are needed before cobyrinic acid (**11**) is reached including a) ring contraction, b) more C-methylations, c) decarboxylation of the C-12 acetate residue, and d) possible redox changes. Before the final "surge to the summit," important knowledge had been gained concerning steps a) and b). Multiple labeling experiments on a microscale proved that C-20 and its attached methyl group are extruded as acetic acid (step a). For step b) the foregoing technique of pulse-labeling had been used earlier to find out the order of attachment of the additional five methyl groups needed to generate cobyrinic acid (**11**). The method was first developed to establish that the fourth methyl group is placed at C-17, and extension of the approach proved that the α methyl group at C-12 of **11** is the fifth one followed by that at C-1. Those at C-5 and C-15 were shown certainly to be the last ones added with roughly similar timing.

The reader now has a bird's-eye view of the start of the B_{12} biosynthetic pathway from succinyl CoA (**3**), available from primary metabolism, via ALA **4**, and running through to precorrin-3A (**10**) with every intermediate set in place (Scheme 1). Then there is a huge gap before cobyrinic acid (**11**) is reached. But acetic acid is extruded at some stage between **10** and **11**, and also the order of the last five methylations is established (17, 12α, 1, 5/15).

Naturally, great efforts were made over many years to isolate new intermediates from *Pr. shermanii* cells that follow precorrin-3A (**10**), but to no avail. Looking back from our present vantage point, one can see that *Pr. shermanii* was not the best organism for these studies, since the stages beyond precorrin-3A (**10**) involve cobalt complexes, and these may well be difficult to handle. A new way through the blockage was needed, and happily this came from research on a different organism, the aerobic bacterium *Pseudomonas denitrificans*. Fortunately, the strain SC510,[9] which is closely related to the strain used industrially and a high B_{12} producer, could be used. The productivity of this strain had been significantly improved relative to that of the

starting strain (MB580) by numerous chemical and physical steps of mutagenesis.[9] High production of vitamin B_{12} implies a high level of the relevant enzymic activities, obviously a great advantage for work on the isolation and characterization of the enzymes as well as for related biosynthetic studies. These enzymic levels are normally quite low in wild-type strains, resulting in production at best of only a few tens of milligrams of the vitamin per liter of culture. This switch to *Ps. denitrificans* with addition of the power of genetics and molecular biology proved decisive in moving the research forward again in a way beyond all our expectations.

3. Laying the Biological Foundations: Cloning of the *cob* Genes of *Ps. denitrificans*

3.1. Isolation of the Cob Mutants

When this work was initiated, no gene nor even a mutant deficient in cobalamin synthesis (a Cob mutant) in any bacterium had ever been isolated. Since, in addition, no enzyme of the pathway had been purified to homogeneity, no sequence data nor antibodies to any of the proteins were available. Therefore the plan was to clone the *cob* genes[10] by isolating mutants and performing genetic complementation. The biosynthetic pathway to vitamin B_{12} requires a large number of different enzymatic steps, and so the isolation of a very large number of mutants blocked in cobalamin synthesis was necessary to increase the likelihood that mutants deficient in most of the steps would be obtained. Two approaches were used to isolate Cob mutants[10] in *Pseudomonas putida* and *Agrobacterium tumefaciens*, both gram-negative bacteria that produce cobalamin under aerobic growth conditions.[9]

In *A. tumefaciens* the mutants were mostly obtained by chemical mutagenesis with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine. More than 22000 single colonies were analyzed individually for cobalamin synthesis by a microbiological assay.[9] This yielded 148 Cob mutants with reduced levels of cobalamin synthesis. In *Ps. putida* mutants were obtained by transposon Tn*5* mutagenesis. Transposon Tn*5* is a 5.7 kilobase (kb) segment of bacterial DNA that can insert with high frequency into the bacterial chromosome and contains a gene imparting resistance to the aminoglycoside antibiotic kanamycin. When the transposon is introduced into a recipient bacterium on a plasmid that is not maintained when the bacterium replicates, only those cells in which the transposon has inserted into the chromosome can survive in the presence of kanamycin. Selection of such kanamycin-resistant clones gives a series of mutants that carry a single copy of Tn*5* randomly inserted into the genome.[11] In this case, Cob mutants were identified as being those colonies unable to use ethanolamine as a source of nitrogen in the absence of added cobalamin. This selection depends on the fact that deamination of ethanolamine by ethanolamine ammonia-lyase requires coenzyme B_{12} as a cofactor. From 6400 mutant colonies, 26 were found to be unable to grow on the ethanolamine medium and were classed as Cob mutants.

3.2. Cloning 78 kb of DNA from *Ps. denitrificans* Carrying the *cob* Genes

The next step was to clone the *Ps. denitrificans cob* genes that "complemented" the foregoing mutations (i.e. they were able to restore cobalamin biosynthesis in the Cob mutants). For this purpose, a genomic library of the rifampin-resistant *Ps. denitrificans* strain SC510 Rif^r was constructed in *E. coli* on a plasmid (pXL59) which was capable of being transferred (or mobilized) into a wide range of other bacteria (including *Ps. denitrificans*) through a natural phenomenon called conjugation. This library consisted of approximately 3600 separate strains of *E. coli*, each with a plasmid carrying a different DNA insert from the *Ps. denitrificans* genome, with an average size of 13 kb. This library of plasmids should, statistically, represent more than 99% of the *Ps. denitrificans* genome.

This plasmid library was then mobilized in turn into each of Cob mutants prepared above. For each mutant, the 3600 different clones were assayed for their production of cobalamin by selecting colonies able to grow on the ethanolamine-containing medium or by looking directly for clones producing cobalamin at a level close to that of the parent strain. In such clones, the mutation was said to be complemented by the plasmid it harbored. Such a plasmid was therefore carrying at least one *Ps. denitrificans cob* gene responsible for the correction of the genetic defect of the mutant. In this way, 11 plasmids from the library were found to complement most of the mutants (17 out of 26 mutants in *Ps. putida* and 134 out of 148 mutants in *A. tumefaciens*). The inserts of the 11 plasmids were from four different genomic loci, referred to as complementation groups A to D, and they represent between them 78 kb of DNA. The loci are at least 10 kb apart, indicating that the genes are, to some extent, scattered over the chromosome of *Ps. denitrificans*.[12]

Smaller DNA fragments from this 78 kb of DNA were subcloned on the same mobilizable plasmid. By comparing which mutants each recombinant plasmid was able to complement, at least 14 different *cob* genes were identified within the 78 kb.

3.3. Genetic Analysis and Nucleotide Sequence Determination of the *cob* Genes

A genetic analysis was performed in order to identify all the genes carried by the cloned 78 kb of DNA. In essence, Tn5 transposon mutagenesis was used again to introduce further mutations into most parts of the 78 kb. This analysis revealed the presence of six more *cob* genes.[13–17] Altogether 22 *cob* genes were found and were named *cobA* to *cobQ* and *cobS* to *cobW*. Then the nucleotide sequence was determined for 35.9 kb out of the cloned 78 kb of DNA, including all 22 genes. In addition to the *cob* genes, eight other open reading frames (stretches of DNA that appear to code for proteins) were also found in the sequenced DNA. The organization of the genes in the four clusters (or complementation groups) is shown in Figure 1.

From the nucleotide sequence, the amino acid sequences of the Cob proteins could be predicted. This has proved extremely valuable since almost all the *Ps. denitrificans* genes required for

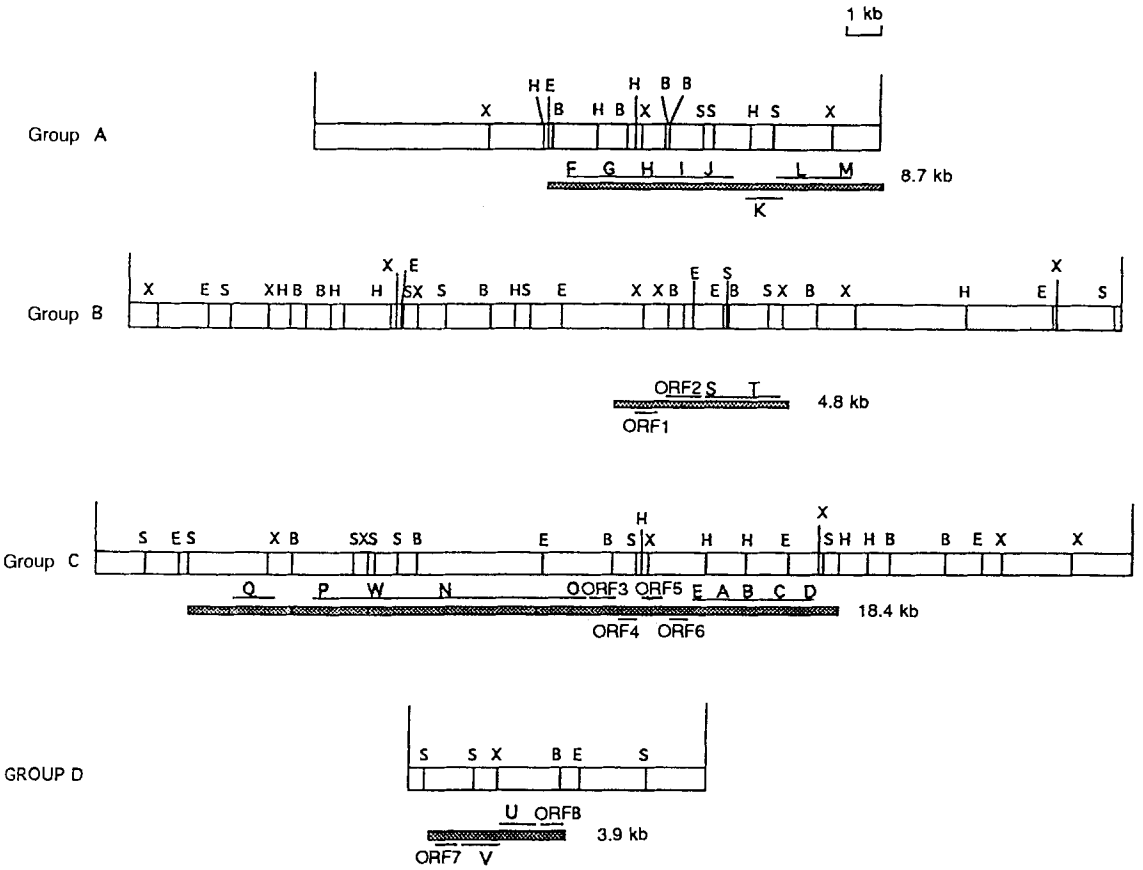


Fig. 1. Restriction map of the four complementation groups from *Ps. denitrificans*. Locations of the *cob* genes are shown by the corresponding letters below the DNA strand; open reading frames (ORFs) of unknown function are also shown. Sequenced fragments are indicated by hatched lines. A line above the hatched line indicates that the coding strand goes 5′ 3′ from left to right. Enzymes: B, *Bam* H1; E, *Eco* R1; H, *Hind* III; S, *Sst* 1; X, *Xho* 1.

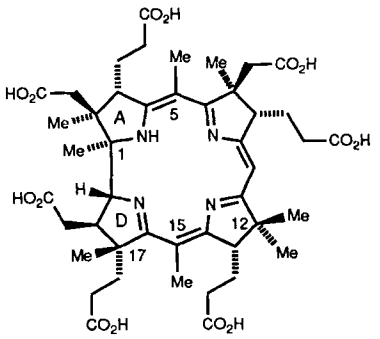
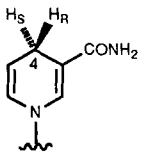
coenzyme B_{12} synthesis were present among the 22 *cob* genes. Furthermore, the amino acid sequences of the Cob proteins could be compared with sequences in protein databases, and this allowed important deductions to be made about the probable functions of some proteins, particularly the methyltransferases. In addition, the *hemA* gene from *Ps. denitrificans*, encoding 5-aminolevulinic acid synthase, was also cloned and sequenced.[18] This gene was found not to be linked with any of the four complementation groups found for the *cob* genes.[12]



The foregoing work on gene cloning was of great importance for parallel research in enzymology and structural chemistry. The results from these two areas then provided positive feedback for the molecular biology. Thus, for many of the mutant strains, identification of the intermediate accumulated allowed the blocked step to be located and correlated with the gene that complemented the mutation.[13–16] Details of the mutants that accumulated the later, known intermediates on the B_{12} pathway are given in Table 1 towards the end of this review. Also, by inserting a particular gene into a multicopy plasmid, then production of the corresponding protein is enhanced, which greatly helps the enzymatic and chemical research. It would be invidious in an interdisciplinary effort to pick out any area as the most important, but the contribution from genetics and molecular biology was huge.

4. The Surge to the Summit

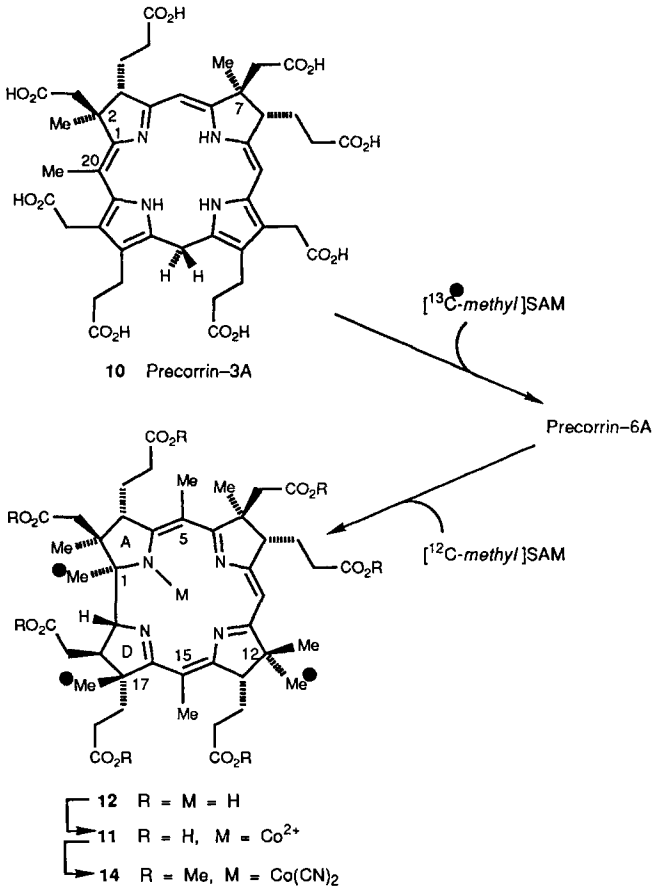


4.1. Isolation of Precorrin-6A and Proof of Its Surprising Structure

"Great oaks from little acorns grow." It was the crucial observation of a yellow fluorescence that corresponds to the acorn, and the whole story in the remaining part of this review is what grew from it. Cells of one recombinant strain of *Ps. denitrificans* [SC510(pXL253)], in which eight of the foregoing *cob* genes (*F*, *G*, *H*, *I*, *J*, *K*, *L*, and *M*) had been amplified, exhibited a strong yellow fluorescence under ultraviolet light. Fortunately, the substance responsible had recently been isolated and identified from *Ps. denitrificans* SC510 Rif^r;[19] it was hydrogenobyrinic acid (**12**), the cobalt-free analogue of cobyrinic acid (**11**). This was quite unexpected because although amidated derivatives of hydrogenobyrinic acid (**12**) had been found previously,[20] the parent had never been isolated and was thought not to occur in nature.[21] We will describe later how the intermediacy of hydrogenobyrinic acid (**12**) for the biosynthesis of vitamin B_{12} in *Ps. denitrificans* was clearly established. So this strain, producing considerable amounts of a late corrinoid precursor of vitamin B_{12}, was the ideal vehicle for biosynthetic experiments. A major effort then led to the development of a cell-free enzyme system from this strain which efficiently converted precorrin-3A (**10**)[22] through all the many steps into hydrogenobyrinic acid

(**12**). The latter could be detected on a minute scale by high-pressure liquid chromatography (HPLC)[23] with a fluorescence detector. The way was then open to a) optimize the incubation conditions and b) determine which cofactors are required for the conversion of precorrin-3A (**10**) into hydrogenobyrinic acid (**12**). It turned out that in addition to SAM, reduced nicotinamide adenine dinucleotide phosphate (NADPH) (**13** shows the relevant partial structure) was essential for this conversion.

12 Hydrogenobyrinic acid



13
NADPH
partial structure

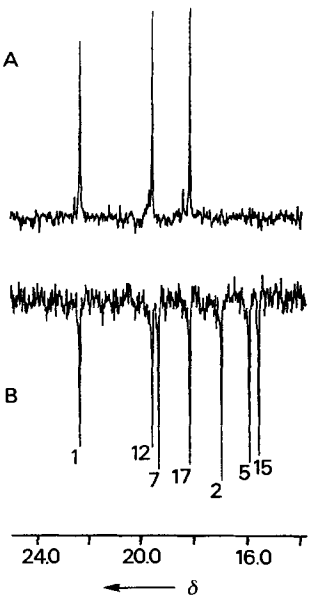
Research on vitamin B_{12} has been full of surprises, and the involvement of NADPH in the biosynthesis was one of them. Workers in the field had all thought it likely that B_{12} biosynthesis would not require external redox reagents. Thus, there was naturally intense interest in knowing what the NADPH does. To find out, the incubation was repeated with omission of NADPH; this experiment yielded a huge prize. Hydrogenobyrinic acid (**12**) was no longer produced and a new pale-yellow pigment accumulated in its place. When this new product, prepared enzymically in doubly labeled form (^3H, ^{14}C), was incubated with the above-mentioned enzyme system together with all the cofactors including NADPH, it was converted into hydrogenobyrinic acid (**12**) in high yield (50–90%) and without significant change in the ^3H:^{14}C ratio. This evidence left no doubt that after a long frustrating period, a new intermediate for B_{12} biosynthesis had at last been found.[24]

Preparation of the new product from [2,7,20-*methyl*-^{14}C]precorrin-3A **10** and [*methyl*-^{3}H]SAM established that three new methyl groups had been attached to precorrin-3A (**10**) during this conversion. Thus, the pale-yellow intermediate had been formed by hexamethylation of uro'gen III **7**, and hence it was named precorrin-6A.[5] The ^{14}C-labeling of the initial precorrin-3A (**10**) yielded another bonus in that the ^{14}C activity of precorrin-6A fitted with loss of its C-20 methyl group somewhere in the sequence leading to precorrin-6A. This result, combined with the earlier discovery with *Pr. shermanii* that ring contraction involved loss of C-20 and its attached methyl group (as acetic acid), gave strong indications that precorrin-6A was a contracted macrocycle.[24]

To which sites are the three new methyl groups attached in precorrin-6A? Initially this question was tackled indirectly by preparing precorrin-6A from unlabeled precorrin-3A (**10**) and using [*methyl*-^{13}C]SAM to label the three new methyl groups (Scheme 2). The product was then converted enzymically into hydrogenobyrinic acid (**12**), this time using unlabeled SAM. For

Scheme 2. Determining the position of the methyl groups in precorrin-6A.

analysis, **12** was transformed via cobyrinic acid (**11**) into heptamethyl cobyrinate (**14**, cobester) by nonenzymic cobalt insertion followed by esterification (Scheme 2). This approach was chosed because the ^{13}C NMR spectrum of cobester had been fully assigned.[25, 26] The ^{13}C NMR spectrum (Fig. 2) showed that the C-methyl groups appearing in cobester at C-17, C-12α,



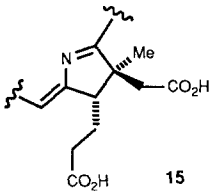


Fig. 2. Proton noise decoupled ^{13}C NMR spectrum (A) of labeled cobester (**14**) biosynthesized from precorrin-6A and (B) natural abundance ^{13}C-signals from all the C-methyl groups of unlabeled cobester (**14**).

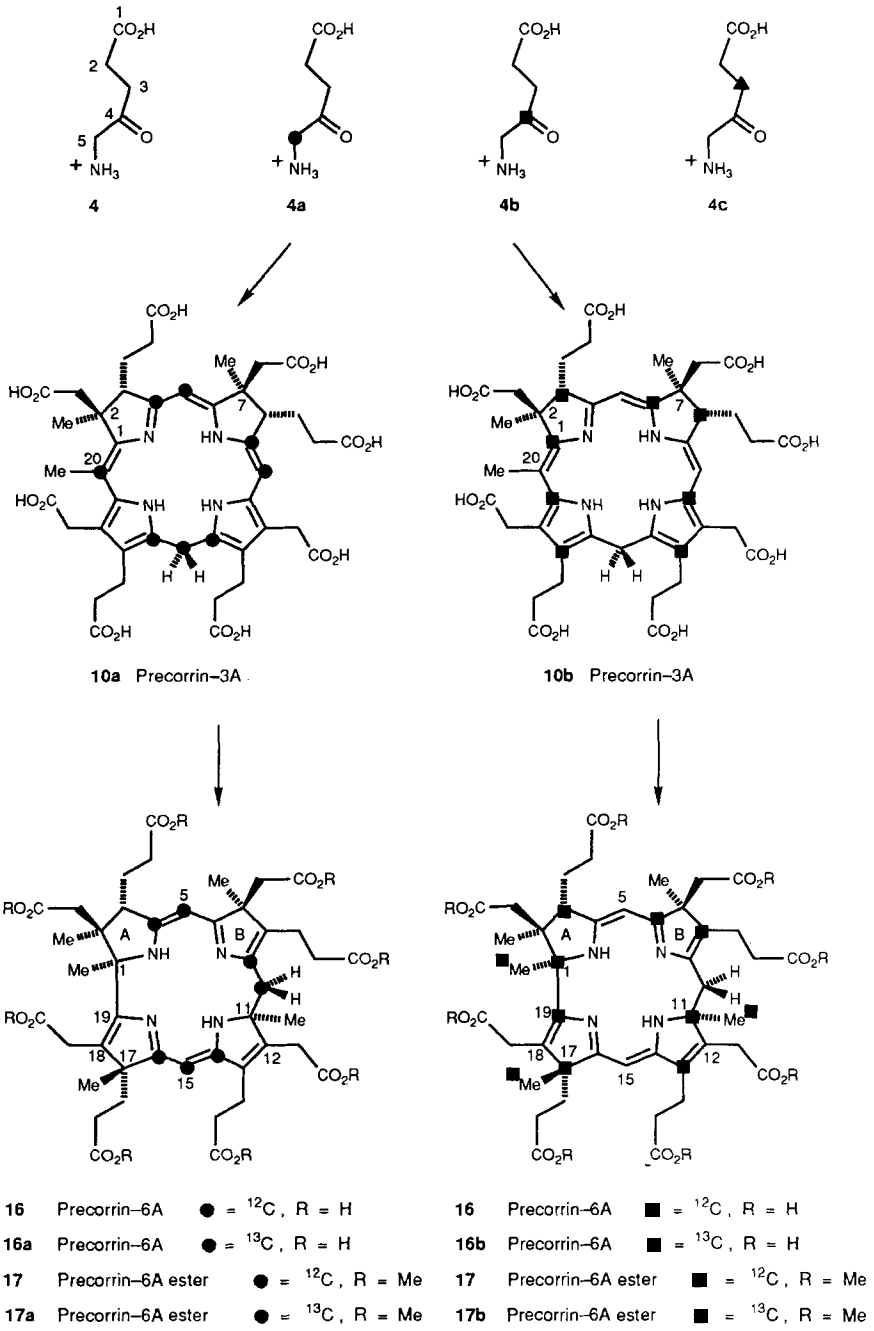
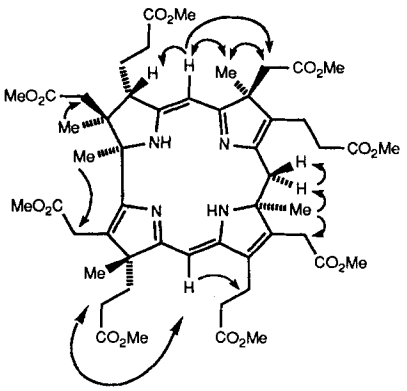
and C-1 are present in precorrin-6A. These findings fit in well with the earlier results from pulse labeling, which showed the methyl groups at C-5 and C-15 of cobyrinic acid to be the ones added last. More recently, this has been shown to be true also for hydrogenobyrinic acid (**12**).[19]



The mass spectrometric study of precorrin-6A methyl ester (molecular weight 1006) established, again surprisingly, that precorrin-6A itself is an octacarboxylic acid. So the acetate residue at C-12, which must undergo decarboxylation at some stage to generate the 12α-methyl group of hydrogenobyrinic acid (**12**), is still intact in precorrin-6A. This is odd because the decarboxylation will be blocked by methylation at C-12 (see **15**), yet it is certain that one of the C-methyl groups of precorrin-6A appears finally at C-12α in hydrogenobyrinic acid (**12**). The paradox will be resolved shortly. The final bonus from mass spectrometry was the evidence, from the molecular weight of 1006, that precorrin-6A stands at the oxidation level of a dehydrocorrin (seven double bonds) rather than a corrin (six double bonds).[24] So later reduction (by 2H) is needed to adjust the oxidation level of precorrin-6A to that of the final corrin **12**. This interlocks with the fact that precorrin-6A accumulates only in the absence of NADPH.

15

This structural information indicated unequivocally that precorrin-6A was a messenger carrying highly important information. It lay roughly at the center of that part of the pathway where nothing was known. Moreover, even the structural information gained by this stage did not fit at all with our previous speculations about what might happen in B_{12} biosynthesis. So it was with great excitement that an intensive effort was started to determine its complete structure. How could this be done? Since precorrin-6A has still not been crystallized, X-ray analysis was not an option. Also, although greatly increased amounts of precorrin-6A could be produced by using large quantities of overexpressed enzymes, these amounts were still rather small, generally in the range of 500 μg to 1 mg. But even the lower end of this range is enough to afford excellent ^{13}C NMR spectra, provided the molecule is produced in ^{13}C-labeled form; this then was the chosen approach.

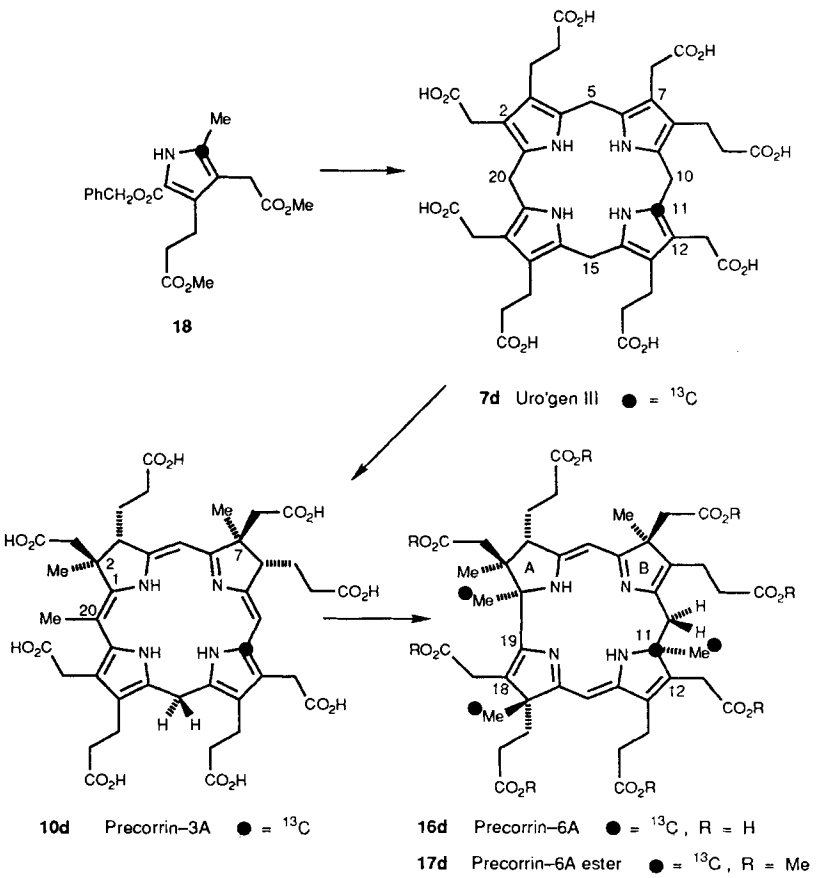


The appropriate combination of overproduced enzymes was used to convert [5-^{13}C]ALA **4a**, for example, into precorrin-3A **10a**[22] (Scheme 3). This labeling pattern follows unambiguously from rigorously established knowledge[2] of the biosynthetic steps from ALA **4** to uro'gen III **7**. The ^{13}C pattern is helpful, as the ^{13}C label at C-20 is the only one that stands alone. The set of three contiguous ^{13}C atoms around C-15 is also unique, whilst the remaining two pairs at C-4/C-5 and C-9/C-10 can be distinguished by suitable experiments. The labeled precorrin-3A **10a** was then converted into precorrin-6A **16a** by the correct set of overproduced enzymes, using unlabeled SAM, and the corresponding octamethyl ester **17a** was isolated for NMR study. Two further samples of precorrin-6A ester **17b** and **17c** (latter not illustrated) were prepared in the same way starting from [4-^{13}C]ALA **4b** and [3-^{13}C]ALA **4c**, respectively. Now

Scheme 3. ^{13}C-Labeling of precorrin-6A **16a** and **16b**.

[*methyl*-^{13}C]SAM was used as cofactor for the stages from precorrin-3A **10b** to precorrin-6A. In this way, every carbon atom of the macrocycle was ^{13}C-labeled in one or other of these three samples, as were the three C-methyl groups added during the stages after precorrin-3A.[27]

It is beyond the scope of this review to give a full account of the NMR analysis, but the key points should be highlighted to show its enormous power. The first sample, **17a**, from [5-^{13}C]ALA **4a**, showed that C-20 of precorrin-3A **10a** had been eliminated and that C-15 was an sp^2 carbon whereas C-10 was



17-NOE

clearly sp^3 hybridized. However, it was the spectrum shown by precorrin-6A ester **17b** from [4-^{13}C]ALA **4b** that gave the shock. The signals from C-1 and C-19 firmly established that these atoms are directly bonded, confirming that ring contraction had occurred. Surprisingly, the three labeled methyl groups were all directly bonded to ^{13}C atoms. This was expected for the methyl groups at C-17 and C-1, but certainly not for the third one. Clearly this group could not be at C-12 (where it finally appears in hydrogenobyrinic acid (**12**)), because that is an unlabeled carbon. All the evidence pointed to methylation at the adjacent center, C-11. A separate study giving unambiguous proof will be described shortly. The spectrum of the sample of precorrin-6A from [3-^{13}C]ALA allowed further features of the illustrated structure to be set in place, as did the study of all three labeled samples **17a**, **17b**, and **17c**, for example by ^{1}H–^{13}C NMR correlation experiments to pick out ^{1}H–^{13}C couplings through up to three bonds. This approach allows a substantial region of the molecule around each ^{13}C-labeled center to be studied, and hence a connectivity pattern of ^{1}H and ^{13}C around the whole macrocycle can be established. An independent set of connections (see arrows on structure **17**-NOE) was gained by studying ^{1}H nuclear Overhauser effects by difference spectroscopy.

The sum of all this evidence led to the striking structure **17** for precorrin-6A ester and hence to structure **16** for precorrin-6A itself.[27,28] The illustrated configurations at C-2 and C-7 depend on the enzymic conversion of precorrin-6A (**16**) in high yield into hydrogenobyrinic acid (**12**), in which the configurations at these centers are beyond doubt. This direct relationship to **12** also sets the C-11 methyl group of precorrin-6A (**16**) in the α-position, because the C-11/C-12 migration of the CH_3 group will probably be suprafacial (see Section 4.4), and the 12α-methyl group of **12** is known to be derived from SAM.[3b] So surprising was this methylation of C-11 that we secured it with unimpeachable evidence (Scheme 4). This was done by unambiguous synthesis[29] of uroporphyrin III carrying a single ^{13}C label at C-11; just the starting material **18** for the synthesis is illustrated. The porphyrin was reduced to [11-^{13}C]uro'gen III **7d**, which was transformed by way of [11-^{13}C]precorrin-3A **10d** using [*methyl*-^{13}C]SAM into precorrin-6A **16d**, which was isolated as its ester **17d**. The ^{13}C NMR signal from C-11, the only label in the macrocycle, was a 38 Hz doublet, as was the signal from its attached methyl group.[29] Structure **16** for precorrin-6A was thus totally secure.

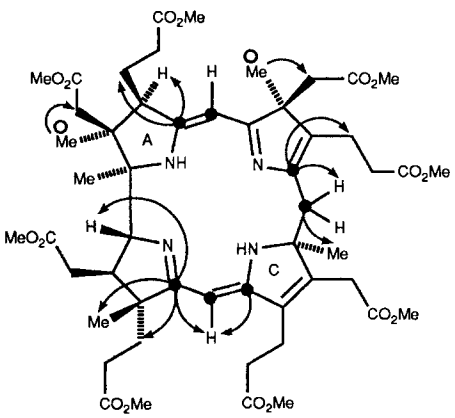
These striking discoveries changed our entire thinking about how vitamin B_{12} is biosynthesized; we had to abandon quite a number of our previously held views. The structure of precorrin-6A (**16**) revealed firstly that the ring-contraction step is not a late stage in the pathway, but has already happened at the hexamethylated stage. Secondly, the oxidation level does not stay constant throughout the biosynthesis. Since precorrin-6A (**16**) has two hydrogens less than either uro'gen III **7** or hydrogenobyrinic acid (**12**), an earlier oxidation and a later reduction step are needed. Thirdly, the 12-acetate residue is still

18 **7d** Uro'gen III ● = ^{13}C

10d Precorrin-3A ● = ^{13}C **16d** Precorrin-6A ● = ^{13}C, R = H **17d** Precorrin-6A ester ● = ^{13}C, R = Me

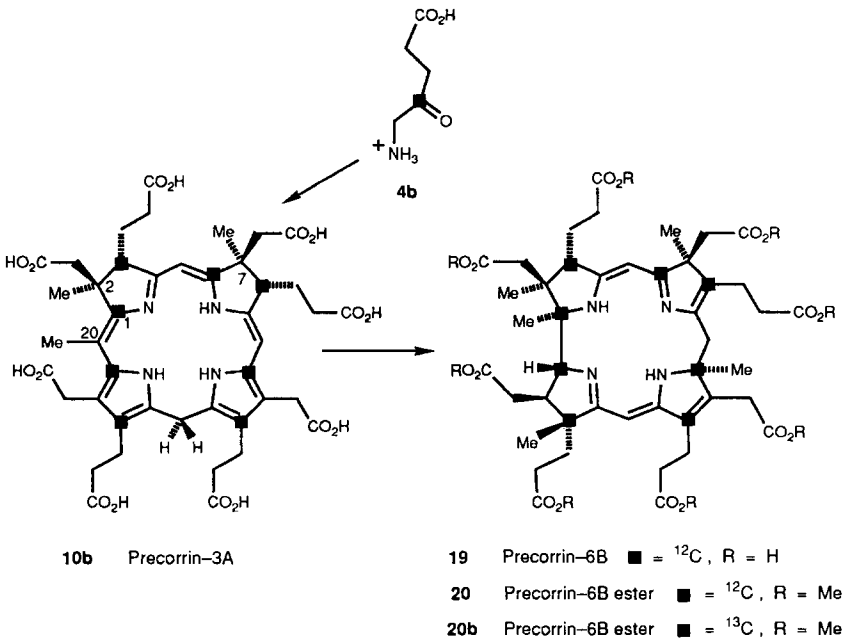
Scheme 4. Confirmation of methylation at C-11 of precorrin-6A **16d**.

intact, and decarboxylation of it does not have to occur before introduction of the fifth methyl group. Perhaps the most surprising realization was that the methyl group located at C-12 when the corrin macrocycle has been built is introduced initially at C-11. Notice that this C-11 methylation prevents the formation of a fully conjugated system, which accounts for the pale-yellow color of precorrin-6A (**16**).



Precorrin-6A (**16**) serves as a crucial staging post on the B_{12} pathway; we can work forward from it towards B_{12} itself and also look backwards to fill in the gap between precorrin-3A (**10**) and precorrin-6A (**16**). Here we will first explore forward to complete the pathway as far as hydrogenobyrinic acid (**12**), which is how we proceeded experimentally.

4.2. Precorrin-6A Reductase and the Structure of Precorrin-6B

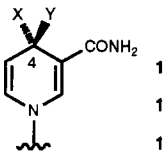


Logic tells us that since precorrin-6A (**16**) accumulated when a reduction step was blocked by exclusion of NADPH, it should be possible to isolate both the reductase enzyme and the normal reduction product, the next intermediate on the pathway. The way in which both were obtained illustrates perfectly how a complex biosynthetic sequence can be explored once the palette of the necessary enzymes is available. However, it should be remembered and emphasized that initially many proteins are known to be involved, but one does not know which enzyme does what!

The reduction product, precorrin-6B (Scheme 5), was first prepared by incubating precorrin-6A (**16**) with the complete set of overproduced enzymes encoded by the 8.7 kb fragment but *without* SAM.[30] This prevented the methylation of precorrin-6B, which, as will be seen, is involved in the next conversion step. So now precorrin-6B accumulated and could be isolated as such or, more conveniently, after esterification. The molecular weight of precorrin-6B was shown by fast-atom bombardment mass spectrometry (FAB-MS) to be 896, and the corresponding value for the methyl ester was 1008. Both values are two units higher than had been found for precorrin-6A (**16**) and its ester **17**, respectively, showing that only a single reduction step had occurred to form precorrin-6B. Moreover, the mass change from precorrin-6B to its methyl ester showed that *eight* carboxyl groups are present; in other words, decarboxylation of the 12-acetate had not occurred at this stage. The foregoing octamethyl ester turned out to be a mixture of the two C-3 epimers. Such ready formation of epimers was already a familiar feature of the chemistry[31] of many of the methylated macrocycles in Scheme 1. In this case it caused no problems, as the epimers were separable and their structures were determined[32] by the same approach developed for the work on precorrin-6A (**16**). Thus, they were biosynthesized from [4-^{13}C]ALA **4b** and, in a separate experiment, from [5-^{13}C]ALA **4a** by combining the actions of the necessary *ten* overproduced enzymes (Scheme 5). The isolated octamethyl ester of the resultant isotopomers of precorrin-6B and its epimer were then extensively studied by NMR; this phase of the work will be illustrated by just one example.

In the high-field ^{13}C NMR spectra of the labeled precorrin-6B ester **20b** and its epimer derived from [4-^{13}C]ALA **4b**, the ^{13}C signals from C-1 and C-19 stood out as being the only ones from directly coupled ^{13}C centers. The chemical shift showed C-19 to be an sp^3 carbon, whereas in precorrin-6A **16** C-19 is sp^2 hybridized. This indicated that the C-18/C-19 double bond of **16** had been reduced in precorrin-6B. As in precorrin-6A ester **17**,

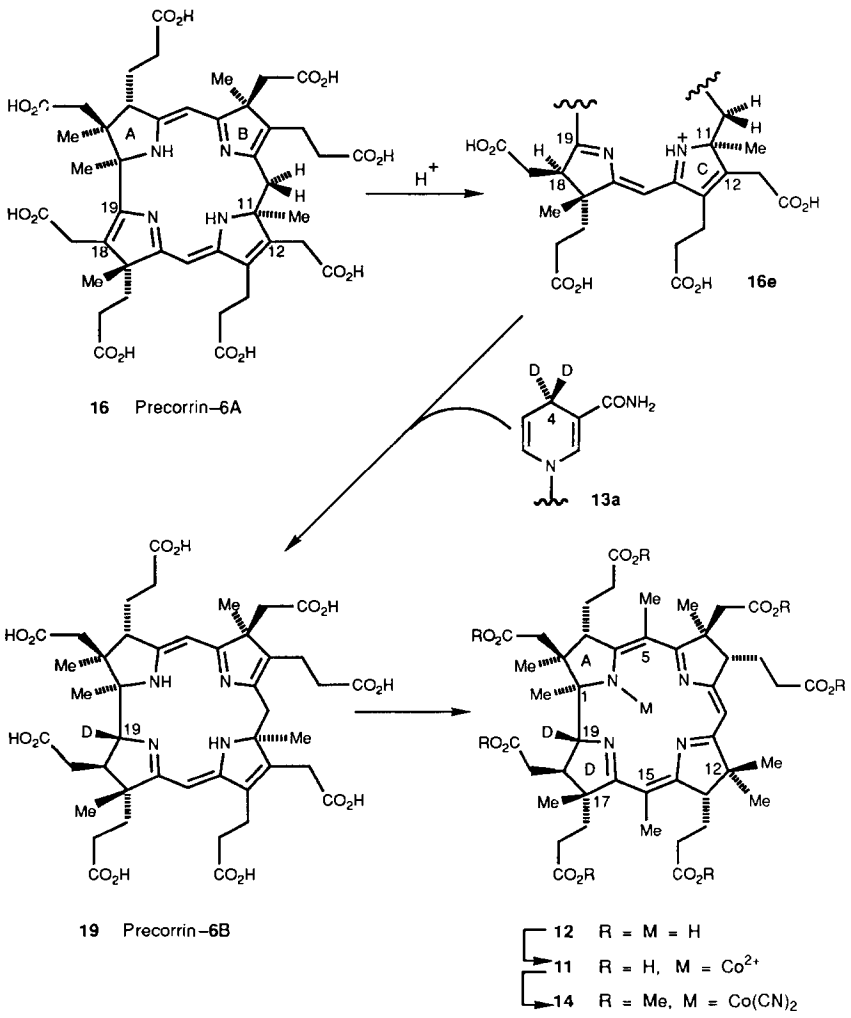
C-8 is sp^2 hybridized and C-10 sp^3 hybridized. In addition, the spectra showed that the 3-*epi* isomer had been formed in slightly larger quantity (60% of total) than the normal isomer with unchanged C-3 configuration. So the former was used for ^{1}H–^{13}C long-range correlation experiments with the delay set to the optimum for couplings of 10 Hz to detect ^{13}C–^{1}H couplings through up to three bonds. This led to the connectivities illustrated by arrows for the 3-*epi*-precorrin-6B ester. The



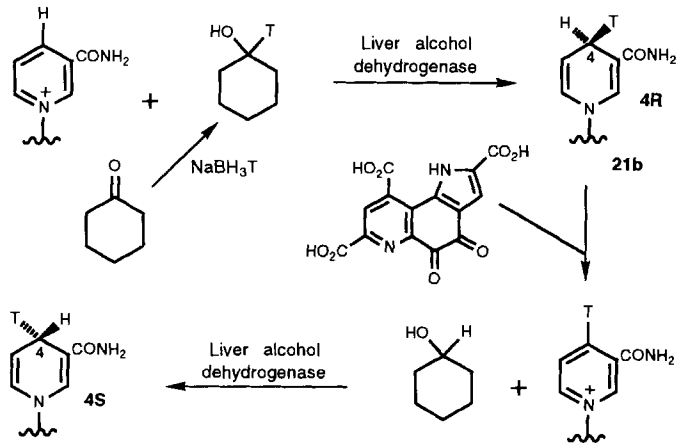
Scheme 5. ^{13}C-Labeling of precorrin-6B **20b**.

full set of results, together with those from the precorrin-6B ester **20a** (not shown) derived from [5-^{13}C]ALA **4a**, led unequivocally to structure **20** for precorrin-6B ester. It follows that precorrin-6B itself has structure[32] **19** or is a close tautomer.[28] Thus at this point on the pathway the oxidation level of precorrin-6B (**19**) has been neatly adjusted to match that of hydrogenobyrinic acid (**12**). The configuration at C-19 of **19** is assigned as illustrated, because precorrin-6B is converted in high yield into hydrogenobyrinic acid (**12**), in which the β configuration of H-19 is beyond doubt.

It was important for fuller understanding to study a) the regiospecificity and b) the stereospecificity of the foregoing reduction process. For a) the question is "To which end of the C-18/C-19 double bond does NADPH deliver the hydride equivalent?" and for b) "From which face of NADPH is it removed?" To answer the first question [4-$^2H_2$]NADPH **13a** was synthesized with 95% deuterium at C-4. It was used to reduce precorrin-6A (**16**) in combination with the greatly enriched reductase enzyme (Scheme 6). The precorrin-6B **19** thus formed was then converted into hydrogenobyrinic acid (**12**) with an enzyme system that was free from **12**. Subsequent nonenzymic insertion of cobalt yielded cobyrinic acid (**11**), which was esterified to give heptamethyl cobyrinate (cobester) **14**. The ^{1}H NMR spectrum of cobester had been fully assigned,[25, 26] and the spectrum of the biosynthetic product established that C-19 carried 25–30% deuterium. Careful study of the ^{2}H-labeled cobester by NMR spectroscopy and mass spectrometry showed that C-19 was the only deuteriated site.[33]



The reason for ^{2}H incorporation at C-19 being only 25–30% even though the NADPH is essentially fully deuteriated at C-4 is probably that the cofactor undergoes partial exchange of the deuterium at C-4 with the medium, a known process (via flavins?). Then the kinetic isotope effect favors transfer of ^{1}H rather than ^{2}H from the large excess of cofactor used. Nevertheless, these results establish that the reductase catalyzes hydride transfer specifically to C-19 of precorrin-6A (**16**). This makes sense mechanistically if precorrin-6A is protonated at C-18 to give **16e** (Scheme 6) before transfer of the hydride ion from NADPH.[33] The synthesis of [4*R*-^{2}H]NADPH **13b** and [4*S*-^{2}H]NADPH **13c** then allowed proof,[34] by exactly the same approach, that the reductase transfers specifically H_R of the cofactor **13**.



13a X = Y = ^{2}H
13b X = H, Y = ^{2}H
13c X = ^{2}H, Y = H

All these experiments proved beyond question that B_{12} biosynthesis in the aerobic *Ps. denitrificans* requires a reduction step. But does this hold true for *Pr. shermanii*, which is normally grown anaerobically or at most microaerophilically. This is a much more difficult problem, and it is helpful to outline how it was solved. The difficulties are that a) since only crude enzyme preparations are available (cf. the use of reasonably pure reductase above), exchange between the nicotinamide cofactors and the medium will be worse than in the foregoing work; b) the turnover to product will be low; and c) if reduction is indeed required in this organism, it is not known whether the cofactor is NADH or NADPH.

These problems were overcome by using the vastly greater sensitivity of tritium labeling. [4*R*-^{3}H]NADH **21b**, [4*S*-^{3}H]NADH **21c**, [4*R*-^{3}H]NADPH, and [4*S*-^{3}H]NADPH were synthesized;[35] the route to the first two compounds is outlined in Scheme 7. The last two were synthesized in a very similar way. The two 4*R* cofactors were combined in one incubation with the complete cell-free enzyme system[7, 36] prepared from *Pr. shermanii* cells with ^{14}C-labeled precorrin-2 (**9**) as the initial substrate. This cell-free system is able to carry out all the necessary biosynthetic steps to convert precorrin-2 (**9**) into cobyrinic acid (**11**). The important result was that tritium was incorporated into the cobyrinic acid (**11**) isolated from the experiment with the 4*R* cofactors but not from the parallel experiment in which the two 4*S* isomers were used. Interestingly, this is the same stereochemical selectivity found for the previous studies with *Ps. denitrificans*. Suitable degradation of the ^{3}H-labeled cobyrinic acid

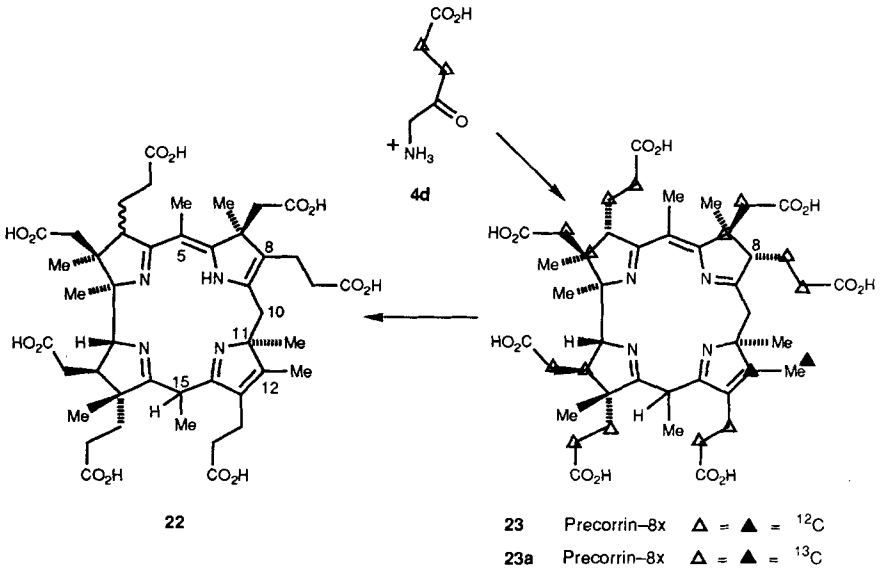
Scheme 6. Proof of the site of hydride delivery in the reduction of precorrin-6A (**16**).

Scheme 7. Synthesis of [4*R*-^{3}H]NADH **21b** and [4*S*-^{3}H]NADH **21c**.

(**11**) proved that the tritium was located somewhere on rings A and D. Apart from the hydrogen atoms of methyl groups, which need not concern us, only H-18 and H-19 are introduced during the conversion of precorrin-2 (**9**) into **11**. Since H-18 is derived from the medium,[37] it follows that the tritium is at C-19.[38] Thus reduction was demonstrated to be a required step for B_{12} biosynthesis in both aerobic and anaerobic (microaerophilic) organisms.

As soon as it was clear that precorrin-6B (**19**) is the dihydro derivative of precorrin-6A (**16**), the chase was taken up to isolate the pure reductase enzyme. As always, the key was to develop a suitable assay, and here a coupled enzyme assay was used.[30] This depended on knowing that the next step beyond precorrin-6B (**19**) in the biosynthetic sequence is catalyzed by a methylase encoded by the *cobL* gene (more about this in Section 4.3). So precorrin-6B (**19**) generated by the reductase was methylated in situ by using a substantial excess of the CobL enzyme and [^{14}C-*methyl*]SAM. Since methylation can only occur after precorrin-6B (**19**) has been produced, determination of the radioactivity of the final product gave a measure of the reductase activity in the sample for assay. It was shown in this way that cell extracts from the recombinant strain in which the 8.7kb DNA fragment had been overexpressed exhibited ten times higher reductase activity than the parent strain without overexpression. The engineered strain was used for the isolation work, but even so, the amount of enzyme in the cells was surprisingly low. As a result, 14000-fold enrichment was needed to obtain precorrin-6A reductase in homogeneous state. It was shown to reduce precorrin-6A (**16**) to precorrin-6B (**19**) by an NADPH-dependent process.[30]

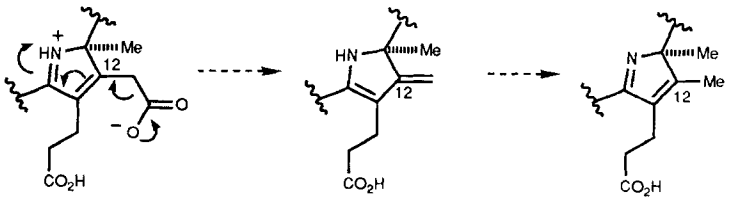
The N-terminal sequence of precorrin-6A reductase, together with three internal sequences obtained after tryptic digestion of the enzyme, showed that this protein is encoded by the *cobK* gene.[30] It is interesting that the *cobK* coding strand is the complementary one to that coding for the other seven *cob* genes carried by the 8.7kb DNA fragment. Also, the *cobK* coding sequence overlaps those for *cobJ* and *cobL* (Fig. 1); this arrangement may possibly control the relative level of expression of *cobK* and its neighbors. A further relationship that appears significant is that CobK shares 24.4% identity and 45% similarity with the CbiJ protein from *Salmonella typhimurium* (Table 2). The two proteins have similar molecular weights, and the regions of identity extend over their entire lengths. The CbiJ protein can therefore reasonably be considered as the homologue in *S. typhimurium* of precorrin-6A reductase in *Ps. denitrificans*. On this basis, it seems highly likely that a reduction step is required for B_{12} biosynthesis in anaerobic *S. typhimurium*.



4.3. Isolation and Structure of Precorrin-8x

It is time to take stock of the changes needed for the conversion of precorrin-6B (**19**) into hydrogenobyrinic acid (**12**). They are, in unknown order at this stage, a) migration of the C-11 methyl group to C-12, b) decarboxylation of the C-12 acetate residue, and c) methylation at C-5 and C-15. The way forward was to screen the available enzymes for their ability to use precorrin-6B (**19**) as a substrate. Since it was certainly possible that methylation is involved in the next step, one study (it was the successful one) assayed for methyl transfer to precorrin-6B from [*methyl*-^{3}H]SAM. This led to the selection of the enzyme encoded by *cobL* which, after isolation on a preparative scale, smoothly converted precorrin-6B (**19**) into precorrin-8x.[39] We will return to this enzyme after describing the structural studies on precorrin-8x.[40]

A more convenient way to prepare precorrin-8x rather than by using the CobL enzyme was based on the observation that the final biosynthetic step which converts precorrin-8x into hydrogenobyrinic acid (**12**) is strongly affected by product inhibition.[39,41] Thus, ^{14}C-labeled precorrin-3A (as **10**), prepared from [4-^{14}C]ALA (as **4**), was incubated with the same collection of eight overproduced enzymes used earlier together with [*methyl*-^{3}H]SAM and a tenfold molar excess of unlabeled hydrogenobyrinic acid. Under these conditions the product was [^{3}H,^{14}C]precorrin-8x rather than labeled hydrogenobyrinic acid, and the ^{3}H:^{14}C ratio indicated that *five* methyl groups had been introduced.[42] Hence the new product is an octamethylated derivative of uro'gen III **7**, and it is therefore referred to as precorrin-8x.[40] Mass spectrometric measurements on precorrin-8x and on its methyl ester confirmed these findings and also showed that this product is an heptacarboxylic acid. Thus the remarkable conclusion was that the CobL enzyme catalyzes two very different types of reactions, decarboxylation and C-methylation. Methylation occurs presumably at C-5 and C-15, since these are the only methyl groups not in place for precorrin-6B (**19**). The doubly labeled precorrin-8x was converted very efficiently into hydrogenobyrinic acid (**12**) by incubation with the complete enzyme system, and there was no significant change in the ^{3}H:^{14}C ratio during this conversion. This is the evidence needed to establish precorrin-8x as a further new intermediate on the pathway to vitamin B_{12}.[42]



In contrast to the reasonably stable octamethyl esters of precorrin-6A (**16**) and precorrin-6B (**19**), the heptamethyl ester of precorrin-8x was so prone to oxidation that it was unsuitable for NMR work. Also, to our dismay, the ^{13}C NMR spectra from precorrin-8x as a solution in slightly acidic water showed a veritable forest of peaks. Eventually we discovered the reason: what must surely have been a single enzymic product initially changed under these very mild conditions into a mixture of at

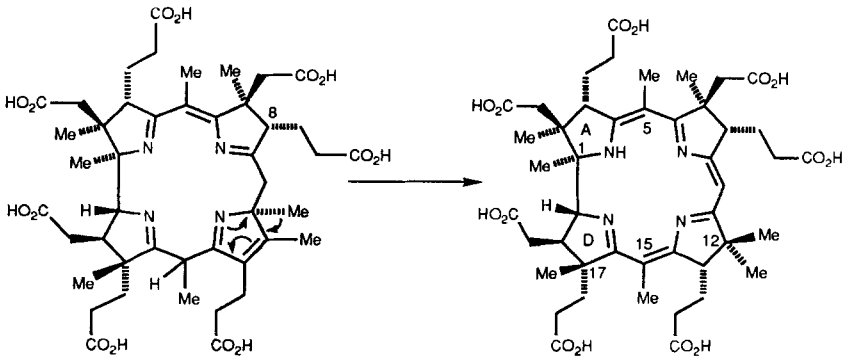
least five closely related compounds. The impasse was overcome when it was observed that all five forms slowly changed to give the same final isomer, which was stable. Now that the target was stationary rather than moving, the multiple ^{13}C-labeling approach, so successful for precorrins-6A (**16**) and 6B (**19**), could be used to establish[43] the structure **22** for the stable form of precorrin-8x (Scheme 8). The two new C-methyl groups were indeed at C-5 and C-15; like C-10, C-15 was sp^3 hybridized, whilst C-8 was sp^2 hybridized. The assignment of the configurations at all the centers apart from C-3 and C-15 depends on the fact that precorrin-8x can be enzymically converted into hydrogenobyrinic acid (**12**). Since, however, hydrogenobyrinic acid is not formed when the stable form of precorrin-8x is incubated with the aforementioned enzyme system, the configurations at C-3 and C-15 (which might have changed) must be left unspecified at present.

Scheme 8. Determination of structure of precorrin-8x (**23**).

Interest now focused on finding out which of the five closely related forms of precorrin-8x was the true biosynthetic intermediate. HPLC separation of the five forms was the next step. One of these compounds was shown to be enzymically converted into hydrogenobyrinic acid (**12**) more rapidly and efficiently than any of the others. Still better, this form was reasonably stable at high pH. So this true intermediate was generated from precorrin-3A (as **10**), which in turn had been biosynthesized from [2,3-$^{13}C_2$]ALA **4d**. This experiment was designed to allow C-12 and its attached carbon to be studied in precorrin-8x; remember for work like this on a semi-micro scale, NMR information is available only at and around ^{13}C-labeled sites. The results showed that a methyl group is attached to C-12 which is itself an sp^2 center; these two carbon atoms are marked on structure **23a** as filled black triangles. This is important because the decarboxylation process initially generates a methylene group, which then tautomerizes into a methyl group (Scheme 9). All the foregoing results together with those from extensive ^1H NMR studies on the true precorrin-8x led to structure **23** for this intermediate.[43] That C-8 is sp^3 hybridized in precorrin-8x (**23**) was indicated by

Scheme 9. Mechanism of decarboxylation of 12-acetate group.

a ^{13}C NMR spectrum of the sample prepared from [4-^{13}C]ALA and [*methyl*-^{13}C]SAM taken quickly in the original weakly acid water before appreciable change to the stable form had occurred. This spectrum showed only a very weak signal around $\delta \approx 99$ where the C-8 signal of the stable form appears, and this signal increased in intensity as the change to **22** took place.



Comment is needed on the formation of at least four other forms from the true precorrin-8x (**23**). The latter can be expected to change to **22** thereby gaining stabilization[44] from the extended amidine system of rings A and B. The two separated chromophores can exist as other tautomers in addition to those shown in **22** and **23**, and epimerization is possible at C-3, C-8, and C-15. Different combinations of these regio- and stereoisomerizations can account for the generation of different forms, all of which eventually fall into the thermodynamic well represented by the stable form **22**. The stereochemical and other details will be addressed in future work when more important problems have been solved. This is the right priority, because the nature of precorrin-8x (**23**) has now been almost entirely revealed.

The enzyme responsible for the conversion of precorrin-6B (**19**) into precorrin-8x (**23**) has been purified to homogeneity[39] from an engineered strain [SC510(pXL253)] of *Ps. denitrificans* by using fast protein liquid chromatography (FPLC). This protein, encoded by the *cobL* gene, is a single polypeptide having M_r 43000 ± 1000, which matches the calculation of 42900 Daltons from the gene sequence. However, gel permeation studies point to strong association in the native state, possibly as an octamer. We have already commented on the remarkable ability of this enzyme to catalyze both C-methylation and decarboxylation. The sequence of the two methylations and decarboxylation is unknown at present. However, when precorrin-6A (**16**) is incubated without SAM with the standard preparation of eight enzymes (including CobL), the end product is precorrin-6B (**19**) and not its 12-decarboxylated form. So it is probable that at least one C-methylation precedes the decarboxylation step. When one compares the CobL sequence with the sequences of other methyltransferases of the B_{12} pathway (CobA, CobI and, as will be seen later, also CobF, CobJ, and CobM), part of the CobL protein can be assigned a methyltransferase function. There is also an additional carboxy-terminal domain of $M_r \approx 20000$ which probably carries the decar-

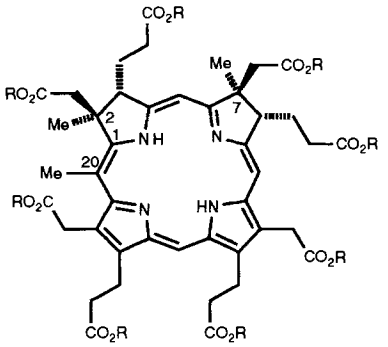
boxylase activity.[14, 39] This dual activity has been rationalized as resulting from the fusion of initially separate ancestral genes, one encoding for C-5/C-15 methylase activity, the other for acetate decarboxylase activity.[39] This interpretation has gained recent support by the description of two separate genes of the B_{12} pathway in *Salmonella typhimurium*, *cbiE* and *cbiT*.[45] These show strong homology with the amino-terminal and carboxy-terminal regions, respectively, of *cobL* (Table 2).

4.4. Final Rearrangement to Form the Corrin Macrocycle

Precorrin-8x (**23**) is isomeric with hydrogenobyrinic acid (**12**), and the conversion of the former into the latter is initiated by migration of the methyl group at C-11 over to C-12. This is a [1,5]sigmatropic rearrangement and will be suprafacial. In this way, the blockage to formation of a conjugated system is removed, and now the molecule can tautomerize and slide into the thermodynamic well represented by the extended conjugated system of hydrogenobyrinic acid (**12**) (Scheme 10). The rearrangement process was known to be catalyzed by an enzyme present in the mixture of overproduced proteins routinely used in many of the foregoing studies. It was first isolated[19] as a protein that specifically bound hydrogenobyrinic acid (**12**). Only later did it become clear that this protein was actually the enzyme catalyzing the formation of hydrogenobyrinic acid (**12**) from precorrin-8x (**23**), and the N-terminal sequence of this protein showed that its gene was *cobH*. Such are the twists and turns of scientific research! By then a strain of *Ps. denitrificans* [SC510 Rif^r(pXL1149)] had been constructed having *cobH* as the only amplified gene. The soluble protein from this strain gave pure CobH enzyme by repeated fractionation by FPLC on a series of different columns; hydrogenobyrinic acid synthase activity served as the assay.[42] Interlocking evidence that the correct enzyme and gene for the C-11/C-12 rearrangement had been located came from a further engineered strain of *Ps. denitrificans* in which *cobH* was not overexpressed. The forward transformation of precorrin-6A (**16**) by the soluble enzyme system from this strain stopped at the stage of precorrin-8x (**23**), which was isolated in 45% yield.[42]

23 Precorrin-8x **12** Hydrogenobyrinic acid

Scheme 10. Rearrangement of precorrin-8x (**23**) to hydrogenobyrinic acid (**12**).



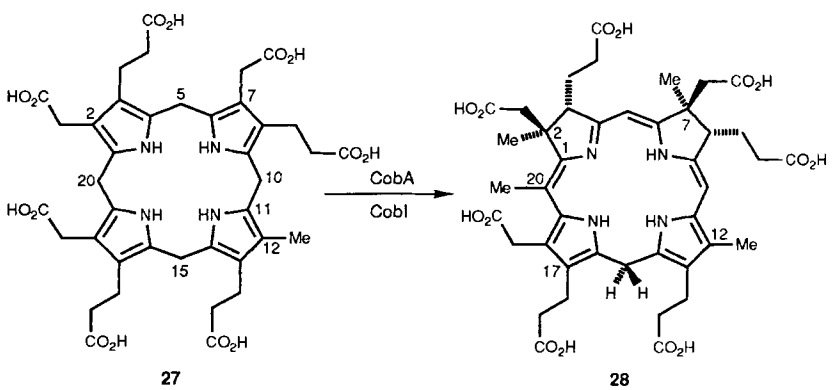
Under the usual denaturing conditions, the CobH enzyme has a relative molecular mass M_r of 22000 ± 1000, and gel permeation studies showed the protein to be monomeric.[42] Enzymes that catalyze rearrangement reactions are particularly interesting, and one wonders how CobH catalyzes the C-11/C-12 methyl migration. Ring-C of precorrin-8x (**23**) is a disubstituted pyrrolenine apparently capable of rearranging on its own[46] — but it does not. Possibly the enzymic trick is to change an unfavorable conformation of precorrin-8x (**23**) as it binds into a favorable one with the stereoelectronics appropriate for rearrangement. Since this enzyme can be obtained in larger quantities and is a relatively small monomeric protein, future research on it should be rewarding.

Our survey has now briefly described the early part of the B_{12} pathway, summarized in Scheme 1, leading from ALA **4** through to precorrin-3A (**10**). Then followed a fuller account of the discovery of precorrin-6A (**16**), which opened the way for the rest of the pathway to be elucidated through to hydrogenobyrinic acid (**12**), adding two further new intermediates, precorrin-6B (**19**) and precorrin-8x (**23**). Having worked forwards from precorrin-6A (**16**), we can now work backwards from it towards precorrin-3A (**10**) to fill the only remaining gap in the route to the first corrinoid intermediate **12**. However, a hidden thread needs first to be picked out.

5. Synthesis Using an Array of Overproduced Enzymes

Many times so far in this review, complex materials have, without further comment, been "synthesized enzymically" using a combination of enzymes available in quantity by overexpression of the corresponding genes. The opportunities opened up by this approach are far too important, especially for organic chemists, to let the topic be somewhat hidden. The in vitro synthesis of precorrin-6A (**16**) from ALA **4**, which was the basis of all the structural work, involved the combined use of nine overproduced enzymes.[24] The similar synthesis of hydrogenobyrinic acid (**12**) required twelve overproduced enzymes to work together in a sequential way.[24] In both cases, quite sufficient material was produced for further enzymic and spectroscopic experiments. As far as we know, these are the earliest examples (1990) in which large numbers of overproduced enzymes have been used for such syntheses, certainly in the tetrapyrrole field. But other groups have provided related examples in this and other fields,[3d, 47] although generally smaller numbers of enzymes are involved.

Comparison of the nonenzymic and enzymic synthetic approaches for the preparation of precorrin-3A (**10**) illustrates well the enormous power of the enzymic route. A stereocontrolled nonenzymic synthesis was developed[48] of the isobacteriochlorin octamethyl ester **30**; the corresponding octacarboxylic acid **29** is the didehydro form of precorrin-3A (**10**). Precorrin-3A (**10**) can readily be prepared from the ester **30**. The synthesis of **30** was the culmination of over ten years of research, which was necessary because initially no route was available for



29 R = H
30 R = Me

synthesis of any isobacteriochlorin macrocycle, even those with simple substituents. This synthesis was a very satisfying one: it yielded a rich harvest of new chemistry, and many excellent chemists were trained during its development. But if one wishes to prepare precorrin-3A (**10**) or its relative **30** for further work, is such a nonenzymic synthesis the way to go? The answer has to be "no". To repeat the synthesis from the beginning would take two first-class chemists at least one year, and the final yield, assuming a reasonable scale at the start, would be 5 mg at best. How does this compare with enzymic synthesis?

Here the starting material, ALA **4**, can easily be synthesized on any desired scale. Scheme 1 shows that five enzymes are needed to transform ALA **4** into precorrin-3A (**10**), namely those encoded by *hemB*, *hemC*, *hemD*, *cobA*, and *cobI*. Strains that overexpress these genes are now available, so providing relatively large quantites of the corresponding enzymes.[49] It is true that many years of work were required to unravel the genetics and molecular biology to reach the present stage, but that is the completed foundation and we can now use these enzymes for synthesis. A standard laboratory-scale enzymic preparation[49] of precorrin-3A (**10**) yields 10–20 mg and, with the enzymes in hand, the whole synthesis from ALA **4** to precorrin-3A (**10**) takes about three days. Even taking into account growing the overproducing strains and isolating or enriching the enzymes, the time required is still just a few weeks. So more material is produced in far less time than for the nonenzymic approach.

It should be borne in mind that many enzymes are not totally substrate specific, and this can be used to advantage for the synthesis of analogues of a particular natural product. This involves the nonenzymic synthesis of a substrate having a structure somewhat different from the natural one. For example, if in Scheme 1, uro'gen III **7** is replaced by its 12-decarboxylated analogue **27** (Scheme 11), which can be synthesized by a straightforward nonenzymic route, the two methylase enzymes (from *cobA* and *cobI*) still function to produce the analogue **28** of precorrin-3A (**10**) having a methyl group at C-12 rather than an acetate residue.[50] Indeed, examples of such syntheses of analogues of natural products abound.[51]

In view of these huge developments in molecular biology and enzymology, how will natural products research look in ten years time? A substantial change seems inevitable, and it is most heartening to see the power of combined nonenzymic and enzymic synthesis. But this is still in the future; our survey can now return to the biosynthetic pathway and to filling the gap between precorrin-3A (**10**) and precorrin-6A (**16**).

27 **28**

6. From Precorrin-3A to Precorrin-6A

6.1. Precorrin-4: Another Surprising Structure

The next step forward in the elucidation of the biosynthetic pathway showed the great value of preparing strains of the organism of interest in which specific genes have been eliminated. For *Ps. denitrificans*, deletion of the *cobM* gene from one strain led to an enzyme preparation that efficiently converted precorrin-3A (**10**) into a new tetramethylated intermediate shown to be precorrin-4.[52] For precorrin-2 (**9**) and precorrin-3A (**10**), the structural work had largely been carried out on the more stable conjugated derivatives (with two hydrogen atoms fewer), which were readily formed by aerial oxidation. The same held true for precorrin-4; it was smoothly converted in air into its didehydro derivative called Factor IV. This could be purified by chromatography which showed, in combination with mass spectrometry, the presence of two isomers having properties indicating that they were epimeric, probably at C-3.[52, 53] Since such epimerization has been observed for almost every intermediate isolated so far from the B_{12} pathway, it need not concern us further. The rest of the studies focused on the major epimer.
