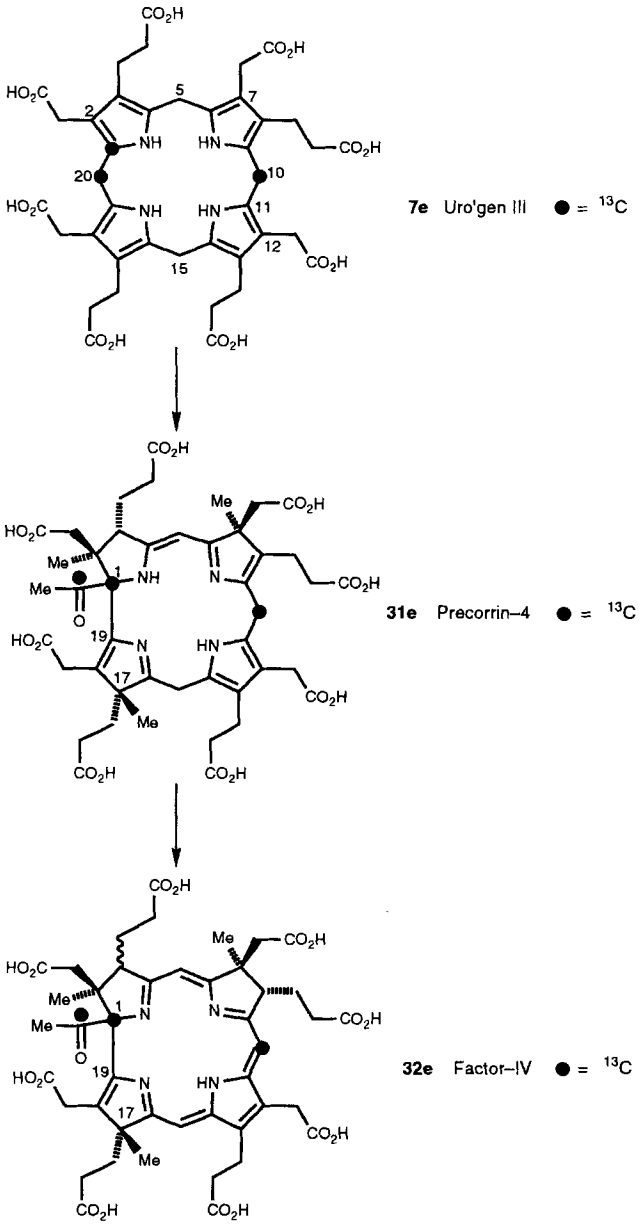
In the same way that precorrin-3A (**10**) had earlier been regenerated from its didehydro analogue **29** by enzymic reduction,[22] so Factor IV was reduced to reform precorrin-4 on incubation with the complete enzyme system including NADH but lacking NADPH. Then the forward biosynthetic steps continued from precorrin-4, but because NADPH was lacking, progress stopped at precorrin-6A (**16**), which was isolated. This result firmly places precorrin-4 on the biosynthetic track to vitamin B_{12}. It cannot be too strongly emphasized that it is essential to provide such clear evidence that a putative intermediate is biosynthetically converted into the final product or, as here, into another established intermediate.

The structural studies followed the approach, by now well established, of preparing three samples of Factor IV from [5-^{13}C]ALA **4a**, [4-^{13}C]ALA **4b**, and [3-^{13}C]ALA **4c**. The ^{13}C NMR and ^{1}H NMR results[52] from these three samples led to structure **32** for Factor IV; for clarity just the first two labeling patterns are shown in Scheme 12. Carbon atoms carry-

Scheme 12. ^{13}C-Labeling of precorrin-4 (**31**) and Factor IV (**32**).

ing the same symbol are ^{13}C-labeled in the same sample, whereas the ^{13}C-labels for carbon atoms marked with different symbols are in different samples. The key observations were that a) C-1 and C-19 are directly bonded, b) a low-field signal (δ = 210.8) shown by the sample **32a** from [5-^{13}C]ALA corresponds to the carbonyl group of the acetyl residue, and c) C-19 is an sp^2 center, thus placing the acetyl group at C-1. Since Factor IV (**32**) and precorrin-4 have a reversible redox relationship, structure **31** can be deduced for precorrin-4. Comparison of this structure with that of precorrin-3A (**10**) shows that both methylation at C-17 and oxidation have occurred (addition of one oxygen overall). This is the increase in oxidation state that is later reversed by the reductase CobK.



Once again, workers in the B_{12} field, and observers of it, were surprised by the structure of precorrin-4 (**31**). The very early ring contraction was one unexpected feature, but the greatest surprise was the appearance of the acetyl group at C-1; this shook our previous conceptions. That an acetyl group would be generated during the ring contraction followed from the likely mechanism.[44] The acetyl group would act as the source of acetic acid, the established extrusion product from ring contraction in *Pr. shemanii* (see Section 2). But everyone's speculations prior to the discovery of precorrin-4 (**31**) placed the acetyl group at C-19 rather than at C-1. This key element of structure **31** for precorrin-4 was supported by unimpeachable evidence derived from a combination of nonenzymic and enzymic synthesis together with NMR spectroscopic studies. [1,10,20-$^{13}C_3$]Uroporphyrin III ester was unambiguously synthesized from the starting material **18** illustrated in Scheme 4, and its ^{13}C NMR spectrum confirmed the direct linkage of the two important ^{13}C atoms C-1 and C-20. The product was hydrolyzed and reduced to yield [1,10,20-$^{13}C_3$]uro'gen III **7e** (Scheme 13), which was enzymically converted into precorrin-3A. After some purification steps, precorrin-3A was finally transformed into precorrin-4 **31e**, and hence into Factor IV **32e**, by incubation with the mixture of enzymes lacking CobM. The ^{13}C NMR spectrum of the labeled Factor IV showed that the signals from the acetyl carbonyl group (originally C-20) and from C-1 were doublets, in other words these carbons are directly bonded. The conclusion that the acetyl group of Factor IV (**32**), and so also of precorrin-4 (**31**), is attached at C-1 is thus a rigorous one.[53] In addition, Factor IV was biosynthesized from precorrin-3A **10b**, which had been prepared from [4-^{13}C]ALA **4b** and [*methyl*-^{13}C]SAM (Scheme 3). [*Methyl*-^{13}C]-SAM was also used in the final step as the source of the fourth methyl group. The doublets in the ^{13}C NMR spectrum of Factor IV from C-17 and the methyl group added last confirmed their direct connection. It was a valuable bonus to be able to observe the singlet from the methyl group of the acetyl residue.[53] Finally with regard to Factor IV, it is interesting that a close relative of the parent contracted macrocycle had been synthesized earlier for other studies.[54]

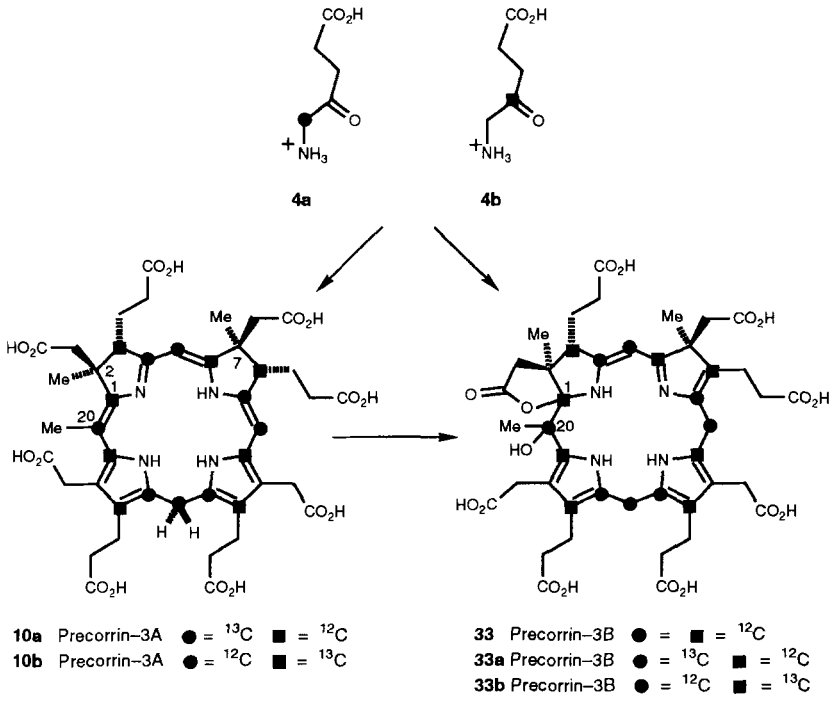
That the fourth methyl group to be attached to the macrocycle appears at C-17 in precorrin-4 (**31**) is in satisfying agreement with the the results of pulse-labeling studies, outlined earlier, on the order of the C-methylations after the third one. In both *Pr. shermanii* and *Ps. denitrificans* methylation occurred first at position 17, followed by 12, then 1, and finally at 5 and 15. The research already described on precorrin-6A (**16**) showed that the fifth methyl group, which resides in the corrins at C-12, is initially placed at C-11. As further transformation of precorrin-4 (**31**) is blocked by deletion of the *cobM* gene resulting in accumulation of precorrin-4 (**31**), and since the sequence of CobM shows it to be a methyltransferase, it follows that CobM is the 11-methyltransferase of *Ps. denitrificans*.[52]

Homogeneous CobM methyltransferase was isolated by a series of chromatographic steps from a strain of *Ps. denitrificans* in which only the *cobM* gene had been overexpressed. The molecular weight of CobM according to the usual SDS-PAGE (SDS-PAGE = sodium dodecylsulfate polyacrylamide gel electrophoresis) was 31 000 $\pm$ 2000. The sequence of the first fifteen residues at the N-terminus of CobM was in full agreement with expectation from the DNA sequence, although the N-terminal methionine had been processed off in the formation of the mature protein.[55]

6.2. A Pause to Catch Breath

The climb to the summit was now almost completed, and these last results are still fairly very recent. What remained to be done? Section 3 described how it was established that *nine* enzymes are required for the biosynthesis of hydrogenobyrinic acid (**12**) from uro'gen III **7**. These enzymes are encoded by the *cob* genes given letters *A*, *F*, *G*, *H*, *I*, *J*, *K*, *L*, *M*. Scheme 1

Scheme 13. Confirmation that the acetyl group of precorrin-4 (**31**) is at position 1.



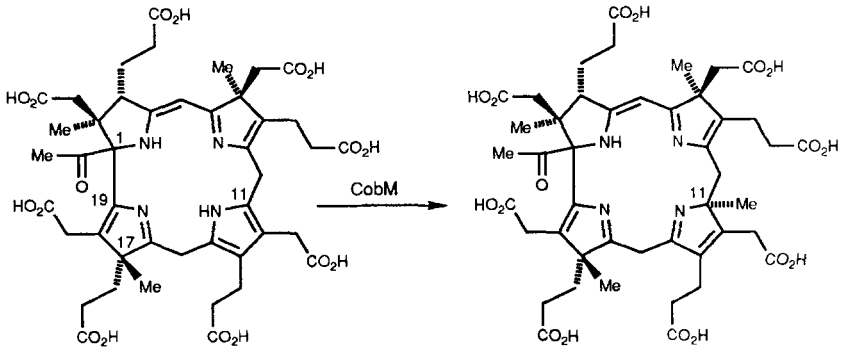
showed that *cobA* and *cobI* are needed to reach precorrin-3A (**10**). Then the main section of the review described how the functions of the enzymes encoded by *cobM*, *cobK*, *cobL*, and *cobH* were discovered. By this stage (March 1993) the remaining questions were apparent: What do the enzymes encoded by the remaining genes do? These genes are *cobG*, *cobF*, and *cobJ*. From what has been described already, the corresponding enzymes must convert precorrin-3A (**10**) into precorrin-6A (**16**) via the known precorrin-4 (**31**), which CobM must methylate at C-11 to form precorrin-5. Moreover, it was clear from comparisons of the sequences of CobF and CobJ with those of the known methyltransferases (CobA, I, M, and L) that these two enzymes are also methyltransferases. CobG, however, was quite different and seemed likely to catalyze the oxidative step which must occur before precorrin-4 (**31**). All this holds together perfectly since now only two C-methylations (at C-17 and C-1) have not been correlated with their enzymes, and CobJ and CobF are strong possibilities. The situation at this point was analogous to solving any multicomponent puzzle (such as a crossword or jigsaw puzzle): as more and more parts are put in place, the easier it is to solve the remainder. And by this stage, almost all the parts were in place.

6.3. Setting the Stage for the Ring Contraction: Precorrin-3B

These remaining problems were studied by testing the CobG, CobJ, and CobF enzymes alone and in combination for their ability to transform precorrin-3A (**10**). These experiments could only be done after construction of strains of *Ps. denitrificans* in which *cobG*, *cobJ*, and *cobF* had been separately amplified.[55] CobJ alone had no effect on precorrin-3A, whereas CobG and CobJ together yielded the known precorrin-4 (**31**). CobJ is a methyltransferase, and from the structure of precorrin-4 (**31**) one can conclude that CobJ must be the 17-methyltransferase. So CobG must act before CobJ. Pointers that CobG is the enzyme acting on precorrin-3A (**16**) had come earlier from eight engineered strains of *Ps. denitrificans* in which the genes *cobF* to *cobM* had been deleted one at a time. Only the strain lacking *cobG* accumulated precorrin-3A (**10**) intracellularly.[56] When tested, CobG alone converted precorrin-3A (**10**) into a new intermediate, which was not further methylated and so named precorrin-3B.[57] As for previous cases, two isomers were isolated and both were converted in high yield into precorrin-4 (**31**), the established B_{12} intermediate, when incubated with the CobJ enzyme and SAM.[55] These isomers are almost certainly epimeric at C-3; but this is a small point and the focus here will be on the major epimer. Mass spectrometry established its molecular weight as 894, which is 16 units higher that of precorrin-3A (**10**) and corresponds to the introduction of one oxygen atom into precorrin-3A (**10**) in forming precorrin-3B. Thus, CobG was confirmed as the oxidative enzyme.[57]

It is not necessary to give a full account of the structure determination of precorrin-3B, because exactly the same approach of multiple ^{13}C-labeling was used as for all the earlier new intermediates. But in addition, its Fourier transform infrared spectrum showed a strong band at 1799 cm^{-1} corresponding to the presence of a γ-lactone. The labeling patterns for two of the three differently ^{13}C-labeled samples of precorrin-3B are collected on structures **33a** and **33b** (Scheme 14). A thorough assignment was made of both the ^{13}C and ^{1}H NMR spectra, and $^{13}C-^{1}H$ short- and long-range connections were established around the macrocycle to add further strength to the assigned structure **33**.[57] In fact, the mass of evidence leaves no doubt that this structure is correct, although the configurations at C-20 and C-1 still need to be determined. The structure of precorrin-3B (**33**) was yet another surprise, since prior to 1990 the general expectation was that the next step beyond precorrin-3A (**10**) was probably C-17 methylation or decarboxylation of the 12-acetate. Also it is most interesting that the oxidative step leading to precorrin-3B (**33**) does not cause the ring contraction; the stage has been set for it to happen during the next conversion into precorrin-4 (**31**) catalyzed by CobJ when methylation of C-17 occurs.

Pure CobG enzyme is a brown-green protein isolated from a strain of *Ps. denitrificans* overexpressing *cobG* and *cobF*. The



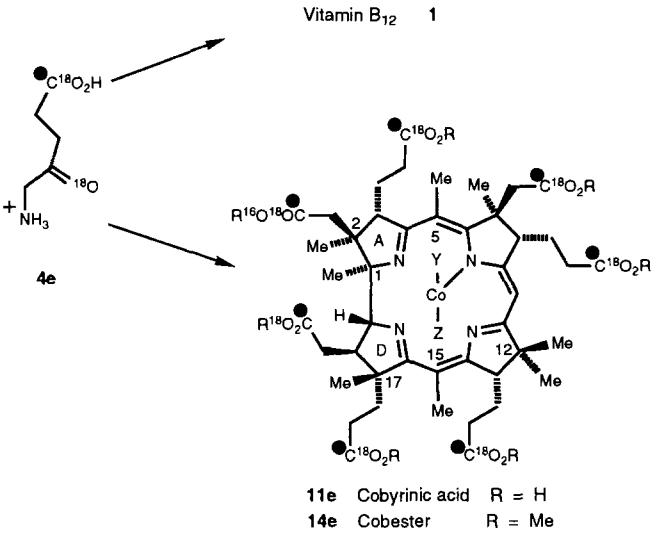
Scheme 14. ^{13}C-Labeling of precorrin-3B **33a** and **33b**.

molecular weight of CobG by SDS-PAGE is 46000 ± 2000. The assay was based on the production of precorrin-4 (**31**) from precorrin-3A (**10**) when the tested extracts were incubated with added CobJ. The properties of CobG and analyses for iron and sulfide all indicated that this enzyme is an iron–sulfur protein having one [4Fe-4S] cluster or two [2Fe-2S] clusters.[55] The C-terminal domain of CobG displays ≈25% identity to the corresponding domains of ferredoxin-sulfite reductase (EC 1.8.7.1), sulfite reductase hemoprotein CysI (EC 1.8.1.2), and ferredoxin-nitrite reductase (EC 1.7.7.1) (Table 2).[58, 59] Importantly, the four cysteine residues proposed to hold the [4Fe-4S] cluster in CysI and spinach nitrite reductase[58] lined up with positions 338, 344, 377, and 381 in the CobG sequence. The pure CobG enzyme catalyzed the conversion of precorrin-3A (**10**) into precorrin-3B (**33**) without added cofactors. Interestingly, under the anaerobic conditions used, this oxidation was roughly stoichiometric with respect to the enzyme. However, recently Scott's group reported the observation of ^{13}C NMR signals corresponding to the structure established above for precorrin-3B (**33**) when precorrin-3A (**10**) was incubated with CobG. The valuable observation was made that the CobG enzyme turns over in the presence of oxygen.[60]

6.4. Precorrin-5, a Structure this Time without Surprises

Already CobM had been pinpointed as the enzyme that methylates C-11 of precorrin-4 (31), and the product should be precorrin-5 (**34**). Also, CobF was the only enzyme left (and it is a methylase) to introduce the methyl group seen at C-1 of precorrin-6A (**16**). A priori, these two steps look reasonably straightforward, and it seemed very probable that this time there would not be surprise cards up the biosynthetic sleeve, and so it turned out. Precorrin-5 could be biosynthesized from precorrin-3A (**10**) by using CobG, CobJ, CobM, and SAM but without CobF[55] or alternatively, from precorrin-4 (**31**) by incubation with CobM and SAM.[61] Again multiply ^{13}C-labeled forms of precorrin-5 were generated as earlier to allow the structure **34** to be deduced by NMR spectroscopy.[61] As can be seen, **34** is the expected 11-methylated derivative of precorrin-4 (**31**) (Scheme 15). How the C-1 acetyl group of precorrin-5 (**34**) might be removed to allow C-methylation at this site will be considered later. The required reactivity is present, however, because the acetyl residue is intrinsically labile[55, 61] and is gradually lost almost certainly as acetic acid,[55] the elimination product found in earlier experiments with *Pr. shermanii*. This deacetylated product was isolated and called Factor V.[55]

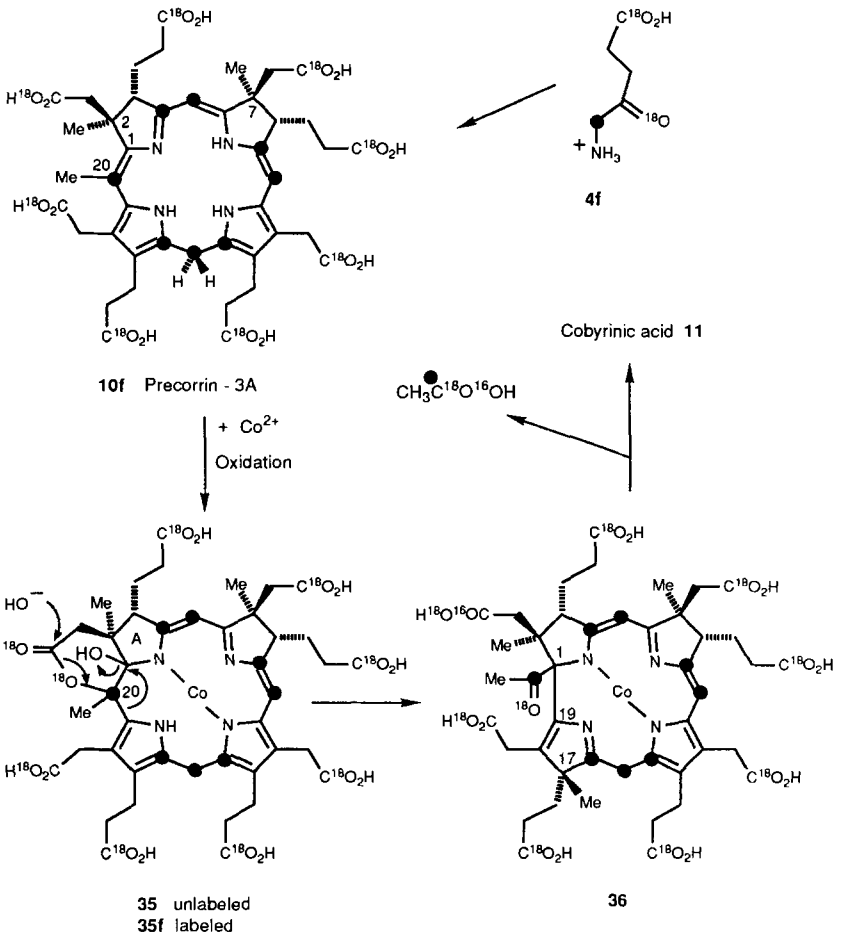
The pathway from ALA **4** to hydrogenobyrinic acid (**12**) is now complete and will shortly be summarized with a mechanistic discussion. First, however, what has been discovered about *Ps. denitrificans* should be correlated with knowledge of the B_{12} pathway in *Pr. shermanii*.



Scheme 15. Structure of precorrin-5 (**34**).

7. A Comparison of the B_{12} Pathways in *Ps. denitrificans* and *Pr. shermanii*

Ps. denitrificans is an aerobe and *Pr. shermanii* is grown microaerophilically, in other words almost anaerobically, for B_{12} production. Yet B_{12} pathways in these two organisms overlap to a large extent. The starting material, ALA **4**, and the product, coenzyme B_{12} (**2**), are the same for both, and all the steps as far as precorrin-3A (**10**) (or possibly precorrin-2 (**9**)) are held in



common. One clear difference is the timing of cobalt incorporation. For *Ps. denitrificans* the intermediates along the entire biosynthetic pathway to hydrogenobyrinic acid (**12**) are cobalt-free. Cobalt incorporation only occurs after the *a,c*-diamide **43** of hydrogenobyrinic acid has been formed; more details of this process will be discussed later. *Pr. shermanii* behaves differently and here, as described in Section 2, cobalt is probably inserted into precorrin-3A (**10**) or possibly into precorrin-2 (**9**). These studies showed that cobalt is inserted rapidly; in the incubation with $^{60}Co^{2+}$ and the complete enzyme system from the cells the incorporation is largely complete within ten minutes.[7] A key question then is, whether the rest of the pathway beyond precorrin-3A (**10**) in *Pr. shermanii* mirrors that in *Ps. denitrificans*; specifically, is the cobalt complex of precorrin-4 (**31**) converted into the cobalt derivatives of all the other precorrins described already, with the final direct rearrangement of cobalto-precorrin-8x into cobyrinic acid (**11**)? Experiments that gave the first indications that this route is indeed followed depended on incubating a set of ^{3}H,^{14}C doubly labeled metal-free precorrins with the enzyme system from *Pr. shermanii*. Small incorporations into cobyrinic acid (**11**), which had the expected ^{3}H:^{14}C ratio, were observed[62a] from precorrin-6A (**16**), precorrin-6B (**19**), and precorrin-8x (**23**). Taking into consideration that hydrogenobyrinic acid (**12**) is not incorporated into cobyrinic acid (**11**),[62b] this study indicated that cobalt complexes of **16**, **19**, and **23** formed spontaneously in the incubation mixtures are the likely intermediates of cobyrinic acid biosynthesis. In addition some hydrogenobyrinic acid (**12**) was synthesized from precorrin-8x (**23**), indicating the existence of enzymic activity in extracts of *Pr. shermanii* that can catalyze the [1,5]-methyl migration irrespective of the presence of the central cobalt ion. As for CobH,[42] this enzyme is likely to be the target of the inhibition by hydrogenobyrinic acid[62b] or by its own product cobyrinic acid.[41] So this is a start, and the way forward with *Pr. shermanii* undoubtedly is to carry out its genetic analysis so that the enzymes operating beyond precorrin-3A (**10**) will become available. This work should be enormously helped by the availability of the palette of enzymes from *Ps. denitrificans*.

Another interesting facet of B_{12} biosynthesis was brought to light by experiments on the side-chain carboxyl groups. When [1-^{13}C,1,4-$^{18}O_3$]ALA **4e** was incorporated into B_{12} **1** in *Pr. shermanii*, NMR studies proved that the C-2 acetamide group had undergone substantial loss of ^{18}O presumably by exchange with the medium,[63] and later this exchange was reported to be almost complete.[64] The presence of ^{18}O directly attached to ^{13}C can be detected by a characteristic upfield shift of the ^{13}C NMR signal relative to its normal position. To help locate where on the pathway this exchange occurs, [1-^{13}C,1,4-$^{18}O_3$]ALA **4e** was incorporated into the earlier intermediate, cobyrinic acid **11e** by using the same organism (Scheme 16). This intermediate has the advantage that both oxygen atoms of the carboxyl group can be examined. ^{13}C NMR spectra were recorded for the corresponding heptamethyl

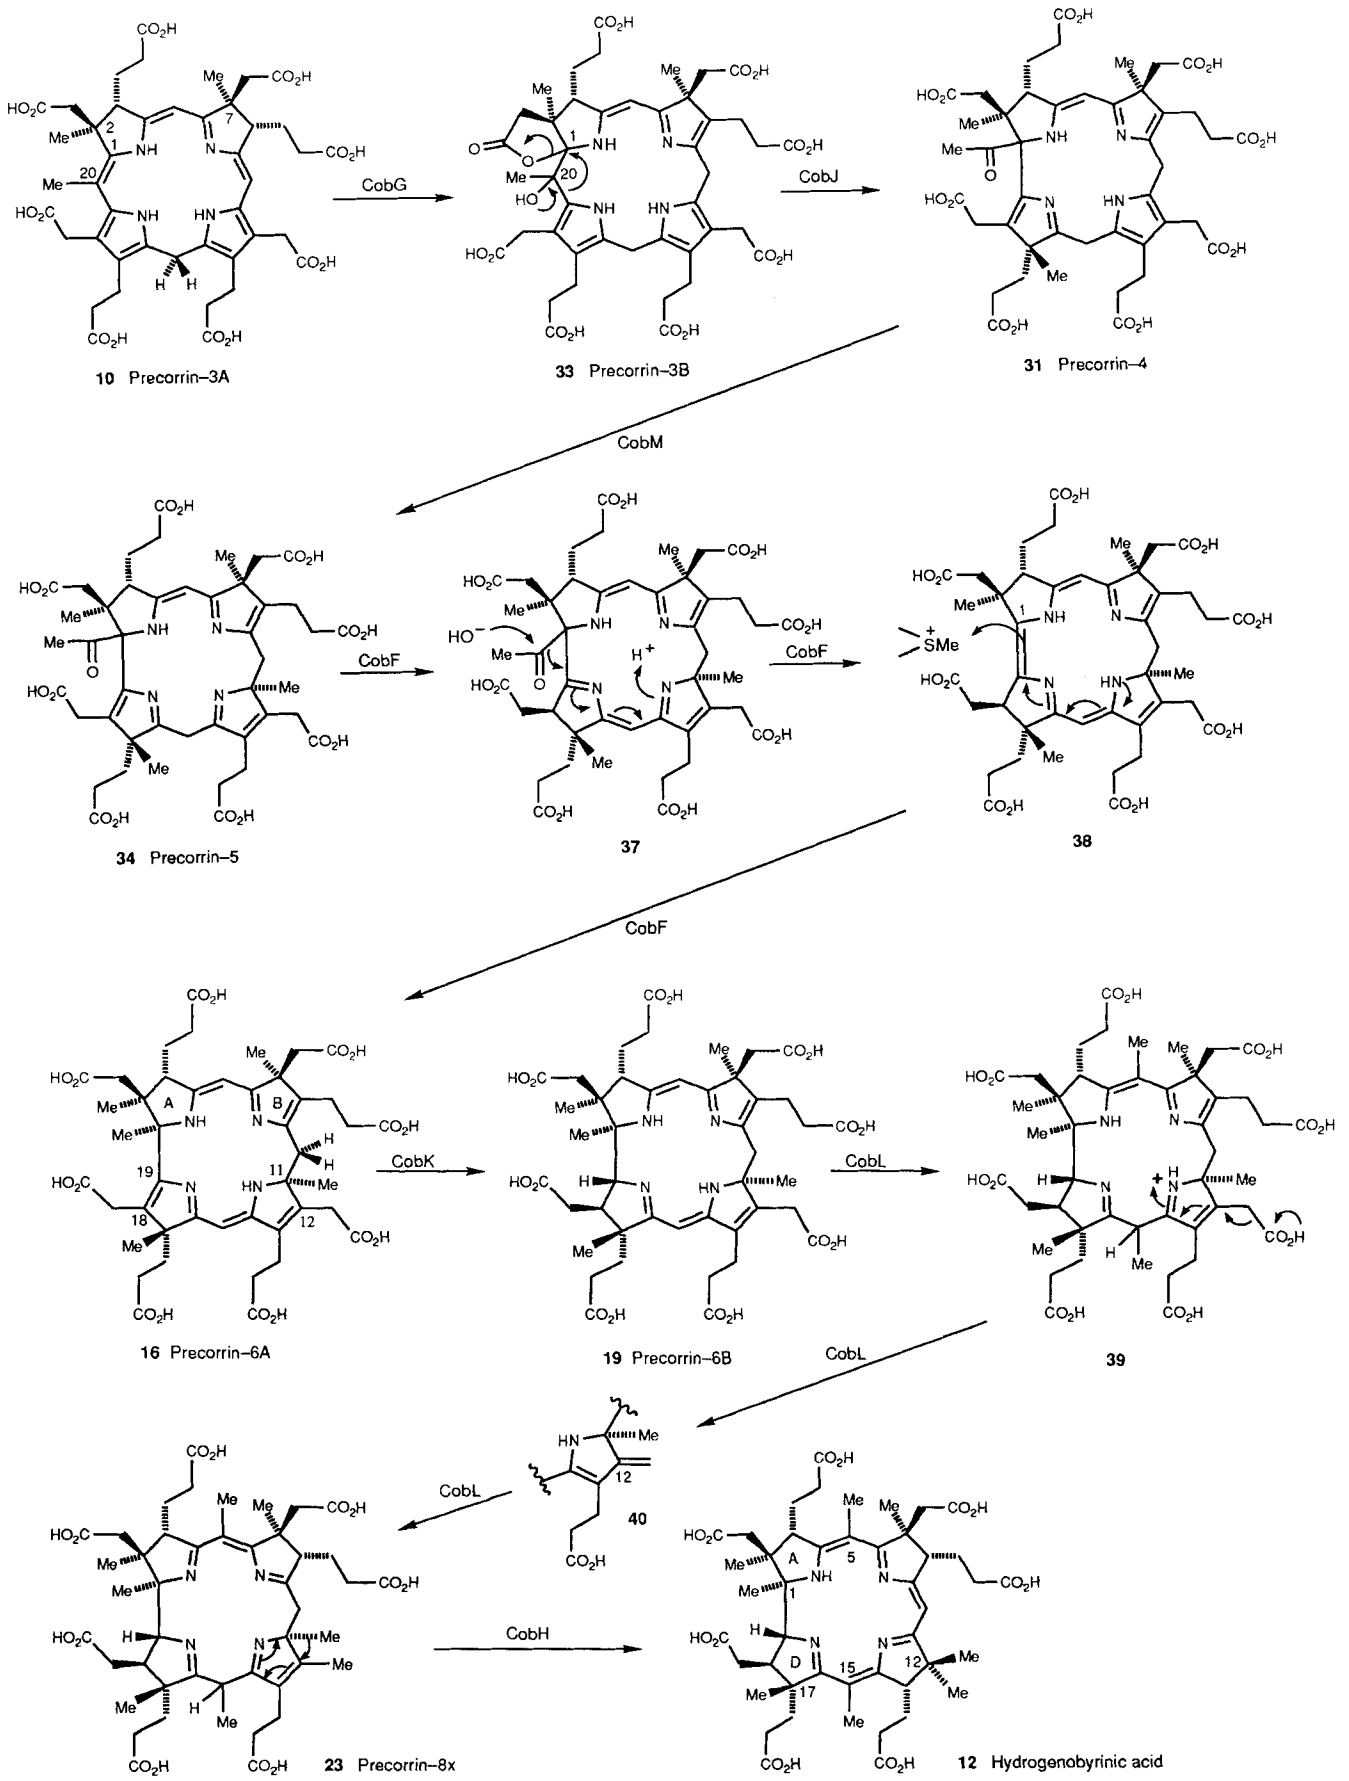
Scheme 16. Study of oxygen exchange from side-chain carboxyl groups during the biosynthesis of cobyrinic acid **11e**.

ester, cobester **14e**. They showed that six of the seven carboxyl groups of cobyrinic acid **11e** had retained both oxygen atoms but that the C-2 acetate had lost one oxygen atom.[65] Whether a similar specific loss of one oxygen atom occurs in the biosynthesis of hydrogenobyrinic acid (**12**) by *Ps. denitrificans* is not yet known; the necessary experiments have not been carried out,

Scheme 17. Transfer of oxygen from a side-chain carboxyl group to the extruded acetic acid during biosynthesis in *Pr. shermanii*.

but they surely will be soon. A first clue as to how this specific loss of oxygen occurs came from examination of the acetic acid produced during the biosynthesis of cobyrinic acid (as **11**) in *Pr. shermanii* from [5-^{13}C,1,4-$^{18}O_3$]ALA **4f** (Scheme 17). This precursor places a ^{13}C atom at C-20 of precorrin-3A **10f**, and it is that carbon that appears finally as the carbonyl C atom of the carboxyl group of the acetic acid. A high-field ^{13}C NMR spectrum of a suitable ester of this acetic acid showed a ^{13}C signal shifted upfield by directly bonded ^{18}O. This result and those from control experiments checking possible exchange of oxygen from CO_2H with the medium indicated that transfer of one ^{18}O atom from a carboxyl side chain to the acetic acid had occurred to a high degree.[66] Presumably the transfer is from the C-2 acetate carboxyl group, since, as reported above, this group specifically loses one of its original oxygen atoms at some biosynthetic stage before formation of cobyrinic acid (**11**). This suggests that in *Pr. shermanii* a somewhat different lactonic intermediate **35** may be involved with δ-lactone formation onto C-20.[66] One can speculate that this occurs because the organism is growing without or at very low levels of oxygen. Also, the presence of cobalt will substantially affect the chemistry of the macrocycle. The δ-lactone **35** is just one possible candidate for the ring-contraction process. Others, for example one having an imine in ring-A, are essentially equivalent in a broad sense. However, structure **35** fits a plausible mechanism whereby ^{18}O could be transferred from the 2-acetate group to the extruded acetic acid.

8. Summary, Discussion, and Mechanisms of the Steps Leading up to Hydrogenobyrinic Acid (12)



The time has come to assemble the entire biosynthetic pathway from uro'gen III **7** through to hydrogenobyrinic acid (**12**); the first section is given in Scheme 1 and the remainder in Scheme 18. It is certainly true that there have been more surprises and remarkable twists and turns along this sequence of steps than anyone had dreamed of. That has been the fascination of it. Equally appealing is the way the chemistry for each transformation prepares the way for the next one. Or is it more accurate to say as Eschenmoser has suggested[44] that as this amazing biosynthesis evolved, the intrinsic reactivity of each intermediate predetermined the nature of the next step?

Scheme 1 shows how the pathway from uro'gen III **7**, the parent of all the "pigments of life," branches off to vitamin B_{12} as a result of C-2 methylation. This step uses the available β-reactivity of pyrroles towards electrophiles (there is α-reactivity as well). An equivalent second methylation at C-7 by the same enzyme, CobA, then gives precorrin-2 (**9**). The third methyl group is inserted by the CobI enzyme at C-20 to form precorrin-3A (**10**). This was a surprising result at the time but can now be seen mechanistically as a β-methylation of an enamine. The story is continued in Scheme 18, which shows precorrin-3A (**10**) undergoing oxidation, catalyzed by CobG, to form the lactonic precorrin-3B (**33**). Looking at structure **33**, it should be recalled that the possible involvement of such lactones in B_{12} biosynthesis was first suggested and discussed by Eschenmoser.[44] CobG could be a monooxygenase or a dioxygenase, and it presumably needs a reducing cofactor; both aspects require further study. The C-1/C-20 double bond attacked is probably the most electron-rich in the molecule.

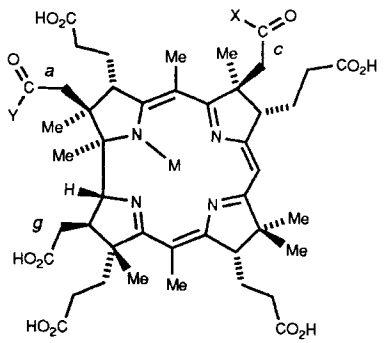
Precorrin-3B (**33**) is now perfectly set for a pinacol-type rearrangement[44] causing ring contraction. This is catalyzed by CobJ, which also carries out methylation at C-17. The contraction step is illustrated in Scheme 18 as occurring before C-17 methylation; this allows the electron-rich pyrrole ring to be the migrating group. Probably the methyl group at C-20 serves to block competing reactions; an example of such competition leading to a dead end in the absence of a methyl group has been provided by studies on related model systems.[44] The contraction step generates precorrin-4 (**31**) and places the acetyl residue at C-1; the ^{13}C NMR evidence provided by using ^{18}O labeling, as for earlier cases, indicated that the carbonyl oxygen of precorrin-4 is derived from molecular oxygen.[67] So this holds also for the C-20 hydroxyl group of precorrin-3B (**33**).

The chemistry carried out for the next two stages through to precorrin-6A (**16**) can only be described as exquisite. Mechanistic explanations were provided at a symposium in March 1993,[68] whereby one step establishes with perfection the reactivity required for the next one. Clearly the acetyl group at C-1 of precorrin-4 (**31**) must be removed to allow later methylation at that site. Arigoni pointed out[68] that the living system can achieve this objective by first methylating C-11, which is one of the α-positions of the only remaining pyrrole nucleus, to afford precorrin-5 (**34**). The C-11 methylation is carried out by the CobM enzyme which, as for CobI, is a straightforward methyltransferase carrying out one C-methylation. The other methyltransferases involved in the B_{12} pathway (CobA, J, F, and L) all achieve something more than just one methylation. Now only simple double-bond tautomerism within precorrin-5 (**34**) is necessary to reach structure **37**, which is the key to eliminating the acetyl group. As illustrated on that structure, the conjugated system across rings C and D allows ready hydrolytic removal of the acetyl group by a reverse Claisen condensation so releasing acetic acid. There is strong evidence to support the elimination of acetic acid in *Ps. denitrificans*[55] just as had earlier been rigorously proven for *Pr. shermanii*. Acetate elimination in this way, which is almost certainly enzyme-catalyzed in vivo, would generate the conjugated structure **38**. It was also highlighted by Battersby[68] that from ring C through to ring D and on to C-1, there is now an extended enamine to allow the C-1 methylation. The immediate product of "electron pushing" on structure **38** would be a tautomer of precorrin-6A (**16**). To reach the latter molecule, simple double-bond shifts are needed plausibly driven by the gain in stabilization by the extended amidine system[44] across rings C and D of precorrin-6A (**16**). Now we have reached the intermediate that started the exciting surge to the summit of Everest.

This is the point at which the oxidation level is adjusted to match that of hydrogenobyrinic acid (**12**). The necessary reduction is carried out by the NADPH-dependent enzyme CobK acting on the C-18 protonated form **16e** of precorrin-6A (**16**) (Scheme 6). Protonation allows delivery of the hydride to C-19; the electron acceptor is the imine of ring C in the protonated system **16e**. Now comes the transformation catalyzed by CobL,

Scheme 18. Biosynthetic pathway from precorrin-3A (**10**) to hydrogenobyrinic acid (**12**) in *Ps. denitrificans*.

the remarkable enzyme showing two very different activities, methyl transfer and decarboxylation. Good reasons were given in Section 4.3 why at least one methylation at C-5 or C-15 probably occurs before the decarboxylation. Note that as for every other C-methylation on this pathway the required reactivity is provided by an enamine. Scheme 18 shows both methyl groups in position before the 12-acetate is modified. It is plausible that the methylation at C-15 initiates the decarboxylation by completing the task, started by the crucial C-11 methylation step, of setting up a protonated pyrrolenine in ring C. Since it is well known that such systems undergo decarboxylation, one finally has a rational explanation of why specifically the 12-acetate group is decarboxylated. The fact that C-15 remains sp^3-hybridized in precorrin-8x (**23**) fits in with these ideas, and this outcome contrasts with the related events at C-5, where the methylation is followed by loss of a proton to regenerate the sp^2 state.



The keen observer will have noticed that the double bond in ring B of precorrin-8x (**23**) is located between N and C-9, whereas in many of the earlier intermediates, for example precorrin-6A (**10**), it appears between C-8 and C-9. The latter arrangement is proved for the isolated ester of precorrin-6A, but the double bond may or may not be in that position in the original enzymic product.[28] The possibility of double-bond migration during enzymic transformations was tested by preparing [^{3}H,^{14}C]precorrin-2 (as **9**) heavily labeled with ^{3}H at C-3 and C-8 (but not exclusively at these positions). The enzyme system from *Pr. shermanii* converted this precursor into cobyrinic acid (as **11**), which was shown by degradation of its ester, cobester (as **14**), to have lost the tritium from 8-H but retained the 3-H label.[69] So even under the enzymic conditions, a mechanism exists, such as the tautomerism discussed above, which exchanges specifically 8-H with the medium.

The decarboxylation step shown on structure **39** with the subsequent tautomerism of the product **40** regenerates the 5,5-disubstituted pyrrolenine system in ring C of precorrin-8x (**23**). This can now undergo a [1,5]sigmatropic suprafacial rearrangement, well-documented for such molecules,[70] which moves the C-11 methyl group to C-12. The blockage to conjugation is thus removed, and the characteristic conjugated chromophore of hydrogenobyrinic acid (**12**) can be established with consequent thermodynamic gain. Reaching hydrogenobyrinic acid (**12**) marked the end of an era; the mystery of how the corrin macrocycle of vitamin B_{12} (**1**) is biosynthesized had been solved. Further steps then lead to the is the construction of coenzyme B_{12} by a route described in the next section. It should be stressed that the research on the pathway beyond hydrogenobyrinic acid (**12**) was highly important in two ways: firstly, in its own right, to establish all the later steps up to coenzyme B_{12} in *Ps. denitrificans*, and secondly, to help solve the problem of how the corrin macrocycle is biosynthesized. Since at the outset 22 genes were known to be involved in the biosynthesis of coenzyme B_{12} (**2**), working out the function of those acting beyond hydrogenobyrinic acid (**12**) allowed crucial deductions about the earlier genes. This strategy was used to show that the products from the genes on the 8.7 kb fragment act in the pathway up to hydrogenobyrinic acid (**12**).

9. Building Coenzyme B_{12} from Hydrogenobyrinic Acid (12)

9.1. Cobalt-Free Corrinoids and the Insertion of Cobalt

The preceding sections have described the enzymes from *Ps. denitrificans* and the associated chemistry for the production of hydrogenobyrinic acid (**12**) in vitro. It has been shown that this organism also accumulates hydrogenobyrinic acid and its *a,c*-diamide **43** in vivo (even in the presence of cobalt ions) but not cobyrinic acid (**11**). This is in contrast to *Pr. shermanii*, which accumulates cobyrinic acid but not hydrogenobyrinic acid. This was the first suggestion that differences may exist in the timing of cobalt insertion in the two organisms; the early insertion process in *Pr. shermanii* was described in Section 2.

11 X = Y = OH, M = Co^{2+}
12 X = Y = OH, M = H
41 X = NH_2, Y = OH, M = H
42 X = NH_2, Y = OH, M = Co^{2+}
43 X = Y = NH_2, M = H
44 X = Y = NH_2, M = Co^{2+}

Several early observations pointed to hydrogenobyrinic acid *a,c*-diamide (**43**) as the substrate for chelation of cobalt in *Ps. denitrificans*. Firstly, in growing cultures of B_{12}-producing strains,[23, 71] as well as in Cob mutants (Table 1), the simplest cobalt-containing corrinoid detected was always cobyrinic acid *a,c*-diamide (**44**) and the most elaborate metal-free corrinoid was hydrogenobyrinic acid *a,c*-diamide (**43**). Secondly, metal-free corrinoids were shown to exhibit much higher affinities for the *a,c*-diamide synthase (CobB) than their cobalt-containing counterparts. Thirdly, CobB mutants accumulate not cobyrinic acid (**11**) but hydrogenobyrinic acid (**12**).[71] From this set of observations, it seemed highly probable that the pathway from hydrogenobyrinic acid (**12**) proceeds by amidation at positions *a* and *c*,[72] followed by cobalt chelation.

Table 1. Cob mutants blocked after completion of the macrocycle.

Mutant strain [a]	Pigment accumulated [d]	Complemented by
G 635, G 2636 [b], G 2638 [b]	hydrogenobyrinic acid **12**	*cobB*
G 622, G 623, G 630	hydrogenobyrinic acid **12** and diamide **43**	*cobN*
G 2035	hydrogenobyrinic acid **12** and -diamide **43**	*cobS*
G 2034, G 2037	none	*cobT*
G 631, G 632, G 633	cobyrinic acid diamide **44**	*cobO*
G 624, G 626	cobyrinic acid diamide **44**	*cobQ*
G 634	cobyric acid **48**	*cobD*
G 643, G 572 [c]	cobyric acid **48**	*cobC*
G 642, G 2043	cobinamide **49**	*cobP*
G 2038, G 2039, G 2040	GDP-cobinamide **51**	*cobV*

[a] Mutant of *A. tumefaciens* C58-C9 Rif^r unless otherwise mentioned [9]. [b] Mutant of *Ps. denitrificans* SC510 [13]. [c] Mutant of *Ps. putida* KT2440 Amp^r Rif^r [9]. [d] Pigments accumulated by mutants of *cobQ* onwards would initially be adenosylated, as shown in structures **47** - **49** and **51**, but were identified after loss of the adenosyl group.

9.2. Hydrogenobyrinic Acid *a,c*-Diamide Synthase

In order to develop an assay for the amidation activity, an HPLC method developed for the detection of cobalt corrinoids[23] was extended to metal-free corrinoids by using fluorescence detection.[71] This method provided proof that crude cell extracts from *Ps. denitrificans* transform hydrogenobyrinic acid (**12**) and cobyrinic acid (**11**) into their respective *c*-monoamide (**41** and **42**) and *a,c*-diamide derivatives (**43** and **44**) in presence of ATP/Mg^{2+} and glutamine.[71] The enzyme catalyzing the two amidation reactions was purified to homogeneity from a recombinant strain exhibiting 20 times the normal activity. This strain harbored a multicopy plasmid carrying five *cob* genes from complementation group C (*cobA* to *E*).[9, 13] N-Terminal amino acid sequencing and estimation of the molecular weight (45000) of the denatured enzyme by gel electrophoresis established that *cobB* is the gene coding for this enzyme.[71, 13] Under nondenaturing conditions an apparent molecular weight of 86000 was observed, indicating formation of a dimer.

Studies of the substrate specifities of this enzyme from *Ps. denitrificans* showed that the *c* side chain is amidated first followed by that at *a*. This sequence is the same as that deduced for *Pr. shermanii* and *Clostridium tetanomorphum* on the basis of isolation and incorporation of partially amidated intermediates using intact cells.[73] However, in these two organisms the substrates are the cobalt corrinoids, whereas for *Ps. denitrificans* the natural substrates are the metal-free corrinoids, which are much better substrates ($K_M < 1\,\mu M$) than the corresponding cobalt complexes ($K_M > 100\,\mu M$). Neither the acetate carboxyl group *g* nor any of the propionate carboxyl groups were amidated by the CobB enzyme. Comparison of the amino acid sequence of CobB with those of other amidotransferases suggested that the "glutamine amide transfer" domain[74] is located at the carboxy terminus of CobB, and allowed the prediction that the cysteine at position 326 is the active site residue involved in "covalent catalysis" of amide transfer.

9.3. Cobalt Insertion into Hydrogenobyrinic Acid *a,c*-Diamide (43)

Assaying for corrinoids by HPLC was again decisive in the detection of cobaltochelatase activity in *Ps. denitrificans*. In the presence of cobalt (Co^{2+}) and ATP/Mg^{2+}, hydrogenobyrinic acid *a,c*-diamide (**43**) was efficiently converted into its cobalt complex **45** (Scheme 19), whereas hydrogenobyrinic acid (**12**) was a much poorer substrate for cobalt insertion. Amplified chelatase activity was detected in strains harboring plasmids containing a 3.8 kb gene named *cobN*.[75]

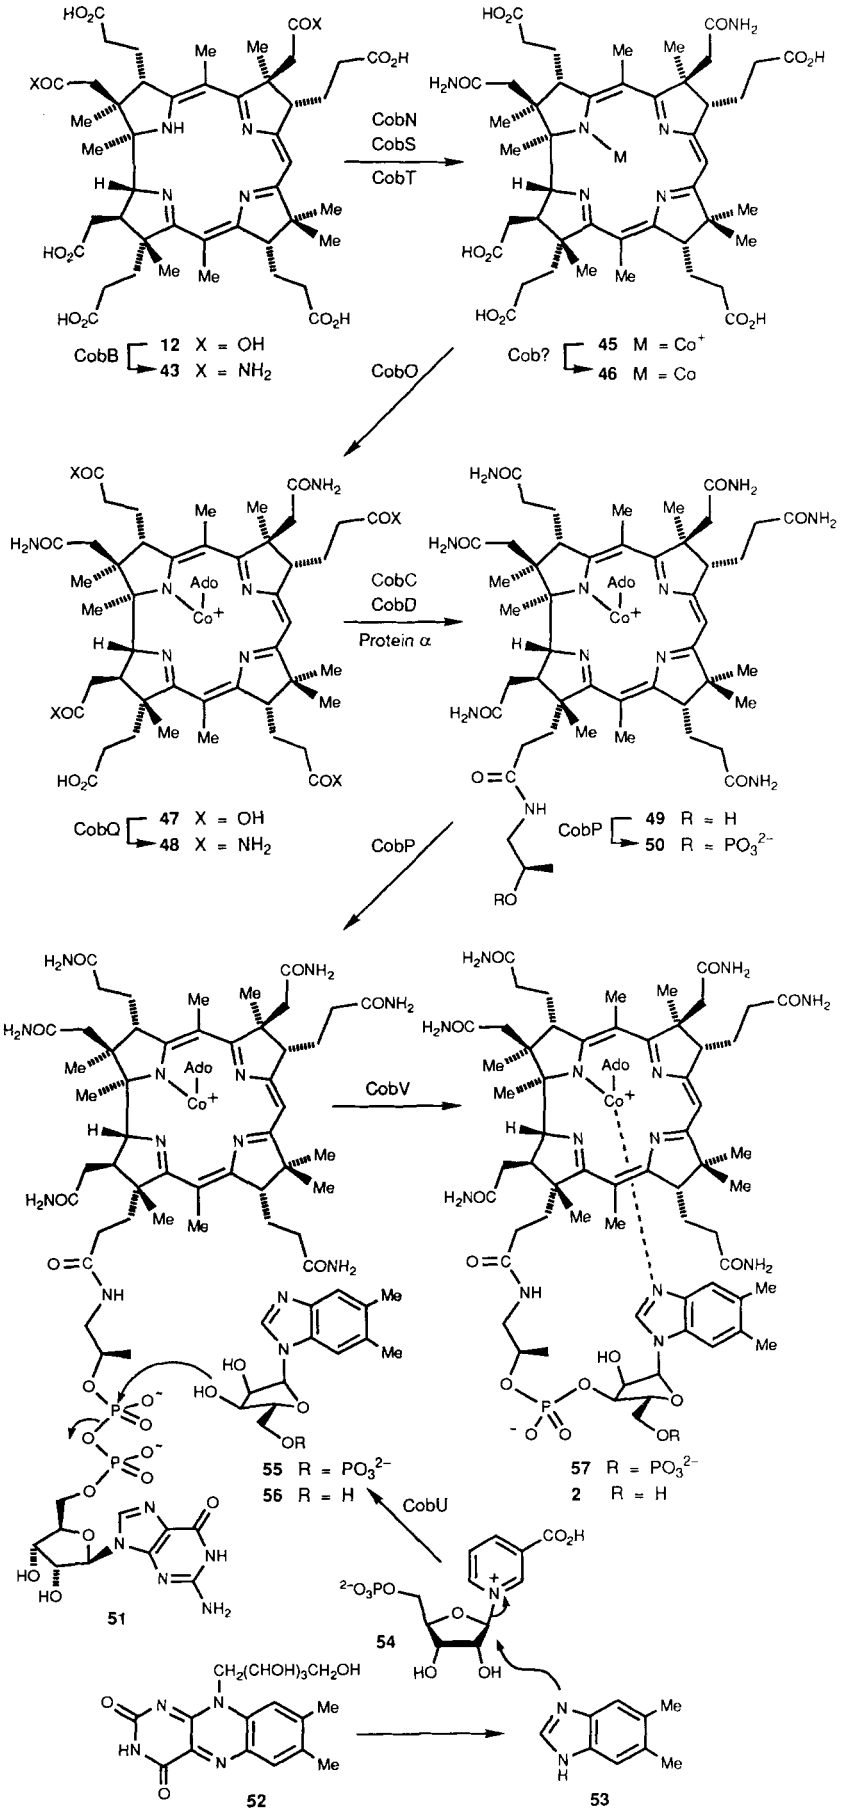
During purification of cobaltochelatase, it emerged that in addition to the *cobN* gene product another protein component was also required. The two components were purified to homogeneity separately. CobN was shown to be a monomeric enzyme with a molecular weight of 140000, whereas its partner was an oligomer with a molecular weight of about 450000, consisting of two subunits with molecular weights of 38000 and 80000. After N-terminal amino acid sequencing, these subunits were shown to be encoded by *cobS* and *cobT*, respectively, the two *cob* genes from complementation group B.[16, 75] The oligomer component of cobaltochelatase was thus called CobST.

Although accumulation of metal-free corrinoids by strains mutated in the *cobN* and *cobS* genes had clearly indicated that these two genes were involved in cobalt insertion (Table 1), *cobT* had earlier been thought to have a different role. In addition, no homology between any of the three genes and the gene coding for ferrochelatase (the enzyme that inserts Fe^{2+} into protoporphyrin to make heme) could be found. Surprisingly, CobST activity was not significantly enhanced in extracts from strains in which *cobS* and *cobT* were amplified.[16, 75]

So far, the individual roles played by CobN and CobST in catalysis have not been elucidated. Binding studies indicated that CobN displays affinity for hydrogenobyrinic acid *a,c*-diamide and, to a lesser extent, for the cobalt ion, whilst CobST possesses one reactive SH group and an ATP-binding site.[75] This latter feature agrees well with the presence on the sequence of CobS of a phosphate-binding motif common to a number of ATP-binding proteins.[16, 76] Both ferrochelatase[77] and magnesium chelatase,[78] involved in heme and chlorophyll synthesis, respectively, are also reported to have a reactive SH group.

The strict dependence of cobaltochelatase activity on hydrolyzable ATP is interesting and magnesium chelatase is also apparently a complex ATP-dependent enzyme made up of two separable components.[78] Interestingly, CobN shows 28% and 22% identity (Table 2) with Oli and BchH, respectively, two proteins that could be involved in Mg^{2+} chelation during (bacterio)chlorophyll biosynthesis.[114, 115] In contrast to ferrochelatase, cobaltochelatase cannot use metals other than cobalt. Comparison of the affinities of the enzyme for hydrogenobyrinic acid (**12**) and its *a,c*-diamide **43** provided clear additional proof that the latter is the physiological substrate for the chelation step.[75] Finally, spectrophotometric monitoring of the reaction carried out under anaerobic conditions allowed identification of the Co^{II} complex, cob(II)yrinic acid *a,c*-diamide (**45**), rather than the Co^{III} complex **44**, as the reaction product, thus establishing that no overall redox change occurs during the cobalt insertion step.[75]

9.4. Reduction of Cob(II)yrinic acid *a,c*-diamide (45) to Co^{I} Complex 46 and Adenosylation



The pioneering work from Bernhauer's group[79] indicated early attachment of the adenosyl group as the upper ligand of cobalt during B_{12} biosynthesis in *Pr. shermanii*. Five partially amidated cobalt corrinoids (di- to hexaamides) can be isolated from cultures of *Ps. denitrificans*, and all are present in their adenosyl forms **47** to **48** (Scheme 19).[80] Thus it appears that the two organisms work in the same way.

It was known[81] that adenosylation of cobalamin in bacteria and eukaryotic cells involves the very nucleophilic Co^{I} corrinoid. Therefore, the next step after insertion of cobalt in *Ps. denitrificans* was expected to be reduction of cob(II)yrinic acid *a,c*-diamide (**45**) to the corresponding Co^{I} derivative **46** by a reductase enzyme. This activity was sought by using two complementary assays[82] differing in the way the extremely labile Co^{I} corrinoid **46** was trapped. In the first assay, the Co^{I} corrinoid was alkylated in situ by radioactive iodoacetic acid, and in

the second assay, the trapping was carried out enzymically by cob(I)alamin adenosyltransferase.[83] These assays allowed cob(II)yrinic acid *a,c*-diamide reductase to be purified 6300-fold to homogeneity. This enzyme is a dimer with a subunit molecular weight of roughly 16000 and was shown to be an NADH-dependent flavoprotein. Analysis of its N-terminal sequence revealed that the corresponding gene was not located on any of the four DNA fragments reported to encode cobalamin biosynthetic enzymes in *Ps. denitrificans*.

The purified enzyme catalyzes the reduction of Co^{II} to Co^{I} in all Co^{II} corrinoids from cob(II)yrinic acid *a,c*-diamide (**45**) to cob(II)alamin (as **1**). Its flavin cofactor is easily dissociable, and the enzyme is totally inactive without an added flavin; flavin mononucleotide (FMN) gives twice the activity that flavin adenine dinucleotide (FAD) does and is probably the preferred natural cofactor.[82] The cob(II)alamin reductase (EC 1.6.99.9), previously partially purified from *C. tetanomorphum*,[84] displayed a similar behavior, suggesting that it is identical in function to the cob(II)yrinic acid *a,c*-diamide reductase in *Ps. denitrificans*.

The adenosylating enzyme from *Ps. denitrificans* was also purified and characterized.[83] The procedures previously used for assaying cob(I)alamin adenosyltransferase activity (EC 2.5.1.17) from *Pr. shermanii* and *C. tetanomorphum*[81] were adapted to monitor adenosylation of any corrinoid by HPLC. A cell extract from a *Ps. denitrificans* strain in which the *cobO* gene was amplified was used as starting material for the purification because it had an elevated adenosylating activity. The purified enzyme, CobO, is a 27 kDa polypeptide encoded by *cobO*. It exists as a dimer and displays a substrate specificity similar to that of cob(II)yrinic acid *a,c*-diamide reductase, in other words, most Co^{I} corrinoids are adenosylated but not cob(I)yrinic acid. Apparently it only has an affinity for corrinoids with amidated *a* and/or *c* acetate side chains. In keeping with this, hydrogenobyrinic acid *a,c*-diamide strongly inhibited the enzyme and was found tightly bound to CobO in vivo.[85] The accumulation of cobyrinic acid *a,c*-diamide (**44**) by CobO mutants[83] (Table 1) supported the view that the main physiological function of CobO is adenosylation of cob(I)yrinic acid *a,c*-diamide (**46**) to give adenosylcobyrinic acid *a,c*-diamide (**47**).

Scheme 19. Biosynthetic pathway from hydrogenobyrinic acid (**12**) to coenzyme B_{12} (**2**).

9.5. From Adenosylcobyrinic Acid *a,c*-Diamide (47) to Adenosylcobinamide (49)

Early studies with *Pr. shermanii* led to ambiguous conclusions with regard to the sequence of amidations of peripheral carboxyl groups *b*, *d*, *e*, and *g*, and of attachment of (*R*)-1-amino-2-propanol.[73] Some authors concluded that the amidations follow a preferred but not strictly obligatory route and that the (*R*)-1-amino-2-propanol group is introduced at a stage that depends on cultivation conditions, whereas others suggested that (*R*)-1-amino-2-propanol is incorporated only after completion of the six other amidations and that the amidations follow one unique sequence. There is evidence that (*R*)-1-amino-2-propanol is derived from L-threonine,[73] but no threonine decarboxylase has been detected in vitamin B_{12} producing organisms.

In *Ps. denitrificans* the incompletely amidated cobalt corrinoids accumulated by growing cells have been purified and identified as adenosylcobyrinic acid *a,c*-diamide (**47**), triamide, tetraamide, and pentaamide as well as adenosylcobyric acid (**48**). The HPLC analyses were carried out after removal of the adenosyl group. Adenosylcobinamide (**49**) was also found in substantial amounts, whereas cobinic acids (which have the aminopropanol group attached but lack some or all of the primary amide groups) could not be detected, suggesting that the amidations precede insertion of (*R*)-1-amino-2-propanol.[80]

Meanwhile, it was found that extracts from strains of *Ps. denitrificans* with a plasmid containing the *cobQ* gene were capable of amidating adenosylcobyrinic acid *a,c*-diamide (**47**). As for the previous amidating enzyme, CobB, this activity required glutamine as the amino donor and ATP/Mg^{2+}. The enzyme responsible for the activity was purified to homogeneity and was indeed identified by its N-terminal sequence as the product of the *cobQ* gene.[80] This enzyme also is a homodimer, with a subunit molecular weight of around 57000. It was shown to catalyze all four amidations from adenosylcobyrinic acid *a,c*-diamide (**47**) to adenosylcobyric acid (**48**) via adenosylated cobyrinic acid triamide, tetraamide, and pentaamide intermediates. Corrinoids lacking the adenosyl group are not substrates.[80] HPLC separation of the intermediates (after replacement of the adenosyl group by cyanide) gave only one peak for each intermediate, suggesting that there is a single sequence of amidations performed by this enzyme.[80] It is perhaps not too surprising that a single enzyme is capable of amidating the three propionate carboxyl groups *b*, *d*, and *e*, but it is certainly interesting that it avoids amidating the fourth propionate group, *f*, whereas it does amidate the remaining acetate carboxyl group, *g*. Comparison of the CobB and CobQ sequences indicates 22% amino acid identity in the two enzymes. This finding leads to the prediction that the conserved cysteine at position 333 in CobQ is the active site residue involved in covalent catalysis.[74]

The enzymic system catalyzing the attachment of aminopropanol to adenosylcobyric acid (**48**) in *Ps. denitrificans* was found by ion-exchange HPLC to comprise two components designated α and β, both necessary for regaining overall activity.[85] The reaction was dependent on ATP/Mg^{2+} and (*R*)-1-amino-2-propanol (K_M 20 mM), and no activity was observed with (*S*)-1-amino-2-propanol or threonine. The enzyme was specific for adenosylcobyric acid (**48**) (K_M 1.6 μM), only weakly active on adenosylcobyrinic acid pentaamide (20% of the control), and inactive on the tetra-, tri-, and diamides. Protein α was purified 50000-fold to homogeneity; it is a 38 kDa polypeptide, the N-terminal sequence of which was not found on any of the four DNA fragments from *Ps. denitrificans* that encode B_{12} biosynthetic enzymes. Protein β was purified 1000-fold and was shown to be part of a large multiprotein complex of molecular mass >1 MDa which was not retained by any gel permeation FPLC column.

Cob mutants of *A. tumefaciens* and *Ps. putida* blocked in either *cobC* or *cobD* had been shown to accumulate adenosylcobyric acid (**48**) (Table 1), indicating that the products of the *cobC* and *cobD* genes are parts of the aminopropanol-attaching enzyme system.[13] To confirm this conclusion, two *E. coli* strains expressing either *cobC* alone or *cobC* and *D* together were constructed.[86] Extracts from the *cobCD* strain exhibited aminopropanol-attaching activity only when supplemented with protein α, indicating that protein β is probably made up of CobC and CobD. Extracts from the strain expressing CobC showed no activity when assayed under the same conditions.[85] In keeping with these results, cell extracts from a *Ps. denitrificans* strain overexpressing the *cobABCD* genes exhibited a tenfold higher level of protein β than the parent strain. Genetic studies have indicated that in *Salmonella typhimurium*[45] also, three genes are involved in the addition of the aminopropanol side chain.

10. From Adenosylcobinamide (49) to Coenzyme B_{12} (2): Building of the Nucleotide Loop

The assembly of the nucleotide loop is the final stage of the pathway to coenzyme B_{12}, and in *Pr. shermanii* this involves a four-step process.[87] It is probable that all the intermediates are adenosylated[79] in this organism also, but much of the early work only identified the compounds after removal of this labile group. However, the adenosylated form of cobyrinic acid *a,c*-diamide (**47**) has recently been isolated and identified from this source.[88] The first step is phosphorylation of the hydroxyl group of the (*R*)-1-amino-2-propanol residue of adenosylcobinamide (**49**) using ATP to yield adenosylcobinamide phosphate (**50**). Transfer of the guanosyl monophosphate (GMP) moiety from a molecule of the triphosphate (GTP) then gives adenosyl-GDP-cobinamide (**51**). Addition of α-ribazole 5′-phosphate (**55**) to the adenosyl-GDP-cobinamide, with loss of the GMP moiety again, yields adenosylcobalamin 5′-phosphate (**57**). Finally, dephosphorylation of this 5′-phosphate leads to adenosylcobalamin (**2**). Noteworthy is the need for a branch to the main pathway for the synthesis of α-ribazole 5′-phosphate (**55**), which is only required for the biosynthesis of coenzyme B_{12}. Methods for the synthesis of the cyano forms of these corrinoid intermediates have been described.[89]

Until our recent work, few studies on the enzymes involved in this part of the pathway had been reported, and the exact number of enzymes and genes necessary to reach coenzyme B_{12} from cobinamide was unknown. Our study began with the isolation and identification of the intermediates in their natural adenosylated forms.[90]

10.1. From Adenosylcobinamide (49) to Adenosyl-GDP-cobinamide (51)

The studies described in Section 9.5 provided adenosylcobinamide (**49**) and an HPLC system for assaying adenosylcorrinoids.[123] These were used in setting up an assay of ATP-dependent phosphorylation of **49**, and the range of strains overexpressing *cob* genes[9] was tested. It was found that genetic amplification of the *cobP* gene substantially increased the level of cobinamide kinase activity normally present in cell extracts.[90] This result was in agreement with the complementation studies, which showed that B_{12} production in strain G 642, a Cob mutant that accumulated adenosylcobinamide (**49**) (Table 1), was restored by introduction of a plasmid containing *cobP*.[9] Concurrently, cobinamide kinase was purified to homogeneity from a strain of *Ps. denitrificans* containing the same plasmid and was found to be a bifunctional enzyme catalyzing phosphorylation and also the next step, transfer of the GMP moiety from GTP to give adenosyl-GDP-cobinamide (**51**).[90] The N-terminal sequence of the purified enzyme identified it as the *cobP* gene product.[15]

This CobP enzyme was therefore a novel and interesting addition to the family of multifunctional Cob enzymes, which includes CobA, CobJ, CobF, CobL, CobB, and CobQ. It is surprisingly small for a bifunctional, homodimeric enzyme, with a subunit molecular weight of only 19442. In many proteins that bind ATP or GTP two consensus sequences make up the nucleotide triphosphate binding sites, but for CobP only one region matching these consensus sequences could be found for each of these substrates.[90] The most striking feature of the catalytic properties of CobP was that GTP is not only the substrate for the second reaction catalyzed by CobP, but it is also a regulator for the first step. It binds with high affinity (K_D 0.22 μM), causing the affinity of the enzyme for its initial substrate, adenosylcobinamide (**49**), to be lowered from 11.5 to 0.4 μM.[90]

In support of the above results, recent genetic studies have demonstrated that a gene[91] from *S. typhimurium*[45, 92] is homologous to *cobP*, and that the corresponding enzyme is responsible for the same two steps catalyzed by CobP; in addition the *S. typhimurium* enzyme seems to have a further function in the assimilation of nonadenosylated cobinamide.[93]

10.2. The α-Ribazole Branch of the Pathway

α-Ribazole (**56**) is an atypical nucleoside in which the unusual base 5,6-dimethylbenzimidazole (DMBI, **53**) is linked by an N-α-glycosidic bond to ribose. Nicotinate-nucleotide:dimethylbenzimidazole phosphoribosyltransferase, also called trans-*N*-glycosidase (EC 2.4.2.21), catalyzes the formation of α-ribazole 5′-phosphate (**55**) from DMBI **53** and β-nicotinate mononucleotide (**54**). This enzyme was partially purified from *Pr. shermanii* by Friedmann.[94] Recently, this enzyme has been purified to homogeneity from a recombinant strain of *Ps. denitrificans* which has the cobU gene amplified and shows an elevated trans-*N*-glycosidase activity.[17] Again the enzyme exists as a homodimer with a subunit molecular weight of 34640. The purified protein was confirmed as the product of the *cobU* gene by its N-terminal sequence. Hydrolysis of α-ribazole 5′-phosphate (**55**) to give α-ribazole (**56**) is carried out in *Pr. shermanii* by a 5′-phosphatase,[95] and this activity is also present in *Ps. denitrificans*.[17]

As DMBI **53** is a component of the standard medium used for growing *Ps. denitrificans* in all our studies,[9] its biosynthesis has not been studied in this organism. However, the conversion of riboflavin (**52**) into DMBI was demonstrated by Renz et al.[96] with crude cell extracts from *Pr. shermanii*, and mechanistic aspects of this transformation are still under investigation.[96b] The requirement for molecular oxygen makes this pathway unlikely in anaerobes, however, and an alternative pathway has recently been proposed for *Eubacterium limosum*.[97] Mutants blocked in the formation of DMBI **53** have been isolated in *S. typhimurium*.[98]

10.3. From Adenosyl-GDP-cobinamide (51) to Coenzyme B_{12} (2)

The last enzyme of the pathway was shown to transfer the adenosylcobinamide phosphate moiety of adenosyl-GDP-cobinamide (**51**) to either α-ribazole (**56**) or its 5′-phosphate **55** to yield adenosylcobalamin (**2**) or its 5′-phosphate **57**. The enzyme also accepted as substrate GDP-cobinamide lacking the adenosyl group[17] and was therefore named cobalamin (5′-phosphate) synthase. It was overexpressed by a factor of 90 in a *Ps. denitrificans* strain carrying a *cobV*-containing plasmid, from which it was purified 55-fold.[17] The most enriched preparations were not homogeneous but apparently consisted of a soluble high molecular weight protein complex made up of six separate proteins. Overexpression of a truncated *cobV* gene (20 codons missing) in *E. coli* also resulted in a significant increase of the cobalamin (5′-phosphate) synthase activity.[17] In addition, two Cob mutants that accumulated GDP-cobinamide (**51**) have their mutations complemented by a plasmid that carries the *cobV* gene[12] (Table 1). All these data provide evidence that *cobV* encodes cobalamin (5′-phosphate) synthase, although direct comparison of the amino acid sequence of the enzyme with that predicted from the gene sequence has not yet been possible.

11. Genetic Analysis of the Four *Ps. denitrificans* Genomic Loci Involved in Cobalamin Synthesis

There is a neat correlation between the genetic organization of the genes (Fig. 1) and the part of the pathway on which their products act. Complementation group C carries *cobA* encoding the first methyltransferase. Then complementation group A codes for all the enzymes involved in the conversion of precorrin-2 (**9**) into hydrogenobyrinic acid (**12**). The products of complementation group C allow the transformation of **12** into adenosyl-GDP-cobinamide (**51**) with CobS and CobT (the only two genes in complementation group B) necessary for cobalt insertion. The formation of α-ribazole phosphate (**55**) and the last step of the pathway require enzymes coded by complementation group D. *Bacillus megaterium* also has four different complementation groups,[99] but in *S. typhimurium* most of the genes are clustered at minute 41.[45] It is worthwhile noting that the genetic and molecular biology studies on these latter two

organisms alone did not lead to any major advances in the knowledge of the biosynthetic steps. Contributions from chemical and enzymological studies are essential, as we hope this review has made clear.

Since the sequences of the 22 Cob proteins in *Ps. denitrificans* were reported,[13-17] the sequences of *cob* genes from other bacteria have been described. The *Ps. denitrificans* Cob proteins have homologues involved in cobalamin synthesis in *S. typhimurium*, *B. megaterium*, *Rhodococcus sp*, *Rhizobium meliloti*, and *E. coli*; the relevant genes and the degree of identity of the proteins are shown in Table 2. In *S. typhimurium* a large number of genes involved in cobalamin synthesis have been cloned and identified.[45] By comparing the sequences of the proteins with those from *Ps. denitrificans*, whose functions are established, likely roles for the *S. typhimurium* proteins have been proposed.[45] However, no homologues have been found in *S. typhimurium* for CobC, E, F, G, N, S, T, and W produced by *Ps. denitrificans*. Conversely, no homologues are known in *Ps. denitrificans* for three genes in *S. typhimurium* (CbiN, CbiQ, and CbiO) which are thought to be involved in cobalt transport.

Escherichia coli has not been shown to synthesize cobalamin, but it does use exogenous cobinamide (**49** without the adenosyl group) to build coenzyme B_{12} (**2**). This organism does have homologues to four proteins of *Ps. denitrificans*, CobA, CobO, CobU, and CobV (see Table 2), and to the corresponding four proteins from *S. typhimurium* with a high degree of identity. The homologue of CobA, which is CysG in *E. coli*, catalyzes the methylation of uro'gen III **7** to give precorrin-2 (**9**), as well as the subsequent oxidation and insertion of iron required for the synthesis of siroheme,[100] whilst the homologues of the other three enzymes are involved in the assimilation of above non-adenosylated cobinamide. The fact should also be noted that the various methyltransferases (CobA, I, F, J, L, and M, and CysG) all share some homology with each other and with motifs found in most, if not all, SAM-dependent methyltransferases.[101]

Identification of the *cob* genes in *Ps. denitrificans* has allowed the effect of gene amplification on the level of synthesis of cobalamin to be studied. Amplification of a fragment carrying the *cobF* to *cobL* genes led to a 30% increase in cobalamin synthesis in a low cobalamin-producing strain, whereas amplification of *cobA* and *cobE* resulted in a twofold increase.[18] These results illustrate how effective genetic engineering can be for the improvement of strains used for the industrial production of compounds such as vitamin B_{12}.

[a] Percentage amino acid identity of the proteins from *S. typhimurium* or other organisms with the homologous protein in *Ps. denitrificans*. The protein sequences from this latter organism were compared with the following data banks: NBRF (release number 38), Swissprot (release number 27), PIR (release number 38), and EMBL (release number 37 plus the new entries until December 1993). The proteins with the highest identities were aligned by using the program developed by Kanehisa (*Nucleic Acids Res.* **1984**, *12*, 203) with the same parameters (minimum length of contiguous homologous amino acids = 2, maximum length for a deletion or insertion = 25, positive value for an insertion = 8, except = 7 for CobN and BchH). [b] Protein from an organism other than *Ps. denitrificans* or *S. typhimurium* proved or likely to be a Cob protein owing to the high level of identity to one of the *Ps. denitrificans* Cob proteins. [c] This *E. coli* protein catalyzes the same reaction as the *Ps. denitrificans* homologues but cannot be properly named a Cob protein since *E. coli* has not been described to synthesize cobalamin but can only synthesize precorrin-2 (for the production of sirohaem) and convert exogenous cobinamide into adenosylcobalamin. [d] ORF: open reading frame; a stretch of DNA at the position reported which probably codes for a protein but for which the corresponding protein has not been characterized.

12. Summary and Outlook

By the end of 1993, all the intermediates on the biosynthetic pathway between uro'gen III **7** and coenzyme B_{12} (**2**) in *Ps. denitrificans* had been isolated and their structures determined. The full sweep of the pathway can be viewed by joining together Schemes 1, 18 and 19. In addition, the enzymes catalyzing each step[102] had been characterized and in most cases, purified to homogeneity. The corresponding genes for all but two[103] of these enzymes had been identified, sequenced, and overexpressed. No one reading the literature on vitamin B_{12} five years ago could have possibly imagined that by 1993 the Everest of B_{12} would have been conquered.

Although the central problem has been solved, a few points need to be clarified:

A) There are two further *cob* genes, *cobE* and *cobW*,[104] essential for B_{12} production, whose functions are unknown.

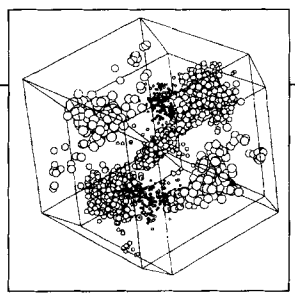
B) Parts of the branch pathways providing (*R*)-1-amino-2-propanol and 5,6-dimethylbenzimidazole should still be studied. It may be relevant that eight other genes located within gene clusters B, C, and D have not been classified as *cob* genes, because mutations in them did not prevent coenzyme B_{12} synthesis. They may be involved in dimethylbenzimidazole biosynthesis or have roles related to B_{12} biosynthesis such as cobalt or B_{12} transport or formation of methyl cobalamin.

C) Experiments must be carried out to probe the mechanism of those biosynthetic transformations involving more than simple C-methylation (e.g. the ring contraction). In addition, some stereochemical details of a few intermediates are still lacking (e.g. for precorrin-8x).

D) Since there are differences between the pathways in *Ps. denitrificans* and other organisms such as *Pr. shermanii* and *S. typhimurium*, the relationship of the intermediates in the latter two organisms to the known ones in *Ps. denitrificans* should be worked out.

E) Lastly, knowledge of the chemistry and genes of the pathway opens the way to other more biological studies into areas such as the regulation of the pathway.

This work must pass to others since the Paris–Cambridge teams, having completed their major task as described in this review, are withdrawing from the field. Satisfyingly, the approach described for the study of B_{12} biosynthesis may serve as a model for solving other complex biosynthetic problems. Undoubtedly, an essential first step is to establish an interdisciplinary team skilled in genetics, molecular biology, enzymology, structural and synthetic chemistry, isotopic labeling, and NMR spectroscopy. We look forward to seeing the routes to other complex natural substances being revealed in this way.



We wish warmly to thank all our colleagues for their many important contributions to the studies outlined in this review. In Paris these include L. Cauchois, S. Rigault, M.-C. Rouyez, C. Guilhot, C. Robin, M. Couder, A. Famechon, M. Chenu, J.-C. Muller, L. Maton, D. Bisch, M. Danzer, B. Monegier, D. Frechet, F. Herman, F. Debu, M.-H. Beydon, M. Rose, L. Naudin, and L. Louvel. In Cambridge they are A. I. D. Alanine, S. Balachandran, K. Ichinose, F. Kiuchi, M. Kodera, Y. Li, S. M. Monaghan, A. R. Pitt, A. Prelle, N. P. J. Stamford, R. A. Vishwakarma, and G. W. Weaver. We gratefully acknowledge financial support from the British Science and Engineering Research Council (SERC), Hoffmann La Roche, Roche Products, Zeneca, the Leverhulme Trust, and Rhône-Poulenc Rorer. We also extend thanks to J. Lunel, B. Brunie, A. Brun, M. Courtier, J.-F. Mayaux, P. E. Bost, J.-B. Le Pecq, and J.-C. Brunie for their constant support, to R. De Mot for providing results prior to publication, to Prof. G. Müller, Stuttgart, for his enthusiastic collaboration, and to him and Dr. C. Abell, Cambridge, for valuable discussions.

[5] Biosynthetic intermediates that occur on the pathway before the first corrin macrocycle is generated are called precorrins. A number is attached corresponding to the number of C-methyl groups that have been introduced from *S*-adenosylmethionine (SAM) to produce that intermediate. Where two or more intermediates carry the same number of SAM-derived methyl groups, they are distinguished by adding letters to the number with A being added for the first such intermediate, B for the second, and so on. In some cases, temporary letters (x and y) have been used until the status of a particular intermediate became clear, so allowing the correct designation to be given later; for example, what was precorrin-6x is now precorrin-6A and precorrin-6y is precorrin-6B. For further details see H. C. Uzar, A. R. Battersby, T. A. Carpenter, F. J. Leeper, *J. Chem. Soc. Perkin Trans. 1* **1987**, 1689.

[22] If used as soon as it is formed, precorrin-3A (**10**) can be employed directly as the substrate for enzymic conversion into later intermediates on the pathway. However, since it undergoes ready oxidation in air, deliberate oxidation is often used to yield the didehydro derivative (an isobacteriochlorin), which is isolated and stored as its stable ester. Subsequent hydrolysis of the ester groups gives the acid, which conveniently undergoes enzymic reduction back to precorrin-3A on incubation with the complete enzyme system from *Ps. denitrificans* and either NADH or NADPH. The biosynthetic steps that follow precorrin-3A (**10**) then proceed normally.

[28] Ready conversion of one double-bond tautomer into another can occur in the macrocyclic B_{12} intermediates. Thus, precorrin-6A (**16**) may have a double bond from N to C-9 rather than at C-8/C-9, which is certainly its position in the isolated ester **17**. These close tautomers are included when one refers to precorrin-6A, and the same holds for all the other structures in this review.

[40] Several well-defined events happen as precorrin-6B (**19**) is converted into precorrin-8x, but no intermediate has been detected. The present indications are that these events all occur in the active site of the single enzyme involved. However, evidence concerning their sequence may be gained in the future. For the time being, therefore, it is best to use the name of precorrin-8x and later either drop the x or replace it by the appropriate capital letter.
[41] Enzyme preparations from *Pr. shermanii* behave similarly; added cobyrinic acid (**11**) strongly inhibits its own formation: S. Monaghan, H. C. Uzar, A. R. Battersby, unpublished.

[102] One more enzyme on the main pathway may exist that has not as yet been characterized—cobalamin 5'-phosphatase. This is not an essential part of the pathway, however, because CobV can catalyze the attachment of α-ribazole

(**56**) (as well as its 5′-phosphate **55**), thus avoiding the need for a subsequent phosphatase.
[103] The two characterized enzymes for which the genes have not been found are the cob(II)yrinic acid *a,c*-diamide reductase and protein z of the aminopropanol attachment system.
[104] CobW is homologous to the product of P47K from *Ps. chlororaphis* (Table 2; we thank A.-M. Crutz-Lecoq for pointing this out to us). The P47K protein seems to be important for the stabilization and/or maturation of nitrile hydratase and might be involved in binding the metal ion to the hydratase. Therefore it is possible that CobW has a role in binding cobalt to CobN.

Y. Ohashi (ed.)

Reactivity in Molecular Crystals

1993. XII, 348 pages. Hardcover. DM 198.00.
ISBN 3-527-29098-2

Do you need to design syntheses that are
- highly selective
- fast
- enantioselective with quantitative enantiomeric yield?

This book describes in detail how best to exploit the enormous synthetic potential of solid state reactions. Written by leading experts, it provides in depth information on
- the theoretical and physico-chemical approach to solid state reactions
- solid-to-solid organic reactions
- stereoselective solid state photoreactions
- reactivity and crystal structure

An ideal companion to Bürgi and Dunitz's *Structure Correlation*, this book will be highly useful to synthetic organic chemists, stereochemists, crystallographers, and solid-state chemists.

Enzymes in Organic Synthesis: Application to the Problems of Carbohydrate Recognition (Part 1)**

Chi-Huey Wong,* Randall L. Halcomb, Yoshitaka Ichikawa, and Tetsuya Kajimoto

Carbohydrates on cell surfaces are information molecules. Although only seven or eight monosaccharides are commonly used as building blocks in mammalian systems, the multifunctionality of these monomers can lead to the assembly of an immense variety of complex structures. Millions of different tetrasaccharide structures, for example, can be constructed from this small number of building blocks, if branching, the stereochemistry of glycosidic linkages, and the modification of hydroxyl and amino groups are taken into consideration. Oligosaccharides therefore represent an effective class of biomolecules that code for a vast amount of information required in various biological recognition processes, such as intercellular communication, signal transduction, cell adhesion, infection, cell differentiation, development, and metastasis. The pace of development of pharmaceuticals based on carbohydrates has, however, been slower than that based on other classes of biomolecules. Part of the reason is the lack of technologies for the study of complex carbohydrates. There is no method to amplify oligosaccharides for sequence analysis. There is no machine available for automated synthesis of oligosaccharides. In addition, the possibly poor bioavailability and difficulties in the large-scale synthesis of carbohydrates have undoubtedly contributed to this slow pace. The enzymatic and chemoenzymatic methods, especially those based on aldolases and glycosyltransferases, described here appear to be useful for the synthesis of mono- and oligosaccharides and related molecules. Further advances in glycobiology will probably lead to the development of new technologies for the study of carbohydrate recognition and for the synthesis of bioactive carbohydrates and mimetics to control the recognition processes.

Keywords: carbohydrates · enzymes · organic synthesis

Recent advances in synthetic organic chemistry have made possible the stereocontrolled synthesis of a large number of organic molecules. The field of synthetic organic chemistry now faces two very important issues: 1) the design of molecules with desirable properties for use in biological or material sciences and 2) the development of economical and environmentally acceptable processes for synthesis. Enzymes are able to contribute to the solution of both these issues and have increasingly been considered as a useful class of catalysts for organic synthesis. Numerous enzyme-catalyzed reactions (especially those based on hydrolytic enzymes such as lipases, esterases; and amidases) have been developed and become familiar to synthetic organic chemists. Recent advances have extended the field of enzymatic synthesis to many other complex types of reactions such as oxidoreductions, carbon–carbon bond–forming reactions, glycosylation reactions, and various group transfer reactions that are difficult or impossible to execute with conventional synthetic methods, thereby broadening the scope of its synthetic utility. One area which holds great promise for the use of enzymes is the synthesis of water-soluble, polyfunctional organic molecules, especially carbohydrate and carbohydrate-like molecules. Conventional synthesis of these molecules often requires multiple protections and deprotections and faces the problem of insufficient stereocontrol. The high regio- and stereoselectivity and mild reaction conditions in enzyme-catalyzed reactions provides a new opportunity to tackle many synthetic problems encountered in carbohydrate synthesis, particularly on a large scale. This review focuses on the use of enzymatic and chemoenzymatic methods for the synthesis of simple and complex carbohydrates and related substances, and their application to the problems associated with carbohydrate-mediated recognition in biological systems.

1. The Current Status of Enzymatic Organic Synthesis

The characteristics of instability, high cost, difficulty in handling, and narrow substrate specificity have been the drawbacks of enzymes as synthetic catalysts. As a result, application of enzymes has traditionally been limited to the analysis and small-scale synthesis of research biochemicals. This perception, however, has changed dramatically in the past ten years as a result of new developments in chemistry, biology, and in industry. Large numbers of known and new enzymes (Table 1) have been used in the transformation of natural or nonnatural substrates to synthetically useful intermediates or final products. Additionally, recombinant DNA technology had made possible the low-cost production of enzymes and the rational alteration of their properties. Perhaps the most useful application of enzyme catalysis is in the area of asymmetric synthesis, especially the synthesis of structurally well-defined molecules that are useful in medicine, agriculture, and biology.[1-5]

The biological activity of most drugs is due to their ability to interfere with receptor–ligand or enzyme–substrate interactions. A rational approach to drug development requires the design, synthesis, and study of a range of substrates, inhibitors, ligands, and derivatives that may be difficult to manipulate with classical synthetic methodology alone. With the potential advantages of enzyme catalysis as a practical route to carbohydrates, as well as the increasing environmental concerns and the regulatory constraints faced in the chemical and pharmaceutical industries, enzyme-based organic synthesis becomes an attractive option that may offer clean and mild processes for the production of materials with high optical purity.

A crucial question is whether an enzymatic approach to synthesis is practical. In many instances when enzymatic transformations are compared with the chemical methodology, they only represent an alternative or improved process, and whether replacement of an existing chemical process with an enzymatic method is beneficial remains an open question. In some cases, however, enyzmatic processes are more cost-effective and have clear advantages over chemical methods. For example, the use of DNA ligases and restriction enzymes to manipulate DNA has no competition from other techniques. Several large-scale enzymatic processes used in industry (resolution of amino acids with

Chi-Huey Wong received his B. S. and M. S. degrees from National Taiwan University, and a Ph.D. in chemistry from Massachusetts Institute of Technology under George M. Whitesides in 1982. After one year of postdoctoral research at Harvard University, he taught at texas A & M University for six years. Since 1989 he has been the Ernest W. Hahn Professor at The Scripps Research Institute. He is also Head of the Frontier Research Program on Glycotechnology at RIKEN, Japan. His current interests are in the area of bioorganic and synthetic chemistry, in particular the development of enzymes for organic synthesis, and the rational design and synthesis of inhibitors of enzymes and receptors. His honors include a Presidential Young Investigator Award in Chemistry, a Searle Scholar in Biomedical Sciences, and an A. C. Cope Scholar of the American Cancer Society. He received the International Carbohydrate Award. He is the author and coauthor of over 250 publications, one book, and 30 patents.

Randall L. Halcomb was born in 1965 and studied chemistry at the University of Alabama, completing his Ph.D. at Yale University under S. J. Danishefsky in 1992. He then spent two years as American Cancer Society Postdoctoral Fellow at The Scripps Research Institute. In June 1994 he joined the Department of Chemistry at the University of Colorado as Assistant Professor. His research interests include the synthesis and study of bioactive natural products and complex carbohydrates.

Yoshitaka Ichikawa was born in Tokyo in 1954. He received his Ph.D. in Agricultural Chemistry in 1986 from the University of Tokyo. He then worked at RIKEN and as postdoctoral associate at Johns Hopkins University and The Scripps Research Institute. He is currently Assistant Professor of Pharmacology and Molecular Sciences at the Johns Hopkins Medical School. His research interests include the synthesis and biological studies of complex carbohydrates.

Tetsuya Kajimoto was born in Osaka in 1960. He received his Ph.D. in Chemistry under K. Fuji in 1989 from Kyoto University. After one year of teaching and research as assistant professor at Kumamoto University, he did his postdoctoral work at The Scripps Research Institute. Since 1991 he has been Deputy Head of the Frontier Research Program on Glycotechnology at RIKEN. His research interests include the development of new technologies for the study of carbohydrate recognition in biological systems and the synthesis of inhibitors to control carbohydrate recognition processes.

Table 1. Enzymes commonly used for organic synthesis.

Enzymes not requiring cofactors	Enzymes not requiring stoichiometric cofactors	Enzymes requiring a cofactor [a]
1) Hydrolytic enzymes:	1) Flavoenzymes:	1) Kinases-ATP
esterases	glucose oxidase	2) Oxidoreductases-NAD(P)(H)
lipases	amino acid oxidases	
amidases	diaphorase	3) Methyl transferases-SAM
phospholipases	FMN reductase	
epoxide hydrolases		4) CoA-requiring enzymes
nucleoside phosphorylase	2) Pyridoxal phosphate enzymes:	
SAM synthetase		5) Sulfuryllyases-PAPS
2) Isomerases and lyases:	transaminases	
glucose isomerase	tyrosinase	
aspartase	δ-aminolevulinate dehydratase	
phenylalanine ammonia lyase	cystathionine synthetase	
fumarase	3) Metalloenzymes:	
cyanohydrin synthetase	galactose oxidase	
3) Aldolases	monooxygenases	
4) Glycosyl transferases	dioxygenases	
5) Glycosidases	hydrogenases

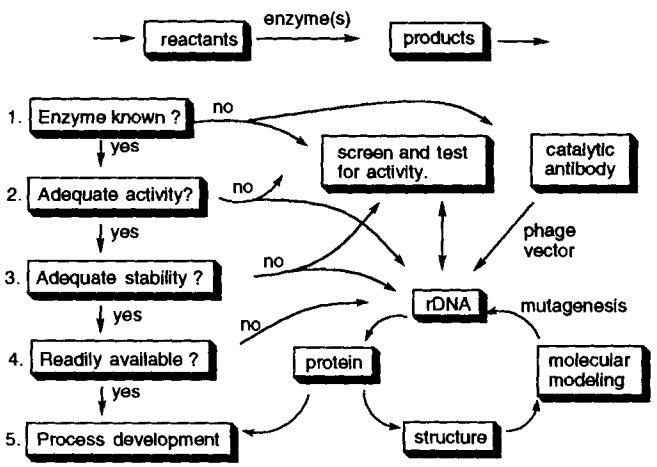
acylase, production of high-fructose corn syrup with glucoamylase and glucoisomerase, transformation of pig insulin to human insulin catalyzed by trypsin, preparation of penicillin analogs with penicillin acylase, synthesis of aspartame with thermolysin, and preparation of acrylamide from acrylonitrile catalyzed by nitrilehydrolase) have demonstrated that enzymatic catalysis can also provide a route to fine chemicals, medicinal agents, and commodity chemicals. In addition, synthesis and modification of mono-, oligo-, and polysaccharides and their conjugates and analogs, regioselective transformation of other complex molecules, and modification of recombinant DNA products such as glycoproteins may be best conducted enzymatically. It should be emphasized, however, that it is frequently less convenient in most circumstances to develop an enzymatic route to a substance required in milligram quantities than to carry through a classical chemical synthesis. When large quantities of that material are required, however, it will be worth the effort to develop appropriate enzymes for that synthesis.

Once a decision has been taken to attempt using enzymes for a given transformation, one or more enzymes capable of performing that type of transformation can be selected and the reaction conditions, such as temperature, pH, solvent, regulator, and protecting group, can be optimized. A number of enzymes are already commerically available, and many more can be easily isolated. The next step is to determine whether the enzyme possesses adequate activity for the desired transformation. Selectivity and specific activity are important factors at this stage. The specific activity of an enzyme is often presented in units (U): 1 U of enzyme will produce 1 μmol of product per minute at its maximum velocity, and the number of units per milligram of enzyme represents that enzyme's specific activity. If the specific activity is too low, the quantity of enzyme required for the synthesis is unrealistically large. In that event, it is necessary to use a more active enzyme, or to develop another enzyme by screening or by site-directed mutagenesis, or to abandon the project to chemical methodology. Similar considerations are also given to the evaluation of selectivity.

If the specific activity and selectivity are high enough to be practical, the remaining steps are relatively straightforward. Procedures can usually be found that will stabilize an enzyme adequately for bench-scale synthesis. Immobilization is usually straightforward, and when it is unsuccessful it may be perfectly practical to use the free enzyme in a homogeneous solution. The technique of site-directed or random mutagenesis can also be used to improve enzyme stability. Large-scale production of the enzyme can then be executed by using recombinant DNA technology. When all kinetic parameters (for example, k_{cat}, the Michaelis constant K_m, the rate of enzyme inactivation) for a desired transformation are available, one can, in principle, conduct a large-scale synthesis. In the case where no enzyme is known for the desired transformation, it is more laborious to find an appropriate enzyme, an chemical methodology may be the choice. The approaches based on screening and catalytic antibodies,[6] however, may be worth the effort if the desired transformation is important. Once a protein catalyst is found, its activity and stability can be improved as described previously. Proteins can also be attached to the surface of phage and screened for desired catalytic properties[7]. The catalytically active RNAs recently discovered have created a new dimension in biocatalysis, and nonprotein biocatalysts based on RNA are now also available to be exploited as synthetic catalysts.[8] Table 2 summarizes the current status of enzymatic catalysis, and Scheme 1 provides a strategic approach to the development of enzymatic catalysts. It is worth noting that although biocatalysts represent a new class of asymmetric catalysts that are useful for a variety of organic transformations, their improvement or alteration of specificity by site-directed mutagenesis remains a difficult task. Synthetic chemists capable of using and developing biocatalysts, however, will have a clear advantage in their ability to tackle the new generation of synthetic problems appearing at the interface between chemistry and biology.



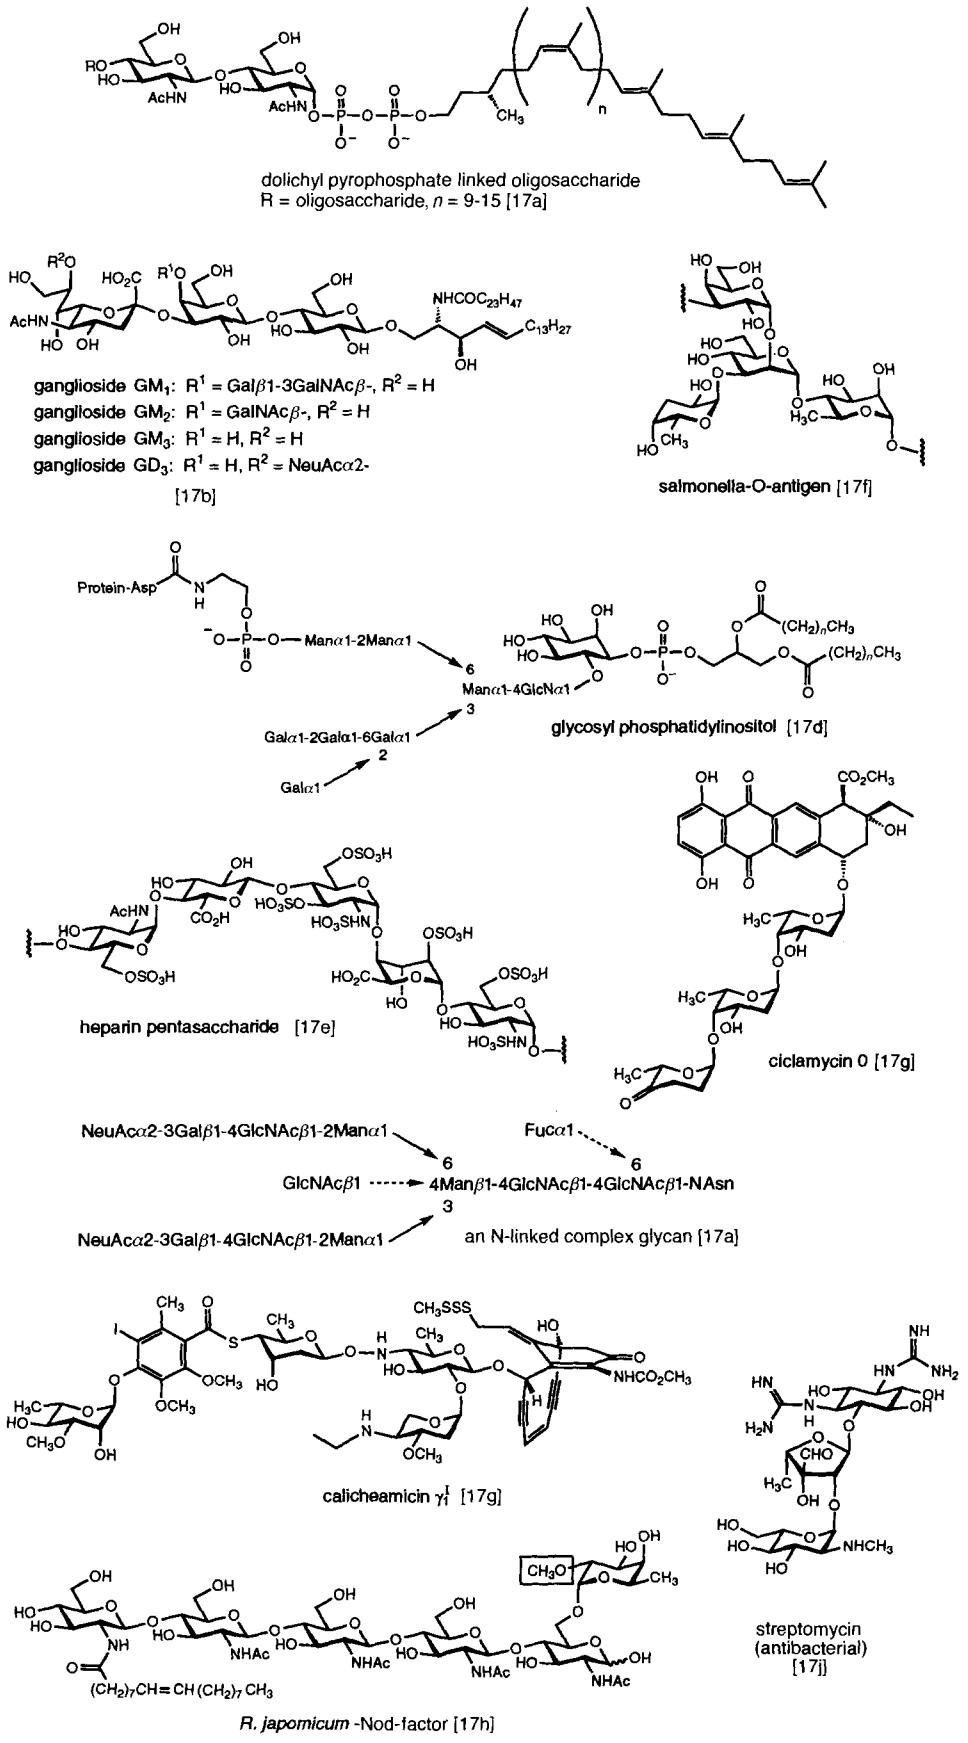
2. Enzymatic Catalysis in Glycobiology and Glycotechnology

Complex carbohydrates and their conjugates in biological systems are either structural or informational molecules. On the cell surface many carbohydrates of glycoconjugates are involved in various types of biochemical recognition processes,[9, 10] including growth, development, immune responses, infection, cell adhesion, metastasis, and numerous signal-transduction events. These compounds often exist in minute

Table 2. Status of certain generic problems in enzymatic catalysis.

Solved	*Current*	*Immediate Future*
immobilization	development of new laboratory-scale uses of enzymes	design and development of new enzymatic catalysts
cofactor regeneration (NAD(P), ATP, CoA, sugar nucleotides)	design of nonnatural substrates	chemoenzymatic synthesis of complex molecules
enzyme deactivation (thiol oxidation protease action)	use with organic cosolvents; one- and two-phase systems	multienzyme systems through metabolic pathway engineering
use of recombinant DNA for large-scale production of enzymes	enzyme stabilization	new catalysts from monoclonal Fab fragments
	overcoming product inhbition	
	cofactor regeneration (PAPS, SAM)	
	modification of enzyme activity and semi-synthetic enzymes	
	mutagenesis for changes in properties	
	exploration of enzymes from new species for synthetic utility	
	scale-up in pharmaceutical synthesis	
	multienzyme systems in synthesis	
	applications in synthesis of fine and specialty chemicals	
	antibody catalysts	

quantities and are difficult to isolate, characterize, and synthesize in quantities large enough for biological study and therapeutic evaluation. Although only seven or eight monosaccharides are commonly found as building blocks in mammalian systems,[11] the multifunctionality of these monomers enables an immense variety of complex structures to be assembled. Millions of tetrasaccharide structures, for example, can be constructed from this small number of building blocks, differing, for instance, in branching sites or the stereochemistry of glycosylation. Oligosaccharides therefore represent a class of molecules that can effectively code for vast amounts of information in various biological recognition process. The enzymes (for example glycosidases) involved in the biosynthesis and degradation of oligosaccharides have been valuable reagents for the determination of oligosaccharide structures,[12] and these enzymes and those involved in the formation of glycoside bonds (for example, glycosyltransferases) have proven to be useful catalysts for the synthesis of saccharides.[13, 14] These glycoenzymes are also interesting targets for inhibition, as they may be involved in metabolic disorders and diseases.[15, 16] Scheme 2 lists a number of naturally occurring carbohydrate structures and glycoconjugates that possess important biological activities.[17] Some of these compounds contain unusual glycosidic linkages or modifications (such as sulfation, methylation) for which an enzymatic synthesis has not been developed. Given the complexity and multifunctional nature of these structures, the synthesis of these and related compounds or designed mimetics in a practical manner remains a challening task. The following describes various types of enzymatic reactions which, when combined with simple chemical transformations, may provide a practical route to numerous sugar-like compounds.



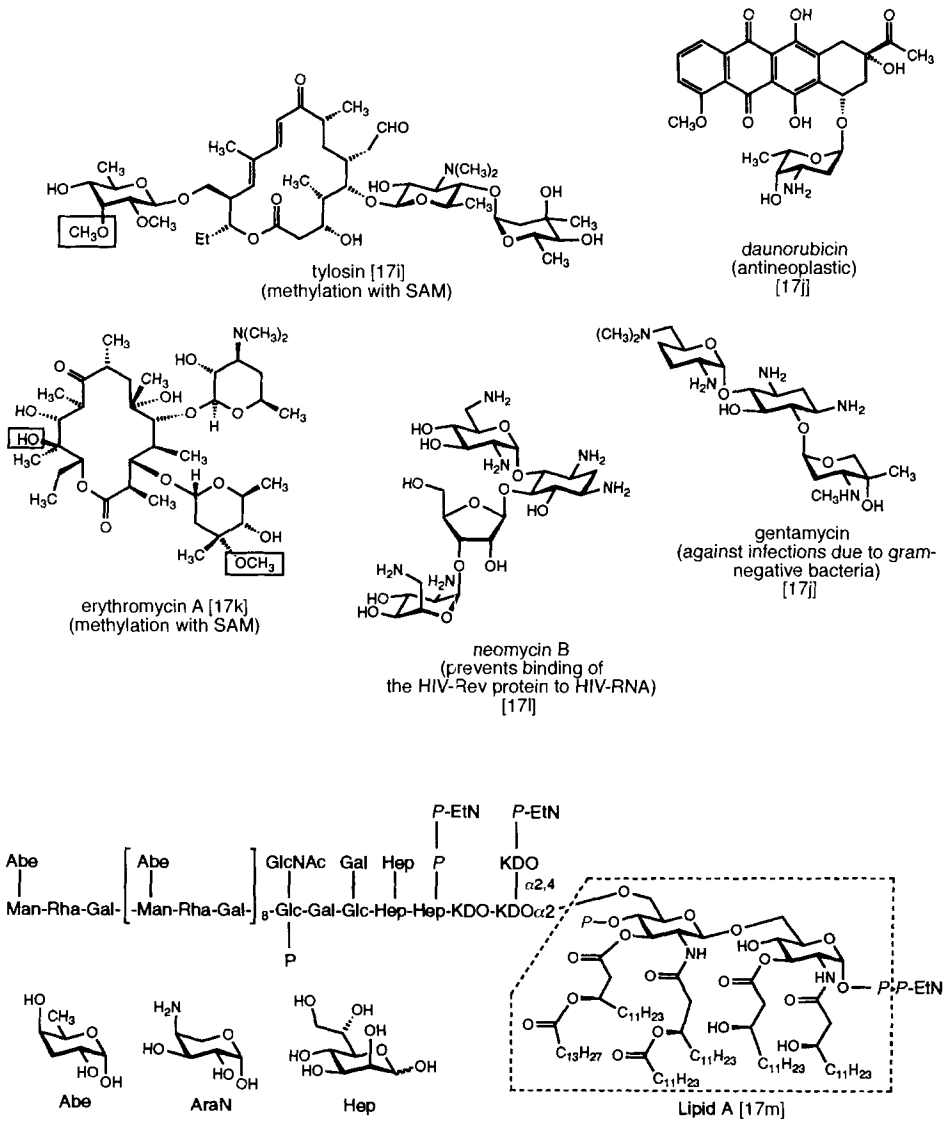
Scheme 1. Strategy for the development of enzymatic catalysts. If the enzyme for a specific reation is known, its specificity, specific activity, and stability may be further improved by protein engineering or screening. If the enzyme is unknown, it may be found by screening or designed by developing a catalytic antibody, and further improved by protein engineering (adapted from ref. [5]).

3. Synthesis of Monosaccharides and Related Structures Based on Aldolases

Aldolases, of which over twenty have been identified to date, usually catalyze the stereospecific aldol condensation of an aldehyde with a ketone donor. Two types of aldolases are known. Type I aldolases, which are primarily found in animals and higher plants, do not require a metal cofactor. In contrast, type II aldolases, found predominately in microorganisms, use a Zn^{2+} cofactor, which acts as a Lewis acid in the active site. In both cases, the aldolases accept a variety of nonnatural acceptor substrates, and in many cases, the stereoselectivity of the reaction is controlled by the enzyme and is highly predictable. Table 3 lists the aldolases which have been studied. The arrows indicate the C–C bond associated with aldol reactions. These enzymes have proven useful for the synthesis of both common and uncommon monosaccharides. Representative examples are the following.

3.1. Fructose-1,6-Diphosphate Aldolase [E.C. 4.1.2.13]

Fructose-1,6-diphosphate (FDP) aldolase catalyzes the reversible aldol addition of dihydroxyacetone phosphate (DHAP) and D-glyceraldehyde-3-phosphate (G3P) to form D-fructose-1,6-diphosphate (FDP), for which $K_{eq} \approx 10^4\ M^{-1}$ in favor of FDP formation (Scheme 3). Both type I and II enzymes have been isolated from a variety of eukaryotes and prokaryotes. Most of the mechanistic studies have been carried out with FDP aldolases from rabbit muscle[18] or yeast.[19] The X-ray structure (2.7 Å)[20] of the enzyme from rabbit muscle (RAMA = *r*abbit *m*uscle *a*ldolase) indicates that Lys-229 is responsible for Schiff-base formation with DHAP.[21] The distance between the Schiff-base nitrogen and the phosphate on G3P (glyceraldehyde-3-phosphate) in the active site of RAMA has been calculated to be 8.3 Å.[22] Another lysine residue in the active site (Lys_{107}), about 8.9 Å from the site of Schiff-base

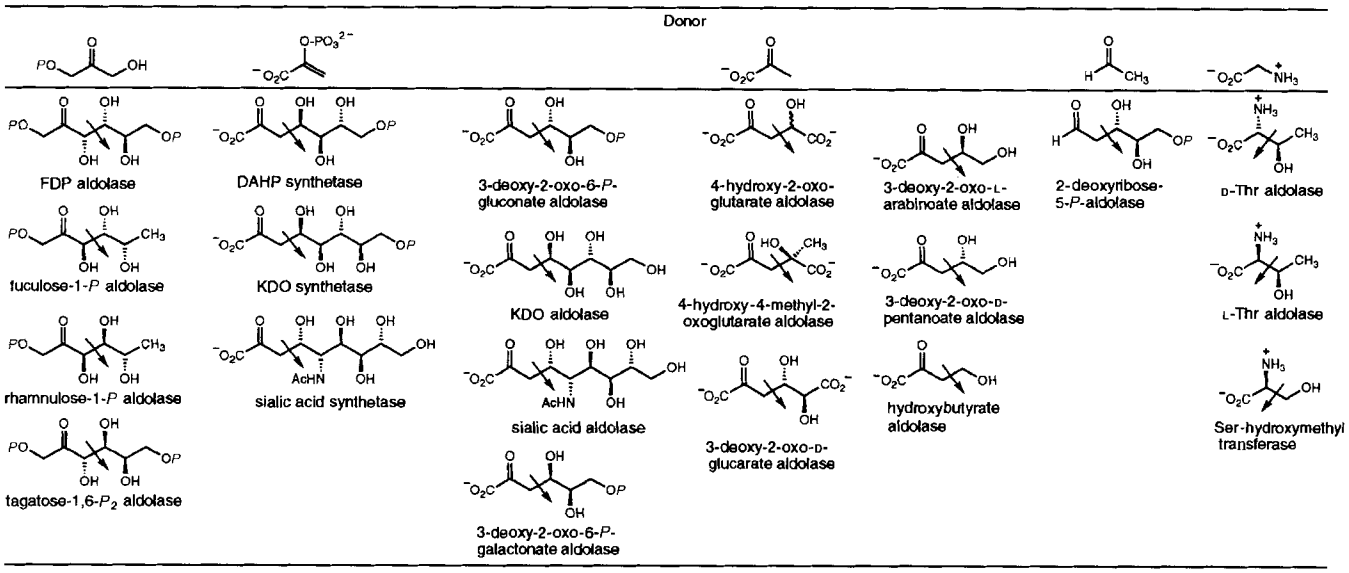


Scheme 2. Biologically active carbohydrates and glycoconjugates. SAM = *S*-adenosylmethionine. DAP = diaminopimelic acid.

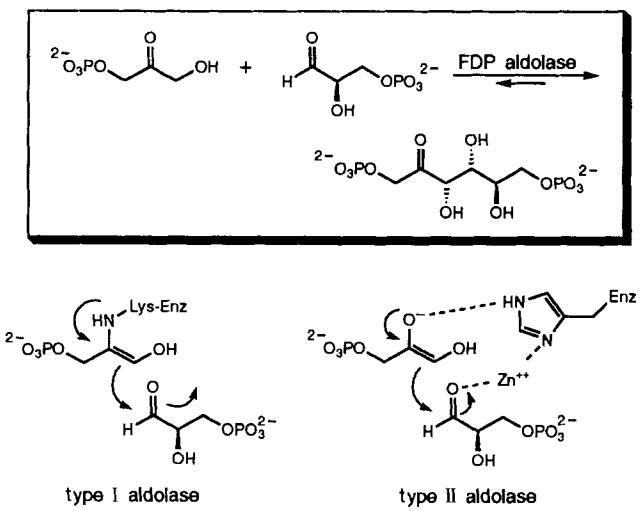
formation,[20] is thought to stabilize the negatively charged phosphate of G3P (Scheme 3). The enzyme RAMA has been cloned and overexpressed, and site-directed mutagenesis studies have identified Asp-33 as another critical residue in catalysis.[23]

Generally, the type I FDP aldolases exist as tetramers ($M_r \approx 160$ KDa), while the type II enzymes are dimers ($M_r \approx 80$ KDa). The sequences of the type I enzymes have a high degree of homology (more than 50%), and the active site sequence is conserved throughout evolution.[20] However, significant differences in the C-terminal regions that may be important in mediating substrate specificity have been identified.[20] Some of the type I aldolases are commercially available and have useful specific activity (around 60 U mg^{-1}). These enzymes are not particularly air-sensitive, although there is an active site thiol group that may be susceptible to oxidation. The half-life of the free enzyme, which is about two days in aqueous solution at pH 7.0,[24] can be lengthened by immobilization or by enclosure in a dialysis membrane.[25] The type II aldolase from yeast is commercially available. Other microbial aldolases have recently been cloned and overexpressed.[24, 26-28] The enzyme from *E. coli* has no thiol group in the active site, and has a half life of approximately 60 days in 0.3 mM Zn^{2+} at pH 7.0.[24] Despite the small degree of homology in primary sequence between the enzymes from *E. coli* (type II) and rabbit muscle (type I), studies have shown they possess almost the same substrate specificity.

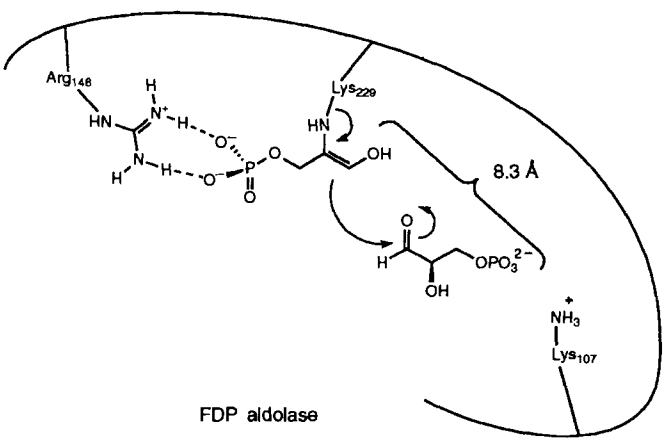
To date, FDP aldolase, especially RAMA, has been the most widely used aldolase in organic synthesis. This enzyme accepts a wide range of aldehyde acceptor substrates with DHAP as the donor to generate 3*S*, 4*R* vicinal diols, stereospecifically, with D-*threo* stereochemistry.[22, 24-25, 29-57] Suitable acceptors include unhindered aliphatic aldehydes,[25] and monosaccharides and their derivatives.[39] Phosphorylated aldehydes react more rapidly



Scheme 2. (continued)



than their unphosphorylated analogs,[39] but aromatic, sterically hindered aliphatic, and α,β-unsaturated aldehydes are generally not substrates.[25] The specificity for the donor substrate is much more stringent. Six DHAP analogs have been found to be poor substrates for RAMA.[25, 40, 44b]



The diastereoselectivity exhibited by FDP aldolase was found to be dependent on the reaction conditions. In a kinetically controlled experiment, the D enantiomer of G3P was accepted by the enzyme with a 20:1 preference over the L enantiomer.[25] A lower enantioselectivity (about 5:1) was observed for the unphosphorylated aldehyde. Racemic mixtures of nonnatural aldehyde acceptors were also partially resolved in a kinetically controlled reaction. In RAMA, the kinetic selectivity is explained by the secondary binding of a charged group with the lysine residue that normally interacts with the phosphate on G3P.[22] When the substrate is constrained by two-point binding, nucleophilic *si* face attack onto the *R* aldehyde is faster, since the *S* aldehyde has a bulky group on the face that the nucleophilic approaches. A study with a series of carboxylated substrates supports this model.[22] When racemic ω-carboxylato-substituted α-hydroxyaldehydes ($^{-}OCO(CH_2)_nCH(OH)CHO$, $n = 1-3, 5$) were treated with DHAP and RAMA, the substrates which had carboxylates that could best overlap with the Lys-107 residue gave the highest enantiomeric excess.

In the cases where the product can cyclize to form a six-membered ring hemiacetal, a racemic mixture of aldehydes is resolved if the enzymatic reaction is under thermodynamical control. Since the reaction is reversible, the product with the fewest 1,3-diaxial interactions will predominate after equilibration. For example, with racemic β-hydroxybutyraldehyde[25, 32] or 2-hydroxymethyl-4-pentenal[32] as substrates, only a single diastereomer with the methyl or allyl group in the equatorial position was obtained (Scheme 4).

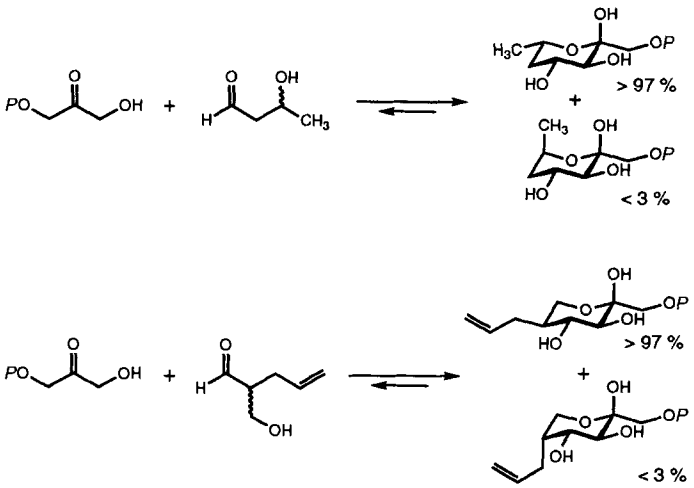


Table 3. Natural substrates for the most important aldolases. Underneath each compound that acts as aldol donor is the name of the relevant enzyme. Arrows indicate the bond formed or broken. FDP = Fructose-1,6-diphosphate, DAHP = dihydroxyacetone phosphate, KDO = 3-deoxy-D-*manno*-octulosonate.

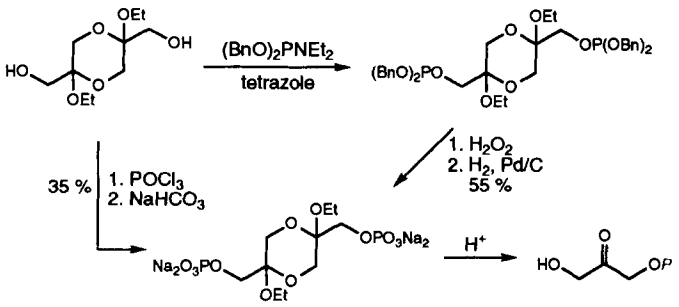
Scheme 3. Mechanism of aldolase-catalyzed aldol reactions.



Scheme 4. Thermodynamically controlled resolution of racemic aldehydes with FDP aldolase from rabbit muscle (RAMA).

3.2. Synthesis of Dihydroxyacetone Phosphate

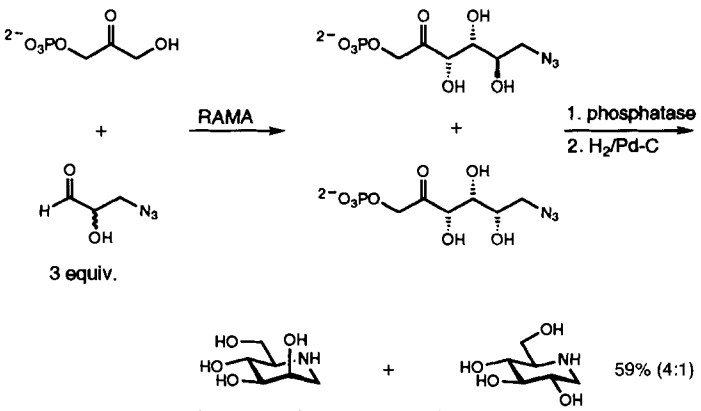
Most conveniently, dihydroxyacetone phosphate (DHAP) can be generated enzymatically in situ from FDP with FDP aldolase and triosephosphate isomerase (TPI).[29, 30] FDP aldolase catalyzes the retro-aldol reaction of FDP to give G3P and DHAP. G3P is rapidly isomerized to DHAP with TPI as the catalyst. One drawback to this method is that the thermodynamics of the reaction may favor the formation of FDP rather than the desired product. The overall reaction may not go to completion, and FDP may also inferfere with product isolation. Another enzymatic method for DHAP synthesis employs glycerol kinase to catalyze the phosphorylation of dihydroxyacetone (DHA) by ATP, with in situ regeneration at ATP.[29] Improved procedures for the synthesis of acetylphosphate and phosphoenolpyruvate (PEP) have been developed[41] in which DHAP is synthesized in 83% yield of approximately 87% puri-

ty with ATP regeneration. DHAP can also be synthesized nonenzymatically by phosphorylation of the ethyl acetal of dihydroxyacetone dimer with $(PhCH_2O)_2PNEt_2$ followed by subsequent oxidation to the phophate with H_2O_2 (Scheme 5),[42] or

Scheme 5. Chemical synthesis of DHAP. Bn = $PhCH_2$.

with either $POCl_3$ or $(PhO)_2POCl$.[43] Reductive cleavage of the aromatic rings, or hydrolysis of the chlorophosphate (for the $POCl_3$ example), yields a stable dimer precursor of DHAP, which can easily be converted into DHAP by acid-catalyzed hydrolysis. The overall procedure with $(PhO)_2POCl$ gives about 55% overall yield of DHAP, compared to 35% with $POCl_3$. A multienzyme system which converts sucrose into DHAP has also been utilized in aldolase reactions.[44a] Glycerophosphate oxidase coupled with peroxidase has also been used in the oxidation of glycerophosphate to DHAP. The enzyme also accepts the corresponding S- and N-phosphates.[44b]

Alternatively, DHAP can be replaced with a mixture of DHA and inorganic arsenate.[31, 45] When DHA reversibly reacts with inorganic arsenate ($k \approx 2.4 \times 10^{-3}\ M^{-1}s^{-1}$) dihydroxyacetone arsenate is formed, which is an analog of DHAP and is also a donor substrate for aldolases. In the presence of RAMA, TPI, and inorganic arsenate, DHA was converted to D-fructose in almost quantitative yield.[45] The arsenate ester of DHA acts as a substrate for the isomerase resulting in the formation of D-glyceraldehyde. D-Fructose is then generated when the remaining DHA arsenate reacts with D-glyceraldehyde in the aldol reaction. Generally, however, when DHA and inorganic arsenate replace DHAP in aldol additions, precautions should be taken, as arsenate is toxic. In addition, reaction rates are relatively small, and low yields of aldol products are often obtained.

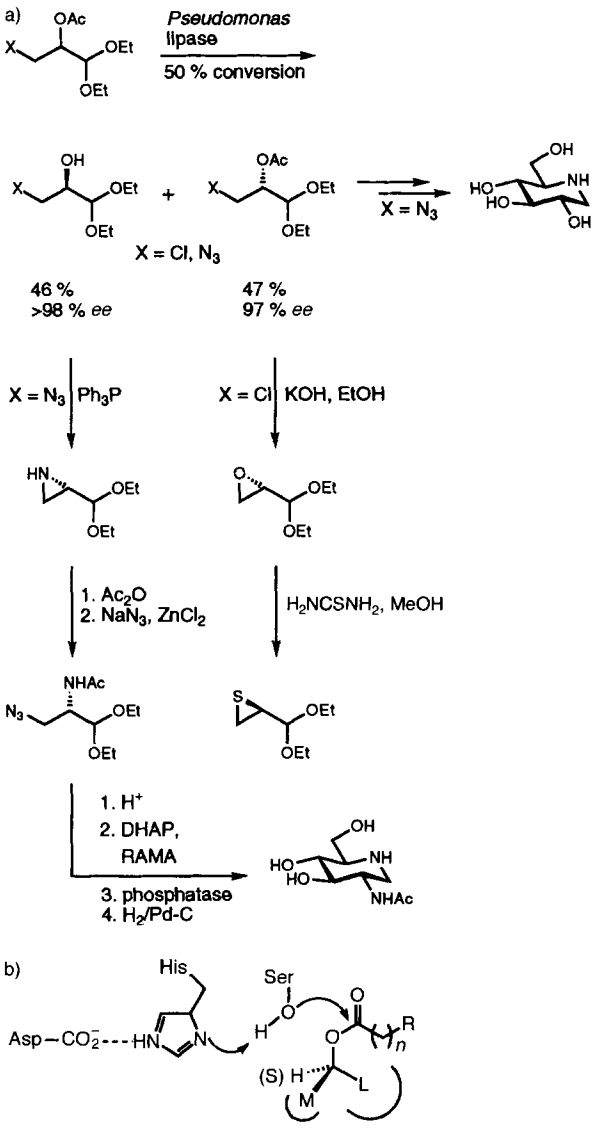


Inorganic vanadate also reacts with DHA to form the corresponding vanadate ester. However, this compound cannot be used as a DHAP analog, since inorganic vanadate also oxidizes DHA. In other organic phosphate-requiring enzymatic reactions where such oxidation does not occur, inorganic vanadate has been used to generate useful substrate analogs.[45]

Although several methods are available for DHAP synthesis and preference may be found in individual cases, that based on $(PhO)_2POCl$ appears to be the most practical. It avoids the problem arising with $POCl_3$ that phosphodiester by-products are formed. The phosphoramidite method does not have the problem of removing the aryl group. The reagent is, however, not commercially available, though it can be easily prepared in the laboratory (from PCl_3, benzyl alcohol, and diethylamine) and stored at room temperature for a long period of time.

3.3. Examples using FDP aldolase

Numerous examples that use FDP aldolase in organic synthesis have appeared recently. These include the production of ^{13}C-labeled sugars,[29, 46–47] nitrogen-containing sugars,[24, 33–35] deoxysugars,[30–32] fluorosugars,[31, 48] and sugars containing seven, eight, or nine carbon atoms[29–30, 32, 39] The aldehydes necessary for FDP aldolase are used in racemic form, but many nonnatural aldehydes prepared as one enantiomer, are employed as such. In general, two groups are used as "masked" aldehydes: a terminal olefin that can be cleaved by ozonolysis,[40] or an acetal that is deprotected through acid hydrolysis.[24] The α-chiral aldehydes can be prepared by nucleophilic ring opening of readily available (*R*)- and (*S*)-glycidaldehyde acetal, or the corresponding thiirane and aziridine.[49] Both enantiomers of glycidaldehyde acetal are prepared by lipase-catalyzed resolution of the diethyl acetal of 3-chloro-2-hydroxypropanal.[24, 49] Following resolution the epoxide is simply generated by treating the chloro alcohol with base. Enzymatic synthesis of novel bioactive sugars using some of these nonnatural aldehydes with FDP aldolase are represented by the examples discussed below.



Aza sugars (polyhydroxy-N-heterocycles) have become increasingly important targets since they have been found to be inhibitors of glycoprocessing.[15, 50] Two potent glycosidase inhibitors, deoxynojirimycin and deoxymannojirimycin, were readily prepared in three steps in which RAMA was used in the key C–C bond-forming step.[33, 34] From racemic 3-azido-2-hydroxypropanal and DHAP, diastereomeric 6-azidoketones were formed. Following the acid phosphatase-catalyzed removal of phosphate and subsequent reductive amination (Scheme 6), the products were isolated in a 4:1 ratio favoring the *manno* derivative. A similar result was obtained with FDP aldolase from *E. coli*.[24] Deoxynojirimycin and deoxymannojirimycin can also be prepared exclusively by utilizing the respective optically pure azidoaldehydes.[24] Both (*R*)- and (*S*)-3-azido-2-hydroxy-

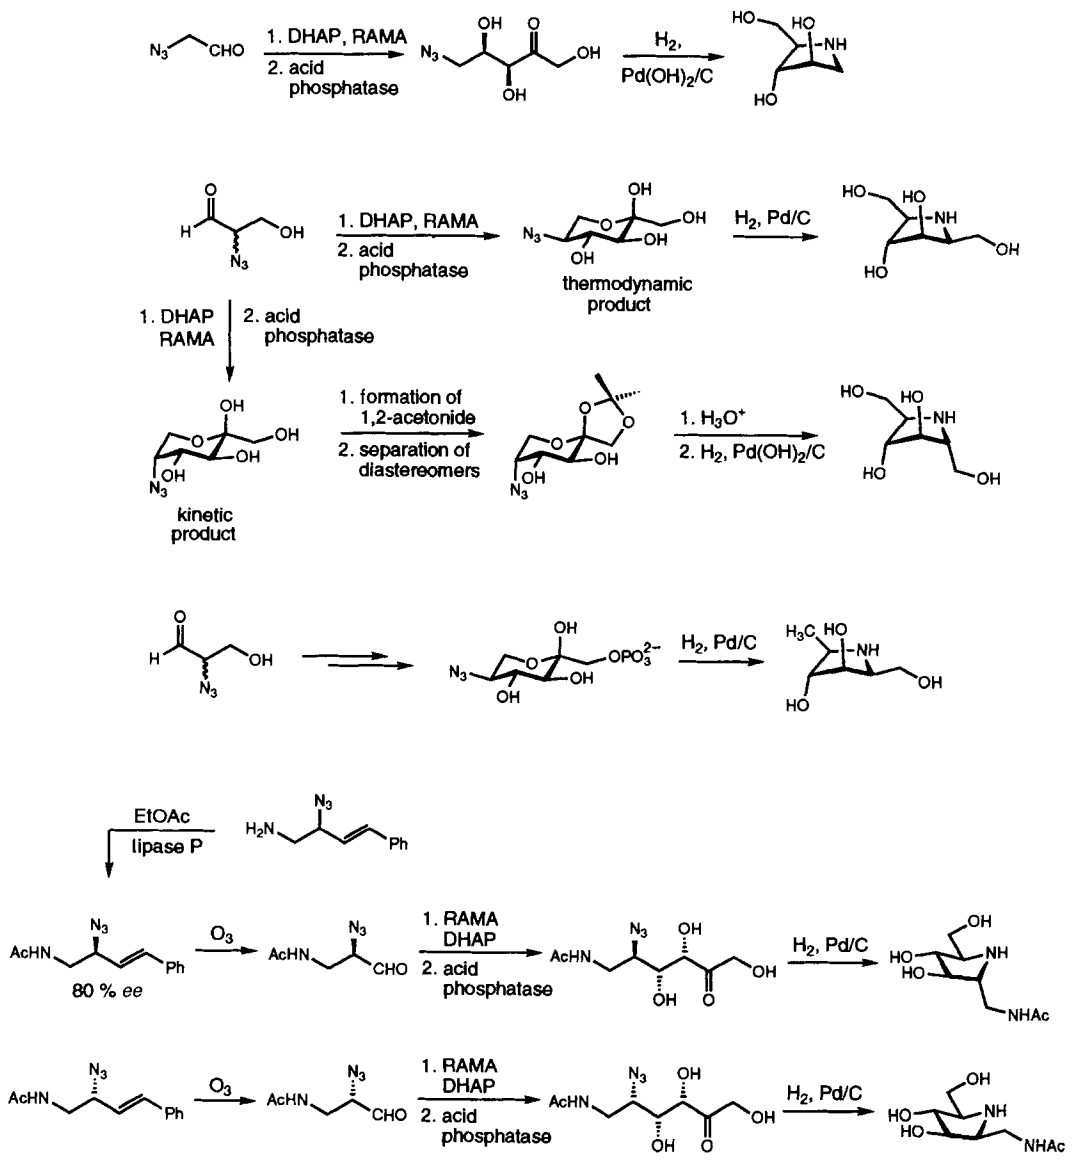
Scheme 6. Synthesis of aza sugars from racemic aldehydes with RAMA.

propanal were obtained in greater than 98% *ee* by resolution of the racemic acetal precursor catalyzed by LP-80 (Scheme 7).[24, 49] In a similar strategy several other 3-substituted 2-hydroxypropanal acetals were made as precursors to a variety of 6-substituted ketoses.[49] The analogous RAMA-catalyzed aldol reaction/reductive amination procedure has also been used in the synthesis of aza sugars derived from N-acetylglucosamine and N-acetylmannosamine, from (*S*)- and (*R*)-3-azido-2-acetamidopropanal, respectively (Scheme 7).[51]

When 2-azidoaldehydes were used as substrates for the RAMA-catalyzed aldol reaction/reductive amination, a number of polyhydroxylated pyrrolidines were synthesized (Scheme 8).[52, 53] 1,4-Dideoxy-1,4-imino-D-arabinitol was prepared from Cbz-protected (Cbz = benzyloxycarbonyl) α-aminoacetaldehyde[24] or azidoacetaldehyde.[52] Both (2*R*,5*R*)- and (2*S*,5*R*)-bis(hydroxymethyl)-(3*R*,4*R*)-dihydroxypyrrolidine were synthesized from racemic 2-azido-3-hydroxypropanal; the kinetic product of the aldol addition was converted into the (2*R*,5*R*) pyrrolidine,[52] while the thermodynamic product gave the (2*S*,5*R*) stereoisomer.[53] Similar transformations with 3-acetamido-2-azidopropanal gave aza sugars structurally related to *N*-acetylglucosamine.[58] A homo-aza sugar was prepared from a four-carbon azidoaldehyde (see Scheme 9).[59] An attempt to prepare seven-membered aza sugars by the same reductive amination process gave a six-membered amino sugar, however (see Scheme 10).[57] The Pd-catalyzed reductive amination of azidoketoses is stereoselective. The reduction presumably proceeds through an imine intermediate, which is further reduced to form a *trans* product. When an axial OH group is present in the imine intermediate, hydrogen is delivered to the face opposite to the axial OH group, presumably for steric reasons (see Scheme 11).

Scheme 7. Synthesis of aza sugars from enantiomerically pure aldehydes with RAMA. a) The chiral aldehydes can be resolved with lipase and converted into useful building blocks and substrates for aldolases. b) The mechanism and stereochemistry of the lipase-catalyzed nucleophilic ester cleavage. S, M, and L stand for the smallest, medium, and largest ligands, respectively.

6-Deoxy aza sugars and their analogs can also be prepared by direct reductive amination of the aldol products prior to removal of the phosphate group.[51] Reduction is thought to occur through the imine 6-phosphate intermediate (Scheme 11).



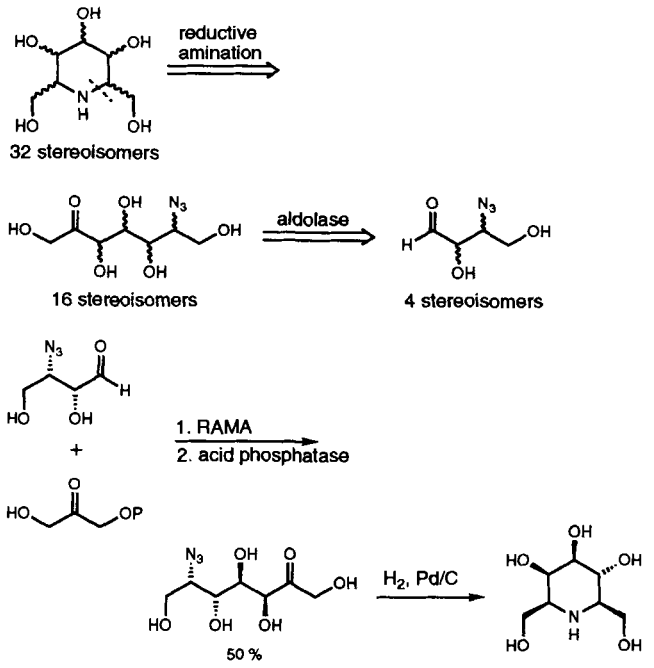
In addition to its application of aza sugars, RAMA catalyzes the synthesis of a variety of oxygen heterocycles. For example, 3-deoxy-D-*arabino*-heptulosonic acid 7-phosphate(DAHP), which is an important intermediate in the shikimate pathway for the biosynthesis of aromatic amino acids in plants, has been synthesized in this way (see Scheme 12)[36] from the substrate *N*-acetylaspartate β-semialdehyde in four steps in 13% overall yield. The enzymatic step produced the desired D-*threo* stereochemistry, and chemical reduction of the ketone gave the desired (6*R*) stereoisomer in 60% diastereomeric excess. Other analogs of DAHP are also potentially available by this route, since RAMA accommodates a number of aldehyde acceptors.

Products from the RAMA-catalyzed aldol reaction can be used to synthesize carbocycles.[38] The protected chloro sugar, generated from the aldolase reaction with chloroacetaldehyde, undergoes nucleophilic attack at the carbonyl carbon by allylmagnesium bromide. Under radical cyclization conditions, a cyclitol is produced (see Scheme 13). When the Grignard reagent is added in tetrahydrofuran, displacement of the chloride occurs to give the C-allyl-*threo*pentuloside as the major product. In principle, this technique can also be applied to the products of other aldolase-catalyzed reactions to provide stereoisomeric derivatives.

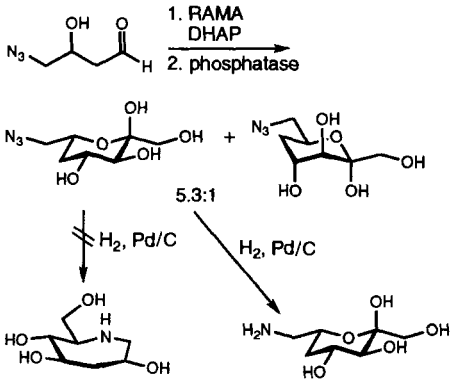
The discovery that RAMA also accepts pentose and hexose phosphates as viable substrates provided a new route to novel high-carbon sugars. Several of these compounds have been synthesized, including analogs of sialic acid and 3-deoxy-D-*manno*-octulosonate (KDO).[39] The reactions are, however, relatively slow.

Synthesis with RAMA is not limited to carbohydrate derivatives. In fact, during the synthesis of the naturally occurring beetle pheromone (+)-*exo*-brevicomin the aldolase reaction was used to establish the two chiral centers in the target molecule (see Scheme 14).[55] Another novel use of RAMA is the synthesis of homo-C-linked nucleosides (see Scheme 15).[60]

As shown in the many examples above, FDP aldolase generates several types of ketose monosaccharides. A number of the important naturally occurring carbohydrates are, however, aldoses. One way to generate aldoses from FDP-aldolase products is by using glucose isomerase (GI = xylose isomerase

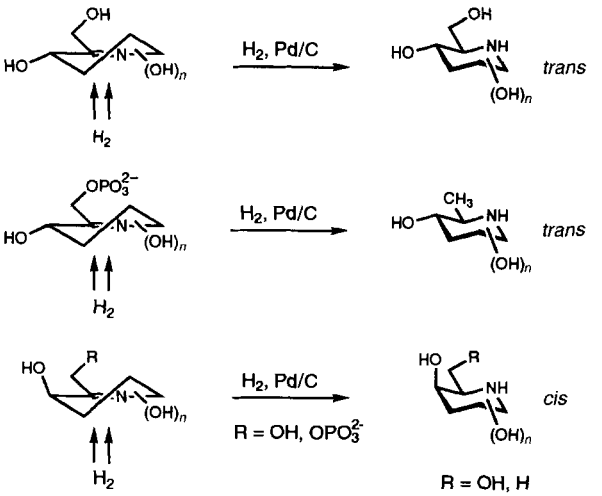


Scheme 8. Synthesis of polyhydroxylated pyrrolidines with RAMA.



[EC 5.3.1.5]).[31, 61] This enzyme catalyzes the isomerization of fructose to glucose and is used in the food industry for the production of high-fructose corn syrup. GI also accepts fructose analogs that are modified at the 3, 5, or 6 positions (see Scheme 16).[31] Several FDP-aldolase products can be isomerized to a mixture of the ketose and aldose, and the two isomers can be subsequently separated using Ca^{2+}- or Ba^{2+}-treated cation exchange resins. Aldose analogs including 6-deoxy-, 6-fluoro-, 6-*O*-methyl-, and 6-azidoglucose have been synthesized with this FDP aldolase/GI methodology. Not all products from FDP aldolase reactions give the desired aldose when subjected to GI. In some cases (for instance, 5-deoxy-D-fructose) the equilibrium lies completely in favor of the ketose, while in others the products from the aldolase reaction are simply not substrates of GI.

An alternative method for aldose generation from the FDP aldolase products is through the "inversion strategy".[37] Here, monoprotected dialdehydes are used as substrates for FDP aldolase to generate protected aldehyde ketoses. The carbonyl group is then stereoselectively reduced, either chemically or enzymatically (with iditol dehydrogenase), and the aldehyde is subsequently deprotected to afford the aldose (see Scheme 17). The NADH-dependent iditol dehydrogenase (IDH) from *Candida utilis* (also known as sorbitol or polyol dehydrogenase [EC 1.1.14]) was used previously to reduce the carbonyl group of ketoses to give the *S* alcohol.[30] The corresponding *R* alcohol was obtained by nonstereoselective reduction of the ketone with $NaBH(OAc)_3$ from which the *S* epimer was selectively removed by oxidation catalyzed by IDH.[37]



While most of the FDP-aldolase reactions use the commercially available aldolase from rabbit muscle, there is still considerable interest in determining the utility of FDP aldolase from other sources.[57] In fact, the type II aldolases from *E. coli*[24] and yeast,[27] which have been subcloned and overexpressed, have the potential to become useful synthetic catalysts, since they are more stable than RAMA and are available from a microbial as opposed to a mammalian source.

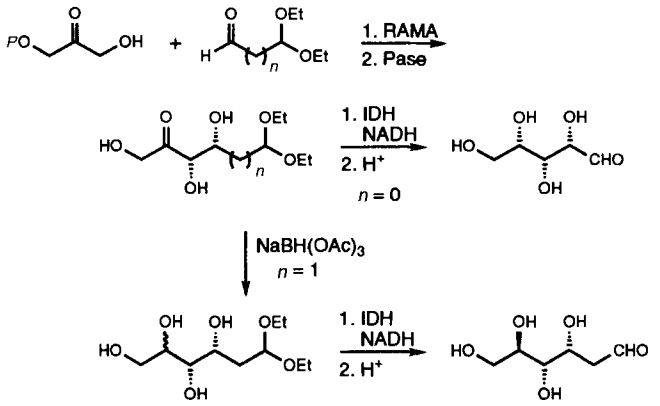
3.4. Fuculose-1-phosphate (Fuc-1-*P*) Aldolase [EC 4.1.2.17], Rhamnulose-1-phosphate (Rha-1-*P*) Aldolase [EC 4.1.2.19], and Tagatose-1,6-diphosphate (TDP) Aldolase



Besides FDP aldolase, there are three other known aldolases which use DHAP as the donor in the aldol reaction: Fuc-1-*P* aldolase, Rha-1-*P* aldolase, and TDP aldolase. Fuc-1-*P* aldo-

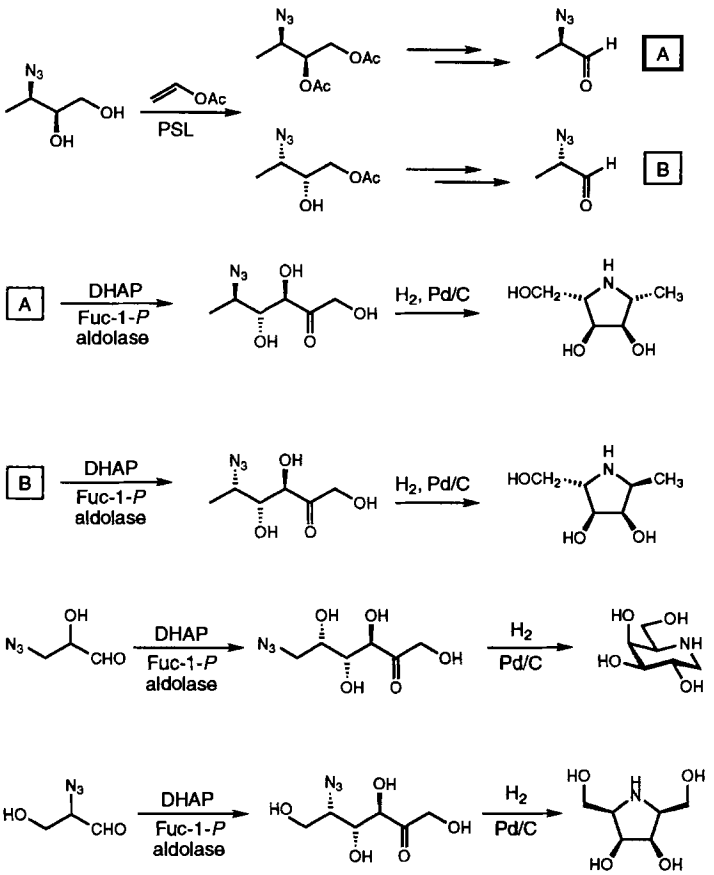
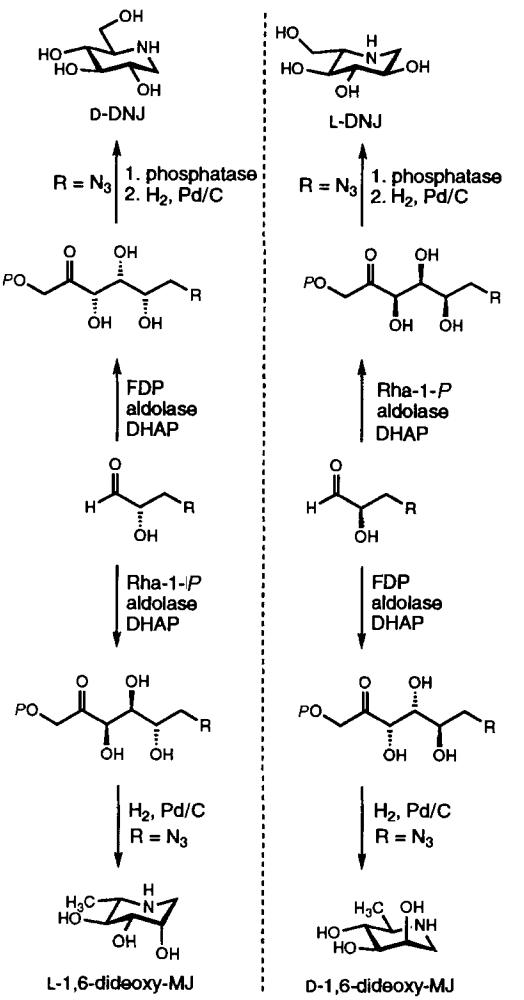
lase catalyzes the reversible condensation of DHAP and L-lactaldehyde to give L-Fuc-1-*P*, and with the same substrates, Rha-1-P aldolase produces L-Rha-1-*P* (Scheme 18). Both of these enzymes are type II aldolases and are found in several microorganisms.[62] Fuc-1-*P* aldolase[63-64] and Rha-1-*P* aldolase[64] have been cloned, overexpressed and subsequently purified. Tagatose-1,6-diphosphate (TDP) aldolase, a type I aldolase involved in the galactose metabolism of cocci, catalyzes the reversible condensation of G3P with DHAP to give D-TDP.

Both Fuc-1-*P* and Rha-1-*P* aldolase accept a variety of aldehydes to generate vicinal diols with D-*erythro* and L-*threo* configurations, respectively.[62-64] While the enzymes yield products with the (3*R*) configuration stereospecifically, the stereoselectivity at C-4 is somewhat diminished for a few substrates.[63] However, sterically unhindered 2-hydroxyaldehydes normally give very high diastereoselectivities.



These two aldolases also show significant kinetic preference for the L-enantiomer of 2-hydroxyaldehydes (>95:5), so they facilitate the kinetic resolution of a racemic mixture of these compounds.[56] Both enzymes have been used in the synthesis of rare ketose-1-phosphates[56] and several aza and deoxyaza sugars.[53, 54, 65] Scheme 19 illustrates the use of Fuc-1-*P* aldolase in the synthesis of five-membered aza sugars, and Scheme 20 illustrates the enantiocomplementary nature of Rha-1-*P* aldolase and FDP aldolase.

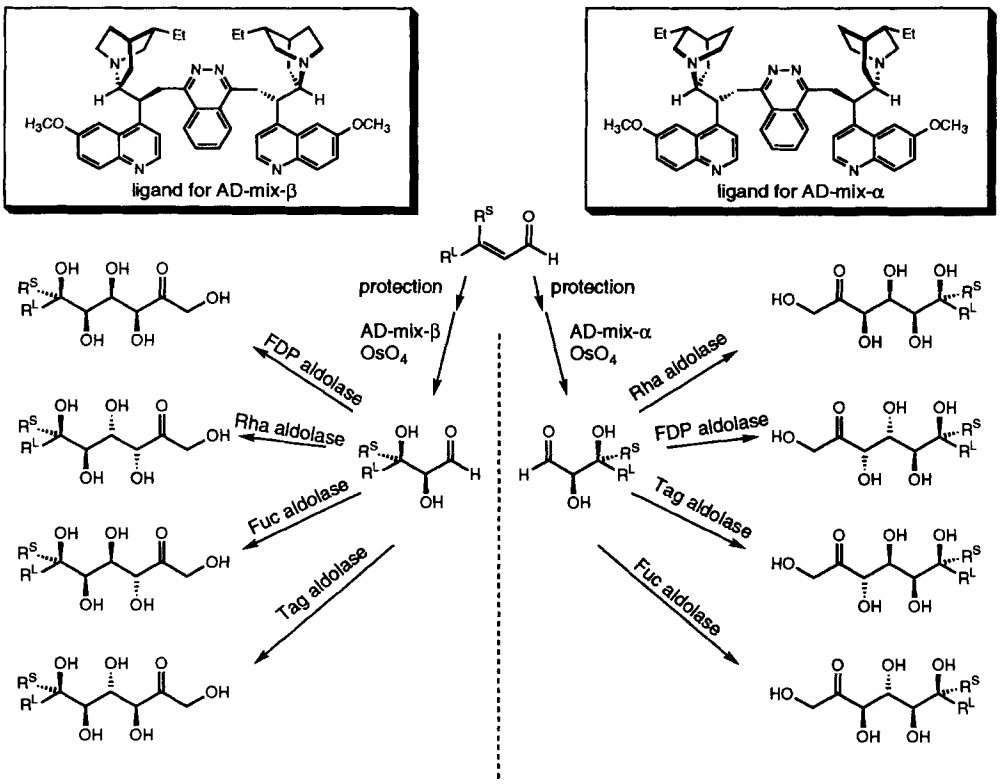
Fuc-1-*P* and Rha-1-*P* aldolases have also been utilized in whole cell systems with DHA and catalytic inorganic arsenate.[45] With L-lactaldehyde and DHA/arsenate as the substrates in the Rha-1-*P* aldolase reaction, the aldol product L-rhamnulose was subsequently isomerized to L-rhamnose, catalyzed by rhamnose isomerase present in the cell. No such isomerization was observed with L-xylulose when the corresponding aldol product formed from glycoaldehyde was the substrate. Recent studies have since shown that both rhamnose and fucose isomerase only accept substrates with a paricular configuration, namely (2*R*,3*R*) and (2*S*,3*R*), respectively.[56]



An alternative method for preparing the same ketose-1-phosphates available from the Rha-1-*P* and Fuc-1-*P* aldolases is to use the rhamnose and fucose isomerases.[56] The isomerase only partially converts the aldose into the ketose, so a second step in which the ketose is phosphorylated drives the reaction to completion. Several ketose-1-phosphates were prepared by using rhamnulose kinase in the second step to give overall yields of 72–90%.

Scheme 18. Aldol addition reaction catalyzed in vivo by fuculose-1-phosphate (Fuc-1-P) aldolase, rhamnulose 1-phosphate (Rha-1-P) aldolase, and tagatose-1,6-diphosphate (TDP) aldolase. Both fucose and rhamnose isomerases can be utilized to isomerize the corresponding ketose after dephosphorylation with phosphatase (Pase).

Scheme 19. Synthesis of aza sugars using fuculose-1-phosphate aldolase and *Pseudomonas* lipase (PSL).

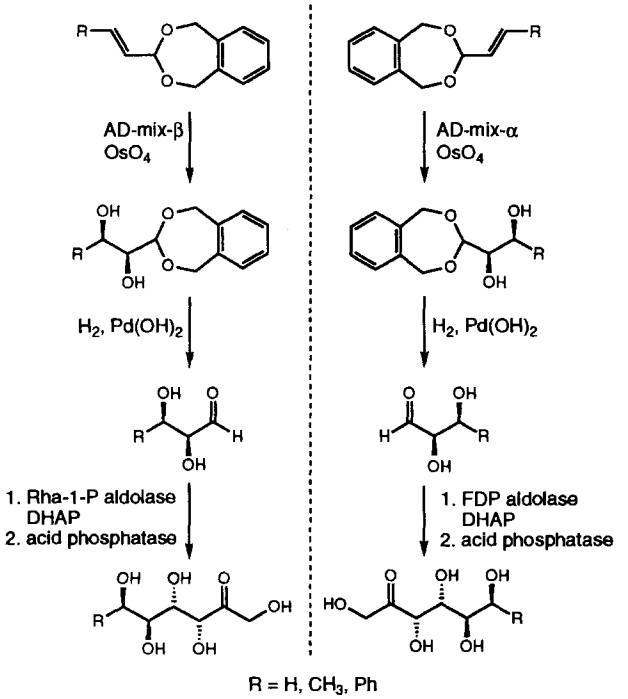


Scheme 20. Aldolase-mediated synthesis of each enantiomer of deoxynojirimycin (DNJ) and 1,6-dideoxymannojirimycin (1,6-dideoxy-MJ).

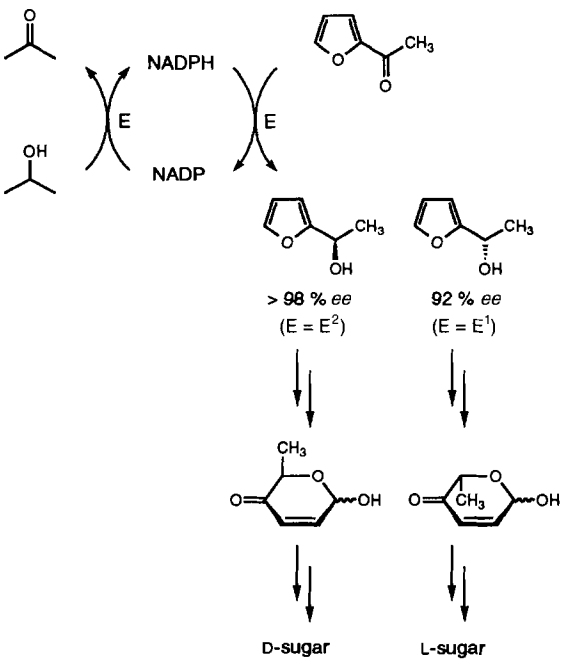
TDP aldolase has been isolated from several sources.[66] The enzym from *E. coli* has a narrow pH profile with an optimum at pH 7.5, but still displays acceptable activity within pH 6.5–7. Like the other DHAP aldolases, TDP aldolase accepts a variety of acceptor substrates for the aldol reaction, including glycoaldehyde, D- and L-glyceraldehyde, acetaldehyde, and *iso*-butyraldehyde.[67] However, in all cases investigated so far, a diastereomeric mixture of products is formed. Also, instead of exhibiting the expected *erythro* configuration as in D-tagatose, more than 90% of each product possessed the *threo* configuration similar to D-fructose. Only with the natural substrate D-glyceraldehyde does the major product (D-TDP) have the tagatose configuration. Due to this lack of stereoselectivity, TDP aldolase is not yet synthetically useful; however, with suitable protein engineering or screening, a highly stereoselective TDP may be created in the future.

From a synthetic point of view, each of the DHAP-dependent aldolases yields a product whose stereochemistry at C-3 and C-4 is complementary to the other products; that is, all four stereochemical permutations are provided by these aldolases. FDP, Rha-1-*P*, Tag-1-*P*, and Fuc-1-*P* aldolases provide four diastereomers from a variety of nonnatural aldehydes. In principle, either of the C-3/C-4 stereoisomeric ketoses is obtainable with these enzymes, which are now available from the American Type Culture Collection (ATCC) as recombinant *E. coli* strains. With a proper choise of aldehyde substrate, the enzymatic aldol reaction provides a new route to many common and uncommon sugars. Although several methods are available for the preparation of enantiomerically pure aldehydes as substrates for aldolases, the osmium-catalyzed dihydroxylation method developed by Sharpless[68] is perhaps the most useful, as it provides either enantiomer for use in enzymatic reactions (Scheme 21). Examples have been shown in the synthesis of enantiomeric D- and L-fructose and derivatives thereof (Scheme 22).[69] Other enzymatic routes to D and L sugars include lipase-catalyzed enantioselective acylation of glycals[70] and *meso* cyclic triols,[71] and alcohol dehydrogenase-catalyzed reductions (Scheme 23).[72]

3.5. *N*-Acetylneuraminic Acid (NeuAc) Aldolase [EC 4.1.3.3] and NeuAc Synthetase [EC 4.1.3.19]

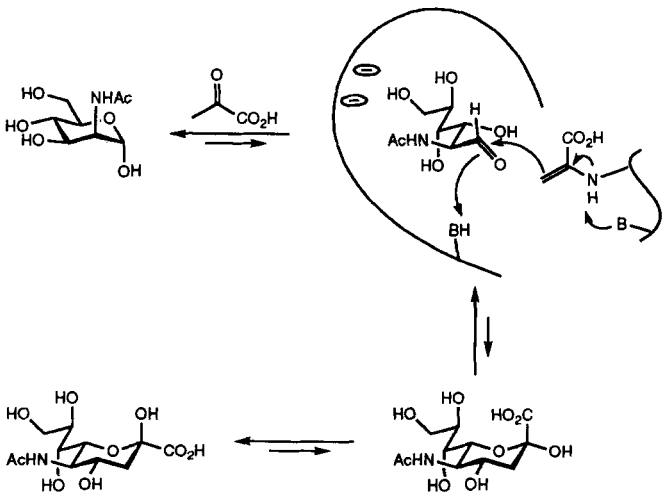


The enzyme NeuAc aldolase, also known as sialic acid aldolase, catalyzes the reversible condensation of pyruvate with D-*N*-acetylmannosamine (ManNAc) to form *N*-acetyl-5-amino-3,5-dideoxy-D-*galacto*-D-*glycero*-2-nonulosonic acid (NeuAc or sialic acid; see Scheme 24).[73, 74] Although the β anomer predominates in solution, the α anomer of NeuAc is the substrate for the enzyme, and the initial products of aldol cleavage are α-D-ManNAc and pyruvate.[75] The enzyme has a catabolic function in vivo, with an equilibrium constant for the retro-aldol reaction



Scheme 21. Strategy for the enantioselective synthesis of all possible isomers of 2-ketohexose. (The larger substituent is indicated by R^L and the smaller by R^S.)

of 12.7 M^{-1}. However, for synthetic purposes, an equilibrium favoring the aldol product can be achieved by using excess pyruvate.[74] NeuAc aldolase has been isolated from both bacteria and animals, and in both cases it is a Schiff base-forming type I aldolase. The optimum pH for activity is 7.5, but it is still active between pH 6 and 9 and is stable to oxygen.[74, 76] The enzymes from *Clostridia* and *E. coli* are now commercially available (Toyobo), and the enzyme from *E. coli* has been cloned and overexpressed.[77] NeuAc aldolase has been used in both free and immobilized form,[78-82] and in some instances it has been enclosed in a dialysis membrane.[83]



Synthetic studies have shown that a high conversion (about 90%) of ManNAc to NeuAc was achieved with the isolated enzyme, although seven equivalents of pyruvate were required. To eliminate the need for excess pyruvate and to aid in the isolation of products, the NeuAc synthesis can be coupled to a more thermodynamically favorable process. One example with ManNAc as the starting material involved the coupling of the NeuAc aldolase reaction with a subsequent sialyltransferase reaction to produce sialyl glycosides.[84] Another variant of this process uses a mixture of ManNAc and GlcNAc whereby the GlcNAc was epimerized to ManNAc chemically,[85] or enzymatically[86] with *N*-acetylglucosamine 2-epimerase. The excess pyruvate can also be decomposed by pruvate decarboxylase (see below).

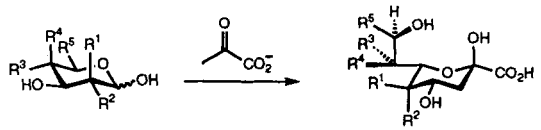
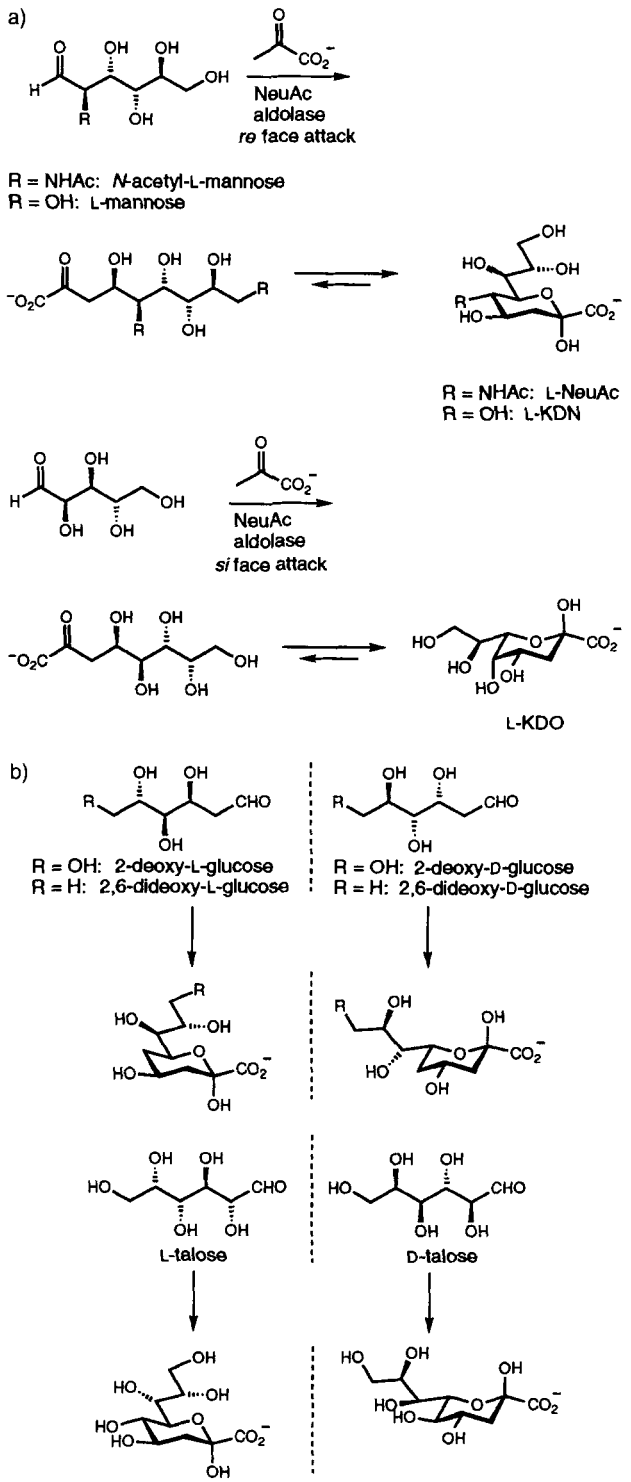


Scheme 24. Mechanism of the NeuAc aldolase catalyzed reaction.

Extensive substrate specificity studies were also carried out with NeuAc aldolase. Only pyruvate is acceptable as the donor; 3-fluoropyruvate, 3-bromopyruvate, 3-hydroxypyruvate, 2-oxobutyrate, and acetylphosphonate are not substrates.[81] In the case of the acceptor substrate the enzyme is more flexible. Substitutions at C-2, C-4, and C-6 of ManNAc are allowed with only a slight preference for the compounds having the same configuration at C-4, C-5, and C-6 as ManNAc.[81, 87–91] Some pentoses and their analogs are also substrates, but aldehydes with two or three carbon atoms are not accepted.



Recently much interest has been stimulated in NeuAc analogs by their role in cellular biology. NeuAc and derivatives are found at the termini of mammalian glycoconjugates and play an important role in biochemical recognition.[92] Polysialic acids are also found in bacteria and mammalian tissues, and may be involved in cell adhesion and cell–cell communication.[10] Because NeuAc aldolase accepts a wide variety of substrates and is readily available, many sialic acid derivatives have been prepared (Table 4) that may be used in biological studies.[93–97]

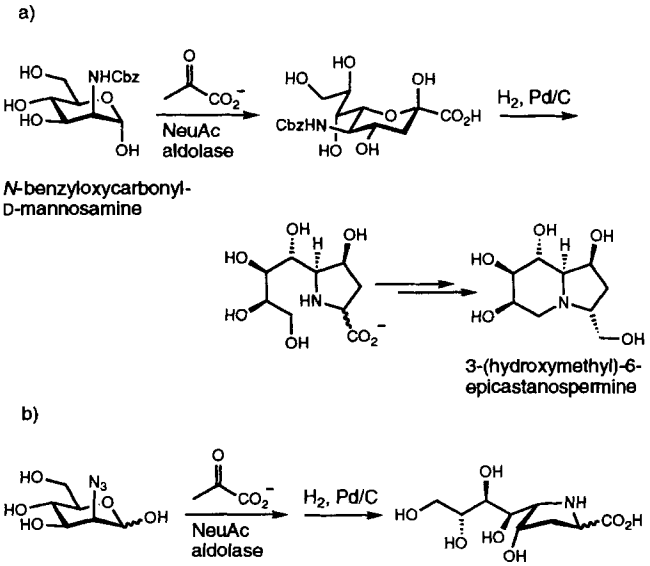
Of the many NeuAc derivatives synthesized so far, most give products with *S* configuration at C-4. Recent observations indicate, however, that under thermodynamically controlled conditions with certain sugars, the absolute configuration at C-4 can be reversed. For example, in the NeuAc aldolase-catalyzed synthesis of KDO a mixture of (*S*)-C-4 and (*R*)-C-4 products were

Scheme 25. a) Synthesis of L-NeuAc, L-KDN, and L-KDO with NeuAc aldolase. b) The substrate-controlled enantiocomplementary nature of NeuAc aldolase reactions with L and D sugars. Left: *re* face attack. Right: *si* face attack.

isolated when D-arabinose was the substrate.[90] NMR studies with several other sugars (for example L-mannose, D-gulose, 2-azido-2-deoxy-L-mannose) showed that over time, products with a C-4 equatorial group predominated, in some cases disregarding the normal stereochemical preference of the enzyme.[98] Apparently, pyruvate attacks the acceptor sugar to give the thermodynamically more stable product, and the facial selectivity is merely a consequence for the preference to form a C-4 equatorial product. Several biologically interesting L sugars were synthesized with this method, including N-LeuAc, L-KDO, and 3-deoxy-L-*galacto*-L-*glycero*-nonulosonic acid (L-KDN, Scheme 25). The excess pyruvate can be decomposed with pyruvate decarboxylase to simplify the product isolation.[98b]

A facile synthesis of 9-*O*-AcNeuAc[79] was improved by regioselective irreversible acetylation of ManNAc catalyzed by subtilisin, followed by a NeuAc aldolase-catalyzed condensation of the resulting 6-*O*-acetylManNAc with pyruvate (Scheme 26).[81] This two-step enzymatic synthesis provided

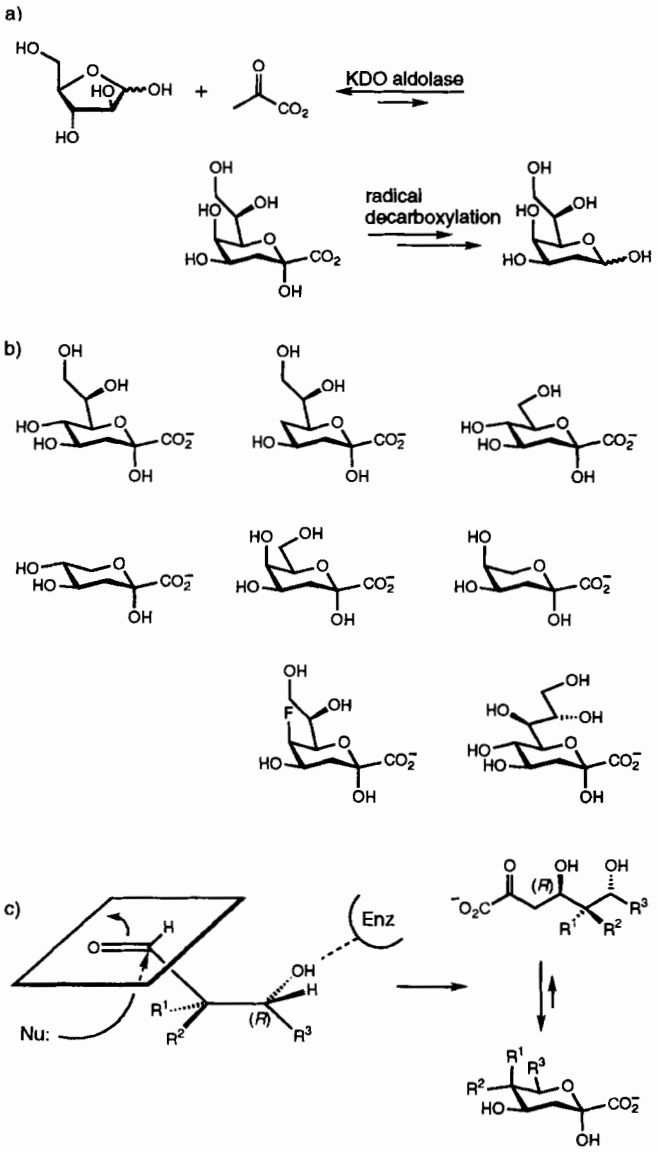


Scheme 26. Synthesis of 9-*O*-Ac-NeuAc by combined use of subtilisin and NeuAc aldolase.

9-*O*-acetyl-NeuAc in about 80% yield. Some other 9-O-acylated NeuAc derivatives may also be prepared in this fashion.[82]

Some other noteworthy examples include the synthesis of the α-methylketoside of an *N*-unprotected NeuAc for use in preparation of *N*-substituted NeuAc.[89] Also, polyacrylamides bearing pendant α-sialoside[95] groups and polymers of C-linked sialosides[96] were prepared and shown to strongly inhibit agglutination of erythrocytes by influence virus. Finally, a derivative of the potent glycosidase inhibitor castanospermine was synthesized starting from a NeuAc-catalyzed addition of pyruvate to *N*-Cbz-D-mannosamine. In this example, a reductive amination step of the aldolase product gives an aza sugar which is a precursor to 3-(hydroxymethyl)-6-epicastanospermine (Scheme 27a).[99] Another five-membered ring aza sugar has recently been prepared based on sialic acid aldolase (Scheme 27b).[100]

The synthesis of NeuAc in vivo is accomplished through NeuAc synthetase,[76] which catalyzes the irreversible condensation of PEP and *N*-acetylmannosamine. Although this enzyme has not yet been isolated and characterized, it may prove synthetically useful in the future, since the forward reaction is favored both kinetically and thermodynamically.

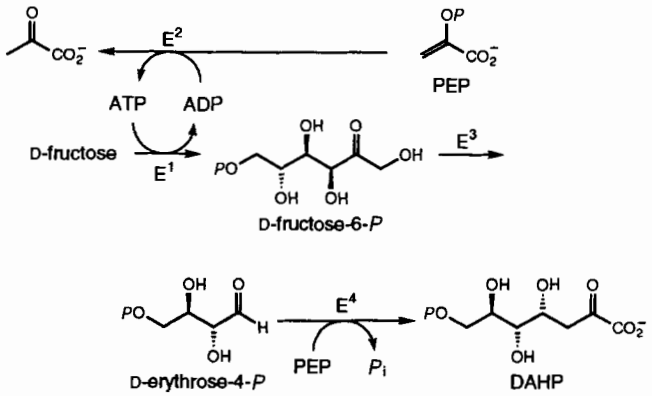


Scheme 27. Synthesis of aza sugars with NeuAc aldolase.

3.6. 3-Deoxy-D-*manno*-2-octulosonate Aldolase [E.C. 4.1.2.23] and 3-Deoxy-D-*manno*-2-octulosonate-8-phosphate Synthetase [E.C. 4.1.2.16]

3-Deoxy-D-*manno*-2-octulosonate aldolase, also known as 2-keto-3-deoxyoctanoate (KDO) aldolase, catalyzes the reversible condensation of pyruvate with D-arabinose to form KDO with an equilibrium constant for the cleavage of 0.77 M^{-1} (Scheme 28). KDO and its activated form CMP-KDO (CMP = cytidine monophosphate) are key intermediates in the synthesis of the outer membrane lipopolysaccharide (LPS) of gram-negative bacteria,[101] so analogs of KDO may inhibit LPS biosynthesis or LPS binding protein.[102–107] KDO aldolase has been isolated and purified from *E. coli*[108] and *Aerobacter cloacae*.[109] Preliminary investigations of this enzyme showed high specificity for KDO for the cleavage, whereas the condensation reaction proceeded with some flexibility; several nonnatural substrates, including D-ribose, D-xylose, D-lyxose, L-arabinose, D-arabinose-5-phosphate, and *N*-acetylmannosamine were reported to be weak substrates (relative rate less than 5% cf. D-arabinose).[108] More recent studies on the substrate specificity showed that the KDO aldolase from *Aureobacterium barkerei*, strain KDO-37-2, accepted an even wider variety of substrates that included trioses, tetroses, pentoses, and hexoses.[110] The enzymes is specific for substrates having *R* configuration at C-3, but the stereochemical requirements at C-2 are less stringent. The C-2 *S* configuration is favored under kinetic control, the C-2 *R* configuration under thermodynamic control. Several aldol addition reactions were conducted on a preparative scale including the synthesis of KDO itself which was obtained in a 67% yield. In each case, the pyruvate attacked from the *re* face of the carbonyl group of the acceptor substrate.

3-Deoxy-D-*manno*-2-octulosonate-8-phosphate synthetase, also known as 8-phospho-2-keto-3-deoxyoctanoate (KDO 8-P) synthetase, catalyzes the irreversible aldol reaction of PEP and D-arabinose 5-phosphate to give KDO 8-P.[111] The enzyme has been isolated from *E. coli*[112] and *Pseudomonas aeruginosa*,[113]

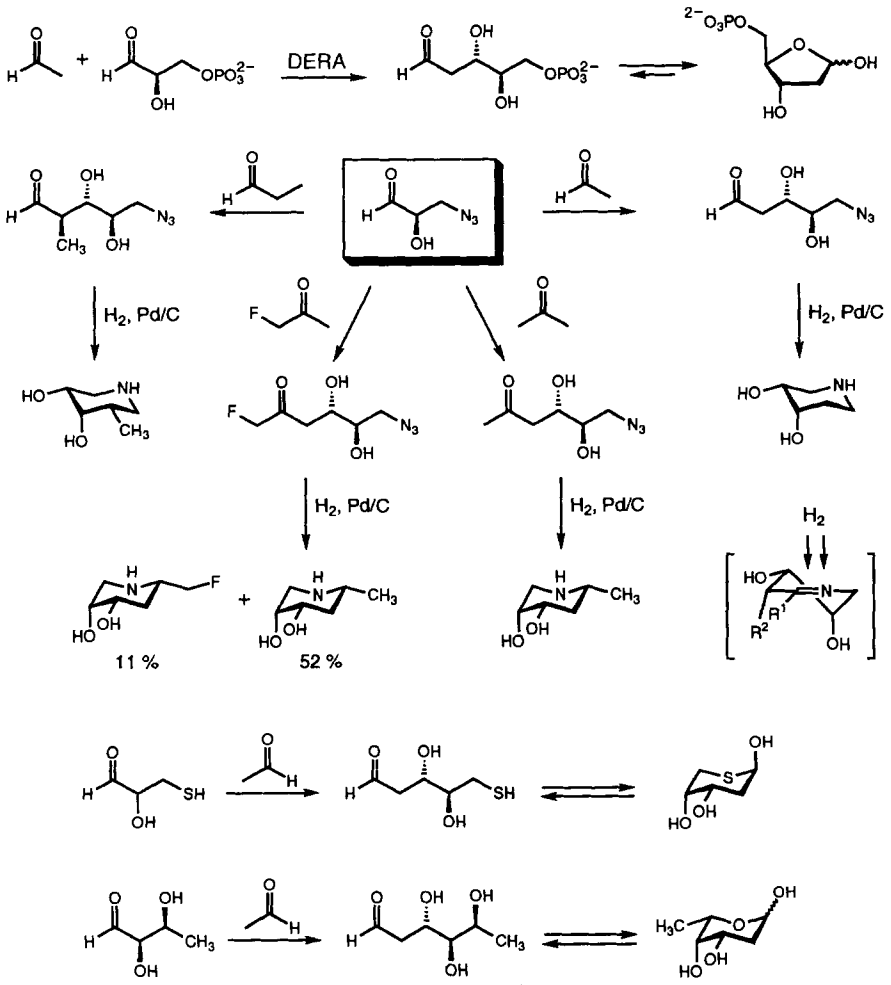


Scheme 28. a) Synthesis of longer chain 2-deoxy sugars with KDO aldolase; b) KDO derivatives synthesized with KDO aldolase; c) mechanism of the KDO aldolase catalyzed reaction: *re* face attack of the nucleophile Nu; the product formed by kinetic control has the *S* configuration (R^1 = OH, R^2 = H), while that favored thermodynamically has the *R* configuration (R^1 = H, R^2 = OH).

and the *E. coli* enzyme has been cloned and overexpressed in *E. coli* and *Salmonella typhimurium*.[114] KDO 8-P itself has been synthesized with KDO 8-P synthetase,[112] and the starting material, D-arabinose-5-phosphate, was generated either by hexokinase-catalyzed phosphorylation of arabinose[108] or by isomerase-catalyzed reaction of D-ribose-5-phosphate.[113] To date, the substrate specificity of KDO 8-P synthetase has not been well investigated, and initial studies indicate this enzyme is very specific for its natural substrates.

3.7. 3-Deoxy-D-*arabino*-2-heptulosonic Acid-7-Phosphate (DAHP) Synthetase [E.C. 4.1.2.15]

DAHP, also known as phospho-2-keto-3-deoxyheptanoate, is a key intermediate in the shikimate pathway for the biosynthesis of aromatic amino acids in plants.[115] In vivo, DAHP synthetase catalyzes the synthesis of DAHP from PEP and D-erythrose-4-phosphate.[116] The enzyme has been cloned and used to synthesize DAHP (Scheme 29).[117] The D-erythrose-4-phosphate necessary for the DAHP synthesis was generated in situ from Fru-6-*P* catalyzed by transketolase in the presence of D-ribose-5-phosphate. The Fru-6-*P* needed for this reaction was generated for D-fructose and ATP catalzyed by hexokinase in the presence of an ATP regeneration system. Further study on this particular enzyme system indicated that it is more efficient and economical to use whole cells containing a DAHP synthetase plasmid.[118] Such a system also provides the other necessary enzymes for the synthesis of DAHP. To date, little study has been conducted to determine the substrate specificity of this enzyme.



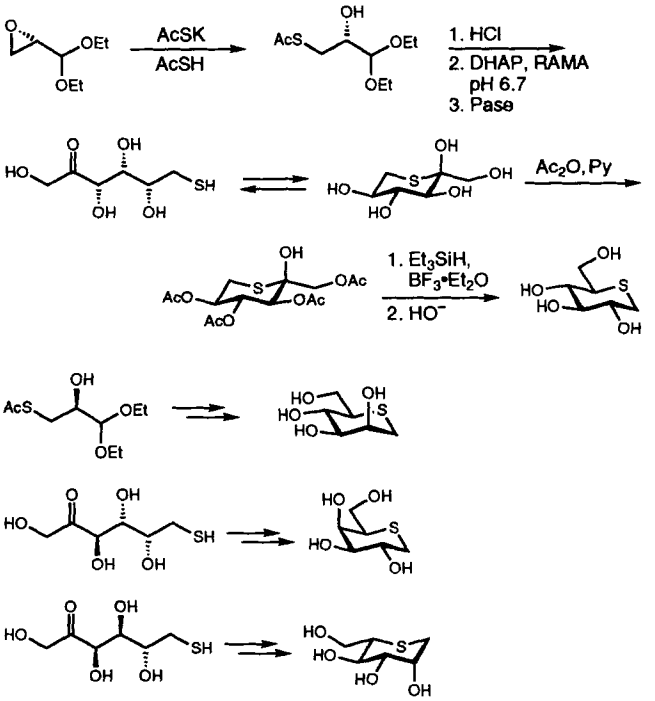
Scheme 29. Multienzyme synthesis of DAHP. E^1: hexokinase, E^2: pyruvate kinase, E^3: transketolase + D-ribose-5-P, E^4: DAHP synthetase.

3.8. 2-Deoxyribose-5-Phosphate Aldolase (DERA) [E.C. 4.1.2.4]

The enzyme DERA[119] is unique among the aldolases in that the donor of the aldol reaction is an aldehyde. In vivo, this enzyme catalyzes the reversible condensation of acetaldehyde and G3P to form D-2-deoxyribose-5-phosphate with an equilibrium constant for the condensation reaction of 2×10^{-4} M (Scheme 30). DERA is a type I aldolase and has been isolated from animal tissues[120] and several microorganisms.[121] The *E. coli* gene encoding the enzyme has been sequenced, subcloned,[122] and subsequently overexpressed in *E. coli*.[123] At 25 °C and pH 7.5 this enzyme is fairly stable and retains 70% of its activity after 10 days.

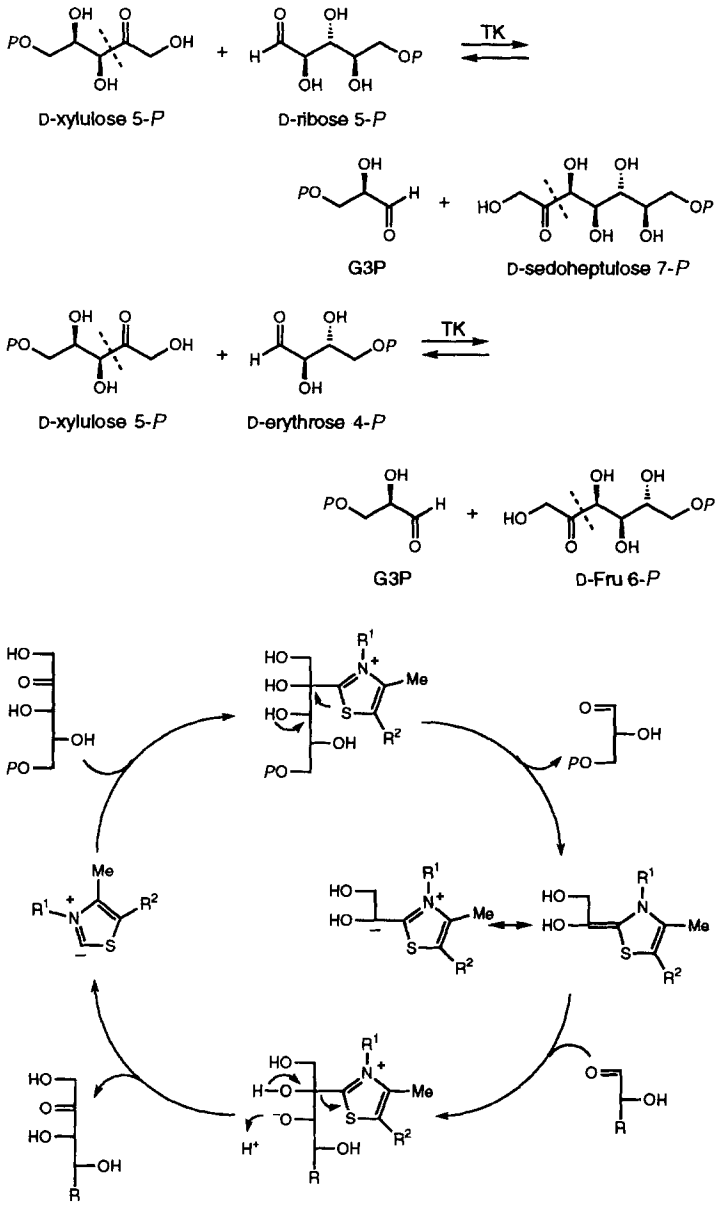
A number of nonnatural substrates are accepted by DERA, and the newly generated chiral center always has the *S* configuration. Specificity studies have been conducted with DERA from *Lactobacillus plantarum* (specific activity of about *6000* $U mg^{-1}$ for condensation)[124a] and *E. coli* (V_{max} = 21 $U mg^{-1}$ for aldol cleavage).[123] The enzyme from *L. plantarum* accepts various acceptor substrates including L-G3*P*, D-erythrose-4-phosphate, glycoaldehyde-phosphate, D-ribose-5-phosphate, D,L-glyceraldehyde, D-erythrose, and D-threose, but not D-ribose or glycoaldehyde.[124b] Only propionaldehyde could replace acetaldehyde as the donor but the rate of reaction

Scheme 30. Synthesis of N-, S-, and O-heterocycles with 2-deoxyribose-5-phosphate aldolase (DERA).



is low. The *E. coli* enzyme, on the other hand, is able to utilize several other donor substrates including acetaldehyde, propionaldehyde, acetone, and fluoroacetone.[123] A number of aliphatic aldehydes, sugars, and sugar phosphates are acceptor substrates. However, in some cases, the rates of the aldol reactions are very low (0.4–1% relative to the natural substrates). Among the several compounds synthesized from the *E. coli* enzymes are a fluoroketose and a trideoxyaza sugar (Scheme 30).

In addition to hydroxy- and azidoaldehydes, thioaldehydes can be used as acceptor substrates, which provides a new route to thiosugars (Scheme 31). Thioaldehydes are also acceptable by other aldolases such as the DHAP-dependent aldolases, and several thioketoses and deoxythiosugars have been prepared.[125] DERA also catalyzes sequential aldol reactions with three aldehyde substrates.[125]

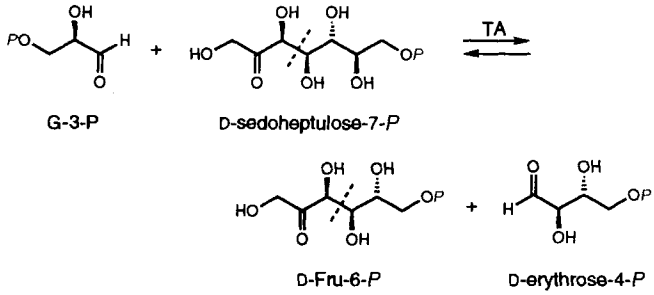


4. Ketol and Aldol Transfer Reactions

4.1. Transketolase [E.C. 2.2.1.1]

One of the enzymes in the pentose phoshphate pathway is transketolase (TK)[126] which reversibly transfers the C-1/C-2 ketol unit from D-xylulose-5-phosphate to D-ribose-5-phosphate to generate D-sedoheptulose-7-phosphate and G3P. The enzyme relies on two cofactors are activity: thiamine pyrophosphate (TPP) and Mg^{2+}. TK from baker's yeast is commercially available,[127] and the enzyme has also been isolated from spinach.[128–129] The enzyme isolated from yeast shows a slightly higher diastereoselectivity (about 100%)[129] than the enzyme from spinach (about 95%), and the newly formed hydroxymethine chiral center always possesses the *S* configuration. In addition to D-xylulose-5-phosphate, D-erythrose-4-phosphate acts as a ketol donor to produce D-Fru-6-*P* and G3P (Scheme 32). β-Hydroxypyruvic acid (HPA) also acts as a ketol donor[130] which is transferred to an aldose acceptor with an activity 4% that of the donor D-xylulose-5-phosphate.[128] One valuable feature of HPA is that once the ketol unit is transferred by TK, carbon dioxide is lost, rendering the overall reaction irreversible. Other analogs of HPA such as 2,3-dioxopropionic acid, 3-hydroxy-2-oxobutyric acid, 2-oxomalonic acid, and 2-oxogluconic acid, are not substrates,[131] but a wide range of aldehydes are ketol acceptors including aliphatic, α,β-unsaturated, aromatic, and heterocyclic alde-

Scheme 31. Synthesis of deoxythiosugars with aldolases. The ketoses in the penultimate and bottom lines are synthesized with Fuc-1-*P* and Rha-1-*P* aldolase as catalysts, respectively.



Scheme 32. Ketol transfer reactions in the oxidative pentose phosphate pathway catalyzed by transketolase (TK), and the mechanism of the catalysis.

hydes.[131-132] The presence of a hydroxy or an oxygen atom at C-2 and/or C-3 accelerates the reaction, while steric hindrance near the aldehyde decreases the rate. β-Hydroxyaldehydes epimeric at C-2 can be efficiently resolved by TK, since only the (2*R*) enantiomers are substrates giving 3,4-D-*threo* products.[131, 133] Beyond the C-2 configuration, the enzyme appears to have no preference for stereochemistry.

A few synthetic examples that employ TK are illustrated in the synthesis of (+)-*exo*-brevicomin[134] and the aza sugar 1,4-dideoxy-1,4-imino-D-arabinitol.[33] Both syntheses involve the condensation of HPA with racemic 2-hydroxyaldehydes in which the ketol units is diastereoselectively transferred to only the D-enantiomer of the aldehyde.

4.2. Transaldolase [E.C. 2.2.1.2]

Like transketolase, transaldolase (TA) is an enzyme in the oxidative pentose phosphate pathway.[126] TA, which operates through a Schiff base intermediate, catalyzes the transfer of the C-1/C-3 aldol unit from D-sedoheptulose-7-phosphate to G3P to produce D-Fru-6-*P* and D-erythrose-4-phosphate (Scheme 33). Although it is commercially available, TA has rarely been used in organic synthesis, and no detailed substrate specificity study has yet been performed. In one application TA was used in the synthesis of D-fructose from starch.[135] The aldol moiety was transferred from Fru-6-P to D-glyceraldehyde in the final step of this multienzyme synthesis of D-fructose.

Scheme 33. Aldol transfer reaction in the oxidative pentose phosphate pathway catalyzed by transaldolase (TA).

Conclusion

The enzymatic aldol addition reaction represents a new, useful method for the synthesis of various sugar and sugar-like structures, which themselves may find use in the study of carbohydrate-mediated recognition or as building blocks for the synthesis of complex carbohydrates. Although only a limited number of aldolases and their reactions are presented in this review, more than twenty different aldolases have been isolated, and several of these have been cloned and overexpressed. Because of the high stereoselectivity and flexibility of the acceptor in these enzymatic reactions, aldolases, and transaldolases are expected to be increasingly used, and the enzymatic aldol reactions will complement many other enzymatic (for example, those based on oxidoreductases and lipases) and nonenzymatic methods available for carbohydrate synthesis.

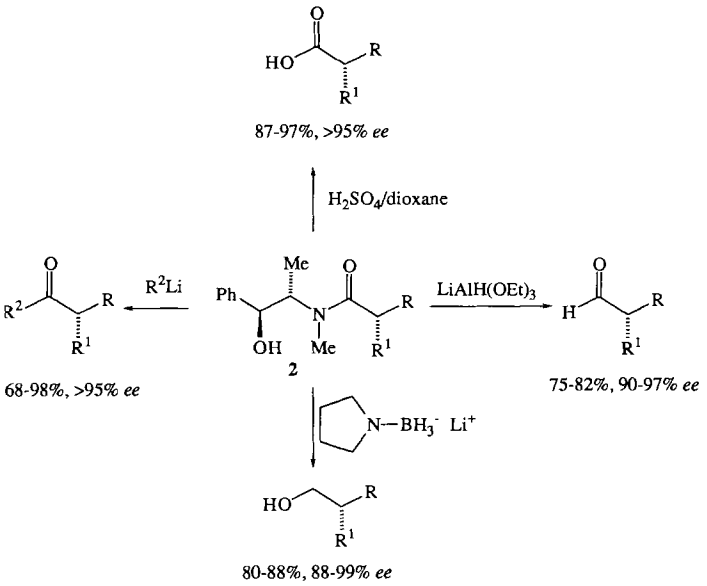
Asymmetric Alkylation of Amide Enolates with Pseudoephedrine and Ephedrine as Chiral Auxiliaries—Unexpected Influence of Additives?**

Karola Rück*

Asymmetric alkylation of carboxylic acid derivatives has been studied intensively for about 15 years.[1] Numerous auxiliaries and tailor-made structures with high steric demands for effective *Re/Si* face differentiation have been synthesized and their efficiency tested.[1, 2] In recent years besides the preparative aspects of enolates, physico-chemical investigations into their structure–reactivity relationships have gained interest.[3] Crystal structure analyses, osmometric measurements, and NMR studies in solution are helpful in the investigation of the factors that may control enolate reactions.[3, 4]

In a recent publication[5] Myers at al. describe a method for alkylating amide enolates having pseudoephedrine as a chiral auxiliary. D-(+)-pseudoephedrine, an industrial product manufactured worldwide in ton quantities, has pharmaceutical applications because of its astringent effect. N-acylation with carboxylic acid chlorides and anhydrides provides crystalline products in high yields (90–95%). After deprotonation with LDA (2 equiv), *N*-acylpseudoephedrine derivatives **1** react with alkyl bromides or iodides efficiently and with high stereoselectivity in the presence of LiCl (6 equiv) in THF (Scheme 1). Even at 0 °C diastereoselectivities of >94% *de* were obtained.



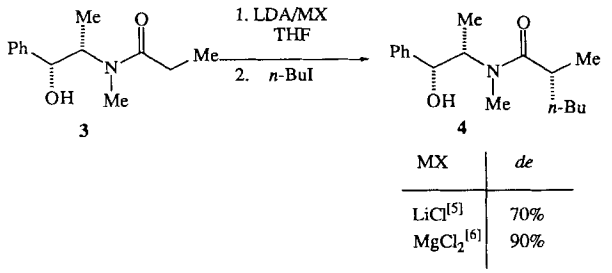
R = Me, Bn, Ph, Cl, *n*-Bu
R^1X = MeI, EtI, *n*-BuI, BnBr

80 - 99%, 94 - >99% *de*

Scheme 1. LDA = lithium diisopropylamide.

α-Alkyl-substituted carboxylic acid derivatives **2** can be isolated in 80–90% yield by simple recrystallization. A wide repertoire of cleavage reactions with recovery of the auxiliary demonstrates the synthetic potential of the pseudoephedrine amides (Scheme 2).

The authors note that the reaction time can be shortened and the conversion increased by addition of LiCl. The concentration



Scheme 2.

of LiCl did not seem to affect the diastereoselectivity of the reaction. Under the same reaction conditions the chiral auxiliary L-(−)-ephedrine led to markedly lower diastereoselectivities. Even in the presence of LiCl the alkylation product from *N*-propionylephedrine (**3**) and *n*-butyl iodide was formed with a diastereoselectivity of only 70% *de*. The work of Myers et al. extends the investigations of Larcheveque et al.,[6] who reported on the alkylation of amide enolates of ephedrine in 1978. Deprotonation of *N*-acylephedrines with LDA in the presence of hexamethylphosphoric acid triamide (HMPA) and subsequent reaction with alkyl halides provided products with diastereoselectivities of < 80:20. Only when $MgCl_2$ was added could diastereomeric ratios of > 95:5 be achieved (Scheme 3). Considering these results, one would not have predicted any great success for experiments with pseudoephedrine. How can the effects brought about by the addition of metal salts be explained?

Since the start of investigations into asymmetric reactions with enolates it has been known that the reactivity and selectivity is influenced not only by the base, but also by the use of cosolvents such as HMPA, and the addition of metal salts or Lewis acids.[1–3, 7] Lithium enolates, in particular, tend to form aggregates by self-assembly.[3] Decisive contributions to the ex-

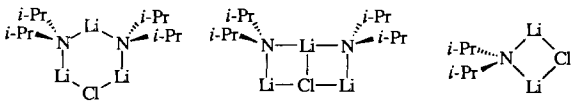
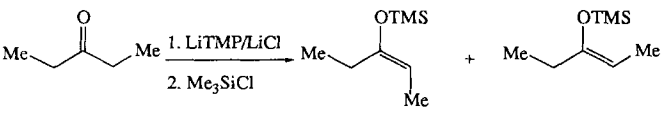
planation of this phenomenon have been made by Seebach et al. by crystal structure analyses of crystalline lithium enolates[8] as well as suggestions regarding the structure of the complexes in solution (Scheme 4).[3b]



Scheme 4. RCH_2Y = alkyl halide.

The method of choice for structure determination in solution is NMR spectroscopy. New investigations based on ^6Li, ^{15}N, and ^{31}P measurements with isotopically labeled samples confirm earlier results and support conclusions about the solvent and concentration-dependent properties of lithium bases such as lithium hexamethyldisilazane (LiHMDS), LDA, and lithium tetramethylpiperidide (LiTMP).[9] Thus ^6Li-^{15}N coupling, for example, permits conclusions to be drawn about the degree of aggregation of $LiNR_2$ derivatives. Even now, despite its carcinogenicity, HMPA is often added to reaction mixtures to increase the reactivity of lithium compounds. Recently, mixed solvates/aggregates between HMPA and lithium bases (LiHMDS, LiTMP, LDA) were proved (Scheme 5).[10-12] The cosolvent does not break up the aggregates[10] but instead promotes formation of open dimers[11] and "triple ions".[12] Correspondingly, exact data

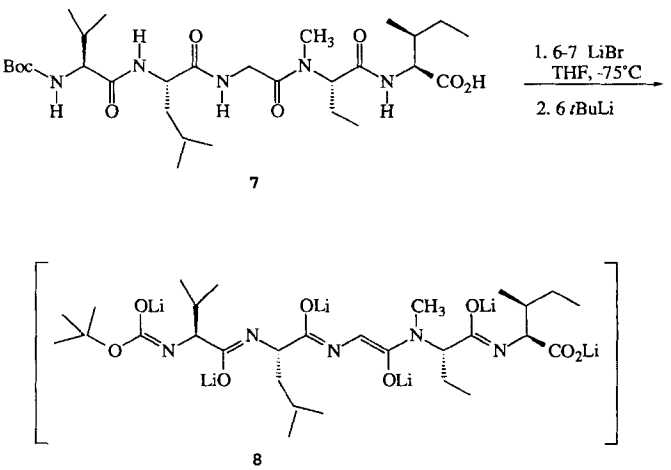


Scheme 5. R'_2N = TMP, R_2N = HMDS.

could be obtained for the structures of complexes of lithium bases and salts and their dependence on the concentration of the added salt (Scheme 6).[9, 10, 13]

Scheme 6.

A further problem in analyzing the reactions of enolates with electrophiles such as alkyl halides is the continually changing concentration of base, enolate, and metal salts during the course of the reaction. For example, stereochemical investigations and trapping experiments on the enolization of 3-pentanone (**5**) with LiTMP in THF demonstrate the consequences of the structural variety of the aggregates (Scheme 7).[10, 13] Whereas at 5% con-



LiCl [equiv.]	E : Z

1-2	10-20 : 1

Scheme 7.

version the E/Z selectivity was 30:1, at greater than 80% conversion an E/Z selectivity of only >10:1 was observed. The addition of 0.3–0.4 equivalents of LiCl led to an E/Z ratio of 50:1; however, further increase in the amount of LiCl to >1.0 equivalents produced results identical to those obtained under salt-free conditions.

In the early 1980s Seebach et al. described similar "nonstoichiometric effects"[3a] for reactions with organolithium compounds.[3a, b, 14, 15] On the basis of these studies they have recently investigated the solubilization and diastereoselective alkylation of polylithiated open-chain and cyclic peptides in the presence of excess lithium salts and bases (Scheme 8).[3b, 16] Glycine and

sarcosine lithium enolates and dilithium azadienolates of peptide lithium salt complexes were alkylated in yields of up to 90% with diastereoselectivities ranging from 1:1 to 9:1.[16]

Davies et al.[17] and Liebeskind et al.[18] also reported on the unusual effect of metal salts[7] in studies on chiral transition metal enolates. In reactions of **9** with aldehydes the stoichiometry of the butyllithium and the added aluminum Lewis acid clearly influence stereoselection (Scheme 9).[18] van Koten et al. conduct-

ed mechanistic studies on the structure–reactivity relationships of zinc and aluminum enolates obtained by the transmetalation of lithium enolates.[19] The aluminum enolate aggregates **12** and **13** were isolated and characterized by crystal structure analysis and NMR spectroscopy (Scheme 10).

12 **13**

Scheme 10.

The work of Myers et al.[5] illustrates the synthetic potential of the use of metal salts (instead of HMPA!) in reactions of enolates. It is not surprising that the mechanism of chiral induction is not yet fully understood; further investigations are necessary.[5] Unanswered questions also remain even for tailor-made, well-established auxiliaries, whose asymmetric induction can be explained convincingly based on the monomer structures and consideration of chelation and steric factors. Thus, we await the results of systematic investigations on the influence of metal salts[7] and new applications of these supposedly well-known reactions.

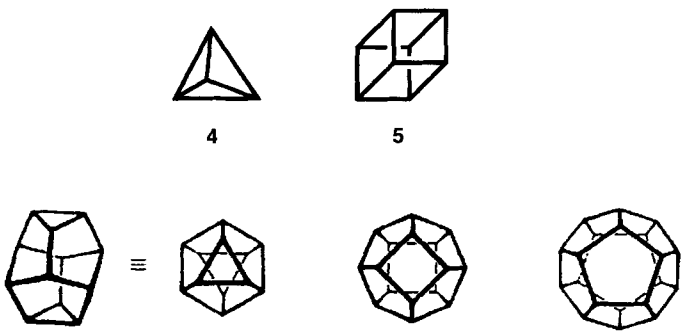
Phosphaalkyne Cyclooligomers: From Dimers to Hexamers—First Steps on the Way to Phosphorus–Carbon Cage Compounds

Rainer Streubel*

The synthesis of 2,2-dimethylpropylidynephosphane **1** (*tert*-butylphosphaacetylene), the first phosphaalkyne stable at room temperature, by Becker et al. in 1981[1] marked the start of a remarkable development of this compound as a synthetic building block in phosphorus heterocycle[2] and complex chemistry.[3] Initial milestones in the oligomerization of **1** were its cyclodimerization in the coordination sphere of cobalt to give the η^4-1,3-diphosphacyclobutadiene complex **2** reported by Nixon et al.[4] and Binger et al[5] in 1986, and the thermal cyclotetramerization of **1** to give the tetraphosphacubane **3** described by Regitz et al. in 1989[6] (Scheme 1). Except for these [2 + 2] cycloadditions of **1**, only reactions with heteroalkenes and higher alkene homologues are known to date.[2, 7]



1 2 3

Scheme 1. The solid black dots here and in the subsequent formula represent *t*BuC groups. Cp = C_5H_5.

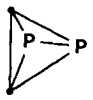
The most recent reports on the synthesis of novel *tert*-butylphosphaacetylene cyclooligomers are presented herein as a progress report in this still evolving field of research. Since parallels with the development of the synthetic chemistry of the acetylene cyclooligomers $(C_2H_2)_n$, from the errors at the outset to the later successes through metal catalysis, are both interesting and instructive, this chemistry will be reviewed briefly beforehand in as far as it concerns the synthesis of highly symmetrical cage molecules of the general formula $(CH)_{2n}$.[8]

The origin of the chemistry of acetylene cyclooligomers dates back to about 1870, to the benzene synthesis of Berthelot[9] and the work of Kekulé.[10] The next important advance was the successful, albeit very laborious, multistep synthesis of cyclooctatetraene (cot) by Willstätter et al. in 1913.[11] The first metal-catalyzed cyclooligomerization of wide-ranging preparative and also theoretical significance was accomplished by Reppe et al. in 1948[12] with the cyclotetramerization of acetylene to cot in the presence of nickel diacetylacetonate. In the following four decades, transition-metal catalyzed cyclizations[13] and cycloadditions[14] of alkynes developed into an extensive and fascinating research area. The homogeneously catalyzed pyridine synthesis[15] through the cyclocotrimerization of alkynes and nitriles is chosen here by way of example. The cyclobutadiene complex of Pettit[16] gave fresh impetus to the debate over the hitherto unsolved problem of "diacetylene" (cyclobutadiene).[17] This chapter was concluded with the matrix-isolation of cyclobutadiene (Chapman et al.[18] and Krantz et al.[19]) in 1973 and the synthesis of tetra-*tert*-butylcyclobutadiene and tetra-*tert*-butyltetrahedrane by Maier et al. in 1978.[20] The kinetic stabilization by the introduction of four *tert*-butyl groups ("corset effect") enabled the isolation and reactivity studies of these *tert*-butyl-substituted cyclobutadiene and tetrahedrane derivatives under standard conditions.[20] Thus, tetra-*tert*-butylcyclobutadiene does not undergo dimerization, unlike the mono-, di-, and tri-*tert*-butyl-substituted cyclobutadiene derivatives.[19, 20]

It is thus already established that tetra-*tert*-butyltetrahedrane, a derivative of the polycyclic hydrocarbon $(CH)_4$ **4**, cannot be obtained through cyclooligomerization; the construction of the hydrocarbon framework follows a multistep synthetic strategy to give the tetra-*tert*-butylcyclopentadienone,[20] from which the tetrahedrane derivative was generated upon irradiation. In the light of this example it is hardly surprising that in the synthetic design of highly symmetrical $(CH)_{2n}$ polycycles, the cyclooligomerization of acetylene derivatives merits a rather insignificant role, which becomes even less important with the complexity of the target molecule.[21] This is illustrated most impressively by the multistep syntheses of cubane $(CH)_8$ (**5**),[22] *p*-[3^2,5^6]octahedrane $(CH)_{12}$ (**6**),[23] *p*-[4^2,5^8]decahedrane $(CH)_{16}$ (**7**),[24] or even dodecahedrane $(CH)_{20}$ (**8**).[25, 26]

4 5

≡



6 7 8

Interest in heteroacetylene cyclooligomers and cyclocooligomers was stimulated by the synthesis of the first azete derivative (azacyclobutadiene),[27] particularly since calculations had predicted a stabilization of the azacyclobutadiene system by the nitrogen atom (decrease in the negative resonance energy).[28] Questions about the possible existence of phosphete and diphosphete derivatives arose, if not earlier, with the syntheses of **2** and **3**. Preliminary ab initio calculations on the problem of phosphaacetylene cyclooligomerization were recently carried out on HC≡P oligomers (HCP → $1/n$ $(HCP)_n$; $n = 2-6$) as models for *t*BuC≡P oligomers. Despite the different theoretical levels,

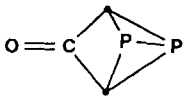
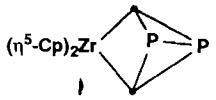
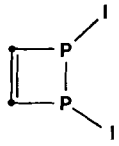
the following trends are emerge: 1) the dimerization of HCP proceeds preferentially in the manner of a head-to-head rather than a head-to-tail dimerization;[29] 2) the relative order of stability is **9** > **10** > **11**;[29-32] 3) energetically, dimerization is distinctly less favorable than tetramerization[31, 32] or even trimerization;[33] 4) the thermodynamic stability of the HCP cyclooligomers improves with an increasing degree of oligomerization *n*.



9

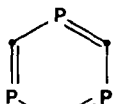


10

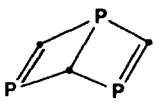


11

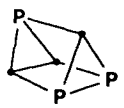
12



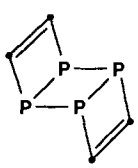
13



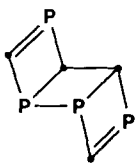
14



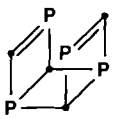
Against the background of these theoretical predictions on the dimerization of the phosphaalkyne HCP, the latest attempts at the synthesis of 1,2- and 1,3-diphosphetes **10** and **11** seem all the more intriguing. Starting from the tricyclic zirconium compound **13**, the synthesis of **10** was realized through a reaction sequence comprising exchange of metal complex fragment, valence isomerization, and reductive elimination; however, under these conditions, **10** dimerizes immediately to the *anti*-tricyclooctadiene **18**.[31] A structural peculiarity of compound **18** is its central, planar P_4 ring. The P–P bond lengths are 221.9 and 223.6 pm with inner ring angles of 89.9 and 90.1°. Further indication of the intermediacy of **10** was obtained by the same research group through the elimination of iodine from **14** with a Pt(0) complex; the end result of this reaction is once again the dimer **18**. Another windfall from the synthesis of tetraphosphacubane **3** was the discovery of compound **19**,[31] which is a new dimer of 1,3-diphosphete **11**. As is also the case for other tetramers,[33] the P=C bonds in **19** are still intact. These, and also the central 1,2-diphosphetane ring, do not, however, exhibit any structural peculiarities. Whereas the dimerization **11** → **20** proceeds analogously to that of 1,3-di-*tert*-butylcyclobutadiene—in terms of a Diels–Alder reaction—the dimerizations **10** → **18** and **11** → **19** observed here reveal an anomaly. Even though the reaction **10** → **18** was classified as a Diels–Alder reaction and **11** → **19** as a dimerization,[32] both recall the problem of the dimerization of tri-*tert*-butylcyclobutadiene on the basis of the stereochemistry of their end products; different radical mechanisms were suggested as an explanation of this two-step process.[20b] This should also be considered when discussing the reaction mechanism for diphosphetes **9** and **10**, since according to the theoretical predictions, the energy separation between the lowest energy singlet and triplet states is smaller for **9** and **10** than for cyclobutadiene.[30]



15

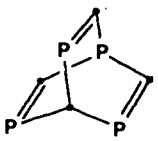


16

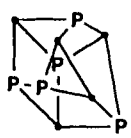


17

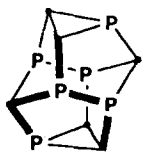
18



19



20



The high efficiency of the metal-controlled synthetic step was once again demonstrated with the synthesis of the 1,3,5,7-tetraphosphabarrelene derivative **21** by Binger et al.[34] Starting from bis(cyclooctatetraene)zirconium and *tert*-butylphosphaacetylene **1**, the zirconium precursor complex for **21** was obtained in 81% yield; mild oxidative decomplexation with hexachloroethane afforded **21** in 88% yield. A η^6-1,3,5-triphosphabenzenezirconium complex was postulated by the authors as a possible intermediate.[35] In this context it is astonishing that no "free" trimers of type **15**–**17** are known to date, although potential precursors such as complexes of **16**[36] have already been reported, and at least the HCP cyclotrimers are thermodynamically more stable than their tetrameric congeners. Possibly more than just a glimmer of hope in this field is the complex-driven 2:1 cyclotrimerization of *tert*-butylphosphaacetylene **1** and acetylene derivatives leading to $1\lambda^3,3\lambda^3$-diphosphabenzene complexes, from which the ligands could be oxidatively liberated.[37]

21

22

23

The synthesis of the first *t*BuCP hexamer **23** with a C_{2h}-symmetric *p*-[3^2,5^6]octahedrane cage is most encouraging and may provide further impetus to the synthesis of phosphorus–carbon cage compounds. In a similar synthesis to that of the known pentamer **22**,[38] compound **23** may, together with other species, be generated from a $[P_2C_3tBu_3]^-/[P_3C_2tBu_2]^-$ mixture by oxidative coupling with $[PtCl_2(cod)]$ (cod = 1,5-cyclooctadiene),[31] though the low yield (ca. 2%) is unsatisfactory and the mechanism has hitherto eluded clarification. The structural relationship between **23** and the cage hydrocarbon **6** is striking and once again demonstrates the potential for interchange between the isolobal fragments CR and P as building blocks in these systems.

As demonstrated by this spotlight on these three current research topics in the synthesis of *t*BuCP cyclooligomers, the oligomerization of pure **1** has advanced "only" as far as the tetramer, but has thrown up a series of highly interesting questions about potential synthetic routes to **9** (possibly from **12**, or perhaps from **18**?) and also the possibility, starting from the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0437 $ 10.00+.25/0

tricyclic compounds **18** and **19**, of striving towards valence isomerization mediated by a heavy metal cation (such as Ag^+) to form tetraphosphacyclooctatetraene (cf. ref. [39]). The synthesis of the first 1,3,5,7-tetraphosphabarrelene **21** ensures that the complex-driven synthesis will also remain an exciting prospect. In particular the synthesis of the *t*BuCP hexamer **23** has opened doors to the development of novel phosphorus–carbon cage compounds. For an understanding of this reaction—do template effects play a role?—as well as the development of any consistent synthetic strategies, a whole series of experiments are, however, still necessary.

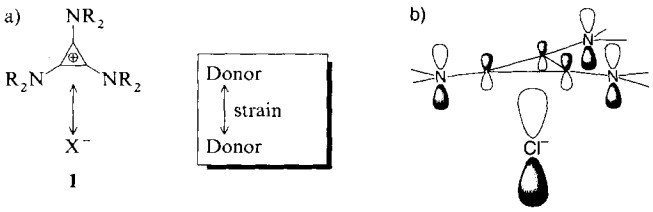
The Consequences of an Electrostatic "Forced Marriage" between Two Electron-Rich Particles: Strained Ion Pairs**



Robert Weiss,* Thomas Brenner, Frank Hampel, and Alexander Wolski

Dedicated to Prof. Paul von Ragué Schleyer on the occasion of his 65th birthday

Two translationally independent electron-rich particles would principally repel each other, unless they had opposing electrical charge and would thus form an ion pair in a suitable solvent. Under these conditions, a novel interionic strain could build up, which would result from the interionic orbital repulsion and should express itself in the increased reactivity of both ionic components towards other reagents. In order to confirm this, salts would have to be synthesized in which electron-rich cations are combined with electron-rich anions. Cations are generally, however, electron-deficient systems; the notable exception to this rule are the tris(dialkylamino)-substituted cyclopropenylium ions, which according to Gerson et al. can be considered as electron-excess systems.[1] These electronic properties are the cause of their unusual behavior in comparison to other carbenium ions: For example, the tris(dimethylamino)cyclopropenylium ion (TDA cation) functions as the donor component in deeply colored charge transfer (CT) salts with tetracyanoethylene (TCNE) or 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ).[2, 3] The TDA cation also behaves as a donor with respect to electron-deficient anions of the type $ElCl_6^-$ (El = Sb, Nb, Ta); in these reactions deeply coloured "inverse CT salts" with one-dimensionally stacked structures result.[4–8] TDA salts can be readily oxidized to give stable isolable radical dicationic salts.[9–11]

If this cation is combined with donor anions (e.g. halide ions), ion pairs of the type **1** are obtained which contain—as required above—two oppositely charged electron-excess systems as electronic antagonists (Scheme 1 a). This is demonstrated in that the $E_{1/2}$ values of about 1.4 V (vs Ag/AgCl; 0.1 N NEt_4Cl/CH_3CN) for the oxidation of both the TDA cation and the chloride ion are almost the same, in spite of the opposing charges of these ions.[12, 13] At the point of maximum electrostatic attraction between the constituent ions of **1** (centrosymmetric arrangement), the orbital repulsion of the two would also have its maximum effect. The latter should be especially pronounced for the corresponding HOMO/HOMO interaction since the interacting orbitals have the same local symmetry (see Scheme 1 b).

We inferred from this, that TDA halides should exhibit a distinctly lower tendency to form inner ion pairs in dipolar aprotic solvents than other known saltlike halides. They are possibly, therefore, highly effective sources of naked halide ions. In order to check this hypothesis, we treated the readily accessible[9] tris(dimethylamino)cyclopropenylium chloride (TDACl) **1a** with acceptors and were thus able to establish a readiness to coordinate which far exceeded our expectations. In this paper, we report on novel compounds with hydrogen bonds whose formation can be interpreted as resulting because of the ion pair strain defined above.

1

Scheme 1. a) **1**: X^- = halide; **1a**: X^- = chloride, R = methyl (TDACl). b) Interacting orbitals involved in the HOMO/HOMO interaction between the ions in **1a**.

We were able to show that defined 1:1 adducts can be precipitated from solutions of carboxylic acids of very different structural types in CH_2Cl_2 in the presence of TDACl **1a**, by addition of nonpolar solvents such as Et_2O or CCl_4. A selection of the products obtained is shown in Table 1. It is noticeable that adduct formation in the homologous series of aliphatic carboxylic acids does not occur for homologues higher than propionic acid. In addition to the decreasing acid strengths of the organic acids, the reason for this can possibly be traced back to the lower lattice energies for increasingly bulky alkyl groups of the organic acid.

Table 1. Selection of TDACl adducts with organic acids and phenols.

acetylenedicarboxylic acid	2:1		

An X-ray structure analysis was carried out for the benzoic acid adduct **2** (Fig. 1). This adduct was obtained in the form of colorless crystals by carefully layering an equimolar solution of the two components in CH_2Cl_2 with Et_2O and allowing the reaction mixture to stand at $-18\,^{\circ}C$.[14] The asymmetric unit of the structure of **2** contains, in addition to TDACl, one molecule of benzoic acid and one molecule of CH_2Cl_2 as solvent. The chloride ion from TDACl forms a strong hydrogen bond with the acidic proton of the benzoic acid (Cl···H 1.988, O–H 0.891, O···Cl 2.870 Å) and a second very weak one to a proton of the solvent molecule CH_2Cl_2 (Cl···H 2.554 Å). The angle of the Cl-H-O unit is 170°.

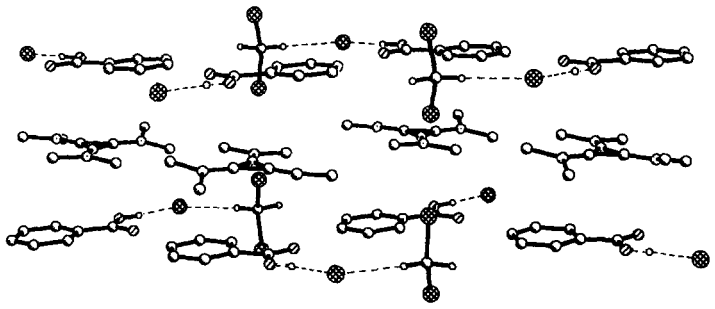

Fig. 1. Crystal structure of **2**. The spheres with lined hatching correspond to O atoms, those with crossed hatching to Cl atoms, those with spots to N atoms; large white spheres correspond to C atoms, small white spheres to H atoms.

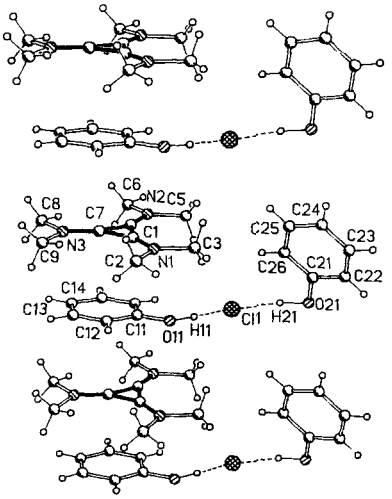

Fig. 2. Crystal structure of **7**. Important distances [Å] and angles [°]: Cl1–H11 2.003(3), Cl1–O11 3.034(9), O11–H11, 1.04(2), Cl1–H21 2.126(8), Cl1–O21 3.086(5), H21–O21 0.96(2); H21-Cl1-H11 120.94.

Although the cyclopropenylium ions and the benzoic acid molecules are stacked in an alternating fashion, the buildup of the structure shows that this is not attributed to π interactions. That the latter is not a prerequisite for the successful formation of adduct can be clearly seen from the tendency of formation of adducts with aliphatic carboxylic acids (Table 1). According to this, the strong hydrogen bond between the carboxylic acid and the Cl^- ion is the decisive energetic factor in the formation of this adduct.

Other excellent chloride donors, such as the salts **3**–**6**, cannot form comparable adducts. This is particularly remarkable in the

$[NEt_4]Cl$ **3** $[C(NMe_2)_3]Cl$ **4** $[N\{P(NMe_2)_3\}_2]Cl$ **5** $[P\{NP(NMe_2)_3\}_4]Cl$ **6**

case of the phosphonium salts **5** and **6**, which according to latest investigations[15] should contain naked chloride ions of high reactivity. The possible conclusion that voluminous spherical chloride salts are not capable of forming such adducts for steric reasons is not valid, because the guanidinium salt **4**, whose planar cation is very similar to that of TDACl as regards geometrical considerations, does not form adducts with hydrogen bonds of the type introduced above.

Analogously, when two molar equivalents of TDACl **1a** are treated with dicarboxylic acids, the corresponding 2:1 adducts are obtained. This adduct formation is accompanied by a break up of the polymeric hydrogen bonds of these carboxylic acids[16] and therefore leads to them dissolving in CH_2Cl_2. These 2:1 adducts can be obtained as stable compounds in a form pure enough for analytical purposes by precipitating with nonpolar solvents. To our knowledge, isolable adducts of carboxylic acids and Cl^- ions which are connected by hydrogen bonds were previously unknown. The driving force of their formation must be considerable, as it requires the annulment of the classical low-energy association patterns of organic acids.[16]

TDACl also forms novel adducts with phenol and phenol derivatives. Some of these adducts are listed in Table 1. The 2:1 phenol/TDACl adduct **7** was obtained in crystalline form by recrystallizing a primary 1:1 adduct of phenol with TDACl from CH_2Cl_2/Et_2O under the above conditions. The result of the X-ray structure analysis is shown in Figure 2.[17] The TDACl and phenol molecules form a stack in which the π-electron systems of the components lie almost parallel to one another. The Cl^- counterion is located in the spaces between the stacks and is involved in two hydrogen bonds which are significantly different as regards their strengths. Judging by the O–Cl distances, one strong hydrogen bond is formed between the chloride ion and the OH group of the phenol molecule sandwiched between two cyclopropenylium ions (O···Cl 3.034, Cl···H 2.003(3), O–H 1.04(2) Å), whereas the corresponding distance in the second hydrogen bond, in which a phenol molecule intercalated in the lattice spaces participates, is 3.086 Å (C···H 2.126(8), O–H 0.96(2) Å). This thus indicates a clearly weaker bonding system.[18] The phenol molecule built into the stack is obviously significantly more acidic than the "free" one. Since both aromatic stack components are classified as electron-excess compounds, a CT arising from the phenol and directed at the TDACl cannot be considered a possible reason for the acidification of the sandwiched phenol. The van der Waals attraction between the π-electron system of the components that would be expected at the interplanar distance of about 3.5 Å is also unable to explain the observed effect. One possible explanation, however, could be found in the assumption that the phenol molecules in the stack are acidified by the electrostatic field effect of the neighboring cyclopropenylium ions. The latter would have a considerably lesser effect on the "free" phenol molecules due to their significantly larger distance from the cationic components.

The coordination behavior of the Cl^- ions in TDACl was not observed until now. We assume that this unusual behavior is due to the release of the ion pair strain defined above which produces an additional thermodynamic driving force.[20]

In addition to the adducts of TDACl introduced in this paper, a whole range of other previously unknown hydrogen-bonded adducts with diverse OH-, NH-, and CH- components were obtained.[21] Related phenomena were also observed with other halide ions. The following publication should be consulted in order to compare the behavior of the analogous iodide salts.[22] Finally, other types of counterion such as N_3^-, OCN^-, or NO_2^-, can be activated in an analogous fashion.

[18] We recently succeeded in determining the X-ray structure of the TDACl/phenol 1:1 adduct. In the previously unpublished structure, the O···Cl distance is 2.936 Å and thus considerably shorter than both the distances in the TDACl/bisphenol adduct. Only one example for a 1:1 H-bonding system is known in the literature between *p*-nitrophenol and the electron-rich methyltri(*p*-nitrophenoxy)phosphonium chloride [19]. The fact that, in spite of the significantly higher acidity of the phenol component ($\delta pK_a \approx 2.5$), an O–Cl distance of 3.015 Å is observed, about 0.08 Å longer than observed in the TDACl/phenol 1:1 adduct, underlines the greater readiness of the chloride ion in TDACl to coordinate.
[19] D. J. Schomburg, *J. Am. Chem. Soc.* **1980**, *102*, 1055–1058.
[20] Of special interest is the structure of TDACl itself. Typically enough, the halides cannot be obtained in solvent-free form. We interpret this as being an indirect indication of the unfavorable coordination relationships in an ionic lattice with electronically similar components, but of opposite charge.

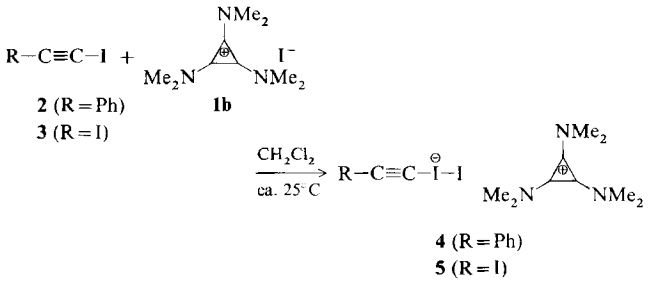
Stable 1:1 Adducts from Iodoacetylenes and Iodide Ions: Ion Pair Strain as an Additional Driving Force?**

Robert Weiss,* Michael Rechinger, Frank Hampel, and Alexander Wolski



Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

The chloride ions of the salt **1a** undergo coordination with unprecedented readiness even with weakly acidic compounds to form novel adducts with hydrogen bonds.[1a] In the case of this salt, there were strong indications that a new type of strain in the corresponding ion pair **1a** is responsible for the unusual reactivity of the chloride ion. In order to check whether this activation is also effective in the case of the "soft" iodide ions, we treated the salt **1b** with organic iodine compounds as soft σ* acceptors. This resulted in the formation of many novel hypervalent adducts.[1b]

1a: X = Cl
1b: X = I

We report here on the reactions of **1b** with 2-iodo-1-phenylacetylene (**2**) as a monofunctional σ* acceptor, and with diiodoacetylene (**3**) as a bifunctional σ* acceptor, in which stable n → σ* adducts between iodide ions and C_{sp}-bonded iodine centers were obtained for the first time.[2] The two 1:1 complexes **4** and **5** were prepared by simply adding tris(dimethylamino)cyclopropenylium iodide (TDAI) (**1b**) to the acetylene component in CH_2Cl_2. Compound **4** was precipitated from the reaction mixture by addition of Et_2O. Recrystallization from CH_2Cl_2/Et_2O delivered **4** in the form of colorless needles which were suitable for an X-ray crystal structure analysis.[4]

2 (R = Ph)
3 (R = I)
1b
4 (R = Ph)
5 (R = I)

The I–I distance of 3.44 Å in the anion of **4** is very long in comparison to that in molecular iodine (2.66 Å),[5] but considerably shorter than the I–I bond length of 4.35 Å which would be expected on consideration of the sum of the van der Waals radii.[5] Compared to the I–I distances of the adducts formed from iodide and neutral compounds with C_{sp^3}-bonded iodine centers (3.57–3.69 Å[6, 7]), the I–I bond in the anion of **4** is very short. It lies in the range of those I–I distances that we found in iodocarbenium iodides with C_{sp^2}-bonded iodine atoms (3.37 Å).[8] The C–I bond of 2.02 Å is longer than that of a noncoordinated iodoacetylene.[9]

One of the remarkable features of **4** is its extremely unusual highly symmetrical ionic lattice (space group *Pbam*), which is made up of an alternating series of purely anionic and purely

[**] This work was supported by the Fonds der Chemischen Industrie.

cationic layers. Both dipole–dipole interactions and hydrogen bonds are determining factors for the buildup of the anionic lattice as a whole (Fig. 1a). In each case, two anions connect to form a head-to-tail adduct by dipole–dipole interactions. These pairs of anions are connected to one another through weak hydrogen bonds between the terminal iodine atom and an *ortho*-hydrogen atom of a neighboring phenyl ring (colored black in Fig. 1a) to give an absolutely planar layer with dense packing.[10]

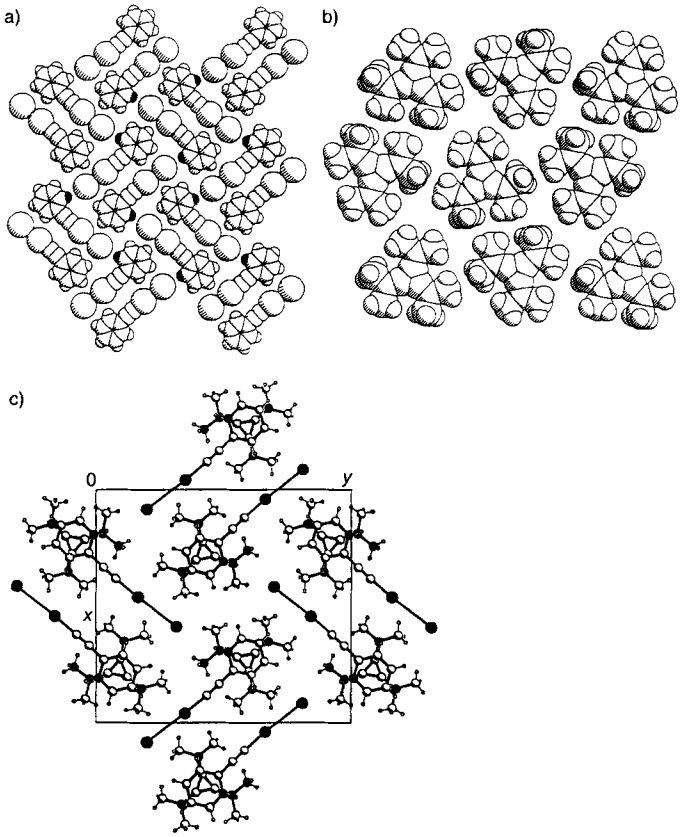

Fig. 1. a) Crystal structure of the anion in **4**. Selected distances [Å]: C–I 2.02, I–I 3.44. b) Crystal structure of the cation in **4**. c) Crystal structure of **4**.

Layers of likewise planar TDA cations lie between the individual anion layers, and are hexagonal closest packed in the lattice (Fig. 1b). Thus, each cyclopropenylium ion is placed directly above or below the phenyl ring of an anion. As in graphite, the distance between the two layers is 3.35 Å.[11] The cohesion of the layers in the lattice is brought about primarily by electrostatic interactions which are superimposed by van der Waals forces. The latter are probably responsible for the stacking of the aromatic components. The crystal structure of **4** is shown in Figure 1c.

In contrast to **2**, diiodoacetylene **3** can function as a bifunctional σ^* acceptor. With the intention of preparing the corresponding 2:1 adduct of TDAI and diiodoacetylene, **1b** and **3** were allowed to react (mole ratio 2:1) in CH_2Cl_2. A colorless precipitate was formed immediately; however, the analysis indicated only a 1:1 adduct of the two components. On cooling the filtrate to $-18\,^{\circ}C$, **5** precipitated with one equivalent of CH_2Cl_2 in the form of colorless needles which were suitable for an X-ray structure analysis.[12] The molecular structure of **5** is shown in Figure 2.

The system TDAI/diiodoacetylene **5** forms a novel hypervalent one-dimensional polymer. The bifunctional σ^*-acceptor centers of diiodoacetylene are each connected by an iodide ion

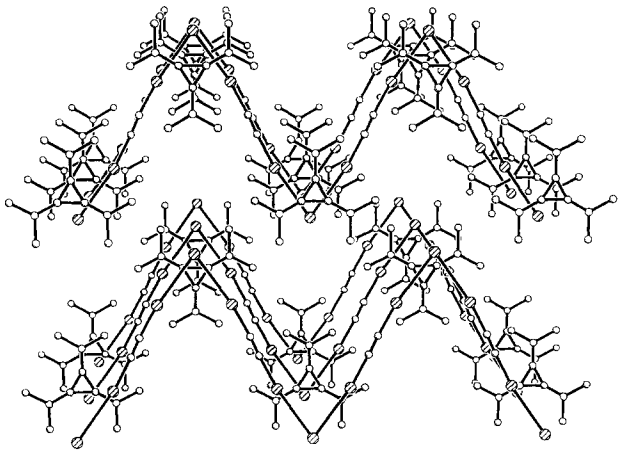

Fig. 2. Crystal structure of **5**. Selected distances [Å] and angle [°]: C–I 2.053, I–I 3.398, I-I-I 69.9; the CH_2Cl_2 molecules are not shown.

which functions as a bifunctional donor with orthogonal lone pairs.[13] The resulting polymeric zigzag chains lie exactly in a plane. Quite remarkable in this is the unusually small bond angle of 70° which occurs on the dicoordinate I^- ion; this value was also determined in $n \rightarrow \sigma^*$ adducts formed from iodide and iodoform;[6, 7] as yet this cannot be explained satisfactorily. Both the I–I bond length of 3.398 Å and the C–I bond length of 2.053 Å lie in the same range as those in the monomeric structure **4**. The TDA cations in **5** are arranged above the partially anionic iodine center at a distance of 3.36 Å and form a stacking structure running perpendicular to the anionic polymer. All cations within a stack are arranged in an eclipsed fashion. A structure that forms part of a "corrugated structure" thus ensues, in which neighboring zigzag chains interlock in the manner shown in Figure 2.

Whereas **4** forms a two-dimensional layer lattice, **5** has only a one-dimensional band structure. Only those TDA cations, which belong to one "anion wire", are found in the same plane. The cations of two neighboring polymeric wires are shifted by 1/2 in the *z* direction. In this way a molecular lattice results which is also found in other TDA salts.[15]

The question posed at the beginning concerning an increased readiness for coordination of the iodide ion in salts **1b**, based on the postulated ion strain, can only be partially answered at the moment. Whereas **2** only forms a hypervalent adduct with **1b**, but not with other iodide donors,[16] **3** can also be successfully treated with alternative sources of iodide.[17] A conceivable reason for this behavior is the known higher σ^* acidity of C_2I_2 compared with that of 2-iodo-1-phenylacetylene (**2**),[18] which could effect a leveling influence with respect to the iodide coordination.

Experimental Procedure

4: **2** (0.15 mL, 250 mg, 1.1 mmol) was dissolved in CH_2Cl_2 (20 mL) and a solution of **1b** (315 mg, 1.1 mmol) in CH_2Cl_2 (5 mL) was added dropwise at room temperature. After the mixture had been stirred for 18 h, the adduct was precipitated by addition of Et_2O, then filtered off and washed twice with Et_2O (10 mL), and dried under vacuum for 8 h. Yield: 520 mg (92%). Single crystals of **4** were obtained by recrystallization from CH_2Cl_2/Et_2O. C, H, N elemental analysis correct; ^{1}H-NMR (400 MHz; $CDCl_3$, 25 °C, TMS): δ = 3.21 (s, 18H, $N(CH_3)_2$), 7.32 (m, 3H, CH), 7.41 (m, 2H, CH); ^{13}C-NMR (100 MHz; $CDCl_3$, 25 °C, TMS): δ = 11.9 (CI), 42.9 ($N(CH_3)_2$), 92.9 (CCI), 117.9, 123.4, 128.1, 128.4, 132.0; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3050 (w), 1545 (ss), 1205 (m), 1070 (m), 1050 (m), 1010 (s), 790 (w), 770 (m), 760 (m), 750 (m), 700 (w), 680 (m); Raman: $\tilde{\nu}$[cm^{-1}] = 3037(w), 2919 (m), 2804 (w), 2147 (s), 2071 (w), 1590 (s), 1210 (s), 1179 (w), 995 (m), 802 (w), 563 (m), 526 (w), 331 (w), 214 (s), 132 (s); MS (70 eV): *m/z* (%): 228 (100) [$C_8H_5I^+$], 127 (8) [I^+], 101 (30) [$C_8H_5^+$].

Tris(dimethylamino)sulfoniumcyclopentadienide $[TAS]^+[C_5H_5]^-$ and Tris(dimethylamino)-sulfoniumpyrrolide $[TAS]^+[C_4H_4N]^-$: Two Isostructural Salts with "Naked" Anions A^- and the "Inverse" Sandwich-Cations $[\{(Me_2N)_3S\}_2A]^+$ ($A = C_5H_5^-$, $C_4H_4N^-$)**

Jens Wessel, Ulrich Behrens, Enno Lork, and Rüdiger Mews*

The cleavage of Si–C bonds by Bu_4NF or similar organic fluorides serves to remove Me_3Si protective groups with subsequent formation of C–H bonds.[1] Intermediates in these reactions are highly reactive carbanions, which, under the reaction conditions chosen, can abstract protons from neighboring molecules. Particularly suitable for the cleavage of Si–element bonds is "TAS-fluoride" (tris(dimethylamino)sulfonium difluorotrimethylsilicate) $[(Me_2N)_3S]^+[Me_3SiF_2]^-$ (**1**),[2, 3] which is readily available in HF-free form; the chemical behavior of the fluorosilicate ion corresponds to that of a "naked" fluoride ion.[4]

From the reaction of TAS-fluoride (**1**) with $C_5H_5SiMe_3$ (**2**) in CH_3CN at $-40\,^{\circ}C$, the TAS salt **3** can be isolated in high yield as a reddish solid [Eq. (a)].

The salt **3** is stable as a solid at room temperature. However, in CH_3CN and CH_2Cl_2, which are suitable solvents at low temperatures, **3** decomposes between $-40\,^{\circ}C$ and $-10\,^{\circ}C$ to give C_5H_6 among the products.

The aim of our investigations was the generation and the detection of "naked" Cp^- ions in the presence of base-free cations (that is, cations not complexed by auxiliary bases such as *N,N,N',N'*-tetramethylethylenediamine (TMEDA)); only two examples of "naked" Cp^- ions have been characterized by structural investigations in transition metal chemistry: $[[Re(NO)(CH_3)(PMe_3)_4]^+[C_5H_5]^-$[6] and $[Rh_2(dmpe)_4(\mu\text{-dmpe})]^{2+}[C_5H_5^-]_2$ (dmpe = 1,2-bis(dimethylphosphano)ethane).[7] In all of the other known structures of cyclopentadienide salts there are interactions between the anions and the cations.[8] This leads to the formation of polymeric structures ("supersandwich" compounds[9]) in alkali metal derivatives; these interactions are not terminated by the complexation of the cations by auxiliary bases.[10]

In TAS salts there are practically no cation–anion interactions in the solid state.[11] Therefore, the TAS^+ ion seemed particularly suitable for the generation of "naked" Cp^- ions. The crystal structure of **3** (Fig. 1) and the view of the crystal lattice (Fig. 2) show that the TAS cyclopentadienide can best be

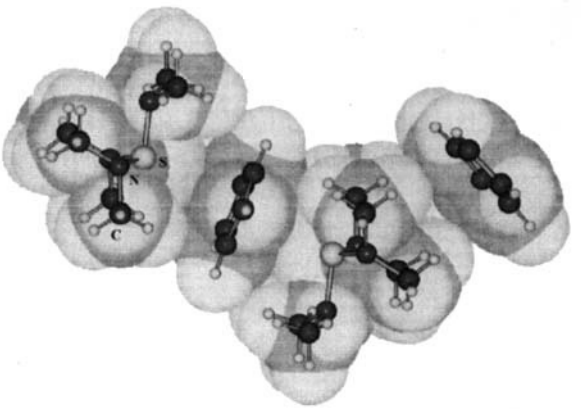

Fig. 1. Crystal structure of **3** (SCHAKAL drawing).

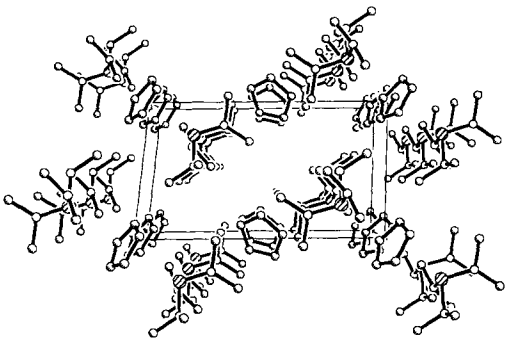

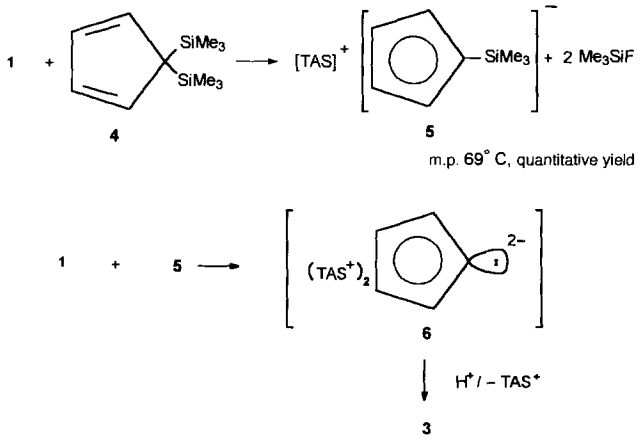

Fig. 2. View of the crystal lattice of **3**.

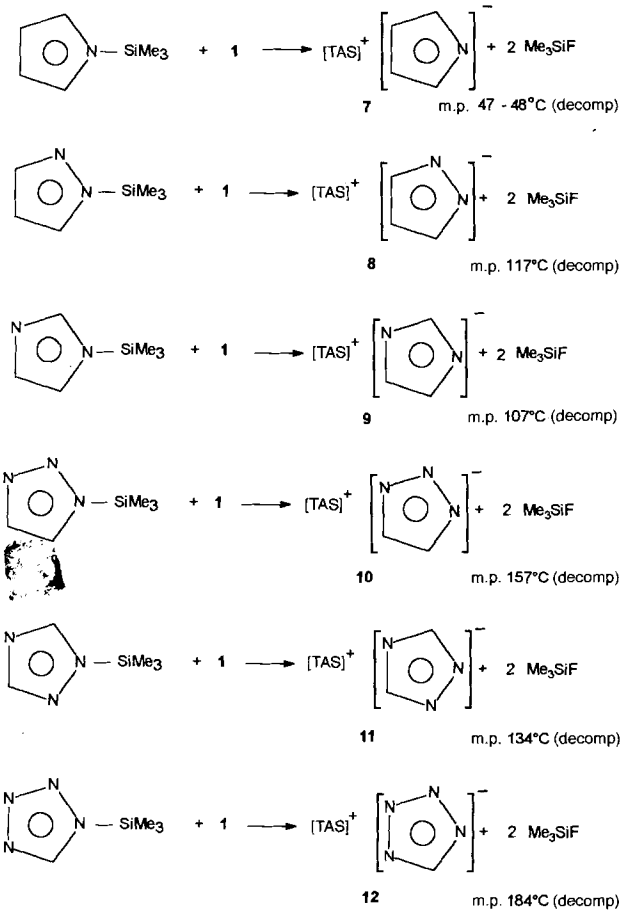
described as a $[(TAS)_2Cp]^+$ cation and a "naked" Cp^- anion.[12] The $[(TAS)Cp(TAS)]^+$ unit can be regarded as an "inverse sandwich". For this type of structure with a Cp unit in the center, there is only one example so far, a lithium compound.[13]

The solid-state structure of **3** can be understood from the anisotropy of the TAS^+ ions. As in the alkali metal cyclopentadienides,[14] the bonds in $[(TAS)_2Cp]^+$ can be regarded as anion–cation Coulomb interactions between the sulfonium centers and the central Cp^- ion, similar to the interactions in contact ion pairs (CIP). Because of the size of the sulfonium center these interactions are weak. The dimethylamino groups in the $(Me_2N)_3S^+$ ions can, again analogous to the chemistry of metal ions, be regarded as ligands or as solvating solvent molecules which separate the cation from the anion. The even weaker interaction between the $[(TAS)_2Cp]^+$ units and the "naked" Cp^- ion is similar to solvent-separated ion pairs (SSIP).[14]



Not only the "naked" Cp^- anion, but also the $[(TAS)Cp(TAS)]^+$ cation lie on symmetry centers of the space group. This results in disorder of both Cp rings. The distances from the sulfonium centers to the middle of the enclosed Cp ring are 313.1(2) and 322.2(2) pm. These values differ somewhat because the mid-point of the Cp ring does not coincide exactly with the center of symmetry. The S–C distances vary between 330.0(4) and 341.0(4) pm, the sum of the van der Waals radii (of S and C) is 350 pm. The distance between the "naked" Cp ring and the sulfur atom of the cationic center is 512.9(2) pm. Both Cp rings were refined as perfect pentagons. The C–C distance of the enclosed Cp^- ring refined to 138.5(3) pm, and that of the "naked" Cp^- ring to 139.6(4) pm.[15] The C–C distances determined here for the C_5H_5 anion are in agreement with the results of ab initio calculations (d(C–C) = 139.3 pm).[16] Furthermore, these calculations indicate that the interactions with positive metal centers such as Li^+ lead to an increase in the C–C distance (141.7 pm); in transition metal derivatives the distances are of the order of 140–143 pm.[17]

The synthesis of $[TAS^+]_2[C_5H_4]^{2-}$ (**6**) via the stable intermediate $[TAS]^+[C_5H_4SiMe_3]^-$ (**5**) failed as a result of the high basicity of the anion of **5**. Thus, only **3** was isolated (Scheme 1).

Scheme 1.

However, $[TAS]^+[C_4H_4N]^-$ (**7**), which is isoelectronic to **6**, can, as for all the other azolide salts, be prepared by cleavage of the Si–N bonds from the corresponding silylated azoles in high yields (92–95%) (Scheme 2).

Scheme 2.

The salts **7**–**12** were produced as pure compounds and unambiguously characterized by structural investigations. The pyrrole salt **7** crystallized in an analogous manner to **3** as $[(TAS)_2pyr]^+[pyr]^-$ (Figs. 3 and 4) in the space group $P\bar{1}$ with almost identical

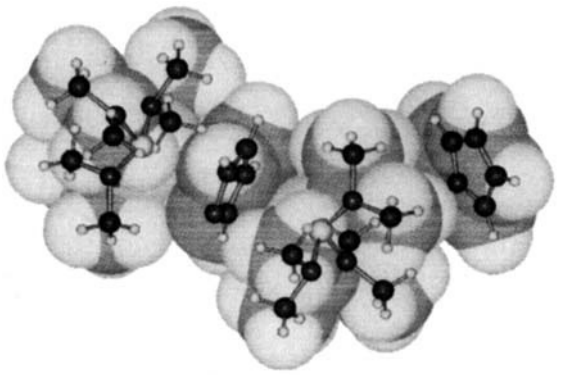

Fig. 3. Crystal structure of **7** (SCHAKAL drawing).

lattice constants.[21] Exact bond lengths for the $C_4H_4N^-$ ion cannot be given, since here, in addition to the disorder described for **3**, there is also a statistical distribution of CH/N. The distances of the sulfonium centers to the middle of the enclosed pyrrole ring are 314.1 and 319.5 pm; the shortest distance from the "naked" $C_4H_4N^-$ ring to the nearest sulfonium center is 508.5 pm.

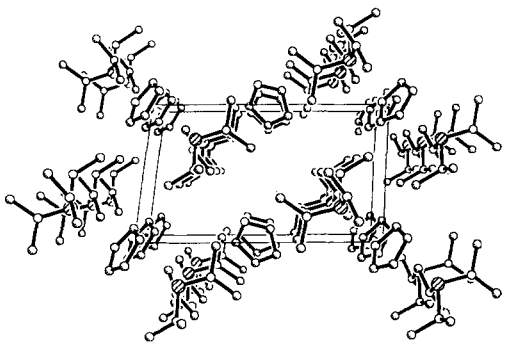

Fig. 4. View of the crystal lattice of **7**.

In **8** there are ion pairs with only weak interactions (distance sulfonium center–center of ring 315.4 pm), in **9**–**12** discrete anions and cations. Hitherto hardly any structural determinations of free azolide ions have been undertaken, and only the structure of the hydrate $Na(HCN_4)\cdot H_2O$[22] is described. In this salt the bond lengths are influenced by strong N···H···O hydrogen bonds. There seems to be very little disordering of the anions in the salts **8**–**12**: only for the imidazolide **9** (Fig. 5) are there larger standard deviations.[23]

As our investigations of **7** show, the TAS azolide salts seem to be considerably more stable than **3**. Elemental analysis and NMR spectra of the solutions indicate that after a day in CH_3CN or CH_2Cl_2 at room temperature there is no noticeable decomposition. Since the TAS azolides are readily soluble and have a relatively high stability they could be interesting as preparative reagents.

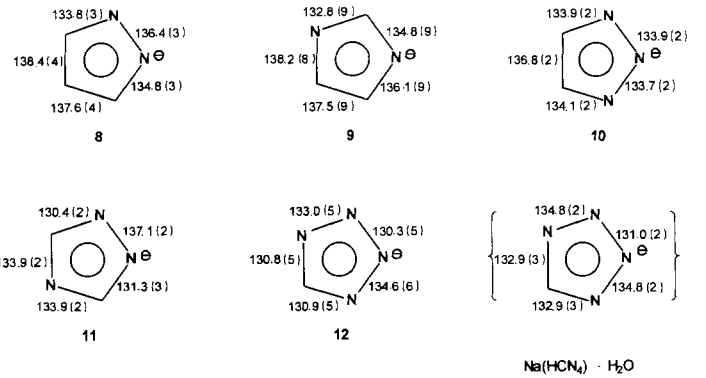

Fig. 5. Experimental bond lengths [pm] in the anions of the salts **8**–**12**. The structure of the anion in $Na(HCN_4)\cdot H_2O$ [21] is included for comparison.

Experimental Procedure

3: In a dry box, TAS-F (**1**; 1.30 g, 4.72 mmol) was placed into a double-tube vessel equipped with a Teflon tap, and $CpSiMe_3$ (**2**; 1.40 g, 10.0 mmol) [24] was introduced by syringe under N_2 into the second tube. CH_3CN (10 mL) was condensed as solvent into the tube containing the $CpSiMe_3$ at −196 °C under vacuum. The reaction vessel was warmed to −40 °C, and the solution of **2** in CH_3CN slowly poured onto **1**. To prevent decomposition reactions, the temperature of the reaction solution must not exceed −40 °C. After 1 h the Me_3SiF produced was removed under vacuum, the reaction solution carefully layered with diethyl ether (50 mL) and stored in a cryostat free from vibrations at −40 °C for two weeks. By decantation of the mother liquor from the crystals, the majority of the starting materials and decomposition products could be removed. After evaporation of the solvent, the crystals were washed with ether, and volatiles were quantatively removed under vacuum. Yield: 1.03 g (95%); m.p. 138 °C (dec.); ^1H NMR (CD_3CN, −40 °C): $\delta = 2.85$ (s, 18H; $[(CH_3)_2N]_3S^+$), 5.53 (s, 5H; C_5H_5).

7: Prepared in a similar manner to **3** from $C_4H_4NSiMe_3$ (1.80g (15.0mmol) [25] and **1** (1.50g, 5.45mmol). Yield: 1.10g **7** (93%, based on **1**); m.p. 47–48 °C (dec.); ^1H NMR (CD_3CN, 30 °C): $\delta = 2.85$ (s, 18H; $[(CH_3)_2N]_3S^+$), 6.08 ("t", 2H (3,4)), 6.76 ("t", 2H (2,5)); $^{13}C\{^1H\}$ NMR (CD_3CN, 30 °C): $\delta = 38.6$ ($[(CH_3)_2N]_3S^+$), 104.7 (C(3,4)), 126.8 (C(2,5)).

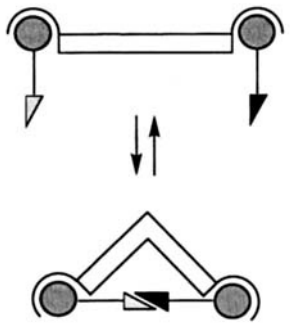
Light-Switchable Catalysis in Synthetic Receptors**

Frank Würthner and Julius Rebek, Jr.*

Controlling physical or chemical properties of molecules by external signals, for example light, is a popular subject of current research.[1–3] Much work is inspired by natural systems that use light as an energy source (e.g. in photosynthesis, in bacteria ion pumps) or as information to regulate biological processes (e.g. photomovement, photomorphogenesis).[2] Specifically, in the process of vision light-irradiation causes a *cis* → *trans* isomerization of retinal that induces a conformational change in the conjugated protein. The change of molecular shape initiates an enzymatic cascade that ultimately leads to a neural response.[4]

Recently, we have examined coupling reactions between aminoadenosine **1** and *p*-nitrophenyl ester **2** to give amide **3**. This reaction can be catalyzed by template molecules containing two adenine receptors linked by aliphatic or aromatic spacers.[5] The adenine receptor itself consists of two imides derived from Kemp's triacid attached to a carbazole moiety. These provide high binding affinities by chelating the purine nucleus ($K_a = 10^4$–10^5 M^{-1} in chloroform) and result in a predictable structure for the complex.[6]

Here we describe the properties of a new synthetic receptor **4** that mimics the first two steps of the vision process—the activation of a catalytic functionality by a light-induced change in molecular geometry (Fig. 1).[7]



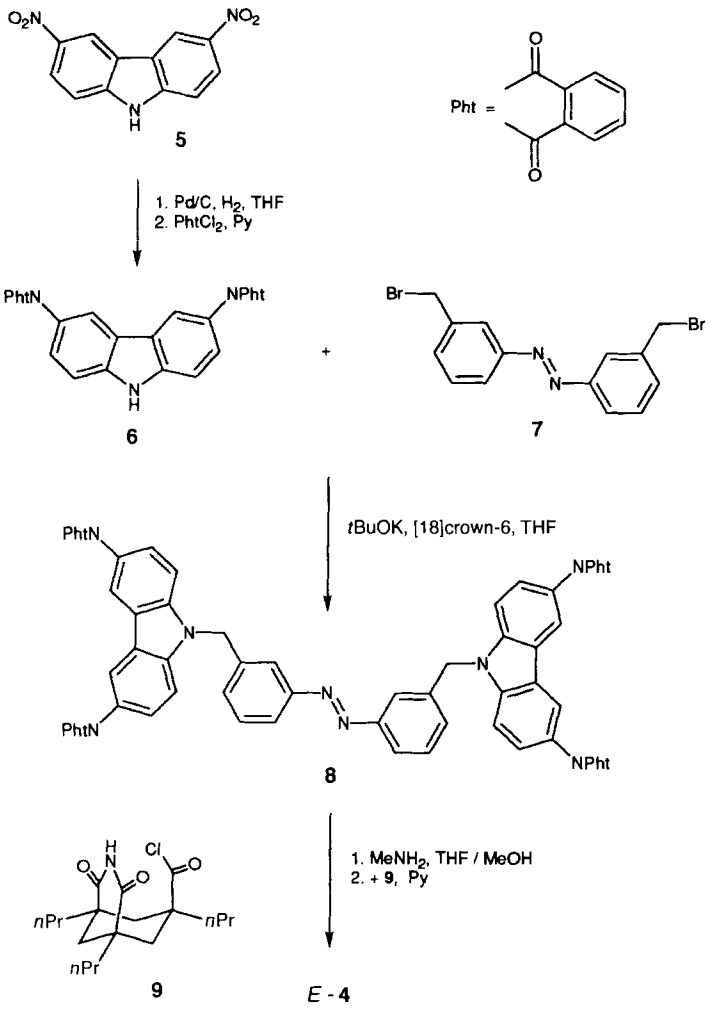


Fig. 1. Schematic representation of the switching by means of a structural change that brings the reactive groups (triangles) in close proximity.

The *trans*-azobenzene receptor **4** was prepared as shown in Scheme 1. Reduction of 3,6-dinitrocarbazole[8] with hydrogen on 10% Pd/C gave crude 3,6-diaminocarbazole, which was treated with phthaloyl dichloride to form the phthaloyl-protected diamine **6** in 80% yield. Two equivalents of **6** were treated with potassium *tert*-butoxide and alkylated with bis-3,3′-(bromomethyl)-azobenzene (**7**)[9] to give **8** in 40% yield. Deprotection of **8** with methylamine in THF/methanol and subsequent treatment of the resulting tetraamine with a slight excess of the tripropyl

Scheme 1. Synthesis of **4**; Py = pyridine.

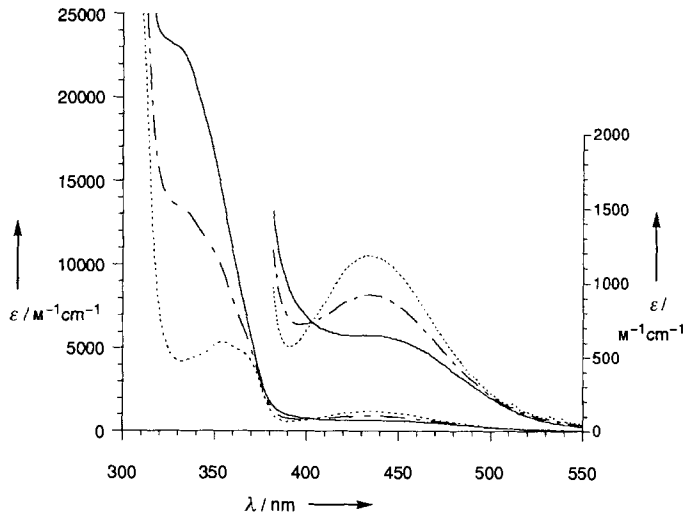

Fig. 2. UV/Vis spectra of receptor **4** in chloroform: *E*-**4** (——), *E*/*Z*-**4** in photostationary equilibrium at 366 nm (–·–·–), calculated spectrum of *Z*-**4** (·····).

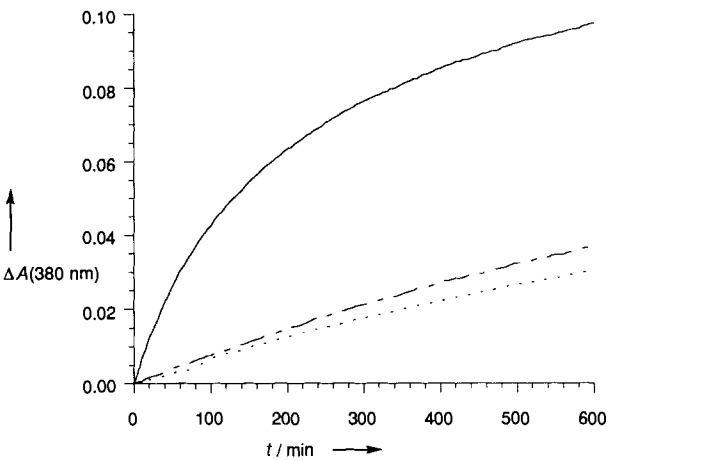

Fig. 3. Changes in absorption ΔA during the reaction of **1** and **2** in the absence of **4** (·····) and in the presence of one equivalent of *E*-**4** (–·–·–), and *E*/*Z*-**4** in its photostationary equilibrium at 366 nm (——).

imide acid chloride **9** in boiling pyridine gave receptor *E*-**4** in 55% yield.[10]

Receptor **4** showed the typical switching behavior of an azobenzene:[11] Depending on the wavelength chosen, different photostationary equilibria can be obtained which are interswitchable. Irradiation with light of wavelength of 366 nm yields a 1/1 mixture of *E* and *Z* isomer, whereas visible light causes conversion to an equilibrium with an *E*/*Z* ratio of 70/30.[12]

These mixtures exhibit high stability at room temperature in the dark, but may be converted to the pure *E* isomer at elevated temperature.[13] Compared to 3,3′-dimethylazobenzene, which exhibits a composition of 90% *Z* and 10% *E* isomer in its photostationary equilibrium at 366 nm, **4** shows a reduced range of interconversion. This may be attributed to absorption bands of the carbazole chromophore, which alter the ratio of excited *E* isomer to excited *Z* isomer by means of their absorption coefficients $\varepsilon(E)$ and $\varepsilon(Z)$. The remaining absorption band at 340–380 nm in the calculated spectrum of *Z*-**4** is characteristic for 3,6-bis(acylamino)-substituted carbazoles (Fig. 2).

The effect of receptor **4** on the rate of reaction between **1** and **2** is shown in Figure 3 and in Table 1.[14] The *E* isomer of **4** has a negligible effect on the reaction rate, but the *Z* isomer (in a 1/1 mixture with the *E* isomer) proved to be an efficient catalyst. Thus irradiation of **4** with light of wavelength 366 nm causes nearly a tenfold enhancement in the coupling rate. The addition of 9-ethyladenine or product **3** as competitive binders causes a drastic decrease of the catalytic activity of the template (Table 1).

These observations support the intermediacy of a termolecular complex composed of **1**, **2**, and **4** which is responsible for the catalytic effect. With adenine–receptor binding constants of 10^4–10^5 M^{-1}[5, 6] the amount of the reaction partners **1** and **2** in the termolecular complex [**1**·**2**·*Z*-**4**] at the beginning of the experiment is estimated to be in the range of 5–10%. These termolec-

Table 1. Effect of one equivalent of template **4** having different *E*/*Z* ratios on the initial rate of amide bond formation between **1** and **2** [14].

E/*Z* Ratio	Additives[a] (equiv)	Acceleration[b]
100/0	-	1.2
70/30	-	6.3
50/50	-	10.5
50/50	**3** (1)	1.7
50/50	9-EA (10)	1.9

[a] Competitive inhibitors; 9-EA = 9-ethyladenine. [b] Increase of the initial rate compared to that of the uncatalyzed reaction ($k = 1.5 \times 10^{-8}$ M min^{-1} [5]). All experiments were performed at lease twice. The statistical errors are <10%.

ular complexes produce high effective molarities which may result in fast reactions if the geometry of the supramolecular assembly is favorable and brings the two substrates close together. Both space-filling models and calculations (MacroModel) indicate several conformations for the termolecular complex [**1**·**2**·*Z*-**4**] in which the reactive groups of **1** and **2** are in close proximity, leading to a tetrahedral reaction intermediate that is tightly bound. For the more extended *E* isomer, however, reactive conformations are hardly accessible without energetically unfavorable distortions of the termolecular complex.[15] Hence, the geometrical isomerization of template **4** induced by light allows the control of its catalytic activity.

In summary, the system provides an example of photocontrolled template catalysis. The performance of this system mimics the integration of photoresponsive and catalytic functions in biological systems like rhodopsin, the natural phototrigger in the vision process.

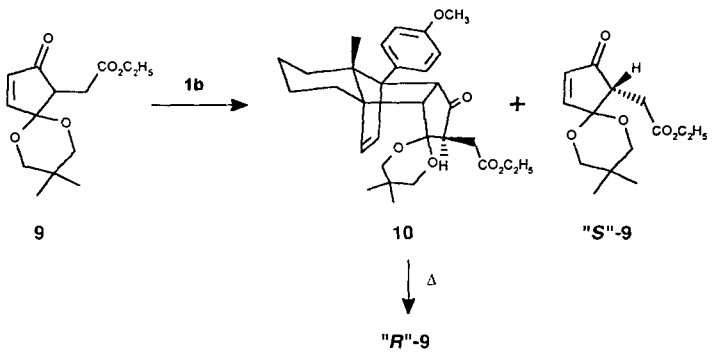
[10] To obtain pure *E*-**4**, the last step of the reaction and the chromatographic purification were performed under exclusion of light. All new compounds were characterized by ^{1}H NMR spectroscopy (300 MHz) and high-resolution mass spectrometry.
[11] a) H. Rau, *Angew. Chem.* **1973**, *85*, 248–258; *Angew. Chem. Int. Ed. Engl.* **1973**, *12*, 224–235; b) H. Rau in ref. [1], pp. 165–192; c) J. Griffiths, *Chem. Soc. Rev.* **1972**, *1*, 481–493.
[12] Irradiation at 366 nm was performed with a 4 W UV lamp. At a concentration of 0.05 mM **4**, the photostationary equilibrium was obtained after about 5 min. The *E*/*Z* ratio was determined by ^{1}H NMR spectroscopy (300 MHz).
[13] The rate constant of the thermal reisomerization at 25 °C in chloroform is less than 3×10^{-5} min^{-1}. Therefore absorption changes due to $Z \rightarrow E$ interconversion were negligible under the experimental conditions of our catalysis investigations.
[14] The experimental conditions are the same as those described in ref. [5]: c(**1**) = c(**2**) = 0.05 mM, c(Et_3N) = 4 mM at 25 °C in chloroform. Under these conditions hydrolysis of **2** is negligible and the reaction can be monitored spectrophotometrically at 380 or 390 nm following the release of *p*-nitrophenol.
[15] The slight accelerating factor may be due to a small catalytic effect of the template on the reactivity of the *p*-nitrophenyl ester **2**.

Discrimination between Enantiotopic Groups in a Diels–Alder Reaction**

Peter G. Jones, Hilmar Weinmann, Ekkehard Winterfeldt*

Dedicated to Professor H. M. R. Hoffmann on the occasion of his 60th birthday

While studying the totally regioselective cycloadditions of enantiomerically pure cyclopentadienes of type **1**,[1] we observed a marked degree of chiral recognition when alkyl-substituted 2π electron systems such as **2**, **4**, and **9** were used as dienophiles. In the case of **2** and **9**, only the (*R*) enantiomer was incorporated into the adduct (see **3** and **10**); the (*S*) enantiomer was recovered with high enantiomeric purity (>98% *ee*) (Schemes 1 and 2).[2, 3]



Scheme 1.

These results show clearly that the oxygen atom is less sterically demanding than a CH_2 group in the addition reaction (see **4**), although one would otherwise have expected electronic repulsion between the π electrons of the double bond and the lone

Scheme 2.

pairs of the oxygen. Following the assumption that the reaction represents a general and reliable technique for discriminating between the faces of a molecule, we chose the spirolactone **11** as a promising dienophile for the following reasons: firstly, it is easily prepared in large quantities;[4] secondly, based on the above considerations we expected regioselective and facially selective cycloadditions with differentiation between two enantiotopic groups, leading to the Diels–Alder adduct **12** (Scheme 3); finally, a diastereoselective epoxidation and subsequent retro-Diels–Alder reaction should afford the spirolactone **14**, which displays structural analogies to the manumycin antibiotics.[5]

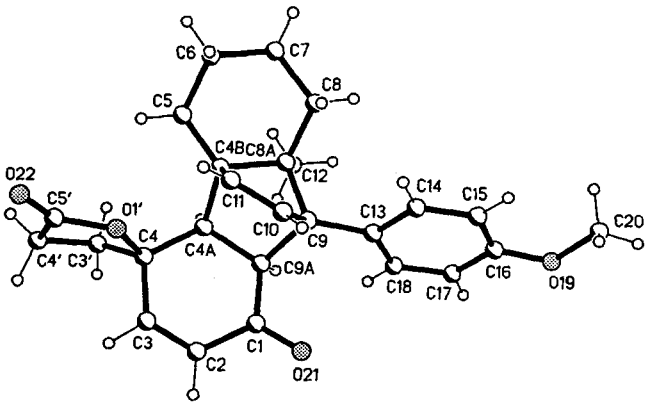
At this point we should stress that this differentiation between enantiotopic groups allows the entire prochiral starting material to be converted to a single enantiomer in a predictable way. Additionally, since *ent*-**1** is also available, both enantiomers of spirolactone **14** and its derivatives are available for studying the relationship between absolute configuration and biological activity. It may be mentioned in passing that the current results also contribute to the discussion as to the "size" of a lone pair.[6] After much controversy it seems that arguments in favor of such steric requirements should be reinterpreted in terms of solvation effects, a phenomenon that may safely be excluded in our case.

We were indeed able to demonstrate that **11** reacts with **1b** to form a single cycloadduct in high yield (92%). If one is guided by a recent review article concerning the discrimination between enantiotopic groups,[7] this is the first such example from the area of cycloadditions.

Although the configuration of **12** had at this stage not been rigorously demonstrated despite complete spectroscopic data, we convinced ourselves of the perfect diastereoselectivity of the epoxidation providing **13** and of the release of the epoxylactone **14** (for which biological activity was unambiguously demonstrated[8]) by flash vacuum pyrolysis.

With respect to the question of electronic repulsion, we have also studied the cycloaddition of the spiroether **15**[4] (Scheme 3) and again obtained a single cycloadduct, although the electron density at the ether oxygen of this compound should be higher. The spectroscopic data, including nuclear Overhauser effect (NOE) measurements, again failed to provide completely unambiguous proof of the configurations, and although we were able to reduce selectively the double bond of the unsaturated ketone by using a variant of the ultrasound-promoted Luche reduction,[9] the spectroscopic data of compound **17** still left doubt as to the absolute configuration.

Since we were interested in configuration–activity studies, we had already prepared the adducts *ent*-**12** and *ent*-**17** from the (*R*)-**1**; this series provided crystals of compounds *ent*-**12** and *ent*-**17** suitable for X-ray structure analyses. The structure analyses were carried out at low temperature because of the conformational flexibility of the five-membered spiro rings,[10] and indeed provided the final structural proof (Fig. 1).



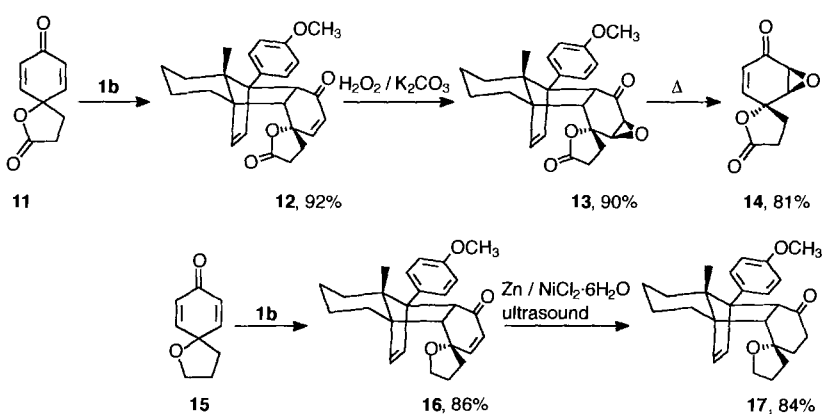


Fig. 1. Structure of the spirolactone adduct *ent*-**12** in the crystal.

Experimental Procedure

Spirolactone adduct **12**: A solution of 240 mg (1 mmol) of diene **1b** and 164 mg (1 mmol) of spirolactone **11** in 0.4 mL of freshly distilled dichlormethane was subjected to a pressure of 6.5 kbar in a Teflon tube for 14 d at 20 °C. After removal of solvent and purification by column chromatography on silica, 372 mg (0.92 mmol, 92%) of a white solid was obtained (m.p. 157 °C). $[\alpha]_D^{20} = -192.8°$ ($c = 1$ in $CHCl_3$); UV/Vis (CH_3OH): $\lambda_{max} = 225$ nm; IR (KBr): $\nu = 2925$ (m), 2862 (w), 1779 (vs), 1669 (s), 1516 (s), 1291 (m), 1177 (s), 1042 (w), 910 (w), 825 (w) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): $\delta = 0.47$ (bd, $^3J(H,H) = 16$ Hz, 1H), 0.82 (s, 3H), 1.10–2.85 (m, 12H), 3.8 (s, 3H), 3.84 (d, $^3J(H,H) = 10$ Hz, 1H), 5.82 (d, $^3J(H,H) = 14$ Hz, 1H), 5.87 (d, $^3J(H,H) = 7.5$ Hz, 1H), 6.12 (d, $^3J(H,H) = 7.5$ Hz, 1H), 6.54 (dd, $^3J(H,H) = 14$ Hz, $^3J(H,H) = 1$ Hz, 1H), 6.88 (d, $^3J(H,H) = 11$ Hz, 2H), 7.31 (d, $^3J(H,H) = 11$ Hz, 2H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 15.2$, 21.0, 23.8, 27.16, 27.2, 22.8, 38.8, 49.4, 50.1, 55.1, 61.5, 62.3, 71.8, 84.2, 113.1, 128.4, 129.1, 130.8, 136.2, 138.4, 149.1, 158.4, 175.8, 198.1; MS (130 °C): *m/z* (%): 405 (1) $[M^+ + 1]$, 404 (3) $[M^+]$, 279 (1), 240 (30), 225 (11), 197 (9), 164 (39), 149 (9), 136 (17), 122 (34), 107 (21), 91 (100), 82 (23), 73 (37); High-resolution MS ($C_{26}H_{28}O_4$): calcd 404.1988, found 404.1999.

Spiroether adduct **16**: A solution of 240 mg (1 mmol) of diene **1b** and 150 mg (1 mmol) of spiroether **15** was treated as above, to yield 336 mg (0.86 mmol, 86%) of a white foam. $[\alpha]_D^{20} = -133.1°$ ($c = 1$ in $CHCl_3$); UV/Vis (CH_3OH): $\lambda_{max} = 226$ nm; IR (KBr): $\nu = 2920$ (m), 2861 (w), 1666 (s), 1515 (s), 1250 (s), 1181 (m), 1034 (m), 824 (w), 752 (w) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): $\delta = 0.44$ (bd, $^3J(H,H) = 14$ Hz, 1H), 0.80 (s, 3H), 1.10–

Discrete Crown-Shaped Te_8 Rings in Cs_3Te_{22}

William S. Sheldrick* and Michael Wachhold

The structural chemistry of the tellurium-rich tellurides has become a field of intensive research interest in recent years.[1] In analogy to the lighter Group 16 elements, sulfur and selenium, chainlike Te_n^{2-} [2] anions have been characterized, which may be considered to be derived from the infinite helices of the thermodynamically stable elemental modification.[3] However, most of the known telluride anions exhibit structures, which emphasize the propensity of the heavier element to increase its coordination number beyond two. Typical is the formation of T-shaped building units $TeTe_3^{n-}$ (e.g. in $NaTe_3$ [4] or $CsTe_4$ [5]) or square-planar building units $TeTe_4^{n-}$ (e.g. in Rb_2Te_5 [6] or Cs_2Te_5 [7]). Examples are known both for infinite one- to three-dimensional anionic structures as well as for anionic species composed only of discrete fragments.[1]

[*] Prof. Dr. W. S. Sheldrick, Dipl.-Chem. M. Wachhold

Telefax: Int. code + (234)7094109

The synthesis of binary cesium tellurides has mainly been achieved from the elements themselves through use of high-temperature melts[5, 8] or ammonothermal reaction.[2, 6, 7] An alternative method is provided by the reduction of Cs_2TeO_3 (for Cs_2Te, Cs_2Te_3) or $Cs_2Te_2O_5$ (for Cs_2Te_2) with H_2 at temperatures between 663 and 703 K.[9]

We have recently reported the preparation of $RbTe_6$ by the reaction of Rb_2CO_3 with Te in overheated methanol at 190 °C, a reaction which is only successful in the presence of Ge.[10] $RbTe_6$ contains a higher metal-to-tellurium stoichiometric ratio than all other previously characterized alkali metal tellurides. It seems reasonable to assume that the formation of this rubidium telluride takes place by way of a surface reaction. In continuation of this previous work, we have now investigated the reaction of M_2CO_3 (M = K, Rb, Cs) with Te and As_2Te_3 under analogous conditions, which leads to the formation of tellurium-rich tellurides such as K_2Te_3 [2] and product mixtures of $RbTe_6$ [10] and Rb_2Te_5 [6] as well as Cs_3Te_{22} and $CsTe_4$ [5] in good yields (30–70%). The reaction of Cs_2CO_3 with As_2Te_3 alone in superheated methanol at 195 °C yields only the compound Cs_3Te_{22}, which exhibits a strikingly novel crystal structure.[11]

The crystal lattice of Cs_3Te_{22} (Fig. 1) contains both crown-shaped Te_8 rings and layer anions $^2_\infty[Te_4Te_{4/2}^{3-}]$. Comparison of

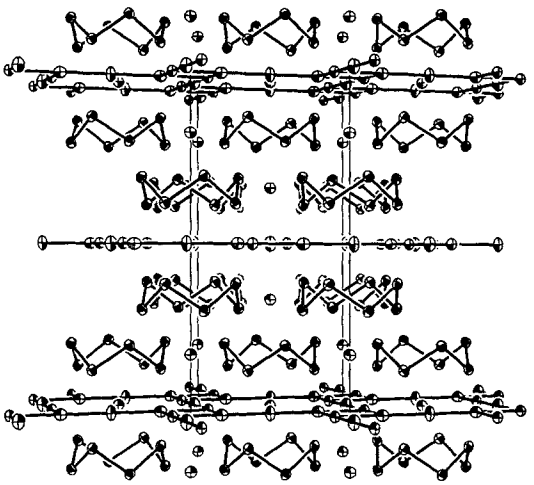

Fig. 1. Projection of the crystal structure of Cs_3Te_{22} perpendicular to [100].

the bond lengths and angles in the Te_8 rings with those of the element structures of S, Se, and Te allows the conclusion, in accordance with the Zintl–Klemm concept, that the negative charge in Cs_3Te_{22} has been fully transferred to the layer anions. For instance, the Te–Te distance of 2.8345(8) Å and the Te-Te-Te angle of 103.14(2)° in the helical chain of the thermodynamically stable elemental modification of tellurium[3] are only marginally larger than the average values of 2.80(2) Å and 100.0(16)° in the Te_8 rings of Cs_3Te_{22}. The Te_8 rings may be regarded as completing the series set up by the elemental structures X_8 of the lighter homologues S and Se.[12] Thus, the average X-X-X angle diminishes from 108.2(6)° in α-S_8 [13] through 105.7(16)° in α-Se_8 [14] to 100.0(16)° in Cs_3Te_{22}; at the same time the torsion angles X-X-X-X increase within the series, with their average values being 98.5(19)° in α-S_8, 101.3(32)° in α-Se_8 and 106.8(3)° in Cs_3Te_{22}. In contrast to the essentially undistorted crown conformation of the Te_8 rings in Cs_3Te_{22}, bicyclic structures have been observed for the known ionic species Te_8^{2-} and Te_8^{2+}. The Te_8^{2-} anions in $[K([15]crown\text{-}5)_2]_2Te_8$ contain both a four- and a five-membered ring, which are connected to one another by a

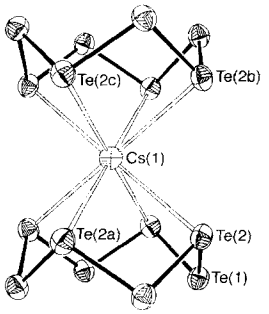

Fig. 2. Coordination of the cesium atom Cs(1) by two Te_8 rings. Bond length [Å] and angles [°]: Cs(1)-Te(2) 3.892(1); Te(2)-Cs(1)-Te(2a) 67.61(1), Te(2)-Cs(1)-Te(2b) 76.22(2), Te(1)-Cs(1)-Te(2c) 112.29(1).

central Te atom that is effectively square-planar coordinated.[15] In contrast, the structure of the Te_8^{2+} ion in $Te_8(WCl_6)_2$ is composed of two condensed five-membered rings, both of which exhibit an envelope conformation.[16] The stabilization of the neutral crown-shaped Te_8 rings[12] takes place in Cs_3Te_{22} in the coordination sphere of the cesium atom Cs(1), which is surrounded by what is effectively a cube of tellurium atoms Te(2) from two Te_8 rings (Fig. 2). It is interesting to note in this context, that Chivers et al. have recently very tentatively assigned a weak resonance at $\delta = 848$ in the ^{125}Te NMR spectrum of an S-Te melt to a Te_8 ring.[17]

The novel polyanion $^2_\infty[Te_4Te^{3-}_{4/2}]$ contains two crystallographically independent Te atoms, which exhibit different coordination geometries, namely linear and T-shaped (pseudo trigonal bipyramidal). Their mode of connection leads to the formation of Te_4 and Te_{12} squares (Fig. 3). An average Te–Te distance of 2.97 Å is observed in the comparable anion structure of $CsTe_4$,[5] which is composed of connected $TeTe_3^-$ building units. The increase in charge for the formally $TeTe_3^{2-}$ groups in Cs_3Te_{22} leads, as would be expected, to an increase in the average Te–Te bond length (3.03 Å). Derivation of the anion structure in Cs_3Te_{22} from a planar 4^4 net may be achieved by removal of 2/5 of all Te atoms.

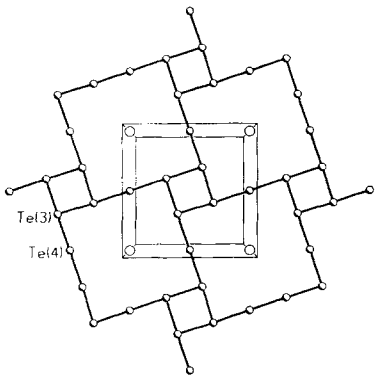

Fig. 3. Thinned 4^4 net of the layer anions $^2_\infty[Te_6^{3-}]$ with the unit cell. Bond lengths [Å] and angles [°]: Te(3)-Te(3) 3.003(2), Te(3)-Te(4) 3.077(1); Te(3)-Te(4)-Te(3) 180, Te(3)-Te(3)-Te(3) 90, Te(3)-Te(3)-Te(4) 88.53(4), 178.53(4).

The crystal structure of Cs_3Te_{22} exhibits two secondary Te(3)-Te(2) and four secondary Te(4)-Te(2) bonds of lengths 3.424(1) and 3.444(1) Å, respectively, between layer anions and Te_8 rings. In addition to the atom Te(3) of the Te layer ($4 \times 4.129(1)$ Å) both of the ring atoms Te(1) ($4 \times 4.096(1)$ Å, $4 \times 4.330(1)$ Å) and Te(2) ($4 \times 4.152(1)$ Å) are involved in the coordination of Cs(2) atom (see Fig. 1).

Two partial structures which embody contrasting aspects of tellurium chemistry are thus united by means of cationic stabilization in the crystal structure of Cs_3Te_{22}. Whereas the crown-shaped Te_8 rings are similar to the X_8 units of the lighter homologues S and Se, the layer anions $^2_\infty[Te_6^{3-}]$ may be derived from the α-Po structure of the heavier homologue.[1, 18]

Experimental Procedure

Cs_2CO_3 (0.157 g, 0.48 mmol) and As_2Te_3 (0.518 g, 0.97 mmol) in methanol (0.5 mL) were heated to 195 °C in a Carius tube under argon (heating rate 10 °C h^{-1}). After 2 d the tube was cooled to room temperature at a rate of 3 °C h^{-1} to afford gray crystals of Cs_3Te_{22} with metallic appearance (70% yield) as precipitate. The reflections of an X-ray powder diagram of the product could be indexed for Cs_3Te_{22}.

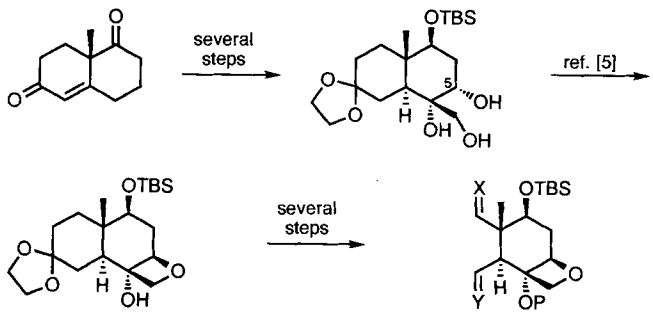
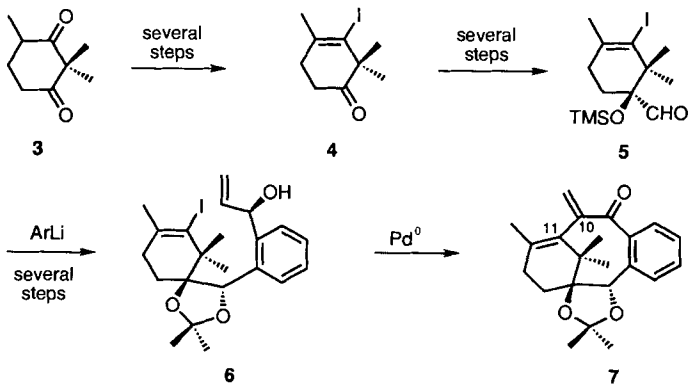
A Novel Intramolecular Heck Reaction: Synthesis of a Cholesterol–Baccatin III Hybrid**

John J. Masters,* David K. Jung,
Samuel J. Danishefsky,* Lawrence B. Snyder,
Tae Kyo Park, Richard C. A. Isaacs, Cheryl A.
Alaimo, and Wendy B. Young

Taxol (**1**) is already playing a useful role in cancer chemotherapy.[1] While the ultimate limits of its applicability awaits precise definition, taxol or related compounds will clearly be part of the arsenal of clinically useful agents in the treatment of cancer. From the standpoint of chemistry, this series commands special attention.[2] It was never probable, nor is it now likely, that total synthesis would provide a useful route to the core structure, baccatin III (**2**) or to taxol (**1**) itself. Apparently no combination of starting materials is close enough in structure to baccatin III, in all its detail, to allow for formation of this natural product in anything but a multistep synthesis. Accordingly, total syntheses are not likely to be competitive with phytochemical routes.





Nonetheless, the intellectual and experimental challenges associated with a total synthesis of baccatin III and taxol, only recently achieved in stunning and concurrent fashion by groups headed by Holton[3] and Nicolaou,[4] properly hold a special fascination for chemists. The baccatin III problem has already served to stimulate new conceptual and methodological advances in organic synthesis.[2] Moreover, continued interest in this field is fueled by the reasonable hope that synthetic mastery over the taxol problem will lead to simplified new structures which could not have been derived from baccatin III itself.

Our program in the taxol area has been directed along several lines. Our laboratory developed an enantiospecific route (by catalytic means) to the CD substructure of baccatin, with handles for attachment to ring A substructures.[5, 6] In these efforts, closure of the oxetane ring by inversion at C-5 in a fully functionalized system was demonstrated for the first time (Scheme 1). The total syntheses of Nicolaou et al. and Holton et al. both used this strategy.[7]

The starting material for A-ring constructs was the readily available 2,2,4-trimethylcyclohexane-1,3-dione (**3**).[8] Among the compounds obtained from **3** were the vinyl iodide **4**[9] and thence aldehyde **5**. Compound **6**, derived from **5**, was amenable to intramolecular Heck vinylation reactions thereby producing products of type **7** (Scheme 2).[10]

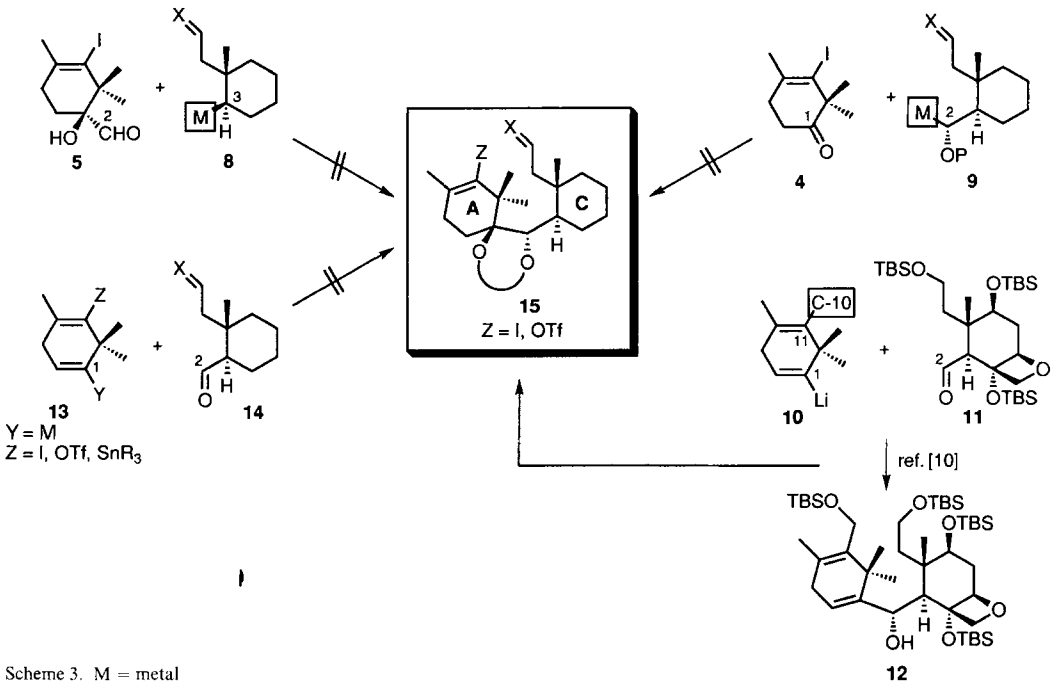
Scheme 1: TBS = *tert*-butyldimethylsilyl.

Scheme 2. Ar = aryl.

At this juncture, it was necessary to verify the applicability of the intramolecular Heck reaction to an aliphatic C ring based construct containing the C-19 methyl group. It is clear from the study of taxol literature[2] that methods successful in simpler structures may fail in more complex models in which closure triggers strong repulsion between the methyl groups at C-17 and C-19. In the research described here, we probed the applicability of a C-10/C-11 closure by an intramolecular Heck reaction, even in the context of such an abutment.

To answer this fascinating question, however, it was necessary to break new ground relative to the synthetic approach that led to substrates such as **6**. We focused on reaching a generic target of type **15**. It is instructive to consider the difficulties that had to be overcome in pursuing such a program (see Scheme 3).

The prospects of entering the required manifold by coupling a stereochemically defined secondary sp^3-type C-3 nucleophile such as **8** with an aldehyde of type **5** seemed particularly bleak. Alternatively, delivery of a sophisticated C-2 based nucleophile such as **9** to the hindered C-1 based ketone **4**, showed no promise based on early reconnaissance. Less forbidding was the possibility of adding a C-1 based vinyl nucleophile to a C-2 aldehyde. The feasibility, in principle, of such a C-1/C-2 coupling with a fully functionalized CD construct was in fact reported by our laboratory (**10** + **11** → **12**).[10] The use of a non-oxetane containing aldehyde in this context was a key element in Nicolaou's total synthesis of taxol by formation of the C-9/C-10 bond.[4, 11] Since we were now focusing on a C-10/C-11 bond closure, strict adaptation of our earlier route would require excision of the one carbon fragment mounted at C-11 (cf. $TBSOCH_2$ in **12**).



The use of A-ring constructs such as **13**, which simultaneously include the C-1 sp^2 nucleophile and the C-12/C-11 double bond with functionality suitable for a Heck reaction or a related closure, was a priori plausible. In fact, we explored several permutations summarized as **13** + **14**, wherein **14** was derived by

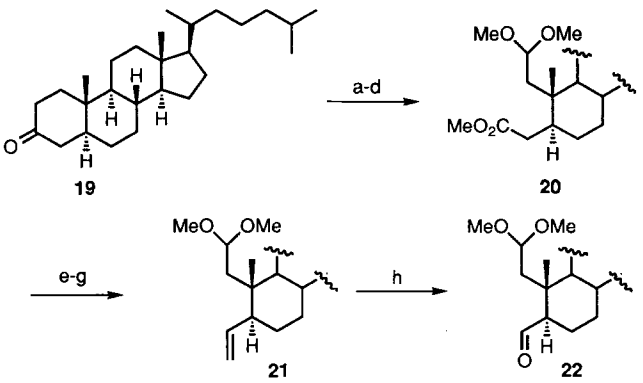
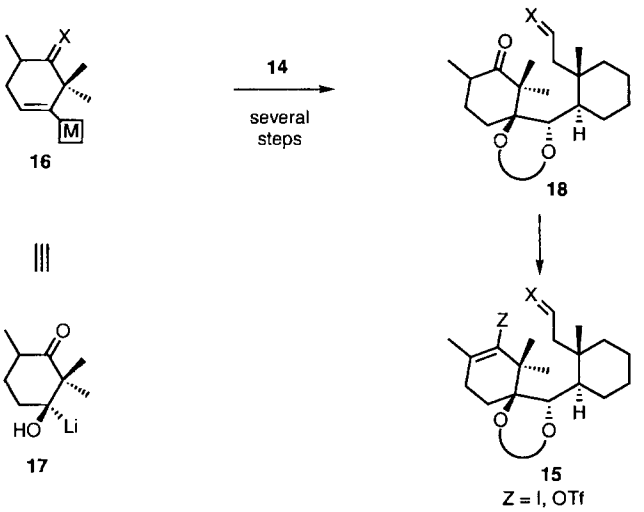


Scheme 3. M = metal

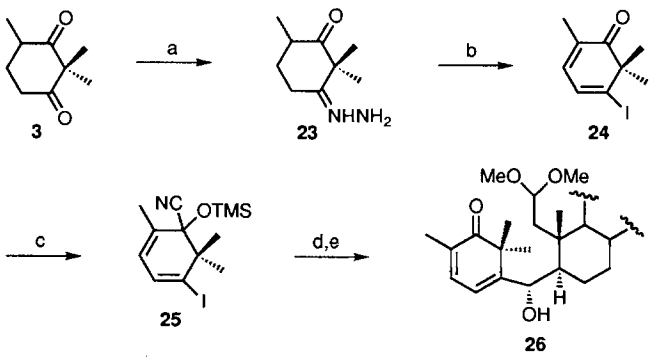


degradation of suitable cyclic precursors. This investigation was set aside when we were unable to generate a viable version of **13**.

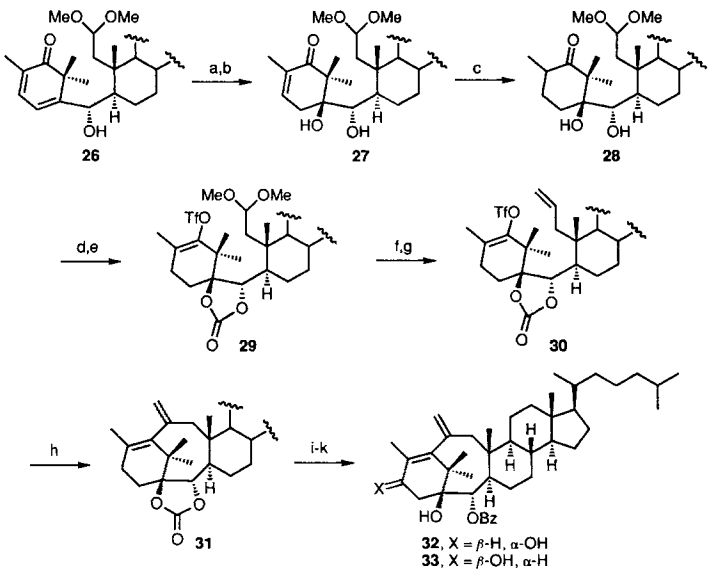
Accordingly, we were obliged to examine the possibility of introducing the "pre-Heck functionality" at C-11 *after* the coupling of C-1 and C-2 had been achieved (cf. **15** in Scheme 4). Unveiling of the implement at C-11 for the Heck reaction would occur at a late stage, perhaps from a ketone such as **18**. Also, it would be necessary to achieve formal hydration of the C-14/C-1 double bond and, probably, to constrain the oxygen atoms at C-1 and C-2 in a cyclic arrangement, which would be conducive to a successful C-10/C-11 closure. Viewed in these terms, the desired A-ring unit would be based on the C-1 sp^2 nucleophile **16** (X unspecified), which would serve as a functional equivalent to the hypothetical nucleophile **17**.

5α-Cholestan-3-one (**19**) served as a suitable saturated C-ring substrate to test these issues (Scheme 5).[12] The commercially available steroid was degraded to acetal ester **20**. The C-2 ester was converted to the vinyl compound **21** by reduction followed by the standard Grieco-type protocol.[13] Ozonolysis of **21** afforded the desired C-2 aldehyde acetal **22**.

Scheme 5. a) $NaN(SiMe_3)_2$, THF, TBSCl, −78 °C, 92%; b) dimethyldioxirane, CH_2Cl_2, 0 °C, then Amberlyst 15, 88%; c) $Pb(OAc)_4$, 1/1 MeOH/C_6H_6, 0 °C, quant.; d) MeOH, pyridinium *p*-toluenesulfonate (PPTS), 70 °C, 89%; e) $LiAlH_4$, THF, 0 °C, quant.; f) *o*-$NO_2C_6H_4SeCN$, Bu_3P, THF, room temperature (RT), 86%; g) H_2O_2, THF, RT, 90%; h) O_3, CH_2Cl_2, −78 °C, then PPh_3, 91%.



Scheme 4.



The starting material for a compound analogous to **16** was iododiene **25**, which was available from **3** by a three-step sequence (Scheme 6). The first step was formation of monohydrazone **23** at the less hindered C-1 position. Treatment of **23** with iodine and diazobicyclononane (DBN) in refluxing THF gave iododienone **24**, which was converted to **25** by cyanation. Remarkably, it was possible to lithiate vinyl iodide **25**. The lithium compound thus produced reacted with aldehyde **22** to afford, after decyanation, dienone **26** as a single stereoisomer at C-2.[14]

Compound **26** could be transformed into a desired masked precursor of type **15** for the Heck reaction (Scheme 7). A key reaction was the epoxidation of **26** mediated by vanadyl acetylacetonate to give a single β-epoxide.[11, 15] Exposure of this

enone epoxide to the action of hydrogen and 10% palladium on charcoal in ethanol led to the γ-hydroxyenone **27**. In this way the critical hydroxyl functions at C-1 and C-2 were introduced. Stabilization of the C-1 hydroxyl group was achieved by subsequent reduction of the enone. The hydroxyl groups at C-1 and C-2 in diol **28** were engaged as a cyclic carbonate.[16] The critical enol triflate linkage (see **29**) was introduced by deprotonation of the ketone by using potassium bis(trimethylsilyl)amide in the presence of *N*-phenyltrifluoromethanesulfonimide.[17] Cleavage of the acetal linkage gave rise to an aldehyde which upon methylenation gave the desired **30** in an overall yield of 16% from 5α-cholestan-3-one (**19**). The stage was now fully set for testing the intramolecular Heck reaction.

In the event, treatment of **30** with tetrakis(triphenylphosphane)palladium(0) and potassium carbonate in acetonitrile at 85 °C afforded the goal system **31** (50% yield), whose structure was verified crystallographically.[18] Opening of the carbonate linkage with phenyllithium[3, 4] afforded the C-2 benzoate which upon allylic oxidation and reduction produced the steroidal baccatin III construct **32** along with its C-13 epimer **33**.[19] The concise synthetic approach described here should allow access to other functionalized ABC baccatin III hybrid systems.

Experimental Procedure

All compounds reported displayed satisfactory ^1H NMR, IR, and mass spectra.

31: A 15 mL flask was charged with **30** (94.7 mg, 0.135 mmol), K_2CO_3 (37.0 mg, 0.270 mmol), and 4 Å molecular sieves. The mixture was taken up in 5 mL of CH_3CN and the flask placed in an 85 °C oil bath. $[(Ph_3P)_4Pd]$ (179 mg, 0.155 mmol) was added to the mixture in portions (5–10 mg) over 4.5 h, so as to maintain an ambered colored solution. Upon complete addition, the mixture was allowed to stir at 85 °C for an additional 0.5 h. The mixture was then cooled to ambient temperature, diluted with diethyl ether, filtered through a pad of Celite, and concentrated in vacuo. The residue was dissolved in diethyl ether, washed with saturated NH_4Cl (2×), and dried (K_2CO_3). Concentration in vacuo and purification of the residue by flash chromatography (SiO_2, 92/8 petroleum ether/diethyl ether) afforded 37.2 mg (50%) of **31** as a colorless solid. M.p. 204–205 °C; $[\alpha]_D = 34.0$ ($c = 0.47$; CH_2Cl_2); IR (film): $\nu = 2950, 2934, 2867, 1806, 1623, 1457, 1443, 1375, 1034\ cm^{-1}$; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.10$ (s, 1H), 4.62 (s, 1H), 4.51 (d, 1H, $J = 5.6$ Hz), 2.81–2.70 (m, 1H), 2.45 (d, 1H, $J = 16.7$ Hz), 2.20–2.11 (m, 1H), 2.14 (d, 1H, $J = 16.5$ Hz), 2.06–1.87 (m, 4H), 1.85–1.70 (m, 3H), 1.78 (s, 3H), 1.68–1.60 (m, 1H), 1.57–1.45 (m, 3H), 1.40–0.70 (m, 16H), 1.32 (s, 3H), 1.23 (s, 3H), 0.89 (d, 3H, $J = 6.5$ Hz), 0.87 (d, 3H, $J = 6.6$ Hz), 0.86 (d, 3H, $J = 6.6$ Hz), 0.81 (s, 3H), 0.64 (s, 3H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 154.8, 143.6, 140.1, 134.4, 116.4, 93.6, 81.3, 56.8, 56.1, 49.4, 44.9, 43.3, 42.5, 41.5, 40.2, 39.9, 39.5, 36.1, 35.7, 35.6, 32.1, 30.1, 28.2, 28.0, 25.7, 24.1, 23.9, 23.7, 23.1, 23.0, 22.8, 22.5, 21.8, 20.5, 18.6, 18.2, 12.1$; MS ($NH_3$): calcd for $C_{37}H_{58}O_3$ (M^+) 550, found $(M+1)^+$ 551, $(M + NH_4)^+$ 568.

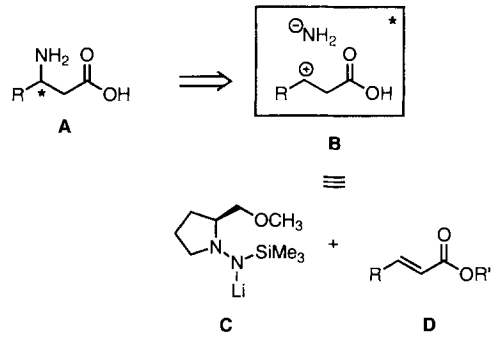
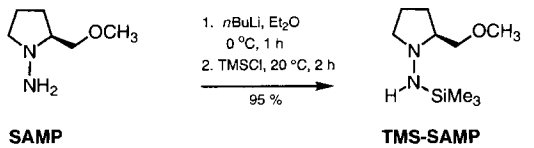
[18] The insertion step was particularly slow and resulted in precipitation of palladium(0). The use of stoichiometric $[Pd(PPh_3)_4]$ was required to obtain good yields of **31**.
[19] The stereochemistry of the C-13 carbinol center was determined from NOE experiments.



Enantioselective Synthesis of β-Amino Acids: TMS-SAMP as a Chiral Ammonia Equivalent for the Aza Analogous Michael Addition to α,β-Unsaturated Esters**

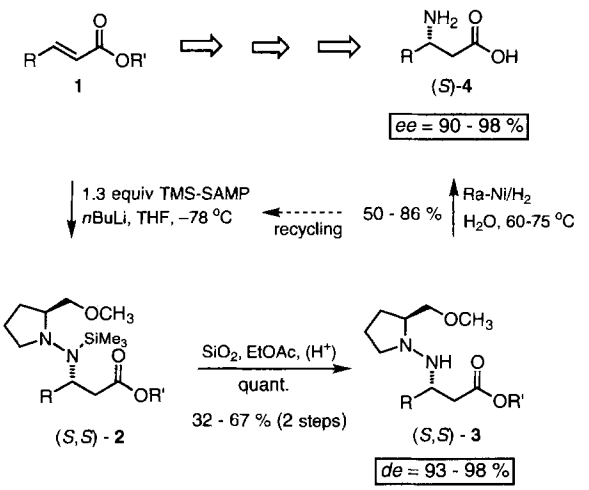
Dieter Enders,* Heiner Wahl, and Wolfgang Bettray



Dedicated to Professor Wilhelm Keim on the occasion of his 60th birthday

β-Amino acids **A** have achieved premier importance as substructures of numerous biologically active natural products[1] as well as building blocks for β-lactam antibiotics.[2] This is reflected by the ever increasing research activity in the field of their stereoselective synthesis.[3] One approach to this class of compounds makes use of enantiomerically pure building blocks provided by nature, for example aspartic acid.[4] On the other hand an increasing number of methods based on asymmetric synthesis can be applied.[5] Besides numerous methodologies for C–C bond formation some asymmetric approaches to C–N bond connections in accordance with the retrosynthetic analysis **A**⇒**B** have been developed in the recent past.[6–8] Using aza analogous Michael additions, achiral N-nucleophiles can be added to chiral Michael acceptors.[6] Alternatively chiral donors of amine functionality, especially N-silylated amides, have proven to be versatile soft nucleophiles,[8] for example **C** can be added to α,β-unsaturated ester **D** as achiral Michael acceptor.

We report here on a highly enantioselective synthesis of β-amino acids by hetero-Michael addition of (*S*)-2-methoxymethyl-1-trimethylsilylaminopyrrolidine (TMS-SAMP)[9] and its enantiomer TMS-RAMP, as chiral ammonia equivalents to (*E*)-configurated enoates.[10]



The new hydrazine auxiliary is prepared from SAMP and RAMP,[11] respectively, the well-established auxiliaries in asymmetric synthesis, by metalation with *n*-butyllithium in diethyl ether at 0 °C and subsequent silylation with chlorotrimethylsilane. TMS-SAMP and TMS-RAMP, respectively, are obtained by distillation in 95% yield as colorless liquids, which can be stored at −25 °C under argon (Scheme 1).[12]

Scheme 1. Synthesis of hetero-Michael donor TMS-SAMP.

In the synthesis of β-amino acids (Scheme 2), 1.3 equivalents of TMS-SAMP in tetrahydrofuran were metalated with *n*-butyllithium at −78 °C. The nucleophile **C** formed in this way was treated with the α,β-unsaturated esters **1** at −78 °C, affording the N-silylated β-hydrazinoesters (*S*,*S*)-**2** through conjugate addition. When simple methyl esters are used as Michael acceptors 1,2-addition occurs as a side reaction, leading to the formation of the corresponding α,β-unsaturated acyl hydrazides. The latter are formed exclusively if the unsilylated SAMP is used. The problem of 1,2-addition can be avoided by employing sterically

Scheme 2. Enantioselective synthesis of β-amino acids **4** by aza analogous Michael addition of TMS-SAMP to enoates.

demanding *tert*-butyl esters (R′ = *t*Bu). In addition better yields are obtained (see. **3b, i**, Table 1). Although the pure N-silylated β-hydrazinoesters **2** can be principally prepared by distillation [(*S,S*)-**2a** : 30% yield; *de* = 95%], it is recommendable to directly desilylate the crude products by stirring with a suspension of silica gel in ethyl acetate. The desilylation times are strongly dependent on the nature of the R group, ranging from 4 to 72 h (GC control). A significant reduction of the reaction time to 3 h is readily accomplished by the addition of a catalytic amount of

[a] Total yield over two steps. [b] Determined by ^1H and ^{13}C spectroscopy. [c] TMS-RAMP was used as chiral auxiliary.

hydrochloric acid. Elution of the silica gel with methanol and subsequent chromatographic purification of the crude products (silica gel; petrol ether/ ethyl acetate 3/1) affords the β-hydrazinoesters (*S,S*)-**3** as pale yellow oils in 32–67% yield and with diastereomeric excesses of 93–98% *de* (determined by ^1H and ^{13}C NMR spectroscopy, Table 1). A conceivable diastereomeric enrichment by column chromatography can be ruled out due to the facile detection of both diastereoisomers by thin layer chromatography (molybdatophosphoric acid without heating). Furthermore, the correspondence of the *de* values of (*S,S*)-**2a, b** (determination by gas chromatography) and (*S,S*)-**3a, b** suggests that the acidic desilylation proceeds without epimerization.

Finally, the hydrazinoesters **3** are converted to the corresponding β-amino acids (*S*)-**4** by hydrogenolytic N–N cleavage with concomitant saponification of the ester function in an autoclave using Raney nickel and are obtained, after chromatographic purification (silica gel, ethanol/water 9/1), in 50–86% yield and with enantiomeric excesses of 90–98% *ee* (Table 2).

The determination of the enantiomeric excesses was carried out after derivatization of the corresponding methyl esters[13] with (*S*)-(+)-3,3,3-trifluoro-2-methoxy-2-phenylpropanoyl chloride (Mosher acid chloride) to the Mosher amides[14] by ^1H and ^{19}F NMR spectroscopy as well as gas chromatography. The comparison of the found *de* and *ee* values shows a slight divergence of 2–4%, which is in line with our experiences concerning N–N cleavage of similar hydrazines with Raney nickel.[15] The determination of the absolute configuration of the synthetic β-aminobutyric acid (*S*)-**4a** was carried out by comparison of the optical rotation with literature data ($[\alpha]_D^{18}$ = + 38.8 (*c* = 0.48, H_2O) for (*S*)-aminobutyric acid).[16] Under the assumption that all substrates react along the same reaction pathway, the β-amino acids **4b, c** and **4e–i** were also assigned the (*S*) configuration. Compound **4d** was assigned the (*R*) configuration because of the formal inversion of the substituent priorities in accordance with the CIP rules.

Table 2. Preparation of β-amino acids **4** by N–N bond cleavage of the hydrazinoesters **3**.

[a] The *ee* values of the β-amino acid methyl esters were determined as their corresponding Mosher's amides, prior to recrystallization [13]. [b] After one recrystallization from MeOH/EtOH [(*S*)-**4a**], MeOH/H_2O [(*R*)-**4a**], EtOH [(*S*)-**4b**·**c**·**f**–**i**, (*R*)-**4d**], MeOH/Et_2O [(*S*)-**4e**]. [c] With decomposition. [d] TMS-RAMP was used as chiral auxiliary. [e] Starting from the methyl esters (R′ = Me). [f] These results are based on the corresponding *de* values of the hydrazinoester **3** assuming a divergence of 2–4%.

The enantiomers (*R*)-**4**, as exemplified by (*R*)-**4a**, can be synthesized in an analogous fashion by the use of TMS-RAMP as N-Michael donor (Tables 1 and 2).[17]

The new variant of asymmetric hetero-Michael addition described herein, using TMS-SAMP as a chiral ammonia equivalent, opens a highly enantioselective pathway to β-amino acids and therefore to β-lactams.

Preliminary results show that the described methodology can be extended successfully to a Michael tandem process, that is an aza analogous 1,4-addition with subsequent α-alkylation of the intermediate ester enolate.[18]

Experimental Procedure

TMS-SAMP: To a stirred solution of SAMP (11.7 g, 90 mmol) in diethyl ether (100 mL) was added *n*-butyllithium (59.5 mL, 95 mmol, 1.6 M solution in hexane) at 0 °C under argon. After 1 h the reaction mixture was allowed to warm to room temperature and chlorotrimethylsilane (10.3 g, 95 mmol) was added. The solution was then heated to reflux for 1 h to complete the silylation. The solution was filtered to remove the precipitated LiCl, the ether was evaporated, and the residue was finally distilled to give 17.2 g (95%) TMS-SAMP as a colorless liquid [b.p. = 34–36 °C (0.2 Torr); $[\alpha]_D^{22}$ = − 99.3 (neat)].

4: *n*-Butyllithium (8.13 mL, 13 mmol, 1.6 M solution in hexane) was added dropwise to TMS-SAMP (2.63 g, 13 mmol) in THF (40 mL) at −78 °C. To complete metalation the solution was stirred for 30 min at −78 °C and then the enoate **1** (10 mmol) was added slowly at −78 °C and the mixture was stirred at this temperature for 3–18 h. The hydrolysis was carried out by pouring the reaction mixture into saturated $NaHCO_3$ solution (30 mL). The solution was extracted three times with dichloromethane, the combined extracts were dried over Na_2SO_4, and the solvent was removed in vacuo. The crude 1,4-adducts (*S,S*)-**2** were obtained as yellow oils. To achieve desilylation the adducts were dissolved, with a suspension of weakly acidic silica (40 g, type 60, 63-100 mesh, Merck), in ethyl acetate containing concentrated HCl (0.5 mL) and stirred at ambient temperature under an argon atmosphere. After complete removal of the silyl group (GC-control) the silica was washed with absolute methanol and then the solvent was removed in vacuo. The resulting brown oils were purified by flash column chromatography (silica gel, eluant: petrol ether/ethyl acetate 3/1), without diastereomeric enrichment, to give the pure β-hydrazinoesters (*S,S*)-**3** as pale yellow oils.

Preparation of Raney nickel for the N–N bond cleavage, (2–4 mmol per preparation): Ni-Al alloy (1 g per mmol of the β-hydrazinoester (*S,S*)-**3**) was suspended in H_2O (15 mL), then solid NaOH was added until no further evolution of hydrogen was observed. The suspension was heated to 70 °C for 30 min in a water bath, the solvent decanted, and the nickel sponge washed three times with water (10 mL). This yielded the catalyst with an estimated activity of W-9 [19].

N–N Bond cleavage: The N–N bond cleavage with concomitant ester hydrolysis was carried out in an autoclave with water (10 mL per mmol of β-hydrazinoester (*S,S*)-**3**) as solvent and Raney nickel as catalyst (reaction time: 17–20 h; temperature: 60–75 °C; H_2 pressure: 7.5–9.5 bar). After quantitative conversion (thin layer chromatographic control) the Ni-sponge was removed by filtration through celite, and the filtrate was concentrated in vacuo (water bath: 50–60 °C) to give a pale

solid. Upon flash column chromatography (silica, eluant: ethanol/water 9/1) and removal of traces of the solvent in vacuo the β-amino acids **4** were obtained as colorless, crystalline compounds after recrystallization from MeOH/EtOH [(*S*)-**4a**], MeOH/H_2O [(*R*)-**4a**], EtOH [(*S*)-**4b**, **c**, **f**–**i**, (*R*)-**4d**], MeOH/Et_2O [(*S*)-**4e**], respectively.

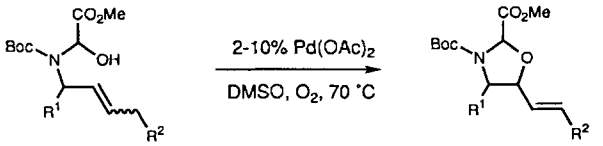
Sulfoxide-Stabilized Giant Palladium Clusters in Catalyzed Oxidations**

Rolf A. T. M. van Benthem, Henk Hiemstra,* Piet W. N. M. van Leeuwen, John W. Geus, and W. Nico Speckamp

Large transition metal clusters are gaining increasing attention as research targets for several reasons. Their existence on the borderline[1] between molecular states with discrete quantum energy levels and the actual metallic state with its typical bulk properties raises the interest of not only physicists and material scientists[1–3] but also of chemists working in the field of catalysis.[4–7] Since these species are also on the borderline between homogeneous and heterogeneous catalysts, they may perhaps have typical characteristics of both.



The feasibility of preparing platinum group transition metal clusters and colloids by reducing inorganic complexes in the presence of an appropiate stabilizing ligand such as phenanthroline has been demonstrated by Moiseev et al.[4] and Schmid et al.[1, 6] Phosphanes were also shown to be useful ligands for this pur-

[**] This investigation was supported by the Innovation Oriented Research Program on Catalysis of the Dutch Ministry of Economic Affairs.

pose.[7, 8] This communication describes the first example, to our knowledge, of sulfoxide-stabilized giant palladium clusters.[9]

Recently, we suggested[10] that large palladium clusters may be the catalytically active species in the oxidative cyclization of allylic *N*-hydroxymethyl carbamates (Scheme 1).[10, 11] It was

Scheme 1. Pd^{II}-catalyzed oxidative 5-*exo* cyclization of *N*-hydroxymethylamines. DMSO = Me_2SO.

shown that the solvent dimethyl sulfoxide (Me_2SO) plays an essential role in this process. Molecular oxygen could be employed as the stoichiometric oxidant in the absence of the common cocatalysts,[12] and Pd-black did not precipitate. Larock et al.[13] also observed that molecular oxygen alone is remarkably efficient in reoxidizing palladium in Me_2SO in the oxidative lactonization of unsaturated acids. Apparently, the catalytic system $Pd(OAc)_2/Me_2SO/O_2$ is quite versatile for oxidative reactions.[14] This prompted us to further explore the nature of this remarkable system.

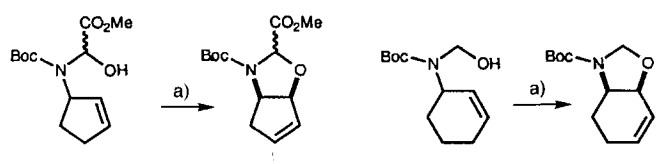
We presumed that after initial reduction of $Pd(OAc)_2$ by the oxidative cyclization [Eq.(a)], the palladium(0) species formed is stabilized by Me_2SO as a ligand (L), and readily reoxidized by molecular oxygen [Eq.(b)] to catalyzed further cyclizations

$$Pd(OAc)_2 + \text{substrate} \rightarrow \text{product} + 2\,HOAc + Pd^0 \quad (a)$$

$$x\,Pd^0 + 2y\,HOAc + z\,L + 1/2y\,O_2 \rightarrow [Pd_x(OAc)_{2y}L_z] + y\,H_2O \quad (b)$$

[Eqs.(c), (d), and (a)]. Whether a polynuclear compound is the actual catalytically active species [Eq.(c)] or merely a precursor

$$[Pd_x(OAc)_{2y}L_z] + \text{substrate} \rightarrow \text{product} + 2\,HOAc + [Pd_x(OAc)_{2y-2}L_z] \quad (c)$$



$$[Pd_x(OAc)_{2y}L_z] \rightarrow [Pd_{x-1}(OAc)_{2y-2}L_z] + Pd(OAc)_2 \quad (d)$$

of an active mononuclear species [Eq.(d)] remains to be established.[19] The unique role of Me_2SO in this process is most likely

$$[Pd_x(OAc)_{2y-2}L_z] + 2\,HOAc + 1/2\,O_2 \rightarrow [Pd_x(OAc)_{2y}L_z] + H_2O \quad (e)$$

linked to its two coordination modes. During the catalytic cycle the palladium catalyst can interact with either the "hard" oxygen lone pairs or the "soft" sulfur lone pair.[9, 15]

The substrates used for this investigation, the *N*-hydroxymethyl carbamates **1**[10, 11] and **3**, differ in reactivity towards $Pd(OAc)_2$. At room temperature cyclopentenylamine derivative **1** undergoes oxidative cyclization immediately upon addition of the catalyst to the reaction mixture, which then turns dark red-

Scheme 2. Reagents and conditions: a) 0.1 equiv $Pd(OAc)_2$, Me_2SO; $c = 0.2$–0.02 M; ca. 25–60 °C.

brown. According to TLC, this corresponds to about one turnover [Eq.(a)]. However, in the presence of molecular oxygen the subsequent reactions occur more slowly at this temperature.[16] When the first turnover is achieved under an argon atmosphere, the reaction stops at this point but the catalyst remains active. Thus, even after the reaction mixture is left for longer periods under argon at room temperature or 75 °C, purging the flask with molecular oxygen results in fast completion of the reaction. In contrast, cyclohexenylamine derivative **3** is virtually unreactive at room temperature. A comparable reaction rate for oxidative cyclization is reached at 60 °C. Again, the first turnover occurs much faster than the subsequent ones.

Typical reaction mixtures consisting of **1** or **3** and 0.10 equiv $Pd(OAc)_2$ under an atmosphere of molecular oxygen with concentrations between 0.2 and 0.02 M in Me_2SO were prepared for TEM imaging[18] according to published methods.[7, 17] Bright- and dark-field TEM images clearly showed the presence of large palladium clusters with more or less uniform size distribution in all samples. Figure 1 shows bright-field TEM images of a sample that was taken from a reaction mixture of **1** within seconds after the addition of $Pd(OAc)_2$ at room temperature, proving that the clusters are formed almost instantaneously. The particles are

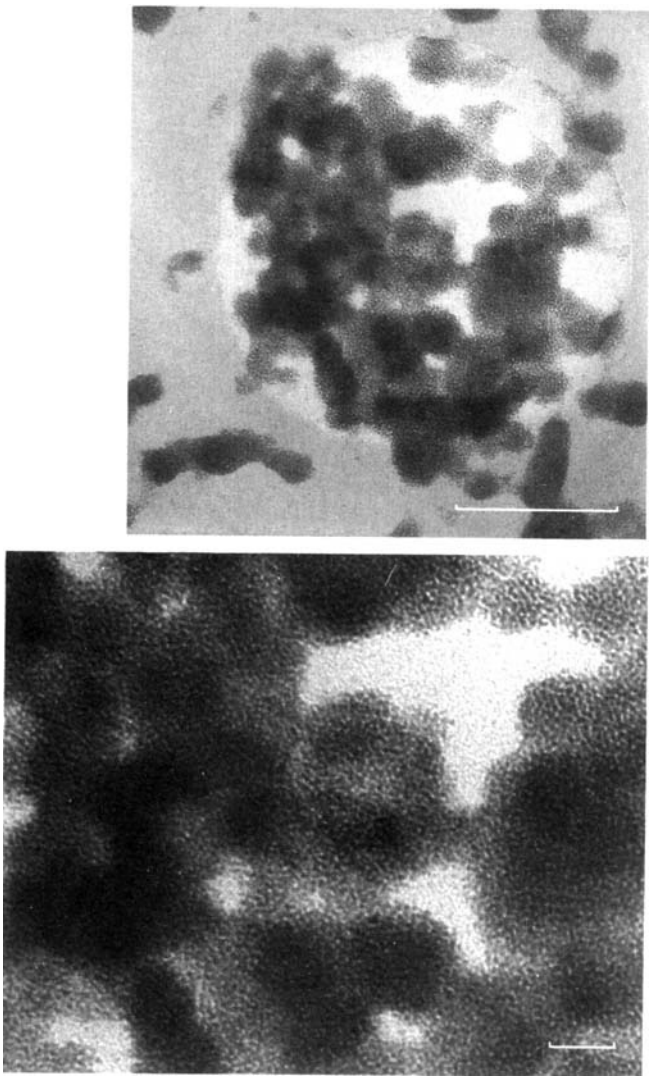


Fig. 1. Top: Typical TEM image of Me_2SO-stabilized palladium clusters (size 26 ± 4 Å). The bar corresponds to 100 nm. Bottom: Enlargement of a section of Fig. 1, top. The bar corresponds to 10 nm.

26 ± 4 Å in size, corresponding to five- and six-shell clusters in the full-shell concept terminology.[1] TEM images from samples taken later in the course of the reaction did not differ substantially from the first one.

Hence, we must conclude that the clusters observed are involved in the reoxidation process [Eq.(e)] and in the catalytic process according to either Equation (c) or (d). The high affinity of the surfaces of large palladium clusters for molecular oxygen is known.[1, 4, 6, 7] The oxidative cyclization [Eq.(c)] is also believed to take place at the surface of the cluster.

As already mentioned, the reaction of **3** proceeded more slowly than that of **1**. Figure 2 shows TEM images of a sample taken after a reaction time of one minute at 60 °C. The size distribution is slightly less homogeneous and the particles are somewhat smaller as they vary in size from 15 to 27 Å, corresponding to three-, four- and five-shell clusters. As with carbamate **1**, the size distribution remains virtually unchanged during the course of the reaction.

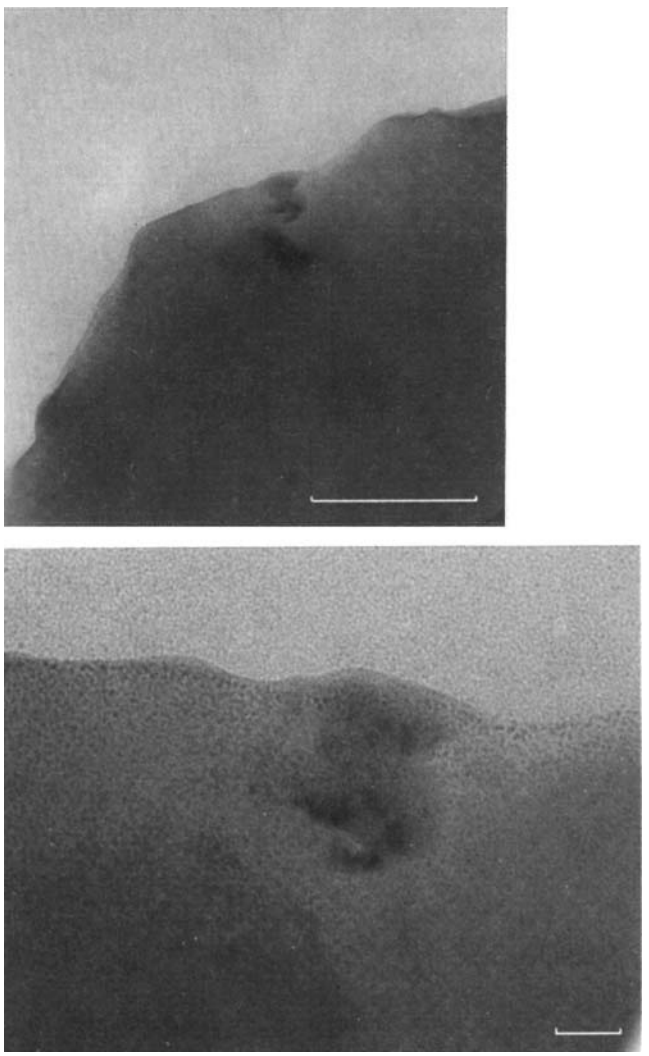

Fig. 2. Typical TEM image of Me_2SO-stabilized palladium clusters (size 21 ± 6 Å). The bar corresponds to 100 nm. Bottom: Enlargment of a section of Fig. 2, top. The bar corresponds to 10 nm.

The clusters formed with **1** after two turnovers at room temperature could be isolated as a black powder without loss of catalytic activity (Experimental Procedure). In elemental analyses of different batches the ratio of the number of Me_2SO molecules per Pd atom was found to range from 2.5–3.0/10. In the IR spectrum of these materials strong absorption bands at 1023 and 1127 cm^{-1} (S=O) indicated that Me_2SO is coordinated through both the O and S atoms (-32 cm^{-1} and $+72$ cm^{-1}, respectively, relative to the S=O absorption band of "free" Me_2SO at 1055 cm^{-1}).[9]

To the best of our knowledge, this is the first identification of isolated clusters *after* a *homogeneously* catalyzed reaction. The clusters reported by others[4] were characterized in stable form after preparation and *subsequently* shown to homogeneously catalyze oxidative reactions. It may well be that the clusters are modified under the reaction conditions (and remain or become catalytically active). For example, although these small metal particles in isolated form appear to be stable to molecular oxygen, oxidation to metal oxides by molecular oxygen in solution cannot be ruled out. Preliminary results of elemental analyses of our cluster material indeed suggest a PdO structure.

In conclusion, we have demonstrated 1) the feasibilty of preparing giant palladium clusters by reduction of $Pd(OAc)_2$ under an oxygen atmosphere with Me_2SO as both the solvent and the stabilizing ligand, and 2) the involvement of these Me_2SO-stabilized palladium clusters in a catalytic homogeneous oxidative reaction.

At present, we are working on further establishing the structure and nature of the clusters observed and determining whether they are the actual catalytically active species.[19]

Experimental Procedure

Palladium acetate (100 mg, 0.44 mmol) was dissolved in 2 mL of Me_2SO (previously dried and distilled from CaH_2). The flask was repeatedly evacuated and purged with molecular oxygen. Compound **1** [10] (240 mg, 0.88 mmol) was added at room temperature with vigorous stirring. The reaction mixture was heated at 40 °C for one minute and deemed complete by TLC and ^1H NMR spectroscopy. To the reaction mixture was added 100 mL of toluene (previously dried over sodium wire and distilled from P_2O_5). After 72 h at -20 °C a fluffy dark-brown solid had precipitated. The light brown toluene supernatant containing the oxazolidine product **2** and Me_2SO was decanted. The residue was washed by decantation with toluene (3×50 mL; the collected toluene layers yielded after aqueous workup 221 mg (93%) of crude **2**) and pentane (3×50 mL). A black powder (57 mg) was obtained after drying in vacuo. FTIR spectra were recorded (KBr disk) on a Nicolet 510 M FTIR spectrometer. The following procedure showed the material to be still highly catalytically active. In analogy to the published method [10], 4.2 mg of this material corresponding to an equal amount of $Pd(OAc)_2$ (0.02 mmol) was dissolved in 5 mL of dry Me_2SO. The flask was equipped with a septum and repeatedly evacuated and purged with molecular oxygen. An atmosphere of pure molecular oxygen was ensured throughout the procedure by means of a balloon. Under vigorous stirring **1** (271 mg, 1.00 mmol) was added at room temperature, and the clear dark brown mixture was heated to 70 °C. After 2 h of vigorous stirring the reaction was complete by TLC. The light yellow reaction mixture was poured into 50 mL of water and extracted with four 20 mL portions of a 1:1 mixture of diethyl ether and petroleum ether (b.p. 40–60 °C). The collected organic phases were dried over $MgSO_4$ and concentrated in vacuo. Purification (flash chromatography, ethyl acetate/hexanes 1:3, $R_f = 0.45$) provided **2** (242 mg, 0.90 mmol, 90%, 1:1 mixture of isomers) as a colorless oil.

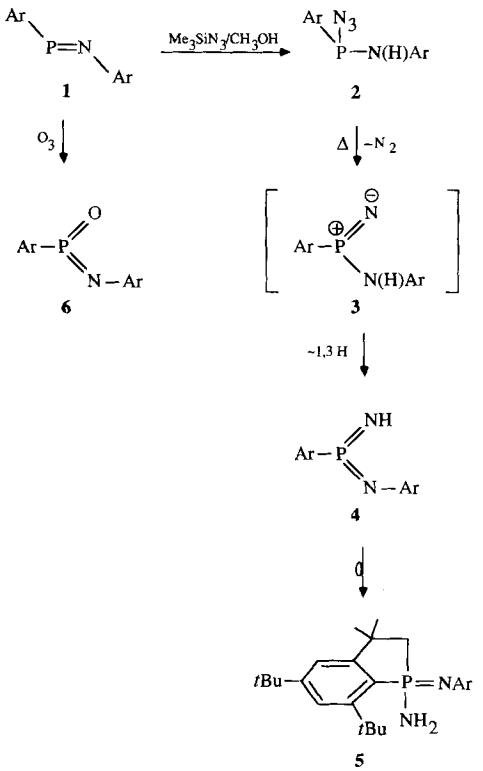
[16] With 0.1 equiv $Pd(OAc)_2$ this reaction reached completion after 20 h at room temperature.
[17] The samples were diluted 50-fold with 96% ethanol. A film of this solution was applied with a platinum wire eye onto a 2.3 mm copper grid previously covered with an amorphous carbon film. The sample was allowed to concentrate to dryness in air and was then ionized.
[18] TEM images were obtained on a Philips EM 420 electron microscope operating at 120 kV.
[19] Criteria for determining whether a reaction is catalyzed by a cluster or a mononuclear species are summarized in ref. [5b].

Synthesis, Structure, and Reactivity of an Imido- and an Oxo(imido)phosphorane R–P(=X)=NR (X = NH, O; R = $tBu_3C_6H_2$**

Martin Larbig, Martin Nieger, Volker von der Gönna, Alexander V. Ruban, and Edgar Niecke*



Dedicated to Professor Alfred Schmidpeter on the occasion of his 65th birthday

Bis(imino)phosphoranes are versatile synthetic building blocks for phosphorus–nitrogen heterocycles[1] and moreover have gained significance as ligands for homogeneous catalytic processes.[2] The possibility of extending the synthetic potential of these compounds by functionalization of an imine nitrogen atom[3] was the stimulus for the investigations described. We report here on the synthesis and structure of the first imido(imino)phosphorane (**I**) and on the structure of the oxygen derivative (**II**) isoelectronic to **I**. The existence of an oxo(imino)phosphorane had previously been based on NMR spectroscopic evidence only.[4]

I **II**

Treatment of the bisaryliminophosphane **1**[5] with trimethylsilylazide in the presence of one equivalent of methanol afforded the NH-functionalized amino(azido)phosphane **2** in a smooth reaction (Scheme 1). Compound **2** could be isolated as colorless

Scheme 1. Ar = 2,4,6-$tBu_3C_6H_2$.

thermally stable crystals. In solution, **2** decomposes above 40 °C with the elimination of nitrogen. The initially formed phosphinonitrene intermediate **3**[3] is stabilized by a 1,3-H shift[7] to give the imido(imino)phosphorane **4**. The iminophosphorane **5** isomeric to **4** is a by-product of the reaction, which can be obtained quantitatively by heating the reaction mixture for several days under reflux. The conversion **4** → **5** involves the CH activation of an *ortho*-positioned *tert*-butyl group on the phosphorus substituent by the highly electrophilic phosphorus center. One insertion reaction corresponding to this isomerization is also documented for the analogous aryldithioxophosphorane[8] and is thought to be responsible for the unsuccessful attempts at the synthesis of a kinetically stabilized aryldioxophosphorane.[9] The oxgen derivative **6** isoelectronic to **4** can be obtained by ozonization of **1** in CH_2Cl_2.

The composition and constitution of the compounds **2**, and **4**–**6** can deduced from the high-resolution mass spectra (molecular ion) and the results of NMR measurements. The constitution of **2** as that of an azidophosphorane and not that of a 4,5-dihydro-1*H*-tetraazaphosphole[10] is based on the presence of an intense absorption at 2105 cm^{-1} in the IR spectrum and the downfield position of the ^{31}P NMR signal ($\delta = 96.0$, $^2J(H,P) = 5.9$ Hz). The presence of an imido group in the vicinity of a coordinatively unsaturated phosphorus center in **4** is revealed by the structure of the doublet ($^2J(H,P) = 22.3$ Hz) and the typi-

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 334) and the Fonds der Chemischen Industrie.

cal position of the ^{1}H NMR (δ = 5.51) and ^{31}P NMR signals (δ = 45.8 Hz). The cyclic structure of **5** is indicated for example in the ^{13}C and ^{1}H NMR spectra by a methylene group linked with the phosphorus atom [$\delta(^{13}C)$ = 40.5 (J(P,C) = 76.3 Hz); $\delta(^1H)$ = 1.75 (J(H,P) = 11.0 Hz), 2.21 (J(H,P) = 12.0, J(H,H) = 15.1 Hz)].

The crystal structures of the compounds **2**, **4**, and **6** were confirmed by X-ray structure analyses. Figure 1 shows the molecular structure of the azidophosphane **2**. Like the azide groups in

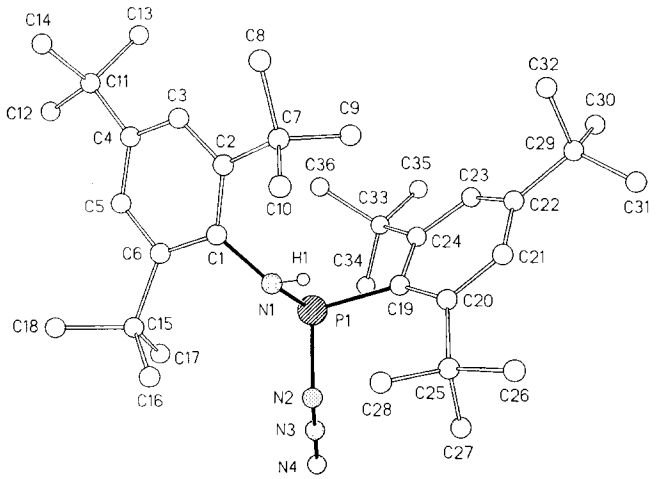

Fig. 1. Molecular structure of **2** in the crystal. Selected bond lengths [pm] and angles [°]: P1–N1 168.3(5), P1–N2 177.3(4), N2–N3 120.1(7), N3–N4 112.6(7), P1–C19 184.8(6); N1-P1-N2 100.8(2), N1-P1-C19 104.0(2), N2-P1-C19 104.2(2), P1-N1-C1 118.9(4), P1-N2-N3 118.4(4), N2-N3-N4 173.0(6).

the only structurally characterized azidophosphane, 2,4,6-tBu$_3$C$_6$H$_2$P(N$_3$)$_2$,[13] the N$_3$ substituent in **2** is almost linear (angle at N3: 173.0°); the N–N distances differ significantly (N2–N3 120.1 pm, N3–N4 112.6 pm) and the N2 atom is sp^2 hybridized (P1-N2-N3 118.4°). The relatively large P1–N2 distance (177.3 pm) possibly arises due to the repulsive interaction between the lone pairs on the N1 and P1 atoms. The distances P1–N1 (168.3 pm) and P1-C19 (184.8 pm) and the angles at the P atom (N2-P1-C19 104.2°, N1-P1-N2 100.8°, N1-P1-C19 104.0°) are not unusual.

The molecular structures of the phosphoranes **4** and **6** are shown in Figure 2 (the values in square brackets in the following refer to **6**). As in all structurally investigated imino(ylene)phosphoranes,[1] the central phosphorus atom is in a trigonal-planar environment (sum of the angles at P: 360.0° [360.0°]). The two ArP=NAr units adopt the thermodynamically favored E configuration,[14] just like the ArP=NH fragment in **4**. The aryl substituent at P1 is arranged approximately orthogonal to the central π-bond system (angle between the plane C19-P1-N1-N2 [C1-P1-N1-O1] and the aryl plane is 88.8° [89.1°]), in contrast the aryl group at N1 adopts an almost coplanar arrangement (angle between the plane C19-P1-N1-N2 [C1-P1-N1-O1] and the aryl plane is 8.3° [7.6°]). The angle at the imine nitrogen N1 (161.8° [160.0]), indicative of sp hybridization, is unusual. It explains the relatively short P–N1 distance (150.1 pm [148.9 pm]). The strengthening of the P–N1 bond in **4** is compensated by a weakening of the P–N2 bond (154.2 pm). Whether the P–O bond in **5** (146.6 pm) is also weakened cannot be verified due to the lack of data for comparison.[15]

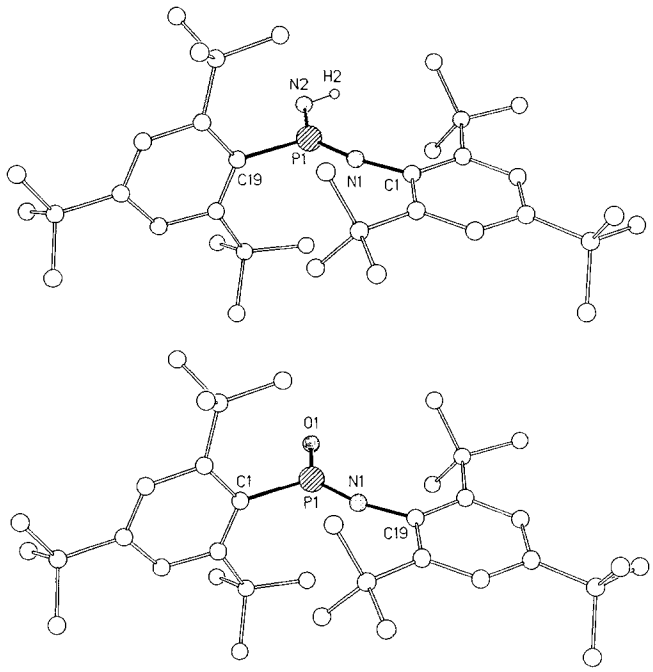

Fig. 2. Top: Molecular structure of **4** in the crystal. Selected bond lengths [pm] and angles [°]: P1–N1 150.1(2), P1–N2 154.2(2), P1–C19 180.1(2), N1–C1 140.8(3); N1-P1-N2 138.6(1), N1-P1-C19 114.1(1), N2-P1-C19 107.3(1), P1-N1-C1 161.8(1). Bottom: Molecular structure of **6** in the crystal. Selected bond lengths [pm] and angles [°]: P1–N1 148.9(2), P1–O1 146.6(2), P1–C1 179.6(2), N1–C19 140.7(2); O1-P1-N1 134.1(1), O1-P1-C1 112.1(1), N1-P1-C1 113.8(1), P1-N1-C19 160.0(1).

Experimental Procedure

2: A solution of the iminophosphorane **1** (5.34 g, 10 mmol), methanol (0.32 g, 10 mmol), and trimethylsilylazide (1.15 g, 15 mmol) in diethyl ether (30 mL) was stirred for about 12 h at room temperature. After the end of the reaction, which was apparent by a color change from deep violet to orange, all volatiles were removed in vacuum and the residue was taken up in hexane. The product was crystallized at 4 °C. Yield: 4.14 g (72%), m.p. 134–136 °C (decomp). ^{31}P NMR (C_6D_6): δ = 96.0 (d, ^2J(P,H) = 5.9 Hz); ^{1}H NMR (C_6D_6) (without aryl groups): δ = 4.86 (d, ^2J(H,P) = 5.9 Hz); MS (70 eV/200 °C) m/z (%): 578 [M^+] (2), 550 [$M^+ - N_2$] (28), 493 [$M^+ - N_2 - t$Bu] (100).

4, **5**: The azidophosphane **2** (1.47 g, 2.5 mmol) was dissolved in hexane (10 mL) and was heated with stirring at 60 °C for about 12 h until complete conversion (^{31}P NMR spectroscopic control). Subsequently, the solution was concentrated to about half and cooled to −30 °C. In this way the product precipitated as white crystals. Yield: 0.8 g (57%). M.p. 153–155 °C. ^{31}P NMR (C_6D_6): δ = 45.8 (d, ^2J(P,H) = 22.0 Hz); ^{1}H NMR (C_6D_6) (without aryl groups): δ = 5.51 (d, ^2J(H,P) = 22.3 Hz); MS (70 eV/190 °C) m/z (%): 550 [M^+] (5), 535 [M^+ – Me] (4), 493 [$M^+ - t$Bu] (100). When the reaction mixture was refluxed for 3d, **5** was formed quantitatively. M.p. 184–187 °C. ^{31}P NMR (C_6D_6): δ = 17.2; ^{1}H NMR (C_6D_6): δ 1.21 (s, 3H; Me), 1.23 (s, 3H; Me), 1.35, 1.48, 1.55, 1.86, 1.88 (all s, each 9H; tBu), 1.75 (dd, 1H, J(H,P) = 11.0, J(H,H) = 15.1 Hz; HCP) 2.21 (dd, J(H,P) = 12.0, J(H,H) = 15.1 Hz; HCP), 2.49 (d, 2H, J(H,P) = 1.3 Hz; H_2NP), 7.28 (dd, 1H, J(H,P) = 3.9, J(H,H) = 1.8 Hz; aryl-H), 7.58 (dd, 1H, J(H,P) = 2.2, J(H,H) = 2.4 Hz; aryl-H), 7.69 (dd, 1H, J(H,P) = 1.4, J(H,H) = 2.4 Hz; aryl-H), 7.72 (dd, 1H, J(H,P) = 5.1, J(H,H) = 1.8 Hz; aryl-H); ^{13}C NMR (C_6D_6) (selection): δ = 40.5 (d, J(C,P) = 76.3 Hz; CH_2P), 39.1 (d, J(C,P) = 7.6 Hz; Me_2CCP), 129.9 (d, J(C,P) = 126.7 Hz; *ipso*-CP); MS (70 eV/190 °C) m/z (%): 550 [M^+] (74), 535 [M^+ – Me] (73), 493 [$M^+ - t$Bu] (100).

6: An ozone-oxygen mixture was bubbled into a stirred solution of **1** (5.35 g, 10 mmol) in dichloromethane (150 mL) at −78 °C until a sudden change in color from violet to yellow took place. The solution was allowed to warm to room temperature and evaporated to dryness in vacuum. The residue was taken up in hexane (ca. 10 mL). The imino(oxo)phosphorane **6** crystallized from this solution at −30 °C. Yield: 4.8 g (87%), m.p. 120–122 °C. ^{31}P NMR (C_6D_6): δ = 34.2; MS (70 eV/180 °C) m/z (%) = 551 [M^+] (16), 494 [$M^+ - t$Bu] (100).

X-ray structure analysis for **2**: $C_{36}H_{59}N_4P$ [11]: colorless crystals, crystal dimensions 0.15 × 0.22 × 0.25 mm; M_r = 578.8; orthorhombic, space group *Pbca* (no. 61), a = 18.153(4), b = 17.684(4), c = 22.505(4) Å, V = 7.224(3) nm^3, Z = 8, $\mu(Cu_{K\alpha})$ = 0.87 mm^{-1}, T = 208 K, $F(000)$ = 2544. 9069 reflections up to $2\theta_{max}$ = 110° were measured on an Enraf-Nonius CAD4 diffractometer, of these 4546 were independent and were used for all calculations. The structure was solved by direct methods

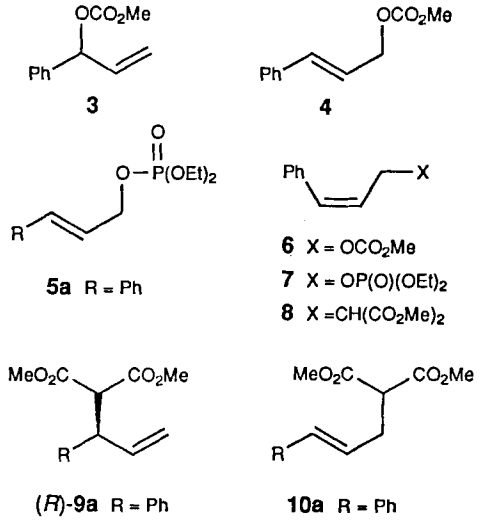
Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution**

Guy C. Lloyd-Jones and Andreas Pfaltz*

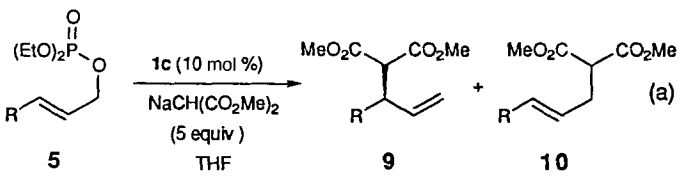
Recently, asymmetric Pd-catalyzed allylic substitution has received considerable attention and excellent enantioselectivities may now be achieved in certain cases.[1–3] Alternative transition metal catalysts for this reaction have been less actively researched. In the group VI series, Faller et al. have described stoichiometric stereospecific alkylations of allylmolybdenum complexes[4] and Trost et al. have done pioneering work on achiral molybdenum and tungsten catalysts with which the regioselectivity is often complementary to the Pd-catalyzed reaction.[5] Herein we report on the properties of tungsten complexes (**1**) of chiral phosphanodihydrooxazoles **2**[2c, d, 3b] as catalysts for enantioselective allylic substitution.[6]

1a M = W, X = Cl, Y = allyl
1b M = W, X = Br, Y = 1-phenylallyl
1c M = W, X = CH_3CN, Y = CO
1d M = W, X = CO, Y = CO
1e M = Mo, X = CH_3CN, Y = CO



2a R = *i*Pr
2b R = Me
2c R = CH_2Ph
2d R = Ph
2e R = *t*Bu
2f R = *i*Bu

In initial experiments, racemic carbonate **3** was treated with $NaCH(CO_2Me)_2$ (2.6 equiv) in the presence of 9 mol% **1a** (THF, 60 °C) to afford (*S*)-**9a** and **10a** in 71% yield with encouraging regioselectivity (**9a**:**10a** = 78:22) but negligible enantioselectivity (5% *ee*). There was no reaction in the absence of catalyst. Primary carbonates **4** and **6** failed to react, however, the corresponding diethyl phosphate **5a** was smoothly converted to a 23:77 mixture of (*R*)-**9a** (82% *ee*) and **10a** in 75% yield, whilst the (*Z*) isomer **7** gave (*S*)-**9a** (17% *ee*) and **8** in 55% yield (**9a**:**8** = 18:82). Control experiments demonstrated that the regioselectivities, but not enantioselectivities were compromised by competing uncatalyzed reactions.[7] Interestingly, stoichiometric reactions of complexes **1a** or **1b** with excess $NaCH(CO_2Me)_2$ resulted in displacement of ligand **2a** and did not yield alkylation products. However, after addition of **5a** to the mixture, slow formation of **9a** and **10a** was observed.



A more reactive as well as more selective catalyst was obtained by the following procedure: $[W(CO)_3(CH_3CN)_3]$ or [W(cycloheptatriene)$(CO)_3$] (10 mol%) was treated first with **2a** (60 °C, THF, 30 min), then $NaCH(CO_2Me)_2$ (2.6 equiv, THF,

60 °C, 2 h), and finally with the allylic phosphate at a range of temperatures (−30–+60 °C). The order of addition[8] and careful exclusion of oxygen were found to be crucial. Using this procedure, **5a** afforded (*R*)-**9a** as the major regioisomer in good yield and with high *ee* (at −10 °C: 95% yield of **9a** + **10a** (72:28), 96% *ee*; at 25 °C: 97% yield (69:31), 92% *ee*). Complex **1c** afforded an equally selective but more reactive catalyst than that generated in situ [Table 1, Eq. (a)].[9] Similarly high

enantio- and regioselectivities were also observed with other aromatic substrates **5b–e**.[10] (*E*)-2-Butenyl phosphate **5f**, on the other hand, reacted with reverse regioselectivity and moderate enantioselectivity. The isostructural Mo complex **1e** was not useful as a catalyst under these conditions (Table 1).

Table 1. Enantioselective allylic alkylation catalyzed by **1c** [Eq. (a)][a].

Substrate	R	*T* [°C]	*t* [h]	Yield [b] (**9** + **10**) [%]	**9**:**10**	*ee* of **9** [%] [c]

7		25	84	84[e]	66:34[e]	30 (*S*)

[a] 10 mol% of **1c**; conditions: see Experimental Procedure. [b] Yields of **9** and **10** after chromatography. [c] Determined by HPLC (Chiralcel OJ). Configurational assignments: (*S*)-(−)-**9a** was converted to (*S*)-(+)-dimethyl phenylsuccinate. This confirms the previous mechanism-based assignment [4c]. (*R*)-(+)-**9b–d**: by CD comparison with (*R*)-(+)-**9a**. (*R*)-(+)-**9e**: by comparison of the CD spectrum of the corresponding 5,6,7,8-tetrahydronaphthyl-propyl derivative prepared by hydrogenation (Pt/Al_2O_3, 50 bar H_2, AcOH) with the spectrum of the phenylpropyl derivative obtained by hydrogenation of (*R*)-(+)-**9a**. [d] Using Mo complex **1e** generated in situ. [e] The products were (*S*)-**9a** and **8** (no (*E*) isomer **10a** detected).

Tungsten complexes of the phosphanodihydrooxazoles **2b, c** decomposed rapidly, whilst bulkier substituents at the stereogenic center (**2d–f**) resulted in dramatically lowered rates and selectivities. The rapid (*E*/*Z*) equilibration and epimerization processes that are prevalent under Pd catalysis[11] were not observed in any of the W-catalyzed reactions, consistent with previous observations by Trost et al.[5b] Hence compared to **5a**, the *Z* isomer **7** yields the opposite enantiomer of **9a** in 30% *ee* together with **8** but no detectable *E* isomer **10a**.

The active complex derived from **1c** is the first example of an enantioselective tungsten catalyst for allylic alkylation. The regio- and enantioselectivities with arylpropenyl phosphates **5a–e** are opposite to those obtained by using analogous Pd(phosphanodihydrooxazole) catalysts.[11] Our results further illustrate the utility of phosphanodihydrooxazole ligands[2c, d, 3b] in asymmetric catalysis.

Experimental Procedure

All manipulations were performed on a vacuum line under Ar with degassed solvents.

1c: A vigorously stirred suspension of [W(CO)$_3$(CH$_3$CN)$_3$] [12] (0.767 mmol) in THF (15 mL) and **2a** (1.34 mmol) was heated to 60 °C for 3 h, cooled to 25 °C, and filtered. The dark red filtrate was carefully layered with hexane (20 mL). After complete diffusion (9 days), the resultant dark red blocks were isolated by filtration, washed with 1:1 THF/hexane (2 × 20 mL) and dried in vacuo to afford **1c** (364 mg; 63%) as a 1:1 complex with THF [6]. Correct elemental analysis for $C_{33}H_{35}N_2O_5PW$. IR(KBr): $\tilde{\nu}_{CO}$ = 1907s, 1792s cm^{-1}.

Allylic substitution: In a glove box, **1c** (0.026 mmol) was transferred into an ampoule equipped with magnetic stirring bar and Young valve. On a vacuum line, THF (2 mL) was added and the mixture stirred at 25 °C for 2 h (deep purple-red solution), then treated with NaCH(CO$_2$Me)$_2$ (1.36 mmol in 1.4 mL of THF, 25 °C, 2 h). The red catalyst solution was frozen (liquid N_2) and combined with **5b** (0.26 mmol in 2 mL of THF). The ampoule was then sealed and warmed rapidly to −13 °C. After 208 h at −13 °C, the reaction mixture was treated with 2.8 M aqueous NH_4Cl (3 mL), extracted with CH_2Cl_2, dried over Na_2SO_4, and evaporated. The crude product (^{1}H NMR: **9b**:**10b** = 80:20) was purified by chromatography (silica gel, 2.5 × 25 cm; hexane/EtOAc 9:1) to afford (*R*)-**9b** (52 mg, 73%) as a colorless oil. $[\alpha]_D$ = +40.2 (*c* = 1.0, $CHCl_3$, 24 °C); HPLC (Chiralcel OJ; 0.46 × 25 cm, 0.5 mL min^{-1}, hexane/*i*PrOH 93:7, detection at 220 nm): t_R 42.8 min (*R*), 48.5 min (*S*). Tenfold scale-up with **5a** gave similar results.

[6] The synthesis and X-ray structures of complexes **1a–d** will be reported elsewhere: G. C. Lloyd-Jones, A. Pfaltz, *Z. Naturforsch. B*, in press.
[7] Uncatalyzed reactions (c(substrate) = 0.09 M in THF, 2.6 equiv of $NaCH(CO_2Me)_2$, 60 °C) gave exclusively the achiral regioisomers (81% **10a** from **5a** after 18 h; 58% **8** from **7** after 24 h). At −13 °C: ca. 1% conversion in two weeks (0.07 M **5a**, 5.5 equiv of $NaCH(CO_2Me)_2$).
[8] Reaction of $[W(CO)_3(CH_3CN)_3]$ with $NaCH(CO_2Me)_2$ in the presence of **2a** resulted in much lower activity. In the absence of $NaCH(CO_2Me)_2$, $[W(CO)_3(CH_3CN)_3]$ presumably reacts with **2a** and **5a** or **7** to generate analogues of **1b**, resulting in lower reactivity and poor regioselectivity. The importance of adding $NaCH(CO_2Me)_2$ before the substrate has also been noted with W(bpy) catalysts (ref. [5b]).
[9] $[W(CO)_3(CH_3CN)_3]$ reacts with **2a** (^1H, ^{31}P NMR, $[D_8]THF$) to yield a mixture including **1c**, **1d**, and $[(\mathbf{2a})_2W(CO)_3]$, the ratios of which depend on the relative amounts of the starting compounds (ref. [6]). Compound **1d** is inactive as a catalyst.
[10] Substrates **5a–e** were prepared from the corresponding aromatic aldehydes: (1) CH_2 = $CHMgCl$, THF, 25 °C, 60–83%; (2) Ac_2O, Et_3N, DMAP, CH_2Cl_2, 25 °C, 86–96%; (3) $[Pd(CH_3CN)_2Cl_2]$ (1 mol%), THF 25 °C, 68–97%; (4) MeOH, K_2CO_3 (cat), 25 °C, 47–81%; (5) $(EtO)_2POCl$, C_5H_5N, DMAP, CH_2Cl_2, 25 °C, 50–80%.

Bis(dicyanomethylene) and Bis(cyanoimino) Derivatives of Indigo and Thioindigo**

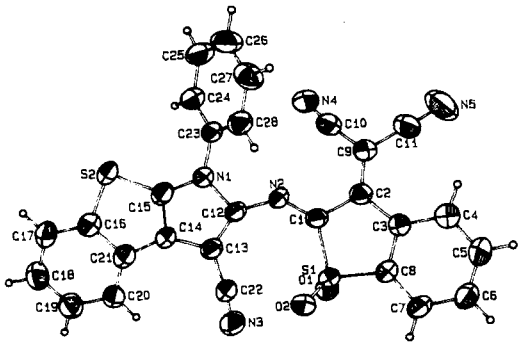
Rudolf Gompper,* Karsten Hartmann, Robert Kellner, and Kurt Polborn

Indigo and related compounds are of great technical importance owing to their properties as dyes. The indigo chromophore giving this class of relatively small and simple molecules their characteristic intense color has been the subject of numerous investigations.[1] Surprisingly, no indigo derivatives are known in which the O atoms of the carbonyl groups have been replaced by other electron-withdrawing groups. We report here on our successful synthesis of compounds of this type.

In our studies we focused on dicyanomethylene and cyanoimino groups, in particular, as acceptor groups. (The analogy between dicyanovinyl and carbonyl functions was discussed in detail previously.[2]) Since these groups extend the π-electron system, it was expected that the resulting chromogens would absorb at longer wavelengths, possibly even in the near-IR (> 700 nm). An additional bathochromic shift due to the twist of the compounds about the central double bond as a result of steric repulsion may also contribute (cf. ref. [3]).

A typical method for the synthesis of indigoid dyes is the condensation of compounds such as indolin-3-one ("indoxyl") or benzo[*b*]thiophen-3(2*H*)-one ("oxythionaphthene") with anils like 2-phenyliminoindolin-3-one ("isatin-2-anil").[4] However, the reaction of benzo[*b*]thien-3-ylmalodinitrile **1a**[5] with anil **3** in acetic anhydride/glacial acetic acid did not lead to the desired thioindigo derivative **2**. Instead an unusual reaction sequence produced a poorly soluble, dark blue compound (λ_{max} = 662 nm (DMSO)), which we assign structure **4a** based on its analytical and spectroscopic data (which are similar to those of the better characterized **4b**). To our knowledge, compounds of this type have not been described previously. The analogous compound **4b** (λ_{max} = 590 nm (DMSO)) was prepared from sulfone **1b**[5b, 6]

and **3**. The crystal structure analysis[7] of **4b** (Fig. 1) shows that the phenyl ring avoids interaction with the dicyanomethylene groups by twisting out of the plane of the tricyclic system. In contrast, the bond to the dicyanomethylene group (C2–C9) is only slightly twisted (8.3°).



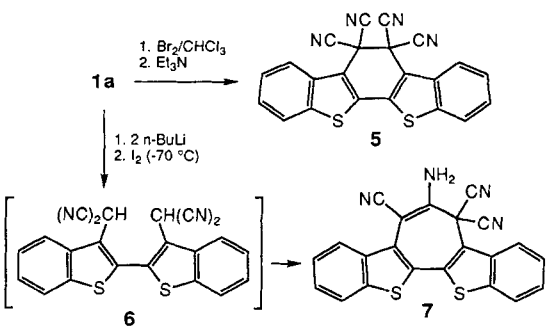


Fig. 1. Crystal structure of **4b** [7] (ORTEP plot). Selected bond lengths [Å] and angles [°]: C1-N 127.3(7), C1-C2 1461(8), C1-S1 180.1(4), C2-C9 136.1(6), C9-C10 144.3(8), C9-C11 142.5(9), C10-N4 141.1(8), C11-N5 113.1(8), C12-N1 142.0(7), C12-N2 133.6(8), C13-C22 142.7(7), C22-N3 112.9(7), C14-C15 138.6(6), C15-N1 134.3(8), C15-S2 171.9(6), C16-S2 177.0(5); C1-N2-C12 134.5(4), C1-S1-C8 92.8(2), C12-N1-C15 107.8(4), C15-S2-C16 89.5(3); C1-C2-C9-C10 6.39(0.87), C1-C2-C9-C11 1.61(0.55), C3-C2-C9-C11 6.22(0.91), C3-C2-C9-C10 10.99(0.53), C12-N1-C23-C24 46.87 (0.52), C15-N1-C23-C28 48.30(0.54).

Thioindigo can be obtained, for example, by treatment of 2-bromobenzo[*b*]thiophen-3(2*H*)-one with base or by reaction of its 2,2-dibromo derivative with benzo[*b*]thiophen-3(2*H*)-one.[8] Despite extensive efforts we were not able to prepare either the mono- or dibromo derivative of **1a** because of the instability of the products. However, treatment of a solution of **1a** in chloroform at room temperature with bromine, followed by addition of triethylamine gave the yellow bi(benzothiophene) derivative **5**

in addition to a small amount of an isomeric yellow compound. Electrocyclization of the *cis* derivative of **2** is presumed to provide **5**. The UV/VIS spectrum of the side product (λ_{max} = 425 nm (CH_2Cl_2)) indicates that it is not **2**, which like its *cis* isomer should absorb at much longer wavelengths.

In the crystal structure analysis[9] of **5** (Fig. 2) the twisted cyclohexadiene ring apparently prevents an eclipsed arrangement of the nitrile groups. As a result the planes of the two

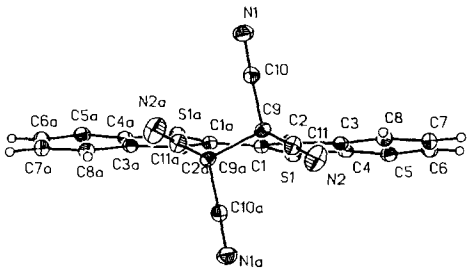

Fig. 2. Crystal structure of **5** [9] (ORTEP plot). Selected bond lengths [Å] and angles [°]: C1-C1a 145.1(6), C2-C9 152.4(4), C9-C9a 161.2(6), C2-C3 143.9(4), C1-S1 170.7(3), C9-C10 148.9(5), C9-C11 147.7(4); C2-C1-C1a 121.8(2), C2-C9-C9a 109.5(2), C1-C2-C3 113.3(3), C10-C9-C11 108.5(3), S1-C1-C2 113.4(2), C2-C3-C4 109.7(3), S1-C4-C3 112.5(2), C1-S1-C4 91.1(1).

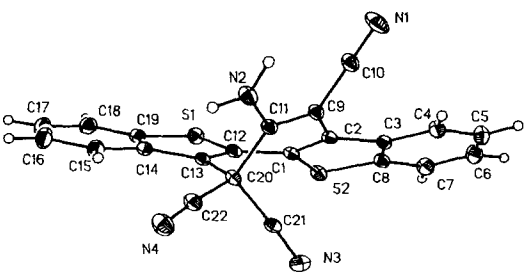
benzo[*b*]thiophene units are tilted in opposite directions forming an angle of 17.8°. The extremely long single bond (C9–C9a; 161 pm) between the CN-substituted C atoms is especially noticeable. The conversion of **5** into **2** was not possible, even though similar reactions are known for related systems.[10]

The most common approach for the synthesis of indigoid compounds is the oxidative coupling of appropriate methylene-active "monomers" and dehydration of the resulting "dimers". Reaction of **1a** with oxidizing agents such as aerial oxygen and potassium dichromate, which are used to convert benzo[*b*]thiophene-3(2*H*)-one into thioindigo, did not lead to **2** or **5**. However, **1a** can be lithiated with butyllithium in THF at −70 °C and at the same temperature the lithium salt subsequently oxidized with iodine. The fleeting intermediate **6** undergoes ring closure to give the cycloheptatriene derivative, whose structure is similar to that of dimethylcycloheptadithiophenone.[11] We attempted to prepare the dianion of **6** by addition of two further equivalents of butyllithium and then oxidize it with iodine, but this did not succeed.

In the crystal structure analysis[12] of **7** (Fig. 3) the folding of the seven-membered ring and the slight tilt of the benzo[*b*]thiophene planes in opposite directions are evident.



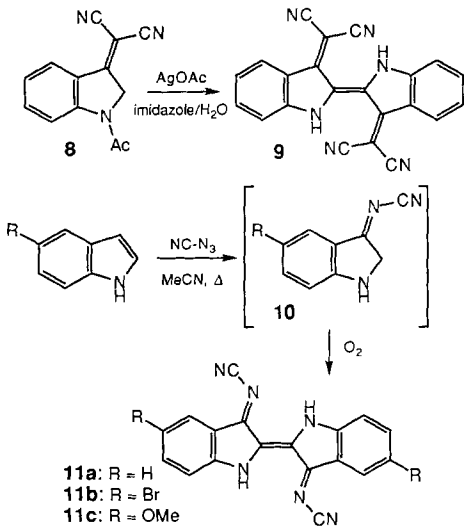


Fig. 3. Crystal structure of **7** [12] (ORTEP plot). Selected bond lengths [Å] and angles [°]: C1-C12 143.4(3), C1-C2 137.5(3), C2-C9 146.4(2), C9-C11 136.5(3), C11-C20 153.8(3), C13-C20 152.6(3), C12-C13 136.4(3), C1-S2 173.3(3), C8-S2 173.2(3), C3-C8 140.1(3), C2-C3 145.0(3); C1-C2-C9 123.9(2), C2-C9-C11 125.3(2), C11-C20-C13 107.4(1), C12-C13-C20 117.5(2), C1-C12-C13 126.1(2); C2-C1-C12-C13 −34.4(0.1), S2-C1-C12-S1 −34.0(0.2).

The conditions used for the conversion of **1a** into **5** or **7** did not convert indole derivative **8**[5b, 13] into **9**. However, oxidation of **8** to give **9** was possible with silver salts in the presence of organic bases. The best results were obtained with silver acetate in a mixture of two parts water and one part imidazole at 100 °C. Compound **9** forms as a dark green, poorly soluble powder and

can be purified by extractive recrystallization from chlorobenzene. The "medium effect" known for indigo is especially interesting here. A thin layer of solid **9** on a quartz plate absorbs at significantly longer wavelengths than in DMSO solution (λ_{max} = 778 vs 746 nm).

The bis(cyanoimino) derivatives **11** of indigo are formed by treatment of indoles with a solution of cyanogen azide in acetonitrile at reflux. In analogy to the conversion of olefins into *N*-cyanoimines by cyanogen azide[14] it can be assumed that indoline derivatives **10** form as intermediates, which are then oxidized by aerial oxygen to give **11**. The longest wavelength absorption of **11a** in DMSO lies at 751 nm (**11b**: 765; **11c**: 813 nm). Compounds **9** and **11** absorb at significantly longer wavelengths than indigo (λ_{max} (DMSO) = 621 nm), and are thus new near-IR dyes.

Like indigo, **9** and **11** can be converted to colorless, water-soluble forms by treatment with alkaline sodium dithionite solution. For **9** this process is irreversible; in the case of **11** the dye can be recovered by exposure to aerial oxygen or treatment with $K_3[Fe(CN)_6]$.

In conclusion the UV/VIS spectra of **9** and **11** display the anticipated strong bathochromic shift relative to that of indigo. Since crystal structure analyses of the new compounds are not available, the bonding relationships in **9** and **11** must be derived from AM1 calculations.[15] These indicate that in contrast to planar **11a**, **9** has a convex structure, in which the planes of the benzene rings are tilted towards each other forming an angle of 133°; the C atoms of the central C=C bond are only slightly *cis* pyramidalized (4°). The pronounced distortion of the entire chromophore explains why **9** absorbs at somewhat shorter wavelengths than **11a**, even though dicyanomethylene systems usually absorb at longer wavelengths than cyanoimine systems.[5b]

The fact that **9** could be prepared but **2** still remains elusive points out that the gain in energy upon formation of two benzothiophene systems is a key contribution to the stability of **5**. Consistent with this, the putative "dithio-thioindigo" is actually a 1,2-dithiine derivative[16] and structurally comparable to **5**.

Experimental Procedure

3: A solution of **1a** [5] (2.0 g, 10.09 mmol) in ethanol was treated with nitrosobenzene (1.18 g, 11.00 mmol). After addition of 0.2 mL of piperidine, the reaction mixture was stirred at room temperature for 30 min. The red precipitate was removed by vacuum filtration, washed with ethanol and ether, and recrystallized from ethanol. Yield 1.41 g (45%); dark red crystals, m.p. 165–166 °C. IR (KBr): ν = 3073, 2216, 1585, 1532, 1442, 1328, 1295, 1108, 771, 728, 685 cm^{-1}. – UV/VIS (DMSO): λ_{max} (ε) = 515 nm (22390). – ^1H NMR (400 MHz, [D$_6$]DMSO): δ = 7.31 (m, 4H), 7.41 (d, ^3J = 7.4 Hz, 1H), 7.47 (t, ^3J = 8.1 Hz, 2H), 7.57 (t, ^3J = 7.4 Hz, 1H), 8.60 (d, ^3J = 8.2 Hz, 1H). – ^{13}C NMR (400 MHz, [D$_6$]DMSO): δ = 79.04, 113.16, 114.00, 121.91, 124.02, 126.93, 127.52, 128.30, 128.60, 129.54, 135.86, 142.95, 147.49, 156.99. – MS (245 °C): *m/z* (%) = 287 (100, M^+), 261 (26, M^+ – CN), 184 (40, M^+ – CN – Ph), 157 (3, M^+ – HCN – CN – Ph), 77 (20, Ph^+).

4a: A mixture of **3** (0.17 g, 0.59 mmol), **1a** (0.14 g, 0.71 mmol), 5 g of acetic anhydride, and 1 g of glacial acetic acid was heated at reflux for 10 min. The reaction mixture was cooled, and the dark blue precipitate removed by vacuum filtration, washed with hot ethanol and ether, and recrystallized from a large volume of xylene. Yield 0.11 g (39%); fine, blue-violet, metallic needles, m.p. 358–359 °C. IR (KBr): ν = 3030, 2216, 1585, 1511, 1436, 1411, 1289, 1112, 1064, 770, 761, 739 cm^{-1}. – UV/VIS (DMSO): λ_{max} (ε) = 662 (15140), 319 nm (11750). – MS (250 °C): *m/z* (%) = 485 (26, $M^+ + H_2$), 483 (100, M^+), 458 (28, 485 – HCN), 432 (19, 458 – CN, 380 (9, M^+ – CN – Ph), 366 (7, M^+ – CN – NPh), 289 (9, $C_{17}H_{11}N_3S$), 274 (32, $C_{17}H_{10}N_2S$), 261 (4, $C_{16}H_9N_2S$), 246 (7). – High-resolution MS (250 °C, ref. = 480.9697): *m/z* = 483.0626 (calcd. 483.0621).

4b: Conditions analogous to those for **4a** were used but with **3** (0.65 g, 2.26 mmol) and 0.52 g of **1b** [5b,6]. Yield 0.21 g (39%); blue-violet crystals; m.p. >350 °C. IR (KBr): ν = 2223, 1595, 1539, 1436, 1383, 1322, 1227, 1170, 1052, 764, 745, 730 cm^{-1}. – UV/VIS (DMSO): λ_{max} (ε) = 590 (4470), 294 nm (10715). – MS (200 °C): *m/z* (%) = 515 (12, M^+), 451 (20, $M^+ - SO_2$), 424 (8, $M^+ - SO_2$ – HCN), 289 (100, $C_{17}H_{11}N_3S$), 261 (25, $C_{16}H_9N_2S$), 246 (17), 212 (51, $C_{11}H_4N_2OS$), 184 (19).

5: Compound **1a** (0.99 g, 5.00 mmol) was dissolved in 50 mL of anhydrous chloroform under nitrogen. A mixture of bromine (0.80 g, 5.00 mmol) and 10 mL of anhydrous chloroform was added dropwise to this solution. The reaction mixture was stirred at room temperature for ca. 12 h. Then a mixture of triethylamine (1.11 g, 11.0 mmol) and 7 mL of anhydrous chloroform was added dropwise. The reaction mixture was again stirred at room temperature for ca. 12 h before 500 mL of chloroform was added. The solution was washed successively with water, saturated sodium bicarbonate solution, saturated sodium thiosulfate solution, and water. The solution was dried over magnesium sulfate, filtered and concentrated to dryness. The residue was recrystallized from acetic anhydride. Yield 0.40 g (41%); pale yellowish platelets, m.p. 301 °C (decomp). The product was purified further by fractional crystallization from toluene, yielding in addition to **5** (pale yellow platelets, m.p. 311–312 °C (decomp)) a small amount of an isomer (fine yellow needles, m.p. >360 °C). **5**: IR (KBr): ν = 3060, 2255, 2248, 1510, 1461, 1436, 1322, 1315, 1242, 759, 727 cm^{-1}. – UV/VIS (CH_2Cl_2): λ_{max} (ε) = 386 (18620), 367 (23990), 350 (21380), 329 (sh, 14450), 257 (17380), 228 nm (30200). – ^1H NMR (400 MHz, $CDCl_3$): δ = 7.60 (ddd, ^3J = 8.1 Hz, ^3J = 7.2 Hz, ^4J = 1.2 Hz, 2H, H-3, H-8), 7.67 (ddd, ^3J = 8.4 Hz, ^3J = 7.2 Hz, ^4J = 1.2 Hz, 2H, H-2, H-9), 7.99 (mc, ^3J = 8.1 Hz, 2H, H-4, H-7), 8.46 (mc, ^3J = 8.4 Hz, 2H, H-1, H-10). – ^{13}C NMR (400 MHz, $CDCl_3$): δ = 43.41, 109.31, 112.42, 121.78, 123.63, 127.25, 127.51, 134.39, 134.67, 139.73. – MS (90 °C): *m/z* (%) = 392 (100, M^+), 366 (10, M^+ – CN), 340 (31, M^+ – 2CN), 334 (4, M^+ – SCN), 328 (2, $M^+ - C_3N_2$), 327 (3, $M^+ - C_3HN_2$), 313 (1, M^+ – HCN – 2CN), 308 (4, M^+ – 2CN – S), 302 (6, M^+ – CN – C_3N_2), 295 (4), 284 (2, $M^+ - C_6H_4S$), 196 (4, M^{2+}), 170 (4).

7: To a solution of **1a** (1.98 g, 10.0 mmol) in 75 mL of anhydrous THF at −70 °C under nitrogen was added dropwise a 15% solution of butyllithium in hexane (6.7 mL, 11.0 mmol). After 30 min at room temperature the reaction mixture was again cooled to −70 °C, and iodine (1.27 g, 5.00 mmol) was added. The reaction mixture was allowed to warm slowly to room temperature, stirred for ca. 12 h, and then poured into 400 mL of water with stirring. The initially formed oil crystallized after prolonged stirring. The crystals were removed by vacuum filtration and dried under vacuum. 1.46 g of the crude product was recrystallized from a large volume of ethanol. Yield 0.96 g (49%); pale pinkish platelets, m.p. 236–237 °C. IR (KBr): ν = 3433, 3360, 3205, 3056, 2205, 1636, 1569, 1317, 1227, 766, 753, 735 cm^{-1}. – UV/VIS (DMSO): λ_{max} (ε) = 377 (2455), 341 (sh, 15490), 293 (35480), 265 nm (22910). – ^1H NMR (400 MHz, [D$_6$]DMSO): δ = 7.58–7.71 (m, 4H, aryl-H), 8.15 (s, 2H, NH_2), 8.16 (mc, 1H, aryl-H), 8.19 (d, ^3J = 8 Hz, 1H, aryl-H), 8.40 (mc, 1H, aryl-H), 8.69 (d, ^3J = 8 Hz, 1H, aryl-H). – ^{13}C NMR (400 MHz, [D$_6$]DMSO): δ = 40.39, 73.29, 110.80, 115.28, 117.32, 121.77, 123.28, 123.6, 123.81, 125.48, 125.98, 126.40, 127.16, 127.71, 129.29, 133.36, 135.13, 136.07, 138.57, 140.03, 145.28. – MS (195 °C): *m/z* (%) = 394 (28, M^+), 368 (5, M^+ – CN), 340 (6, M^+ – 2HCN), 330 (100, $M^+ - C_3N_2$), 302 (8, M^+ – CN – $C_3H_2N_2$), 197 (4, M^{2+}), 165 (5).

9: To a solution of 5.0 g of imidazole in 10 mL of water at 100 °C was added **8** [5b,12] (0.75 g, 3.38 mmol). After 1 min silver acetate (1.50 g, 8.99 mmol) was added and the mixture stirred for 2 min. The mixture was vacuum-filtered while still hot and the residue washed with boiling dimethylformamide (2 × 20 mL). The dark green residue was extractively recrystallized from chlorobenzene. Yield 0.23 g (38%); dark green amorphous powder, m.p. >350 °C. IR (KBr): ν = 3292, 2206, 1605, 1590, 1406, 1310, 1221, 747 cm^{-1}. – UV/VIS (DMSO): λ_{max} = 746, 674, 435, 395 nm. – MS (245 °C): *m/z* (%) = 358 (100, M^+), 332 (13, M^+ – CN), 331 (18, M^+ – HCN), 305 (11, M^+ – HCN – CN), 278 (18, M^+ – 2HCN – CN), 180 (5, $C_{11}H_6N_3$).

11a: A solution of cyanogen bromide (3.70 g, 34.95 mmol) in 50 mL of anhydrous acetonitrile was treated with sodium azide (2.60 g, 39.92 mmol) and stirred at room temperature for 90 min. After the precipitate was filtered off, indole (4.0 g, 34.2 mmol) was added to the light yellow solution, which was then heated to reflux. After 1 h the resulting dark green precipitate was removed by vacuum filtration, washed with hot acetonitrile, and dried. Crude yield 1.50 g (28%); purification by recrystallization from xylene; fine blue-green needles, m.p. >350 °C. IR (KBr): ν = 3281, 2160, 1610, 1540, 1456, 1312, 1109, 763 cm^{-1}. – UV/VIS (DMSO): λ_{max} (ε) = 751 (28184), 558 (2240), 378 (11220), 306 nm (36310). – MS (245 °C): *m/z* (%) = 310 (76, M^+), 284 (14, M^+ – CN), 283 (25, M^+ – HCN), 269 (6, M^+ – HNCN), 257 (18, M^+ – HCN – NCN), 181 (10, $C_{10}H_5N_4$), 156 (6, $C_9H_6N_3$), 155 (6, $C_9H_5N_3$).

Correct elemental analyses were obtained for all compounds.

A Cyclic Hexairon(III) Complex with an Octahedrally Coordinated Sodium Ion at the Center, an Example of the [12]Metallacrown-6 Structure Type**

Andrea Caneschi, Andrea Cornia, Stephen J. Lippard*

Over the past ten years, several studies have been carried out to investigate possible pathways for the hydrolytic aggregation of iron(III) in an aqueous environment.[1] One strategy has been to use suitably designed polydentate organic ligands to control the chemical routes leading ultimately to the deposition of solids containing a portion of the α-FeO(OH) (goethite) crystal lattice. In this manner, a variety of polynuclear iron-oxo aggregates has been isolated either from aqueous[2, 3] or nonaqueous[4, 5] solutions. In particular, new synthetic techniques have been developed that take advantage of hydrolytic polymerization processes involving iron(II)/iron(III) in nonaqueous solvents to build up polyiron-oxo aggregates, which may serve as models for the mineral core in ferritin.[5] Large polyiron complexes are also of interest for obtaining nanometer-size magnetic particles.[6] The possible use of hydrolytic processes in the deposition of thin layers of iron oxides[7] makes them attractive entities for materials science as well.

Solution studies have provided evidence for the existence of a cyclic hexanuclear iron(III) species, in which the metal ions are connected by two hydroxo ligands, tentatively formulated as **1**. Such a species may be responsible for the reversible gelation

$[Fe_6(OH)_{12}(sor)_6]^{6-}$ **1**, H_2sor = sorbitol

phenomena observed upon careful neutralization of concentrated alkaline aqueous solutions of iron(III) and sorbitol.[8] We report here on the preparation and characterization of the hexanuclear iron(III) compound **2**. A solid-state X-ray diffraction study reveals that **2** has precisely the same overall ring structure as that proposed for the $[Fe_6(OH)_{12}]^{6+}$ core in **1**, and surprisingly that this ring serves as a host for the sodium ion.[9] Compound **2** thus qualifies as an authentic example of the [12]metallacrown-6 structure type.[10]

$[NaFe_6(OCH_3)_{12}(dbm)_6]Cl \cdot 12\,CH_3OH \cdot CHCl_3$ **2**, Hdbm = dibenzoylmethane

The crystal lattice of **2**[11] comprises centrosymmetric $[NaFe_6(OCH_3)_{12}(dbm)_6]^+$ cations (Fig. 1), as well as disordered chloride anions, chloroform, and methanol molecules. The six iron atoms are located at the vertices of an almost regular hexagon, with Fe···Fe separations in the range 3.18–3.20 Å, vertex angles of 119.5–120.5°, and average deviations of ±0.024 Å from the best least-squares plane. The diameter of the ring, defined as the average distance between two opposing iron atoms, is 6.39(2) Å. Bis(methoxo) bridges connect adjacent iron atoms; the remaining two sites of the distorted octahedral coordination sphere of each iron(III) center are occupied by a chelating dibenzoylmethanido ligand. Adjacent Fe_2O_2 planes through each pair of methoxo ligands and their two bound iron atoms are twisted with respect to each other and form dihedral angles of 120–121° with the mean plane of the Fe_6 ring. As a consequence, within each layer of six oxygen atoms contributed by the methoxo bridges, one above and one below the plane through the iron(III) centers, three oxygen atoms lie closer to the virtual C_6 symmetry

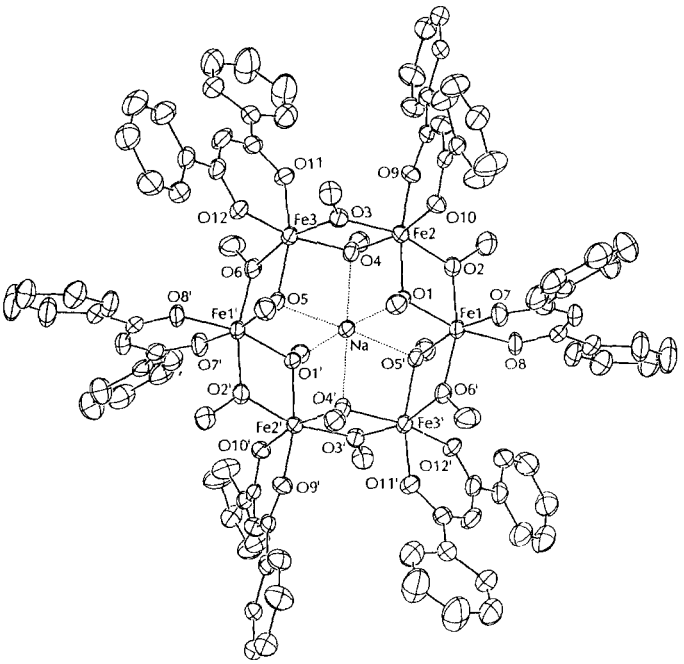

Fig. 1. ORTEP representation of the cation in **2** with atom labels. Hydrogen atoms have been omitted for clarity. An inversion center relates primed atoms to unprimed ones. Thermal ellipsoids enclose 50% probability. Relevant distances [Å] and angles [°]: Fe1-O1 2.022(3), Fe1-O2 2.005(5), Fe1-O5′ 2.019(3), Fe1-O6′ 2.003(5), Fe1-O7 1.983(3), Fe1-O8 1.975(4), Fe2-O1 2.029(5), Fe2-O2 2.001(3), Fe2-O3 2.016(4), Fe2-O4 2.025(3), Fe2-O9 1.998(5), Fe2-O10 1.977(3), Fe3-O3 2.003(3), Fe3-O4 2.027(4), Fe3-O5 2.032(5), Fe3-O6 2.007(3), Fe3-O11 1.979(5), Fe3-O12 1.996(4), Fe1-Fe2 3.184(1), Fe1′-Fe3 3.197(1), Fe2-Fe3 3.201(1), Na-O1 2.338(3), Na-O4 2.374(4), Na-O5 2.341(3); O1-Fe1-O2 75.5(2), O1-Fe1-O5′ 94.4(1), O2-Fe1-O5′ 93.1(2), O6′-Fe1-O1 94.7(2), O6′-Fe1-O5′ 75.1(2), O7-Fe1-O1 89.5(1), O7-Fe1-O2 99.8(2), O7-Fe1-O6′ 92.3(2), O8-Fe1-O2 92.5(2), O8-Fe1-O5′ 93.0(1), O8-Fe1-O6′ 98.4(2), O8-Fe1-O7 85.9(1), O4-Fe2-O3 74.9(1), O9-Fe2-O4 89.2(2), O9-Fe2-O3 99.6(2), O10-Fe2-O3 91.6(1), O10-Fe2-O9 86.9(2), O10-Fe2-O2 99.7(1), O10-Fe2-O1 92.5(2), O2-Fe2-O9 92.5(2), O2-Fe2-O4 94.8(1), O1-Fe2-O2 75.5(2), O3-Fe2-O1 92.7(2), O4-Fe2-O1 94.3(1), O4-Fe3-O3 75.1(1), O5-Fe3-O3 95.4(2), O5-Fe3-O4 95.0(2), O6-Fe3-O4 92.8(1), O6-Fe3-O5 74.7(2), O11-Fe3-O3 101.3(2), O11-Fe3-O4 92.6(2), O11-Fe3-O6 89.7(2), O12-Fe3-O3 89.9(1), O12-Fe3-O5 90.1(2), O12-Fe3-O6 102.6(1), O12-Fe3-O11 86.6(2), Fe1-Fe2-Fe3 119.51(3), Fe2-Fe3-Fe1′ 119.90(3), Fe3′-Fe1-Fe2 120.52(3), O4-Na-O1′ 101.8(1), O5-Na-O1′ 78.6(1), O5-Na-O4 78.8(1), O1-Na-O5 101.4(1), O1-Na-O4 78.2(1), O5-Na-O4′ 101.2(1).

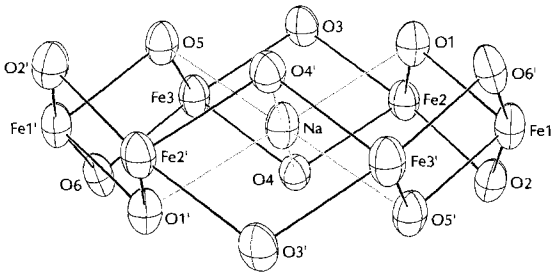

Fig. 2. ORTEP view of the iron–oxygen core of the cation in compound **2** with atom labels. An inversion center relates primed atoms to unprimed ones. Thermal ellipsoids enclose 50% probability.

axis of the hexamer than the other three. The corresponding O–C vectors are almost perpendicular to the mean plane of the ring, subtending angles of 86.0–87.6°. The remaining six methoxo ligands are directed outward from the center of the ring, and their O–C vectors form remarkably acute angles of 45.8–53.8° with the ring plane.

The sodium ion resides on a special position of $\bar{1}$ symmetry in the center of the ring, as unambiguously indicated by difference electron density maps. It is surrounded by a distorted octahedral cage of oxygen atoms (O1, O1′, O4, O4′, O5, and O5′) from the bridging methoxo ligands (Fig. 2). The Na–O distances (2.34–2.37 Å) reveal appreciable interactions of the sodium atom with the host cavity. As a consequence, average Fe–O(CH_3) distances for the methoxo ligands interacting with sodium are slightly longer than the remaining ones (Fig. 1). The O-Na-O and O-Fe-O angles in the four-membered rings are 78–79° and 94–95°, respectively.

Compound **2** is EPR silent at liquid-helium temperature, indicating a diamagnetic ($S = 0$) ground state. At higher temperatures, a broad signal appears at $g = 2$. Preliminary magnetic susceptibility measurements are consistent with these observations and reveal overall antiferromagnetic exchange coupling interactions between the paramagnetic iron(III) centers ($J = 20\ cm^{-1}$; $\mathcal{H} = J \sum_{i>j} (\boldsymbol{S}_i \cdot \boldsymbol{S}_j)$).

The ring structure of **2** is not unprecedented in transition metal chemistry[12, 13] and directly resembles some hexanuclear nickel(II) and palladium(II) alkanethioates.[13] Although polynuclear iron–sulfur complexes having a ring structure are well known,[14] the only cyclic oxygen-bridged iron complex reported so far is $[Fe(OCH_3)_2(O_2CCH_2Cl)]_{10}$.[15] In this respect, **2** is unique since it contains the $[Fe_6(OCH_3)_{12}]^{6+}$ core having only alkoxo bridges. This feature makes it an especially good structural model for cyclic intermediates proposed for the polyalcohol-promoted hydrolysis of iron(III) salts.[8] Moreover, because of its ability to harbor an alkali metal ion guest in a highly symmetric cavity comprising solely oxygen donors from monodentate bridges, the $[Fe_6(OCH_3)_{12}]^{6+}$ core of **2** can be considered a genuine inorganic analogue of [12]crown-6. An encapsulated sodium ion has similarly been found at the center of a cyclic hexacopper(II) complex,[16] but the structure is somewhat more complex owing to the present of bidentate bridging ligands, and its resemblance to [12]crown-6 is consequently less exact. Other inorganic systems described as metallacrowns have been reported in which additional bridging ligands are required to stabilize the host–guest complex.[10, 16, 17]

Finally, we note that the Anderson-type[18] topology of the iron(III) centers and sodium ion observed in **2** is reminiscent of the $[Fe_7(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_4\{(\mu_3\text{-}O)\text{-}Fe\}_2]^{13+}$ core found in complexes **3** and **4**.[3] This feature can be regarded as a fragment of a two dimensional AX_2 lattice such as found for CdI_2, which bears some resemblance to the structure of goethite. A similar

$[Fe_{17}(O)_4(OH)_{16}(heidi)_8(H_2O)_{12}]^{3+}$ **3** $[Fe_{19}(O)_6(OH)_{14}(heidi)_{10}(H_2O)_{12}]^{+}$ **4**

disposition of metal centers connected by μ_3-OCH_3 and μ_2-OPh ligands has been observed in an heptanuclear iron(II) aggregate.[19] Characteristic of these systems, and particularly evident from space-filling models of **2**, **3**, and **4**, is a flat, disklike structure with a peripheral hydrophobic shell afforded by the pendant organic ligands. The great tendency of the oxygen atoms to form hexagonal close-packed arrays is not altered by the presence of the organic moieties.

Modified Triple Resonance NMR Experiments with Optimized Sensitivity for Rapidly Exchanging Protons**

Wolfgang Jahnke and Horst Kessler*

Multidimensional NMR spectroscopy has developed into the premier method for determining high-resolution structures of molecules in solution. A major concern in the development of pulse sequences is improving the sensitivity of the NMR experiments.[1] The weakest signals in NMR spectra often arise from amide protons that exchange rapidly with the solvent water, and these weak signals often constitute the limiting factor in signal assignment and structure determination of proteins. The intensity of these resonances can be enhanced when the water signal is not saturated during the pulse sequence.[2-4] We describe here modified triple resonance experiments in which the water signal is not saturated and composite pulse proton decoupling is used. The modified pulse sequences yield a sensitivity gain of up to 50% for rapidly exchanging amide protons, where enhanced sensitivity is of outstanding importance.

Biological macromolecules like proteins and nucleic acids are usually investigated in aqueous solution and under semiphysiological conditions, in other words at roughly neutral pH. Under these conditions chemical exchange takes place between protons of the molecule under investigation (e.g. a protein) and the solvent water. Besides protons of ionizable groups in the side chains, backbone amide protons exchange with the solvent protons at rates ranging from reciprocal milliseconds to reciprocal years. Hydrogen exchange has been the subject of several investigations,[5,6] and it can be expected that the dynamic feature of hydrogen exchange can enhance our understanding of structure and dynamics of proteins and nucleic acids. Hydrogen exchange, however, is not a pure blessing. Very rapidly exchanging protons such as hydroxyl groups of protein side chains or amide protons at the protein N-terminus are not found in the spectrum under normal conditions, and crucial amide proton signals are attenuated if presaturation is used.

It has recently been pointed out[2,3] that the signals of rapidly exchanging protons are attenuated not only by presaturation, but also by other methods used to suppress the water signal such as spinlock pulses[7] and gradients,[8] when the water signal is saturated prior to acquisition. This is due to the long T_1 relaxation time of water protons (4–5 s), which is much longer than the T_1 time of protein protons. The delay between successive scans is optimized for the relaxation of the protein protons and is too short for the magnetization of the water protons to relax back near thermal equilibrium. Instead, the water magnetization remains in a semisaturated state during the entire experiment, typically reaching less than 30% of its equilibrium value just before the next scan.

Several methods have been described for overcoming this problem by not saturating the water signal prior to acquisition, while still ensuring that water does not interfere with the detection of the desired protein signals. These methods include selective pulses on the water resonance,[2] improved phase cycling of proton pulses,[3,4] and the constructive use of radiation damping;[4] all of these methods result in alignment of water magnetization on the $+z$ axis before or shortly after acquisition. While selective pulses may be undesirable due to imperfect excitation profiles,[9] neither of the other two methods describes the possibility for proton decoupling by a composite pulse decoupling sequence. This type of decoupling is desirable when the desired coherence resides on nitrogen or carbon because of more favorable relaxation behavior.[10] It is not immediately obvious how composite pulse decoupling can be incorporated into pulse sequences where water magnetization must end up in a defined state (e.g. at the $+z$ axis) before acquisition. First, it seems that the decoupling time must be an integer multiple of the time required for one decoupling cycle, but this is hard to achieve if the decoupling time includes an incrementable delay such as the t_1 time. Second, B_0 field gradients applied during composite pulse decoupling interfere with the decoupling and should be avoided.

We propose here a modification of pulse sequences that allows the use of composite pulse decoupling for any desired time period, while improved sensitivity of rapidly exchanging amide protons is still achieved since water magnetization is realigned along the $+z$ axis prior to acquisition. The modification is illustrated with the constant time (CT) HNCA and HN(CO)CA experiment[11,12] in Figure 1, but can be applied to many NMR experiments.

The CT-HNCA sequence (Fig. 1a) starts with excitation of the amide protons, whose magnetization is subsequently transferred to ^{15}N by an INEPT transfer. During the delay needed to develop the ^{15}N-$^{13}C^{\alpha}$ coupling, ^{15}N coherence refocuses with respect to protons, and is completely refocused after $1/2\,^1J(N,H)$, approximately 5.5 ms. At this time composite pulse decoupling should start. The decoupling phase is irrelevant for protein protons, but is crucial to keep water magnetization in a defined state. The water magnetization has been aligned at the $-y$ axis by the first 90° proton pulse with phase x; it stays there since its resonance corresponds to the carrier frequency and is thus not affected by the following two proton pulses with phase $+/-y$. Proton decoupling is now possible if a sequence is selected that applies pulses only along one axis, and if this axis is chosen to be the y axis. The DIPSI-2 sequence,[13] for example, can be applied successfully along the y axis in this case. After $^{13}C^{\alpha}$ frequency

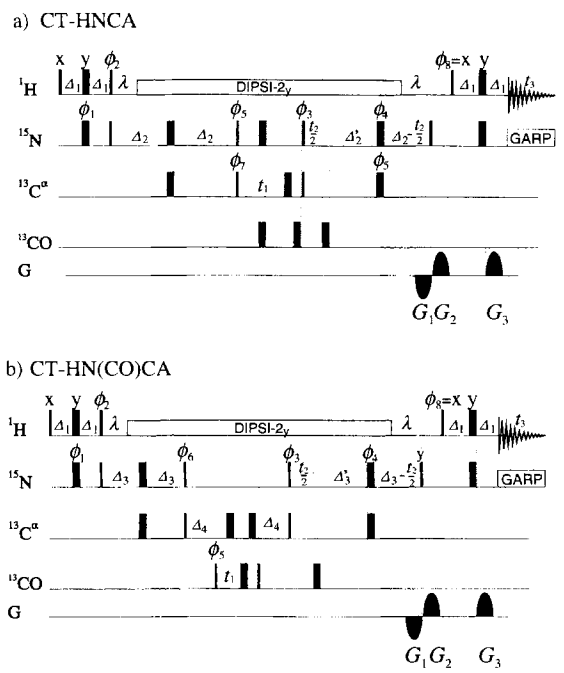

Fig. 1. Modified pulse sequences of a) CT-HNCA and b) CT-HN(CO)CA experiments. The strength of the B_1 decoupling field was 8.3 kHz. Thin and thick bars refer to 90° and 180° pulses, respectively. Pulses are applied along the x axis, unless otherwise indicated. Variable pulse phases are as follows: a) $\phi_1 = x, -x$; $\phi_2 = y, -y$; $\phi_3 = x$; $\phi_4 = 4(x), 4(y), 4(-x), 4(-y)$; $\phi_5 = 16(x), 16(-x)$; $\phi_7 = 2(x), 2(-x)$; receiver $= 2(x,-x,-x,x,-x,x,x,-x), 2(-x,x,x,-x,x,-x,-x,x)$. b) $\phi_1 = x, -x$; $\phi_2 = y, -y$; $\phi_3 = x$; $\phi_4 = 4(x), 4(y), 4(-x), 4(-y)$; $\phi_5 = 2(x), 2(-x)$; $\phi_6 = y, -y$; receiver $= 2(x), 4(-x), 2(x)$. Pulsed B_0 field gradients are sine-shaped and are applied for 1 ms, followed by a delay of 0.5 ms. Their relative strength is $G_1 = -39.6$, $G_2 = 39.6$ and $G_3 = 4$, with 100 being approximately 50 Gauss cm^{-1} at the center of the gradient. Gradient G_2 must be carefully optimized for maximum refocusing of water. Delays are as follows: $\Delta_1 = 2.25$ ms, $\lambda = 5.5$ ms, $\Delta_2 = 11$ ms, $\Delta'_2 = \Delta_2 - \tau_{180}(^{13}CO)$, $D_3 = 10$ ms, $\Delta'_3 = \Delta_3 - \tau_{180}(^{13}CO)$; $\Delta_4 = 6$ ms.

labeling in t_1 with decoupling of ^{15}N and ^{13}CO, a Bloch–Siegert shift compensating for the 180° pulse on ^{13}CO, and CT ^{15}N evolution in t_2, the coherence is transferred back to the amide protons, and is refocused and detected. Gradients G_1 and G_3 are included to select for the desired coherence pathway.

Water magnetization is spinlocked along the $-y$ axis by the DIPSI-2 decoupling sequence and is defocused by gradient G_1. It is not possible to refocus water magnetization by splitting G_1 into two gradients of the same strength but opposite sign on each side of a ^{15}N 180° pulse, since one of the gradients would have to be applied while composite pulse decoupling is active. Instead, the gradient for refocusing water magnetization is applied after the following ^{15}N 90° pulse, at a time when the protein magnetization is in an I_zS_z state but water magnetization is in the transverse plane. After the refocusing gradient G_2, the water magnetization is aligned along the $-y$ axis. It is then turned to the $-z$ axis by the 90° pulse with phase $\phi_8 = x$, and turned to the $+z$ axis by the following 180° proton pulse. A one-dimensional experiment shows that the longitudinal water magnetization reaches as much as 80% of its equilibrium value after this sequence. That means that exchanging amide protons obtain almost the full longitudinal magnetization from water protons and their signals are not a priori attenuated by the exchange process. Any water magnetization that is not realigned along the $+z$ axis (due to imperfect pulses or radiation damping) is defocused by gradient G_3, which supplies excellent suppression of the water signal.

The modified pulse sequence has been tested on a 2 mM sample of completely ^{15}N- and ^{13}C-labeled mannose permease domain IIA^{Man} at 310 K and pH 7.5.[14] This homodimer of 31 kDa contains a number of rapidly exchanging amide protons,[6] for which a considerable increase in sensitivity is expected when the water magnetization is flipped back to thermal equilibrium before acquisition. Figure 2 shows rows through the first 2D planes of

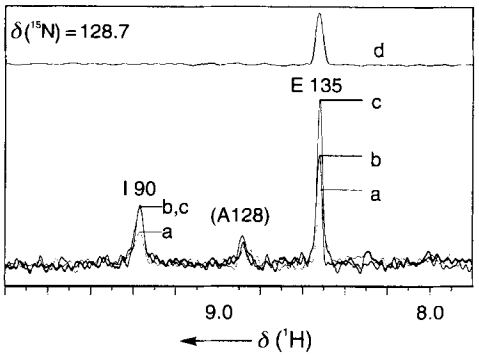

Fig. 2. ^1H rows from the first planes of CT-HNCA spectra taken at a ^{15}N frequency of 128.7. It can be seen that the proposed pulse sequence of Fig. 1a gives the best sensitivity for the rapidly exchanging amide proton. Residues A128 and E135 resonate at a slightly different ^{15}N frequencies. All experiments were recorded and processed under identical conditions on a Bruker AMX600 spectrometer with triple resonance equipment and self-shielded pulsed field gradients. 256 transients were accumulated for each of the 80 t_1 increments. The recycle time between successive scans including acquisition was 1.1 s.

spectra obtained with different versions of HNCA experiments: the CT experiment using 180° pulses for proton decoupling[11] (curve a), the CT experiment with composite pulse proton decoupling[11] and saturation of the water signal ($\phi_8 = y$ in Fig. 1a) by pulsed field gradients (curve b), and CT-HNCA (as described in Fig. 1a) using composite pulse proton decoupling and flipping water magnetization back to thermal equilibrium (curve c). In addition the corresponding row through a MEXICO spectrum is shown,[6] in which only rapidly exchanging protons give rise to cross peaks (curve d). It is obvious that proton decoupling by a composite pulse decoupling sequence (curve b) yields considerably higher sensitivity than decoupling by 180° pulses (curve a), as expected for a protein of this size.[10] An additional substantial increase in sensitivity is gained for rapidly exchanging amide protons if the water signal is not saturated prior to acquisition. This is seen in curve c for residue E135, which has a rapidly exchanging amide proton (curve d). The signal-to-noise ratio for this peak is about 50% higher when the water magnetization is flipped back to equilibrium before acquisition. Residue E135 is located near the C-terminus of the protein in a flexible part of the molecule that is not involved in regular secondary structure. Thus, E135 gives rise to a strong cross peak in spite of its rapidly exchanging amide proton. It is important to note, however, that since most other rapidly exchanging amide protons yield much weaker signals, the sensitivity enhancement obtained specifically for these signals is of outstanding importance.

In conjunction with the described possibility of using composite pulse proton decoupling, the technique of flipping water magnetization back to thermal equilibrium before acquisition can be applied without compromise to a wide variety of NMR experiments. Since the technique enhances the signal intensity predominantly for the weak resonances, for which enhanced sensitivity is most important, it can be expected that assignment of NMR spectra is greatly facilitated by this technique.

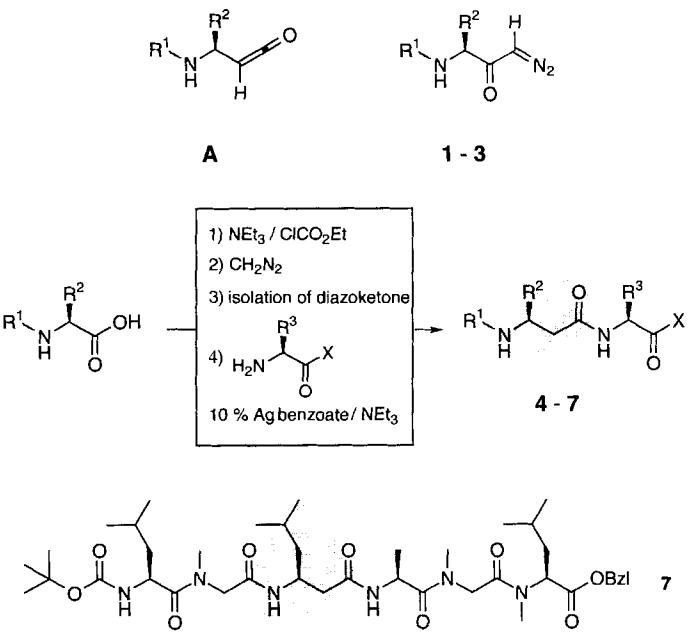
The Arndt–Eistert Reaction in Peptide Chemistry: A Facile Access to Homopeptides**



Joachim Podlech and Dieter Seebach*

β-Amino acids, though less abundant than α-amino acids, are components of natural peptides.[1] In recent years their importance for the preparation of modified peptides[2] and β-lactam antibiotics[3] has increased enormously. Quite a number of methods for the synthesis of enantiopure β-amino acids exists already.[4] Still it would be a conceptually new, simple approach for the construction of peptides containing β-amino acids, if the generation of the β-amino acid moiety could be combined with a peptide coupling step. To this end, we have now applied to peptides the chain extension of carboxylic acids developed by Arndt and Eistert.[5, 6]

When we started this work, it was not certain whether the peptidic ketenes **A** formed in this reaction could be trapped intermolecularly, and if so, whether they would couple selectively with the free amino function of a second peptide.

At first we simply coupled two amino acids following the sequence of steps outlined in Scheme 1. Activation of Z-protected alanine with ethyl chlorocarbonate to give the mixed anhydride and reaction with diazomethane in THF or Et_2O afforded the corresponding diazoketone **1** (R^1 = Z, R^2 = Me) in 80% yield. Like all compounds of this type obtained in the course of this investigation, the diazo compound **1** is a solid and could be purified by chromatography on silica gel or by recrystallization. A solution of **1** and 2–4 equivalents of valine benzyl ester[7] in THF was treated with Et_3N and a catalytic amount of silver benzoate at low temperature, yielding the homodipeptide **4**. In the same manner the protected di- and tripeptides Z-Ala-Ala-OH and Boc-Leu-Sar-Leu-OH were coupled via diazoketones **2** and **3**, respectively, with the tripeptides H-Ala-Sar-MeLeu-OBzl and H-Leu-Sar-Leu-OMe[8] (see Table 1). The formation of both the diazoketones and the homopeptides proceeds with good to very good yields. The products were characterized by mass spectrometry, elemental analysis, and by their optical rotation. Owing to the presence of rotamers, the NMR spectra are not informative, except for those of the protected dipeptides. All components of the peptide derivatives obtained are enantiopure, as proved by degradation to the free α- and β-amino acids and analysis by gas chromatography on chiral columns.[9]

To test whether the ketene of type **A** is actually the immediate precursor to the homopeptide derivatives, we decomposed (12% AgOCOPh, 6 h) the diazoketone **2** in THF in the absence of a nucleophile and then added MeOH. The methyl ester **9** was formed in virtually the same yield as when the reaction was

Scheme 1. Ketene **A** and diazoketones **1**–**3** generated as intermediates in the Arndt–Eistert reaction with amino acid and peptide derivatives, and coupling with homologation of two amino acids or two peptides to homopeptides (**4**–**7**). The formula of one of the synthesized homohexapeptides **7** is given. For R^1, R^2, R^3, and X see Table 1.

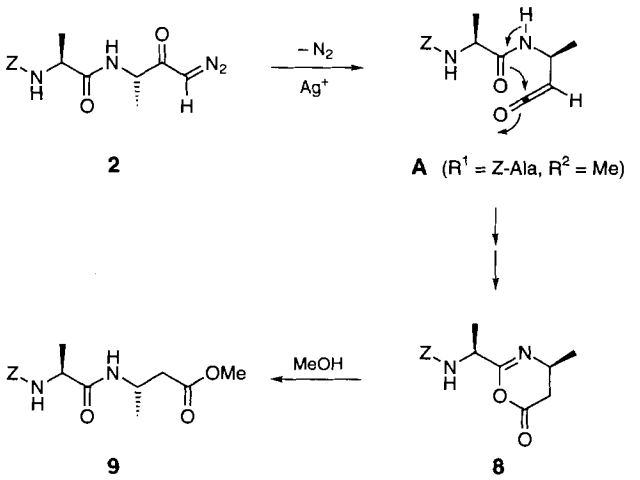


Table 1. Diazoketones **1**–**3** and homopeptide derivatives **4**–**7** synthesized according to Scheme 1. Abbreviations: Bzl = $PhCH_2$, Z = BzlOCO, Boc = *t*BuOCO, *i*Bu = CH_2CHMe_2. Optical rotations were measured in $CHCl_3$ with $c \approx 1$.

Cmpd.	R^1	R^2	R^3	X	Yield [%]	$[\alpha]_D$
1	Z	Me			80

carried out in methanol as the solvent (Scheme 2). Since we did not consider it likely that the ketene was stable for 6 h, we examined a solution prepared in [D_6]THF by NMR spectroscopy. We found that not the ketene, but the dihydrooxazinone **8** is present in the solution,[10] and is stable for at least 12 h when air is excluded. This heterocycle is a cyclic imino anhydride, in other words an activated derivative, and reacts with nucleophiles to give the desired homopeptides.[11]

Scheme 2. Experiment used to identify the intermediate **8** formed from a peptidic ketene **A** and methanolysis product **9** (m.p. 111–113 °C, $[\alpha]_D = -46.9$ ($c = 1.06$, $CHCl_3$)).

The method for the synthesis of homopeptides presented here allows for an insertion of a β-amino acid at any stage of a peptide synthesis.[12] The active acyl derivative (**A** or dihydrooxazinone) involved reacts not only with amino acid esters and peptides with an unprotected N-terminus, but also with other nucleophiles. Experiments along these lines, for instance reactions with carbohydrates and 3-hydroxybutanoic acid oligomers[13] are in progress. The plethora of possibilities suggests that the method may be used for constructing new types of peptide-containing combinatorial libraries.[14]

Experimental Procedure

Diazoketone **3**: Et_3N (1.39 mL, 10.0 mmol) and $ClCO_2Et$ (953 μL, 10.0 mmol) were added to a solution of Boc-Leu-Sar-Leu-OH (4.16 g, 10.0 mmol) in THF (50 mL, distilled from Na/K) at −15 °C under argon. After 15 min the resulting solution was allowed to warm to −5 °C and then treated with a solution of CH_2N_2 [15] in ether, until the yellow color of CH_2N_2 persisted over a longer period of time. The mixture was allowed to warm to room temperature and stirred for an additional 3 h. Excess CH_2N_2 was destroyed by vigorous stirring or by addition of a small amount of HOAc. After aqueous workup by extraction with saturated $NaHCO_3$, NH_4Cl, and NaCl solutions, the organic solution was dried ($MgSO_4$) and concentrated to dryness. Chromatography on silica gel (ethyl acetate/hexane 2/1) gave diazoketone **3** in 86% yield (3.76 g, 8.60 mmol).

Protected homohexapeptide **7**: A solution of silver benzoate (16.0 mg, 70.0 μmol) in Et_3N (215 μL, 1.54 mmol) was added to a solution of **3** (238 mg, 541 μmol) and H-Ala-Sar-MeLeu-OBzl (528 mg, 1.40 mmol) in THF (10 mL) at −25 °C under argon with exclusion of light. The reaction mixture was warmed to room temperature over 3 h, and some Et_2O was added. After workup by extraction with HCl (0.2 N, 2 ×) and saturated NaCl, $NaHCO_3$, and NaCl solutions, the organic solution was dried ($MgSO_4$) and concentrated to dryness. The residue was purified by chromatography on silica gel (ethyl acetate) to give the protected homopeptide **7** (257 mg, 326 μmol, 60%).

[6] There are numerous reports about the application of this reaction for the homologation of α- to β-amino acids [4, 5b]. In almost all cases the enantiopurity of the products formed with retention of configuration was not determined by modern analytical techniques (NMR spectroscopy, gas chromatography) (K. Balenović, I. Jambrešić, B. Gašpert, D. Cerar, *Recl. Trav. Chim. Pays-Bas* **1956**, *75*, 1252–1258; K. Balenović, D. Fleš, I. Jambrešić, *Croat. Chem. Acta* **1956**, *28*, 303–305 and references therein). We used the following amino acid derivatives in the Arndt–Eistert reaction (activation via the mixed anhydrides): Z-Ala-OH, Z-Phe-OH, Boc-Phe-OH, Boc-*tert*-Leu-OH, Boc-Orn(Boc)-OH, Z-Phg-OH, Boc-Phg-OH. Analysis of the Mosher derivatives showed that all reactions, except for that of phenylglycine (Phg), occur with more than 98% retention of configuration. We tested milder activation methods with phenylglycine. Activation with isobutyl-2-isobutyloxy-1(2*H*)-quinolinecarboxylate (IIDQ) afforded diazoketone (10% racemization, as with $ClCO_2Et$), but reaction with *N*-hydroxysuccinimide/dicyclohexylcarbodiimide (HOSu/DCC) or benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (PyBOP) did not.
[7] The reaction could not be carried out with the hydrochloride of the amino acid ester.
[8] For the preparation of the di- and tripeptides used here, see: H. G. Bossler, D. Seebach, *Helv. Chim. Acta* **1994**, *77*, 1124–1165.
[9] S. Abdalla, E. Bayer, H. Frank, *Chromatographia* **1987**, *23*, 83–85; the enantiopurity of the β-amino acids could be determined by this method as well.
[10] Compound **8** was unambiguously identified by ^1H, ^{13}C, DEPT, COSY, and HETCOR NMR spectroscopy. In an analogous experiment the diazoketone from Z-alanine yielded Z-HomoAla-OMe when methanol was added after 6 h.
[11] Dihydrooxazinones of this type were generated from various β-amino acid derivatives by other methods and used as active esters (C. N. C. Drey, E. Mtetwa, *J. Chem. Soc. Perkin Trans. 1* **1982**, 1587–1592 and references therein).
[12] The method appears to be applicable to all appropriately protected amino acids except for tryptophane and histidine.

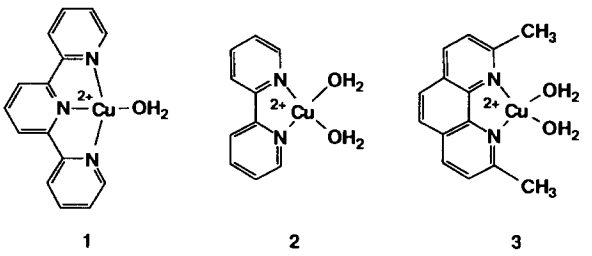
Rapid Hydrolysis of RNA with a Cu^{II} Complex**



Barry Linkletter and Jik Chin*

Over the years, many interesting artificial enzymes that hydrolyze the phosphate diester bonds of RNA have been reported. They include nonmetallic compounds[1] as well as transition metal complexes[2] and lanthanide complexes.[3] Sequence-specific hydrolysis of RNA has recently been achieved by using various metal complexes covalently attached to deoxyoligoribonucleotides.[4, 5] Although these results are promising, the reactivities of artificial RNases fall far short of natural RNases. Typically, the half-life for artificial RNase-catalyzed hydrolysis

[**] Financial support was provided by the National Science and Engineering Council of Canada and the U.S. Army Research Office.

of RNA at neutral pH and 50 °C ranges from hours to days. Hence there is much current interest in increasing the reactivity of artificial RNases as well as in understanding factors affecting the reactivity of such catalysts. $[Cu(terpy)(OH_2)]^{2+}$ (**1**) and $[Cu(bpy)(OH_2)_2]^{2+}$ (**2**) are two of the most reactive transition metal complexes reported to date for hydrolyzing the phosphate diester bonds of RNA (terpy: terpyridyl; bpy: 2,2'-bipyridyl).[2, 4] Here we compare the reactivity of [Cu(neocuproine)$(OH_2)_2$]$^{2+}$ (**3**) for hydrolyzing ApA to those of **1** and **2**.

1 **2** **3**

Copper complexes, **1**, **2**, and **3** were freshly generated in solution from the corresponding chlorides. Cleavage of ApA to A, Ap, and pA was monitored by high-pressure liquid chromatography (HPLC). Optimal reactivity of the copper complexes is reached at solution pH values close to the pK_a of the copper-coordinated water molecules. The pK_a values of the coordinated water molecules in **1**, **2**, and **3** are 8.2, 7.8, and 7.0, respectively, indicating that the copper center in **3** is the most Lewis acidic. The pseudo-first-order rate constants for **1**, **2**, and **3** (10 mM) promoted cleavage of ApA (0.5 mM) at the respective optimal pH values are $1.9\times10^{-5}\,s^{-1}$, $1.9\times10^{-7}\,s^{-1}$, and $3.9\times10^{-3}\,s^{-1}$. The half-lives for **1**, **2**, and **3** promoted cleavage of ApA are 10 hours, 42 days, and 3 minutes, respectively. All of the reaction solutions were buffered with *N*-(2-hydroxyethyl)piperazine-*N'*-2-ethanesulfonic acid (HEPES, 10 mM) and kept at 25 °C. A typical HPLC plot for **3** (10 mM) promoted cleavage of ApA (0.5 mM) at pH 7 and 20 °C is shown in Figure 1. The concentration of 2',3'-cAMP accumulates appreciably during the cleavage reaction, and it is subsequently converted to 3'-AMP and 2'-AMP in a ratio of about 6 to 1. It is evident from the HPLC plot that the cleavage reaction occurs hydrolytically at the phosphate rather than oxidatively at the ribose ring.

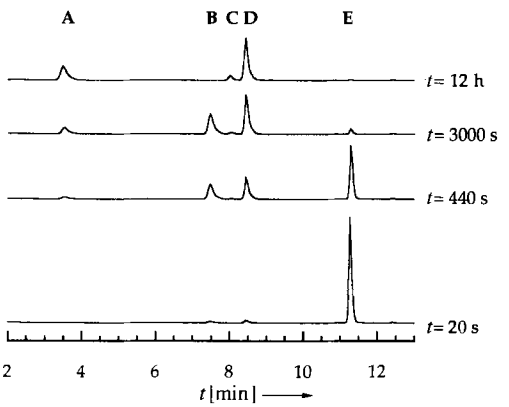

Fig. 1. Chromatograms for hydrolysis of ApA (0.1 mM) catalyzed by **3** (10 mM) in the presence of 10 mM HEPES buffer (pH 7) at 20 °C (after 20, 440, and 3000 s, and after 12 h). The traces shows disappearance of ApA (E) and appearance of adenosine (D) and 2',3'-cAMP (B), which opens to 3'-AMP (A) and 2'-AMP (C).

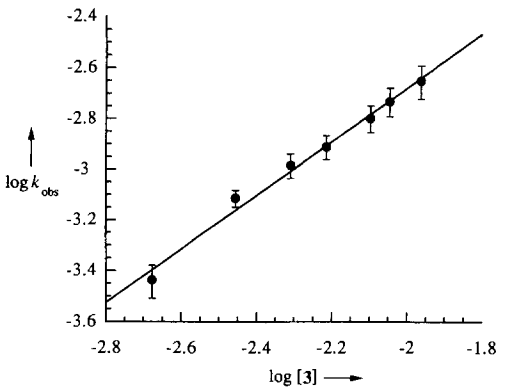
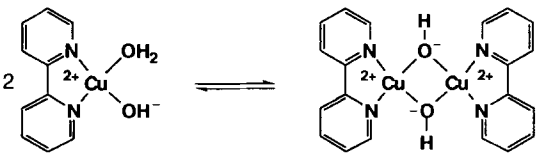
The rate of cleavage of ApA is first order (Fig. 2) with respect to the concentration of **3**, clearly indicating that the cleavage reaction is a mononuclear process (slope: 1.06; intercept: −0.56; correlation coefficient: 0.994). Interestingly, **3** is over 200 times more effective than **1** and over 20000 times more effective than **2** for catalyzing ApA cleavage. A phosphate diester coordinated to Co^{III} as a monodentate ligand hydrolyzes only about 10^2 times faster than the free phosphate diester.[6] Hence the dramatic difference in the reactivities of **1**, **2**, and **3** is unlikely to be solely due to the difference in the Lewis acidities of the metal complexes.





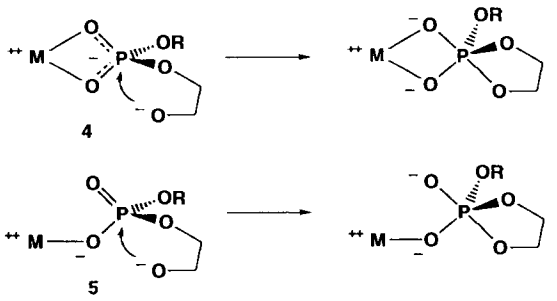


Fig. 2. Dependance of k_{obs} [s^{-1}] on the concentration of **3** [M] for hydrolysis of ApA (0.1 mM) in 10 mM HEPES buffer (pH 7) at 20 °C, as a log/log plot.

At neutral pH, **2** dimerizes[7] with an equilibrium constant of $1\times10^5\,M^{-1}$ [Eq. (a)], and the dimer is inactive for hydrolyzing ApA. At pH 7.8, only about 8% of **2** is in the monomeric form. In contrast, **3** does not dimerize appreciably under the reaction condition owing to the steric effect of the two methyl groups. When the dimerization of **2** is accounted for, **3** is still about 1000 times more reactive than **2** for hydrolyzing ApA.

(a)

One possible mechanism that can account for the high reactivity of **3** involves chelation of the phosphate diester to the copper complex resulting in double Lewis acid activation. In general, a phosphate diester that is chelated to a metal center (**4**) should hydrolyze more rapidly than a phosphate diester that is singly coordinated to a metal center (**5**). In the former case the

4 **5**

developing negative charge is stabilized by the cationic metal center, while in the latter case the developing negative charge is not stabilized by the metal. The metal center in **4** is providing double Lewis acid activation, while the metal center in **5** is providing single Lewis acid activation. We recently showed that a dinuclear metal complex can rapidly cleave an RNA model compound by providing double Lewis acid activation.[8] The two methyl groups in the neocuproine ligand should decrease the O-Cu-O bond angle in **3**, which should facilitate the chelation of phosphate diesters. In octahedral Co^{III} complexes, the O-Co-O bond angles in chelated phosphates are significantly smaller than the 90° angle found in regular octahedral complexes.[9]

Among simple compounds, lanthanides and their complexes are the most reactive for hydrolyzing nucleic acids.[10] However, enzymes use transition metals, Mg^{2+}, or Ca^{2+} to cleave phosphate esters. Consequently, there is considerable interest in developing simple transition metal, Mg^{2+}, or Ca^{2+} complexes that efficiently hydrolyze the phosphate diester bonds of RNA. Complex **3** represents by far the most reactive transition metal complex reported to date for hydrolyzing RNA.

Experimental Procedure

The copper chloride complexes [Cu(terpy)Cl]Cl, [Cu(bpy)Cl_2], and [Cu(neocuproine)Cl_2] were prepared by mixing the appropriate ligands with $CuCl_2$ in methanol. All of the ligands and $CuCl_2$ are soluble in methanol, whereas the complexes precipitate out of the solvent. Cleavage of ApA was monitored by HPLC (Hewlett-Packard 1090). In a typical kinetic experiment, a solution of ApA (0.5 mM), **3** (10 mM), and HEPES (10 mM) was allowed to react at pH 7.0 and 25 °C. Aliquots (50 μL) of the reaction mixture were quenched with 100 mM ethylenediaminetetraacetic acid (EDTA) (50 μL). The quenched solutions (10 μL) were injected onto a C-18 reversed-phase column (5 μm Hypersil maintained at 40 °C) and eluted for 5 min with $NH_4H_2PO_4$ (0.2 M at pH 5.5) followed by a 0–50% linear gradient of $NH_4H_2PO_4$ (0.2 M at pH 5.5) and methanol/water (3:2) solutions over 10 min with a flow rate of 0.5 mL min^{-1}.

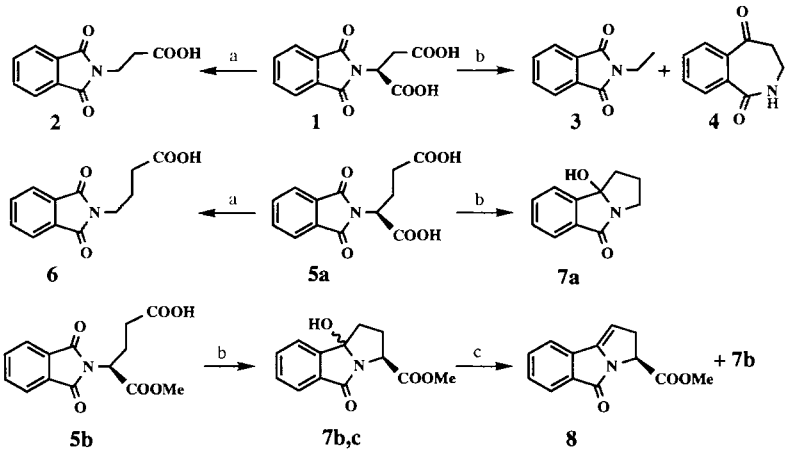
Photo Electron Transfer Induced Macrocyclization of *N*-Phthaloyl-ω-amino-carboxylic Acids**

Axel G. Griesbeck,* Andreas Henz, Karl Peters, Eva-Maria Peters, and Hans Georg von Schnering



In the presence of strong electron donors such as arene carbonitriles,[1] heteroarenes,[2] and iminium cations,[3] aliphatic carboxylic acids and the respective anions can be photochemically decarboxylated. The carbon radicals produced undergo fragmentation or (re)combination. Intramolecular versions of these reactions yield complex products, for example spiroannulated heterocycles.[4] During our investigations on the photochemistry of *N*-phthaloylamino acids[5] we discovered a surprisingly efficient synthesis of systems containing medium-sized and large rings.

The photochemical approach to macrocycles requires a strong electron-donating substituent (e.g. thioether, enamine) in the side chain of the *N*-alkylphthalimide. The phthalimide chromophore behaves as an electron-accepting group ("remote photocyclization").[6] A disadvantage of this method is in all cases the incorporation of the electron donor into the ring system formed. An approach in which formation of the new O–C single bond is combined with extrusion of the electron donor would be promising.[7] ω-Aminocarboxylic acids could be suitable substrates; however, only the photochemical reactivity of α-amino acids has been reported up to now.[8] The corresponding *N*-phthaloyl derivatives are decarboxylated when irradiated at 300 nm. This reaction proceeds with high regioselectivity also in the presence of other carboxyl groups in β- or γ-position. Even prolonged photolysis does not cleave these remote substituents. We have used this principle for the synthesis of deuterium-labeled β- and γ-aminocarboxylic acids.[9] A decisive factor for the efficiency and regioselectivity might be formation of a intramolecular hydrogen bond. Presumably this reaction proceeds by a primary proton transfer[10] to the electronically excited phthalimide group (Excited State Proton Transfer, ESPT[11]) followed by an electron transfer step. Since remote carboxyl groups do not form this hydrogen bond, this initial proton transfer step cannot occur.

Electron transfer even from remote positions is possible for carboxylic acid anions when primary proton transfer is no longer necessary. Irradiation of *N*-Pht-aspartic acid **1** (Pht = phthaloyl) in acetone leads to *N*-Pht-β-amino-propionic acid **2** in quantitative yield. In the presence of ten equivalents of sodium carbonate, however, a 9:1 mixture of *N*-ethylphthalimide **3** and the cyclized compound **4** was isolated (Scheme 1). Still decarboxylation from the α-position is considerably faster, as was demonstrated for the glutamic acid derivative **5a**: irradiation under nonionic conditions leads to *N*-Pht-γ-aminobutyric acid **6** as the sole product. In the presence of sodium carbonate (ionic conditions) the benzopyrrolizidine **7a** is formed in 76% yield.

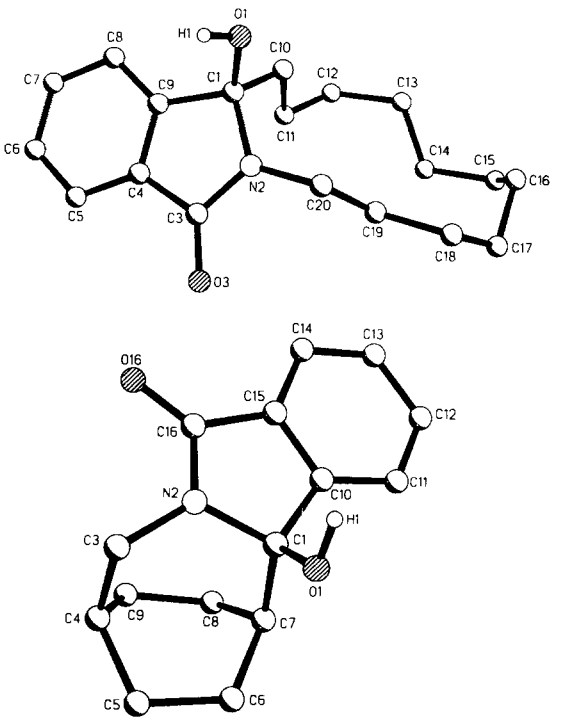
Scheme 1. a) 10 mM in acetone, 20 °C, *hv*, $\lambda = 300$ nm, N_2, 12 h; b) 10 mM in acetone, 10 equiv K_2CO_3, 2% H_2O, 20 °C, *hv*, $\lambda = 300$ nm, N_2, 12 h; c) 0.1 equiv CF_3COOH in CH_2Cl_2, 0 °C.

The UV absorption of the amide chromophore (e.g. in **7a**) is strongly blue-shifted relative to that of the substrate **5a**. Thus, **7a** is produced by a sequence of α- and γ-decarboxylation. Under identical conditions the corresponding C-protected glutamic acid derivative **5b**[12] provides a mixture of diastereomeric benzopyrrolizidines **7b** and **7c**, of which one isomer undergoes dehydration to form the enantiomerically pure enamide **8** when treated with trifluoroacetic acid. The other diastereomer (presumably the *cis* isomer) does not undergo dehydration.[13] After these "finger exercises" with short-chain amino acids (**5b**, **9**, **11**) we examined potential substrates for the synthesis of macrocycles. The 12-aminododecanoic acid derivative **13**[14] can be converted into azacyclotridecane **14** in 81% yield (Scheme 2, yields after recrystallization). Mass spectrometric analysis of compound **14** already indicated that no dimerization had occurred, a reaction that had to be expected because of the relatively high concentration (10 mM in acetone). The structure of **14** was additionally proven by X-ray analysis[15] (Fig. 1). In analogy to these results the spectroscopic data shows that dimers are not formed in any of the cases investigated. We assume therefore that already in the electronic ground state intramolecular complexation between the carboxylate anion and the phthalimido moiety makes intermolecular reactions unfavorable. The role of the countercation also accounts for this assumption: in the presence of ten equivalents of pyridine photodecarboxylation of **9** is drastically slower than the analogous reaction in the presence of sodium carbonate.

Scheme 2.

The synthesis of macrocyclic ring systems is unproblematic (Scheme 3): the 26-membered cyclic dipeptide **16** can be generated from the easiliy available substrate **15**[16] in 60% yield. Even substrates that are conformationally less flexible in the ground state can be efficiently converted under the photochemical conditions. For example, intramolecular (through-space) interactions between donor and acceptor groups cannot exist in the *trans*-cyclohexane derivative **17**. Still the tricyclic carbinol **18** is formed in 81% yield after relatively short irradiation time. Again no dimeric products are formed. After extrusion of CO_2 the C-radical centers combine with inversion at the α-C center to give **18** (Fig. 1).[15] 1,4-Donor–acceptor-substituted cyclohexanes have been widely studied as model systems for the investigation of electron transfer reactions ("superexchange mechanism" or "through-bond coupling ET").[17]



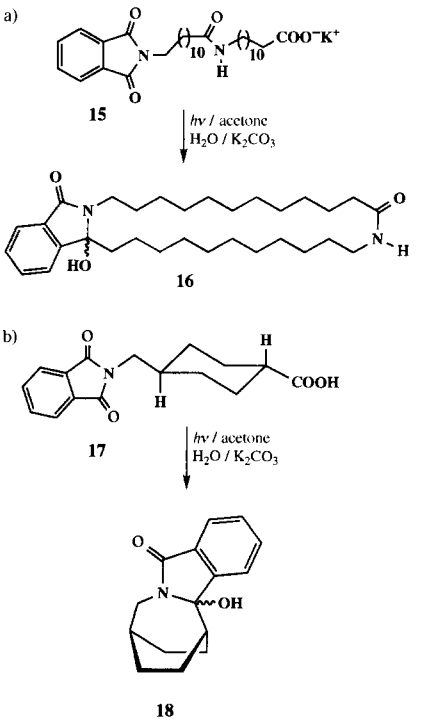


Fig. 1. Crystal structures of **14** (top) and **18** (bottom).

Scheme 3. a) Photocyclization of **15** to give **16**; b) photocyclization of **17** to give **18**.

This new synthesis of medium-sized ring systems and macrocycles may also be applied for the synthesis of cyclopeptides and macrocyclic crown ethers.

Experimental Procedure

A solution of 690 mg (2 mmol) of **13** in 200 mL of acetone was charged with 1.5 g of sodium carbonate in 3 mL of water and irradiated for 12 h at room temperature under a constant stream of nitrogen (Rayonet RPR-208 chamber reactor, eight RUL-3000 Å lamps, ca. 800 W). After evaporation of the solvent the residue was treated with 10 mL of ether, and the yellow precipitate was collected. Recrystallization from acetone gave 520 mg (81%) of **14** as colorless plates, m.p. 166–168 °C; ^{1}H NMR (250 MHz, $CDCl_3$): δ = 0.88–1.01 (m, 1H), 1.20–1.70 (m, 16H), 1.91–2.02 (m, 1H), 2.22–2.47 (m, 2H), 3.34–3.52 (m, 2H), 4.09 (s, 1H, OH), 7.57–7.63 (m, 1H), 7.68–7.80 (m, 3H); ^{13}C NMR (63 MHz, $CDCl_3$): δ = 21.3, 24.7, 24.8, 25.5, 26.0, 26.7, 26.8, 26.9, 28.4, 36.4, 38.5 (all CH_2), 91.6 (C_q), 121.5, 123.1, 129.2 (all CH), 131.0 (C_q), 132.1 (CH), 147.1, 168.3 (both C_q).

Computational Evidence for the Existence of Cu^{III} Intermediates in Addition and Substitution Reactions with Dialkylcuprates**

Andrea E. Dorigo, Jutta Wanner, and Paul von Ragué Schleyer*

Dialkylcuprates are widely used nucleophilic agents in organic synthesis. Whether these species function as electron transfer[1] agents or react nucleophilically[2] has been debated at length, yet the mechanism remains unresolved. A potential problem with the nucleophilic mechanisms proposed by Corey[2] for additions to unsaturated bonds, and by Goering et al.[3] and Kreft[4] for substitution reactions, is that in both cases a Cu^{III} intermediate is involved.[5] To date, there is no direct experimental evidence for the existence of trialkylcopper structures. We now demonstrate computationally that trimethylcopper, $Cu(CH_3)_3$, indeed corresponds to an energy minimum when the copper center is stabilized by donors such as water or ammonia. Even in the absence of such electron donors, $Cu(CH_3)_3$ corresponds to a minimum at some of the levels of theory employed. These findings support the intermediacy of trialkylcopper species in the presence of ether solvents and/or nitrogen ligands, which are commonly used in dialkylcuprate reactions. We also show that $Cu(CH_3)_3$ and the inorganic CuF_3 molecule[6] have similar geometries; however, the copper center in the former has a much smaller natural charge than in the latter. The copper charge in $Cu(CH_3)_3$ is, in fact, similar to that in the Cu^{II} organocopper species $[CuCH_3]^+$ and $Cu(CH_3)_2$.

Ab initio calculations[7, 8] were performed on $Cu(CH_3)_3$ and its complexes with H_2O and NH_3. For comparison, CuH_3 and its complexes were investigated similarly. MP2 optimizations were performed first using a split-valence basis set[9] (basis set A) for structures **1**–**10** (Fig. 1). The second, larger basis set (designated APOL), employed for all structures except **7**, consisted of A augmented with polarization functions[10, 11] for copper and all atoms directly bonded to copper. Optimized geometries with the two basis sets are similar for all systems. Single-point energy calculations at the QCISD/APOL level were performed on the MP2/APOL geometries of structures **5**, **8**, and **9** (ethane). Analytical frequency analyses were performed both at MP2/A and MP2/APOL level to determined the nature of each stationary point (that is, whether it is a minimum, which is an intermediate, or a saddle point, which is a transition structure). Further geometry optimizations and frequency calculations on **5** were performed with density functional theory, using the non-local functional developed by Becke et al.[12] for the exchange terms and by Lee, Yang, and Parr[13] for the correlation; this formalism is denoted as BLYP in the following discussion. The APOL basis set was used for these calculations. The solvation of structure **5** was also investigated with the self-consistent reaction field (SCRF)[14] method to mimic the effect of an ether medium (the dielectric constant of ether, 4.197, was used). Table 1 lists the absolute energies, together with the number of negative eigenvalues of the Hessian matrix, of CuH_3 systems **1**–**3**, $Cu(CH_3)_3$[15] systems **4**–**6**, and of the transition structure (**7**) for the decomposition of **5** into $(H_2O)CuCH_3$[15]

[**] This work was supported by the Volkswagen-Stiftung, by the Convex Computer Corporation, and by the Fonds der Chemischen Industrie. We are grateful to Professor Kisch (Universität Erlangen-Nürnberg) for useful discussions.

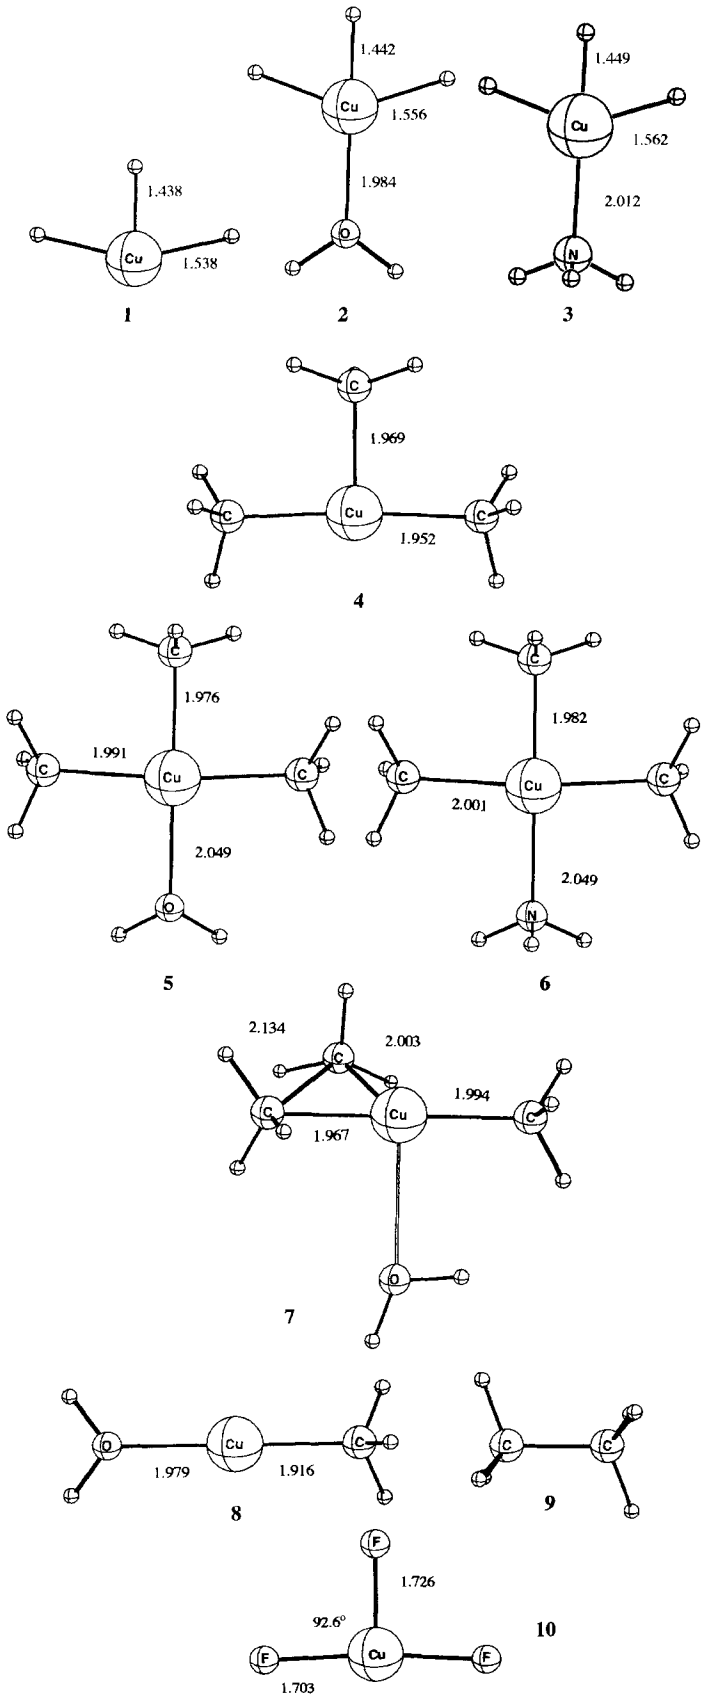

Fig. 1. Geometries of **1**–**6** and **8**–**10** optimized at the MP2/APOL level and of **7** optimized at the MP2/A level. Bond lengths are given in Å.

(**8**) and C_2H_6 (**9**). Figure 1 depicts the optimized geometries of **1**–**10**; selected parameters are given.

CuH_3 (**1**) was optimized in C_{2v} symmetry and its complexes with NH_3 and H_2O (**2** and **3**) in C_s symmetry. All three species are transition structures, both at MP2/A and MP2/APOL levels (Table 1). The MP2/APOL results are discussed here. The negative eigenvalue is large (ranging from $-791\ cm^{-1}$ to $-981\ cm^{-1}$) and corresponds to the formation of an H_2 molecule. The exothermicity of the reaction $\mathbf{1} \rightarrow CuH + H_2$ is 127.7 kcal mol^{-1}. $Cu(CH_3)_3$ (**4**; C_s) likewise is a transition structure (the negative eigenvalue of $-208\ cm^{-1}$ represents ethane formation). In contrast, both **5** and **6** lie at minima; however, since the frequency of the vibration that corresponds to ethane formation is small (99 cm^{-1} and 108 cm^{-1} for **5** and **6**, respectively), fragmentation should proceed readily. In all cases, the trialkylcopper fragment is T-shaped, as predicted theoretically by Hoffmann and Kochi.[16]

In order to assess the kinetic stability of **5** vis-à-vis loss of C_2H_6,[17] we calculated the transition structure **7**, which lies 13.9 kcal mol^{-1} above **5** at MP2/A. The energy of the products of the fragmentation of **5** (ethane (**9**) and the complex (**8**) between $CuCH_3$ and H_2O) lies 52.3 kcal mol^{-1} below that of **5** at QCISD/APOL//MP2/APOL. Structure **5** is thus kinetically stable though strongly disfavored thermodynamically relative to the reaction products. While we have not attempted to locate an analogous transition structure for the fragmentation of **6**, its kinetic stability can be expected to be similar to that of **5**, because the lowest calculated vibrational frequencies are similar (see Table 1).

Structure **5** corresponds to a minimum even at other levels of theory (see Table 1): SCRF optimization of **5** ($\varepsilon = 4.197$) gave a similar geometry to that already calculated in the absence of an electric field. Here the lowest vibrational frequency (84 cm^{-1}) is only slightly lower than the value calculated previously (99 cm^{-1}). Even BLYP/APOL geometry optimization and fre-

Table 1. Absolute energies (in −Hartree) calculated at the following levels: MP2/A (**1**–**10**), MP2/APOL (**1**–**6**, **8**–**10**), QCISD/APOL (**5**, **8**, **9**), SCRF/APOL (**5**), and BLYP/APOL (**4**, **5**). Values in parentheses (in cm^{-1}) refer to the number of negative eigenvalues of the Hessian matrix and the lowest positive vibrational frequency (for minima) or the negative vibrational frequency (for saddle points). Values in square brackets give the relative energies of **5**, **7**, and [8] and [9] (in kcal mol^{-1}).

quency calculation gave **5** to be a minimum (vibrational frequency = 88 cm^{-1}).

While trialkylcopper compounds have not been isolated experimentally, some inorganic Cu^{III} systems are known.[6] In all such systems, copper is bound to strongly electronegative atoms. As a model we chose CuF_3 (**10**) and calculated its structure to compare with the structural and electronic features of its organometallic counterparts **4**–**6**. The C_{2v}-symmetric structure for the CuF_3 minimum at MP2/APOL is T-shaped,[16] just like that of the trialkylcopper fragment in **4**–**6**. The occupied valence orbitals are similar in the two cases and corresponds to a d^8 electronic configuration at copper, as postulated by Hoffmann and Kochi.[16] However, natural population analyses reveal significant differences in the electronic charges on the copper centers in **4**–**6** and in **10**. Details of the structures for the minima **5** and **10** are important; all results refer to the APOL basis set. The natural population analysis[7] charge is 1.96 for copper in **10**. As expected, this is larger than that in CuF_2 (1.71). In contrast, the charge on copper in **5** is only 1.16 as a result of large back-donation from the methyl groups to the (formally) tripositive copper. Indeed, the charge of 1.16 is substantially smaller than that in $Cu(CH_3)_2$ (1.46), and only slightly larger than that in the $[CuCH_3]^+$ cation (1.05). Both of these molecules are Cu^{II} species. Thus, it is misleading to describe **5** as a Cu^{III} molecule, even though the copper is covalently bound to three centers. The charges on the CH_3 groups *trans* and *cis* to the water fragment in **5** are −0.12 and −0.52, respectively. Thus, **5** may be best viewed as a complex between $[CuCH_3]^+$ and the ethane radical anion.

Our calculations indicate that trialkylcopper intermediates stabilized by either nitrogen or oxygen nucleophiles correspond to local energy minima and are therefore viable reaction intermediates. It is known that, in contrast to copper, gold(III) compounds are fairly stable. The origins of this difference in stability are now being investigated.

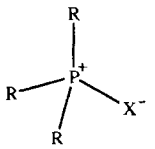
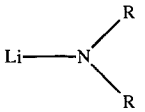
[16] The preference for a C_{2v}-symmetric (T-shaped) structure in CuX_3 systems is due to a first-order Jahn-Teller distortion of the trigonal planar D_{3h} structure; see S. Komiya, T. A. Albright, R. Hoffmann, J. K. Kochi, *J. Am. Chem. Soc.* **1977**, *99*, 8440; K. Tatsumi, R. Hoffmann, A. Yamamoto, J. K. Stille, *Bull. Chem. Soc. Jpn.* **1981**, *54*, 1857; P. Schwerdtfeger, P. D. W. Boyd, *Inorg. Chem.* **1992**, *31*, 327; S. Komiya, T. A. Albright, R. Hoffmann, J. K. Kochi, *J. Am. Chem. Soc.* **1976**, *98*, 7255. The authors of the last paper predict that the triplet states of CuX_3 species have D_{3h} symmetry. BLYP/APOL geometry optimization of the triplet state of **4**, $^3Cu(CH_3)_3$, indeed gives a structure with an essentially trigonal-planar coordination geometry for copper; however, this structure lies 13.9 kcal mol^{-1} above **4** in energy at this level.
[17] For other examples of a reductive elimination from a tetracoordinate d^8 system, see J. J. Low, W. A. Goodard, III, *J. Am. Chem. Soc.* **1984**, *106*, 6928, 8321; *ibid.* **1986**, *108*, 6115; *Organometallics* **1986**, *5*, 609.

The First Unambiguous Characterization of a Neutral Phosphorus Ylide–Lithium Complex: Isolation, Structure, and Ab Initio Investigations of $[(PhCH_2)_2NLi \cdot CH_2PPh_3]_2$**



David R. Armstrong, Matthew G. Davidson,* and David Moncrieff



The Nobel Prize-winning discovery by Wittig of the reaction that bears his name[1] signaled the beginning of interest in phosphorus ylides. Though this interest was then in the realm of organic synthesis,[2] the mid-1960s saw the advent of the inorganic chemistry of these compounds. The isolation and characterization of (initially) silicon derivatives led rapidly to the development of an extensive literature of p-block and transition metal chemistry associated with both stabilized and nonstabi-

lized ylides.[3] However, the isolation and structural characterization of adducts of inorganic alkali metal salts and ylides, and of alkali metalated organic complexes with neutral phosphorus ylides has remained an unexplored area. This is surprising on two counts. Firstly, alkali metals are intimately associated with the generation of ylides from phosphonium halides.[4] Secondly, the use of phosphorus–carbon ylides (**1**, where X = CH_2) as neutral donors to early main group metals is only a small conceptual step from the use of isoelectronic phosphane oxide donors (**1**, where X = O) such as hexamethylphosphoramide [HMPA, **1a**]. This is a common Lewis base in the chemistry of

1a; R = Me_2N, X = O
1b; R = Ph, X = CH_2
1c; R = Ph, X = CH_2, NH, O
1d; R = H, X = CH_2, NH, O

2a; R = CH_2Ph
2b; R = H

alkali metal species,[5] and its phosphorus–oxygen bond has been shown by ab initio calculations to possess ylidic character.[6] We now report the crystal structure, solution behavior, and MO calculations for a simple, nonstabilized ylide complex of a lithium amide, the first neutral ylide complex of an alkali metal compound to be characterized in the solid state.

The well-characterized dibenzylamidolithium (**2a**) system[7] was chosen as a suitable metalated organic compound for complexation by a neutral ylide. Uncomplexed dibenzylamidolithium is trimeric in the solid state through formation of an Li_3N_3 ring, and with neutral Lewis base donors forms dimeric complexes containing Li_2N_2 rings.[7a] Triphenylphosphonium methylide (**1b**) was chosen as a suitable ylide, first since it is a readily isolable solid, second, any complexation to lithium through the ylidic carbon would be sterically unhindered, and third, its solid-state structure has been determined[8] thereby allowing structural and bonding effects within the ylide to be evaluated upon complexation to lithium.

Reaction of *n*BuLi with a chilled toluene/hexane solution of dibenzylamine and **1b** afforded a red precipitate, which dissolved on warming to give a deep red solution and on renewed cooling gave dichroic red/yellow crystals (see Experimental Procedure). ^{1}H NMR spectroscopy and elemental analysis suggested that the neutral complex **3** had indeed been isolated, and such

$[(PhCH_2)_2NLi \cdot CH_2PPh_3]_n$ **3**

was confirmed by a single-crystal X-ray diffraction study,[9] which revealed **3** to be dimeric ($n = 2$) in the solid state. The structure of **3** (Fig. 1) contains an unremarkable Li_2N_2 core [Li1–N1 2.013(4), Li1–N1a 2.000(4) Å; Li1-N1-Li1a 76.2(2), N1-Li1-N1a 103.8(2)°]. However, the coordination sphere of the three-coordinate lithium is completed by unprecedented terminal complexation of an ylidic carbon atom [C61-Li1 2.207(4) Å; P1-C61-Li1 130.8(2) Å]. This remarkably short C–Li distance falls within the lower end of the 2.1–2.4 Å range observed in the solid state for lithium alkyls.[5a] Not unexpectedly, coordination of the ylide to lithium in **3** renders the ylidic methylene group considerably more pyramidal within the complex than is observed in the crystal structure of **1b**[8] [in **3**, the sum of three angles (excluding those involving Li1) around C61 is 334°, compared to 353° in **1b**]. The P–C bond is, however, only slightly elongated by complexation [in **3**, P1–C61 = 1.702(2) Å; in **1b**, average P–C = 1.693 Å]. Complexation to lithium also effects little change in the geometry about phosphorus; distortions from ideal (localized C_{3v}) symmetry as have also been noted for **1b** are observed in **3** in that the C(phenyl)–P distance perpendicular to the methylene plane is elongated relative to the other two [P1–C31 = 1.835(2), P1–C41 = 1.811(2), P1–C51 = 1.813(2) Å], and the corresponding C(phenyl)-P1-C(methylene) angle is significantly larger than the other two [C31-P1-C61 = 118.08(10), C41-P1-C61 = 110.13(11), and C51-P1-C61 = 110.42(11)°].

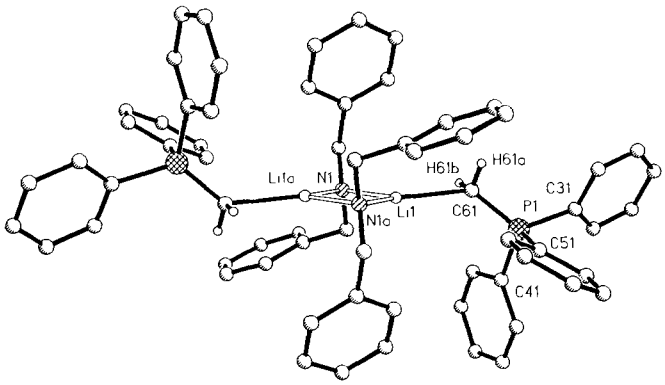

Fig. 1. Crystal structure of **3** (all hydrogen atoms except those of the ylidic carbon atoms are omitted for clarity). Selected bond lengths and angles: Li1–N1 2.013(4), Li1–N1a 2.000(4), Li1–C61 2.207(4) Å, C61–P1 1.702(2); Li1–N1–Li1a 76.2(2), N1–Li1–N1a 103.8(2), Li1–C61–P1 130.8(2).

To our knowledge, only two compounds with interactions between alkali metals and phosphorus ylides have previously been structurally characterized. Contrasting with **3** where the ylide acts only as a Lewis base donor, both are structures of metalated, anionic ylides. In both cases this results in delocalization of the negative charge over two or more carbanionoid centers: in $\{[Li(CH_2)P(C_6H_5)_2(CH_2)]_2(dioxane)_3\}_2 \cdot (dioxane)$[10] the molecular structure comprises an eight-membered ring in which two $[(CH_2)P(C_6H_5)_2(CH_2)]^-$ ligands bridge two lithium centers. In $[K(CHC_6H_5)P(CH_3)_2(CHC_6H_5)]_\infty$[11] the negative charge is further delocalized into the benzylic ring, which results in an interaction of the metal with *ortho* and *para* aromatic carbon atoms in addition to that with the two ylidic carbon atoms. The only other related crystal structure is that of a magnesium–uranium complex containing two neutral phosphorus ylide donors to magnesium. Here though, as the authors readily concede, only one crystal of the complex was serendipitously recovered from a NMR tube in which no magnesium compounds were thought to be present, and no rational synthesis could be developed.[12]

Though **3** is dimeric in the solid state, preliminary cryoscopic relative molecular mass (RMM) measurements suggest the presence of a monomer⇌oligomer equilibrium in benzene solution. At low concentration (0.0006 M, expressed in terms of monomer) the predominant species is monomeric (RMM = 464 ± 20, degree of association, $n = 0.97 \pm 0.04$), whereas at higher concentration (0.0010 M) RMM = 547 ± 25 ($n = 1.14 \pm 0.03$) indicating that some aggregation to higher oligomers takes place. Variable-concentration cryoscopic studies[13] are underway in order to quantify the nature of this oligomerization fully, though on the basis of the dimeric solid-state structure of **3**, it seems reasonable to propose that a monomer⇌dimer equilibrium operates. Although these data

alone do not preclude an alternative scenario of ligand dissociation taking place at low concentration (that is, $\mathbf{3}_n \rightleftharpoons \mathbf{2a}_n + n\,\mathbf{1b}$) this possibility may be discounted by variable-concentration ^{1}H NMR data. The signal due to the two protons of the ylidic carbon, which appears as a doublet due to $^2J_{PH}$ coupling, provides particularly useful information. At all concentrations of **3** in benzene this signal is shifted to higher frequency, and the coupling constant is reduced relative to that of the free ylide (see Experimental Procedure). In addition, the coupling constant is concentration-dependent for benzene solutions of **3**, whereas it is not for those of the free ylide. In dilute solution (0.0006 M) $^2J_{PH}$ = 3.3 Hz, whereas in more concentrated solution (0.044 M) $^2J_{PH}$ = 4.8 Hz ($^2J_{PH}$ = 7.2 Hz for the free ylide). Taking into account the cryoscopic results in the same solvent, the value observed for dilute solutions may be ascribed to the monomeric species, and that observed for higher concentrations to an oligomer (probably a dimer), or to an averaged value between that of the monomer and a higher oligomer. The fact that $^2J_{PH}$ *decreases* on dilution is consistent with an increase in the proportion of monomer present in solution. One would expect lithium to exert a greater influence over the electronic structure of the ylide (and therefore the observed coupling constants) in a monomer where the metal is only two-coordinate than it would in an oligomer where the lithium would be (at least) three-coordinate. If ligand dissociation from the dimer was taking place one would expect $^2J_{PH}$ to *increase* on dilution as a greater proportion of the free ylide becomes present in solution.

In addition to the solid-state and solution studies described above, features of phosphorus ylide complexation to lithium amides have come from theoretical calculations. Though many calculations have previously been performed on phosphorus ylides and related compounds,[14] none have dealt specifically with the coordination of neutral ylides to lithium compounds. Ab initio calculations have now been performed on a series of model compounds.[15] In addition to monomeric and dimeric models for **3**, isoelectronic iminophosphorane (**1**, where X = NH) and phosphane oxide (**1**, where X = O) complexes have also been studied. Optimization of monomeric adducts of the type **2a**·**1c** between lithium amide and a donor molecule gives complexation energies (the decrease in energy on bringing the two components together) of 25.5, 31.4, and 29.8 kcal mol^{-1} for X = CH_2, NH, and O, respectively. For dimeric adducts of the type $(\mathbf{2b}\cdot\mathbf{1d})_2$, complexation energies are, in all cases, less than for monomers (13.9, 19.3, and 20.5 kcal mol^{-1} for X = CH_2, NH, and O, respectively), though this reduction is more than compensated for by the stabilization gained by dimerization (20.6, 23.6, and 21.8 kcal mol^{-1} for X = CH_2, NH, and O, respectively). These results demonstrate that while the complexation energy of a phosphorus–carbon ylide to an alkali metal is less than that of the corresponding phosphane oxide or a iminophosphorane, it is of the same order of magnitude. That this is so is perhaps surprising and suggests that Lewis base donors containing ylidic carbon atoms may be used in alkali metal chemistry alongside more usual nitrogen- and oxygen-containing donors.

The synthesis of complex **3** is significant on several fronts. Firstly, it provides the first unambiguous structural characterization of such a complex. Secondly, lithium salts (invariably lithium bromide, present as a product from the generation of ylides from phosphonium bromide precursors) can have an effect on alkene stereochemistry in Wittig reactions,[2] and metalated (lithiated) ylides have also seen some synthetic utility, because they show enhanced reactivity over neutral ylides.[16] The effect of lithium amide–phosphorus ylide complexes on the course of Wittig reactions is currently being investigated. Thirdly, complexes like **3** may also find application as precursors for the preparation of ylide complexes with organometallic compounds of transition metals. Reactions of **3** and similar complexes with transition metal halides have been performed, and products are currently being characterized. Fourthly, the results of the calculations demonstrate the ability of ylidic carbon atoms to act as Lewis base donors to alkali metals. Systems containing ylidic carbon atoms stabilized by atoms other than phosphorus (S, N, As, and C) are, therefore, potential Lewis base donors to alkali metals. Lastly, the presence of hydrogen atoms on the donor atom of a complexant molecule, as in **1b**, provides reactivity at the point of complexation not available with common N- or O-containing donors. Potentially, this allows further metalation of a complex at this site, thereby providing a route to novel complexes containing different metals and different anions.

Experimental Procedure

1b was prepared and isolated according to ref. [17]. ^{1}H NMR (250 MHz, C_6D_6, TMS): δ = 0.80 (d, 2H, Ph_3PCH_2, $^2J_{PH}$ = 7.2 Hz), 7.00–7.07 (m, 9H, *m*- and *p*-Ph_3PCH_2), 7.72–7.78 (m, 6H, *o*-Ph_3PCH_2).

3: *n*-Butyllithium (1.6 mL of a 1.6 M solution in hexanes, 2.5 mmol) was added under nitrogen to a cooled (about 0 °C), stirred solution of **1b** (0.69 g, 2.5 mmol) and dibenzylamine (0.55 mL, 2.5 mmol) in hexane:toluene (1:1, 10 mL). The yellow solution immediately turned deep purple, and with further stirring a pink solid precipitated. Addition of toluene (30 mL) and heating (to about 70 °C) caused complete dissolution of the solid. After standing at room temperature for 3 h the solution yielded dichroic red/yellow crystals suitable for crystal structure analysis (0.72 g, 60%), m.p. 168–169 °C, satisfactory C, H, N, and P analysis. ^{1}H NMR (250 MHz, C_6D_6, TMS): 0.0006 M: δ = 0.73 (d, 2H, Ph_3PCH_2, $^2J_{PH}$ = 3.3 Hz), 4.00 (s, 4H, $(PhCH_2)_2N$), 7.00–7.47 (m, 19H, *m*- and *p*-Ph_3PCH_2 and $(PhCH_2)_2N$), 7.63–7.70 (m, 6H, *o*-Ph_3PCH_2); 0.042 M: δ = 0.52 (d, 2H, Ph_3PCH_2, $^2J_{PH}$ = 4.7 Hz), 4.06 (s, 4H, $(PhCH_2)_2N$), 6.97–7.38 (m, 19H, *m*- and *p*-Ph_3PCH_2 and $(PhCH_2)_2N$), 7.51–7.56 (m, 6H, *o*-Ph_3PCH_2).

$C_{60}H_{60}$ and $C_{54}H_{48}$: Silver Ion Extraction with New Concave Hydrocarbons**

Jens Gross, Gabriele Harder, Fritz Vögtle,* Holger Stephan, and Karsten Gloe

Spherical hydrocarbons containing a cavity are of interest for both fullerene and host–guest chemistry. Three-dimensionally linked molecular structures made up of sixty carbon atoms may be possible precursors for the direct synthesis of fullerenes. On the other hand, the hydrophobic cavity of such spherical hydrocarbons, which is accessible through variable openings on the surface of the molecule, may host metal ions like Ag^{I}[1] and Ga^{I},[2] as well as charged[3] and uncharged[4] organic molecules. Some time ago we reported on a first spherical concave hydrocarbon **1** in which four benzene rings are linked by six ethano bridges.[5, 6] $C_{36}H_{36}$ represents the smallest member of a family of macropolycyclic hydrocarbons based on 1,3,5-trimethylenebenzene subunits. In Figure 1 (top) two further members of this series of homologues are depicted, which fit the formula $[C_9H_9]_{2n}$, in this case $n = 2$, 3, and 4.[7]

In the group of compounds with only 1,3,5-substituted benzene spacers no "spheriphanes" with 60 or 70 carbon atoms can be realized, yet these compounds are desirable in view of possible conversion to fullerenes. Compounds **4**–**6** (Fig. 1, bottom) indicate that other similar concave hydrocarbons are conceivable, which are constructed from benzene rings without exclusively 1,3,5-substitution or which contain other spacers. We report here on the syntheses of the previously unknown spherical hydrocarbons $C_{60}H_{60}$ **4** and $C_{54}H_{48}$ **5**, which affirm the universal applicability of the strategy of the synthesis of **1**.

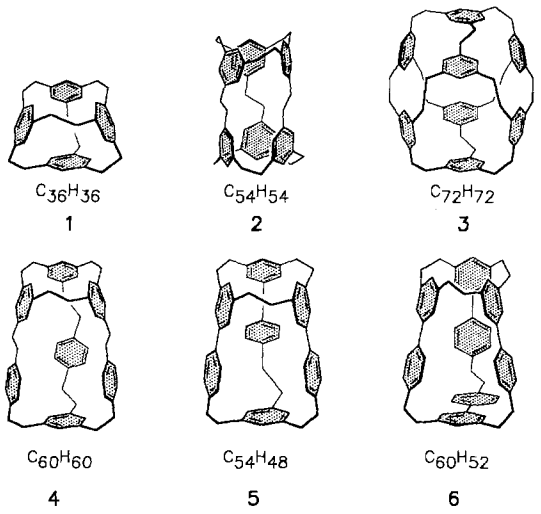

Fig. 1. Top: $C_{36}H_{36}$, $C_{54}H_{54}$, and $C_{72}H_{72}$ as members of the series of spherical hydrocarbons based on 1,3,5-trimethylenebenzene. Bottom: Some selected concave hydrocarbons linked by other than exclusive 1,3,5-connection of the benzene rings and different spacers.

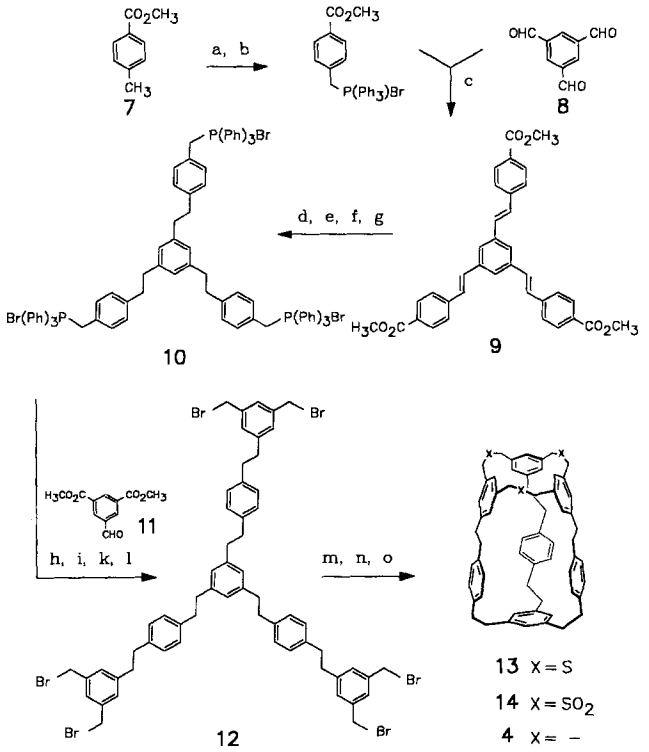
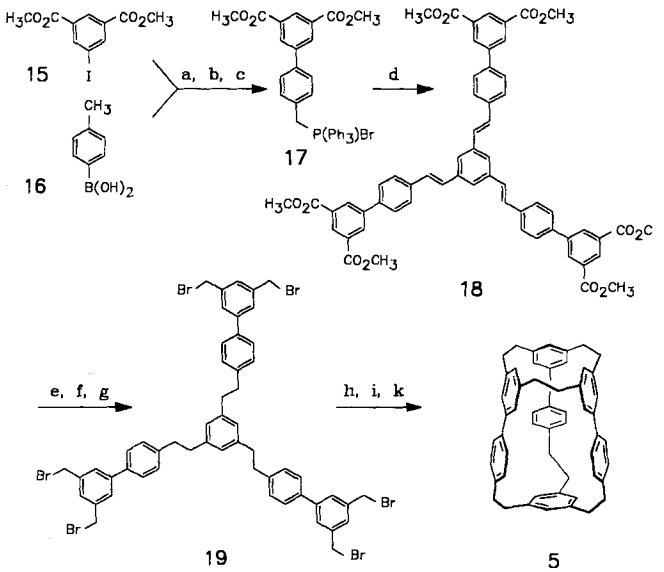


Synthesis of $C_{60}H_{60}$: The cyclization compound **12** was obtained from methyl *p*-toluenecarboxylate (**7**) in eleven synthetic steps. Bromination with *N*-bromosuccinimide (a in Scheme 1) phosphorylation, and threefold Wittig reaction with 1,3,5-benzenetrialdehyde **8**[8] yielded triene **9** as a mixture of isomers. Three-step refunctionalization (hydrogenation of the double bonds (d), reduction of the ester and subsequent acylation (e), and reaction with hydrobromic acid/glacial acetic acid (f)) gave the corresponding benzyl bromide, whose phosphorylation yielded in turn the Wittig compound **10**. Threefold olefination with dimethyl 5-formylisophthalate and application of the refunctionalization sequence (h, i, k, l) provided cyclization compound **12**. The macrotricyclic phane **13** was generated by a sulfide cyclization reaction[9] under dilution conditions[10] (m). Subsequent oxidation to **14** (n) followed by pyrolytic desulfurization[11, 12] (o) afforded the new decacyclic hydrocarbon **4**[13] (total yield from **12**: ≈5%). Direct cyclization of **12** with phenyllithium, which was a favorable alternative in the synthesis of $C_{36}H_{36}$, yielded only traces of polycycle **4**.

Synthesis of $C_{54}H_{48}$: Phosphonium bromide **17** was obtained by Suzuki coupling of dimethyl 5-iodoisophthalate with dihydroxy-*p*-tolylborane (**16**, *p*-tolylboronic acid)[14] (a in Scheme 2), followed by bromination with *N*-bromosuccinimide (NBS, b), and phosphorylation (c). Compound **17** was converted into triene **18** by a threefold Wittig reaction with 1,3,5-benzenetrialdehyde (d) analogous to the synthesis described before. Hydrogenation (e), reduction of the methyl ester and subsequent acetylation (f), and bromination (g) provided the cyclization compound **19**, which was converted into hydrocarbon **5**[15] through sulfide cyclization reaction (h), oxidation to the sulfone (i), and pyrolytic desulfurization reaction (k) (total yield from **12**: 3.5%).



The two new macrotricycles **4** and **5** are high-melting compounds; their mass spectra display only the molecular ion peak

Scheme 2. a) $[Pd(Ph_3)_4]$, 2 N Na_2CO_3, toluene argon, 95 °C, 8 h, 78%; b) NBS, azobisisobutyronitrile, CH_2Cl_2, *hv*, reflux, 73%; c) PPh_3, $CHCl_3$, 3 h reflux, 96%; d) Li/MeOH, THF, argon; 57%; e) 3 bar H_2, Pd/C (10%), toluene, 99%; f) $LiAlH_4$, THF, argon, 2 h reflux, then Ac_2O, 4 h reflux, 86%; g) HBr/glacial acetic acid (33%), 8 h at 60 °C, 73%; h) dilution conditions, 3 equiv $Na_2S \cdot 9H_2O$, 10 equiv Cs_2CO_3, benzene/EtOH (1:1), argon, 8 h reflux, 13%; i) 12 equiv *m*-chloroperoxybenzoic acid, $CHCl_3$, 24 h at room temperature, 71%; k) 10^{-2} Torr, 600 °C, 38%. Overall yield h–k: 3.5%.

and no fragmentation. While **5** shows only poor solubility in most organic solvents, **4** has good solubility properties because of the numerous ethano bridges and thus satisfies an important prerequisite for the investigation of host–guest interactions. The symmetry of the compounds is evident in their NMR spectra.[16, 17] Due to isochronism of protons in compound **5** only three ^1H NMR signals are observed for the aromatic protons, for **4** on the other hand, five.

By molecular modeling calculations[18] we determined the structures and dimensions of the cavities of the macrocycles (Fig. 2) in order to choose suitable guests for complexation

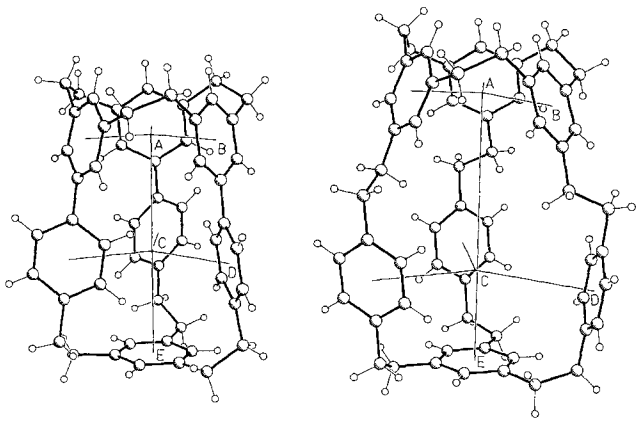

Fig. 2. The structures determined by molecular modeling [18] permit an estimation of the dimensions of the cavities [20]. Left: $C_{54}H_{48}$: A–B 250 pm, C–D 315 pm, A–E 800 pm. Right: $C_{60}H_{60}$: A–B 270 pm, C–D 415 pm, A–E 947 pm.

studies. Hydrocarbon **5**, for example, provides a tailored niche for an acetonitrile molecule, whereas **4** with its larger cavity could include molecules like adamantylamine or *tert*-butylamine.[3] While crystallization experiments for the preparation of the corresponding complexes have not been successful so far, preliminary tests show that the complexes may be obtained under extremely high pressures.[19]

In addition to small neutral molecules metal ions such as silver(I) are potential guests.[21] While the known π-prismands[1a, b, 2] and π-spherands[1c] form rings around Ag^I or Ga^I, the concave hydrocarbons could include ions within their three-dimensionally linked molecular frameworks. In extraction experiments of silver ions from aqueous solution[22] we determined the extraction efficiency of hydrocarbons **1**, **4**, and **5**, the well-known π-prismand **20**, and π-spherand **21**, as well as the reference compounds **22** and **23**[23] quantitatively.[24] Aqueous silver nitrate/picric acid solutions were extracted with a chloroform phase containing the hydrocarbon ligand in different concentrations (Fig. 3). The determination of the silver ion content in both phases with the radiotracer method[25] permits a comparison of the extraction efficiency and gives information about the stoichiometry of the complex.

As expected, reference compounds **22** and **23**, whose cavities are too small, do not extract Ag^I ions (Fig. 4). $C_{36}H_{36}$ **1** and tetraene **20** form 1:1 complexes in the organic phase, but show relatively poor extraction efficiency. $C_{54}H_{48}$ **5** extracts silver(I) in a comparable magnitude. The [2.2.2]paracyclophane **21** is able to extract efficiently over a wide range of concentrations because of its good solubility (at a ligand concentration of 5×10^{-2} M, 67% of the Ag^I is extracted) forming an 1:1 complex also. However, the best silver ion extraction is possible with

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0482 $ 10.00+.25/0

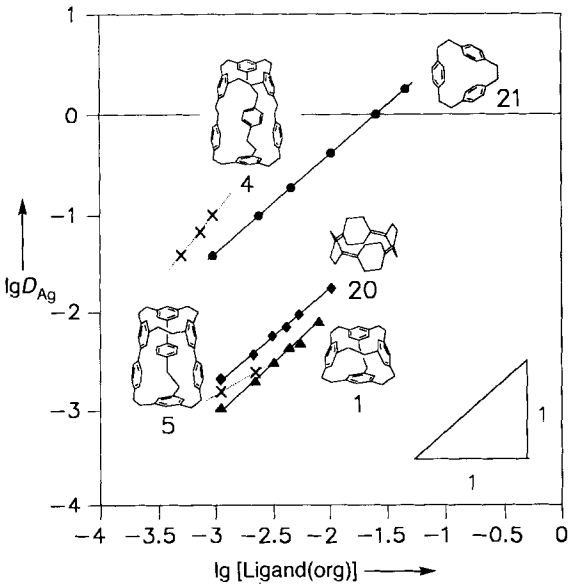

Fig. 3. The dependence of the distribution proportion D_{Ag} (D_{Ag} = [Ag] in chloroform)/[Ag] in water) on the concentration of the ligand in chloroform gives information about the extraction capacity and the composition of the complex. (Conditions: aqueous phase: $[AgNO_3] = 2.7 \times 10^{-4}$ M, [picric acid] $= 1 \times 10^{-2}$ M; organic phase: [ligand] $= 5 \times 10^{-4} - 5 \times 10^{-2}$ M in $CHCl_3$).

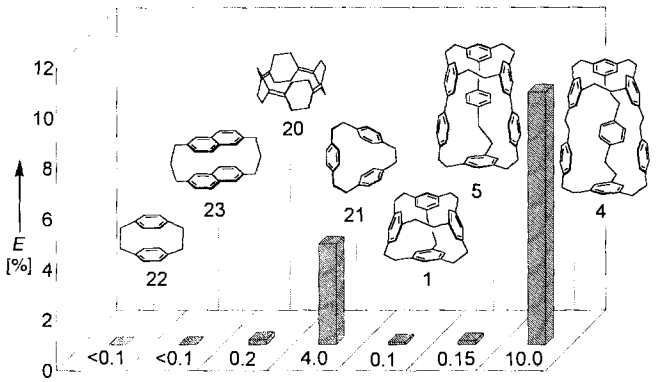

Fig. 4. Comparison of the extractabilities of Ag^{I} by selected hydrocarbons; [ligand] $= 1 \times 10^{-3}$ M in $CHCl_3$.

$C_{60}H_{60}$ **4**, which extracts more than twice as much Ag^{I} in comparison to **21** at low ligand concentrations (up to 1×10^{-3} M).[26] At higher concentrations the complex precipitates, and further investigations are not possible with this extraction system. Because of the few measured quantities, definite determination of the complex composition for both **4** and **5** is not possible.[27]

In comparison to complex ligands containing heteroatoms such as thiacrowns, which bind metal ions through their free electron pairs, we expect a more selective extraction of silver ions with the new concave hydrocarbons. Therefore, we investigated the extraction efficiency of the hydrocarbons **1**, **21**, and **4**, which were available in sufficient amounts, for different alkali, alkaline earth, and transition metal ions (Fig. 5). While **21** does not extract detectable amounts of either alkali metal ions or Tl^{I} and Hg^{II}, which have ionic radii comparable to that of Ag^{I}, an extractability of 0.1% for Tl^{I} is found with $C_{36}H_{36}$ (for Na^{I}, Ca^{II}, Zn^{II}, Hg^{II} < 0.1%). In the case of $C_{60}H_{60}$ the extractabilities for sodium, calcium, and zinc are also below 0.1%; for

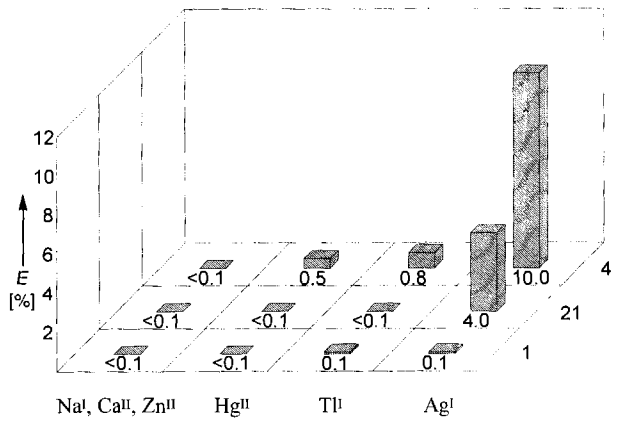

Fig. 5. Comparison of the extractabilities E of selected cations by the hydrocarbons **1**, **21**, **4** ([ligand] $= 1 \times 10^{-3}$ M in $CHCl_3$). The extractabilities of Na^{I}, Ca^{II} and Zn^{II} were investigated in separate experiments).

mercury and thallium the values are slightly higher with 0.5 and 0.8%, respectively (Fig. 5). Relative to other hydrocarbons $C_{60}H_{60}$ shows the highest extraction efficiency for silver observed to date and high selectivity. These results indicate that concave hydrocarbons not only form a new family of structurally appealing molecules but may also be of interest as selective host molecules.

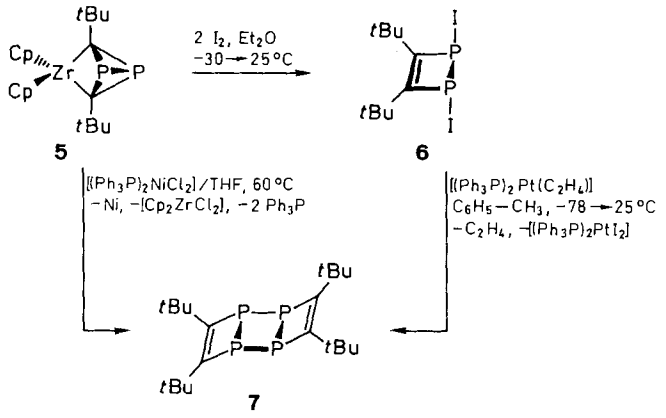
Tetraphosphatricyclo[4.2.0.0^{2,5}]octadienes; New Phosphaalkyne Cyclotetramers Derived from $\lambda^3\sigma^2$-Diphosphetes**

Bernhard Geissler, Stefan Barth, Uwe Bergsträsser, Michael Slany, Julie Durkin, Peter B. Hitchcock, Matthias Hofmann, Paul Binger,* John F. Nixon,* Paul von Ragué Schleyer,* and Manfred Regitz*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

In the cyclooligomerization of alkynes there is a special interest in their cyclotetramers as also is the case in the series of phosphaalkynes (RC≡P). Following the original thermal cyclotetramerization of *t*BuC≡P with low selectivity to the tetraphosphacubane **1**,[1] specific high-yield syntheses[2] enable a detailed study to be made of the reactivity of this pentacycle.[3, 4]

Utilizing a stepwise route, the polycyclic isomers **2** and **3** containing phosphaalkene units are now accessible[5] which, on heating, quantitatively transform to the more thermodynamically stable compound **4**, which only contains $\lambda^3\sigma^3$-phosphorus atoms.[6, 7]



We now report the syntheses of the tetraphosphacyclooctadienes **7** and **13**, which represent a new type of phosphaalkyne cyclotetramer, and also present results of ab initio calculations on HC≡P cyclooligomers.

Treatment of the tricyclic zirconium compound **5**[2, 8] with $[(PPh_3)_2NiCl_2]$ leads to the removal of the $ZrCp_2$ fragment and to a dimerization resulting in the formation of the phosphaalkyne cyclotetramer **7** in 70% yield.

Treatment of the dihydrophosphete **6**, which is readily accessible from the reaction of **5** with iodine and whose structure has been established,[9] with $[(PPh_3)_2Pt(C_2H_4)]$ followed by iodine elimination and a further dimerization leads to the same product

[**] Phosphorus Compounds Part 91. This work was supported by the Volkswagen Foundation, the Deutsche Forschungsgemeinschaft (Graduiertenkolleg, "Phosphor als Bindeglied verschiedener chemischer Disziplinen"), the Fonds der Chemischen Industrie and the Landesregierung von Rheinland-Pfalz. Part 90: K. K. Laali, B. Geissler, O. Wagner, J. Hoffmann, R. Armbrust, W. Eisfeld, M. Regitz, *J. Am. Chem. Soc.* **1994**, *116*, 9407–9408.

7 in 95% yield. Phosphaalkyne cyclotetramers of this structural type were previously unkown.

It seems likely that the tricyclic compound **7** results from the dimerization of the intermediate 1,2-diphosphete **10**.[10] The dehalogenation **6** → **10** appears very likely and the formation of **10** from **5** can also be readily rationalized. Thus, if one initially assumes that the transfer of the $P_2C_2tBu_2$ fragment from **5** to the $(Ph_3P)_2Ni$ group affords **8**,[11] the isomerization of **8** could result in diphosphanickelacyclopentadiene **9**. Elimination of the $(PPh_3)_2Ni$ fragment, which breaks up into Ni and PPh_3 (both isolated) under the reaction conditions (60 °C), is the final step leading to the formation of **10**. Similar types of C–C combinations are well known in synthetic organic chemistry.[12]

The elemental analysis and mass spectrometric data on **7** (see Table 1) confirm its cyclotetrameric composition. The NMR signals of the phosphorus atoms ($\delta = -23.4$), the sp^2-hybridized framework C atoms ($\delta = 172.4$), and the carbons and protons of the *t*Bu groups (see Table 1) are clearly indicative of the high symmetry of the cyclotetramer **7**.

The tricyclic structure of **7** has been fully established by a single crystal X-ray analysis[13, 14] and reveals an *anti*-arrangement of the two olefin units around a central cyclotetraphosphane unit. The presence of an inversion center in **7** is reflected by the identical pairwise sets of bond lengths and bond angles (Fig. 1).

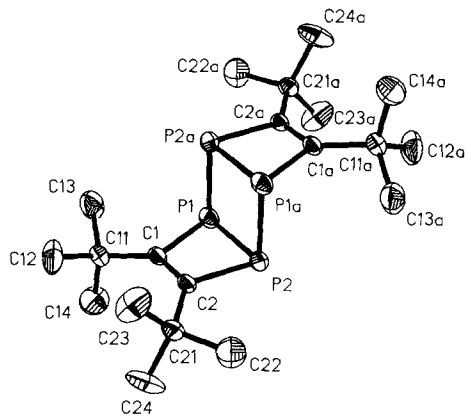

Fig. 1. Crystal structure of **7** (thermal elipsoid plot). Selected bond lengths and angles are listed in Table 2.

The four P atoms in **7** lie in a plane and form a rectangle whose edge lengths are 2.219 (calc. 2.283) and 2.236 (calc. 2.245) Å; the internal angles of 89.9 (calc. 90.0) and 90.1 (calc. 90.0)°, lie in the ideal range (see Table 2). Comparable structural data are already known for the related *trans*-1,2,4,5-tetraphosphatricyclo[3.1.0.0.^{2,4}]hexane system,[15] which also contains a planar P_4 unit. Monocyclic tetraphosphanes show comparable P–P distances but the P_4 unit is usually folded.[16] The atoms comprising the dihydrodiphosphete units C1, C2, P1, P2 and C1a, C2a, P1a, and P2a, respectively, lie in a plane and are arranged as a trapezium. The fold angle along the P1–P2 or P1a–P2a axis is 97.9 (calc. 96.5)°.

As previously mentioned, a high-yield synthesis of the tetraphosphacubane **1**, resulting from treatment of the zirconium

Table 2. Selected bond lengths [Å] and bond angles [°] for compounds **7** and **13** in comparison with the calculated values for the HCP cyclotetramers **7a** and **13a**, respectively (see Fig. 3).

compound **5** with C_2Cl_6, probably involves the intermediacy of the 1,3-diphosphete **11** and the tricyclic compound **12**.[2] We now report that under the same conditions a new cyclotetramer of *t*BuC≡P is also formed albeit in very low yield, which has not been previously observed and which has the structure **13**.

In the ^{31}P NMR spectrum of **13** there are two pseudo triplets of an A_2X_2 spin system (δ = 44.5, 398.2, ^2J(P,P) = 29.1 Hz) indicative of $\lambda^3\sigma^3$- and $\lambda^3\sigma^2$-phosphorus atoms. In contrast to the ^1H NMR spectrum of cyclotetramer **7**, that of **13** exhibits two signals (18H each). The mass spectrum provides confirmation of the cyclotetrameric structure (see Table 1).

This new cyclotetramer also has a tricyclic structure with a central 1,2-diphosphetane unit to which are attached two phosphaalkyne moeities with an *anti*-conformation, bonded as indicated by the crystal structure.[14, 17] The twofold rotation axis in **13** is reflected in the similar bond lengths and bond angles of the *trans*-dihydrodiphosphete rings (Fig. 2).

The bond length C2–P2 1.672 (calc. 1.698) Å lies in the expected range for phosphaalkenes.[18] Likewise the bond lengths within the diphosphetane unit (see Table 2) are in accord with the structural parameters found in monocyclic 1,2-diphosphetanes.[19, 20] The obvious explanation is that **13** is formed by a "head-to-head" dimerization of **11**, while the "head-to-tail" process (**11** → **12**) leads finally to the tetraphosphacubane **1**.

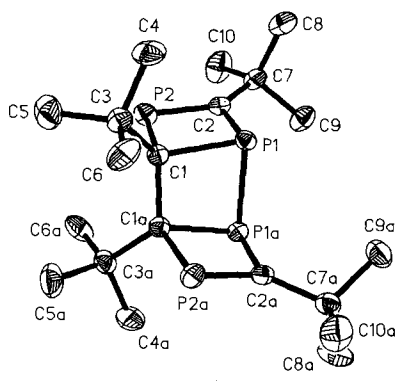

Fig. 2. Crystal structure of **13** (thermal elipsoid plot). Selected bond lengths and angles are listed in Table 2.

Model calculations, however, show that the postulated intermediate **12a** is 9.1 kcal mol^{-1} more stable than **1a** (see Fig. 3). For compound **12a**, the *cis* configuration is 0.9 kcal mol^{-1} more stable than the *trans* isomer. For compound **13a**, the *cis* configuration (1.4 kcal mol^{-1}) is also more favored. Probably, steric interactions in *cis*-**13** prevent its formation. The *trans*-configuration **7** is already preferred in the model (**7a**) (E_{rel} = – 3.6 kcal mol^{-1} relative to *cis*-). The domination of the dimerization **11** → **12** (product ratio **1** (via **12**):**13** ≈ 70:1) may be the result of kinetic factors; the unsubstituted tricycles **7a** and **13a** are energetically more favorable than the cubane **1a** (see Fig. 3).

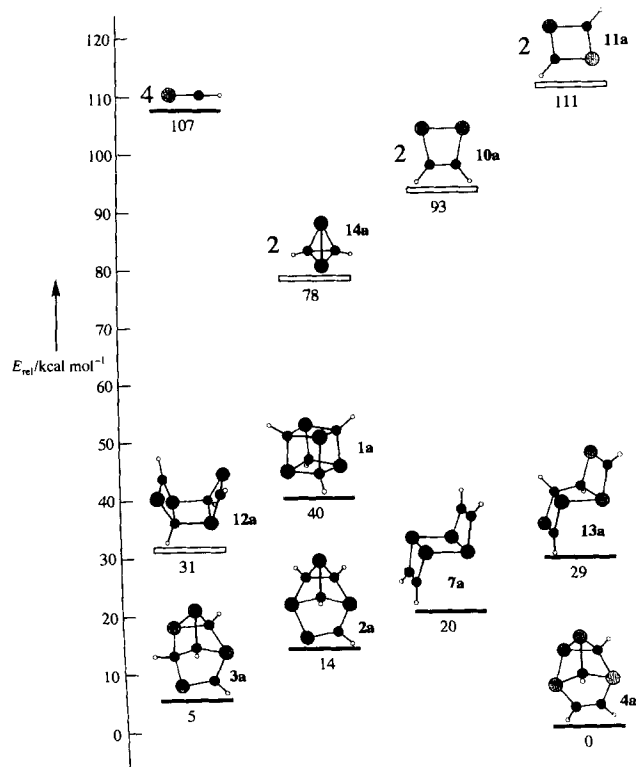

Fig. 3. Relative energies for HCP oligomers [23]. Hydrogen is white, carbon is black, and phosphorus is gray in the structures shown; black bars indicate where the *C*-alkyl derivatives are known experimentally, and white bars represent postulated structures.

Following our success in converting **5** with the P-coordinate [Fe(CO)$_4$] fragment into the η^4-ligated [Fe(CO)$_3$] complex **11**, by detaching the Cp_2Zr unit with C_2Cl_6,[2] we now provide further convincing evidence for the intermediacy of this 1,3-diphosphete in the conversion of the dimer complex **5** into the tetraphosphacubane **1**. In this connection it should be noted that the originally anticipated formation of the diphosphatetrahedrane **14** as an intermediate between **5** and **11** now seems unlikely. The unsubstituted 1,3-diphosphete **11a** has a considerably higher energy of formation than the isomeric tetrahedrane (see Fig. 3), which makes the isomerization of the initially generated diphosphatetrahedrane into the 1,3-diphosphete unlikely.[10, 21, 22]

For **2a** and **3a**, energies of 13.9 and 5.0 kcal mol^{-1}, respectively, relative to **4a** are calculated which is in good agreement with the observed thermal isomerizations **2** → **4** and **3** → **4**, respectively.[6, 7] The cubane **1a** is the most unfavorable of all the tetramers studied (see Fig. 3).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0486 $ 10.00+.25/0

The reaction energies for 2 **10a** → **7a** and 2 **11a** → **13a** are −72.8 and −82.0 kcal mol^{-1}, respectively. They are therefore considerably higher than the HCP dimerization energies to **10a** and **11a**.

Experimental Procedure

7 from **5**: To the suspension of bis(triphenylphosphane)nickel dichloride (1.27 g, 1.95 mmol) in tetrahydrofuran (50 mL) was added the zirconium complex **5** (0.82 g, 1.95 mmol) [2, 8], and after the solution had been heated for 4 h at 60 °C the solvent was removed at 30 °C/10^{-3} mbar. The residue was dissolved in *n*-pentane (50 mL) and elemental nickel and zirconium dichloride were filtered off with a frit filled with a 3 cm high layer of celite. Repeated removal of solvent afforded **7** which was still contaminated with triphenylphosphane, the latter could be removed by sublimation (70 °C/10^{-3} mbar)(^{31}P NMR monitored). Yield: 0.27 g (70%) colorless crystals; m.p. 240 °C (from ether at −78 °C).

7 from **6**: To a stirred solution of the dihydrodiphosphete **6** (0.91 g, 2.0 mmol) [9] in toluene (15 mL) was added at −78 °C η^2-ethene-bis(triphenylphosphane)platinum(0) (1.51 g, 2.02 mmol). After the reaction mixture had been warmed to room temperature, the insoluble residue was removed by filtration over celite and the filtrate evaporated to dryness. The residue was redissolved in *n*-pentane and a second filtration over celite resulted in a solution which was evaporated to dryness and purified as above. Yield: 0.38 g (95%) colorless crystals. These were identical with the product obtained from **5** (NMR spectroscopy).

13 from **5**: To a solution of **5** (1.4 g, 3.3 mmol) in benzene (10 mL) was added hexachloroethane (0.79 g, 3.3 mmol) and after the solution had been stirred for 5 d at room temperature it was evaporated to dryness at 25 °C/10^{-3} mbar. The resulting orange-yellow product was treated several times with petroleum ether (60–80 °C), the extracts collected and concentrated to about 5 mL in vacuo and then left to crystallize at 5 °C. After removal of the solvent with a syringe, **13** could be separated by hand as 2–3-mm-long small orange-red crystals from the tetraphosphacubane **1** [2]. Yield: 18 mg (1%). m.p. 135–136 °C.

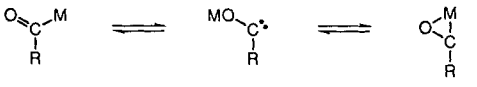
Crystal Structure of the Dimeric (4-*tert*-Butylthiazolato)(glyme)lithium: Carbene Character of a Formyl Anion Equivalent**

Gernot Boche,* Christof Hilf, Klaus Harms, Michael Marsch, and John C. W. Lohrenz

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday



The question whether *nucleophilic acylations* with reagents of type **1** are possible has a long history.[1] Although compounds of type **1b** are comparatively easily accessible, the species **1** are only of limited use in synthesis. Not without reason was the concept of "Umpolung" created in the search for new methods of nucleophilic acylations.[2]

One of the problems is that the compounds **1** react like the isomeric alkoxycarbenes **1′**. Some dimerize rapidly even at −120 °C. This is in agreement with results of quantum-mechan-

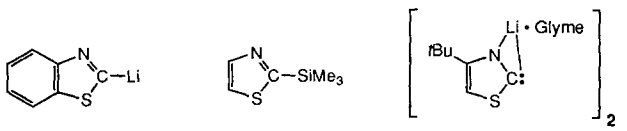
ical calculations for lithiated formaldehyde LiCH=O, which predict a C–O bridged structure **1"a** (R = H, M = Li) with a distinct carbene character.[3] Lithiated aldimines **2** seem to have a smaller propensity for dimerization, but this alternative has not gained any broader application.[4]



1 **1'** **1"**

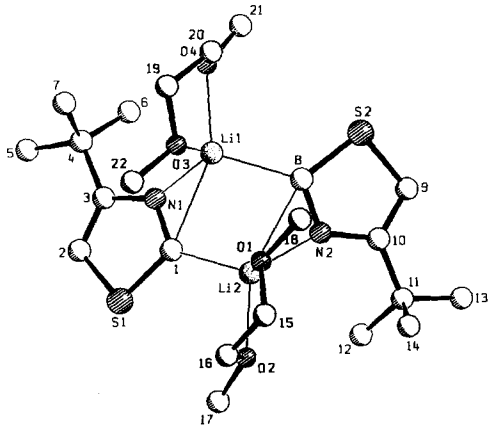
b : R = NR_2
M : Li, Na, K, MgHal, etc.

2 **3** **4**

Experiments with 2-lithio-4,5-dihydrooxazole (**3**) and 2-lithiooxazole (**4**) failed because of the easy ring-opening to the corresponding alkoxyisocyanide.[5] In contrast, lithiated benzothiazole **5**[6] and especially silylated thiazole **6**[7] have proven to be excellent formyl anion equivalents—one of the reasons is

5 **6** [**7** • Glyme]$_2$

the easily reducible C–S bond. In the following we report on the crystal structure analysis of the lithiated 4-*tert*-butylthiazole **7**, which crystallizes with glycol dimethyl ether (glyme) as [**7** · glyme]$_2$ (Fig. 1). Dimer [**7** · glyme]$_2$ proves, for the first time, the carbene character of a formyllithium equivalent.[8]



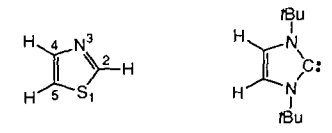


Fig. 1. Crystal structure of the dimeric (4-*tert*-butylthiazolato)(glyme)lithium [**7** · glyme]$_2$ [9].

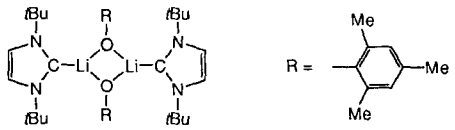
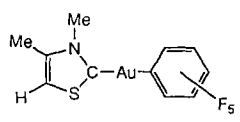


To this end we compare the structure of [**7** · glyme]$_2$ with that of thiazole **8**,[13] the recently characterized carbene **9**,[14] and with the calculated structure of the lithiated formaldehyde **1"a** (R = H, M = Li).[3]

In [**7** · glyme]$_2$ Li1 (Li2) is closely bound to N1(N2) [199.0(5) (201.1(5)) pm], but only loosely to C1(C8) [251.2(5)–(255.8(5)) pm].[16] The angle N1-C1-Li1 (N2-C8-Li2) amounts to 51.9(2) (51.1(2))°. Thus the distance between Li1(Li2) and the carbene C atom C1 (C8) is considerably larger than in **1"a** (R = H, M = Li), where Li–C = 189.1, Li–O = 183.5 pm and Li-C-O = 67.6° (MP2/6-31G*).[3] In the thiazole rings of [**7** · glyme]$_2$ the following distances were determined: C1–N1 (C8–N2) 133.2(4) (132.6(3)) pm; N1–C3 (N2–C10) 139.4(3) (139.2(3)) pm; C1–S1 (C8–S2) 176.3(3) (176.1(3)) pm; S1–C2(S2–C9) 170.8(3) (171.4(3)) pm; C2–C3 (C9–C10) 134.2(4) (134.8(4)) pm. In comparison with thiazole **8** the bond to the carbene-C1 atom are longer by 2.8 (2.2) pm (C1–N1 (C8–N2)) and by 3.9 (3.7) pm (C1–S1 (C8–S2)).[17] In the case of the carbene **9** a lengthening of the $C_{(carbene)}$–N bonds (by about 4 pm) is also observed on going from the corresponding imidazolium salt to **9**.[14] The small N-C-N angle is considered to be especially significant for the carbene structure of **9**: it decreases from 108.5–109.7° in imidazolium salts to 102.2° in **9**.[14] Similarly, the angle N-C-S of 115.1(8)° in thiazole **8** decreases in [**7** · glyme]$_2$ to N1-C1-S1 (N2-C8-S2) 107.9(2) (108.1(2))°. This is in line with calculations of structures of singlet carbenes, which yield R^1-C-R^2 angles of this order of magnitude.[18] Thus, the lithiated thiazole **7** has all the structural features of a lithiated formyllithium equivalent with distinct carbene character.[19, 20]

8 **9**



Soon after the discovery of stable nucleophilic carbenes, Lewis acid adducts of these compounds with various metals were characterized.[21] A carbene complex (**10**) from **9** with Li^+ as the Lewis acid has only recently been reported.[22]

10

Since the complexation of the carbene C-atom by Li^+ in [**7** · glyme]$_2$ is "inevitable" because of the dimerization, it is interesting to investigate the influence of the Lewis acid Li^+ on the carbene structure by comparing **10** with **9**. The $C_{(carbene)}$–N bonds in **10** (136.9 and 136.6 pm) are almost as long as those in **9** (136.7 and 137.3 pm); the N-C-N angles in **10** (102.8°) and **9** (102.2°) are also essentially the same. Hence, in this case Li^+ as the Lewis acid has not influence on the carbene structure. We conclude from these observations that this also applies to the carbene structure of the lithiated 4-*tert*-butylthiazole **7**. The $C_{(carbene)}$–Li distances in **10** (215.2 pm) and in [**7** · glyme]$_2$, (C1–Li2 = 217.7(5) and C8-Li1 = 217.5(5) pm) are nearly identical.[23, 24]

Similarly, a comparison of [**7** · glyme]$_2$ with the gold–carbene complex **11**[25] does not show any significant influence of the metal atom. The $C_{(carbene)}$–N distance in **11** (133.3 pm) is virtually the same as the one in [**7** · glyme]$_2$ (132.6 and 133.2 pm). The N-C-S angles are also comparable: they amount to 105.7° in **11**, and 107.9° and 108.1° in [**7** · glyme]$_2$. A slightly larger deviation is found only in

11

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0488 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 4

the $C_{(carbene)}$–S bonds, which are 172.1 pm in **11** and 176.3 (176.1 pm) in [**7** · glyme]$_2$.

In conclusion, the structure of the formyllithium equivalent [**7** · glyme]$_2$ corresponds to that of a nucleophilic carbene. The complexation with the Lewis acid Li^+ (dimerization) has essentially no influence on the structure.

Experimental Procedure

[**7** · glyme]$_2$: 4-*tert*-butylthiazole (141 mg, 1.00 mmol) in glycol dimethyl ether (2.7 mL) and *tert*-butyl methyl ether (0.1 mL) was deprotonated at −75 °C with 1.6 M methyllithium (0.7 mL, 1.12 mmol) in diethyl ether (30 min). After 5 days at −50 °C crystals of [**7** · glyme]$_2$ suitable for X-ray crystallography precipitated. Yield: 26 mg (18%). ^{1}H NMR ([D$_8$]THF, −50 °C): δ = 1.40 (s, 9H, C(CH_3)$_3$), 6.79 (s, 1H, H5). ^{13}C NMR ([D$_8$]THF, −50 °C): δ = 31.05 (C(CH_3)$_3$), 34.55 (*C*(CH_3)$_3$), 110.98 (C5), 166.24 (C4), 226.33 (C2). The ^{13}C resonance of the carbene C-atom in **9** is detected at δ = 213.2 [14a], the corresponding resonance of the gold complex **11** at δ = 214.5 pm [25]. The chemical shifts of the carbene-C signals in the ^{13}C NMR spectra of [**7** · glyme]$_2$, **9**, and **11** correspond to the results of quantum-mechanical calculations [14d].

[23] MP2/6-31G* model calculations support the negligible influence of the complexation on the structure with Li^+ as Lewis acid. For example, the N-C-S angle in lithiothiazole (most stable singlet) is calculated to be 107.9°, while 108.6° results for a lithiothiazole · LiOH complex. For comparison: the calculated angle for the thiazole **8** is 115.4°.

[24] In an earlier paper we reported on the following four calculated structures of the Li/O carbenoid model, Li-CH_2-OH: 1. Li bridges C–O; 2. Li is bound only to C; the structure is 3. $H_2C\cdots OH(Li)$ and 4. $H_2C\cdots LiOH$. Experimental evidence has been found for the model cases 1–3. G. Boche, A. Opel, M. Marsch, K. Harms, F. Haller, J. C. W. Lohrenz, C. Thümmler, W. Koch, *Chem. Ber.* **1992**, *125*, 2265–2273. The structures of [**7** · glyme]$_2$ and **10** now experimentally verify the fourth (high-energy) model structure.

Common Origin of Enthalpic and Entropic Substituent Effects in Reactions of Benzhydryl Cations with Nucleophiles

Matthias Patz, Herbert Mayr*, Jörg Bartl, and Steen Steenken

Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday

The investigation of substituent effects is one of the most important tools for the determination of reaction mechanisms. While effects of substituents on equilibria and rates of chemical reactions are usually attributable to differences in enthalpy, changes in the entropy of activation, particularly for reactions of reactive intermediates (fast reactions), have been recognized to be the origin of observed substituent effects.[1-3] For the reactions of *para*-substituted benzhydryl cations with π-nucleophiles, we now demonstrate that the change from enthalpic to entropic substituent effects occurs within these reaction series on going from slow to fast reactions. Consequently, the reactivity of the nucleophile determines whether changing substituents in the electrophile affects $\Delta H^{\neq}$ or $\Delta S^{\neq}$.

Detailed mechanistic investigations of the reactions of benzhydryl cations with alkenes[4] and other π-systems[5] have shown that generally the C–C bond formation is the rate-determining step of the reaction sequence depicted in Scheme 1, that

Scheme 1. The reaction of benzhydryl cations with compounds containing π-electron systems. **2**, $R^1 = R^3 = CH_3$, $R^2 = R^4 = H$; **3**, $R^1 = R^2 = H$, $R^3 = CH_3$, $R^4 = C_2H_5$; **4**, $R^1 = R^2 = R^3 = H$, $R^4 = Si(CH_3)_3$; **5**, $R^1 = R^2 = CH_3$, $R^3 = H$, $R^4 = Si(CH_3)_3$.

is, the measured rate constant represents the attack of the carbenium ion at the π-system. Reduction of the electron-donating ability of the substituents X and Y in the carbenium ion **1** gives rise to an acceleration of the reactions, which is caused entirely by the decrease of the enthalpy of activation while the entropy of activation remains constant within the accuracy of the measurements (Fig. 1). An analogous pattern has been observed for many reaction series with $k < 5 \times 10^4$ L mol^{-1}s^{-1}.[6]

For the reaction of the bis(*p*-tolyl)carbenium ion (**1**; X = Y = CH_3) with 2-methyl-2-butene (**2**) in CH_2Cl_2, rate constants k of $(6.9 \pm 0.3) \times 10^4$ L mol^{-1} s^{-1}, almost independent of temperature between -70 and -40 °C, have been observed, from which an activation energy E_a of (0.4 ± 0.6) kJ mol^{-1} and an enthalpy of activation $\Delta H^{\neq}$ of (-1.4 ± 0.6) kJ mol^{-1} (Fig. 1 top) can be calculated. Though no enthalpic barrier is present,

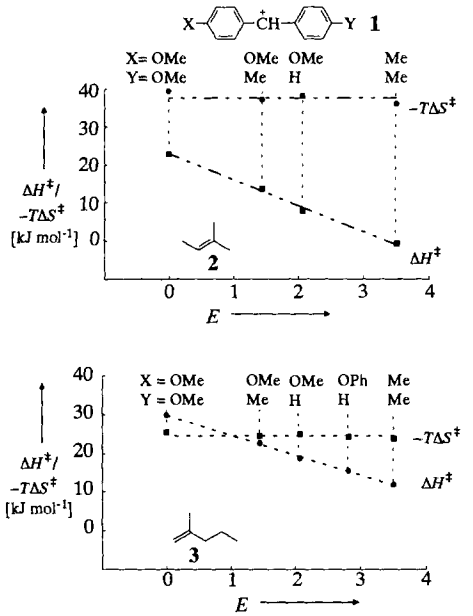

Figure. 1. Correlation between the activation parameters of the reactions of **2** (top), and **3** (bottom) with benzhydryl cations and their electrophilicities. $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were calculated from rate measurements at -70 to -30 °C [6]; electrophilicity parameters E were obtained from ref. [7].

the observed rate constants are five orders of magnitude below the diffusion limit as a result of the large entropy term $-T\Delta S^{\neq}$. How do carbenium ions, which are less stabilized by substituents than **1** (X = Y = CH_3), behave?

To investigate the reactions of more electrophilic benzhydryl cations (**1**) with the same nucleophiles (**2**–**5**), we used the laser pulse method, employing acetonitrile as a solvent because photolysis of benzhydryl chlorides in dichloromethane almost entirely causes homolytic cleavage of the C–Cl bond.[8] As variation of the solvent has only a very small influence on the rates of the reactions of carbenium ions with neutral nucleophiles,[7,9] the rate constant measured for the reaction of the bis(*p*-chlorophenyl)carbenium ion (**1**, X = Y = Cl) with **2** ($k = 7.4 \times 10^7$ L mol^{-1} s^{-1}, CH_3CN, 20 °C) indicates that the replacement of X = Y = CH_3 by Cl in **1** causes an increase of reactivity by almost three orders of magnitude.[10] Since there was no enthalpic barrier even for the reaction of the considerably less reactive carbenium ion (**1**, X = Y = CH_3) with **2**, the further increase of reactivity must be due either to negative values of $\Delta H^{\neq}$ or to an increase of $\Delta S^{\neq}$. Two extreme cases are conceivable: The entropy of activation remains constant while $\Delta H^{\neq}$ becomes negative, or $\Delta H^{\neq}$ remains zero and the isentropic series (constancy of $\Delta S^{\neq}$ shown in Figure 1) does not include the reactions with more electrophilic carbenium ions. Within the Arrhenius formalism, the second possibility corresponds to an increase of the preexponential factor at constant activation

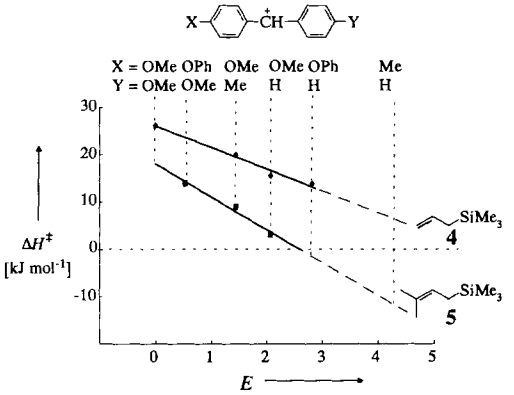
energy. To differentiate these two possibilities, we studied the temperature dependence of the reaction of **2** with the benzhydryl cation **1** (X = Y = Cl) generated by laser flash photolysis in acetonitrile.[8] In eight experiments from −18 to +21 °C we observed temperature-independent rate constants of $(7.4 \pm 0.5) \times 10^7\,L\,mol^{-1}\,s^{-1}$ yielding the Arrhenius parameters $E_a = (-0.6 \pm 1.2)\,kJ\,mol^{-1}$ and $\lg A = 7.54 \pm 0.22$ and the Eyring parameters $\Delta H^{\neq} = (-2.9 \pm 1.1)\,kJ\,mol^{-1}$ and $\Delta S^{\neq} = (-104 \pm 4)\,J\,mol^{-1}\,K^{-1}$.

The thousandfold increase in reactivity on employing the dichloro- instead of the dimethyl-substituted benzhydryl cation is thus due to a change of the entropy term while $\Delta H^{\neq}$ remains close to zero. Though the initial question has thus been answered, the argument is weakened by the fact that a change of solvent could not be avoided for methodical reasons. We have, therefore, corroborated our conclusion by an additional experiment.

Like the alkenes **2** and **3**, the allylsilanes **4** and **5** also react with the *p*-methoxy- and phenoxy-substituted benzhydryl cations **1** at −70 °C in CH_2Cl_2 at rate constants from 10^{-1} to $10^4\,L\,mol^{-1}\,s^{-1}$. Again the change of reactivity is entirely due to a variation of $\Delta H^{\neq}$ while $\Delta S^{\neq}$ remains constant in both reaction series [for **4** $\Delta S^{\neq} = (-118.5 \pm 5.6)\,J\,mol^{-1}\,K^{-1}$; for **5** $\Delta S^{\neq} = (-163.9 \pm 2.8)\,J\,mol^{-1}\,K^{-1}$]. Extrapolation of the straight lines shown in Figure 2 yields a positive enthalpy of



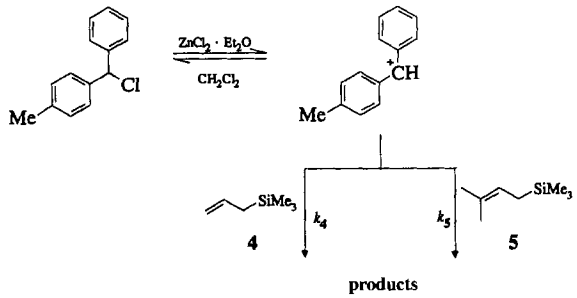


Figure 2. Correlation between the enthalpy of activation $\Delta H^{\neq}$ for the reactions of **4** [5a] and **5**[5a] with benzhydryl cations and their electrophilicity *E*.

activation for the reaction of the benzhydryl cation **1** (X = CH_3, Y = H) with **4** [$\Delta H^{\neq} = (6.2 \pm 2.9)\,kJ\,mol^{-1}$] and a negative value of $\Delta H^{\neq}$ [$(-12.0 \pm 1.7)\,kJ\,mol^{-1}$] for the corresponding reaction with **5**.

The relative reactivities of the two allylsilanes towards **1** (X = CH_3, Y = H) determined by competitive experiments show a strong dependence of the competition constant (k_5/k_4) on temperature (Scheme 2). By plotting $\lg(k_5/k_4)$ against $1/T$ the activation parameters $\Delta\Delta H^{\neq} = (11.7 \pm 0.6)\,kJ\,mol^{-1}$ and $\Delta\Delta S^{\neq} = (30.8 \pm 2.5)\,J\,mol^{-1}\,K^{-1}$ are obtained. Since a positive value of $\Delta H^{\neq}$ is extrapolated for the reaction of **1** (X = CH_3, Y = H) with **4** (Fig. 2), we can conclude that this reaction is part of the isentropic series [$\Delta S^{\neq} = (-118.5 \pm 5)\,J\,mol^{-1}\,K^{-1}$] in analogy to the situation for numerous related reaction series.[5, 6] The remarkable decrease of the difference of entropy from [$\Delta S_4^{\neq} - \Delta S_5^{\neq} = (45.4 \pm 6.4)\,J\,mol^{-1}\,K^{-1}$] for the less reactive benzhydryl cations of Figure 2 to $(30.8 \pm 2.5)\,J\,mol^{-1}\,K^{-1}$ for **1** (X = CH_3, Y = H) must therefore be due to the fact that the entropy of activation for the reaction of **5** with **1** (X = CH_3, Y = H) is less

negative by $15\,J\,mol^{-1}\,K^{-1}$ compared to $\Delta S^{\neq}$ of the reactions of **5** with the methoxy- and phenoxy-substituted benzhydryl cations. As discussed above for the reactions with **2** and **3**, these reaction series also show that an increase of the electrophilicity of carbenium ions occurs with constant entropy of activation and a decrease of $\Delta H^{\neq}$ as long as there is an enthalpic barrier. When the enthalpic barrier has disappeared, the increase of electrophilicity is predominantly caused by an increase of $\Delta S^{\neq}$ which corresponds to an increase of the preexponential factor in the Arrhenius equation.

How can the discontinuous behavior of $\Delta S^{\neq}$ be explained? As $\Delta S^{\neq}$ represents a measure for the position of the transition state, we conclude that this remains unchanged within a reaction series,[11] as long as there is an enthalpic barrier. Only in the absence of an enthalpic barrier is an increase in the electrophilicity of the carbenium ions associated with a shift of the transition state (defined as the maximum of the Gibbs enthalpy[12]) towards the reactants. Assuming the same trajectory, the increase of $\Delta S^{\neq}$ can be rationalized, because at an earlier position of the reaction coordinate fewer degrees of freedom are restricted. As discussed for the additions of carbenes to alkenes by Houk et al.,[11] the large entropy contribution shifts the maximum of the Gibbs enthalpy (transition state) to a position of the reaction coordinate where the enthalpy of the activated complex is already lower than that of the reactants.

Alternatively, the increase of the entropy of activation can be explained by assuming that in cases without an enthalpy barrier activated complexes with different structures are involved, since lifting of the energy levels of the reactants now causes a broadening of the reaction channel and an increase in the number of only downhill trajectories.

The change from isentropic regions to regions with variable entropy, which has been demonstrated experimentally for two examples, might be a general phenomenon. Since bimolecular reactions typically have entropies of activation between −80 and $-180\,J\,mol^{-1}\,K^{-1}$, which contribute 23 to $53\,kJ\,mol^{-1}$ to $\Delta G^{\neq}$ at 20 °C, substituent effects should generally be observable as entropic effects when the rate constants *k* exceed values from 2×10^3 to $4 \times 10^8\,L\,mol^{-1}\,s^{-1}$ (from $\Delta H^{\neq} = 0$ and $\Delta S^{\neq} = -180$ and $-80\,J\,mol^{-1}\,K^{-1}$, respectively).

In agreement with this conclusion, Scaiano, Berson et al.[13] reported that the same order of reactivities of dienophiles that Sauer et al.[14] observed in reactions with 9,10-dimethylanthracene and cyclopentadiene (isentropic series) also holds for 3,4-dimethylenefuran, although the reactions with 9,10-dimethylanthracene and cyclopentadiene are characterized by variable values of $\Delta H^{\neq}$ and a constant $\Delta S^{\neq}$, whereas the reactions with the singlet diradical have almost equal (slightly nega-

tive) values of $\Delta H^{\neq}$, and the differences in reactivity are due to differences in the entropy of activation. Depending on the nature of the reaction partner, electronic substituent effects thus can affect either $\Delta H^{\neq}$ or $\Delta S^{\neq}$.

The First Distibabutadiene: Synthesis and Structure of *trans*-1,4-Bis(trimethylsiloxy)-1,4-bis(2,4,6-tri-*tert*-butylphenyl)-2,3-distibabutadiene**

Peter B. Hitchcock, Cameron Jones, and John F. Nixon*

Despite the considerable interest that has recently been shown in compounds containing phosphorus–carbon or arsenic–carbon multiple bonds,[1] the knowledge of analogous antimony compounds is sparse. In fact, structurally characterized examples of such compounds can be confined to a few cases where a λ^3,σ^2 Sb–C double bond is stabilized in an aromatic cyclic system, for example, **1**[2] and **2**.[3] Only in one of the canonical forms of resonance-stabilized λ^5,σ^4 stibonium ylides such as **3** have acyclic Sb–C double bonds been proposed.[4] As part of a continuing study of higher group 15 congeners with low coordination numbers,[5] we now report the synthesis and X-ray crystal structure of the first distibabutadiene **4**, which contains the first example of an acyclic λ^3,σ^2 Sb–C double bond.

Treatment of $Li[Sb(SiMe_3)_2(dme)]$[6] with the acid chloride **5** (Scheme 1) in dimethoxyethane (dme) afforded the deep red, mildly air-sensitive complex **4** (18% yield) after recrystallization from hexane. Although all manipulations were carried out in the

Scheme 1. Synthesis and proposed mechanism for the formation of **4**.

dark, considerable quantities of elemental antimony precipitated from solution during the course of the reaction (4 days), which seemingly accounts for the low yield of **4**. Moreover, when the less sterically hindered acid chloride *t*BuCOCl was employed in place of **5**, no 2,3-distibabutadiene formation was observed; instead high yields of the novel 2-stiba-1,3-dionate, $[\{[LiO(t\text{Bu})CSbC(t\text{Bu})O]_2(dme)\}_\infty]$ were obtained.[7] The phosphorus analogue of **4** has been reported in low yields as a product of the high temperature reaction of $P(SiMe_3)_3$ with **5**.[8] Similar attempts to form **4** by the reaction of $Sb(SiMe_3)_3$ with **5** led only to decomposition products. The heterobutadiene **4** was characterized by elemental analysis, mass spectrometry, ^1H NMR spectroscopy, and a single crystal X-ray structure determination.

From its molecular structure[9] (Fig. 1), compound **4** lies on an inversion center; atoms C1, Sb, Sb′, and C1′ are coplanar and adopt the sterically favourable *trans* configuration. The

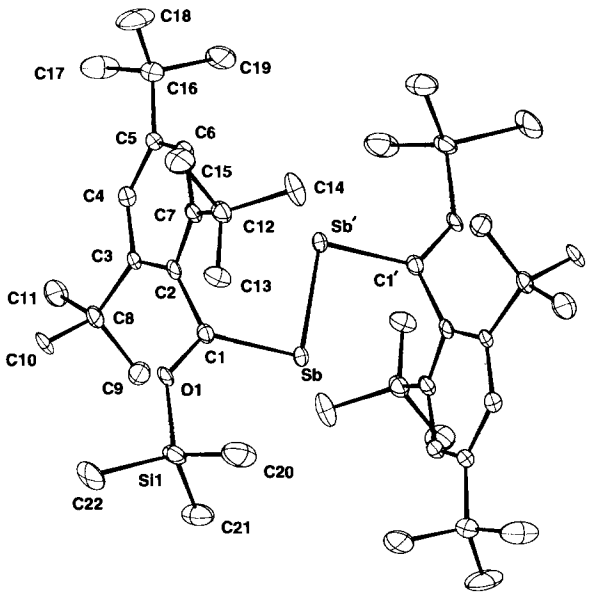

Fig. 1. Molecular structure (ORTEP, thermal ellipsoids represent 50% probability) of **4**. Important bond lengths [Å] and angles [°]: Sb–Sb' 2.774(1), Sb–C1 2.056(10), C1–O1 1.370(12), C1–C2 1.483(13), O1–Si1 1.676(7); Sb'-Sb-C1 94.7(3), Sb-C1-C2 123.0(7), Sb-C1-O1 122.2(7), C2-C1-O1 114.8(8), C1-O1-Si1 134.5(6).

coordination environment around the alkene carbon C1 is one of a trigonal plane (sum of the angles = 360.0°), which subtends a dihedral angle of 6(2)° with the plane of this butadiene backbone. The angle C1-Sb-Sb' [94.7(3)°] is considerably distorted from the 120° expected for an sp^2-hybridized Sb center and is significantly less than the corresponding C-P-P angle in related 2,3-diphosphabutadienes, for example $[P=C(OSiMe_3)(tBu)]_2$ [100.7(4)°].[10] To the best of our knowledge there are no known structurally characterized examples of 2,3-diarsabutadienes for comparison. This apparent trend to lower C-E-E angles for heavier elements E of group 15 can be explained by the inert s-pair effect and has been observed in the similar compound series RE=ER (E = N, P, As).[1]

It seems possible from the bond lengths within the molecule that a degree of double-bond delocalization is occurring. The distance Sb–C1 [2.056(10) Å] is longer than predicted in a high level (Hartree-Fock/3-21G* basis set) theoretical study on the stibaalkene $HSb=CH_2$ (2.01 Å),[11] and close to that seen in other delocalized systems [for example **1**, 2.050(5) Å],[2] or resonance-stabilized compounds [for example **3**, 2.049(4) Å].[4] Similarly, the Sb–Sb' distance [2.774(1) Å] is shorter than is normally found for Sb–Sb single bonds in distibanes, R_2SbSbR_2 (for example Ph_4Sb_2, 2.837(1) Å)[12] and is, in fact, close to that typically observed for Sb=Sb bonds η^2-coordinated to transition metal complex fragments, such as in $[Fe\{\eta^2\text{-}[(Me_3Si)_2CH]_2Sb_2\}(CO)_4]$ [2.774(1) Å].[13] However, the shortness of the Sb–Sb' bond in **4** relative to distibanes can also be explained by the smaller covalent radius of its sp^2-hybridized Sb center relative to that of the sp^3-hybridized center in distibanes. Similar shortenings have been observed for P–P bonds involving sp^2- and sp^3-hybridized phosphorus.[1] Therefore, it seems likely that the unusual stability of **4** is derived from a combination of partial double-bond delocalization in addition to the significant steric protection afforded to each antimony center. These factors also explain the apparent robustness of the Sb–Sb bond in **4** as evidenced by the absence of the monomeric fragment $[SbC(2,4,6\text{-}C_6H_2tBu_3)(OSiMe_3)]^+$ in its mass spectrum. In the mass spectra of corresponding 2,3-diphosphabutadiene systems P–P bond cleavage fragments are common.[8]

Considering the mechanism for the formation of **4**, a plausible initial step is a salt elimination reaction giving rise to **6** (Scheme 1). This then undergoes a 1,3-silyl shift yielding the unstable stibaalkene **7**, which then eliminates hexamethyldisilane in a coupling reaction to give the 2,3-distibabutadiene **4**. Similar coupling reactions involving the elimination of Si_2Me_6 have been reported in the formation of disilenes.[14] By contrast, the closely related reaction of **5** with $[Li\{As(SiMe_3)_2\}(thf)_2]$ leads to elimination of hexamethyldisiloxane from the arsenic analogue of **6**, thus affording the arsaalkyne $(2,4,6\text{-}C_6H_2tBu_3)C\equiv As$;[15] comparable stibaalkyne formation was not observed in the present work. We are currently pursuing a stable stibaalkyne by alternative routes in addition to examining the coordination chemistry of **4**.

Experimental Procedure

4: To a solution of $Li[Sb(SiMe_3)_2(dme)]$ (1.20 g, 3.3 mmol) in DME (20 mL) at −40 °C was added **5** (1.02 g, 3.3 mmol) in DME (15 mL). After 4 days (exclusion of light) at 20 °C, volatiles were removed from the resulting solution under vacuum (10^{-3} mbar). The residue was extracted with hexane (40 mL) and filtered, and the filtrate was concentrated under vacuum (10^{-3} mbar) to about 7 mL. Cooling to −30 °C for 12 h yielded **4** as deep red crystals. Yield 280 mg (18%); m.p. 213 °C (decomp.); ^{1}H NMR (250 MHz, C_6D_6, 25 °C, TMS) δ = 0.43 (s, 18H), $OSiMe_3$), 1.39 (s, 18H, *t*Bu), 1.65 (s, 36H, *t*Bu), 7.47 (s, 4H, Ar); MS (70 eV): *m/z* (%): 936(5) [M^+], 879(3) [$M^+ - tBu$], 345(45) [$tBu_3PhCOSiMe_3^+$], 273(100) [tBu_3PhCO^+], 73(60) [$SiMe_3^+$], 57(58) [tBu^+]. Satisfactory microanalytical data were obtained for **4**.

A Wide Spectrum for Analysis

Spectroscopy in Catalysis. An Introduction. By *J. W. Niemantsverdriet*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 288 pp., hardcover DM 148.00, $ 95.00.—ISBN 3-527-28593-8/1-56081-792-5

Heterogeneous catalysis under real conditions is an extremely complicated process, not least due to the complex nature of the catalysts and the structural changes that they undergo as a result of variations in the reacting environment and other external conditions. Ultimately one would like to have experimental methods that could reveal in situ on an atomic scale the chemical processes occurring on catalyst surfaces. As these do not exist, systematic progress in understanding heterogeneous catalysis can only be achieved by the combined use of as many analytical techniques as possible in conjunction with model studies. The latter are important for two reasons. Firstly, they enable one to study systems under well-defined conditions with regard to surface structure, surface composition, and external reaction conditions, so that the dependence on individual variables can be investigated. Secondly, they can be carried out under conditions that are essential for many of the analytical methods; for example, ultra-high vacuum conditions are necessary for all types of electron spectroscopy.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Whereas on the one hand in-situ measurements under real conditions seldom lead to unambiguous conclusions about relationships, model studies on the other hand suffer from the inherent danger of oversimplification and the neglect of "synergistic effects". However, so far there has been no way out of this dilemma (the gap between surface science and catalysis) other than to approach the problem from the two sides simultaneously. With this in mind the book reviewed here makes a particularly useful contribution in describing as wide a range of complementary methods as possible.

The book begins with an introductory chapter outlining the basic features of heterogeneous catalysis, its enormous technological and economic importance, and the scientific problems that it poses. This is followed by seven chapters dealing with the most important methods used to study the physical properties of, and chemical processes occurring at, catalyst surfaces, as follows—Chapter 2: Temperature-programmed surface reaction and desorption techniques; Chapter 3: Photoelectron and Auger electron spectroscopies; Chapter 4: Ion scattering and ion spectroscopy techniques, including mass spectrometry of secondary ions and neutral particles; Chapter 5: Mössbauer spectroscopy; Chapter 6: X-Ray and electron diffraction methods; Chapter 7: Electron microscopy and scanning probe microscopy; Chapter 8: Vibrational spectroscopies with photon and electron excitation. Whereas those methods that depend on particles (electrons, ions, or atoms) for excitation or detection usually require vacuum conditions, the photon techniques can be used in situ. The methods described can provide answers to all the relevant questions, such as those relating to the atomic structure of surfaces, their qualitative and quantitative chemical composition and the distribution of the various surface constituents, the electronic structure of surfaces and adsorbed reacting species, and their vibrational properties as an indication of the nature of the chemical bonding.

The author is a physicist and an active researcher in an institute devoted to catalysis research. Through a good choice of subject matter and the way in which it is presented he makes a valuable contribution to bridging the gap between surface physics and catalyst research. The theoretical fundamentals of the individual methods are treated in a clear and easily understandable way, with just the right amount of detail for an initial assessment of the capabilities and limitations of the techniques for specific applications in catalysis research. Especially useful in this respect are the discussions that have been worked into the text in many places, comparing and evaluating the (mutually complementary) information given by the various methods when applied to a particular problem. Also of special value is Chapter 9, in which three case studies (supported rhodium catalysts, Co/Mo sulfide desulfuration catalysts, and alkali promotors on metal surfaces) are taken as examples, stretching each of the previously described methods to its full capabilities to yield the maximum information about the catalytic system.

The book can be recommended equally for the catalysis scientist, to extend his or her knowledge of the methods, to the surface physicist to stimulate interest in the analytical problems of heterogeneous catalysis, and for the student wishing to specialize in catalysis.

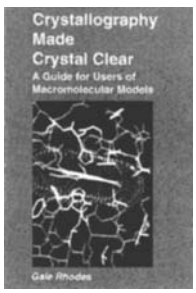
Fundamentals of Photoinduced Electron Transfer. By *G. J. Kavarnos*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 359 pp., hardcover DM 105.00, $ 75.00.—ISBN 3-527-27856-1/0-89573-751-5

This volume is intended to serve as an introduction and course book to accompany a lecture series on photochemistry for students of all branches of the natural sciences. Accordingly, special attention has been given to presenting the subject in a suitable form for teaching purposes. The text is divided into six chapters. The first two, "Introductory Concepts" and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0495 $ 10.00+.25/0



"Properties of Charge-Transfer Intermediates in Photoinduced Electron Transfer", give a general introduction to elementary theoretical models and the variables involved, and a survey of the most important experimental methods for studying electron transfer. The chapters on "Electron-Transfer Photochemistry", "Intramolecular Photoinduced Electron Transfer", and "Photoinduced Electron Transfer in Organized Assemblies and the Solid State" convey a comprehensive picture of the many different types of photoinduced electron transfer processes and the resulting chemical reactions, especially in organic molecules. The systems and reactions in which the initiating step is a photoinduced electron transfer range from isomerizations, cleavage of carbon–carbon bonds and other photochemical transformations, electron transfer processes in micelles, vesicles, and semiconductor surfaces, through to applications in photovoltaic cells and xerography. Lastly Chapter 6, "Theories of Photoinduced Electron Transfer", summarizes the main theoretical approaches to the interpretation and quantitative description of electron transfer rates. Each chapter begins with a useful introduction and ends with an extensive list of references, grouped under subject headings and partly annotated with comments, and a set of exercise problems (without answers).

To summarize the overall impression, the book serves its readers best when describing the many different phenomena, systems, and methods of investigation. Here the numerous figures and tables are a valuable aid to understanding. On the other hand, it is less convincing when dealing with the fundamentals of photoinduced electron transfer. Many of the important concepts involved in the description of these reactions, such as the through-bond and through-space couplings between electron donor and electron acceptor, the reorganization energy, and aspects of the thermodynamics, are treated in a misleading or even incorrect way. One glaring example is the relationship between the electronic coupling H_{el}, the donor–acceptor separation, and the validity of the "Golden Rule" for the rate of electron transfer. On page 308 the dependence of H_{el} on the separation is given as follows: "$H_{el} = H_{el}^0 \exp[-\beta(d - d^0)]$ where β is an orbital parameter, d is the actual separation distance ... Since β is a measure of the ability of an orbital to extend into space and interact with another orbital, the magnitude of interaction between donor and acceptor orbitals is inversely proportional to β." This statement does not make sense. Then, beginning in the second line of page 328: "Importantly, H_{el} is proportional to Δ_t, the distance separating two reactants (as well as their mutual stereoelectronic orientation), and thus by inference is also proportional to the probability that two states couple at a fixed nuclear configuration. The Golden Rule is valid for small Δ_t. If $\Delta_t \gg 0$, the rule breaks down." This is clearly wrong. Lastly, on page 329 we read the following statement about Δ_t: "The horizontal displacement between the minima of these potential energy curves ..." (i.e. the potential energy surfaces for reactants and products as functions of a nuclear coordinate) "... is given by Δ_t." This too is incorrect. Sadly, the list of such inconsistencies could be continued. Thus, the reader who wishes to learn not just about the phenomena but also about the mechanisms—in fact about the "fundamentals of photoinduced electron transfer"—would be better advised to go directly to the secondary literature that is plentifully cited in this book.

Crystallography made Crystal Clear. A Guide for Users of Macromolecular Models. By *G. Rhodes*. Academic Press, New York, 1993. 202 pp., paperback $ 34.95.—ISBN 0-12-587075-2

With the rapid development of molecular biology, and especially of genetic engineering, there is an increasing need for knowledge of the three-dimensional structures of biological macromolecules in full atomic detail. This information is essential in order to understand the mechanisms whereby they function and to achieve controlled biological action by the methods of protein design and drug design. The two methods currently used for structure determination are NMR spectroscopy and X-ray crystallography. NMR spectroscopy has the advantage that one can work with solutions, but difficulties arise with molecular masses above about 20000 u. Crystallography is not subject to this limitation, but suffers from notorious difficulties in obtaining single crystals, and from the necessity to prepare heavy atom derivatives to overcome the "phase problem".

Up to now the molecular biologist or biochemist wishing to learn about protein crystallography has needed to rely either on textbooks of biochemistry or biophysics which typically devote one or two chapters to crystallography, or on textbooks dealing specifically with protein crystallography, which are usually too detailed and contain too much mathematics for easy reading. The book by Gale Rhodes reviewed here exactly fills that gap. In just over 200 pages with many illustrations and without many mathematical formulas, the author explains how a crystal structure analysis is carried out—from the crystallization of the protein through to the final refinement of the structure. The book includes comments on the validity of models and, especially useful in my view, a guide to reading publications on crystallography.

Chapter 1 introduces electron density distributions in protein crystals with the help of colored illustrations and discusses their interpretation in terms of models, so as to kindle the reader's interest in discovering the results of crystallography. Chapter 2 gives a general survey of protein crystallography, and can be regarded as a summary of the chapters that follow. In Chapter 3 the reader learns about the methods used for crystallizing proteins and nucleic acids, and Chapter 4 explains in detail the diffraction of X-rays by the crystal lattice and the recording of the diffraction data using either cameras (film) or modern surface counters. Chapters 5 and 6 explain how the phase angles needed for calculating the electron density distribution in a novel structure are obtained through isomorphic substitution by heavy atoms using Patterson methods, and on the other hand how, in cases where similar related structures are known, the method of "molecular replacement" can be used. The author also describes how the electron density distribution can sometimes be modified (by "solvent flattening"), so as to obtain a significant improvement in signal-to-noise ratio. Chapter 7 is mainly concerned with estimating the quality of a claculated electron distribution, interpreting it in the form of a model displayed on a graphics screen, and refining such a model on the basis of the measured diffraction data. Chapter 8 discusses quality criteria for models, such as Ramanchandran plots, temperature factors, disordered regions in models, and unexpected electron density features which can be attributed to solvent molecules. The chapter ends by analyzing a publication con-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0404-0496 $ 10.00+.25/0

cerned with a lipid-binding protein, which serves to illustrate and summarize the contents of the preceding seven chapters. Chapter 9 contains an excursion into software for displaying and manipulating molecular models.

The text is written in a fluent style and can be quickly understood even by nonspecialists. The few mathematical formulas included are essential for describing the relationships involved, and the figures are instructive and well chosen. The book entirely fulfills its aim of providing a bridge between molecular biologists and biochemists on the one hand and protein crystallographers on the other, and I recommend it to everyone who is concerned with molecular structures. The brevity of the text and the high standard of presentation ("crystal clear") make this a very suitable book to use as an accompaniment to practical sessions or as an introductory course in protein crystallography.

Applications of Mass Spectrometry to Organic Stereochemistry. (Series: Methods in Stereochemical Analysis.) Edited by *J. S. Splitter* and *F. Tureček*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1994. 705 pp., hardcover DM 198.00, $ 125.00.—ISBN 3-527-26525-2/0-89573-303-X

Review articles on mass spectrometric studies of stereoisomeric compounds have appeared at irregular intervals over a period of many years, extending from Meyerson and Weitkamp (1968) through Green (1976, 1978) and Mandelbaum (1977, 1983) up to Tureček (1987). With the publication of this book we now have a comprehensive survey of the field. Twenty well-known authors have contributed articles on 22 topics, covering published work up to 1992. The ability to solve stereochemical problems is certainly not regarded as one of the particular strengths of mass spectrometry, but despite this there exists a surprising wealth of examples where stereochemical differences are clearly reflected in mass spectra. This applies even under the conditions of 70 eV electron impact ionization, which results in the transfer of a large amount of surplus energy, typically 2–10 eV. The likelihood of being able to distinguish between stereoisomers is intrinsically greater if the conversion to the gas phase and the subsequent ionization are carried out under conditions that minimize the excitation of the molecules. This can be achieved by suitable modifications to the instrumental conditions, such as cooling the ion source, the use of low voltage electron impact ionizaion, or substituting more gentle ionization processes such as photoionization, electric field ionization, or chemical ionization.

A short introductory chapter on the techniques of mass spectrometry (author: Falik) is followed by chapters dealing with the structures of ions and the influence of stereochemistry on the mass spectra of acyclic molecules (Splitter). Further chapters discuss the behavior of stereoisomeric cyclic compounds (Eadon, Valente, Tureček, Grützmacher, Vékey, Mandelbaum, Groenewold, Gross). In these compounds the ring structure limits the number of conformers that can exist, and there is then the possibility that this reduced mobility may result in stereospecific rearrangements causing differences in the mass spectra which can be interpreted. Using model compounds as examples, the authors describe in detail the most important types of phenomena, including enthalpy effects, "hidden" stereochemistry, effects of conformational changes, steric effects influencing the accessibility of hydrogen atoms for rearrangements, stabilization of carbocations by neighboring groups, retro-Diels–Alder fragmentations, and examples of the use of field ion kinetics (FIK) and mass-analyzed ion kinetic energy release (MIKE) measurement techniques.

A very informative chapter on the use of chemical ionization (Winkler, Splitter) describes results obtained with *E,Z*-isomeric olefins, and, in greater detail, cyclic compounds. By choosing appropriate reactant gases in the chemical ionization method it is possible to optimize specific fragmentation processes and/or adduct formation for the system under investigation. A separate chapter (Houriet, Tureček) is devoted to the study of stereochemical effects in an ion cyclotron resonance mass spectrometer, a type of instrument uniquely suited for investigating ion–molecule reactions. This technique yields information about the long-term behavior of ions. Next are several chapters on the behavior of stereoisomeric natural products, including terpenes and terpenoids (Enzell, Dahlmann, Bielawski), steroids (Tabet), quinolizidine and indole alkaloids (Tamás) and rotenoids (Kostova, Mollowa). The comprehensive article on the steroids also contains a substantial section on MS–MS "linked-scan" techniques. Other articles report on organometallic compounds (Nekrasov, Zagorewskii), measurements on labeled compounds (Tureček), and the estimation of enthalpies of formation (Splitter).

The material contained in the book is very comprehensive and well presented, although the style varies from one author to another. Often, however, the writers fail to distinguish clearly between textbook-style presentation and the mere cataloguing of facts. For example, the same basic phenomena are described several times over, especially in the early chapters. Few theoretical arguments are put forward to explain the different behavior of stereoisomers, and the structure of the book could have been tightened considerably by consistently separating the discussion of basic principles from the chapters that are more concerned with compound classes, with appropriate cross-references. The lack of sufficient coordination between the chapters is also evident in the dearth of cross-references and the fact that citations of key publications are often repeated.

From the user's point of view one would have preferred the chapter on mass-spectrometric methods to devote more attention to special measurement techniques and their relevance to distinguishing between stereoisomers. Here a critical evaluation of the procedures for determining relative peak heights and the reproducibility of such data with different types of instruments would have been very useful, as also would a discussion of the methods used for distinguishing between stereoisomers. The application of MS–MS techniques using the tandem mass spectrometers that are now becoming more widely available is only touched on briefly.

The book is well produced with a clear typeface, a considerable advantage in a book of this size. It is unfortunate, however, that the publishers have not redrawn the structural formulas, or at least insisted on a uniform style. Their quality varies greatly; often there are no compound numbers, and in some cases the relevant text is far removed from the illustration.

However, these criticisms do not alter the verdict that the comprehensiveness of the book and the overall high quality of presentation will ensure that it becomes a standard work in this field. It can therefore be recommended to all mass spectroscopists involved in the analysis of organic compounds, and to everyone else who wishes to learn about the capabilities of mass spectrometry for analyzing stereoisomeric compounds.

Covalent Inorganic Azides

Inis C. Tornieporth-Oetting* and Thomas M. Klapötke*

The chemistry of covalent inorganic azides originated with the synthesis of aqueous HN_3 solutions by Tony Curtis in 1890. A little later, in 1900, it proved possible to prepare iodine azide, IN_3, as the first member of the meanwhile complete series of halogen azides. Since then it has been possible to synthesize, in addition to HN_3 and the stable salt $H_2N_3^+SbF_6^-$, azide compounds of elements from Groups 13 to 17. In these compounds the N_3 moiety acts as a pseudohalogen and is primarily covalently coordinated to the nonmetal. Only a few organic azides, however, as well as HN_3, $H_2N_3^+$, and all halogen azides have been thoroughly studied with respect to structure and bonding. The combined application of diffraction methods (X-ray and electron diffraction) and microwave spectroscopy together with quantum chemical approaches such as ab initio SCF and density functional calculations have led in the last few years to an improved understanding of the molecular properties of numerous nonmetal azides, almost all of which are explosive. This interaction of theory and experiment has greatly enhanced the development of azide chemistry and has led to realistic expectations for the synthesis of as yet unknown nonmetal azides.

Keywords: ab initio calculations · azides · nitrogen compounds

1. Introduction

Covalent azides have been known for more than 100 years.[1] Table 1 contains a—by no means complete—list of main group azides in which the N_3 group acts as a pseudohalogen and is primarily covalently bound to the corresponding nonmetal. Until now, however, only very few of these compounds could be definitively structurally characterized. Examples include HN_3,[2] $H_2N_3^+$,[3] CF_3N_3,[4] $Te(N_3)_3^+$,[5] XN_3 (X = F,[6] Cl,[7] Br,[8] I[9, 10]), and $I(N_3)_2^-$.[11] If one considers the N_3 fragment as a pseudohalogen (absolute electronegativity according to Mulliken: Cl 8.3, Br 7.5, N_3 7.7 eV),[7b, 12] the hydrogen compound HN_3 and the pseudohalogen–halogen compounds XN_3 (X = F, Cl, Br, I) are the simplest members of this class of substances. This simplicity, combined with the strong tendency to detonate and the, in some cases, considerable toxicity, presents a significant challenge to the experimental chemist.[13] In this article, we wish to illuminate the interaction of experimental, preparative, structural, and theoretical studies in this area of chemistry, using examples of hydrogen and halogen azides with structures that, in most cases, have been definitively determined only over the last five years.[14, 15] Afterwards, the structure and bonding of species related to halogen azides, namely $I_2N_3^+$,[16] $I(N_3)_2^+$,[17] ONN_3,[18] and O_2NN_3,[19] will be discussed, and an outlook for future preparative studies in this field will be given.

2. Synthesis and Spectroscopic Properties

2.1. Synthesis

Covalent azides are highly explosive, especially in pure form. It is therefore imperative that work on a preparative scale is performed under appropriate safety precautions, such as face shields, protective leather clothing, gloves, and ear protection. Experiments should also be performed on as small a scale as feasible. As an example, the explosive decomposition of less than a gram of bromine azide kept in a glass flask which in turn was placed inside a metal-shielded glass Dewar, led to the complete pulverization of the glass and tearing of the metal shielding.[10, 30] All halogen azides are very sensitive in this respect. Chlorine azide and bromine azide are particularly sensitive to small pressure variations and regularly explode when $\Delta p \geq 0.05$ Torr.[8] Characteristic detonation data for some halogen azides and nitrosyl azide, N_4O, have been reported (Table 2).[10] These compounds are potentially better explosives than lead azide (see Table 2), which is used as a detonator. However, they are by far not kinetically stable enough to find use as detonators.[31–33]

Phosphorus nitrile azide, $[PN(N_3)_2]_3$, which can be isolated in pure form, is one of the most nitrogen-rich inorganic compounds (see Table 1).[22] This material is also very shock-sensitive in the solid state and detonates when mechanically stressed and upon exposure to an electric discharge. According to the results of ab initio calculations, the compound possesses approximate C_3 symmetry (Fig. 1),[32] its structure, however, has not yet been experimentally determined by diffraction methods. While the nitrogen-rich cation $As(N_3)_4^+$ is "stable" in SO_2

solutions and has been characterized by multinuclear NMR (^{14}N, ^{75}As) and Raman spectroscopy, the compound $[As(N_3)_4]AsF_6$ is very explosive in the solid state.[28]

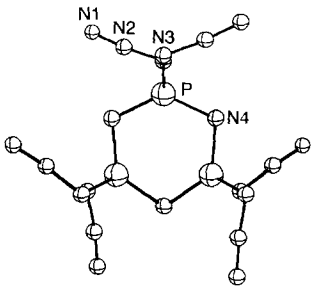

Fig. 1. Calculated molecular structure of $[PN(N_3)_2]_3$ (ab initio methods, RHF/6-31 + G*); d(N1–N2) = 1.16, d(N2–N3) = 1.32, d(N3–P) = 1.79, d(P-N4) = 1.73 Å.

Hydrazoic acid and many of its covalent inorganic (e.g., ClN_3, Me_3SiN_3) and organic derivatives (e.g., CH_3N_3) are also very toxic. HN_3 is as poisonous as hydrogen cyanide.[1a]

In spite of these difficulties (or maybe even because of them), several research groups did early work on the synthesis of hydrazoic acid,[34] its organic derivatives,[13, 35] and halogen azides.[14, 36] Even though HN_3 can be prepared by the action of dilute sulfuric acid on sodium azide or the reaction of nitrous acid and hydrazine, it is most readily synthesized on the preparative scale by the reaction of stearic acid with sodium azide at 100–130 °C in the melt [Eq. (a)].[3] The preparation of the halogen azides is best done according to the Equations (b)–(e).[14] We recently discovered an easy access to chlorine azide in a

$$CH_3(CH_2)_{16}COOH + NaN_3 \xrightarrow{\text{melt, } 110\text{–}130\,^\circ C} CH_3(CH_2)_{16}COONa + HN_3 \quad \text{(a)}$$

$$4\,HN_3 + 2\,F_2 \xrightarrow{\text{gas phase}} 3\,FN_3 + N_2 + NH_4F \quad \text{(b)}$$

$$NaN_3 + Cl_2 \xrightarrow{0\,^\circ C,\ H_2O} ClN_3 + NaCl \quad \text{(c)}$$

$$NaN_3 + Br_2 \xrightarrow{20\,^\circ C/0\,^\circ C,\ \text{pure}} BrN_3 + NaBr \quad \text{(d)}$$

$$AgN_3 + I_2 \xrightarrow{CFCl_3,\ 0\,^\circ C} IN_3 + AgI \quad \text{(e)}$$

Inis C. Tornieporth-Oetting was born on March 19, 1963 in Hamburg, Germany. She studied at the Universität Oldenburg and at the Technische Universität (TU) Berlin, where she also received her doctorate degree in 1992, working under the supervision of Thomas M. Klapötke. She is currently employed as a senior scientist at the TU Berlin. She is the author of more than forty publications and two chapters of books, and together with Klapötke is the coauthor of a textbook on nonmetal chemistry. Her research interests in the area of nitrogen chemistry stretch from the purely inorganic halogen chemistry of this element, including its fluorine chemistry, to the coordination chemistry of organic amino compounds and the study of biologically relevant amino acid model complexes.

Thomas M. Klapötke was born on February 24, 1961 in Göttingen, Germany. He studied at the Technische Universität Berlin and received his doctorate degree there in 1986, working under the supervision of Hartmut Köpf. After postdoctoral work with Jack Passmore at the University of New Brunswick, he completed his habilitation in 1990 at the TU Berlin. In 1995 he was appointed to the Ramsay Chair of Chemistry at the University of Glasgow. He is the holder of the Karl-Winnacker-Stipendium (1994) and has been awarded, amongst others, the Schering-Preis (1987) and the Maier-Leibnitz-Preis (1994). Furthermore, he is the author of more than 120 publications, six chapters of books, and with Tornieporth-Oetting is the coauthor of a textbook on nonmetal chemistry. His research interests encompass the preparative synthesis of unstable nonmetal compounds in the areas of nitrogen–halogen and nitrogen–chalcogen chemistry, including the chemistry of elemental fluorine, as well as the theoretical characterization of the bonding in these compounds.

solvent-free system by the reaction of trimethylsilyl azide and nitryl chloride [Eq. (f)]. After fractional condensation, it was possible to isolate pure liquid ClN_3.[19]

$$3\,Me_3SiN_3 + 3\,ClNO_2 \xrightarrow{-20\,^\circ C} 2\,ClN_3 + Me_3SiCl + Me_3SiOSiMe_3 + 2\,N_2O + N_2O_3 \quad (f)$$

2.2. ^{14}N NMR Spectroscopy

One of the most suitable methods for the characterization of covalent azides in solution is ^{14}N NMR spectroscopy, which has proven to be an invaluable tool for the study of small nitrogen-containing molecules.[37] In addition, during the last few years it was demonstrated that ^{14}N NMR spectroscopy could not only be utilized for the elucidation of structures in solution, but also for the determination of equilibrium constants and thermodynamic parameters.[38, 39] For many covalent azides, such as the halogen azides XN_3 (X = Cl, Br, I), covalent phosphorus and arsenic azides, as well as covalent azide ions such as $As(N_3)_4^+$, the ^{14}N NMR spectra show three well-resolved resonances, which have been assigned to the chemically inequivalent nitrogen atoms.[40–42, 79] Presumably owing to the large quadrupole moment of the nitrogen nucleus, there were no observable $^{14}N-^{14}N$ couplings. This is not surprising when considering the very small coupling constant, estimated at about 30 Hz. Using variable temperature and variable concentration ^{14}N NMR studies it was possible to demonstrate that iodine azide, which is monomeric in the gas phase but polymeric in the crystalline state, as well as alkylarsenic(III) azides, which are oligomeric as pure liquids, dissolve in $CDCl_3$ to give monomolecular solvates. In the temperature and concentration ranges studied, no azide exchange between the arsenic or iodine centers, respectively, was found. Figure 2 shows the ^{14}N NMR spectrum of Me_2AsN_3 as an example; the resonances were assigned according to the numbering shown in Figure 4.

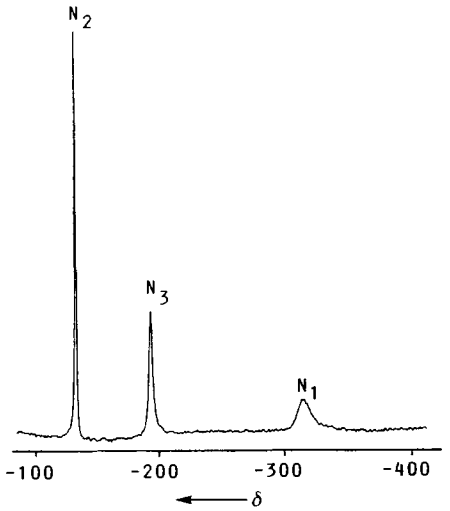

Fig. 2. ^{14}N NMR spectrum of Me_2AsN_3 (28.904 MHz, 1 mol L^{-1}, relative to $MeNO_2$, 22 °C, $CDCl_3$) [42].

3. Stability and Thermodynamics

Ab initio calculations have been used increasingly in recent years to extract bond energies and thermodynamic stabilities of covalent azides from calculated total energies.[18, 43] These data are, for obvious reasons, difficult to obtain experimentally.

The dissociation energies for HN_3 and the halogen azides have been calculated and appropriately corrected to yield dissociation enthalpies at room temperature ΔH [Eq. (g), X = H, F, Cl, Br, I; see also Table 3).[43, 44]

$$XN_3 \longrightarrow N_3 + X + \Delta H_g \quad (g)$$

Reaction (g) is strongly endothermic in all cases and the value calculated for HN_3 agrees well with the experimentally obtained data (85 kcal mol^{-1}).[45] According to Table 3, the $X-N_3$ bond

Table 3. Calculated reaction enthalpies ΔH [kcal mol^{-1}] and calculated standard enthalpies of formation ΔH_f^0 [kcal mol^{-1}] for the reactions (g)–(i) (MP2/6-31 G**) [43].

	ΔH_g	ΔH_h	ΔH_i	ΔH_f^0 (XN_3)
HN_3	96.9	14.9	−144.2	72.1
FN_3	57.8	−25.1	−164.4	82.2
ClN_3	48.5	−11.9	−185.6	92.8
BrN_3	46.9	−3.5	−193.2	102.1
IN_3	45.8	6.5	−191.4	103.6

energy decreases in the order H ≫ F > Cl > Br > I. This result should not be misinterpreted with respect to the stability of the halogen azides, however, since the thermal decomposition of XN_3 is not initiated by the breaking of the $X-N_3$ bond (X = H, F, Cl, Br, I), but, at least in the gas phase, by dissociation into $XN(^3\Sigma^-)$ and $N_2(^1\Sigma_g^+)$ [Eq. (h)]. The decomposition of solid

$$XN_3(^1A') \longrightarrow N_2(^1\Sigma_g^+) + XN(^3\Sigma^-) + \Delta H_h \quad (h)$$

IN_3 is much more complicated and not yet completely understood. Even though the gas phase decomposition reaction according to Equation (h) is spin-forbidden, pyrolysis experiments on HN_3 in the temperature range 285–470 °C have clearly shown that this species fragments into HN and N_2.[46] (See reference [13] regarding the gas phase pyrolysis of $NC-N_3$ and organic azides.) The occurrence of this singlet–triplet coupling during the HN_3 fragmentation has been the subject of extensive quantum chemical calculations at a very high level.[47]

The calculated values for ΔH_h (Table 3) of the halogen azides indicate that, in the gas phase, FN_3 should be least stable and IN_3 most stable. This is in agreement with experimental observations. In addition, the calculated dissociation enthalpy ΔH_h for HN_3 (Table 3) is in very good agreement with the experimental values of 15.0 kcal mol^{-1} [48] and 17.5 kcal mol^{-1}.[49] The dissociation according to Equation (h) is exothermic for FN_3, ClN_3, and BrN_3, and mildly endothermic for IN_3. However, the reaction enthalpies at room temperature ΔH_i, calculated for Equation (i), indicate that all halogen azides possess a large

$$2\,XN_3 \longrightarrow 3\,N_2 + X_2 + \Delta H_i \quad (i)$$

positive enthalpy of formation (Table 3). These two sets of data readily explain the extreme instability of all halogen azides on the one hand, and the slight, but clearly apparent kinetic stability of IN_3 on the other.[14] As was only recently shown experimentally, the dissociation barrier (to XN and N_2) is indeed larger for chlorine azide than for fluorine azide.[50]

The thermodynamic stability of the very labile *N*-oxides ON–N_3 (nitrosyl azide) and O_2N–N_3 (nitryl azide) [Eq. (j) and (k), respectively] has also been the subject of ab initio studies. The dissociation of N_4O into N_2O and N_2 was predicted to be very exothermic ($\Delta H_j^0 = -91$ kcal mol^{-1}).[18] N_4O_2, which so far has only been detected in solutions, also dissociates into the thermodynamically more stable N_2O ($\Delta H_k^0 = -57$ kcal mol^{-1}).[19]

$$ON-N_3 \longrightarrow N_2O + N_2 \quad (j)$$

$$O_2N-N_3 \longrightarrow 2\,N_2O \quad (k)$$

Experimentally it is possible to stabilize halogen azides, particularly iodine azide, through the formation of species that are more highly coordinated. The reaction of IN_3 with numerous nitrogen bases such as pyridine and α,α'-bipyridyl leads to the formation of stable donor–acceptor complexes, in which the nitrogen base is coordinated to the positively polarized iodine atom of IN_3.[51] This distinct polarization of the N–I bond also causes IN_3 to act as a Lewis acid towards halogenide or pseudohalogenide ions. IN_3 reacts with $NMe_4^+N_3^-$ to give the extremely explosive compound $NMe_4^+I(N_3)_2^-$.[52] The analogous species $PPh_4^+I(N_3)_2^-$, however, is not explosive.[52] Interestingly, in addition to the $I(N_3)_2^-$ anion, which, according to the pseudohalogen concept, corresponds to ICl_2^-, the ICl_2^+ analogue, namely the $I(N_3)_2^+$ cation has recently been prepared (see Section 4).[17]

Tetraazidoarsoniumhexafluoroarsenate, $As(N_3)_4^+AsF_6^-$, which can be handled well in SO_2 solutions, is very sensitive in the solid state and detonates upon exposure to mechanical stress or a high frequency discharge. Using a Born–Haber cycle, the reaction enthalpy of the decomposition according to Equation (l) was estimated to be $\Delta H_l = -406$ kcal mol^{-1}.[28]

$$[As(N_3)_4]AsF_6(s) \xrightarrow{\Delta H = -406\ \text{kcal mol}^{-1}} 2\,AsF_3(l) + 6\,N_2(g) \quad (l)$$

4. Structure and Bonding

In contrast to the ionic azides of the type $A^+N_3^-$ (A = metal, NH_4),[1a–i, 53] which all contain a linear N_3 unit of $D_{\infty h}$ symmetry, covalent azides present as discrete XN_3 species in the gas phase (X = H, halogen, etc.) display a bent *trans* C_s configuration with a N-N-N bond angle of approximately $172 \pm 3°$, and two significantly different N–N bond lengths (Fig. 3).[14]

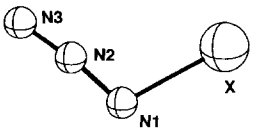

Fig. 3. Depiction of a covalent XN_3 azide in the bent *trans* C_s conformation.

Table 4 contains a summary of experimentally obtained and quantum mechanically calculated structural parameters for XN_3 azides. They show clearly the excellent agreement between the experimental data and those that were quantum mechanically calculated. It was necessary, however, to account for electron correlation (e.g., according to Møller-Plesset)[44] in order to obtain good correlation between the theoretical results and the experimental findings.[14] In addition, it proved to be very helpful to introduce quasirelativistic pseudopotentials for the heavy halogens bromine and iodine to account for relativistic effects. For instance, calculations utilizing an effective core potential often led to better results in less time than all-electron calculations.[54, 55]

What additional information can be gleaned from these MO calculations? The bent N_3 unit in covalent XN_3 azides and the different N–N bond lengths are particularly noteworthy. One of these bonds (N1–N2) is significantly shorter than a typical N–N single bond (1.44 Å), while the other (N2–N3) is slightly longer than the N≡N triple bond in N_2 (1.098 Å).[56] A localized orbital description[57] of the covalent XN_3 azides (X = H, F, Cl, Br, I, NO, NO_2) results in an NBO (natural bond orbital) analysis[57] that yields the configuration shown in Figure 4 as the energetically most favorable Lewis structure. According to this, there is a single bond between N1 and N2 and a triple bond between N2 and N3.

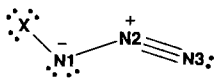

Fig. 4. Lewis structure of covalent XN_3 azides (NBO analysis).

The total energy $E = E(\text{Lewis}) + E(\text{non-Lewis})$ deviates in general only very little from E(Lewis) (most often E(non-Lewis) $< 1\%$ E(Lewis)). Therefore NBOs are well suited to describe the covalent effects in a molecule in accordance with its

Table 4. Structural parameters of covalent XN_3 azides (for atom numbering scheme see Fig. 3): experimental and ab initio data [10, 14, 43].

"natural" Lewis structure. It is best to allow for the non-covalent effects which are ignored in the Lewis structure by a second-order perturbation calculation. The most important non-covalent contributions in the XN_3 system are the π-delocalization over the entire molecule (resonance) on the one hand and a strong intramolecular donor–acceptor interaction on the other. This interaction leads to the transfer of electron density from the filled (X–N1)-σ orbital into the unfilled, antibonding (N2–N3)-π^* orbital, which weakens the X–N1 and N2–N3 bonds, while it strengthens the N1–N2 bond. Table 5 lists linear NLMO (natural localized molecular orbital) bond orders for some XN_3 azides, which were obtained by allowing for noncovalent effects in the NBO analysis.[58] In addition, it is noteworthy that the total bond order (ΣBO) at the central N atom of the N_3 moiety is significantly greater than three in all cases.

Table 5. Linear NLMO bond orders (BO) and overall bond orders (ΣBO) in discrete covalent XN_3 azides (NBO analysis) [a].

[a] HF/6-31 + G*, for Cl, Br, I: ECP, basis set: [5s5p1d]/(3s3p1d) – (DZ + P) [59].

Among the halogen azides ClN_3 has by far the highest X–N1 bond order of 0.90 (Table 5). This is in agreement with the pseudohalogen concept, according to which the azide group has an electronegativity comparable to chlorine, which implies that the pseudohalogen-halogen compound ClN_3 is best compared to Cl_2.[7b] The fact that the stretching frequencies for both compounds are similar ($\tilde{\nu}$(Cl–Cl) = 546, $\tilde{\nu}$(Cl–N_3) = 542 cm^{-1})[7b] is also in agreement with the pseudohalogen theory. The rather high bond orders in the ON–N_3 and O_2N–N_3 bonds in the covalent nitrosyl and nitryl azides are also noteworthy,[18, 19, 29] and in order to take the covalent character of these compounds into account, it might be more useful to term them "tetranitrogen oxide" or "tetranitrogen dioxide".

A comparison of the linear X–N1 bond orders (Table 5) clearly shows the expected weak covalent bonds in the strongly polarized species HN_3, FN_3, and IN_3. A summary of calculated NPA (natural population analysis) charges is given in Table 6.

Table 6. NPA charges δ in covalent XN_3 azides [a].

The experimentally observable weakness of the I–N bond in IN_3 [14, 36] and in inorganic N–I species in general[60] has been ascribed in early, more qualitative discussions to the strong polarity of this bond. The theoretical findings presented here confirm this view from a quantum mechanical basis.

The crystal structure analysis of IN_3 gave a surprising result that is so far unique among the halogen azides. Solid iodine azide is polymeric and present in the form of zigzag chains, with iodine atoms that are doubly coordinated in a linear fashion (Fig. 5).[9] It was also possible to synthesize the doubly coordinated ions $I(N_3)_2^+$[17] and $I(N_3)_2^-$[52] on a preparative scale. In agreement with the VSEPR theory, the coordination mode at the central iodine atom is bent (cation) and linear (anion, which is isoelectronic to the hypothetical $Xe(N_3)_2$), respectively.[61] It is noteworthy that the linear bond order of the I–N bond increases significantly from 0.67 for discrete IN_3 to 0.80 for the $I(N_3)_2^+$ cation (Table 5). Apparently iodine in binary N–I species favors higher coordination numbers, and forms more covalent N–I bonds. The structures of binary bromine–nitrogen compounds are unexplored with the exception of gaseous BrN_3.[8] The determination of the structure of solid bromine azide will be a substantial future challenge.

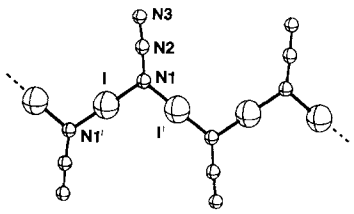

Fig. 5. Polymeric structure of iodine azide in the crystal (for structural parameters see Table 4) [9].

A comparison of the structures of the formally analogous cations $H_2N_3^+$[3] and $I_2N_3^+$[16] (Fig. 6) shows that according to

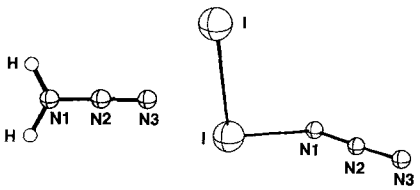

Fig. 6. Structures of the cations $H_2N_3^+$ (left, C_{2v}) and $I_2N_3^+$ (C_s).

the results of an X-ray crystal structure analysis, $H_2N_3^+$ displays C_{2v} symmetry in the crystal (SbF_6^- salt), while the $I_2N_3^+$ cation (in $I_2N_3^+EF_6^-$, E = As, Sb) has a chainlike planar C_s structure, as determined by Raman spectroscopy. This latter result is in agreement with ab inito calculations for which electron correlation was taken into account, which indicated that this C_s structure is only 2 kcal mol^{-1} lower in energy than the C_{2v} conformation, which was not observed experimentally. The two different structures for $H_2N_3^+$ and $I_2N_3^+$ are in accordance with the pseudohalogen concept, in which HN_3 is analogous to HCl, while IN_3 is more closely related to ICl. A comparison of the known structures of H_2Cl^+ (C_{2v}) and I_2Cl^+ (C_s) supports the analogy between $I_2N_3^+$ and I_2Cl^+. In both cases, like in all interhalogen species, the larger halogen occupies the central position.[62]

The structures discussed for the ions $I(N_3)_2^+$[17] and $I(N_3)_2^-$[52] also correspond with those expected by pseudo-

halogen theory and VSEPR theory:[61] $I(N_3)_2^+$ as AX_2E_2 type, bent at the central iodine; $I(N_3)_2^-$ as AX_2E_3 type, with linear coordination at the central iodine (Fig. 7).

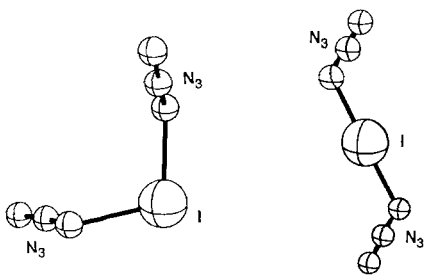

Fig. 7. Structures of the ions $I(N_3)_2^+$ (C_2) and $I(N_3)_2^-$ (C_2).

Even though the chemistry of the N_3 group can frequently be explained by using the pseudohalogen concept, it has not been possible to date to observe the species analogous to Cl_2, namely N_3-N_3. It is likely, however, that such a molecule would be in no way kinetically stabilized. High level quantum mechanical calculations have indicated that the most stable N_6 isomer should possess a twisted chainlike C_2 structure, which lies 188 kcal mol^{-1} above the energy of three N_2 molecules.[63] In contrast to benzene, cyclic hexazine, N_6, should assume a nonplanar twist-boat structure (D_2), which lies 26 kcal mol^{-1} above the energy of the C_2 chain structure.[63]

Suitable correlations of experimental and quantum mechanical molecular data together with calculations of energy hypersurfaces make it possible to estimate the structures of short-lived molecules that cannot be isolated on the preparative scale.[64] Every defined molecular state possesses a certain structure, and changes in its energy or charge distribution cause structural changes that occur through the molecule's specific molecular dynamics. The decomposition of the unstable nitrosyl azide, N_4O, will be used as an example.

N_4O was shown, on the basis of Raman spectroscopy, to have an open-chain C_s structure with a *trans-trans* arrangement at N1–N4 and N1–N2 (Fig. 8, left).[18] This compound has therefore two possible modes of unimolecular decay.[65] On the one hand, rotation around the N1–N4 axis can lead to the *cis-cis* isomer (Figs. 8 right, and 9), which then decomposes, according to the hypersurface shown in Figure 10, via cyclic N_4O into N_2O and N_2. On the other hand, the *trans-trans* isomer can also fragment directly by a change in the N1–N2 distance (Fig. 11). The rotation into the *cis-cis* isomer, however, has a calculated

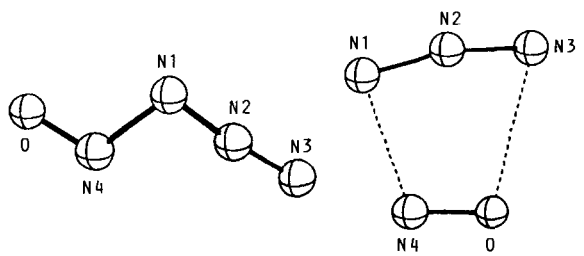

Fig. 8. Structures of nitrosyl azide, N_4O, in the *trans-trans* and *cis-cis* configurations, optimized at the MP2 level.

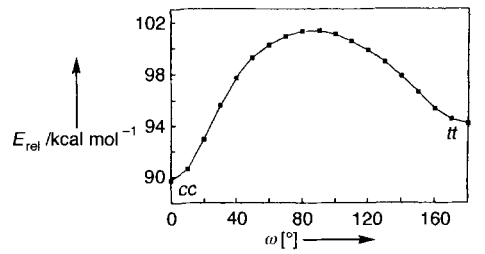

Fig. 9. Rotational barrier for the *cis-cis*/*trans-trans* isomerization of N_4O, calculated at the MP2 level. ω = O-N4-N1-N2 dihedral angle.

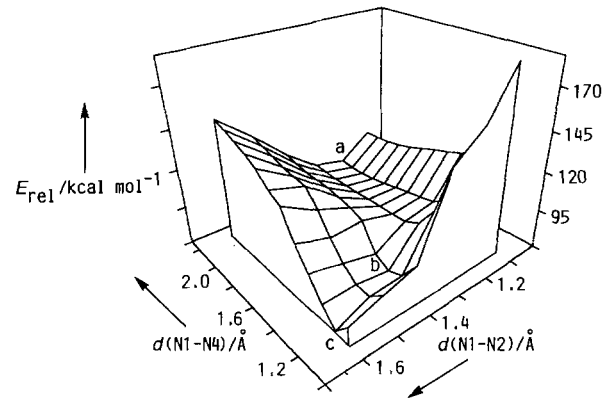

Fig. 10. Two-dimensional MP2 energy hypersurface for the decomposition of *cis-cis* N_4O; a: *cis-cis* N_4O, b: cyclic N_4O (C_{2v}), c: N_2O ($C_{\infty v}$) + N_2.

barrier of 7 kcal mol^{-1} (Fig. 9), while the transition state for the N1–N2 variation lies 24 kcal mol^{-1} in energy above the *trans-trans* isomer. This indicates that a unimolecular fragmentation into N_2O and N_2 is more likely to occur via *cis-cis* N_4O and cyclic N_4O. The calculated potential energy curve for the decomposition without the rotation (Fig. 11) shows that *trans-trans* N_4O does not lead to linear N_2O ($C_{\infty v}$), but rather to cyclic N_2O (C_{2v}). The hypersurface depicted in Figure 11 shows three minima: *trans-trans* N_4O, $C_{\infty v}$-N_2O + N_2, and C_{2v}-N_2O + N_2. Hence *trans-trans* N_4O can decompose not only by the pathway initiated by the rotation into the *cis-cis* isomer, but also by two additional pathways. Interestingly the transition

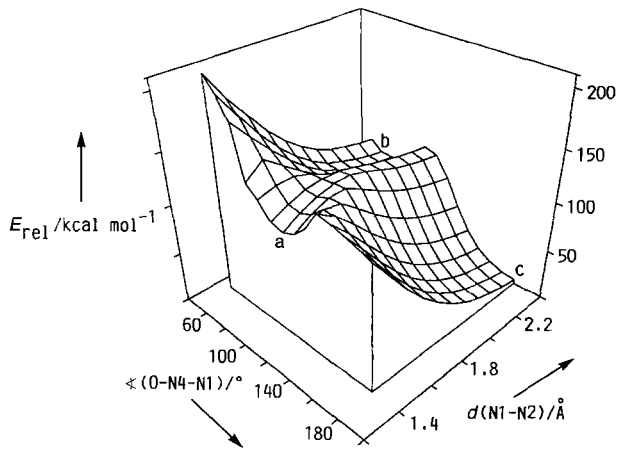

Fig. 11. Two-dimensional MP2 energy hypersurface for the decomposition of *trans-trans* N_4O; a: *trans-trans* N_4O, b: cyclic N_4O (C_{2v}) + N_2, c: N_2O ($C_{\infty v}$) + N_2.

state leading to cyclic N_2O (C_{2v}) is 2 kcal mol^{-1} lower in energy than that for the direct conversion into linear N_2O ($C_{\infty v}$) and N_2. (Quite recently the unimolecular decay of N_4O has been studied on the basis of qualitative increased valence bond representations[65b]).

At this point it appears appropriate to mention the results of pyrolysis experiments with azides in the gas phase.[13] These studies demonstrated that experimental investigations of reactive intermediates are not only of interest for the discovery of new compounds and the development of new synthetic methods. Moreover, it was possible to describe some aspects of the "microscopic" course of azide pyrolyses in a satisfactory way using calculated energy hypersurfaces, which allowed the first more detailed insight into the deceptively simple azide decomposition reaction.

The unimolecular decomposition of nitrosyl azide to N_2 and N_2O also appears to be very simple on the "macroscopic" level. Quantum chemical calculations of the energy hypersurfaces corresponding to the decomposition of N_4O (Figs. 10 and 11), however, do not only confirm the experimental finding of the formation of N_2 and N_2O, but also indicate that this fragmentation occurs in a much more complex manner. The formation of cyclic *N*-oxides as reactive intermediates appears certain. To our knowledge, such compounds have not yet been observed experimentally, therefore the results presented here might encourage more intensive efforts to prove the existence of these species experimentally by the methods of modern gas-phase analytical chemistry.

Furthermore, all molecular nitrogen oxides have a positive enthalpy of formation.[66] Consequently, N_2O_4 and mixtures of NO/N_2O_4 and NO_2/HNO_3 are already in use as environmentally safe (i.e., halogen-free) oxidizing agents in rocket engines, mostly in combination with methylhydrazine as fuel.[67a] There are extensive discussions about the use of extremely unstable *N*-oxides such as N_4O and N_4O_2 (which would be prepared in situ) as one-component fuels for the generation of hypersonic wind tunnels.[67b] Hence knowledge of the molecular decomposition of these unstable *N*-oxides (nitrosyl and nitryl azides) is not only of academic interest, but also of fundamental, if rather specific, interest to applied science.

5. Reactivity

It is not our intention to present a summary of the reactivity of covalent azides that could claim to be complete. This reactivity is extremely multifaceted, particularly in organic synthesis, but also in main group chemistry. Using a few selected examples from inorganic chemistry—with an emphasis on those that maintain the structural integrity of the azide moiety—we will present a glimpse of the chemistry of covalent azides.

The protonation of covalent azides is well known and much studied. The example of the protonated form of hydrazoic acid, $H_2N_3^+$, has already been discussed in Section 4.[13, 68] It can be prepared in superacidic media at low temperatures according to Equation (m). In contrast to many other compounds containing a covalent azide group, $H_2N_3^+SbF_6^-$ is not explosive.

$$HN_3 + SbF_5 + HF \longrightarrow H_2N_3^+SbF_6^- \quad \text{(m)}$$

It has already been discussed in Section 3 that IN_3 forms stable donor–acceptor complexes with many N-bases, including N_3^- [Eq. (n)]. This leads to a stabilization due to the higher

$$IN_3 + N_3^- \longrightarrow I(N_3)_2^- \quad \text{(n)}$$

coordination number (2) at the central iodine atom.[51, 52] During the formal addition of iodide to give $I_2N_3^-$, IN_3 also acts as a Lewis acid [Eq. (o)].[36c, 52a] Analogously, the reaction of IN_3

$$IN_3 + NMe_4^+ I^- \longrightarrow NMe_4^+ I_2N_3^- \quad \text{(o)}$$

with cyanide ions leads to the anion $[N_3I{-}C{\equiv}N{-}I{-}N_3]^-$. This species is assumed to contain a linear NICNIN unit with a bridging cyanide group.[36c, 52a]

Further anions of the type $[X{-}I{-}N_3]^-$ (X = F, Cl, Br, OCN, CN) have been described.[36b] Iodine azide can also react as a base, that is, it is amphoteric in the Lewis sense. This is best demonstrated by the reaction of IN_3 with "I^+" [Eq. (p)][16] and by the formation of the cation $I(N_3)_2^+$ [Eq. (q)][17] (for structures see Section 4).

$$IN_3 + \text{"}I^+\text{"} \xrightarrow{SO_2} I_2N_3^+ \quad \text{(p)}$$
$$(\text{"}I^+\text{"}: 1/2\, I_2 + 3/2\, AsF_5 \longrightarrow \text{"}I^+AsF_6^-\text{"} + 1/2\, AsF_3)$$

$$ICl_2^+ + 2\, AgN_3 \xrightarrow{SO_2} I(N_3)_2^+ + 2\, AgCl \quad \text{(q)}$$

In aqueous media, particularly in the presence of OH^- ions, halogen azides XN_3 (X = Cl, Br, I) hydrolyze in accordance to their bond polarity, that is, the halogen is positively polarized (see Section 4) [Eq. (r)].[36a] Iodine azide, in particular, owes its

$$XN_3 + 2\, OH^- \longrightarrow N_3^- + XO^- + H_2O \quad \text{(r)}$$

extreme reactivity in spite of the relatively high stability of the molecule (see Section 4) to the high polarity of the N–I bond. The iodine atom has acceptor as well as donor properties; the α-N atom (N1) of the N_3 group possesses primarily donor properties.[36c] Due to its significantly higher polarity and the resulting increased reactivity, IN_3 reacts much faster than ClN_3 with metal iodides and metal halogenides in general; an example is the substitution reaction of iodides of Group 13 elements [Eq. (s), E = B, Al, Ga].[36]

$$EI_3 + IN_3 \xrightarrow{\text{benzene}} I_2EN_3 + I_2 \quad \text{(s)}$$

IN_3 has proven useful in organic synthesis for the addition to olefinic double bonds. It was possible to demonstrate that the tendency to homolytic cleavage increases, as expected, in the order $IN_3 < BrN_3 < ClN_3$.[36c, 69] Equations (t) and (u) (R = Me, Ph) show examples of oxidative additions with iodine azide from the areas of purely inorganic chemistry and organometallic chemistry of the elements, respectively.[36]

$$2\, SnCl_2 + 2\, IN_3 \longrightarrow SnCl_2(N_3)_2 + \text{"}SnCl_2I_2\text{"} \quad \text{(t)}$$

$$R_3Sb + IN_3 \longrightarrow R_3SbI(N_3) \quad \text{(u)}$$

There are recent reports about the successful stepwise synthesis of di- and triphosphazenes using the Staudinger reaction and starting with $(CF_3)_2PN_3$ [Eqs. (v) and (w)].[70]

$$(CF_3)_2PI + NaN_3 \longrightarrow (CF_3)_2PN_3 + NaI \quad (v)$$

$$(CF_3)_2PN_3 \xrightarrow{PPh_3,\ -N_2} Ph_3P{=}N{-}P(CF_3)_2 \xrightarrow{(CF_3)_2PN_3,\ -N_2} Ph_3P{=}N{-}P(CF_3)_2{=}N{-}P(CF_3)_2 \quad (w)$$

Covalent triorgano-substituted azides of Group 14 elements have found the greatest preparative application [see also Eq. (f)]. Trimethylsilyl azide, Me_3SiN_3, for instance, has been successfully used by Kurt Dehnicke and others as nitrogen atom donor in the chemistry of sulfur and selenium.[71] In this way the preparation of many new Se–N compounds became possible, for example the neutral species Se_2NCl_3 as well as the cations $(SeCl)_2N^+$ and $(SeCl_2)_2N^+$. Recently, the synthesis of the novel compound $Se_3N_2Cl_2$ was performed, but this species has not yet been structurally characterized [Eq. (x)].[72] Certainly the most

$$3\,Se_2Cl_2 + 2\,Me_3SiN_3 \xrightarrow{CH_2Cl_2} 2\,Se_3N_2Cl_2 + 2\,Me_3SiCl + N_2 \quad (x)$$

spectacular success for the use of Me_3SiN_3 in the area of nonmetal chemistry has been the safe synthesis of polymeric sulfur nitride $(SN)_x$ [Eq. (y)], which up to now had been prepared by using the explosive compound S_4N_4.[73]

$$3\,Me_3SiN_3 + (NSCl)_3 \xrightarrow{MeCN,\ -15\,^\circ C} 3/x(SN)_x + 3\,Me_3SiCl + 9/2\,N_2 \quad (y)$$

The reaction of mesityl azide with bis[2,4,6-tris(trifluoromethyl)phenyl]stannylene, with subsequent elimination of N_2, permitted the preparation of azadistanniridines in good yields [Eq. (z), R* = 2,4,6-$(CF_3)_3C_6H_2$, Mes = mesityl].[74]

$$2\,R^*_2Sn + MesN_3 \longrightarrow R^*_2Sn\text{-}N(Mes)\text{-}SnR^*_2 + N_2 \quad (z)$$

The azide reaction known in organic chemistry can also be applied to the chemistry of phosphorus. For example, the reaction of cyclic alkyldithiophosphonic acid anhydrides with Me_3SiN_3 leads to quantitative yields of N-containing P–S heterocycles.[75] An example from organometallic chemistry is the reaction of Me_3SiN_3 with $R_2Al{-}AlR_2$, which leads to the formation of novel Al–N heterocycles. Depending on the reaction conditions, the azide moiety can be retained intact as a building block for the ring structure in these compounds.[76] In 1990 it was shown that sulfur azides such as $MeSO_2N_3$ can be successfully employed in the 1,3-dipolar cycloadditions of electrophilic azides to 5-alkylidenedihydrotetrazoles.[77] For some time, stannyl azides of the type R_3SnN_3 have found use in organic synthesis.[78]

6. Summary and Outlook

Covalent binary nonmetal azides, as we have exemplified with hydrazoic acid and the halogen azides, have been known for over 100 years, while the isolation on a preparative scale and the complete determination of the structures of these highly explosive species has only been feasible in the last few years. With the aid of high-level, ab initio calculations (taking into account electron correlation) it was possible for the first time to obtain theoretical insight into unusual, experimentally observable structural characteristics of covalent azides in general and halogen azides in particular. The excellent agreement between experiment (electron diffraction, microwave studies) and theory (ab initio) with respect to structural parameters gives credence to those calculated structures for which there are no experimental data due to the extreme lability of the compounds in question, for instance the novel *N*-oxides ONN_3 and O_2NN_3.

Why are we so strongly interested in the preparation of a class of compounds such as the covalent azides that need to be handled with such extreme care and precautions? We wish to demonstrate that even, and particularly, in the area of the main group chemistry of very simple binary compounds there are still many unanswered questions with regard to structure and bonding. There are also many new compounds in this area that are waiting to be synthesized on a preparative scale.

Now that questions about structure and bonding in covalent XN_3 azides appear to be answered to a certain extent, we wish to pay particular attention in the future to comparative discussions of gas-phase and solid-state structures and to the underlying questions of bonding. Until now the pair $IN_3(g)/[IN_3]_x(s)$ remains a singular result. Therefore the experimental determination of further structures of covalent azides, especially in the solid state, is necessary. In addition, the quantum mechanical description of the molecular structures of polymeric covalent species in the solid state, which up to now is unsatisfactory, must be improved. Many of the azides listed in Table 1 have been described in the literature, but in many cases the structural characterization has been incomplete or not performed at all. For instance, how does $tBu_2N{-}N_3$ crystallize? We will face up to these challenges in the future.

We thank our co-workers for their cooperation, especially Dr. Axel Schulz for performing numerous quantum chemical calculations. We are indebted to Prof. Dr. Paul von R. Schleyer, Dr. Peter Buzek, and Prof. Dr. Wolfram Koch, Erlangen, for intensive support which enabled us to perform independent calculations in our research group. Dr. Peter S. White is acknowledged for the collaboration in the area of X-ray crystal structure analyses (NATO, CRG 920034), Prof. Dr. István Hargittai and his co-workers are acknowledged for performing the electron diffraction experiments (partnership TU Berlin/TU Budapest). The experimental work in Berlin was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Bundesministerium für Bildung und Wissenschaft (Graduiertenkolleg). We thank both referees for many critical and stimulating comments.

Chemical Engineering Dynamics

Modelling with PC Simulation

1994. XX, 701 pages with 430 figures.
Hardcover. DM 276.-/ öS 2153.-/ sFr. 256.-.
ISBN 3-527-28577-6

In this book, the reader is guided through the complex study of dynamic chemical engineering systems by the unique combination of a simplified presentation of the fundamental theory (Part 1) and direct hands-on computer experimentation with the provision of 85 accompanying computer-based simulation examples (Part 2) supplied on diskette.

The ISIM digital simulation language is very simple to use and its powerful interactive nature enables the readers to create their own simulations, based on their own specific problems. This powerful dynamic ISIM software is ready to run on any DOS personal computer.

The treatment employed in this book is well tried and tested, based on over 20 years experience in teaching an international post-experience course. Whether for the teacher, the student, the chemist or engineer, this book serves as the key to a greater understanding of chemical engineering dynamics through the fun and enjoyment of active learning.

Enzymes in Organic Synthesis: Application to the Problems of Carbohydrate Recognition (Part 2)**

Chi-Huey Wong,* Randall L. Halcomb, Yoshitaka Ichikawa, and Tetsuya Kajimoto

Recognition of carbohydrates by proteins and nucleic acids is highly specific, but the dissociation constants are relatively high (generally in the mM to high μM range) because of the lack of hydrophobic groups in the carbohydrates. The high specificity of this weak binding often comes from many hydrogen bonds and the coordination of metal ions as bridge between sugars and receptors. Though weak hydrophobic interactions between sugars and proteins have also been identified, the unique shape of a complex carbohydrate under the influence of anomeric and *exo* anomeric effects (the glycosidic torsion angles are therefore often not flexible but are typically somewhat restricted) and the topographic orientation of the hydroxyl and charged groups contribute most significantly to the recognition process. Studies on the structure–function relationship of a complex carbohydrate therefore require deliberate manipulation of its shape and functional groups, and synthesis of oligosaccharide analogs from modified monosaccharides is often useful to address the problem. The availability of various monosaccharides and their analogs for the synthesis of complex carbohydrates together with the information resulting from structural studies (such a NMR or X-ray studies on sugar–protein complexes) will certainly provide a basic understanding of complex carbohydrate recognition. An ultimate goal is to develop simple and easy-to-make non-carbohydrate molecules that resemble the active structure involved in carbohydrate–receptor interaction or the transition-state of an enzyme-catalyzed transformation (for example, glycosidase or glycosyltransferase reactions) and have the approprite bioavailability to be used to control the carbohydrate function in a specific manner. In part one of this review we described various enzymatic approaches to the synthesis of monosaccharides, analogs, and related structures. We describe in this part enzymatic and chemoenzymatic approaches to the synthesis of oligosaccarides and analogs, including those involved in E-selectin recognition, and strategies to inhibit glycosidases and glycosyltransferases.

5. Enzymatic Glycosidic Bond Formation

Nature employs two groups of enzymes in the biosynthesis of oligosaccharides: the enzymes of the Leloir pathway[136] and those of non-Leloir pathways. The Leloir pathway enzymes are responsible for the synthesis of most N- and O-linked glycoproteins and other glycoconjugates in mammalian systems. N-linked oligosaccharides are characterized by a β-glycosidic linkage between a GlcNAc residue and the δ-amide nitrogen atom of an asparagine residue. The less common O-linked glycoproteins contain an α-glycosidic linkage between a GalNAc (or xylose) and the hydroxyl group of a serine or threonine residue. Both O- and N-linked glycoproteins are cotranslationally glycosylated in the endoplasmic reticulum and the Golgi apparatus.[11, 137] The biosynthesis of the N-linked type involves an initial synthesis of a dolichyl pyrophosphoryl oligosaccharide intermediate in the endoplasmic reticulum by the action of GlcNAc-transferases and mannosyltransferases. This structure is further glucosylated, and then the entire oligosaccharide moiety is transferred to an ASn residue of the growing peptide chain by the enzyme oligosaccharyltransferase.[137] The Asn is typically part of the amino acid sequence Asn-X-Ser(Thr), where X is not Pro or Asp.[137–141] Before transport into the Golgi apparatus, the glucose residues and some mannose residues are removed in a process called trimming by the action of glucosidase I and II and a mannosidase to reveal a core pentasaccharide (peptide-Asn-$(GlcNAc)_2$-$(Man)_3$). The resulting core structure is further processed by mannosidases and glycosyltransferases present in the Golgi apparatus to produce either the high-mannose type, the complex type, or the hybrid type oligosaccharides. saccharides are then added sequentially to this core structure to provide the fully elaborated oligosaccharide chain.

In contrast to the dolichyl pyrophosphate mediated synthesis of N-linked oligosaccharides, the glycosyltransferases necessary for the synthesis of O-linked oligosaccharides are located in the Golgi apparatus.[137] The biosynthetic route to the O-linked type is also different. Monosaccharide residues are added sequentially to the growing oligosaccharide chain.

All mammalian cells, with the exception of erythrocytes, contain the necessary elements for glycosylation. In certain secretory cells, however, the preponderance of transferases is greater.[142]

As glycosyl donors, the glycosyltransferases of the Leloir pathway in mammalian systems utilize monosaccharides which are activated as glycosyl esters of nucleoside mono- or diphosphates.[137] Non-Leloir transferases typically utilize glycosyl phosphates as activated donors. The Leloir glycosyltransferases employ primarily eight nucleoside mono- or diphosphate sugars as monosaccharide donors for the synthesis of most oligosaccharides: UDP-Glc, UDP-GlcNAc, UDP-Gal, UDP-GalNAc, GDP-Man, GDP-Fuc, UDP-GlcUA, and CMP-NeuAc. Many other monosaccharides, such as the anionic or sulfated sugars of heparin and chondroitin sulfate, are also found in mammalian systems, but they usually are a result of modification of a particular sugar after it is incorporated into an oligosaccharide structure. A very diverse array of monosaccharides (for example, xylose, arabinose, 3-deoxy-*manno*-octulosonate (KDO), deoxysugars) and oligisaccharides is also resent in microorganisms, plants, and invertebrates.[143, 144] The enzymes responsible for their biosynthesis, however, have not been extensively exploited for synthesis, though they follow the same principles as those in mammalian systems.

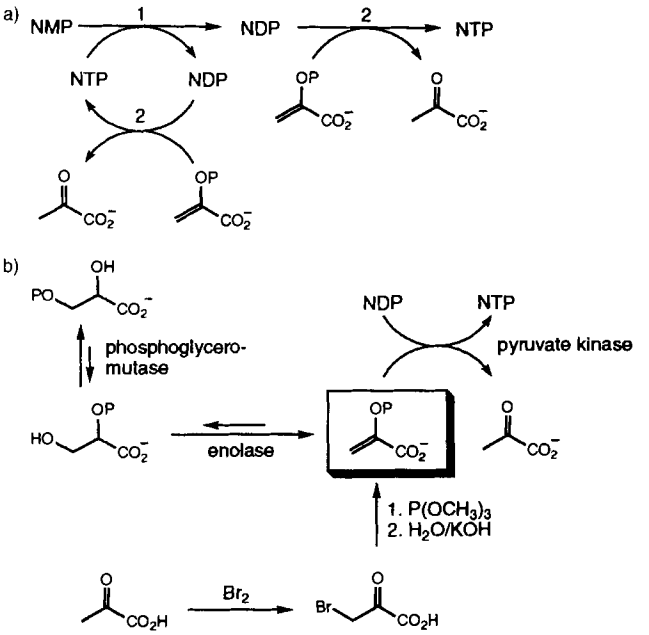
The glycosyltransferases from the Leloir and non-Leloir pathways as well as glycosidases[13] have been exploited for the synthesis of oligosaccharides and glycoconjugates.[14, 145, 146] The function of glycosidases in vivo is to cleave glycosidic bonds; however, under appropriate conditions they can be useful synthetic catalysts. Each group of enzymes has certain advantages and disadvantages for synthesis. Glycosyltransferases are highly specific in the formation of glycosides; however, the availability of many of the necessary transferases is limited. Fortunately, the recent advances in genetic engineering and recombinant techniques are rapidly alleviating these drawbacks. Glycosidases have the advantage of wider availability and lower cost, but they are not as specific or high-yielding in synthetic reactions. Several other enzymatic methods have also been used to synthesize N-glycosides, such as nucleosides.

5.1. Donor Substrates for Glycosyltransferases

Most of the sugar nucleoside phosphates used as substrates for glycosyltransferases[137] are biosynthesized in vivo from the corresponding monosaccharides. The initial step is a kinase-mediated phosphorylation to produce a glycosyl phosphate. This glycosyl phosphate then reacts with a nucleoside triphosphate (NTP), catalyzed by sugar nucleoside diphosphate pyrophosphorylase, to afford an activated sugar nucleoside diphosphate [Eq. (a)]. Other sugar nucleoside phosphates, such as GDP-Fuc and UDP-GlcUA, are biosynthesized by further enzymatic modification of these existing key sugar nucleoside phosphates. Another exception is CMP-NeuAc, which is formed by the direct reaction of NeuAc with CTP [Eq. (b)]. Some of the enzymes involved in the biosynthesis of sugar nucleotides also accept nonnatural sugars as substrates. In general, however, the rates are quite slow, thus limiting the usefulness of this approach.

$$\text{Sugar-1-}P + \text{NTP} \longrightarrow \text{NDP-Sugar} + PP_i \quad \text{(a)}$$

$$\text{NeuAc} + \text{CTP} \longrightarrow \text{CMPNeuAc} + PP_i \quad \text{(b)}$$



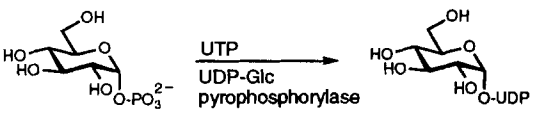
5.1.1. *Preparation of Nucleoside Triphosphates*

Chemical syntheses of some sugar nucleoside phosphates have been reported.[147] Most of these methods involve the reaction of an activated nucleoside monophosphate (NMP)[148–152] with a glycosyl phosphate to produce a sugar nucleoside diphosphate. Of the commonly used activated NMP derivatives, phosphoramidates such as phoshorimidazolidates[153–155] and phosphoromorpholidates[148–152] are considered the most effective. These activated NMPs may also be used to prepare NTPs by reaction with pyrophosphate.[155] A number of chemical methods are available for the synthesis of glycosyl phosphates. Reactions of phosphates with activated glycosyl donors[156] or chemical phosphorylation of anomeric hydroxyl groups[151–153, 157] have proven to be convenient. Additionally, routes via glycosyl phosphites are useful.[158] Enzymatic procedures are also available. Glycogen phosphorylase[159] and sucrose phosphorylase[160] were used to produce α-glucose-1-phosphate. Phosphoglucomutase can also be used to prepare glucose-1-phosphate from glucose-6-phosphate,[161] which is in turn synthesized from glucose by hexokinase.

The appropriate nucleoside triphosphates are utilized as substrates for the biosynthesis of sugar nucleoside phosphates. Biosynthesis-based enzymatic preparation of these donors for use in glycosylations therefore requires a synthesis of NTPs suitable for scale-up.

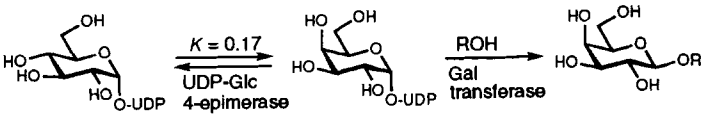
Most preparative-scale enzymatic syntheses of NTPs use commercially available NMPs as starting materials. Alternatively, all of the NMPs can be obtained from yeast RNA digests at low cost,[162] or can be easily prepared chemically. In general, these methods involve the sequential use of two kinases to transform NMPs to NTPs, via the corresponding nucleoside diphosphates (NDPs). Either of three kinases may be used to synthesize NTPs from the corresponding NDPs, each of which uses a different phosphoryl donor: pyruvate kinase [EC 2.7.1.40] uses phosphoenolpyruvate (PEP)[163, 164] as a phosphoryl donor, acetate kinase [EC 2.7.2.1] uses acetyl phosphate, and nucleoside-diphosphate kinase [EC 2.7.4.6] uses ATP. Pyruvate kinase is generally the enzyme of choice, because it is less expensive than nucleoside-diphosphate kinase,[155, 165] and because PEP is more stable and provides a more thermodynamically favorable driving force for phosphorylation than does acetyl phosphate (Scheme 34).

The preparation of NDPs from NMPs is more complicated and requires different enzymes for each NMP. Adenylate kinase [EC 2.7.4.3] phosphorylates AMP[155] and CMP,[166] and also slowly phosphorylates UMP. Guanylate kinase [EC 2.7.4.8] catalyzes the phosphorylation of GMP. Nucleoside-monophosphate



Scheme 34. a) Synthesis of nucleoside triphoshates (NTPs): 1. adenylate kinase ([EC 2.7.4.3], N = A, C, U), guanylate kinase ([EC 2.7.4.8], N = G), nucleoside monophosphate kinase ([EC 2.7.4.4], N = U); 2. pyruvate kinase [EC 2.7.1.40]. b) Synthesis of phosphoenol pyruvate (PEP).

kinase [EC 2.7.4.4] uses ATP to phosphorylate AMP, CMP, GMP, and UMP; however, the enzyme is relatively expensive and unstable.[155] Both CMP and UMP kinases exist but are not commercially available. If ATP is required as a phosphorylating agent, it is usually used in a catalytic amount and recycled from ADP with pyruvate kinase/PEP or acetate kinase/acetyl phosphate.[167] Phosphoenolpyruvate may be prepared chemically from pyruvate[163] or generated enzymatically from D-3-phosphoglyceric acid[164] (Scheme 34).

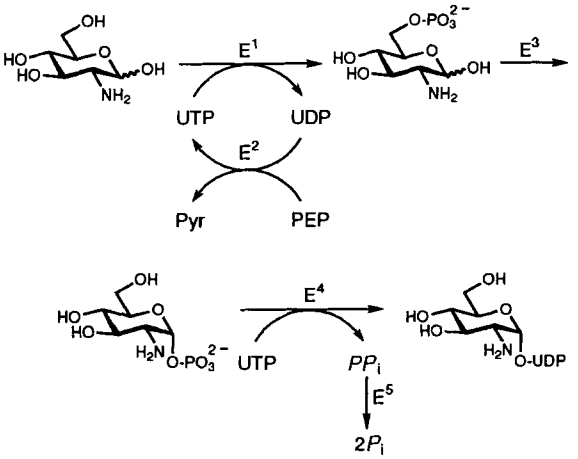


Comparisons of chemical and enzymatic methods for the synthesis of NTPs[155] lead to the conclusion that enzymatic methods provide the most convenient route to CTP and GTP. Chemical deamination of CTP is the best method for preparing UTP.[155] ATP is relatively inexpensive from commerical sources; nevertheless, it has also been synhesized enzymatically from AMP on a 50 mmol scale. Mixtures of NTPs can be prepared fromRNA by sequential reactions catalyzed by nuclease P1, polynucleotide phosphorylase, and pyruvate kinase.[168] This mixture can be selectively converted into a sugar nucleotide with a particular sugar nucleoside diphosphate pyrophosphorylase.[168]

5.1.2. UDP-Glucose (UDP-Glc) and UDP-Galactose (UDP-Gal)

UDP-Glucose has been prepared from UTP and glucose-1-phosphate under catalysis by UDP-glucose pyrophosphorylase (Scheme 35).[155, 161, 169] UDP-Gal can be synthesized in an analogous fashion with UDP-Gal pyrophosphorylase.[170] Additionally, UDP-Gal can be generated from UDP-Glc by epimerization of C-4 with UDP-glucose epimerase[161] (Scheme 36). Though the equilibrium for this reaction favors UD-Glc, it can be shifted by coupling the reaction to an in situ

Scheme 35. Synthesis of UDP-Glc.

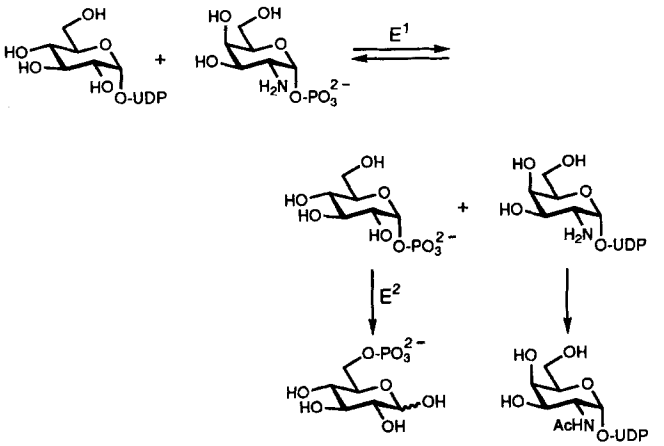


Scheme 36. Synthesis of UDP-Gal and its use in glycosylations.

glycosylation with galactosyltransferase. This concept has been applied to a large-scale synthesis of *N*-acetyllactosamine.[161] For gram amounts, UDP-Gal has been prepared from Gal-1-phosphate and UDP-Glc with UDP-Gal uridyltransferase,[172] followed *in situ* by glycosylation (see Section 5.2.8). Furthermore, UDP-Gal has been synthesized from UMP and Gal by means of dried cells of *Torulopsis candida*.[169] In this system, Gal-1-phosphate and UTP were generated *in situ* as substrates for UDP-Gal pyrophosphorylase. A recent chemical synthesis of UDP-2-deoxygalactose and its use in glycosylations has been recently reported.[173]

5.1.3. UDP-N-Acetylglucosamine (UDP-GlcNAc)

Two enzymatic methods have been developed for the synthesis of UDP-GlcNAc. The first involves a reaction between GlcNAc-1-phosphate and UTP, catalyzed by UDP-GlcNAc pyrophosphorylase.[169] UDP-GlcNAc pyrophosphorylase is currently not commercially available; to produce it, however, a whole-cell process using Baker's yeast can be employed. The enzyme from calf liver[170] can also be used in the synthesis. The second procedure exploits UDP-Glc pyrophosphorylase to catalyze a condensation between UTP and glucosamine-1-phosphate (GlcN-1-*P*) to afford UDP-glucosamine[172a] (Scheme 37). The product UDP-GlcN can then be selectively N-acetylated to provide UDP-

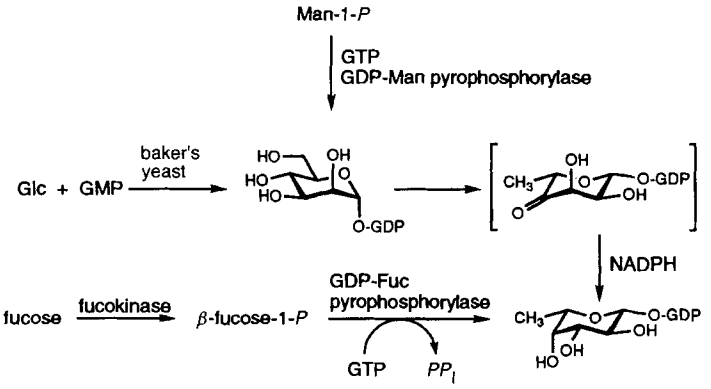


Scheme 37. Synthesis of UDP-GlcNAc. E^1 = hexokinase from yeast, E^2 = pyruvate kinase, E^3 = phosphoglucomutase, E^4 = UDP-Glc pyrophosphorylase, E^5 = inorganic pyrophosphatase, Pyr = pyruvate.

GlcNAc. GlcN-1-*P* was synthesized from GlcN by phosphorylation of the 6-position with hexokinase to give GlcN-6-*P*, followed by a phosphoglucomutase-catalyzed isomerization to provide GlcN-1-*P*. The second sequence can be performed in a hollow fiber reactor.[174]

5.1.4. UDP-N-Acetylgalactosamine (UDP-GalNAc)

UDP-GalNAc can be prepared from GalNAc-1-P and UTP with UDP-GalNAc pyrophosphorylase, or from UDP-GlcNAc with an epimerase; however, the necessary enzymes are not readily available. An alternative procedure has been reported that is based on a UMP exchange reaction between UDP-Glc and GalN-1-*P*, under catalysis by UDP-glucose: galactosylphosphate uridyltransferase [EC 2.7.7.12], which is commercially available (Scheme 38).[171, 175] Galactose-1-phosphate is



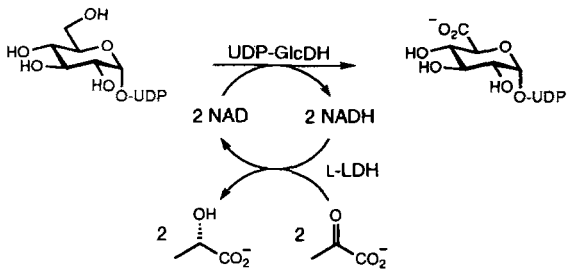
Scheme 38. Synthesis of UDP-GalNAc. E^1 = UDP-Glc: galactosylphosphate uridyltransferase, E^2: phosphoglucomutase.

the natural substrate for the enzyme, but 2-deoxygalactose-1-phosphate, 2-deoxyglucose-1-phosphate, and galactosamine-1-phosphate are also accepted. The equilibrium constant for the exchange reaction is about 1; phosphoglucomutase was therefore added to remove the product Glc-1-*P* and shift the equilibrium toward UDP-GalN. The UDP-GalN thus produced was acetylated with acetic anhydride in a subsequent step to give UDP-GalNAc.

A modification of the latter procedure has been adapted for a large-scale synthesis of UDP-GalNAc.[172b] In this procedure, galactosamine-1-phosphate was prepared with galactokinase coupled to an ATP regeneration system, and used as a substrate for the uridyltransferase. UDP-Glc was regenerated in situ from UTP and the product Glc-1-*P*, under catalysis by UDP-Glc pyrophosphorylase. This also shifts the equilibrium toward the formation of UDP-GalN. Finally, a chemical N-acetylation of the UDP-GalN thus produced with *N*-acetoxysuccinimide provides UDP-GalNAc. This procedure has also been adapted to an in situ synthesis of UDP-GalN for glycosylation, with cofactor regeneration, to provide β-glycosides of GalN (see Section 5.2.8).

5.1.5. GDP-Mannose (GDP-Man) and GDP-Fucose (GDP-Fuc)

GDP-Man has been prepared from Glc and GMP with dried Baker's yeast cells.[82] The procedure involves the biocatalytic conversion of glucose to Man-1-*P*, and a subsequent conversion to GDP-Man with GDP-Man pyrophosphorylase. A cell-free extract from Baker's yeast has also been used to synthesize GDP-Man from mannose.[176] A direct synthesis from chemically prepared Man-1-*P* and GTP, catalyzed by GDP-Man pyrophosphorylase [EC 2.7.7.13] is useful for a large scale (Scheme 39).[155]

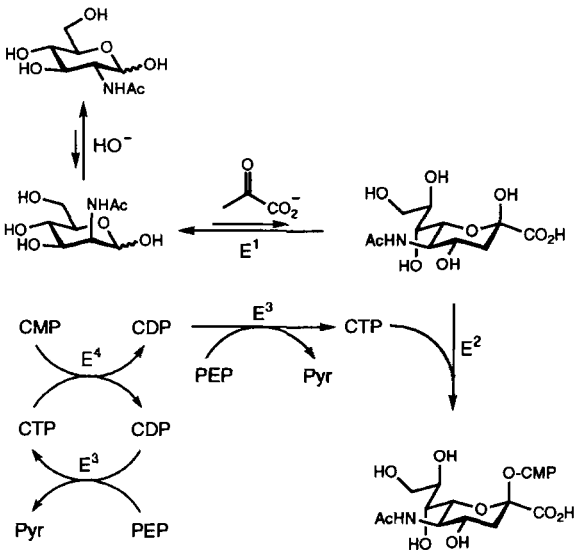


Scheme 39. Synthesis of GDP-Fuc.

GDP-fucose is biosynthesized in vivo from GDP-Man by an NADPH-dependent oxidoreductase enzyme system. Such systems have also been utilized for in vitro synthesis of GDP-Fuc. For example, the conversion of GDP-Man to GDP-Fuc was accomplished with a crude enzyme preparation from *Agrobacterium radiobacter*.[177] NADPH was regenerated in situ from NADP with glucose-6-phosphate dehydrogenase and Glc-6-*P*.[178] In a similar procedure, GDP-Fuc has been generated in situ for use in a glycosylation reaction with α1–3fucosyltransferase (see Section 5.2.3).[179] Enzymes from a minor biosynthetic pathway which synthesize GDP-Fuc from L-fucose-1-phosphate[179] or L-fucose[180] have also been exploited for synthesis.[179, 180] Fucose was phosphorylated by fucokinase [EC 2.7.1.52] to produce Fuc-1-*P*, which subsequently underwent a GDP-fucose pyrophosphorylase-catalyzed reaction with GTP to provide GDP-Fuc. Several practical chemical syntheses of GDP-Fuc have also been reported.[181]

5.1.6. UDP-Glucuronic Acid (UDP-GlcUA)

UDP-Glucuronic acid is biosynthesized by oxidation of UDP-Glc with UDP-Glc dehydrogenase, an NAD-dependent enzyme. Enzyme preparations from bovine liver have been employed for gram-scale syntheses of UDP-GlcUA (Scheme 40).[155, 182] The NAD cofactor was regenerated with lactate dehydrogenase in the presence of pyruvate. Additionally, extracts from guinea pig liver have been used to generate UDP-GlcUA in situ for use in enzymatic glycosylations with glucuronyltransferases.[138]



Scheme 40. Synthesis of UDP-GlcUA.

5.1.7. *CMP-N-Acetylneuraminic Acid (CMP-NeuAc)*

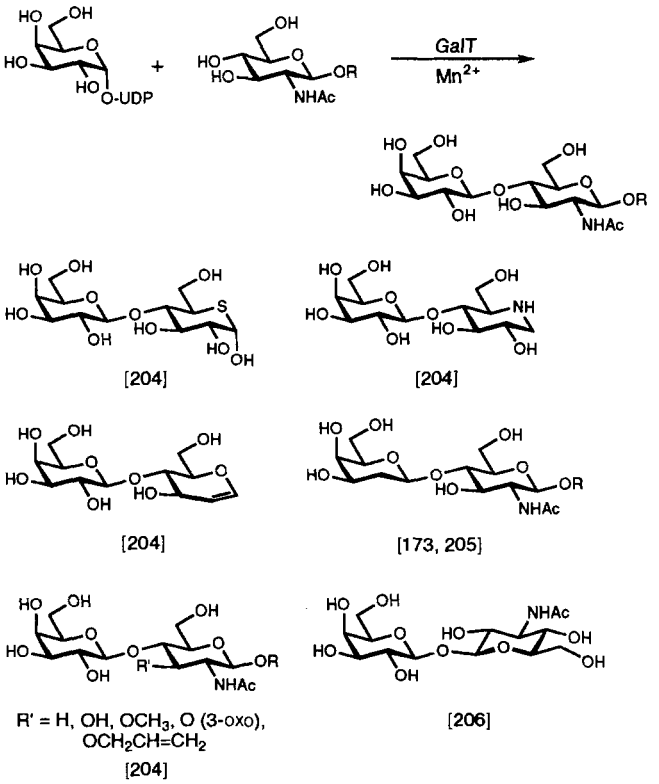
CMP-*N*-acetylneuraminic acid has been prepared enzymatically on small scales (less than 0.5 mmol) from CTP and NeuAc, under catalysis by CMP-NeuAc synthetase [EC 2.7.7.43].[184] An improvement in this procedure, which is suitable for multigram-scale synthesis,[185] has been developed: CTP is itself synthesized in situ from CMP with adenylate kinase and pyruvate kinase. Adenylate kinase catalyzes the equilibration of CTP and CMP to CDP, which is subsequently phosphorylated by pyruvate kinase to provide CTP. Another procedure has been employed in which the NeuAc used in the synthesis of CMP-NeuAc was prepared in a NeuAc aldolase-catalyzed reaction of pyruvate with *N*-acetylmannosamine, which was itself generated from *N*-acetylglucosamine by a base-catalyzed epimerization.[166] In a one-pot synthesis of CMP-NeuAc based on the latter procedure, NeuAc is prepared in situ from *N*-acetylmannosamine and pyruvate, catalyzed by sialic acid aldolase (Scheme 41).[186] Chemical syntheses of CMP-NeuAc have also been reported.[187–189]

The gene encoding *E. coli* CMP-NeuAc synthetase has been cloned[190, 191] and overexpressed in *E. coli* using λ-ZAP vector and the LacZ promotor[192, 193] or PKK223 vector-tac promotor.[194] The enzyme from calf brain has also been cloned and overexpressed. CMP-NeuAc synthetase was shown to accept

Scheme 41. Multienzymatic synthesis of CMP-NeuAc. E^1 = NeuAc aldolase, E^2: CMP-NeuAc synthetase, E^3: pyruvate kinase, E^4: adenylate kinase, Pyr = pyruvate.

several NeuAc derivatives as substrates. For example, 9-deoxy-7,9-dideoxy-, and 4,7,9-trideoxy-NeuAc are all converted into the corresponding CMP-NeuAc derivative.[195] On the other hand, neither the 4-oxo, 7-oxo, or 8-oxo derivatives of NeuAc, nor their dimethylacetals, are substrates for CMP-NeuAc synthetase.[196] The enzyme accepts a variety of modifications at the 9-position, and the hydroxyl group can be replaced with several different groups with little effect on the Michaelis constant K_m.[186, 197–199]

5.2. Substrate Specificity and Synthetic Applications of Glycosyltransferases



In general, for each sugar nucleotide glycosyl donor, many glycosyltransferases exist, each of which transfers the particular donor to different acceptors. These enzymes are generally considered to be specific for a given glycosyl donor and acceptor, as well as for the position and the configuration of the newly formed glycosidic bond. This specificity has led to the "one enzyme–one linkage" concept.[11] In other words, the specificity of the glycosyltransferases ensures fidelity in oligosaccharide sequences in vivo without the use of a template scheme. Though systematic investigations of the in vitro substrate specificity of most glycosyltransferases have not been carried out, some deviations from this picture of absolute specificity have been observed, both in the glycosyl donors and acceptors. Moreover, studies toward the design of inhibitors of glycoprotein biosynthesis[200] have also shown that the specificities of glycosyltransferases are not absolute.

5.2.1. *Galactosyltransferase (GalT)*

Because of its availability, β1–4-galactosyltransferase (UDP-Gal:N-acetylglucosamine β1–4-galactosyltransferase, [EC 2.4.1.22])[201, 202] is one of the most extensively studied mammalian glycosyltransferases with regard to synthesis and substrate specificity. This enzyme catalyzes the transfer of galactose from UDP-Gal to the 4-position of β-linked GlcNAc residues to produce the Galβ1–4GlcNAc substructure. In the presence of lactalbumin, however, glucose is the preferred acceptor, resulting in the formation of lactose, Galβ1–4Glc. The enzyme has been employed in the in vitro synthesis of *N*-acetyllactosamine and glycosides thereof, as well as other galactosides.

Galactosyltransferase utilizes as acceptor substrates *N*-acetylglucosamine and glucose and β-glycosides thereof, 2-deoxyglucose, D-xylose, 5-thioglucose, *N*-acetylmuramic acid, and *myo*-inositol.[201] Modifications at the 3- or 6-position of the acceptor GlcNAc are also tolerated. For example, Fucα1–6GlcNAc and NeuAcα2–6GlcNAc are substrates.[203] Acceptor substrates that are derivatized at the 3-position include 3-*O*-methyl-GlcNAc,[203] 3-deoxy-GlcNAc, 3-*O*-allyl-GlcNAcβOBu, and 3-oxo-GlcNAc.[204] All glycosides of GlcNAc that are substrates for the galactosyltransferase have β-glycosidic linkages. Both α- and β-glycosides of glucose are acceptable; however, the presence of lactalbumin is required for galactosyl transfer onto α-glcosides. Neither D-mannose, D-allose, D-galactose, D-ribose, nor D-xylose are substrates. Monosaccharides that have a negative charge, such as glucuronic acid and α-glucose-1-phosphate, are

also not accepted as substrates. Scheme 42 depicts several disaccharides that have been synthesized with galactosyltransferase.[173, 204–206] A particularly interesting example is the β,β-1,1-linked disaccharide, in which the anomeric hydroxyl of 3-acetamido-3-deoxyglucose serves as the acceptor moiety.[206b] The acetamido function apparently controls the position of glycosylation.

Scheme 42. Some disaccharides synthesized with β1–4galactosyltransferase.

β1–4Galactosyltransferase has also been employed in solid-phase oligosaccharide synthesis and has been used to galactosylate *gluco* or *cellobio* subunits of polymer-supported oligosaccharides and polysaccharides.[207] The resulting oligosaccharides can then be removed from the support by either a photochemical cleavage or a chymotrypsin-mediated hydrolysis. The types of polymer supports employed include polyacrylamide and a water-soluble poly(vinyl alcohol). *N*-Acetylglucosaminyl amino acids and peptides have also been used as substrates for galactosyltransferase to afford galactosylated glycopeptides.[205, 208] The carbohydrate chain can then be further extended with other transferases, such as sialyltransferase.[205, 208] Similarly, the synthesis of a ceramide glycoside, which was subsequently enzymatically sialylated, provided a G_{M_3} analog.[209]

As donor substrates, the β-galactosyltransferase also transfers glucose, 4- and 6-deoxygalactose, arabinose, glucosamine, galactosamine, *N*-acetylgalactosamine, 2-deoxygalactose, and 2-deoxyglucose from their UDP-derivatives to provide an enzymatic route to oligosaccharides that terminate in β-1,4-linked residues other than galactose (Table 5).[210–213] An example worthy of note is the transfer of 5-thiogalactose (entry 8).[212] Although the rate of the enzyme-catalyzed transfer of many of these nonnatural donor substrates is quite slow, this method is useful for milligram-scale synthesis. The α1–3-galactosyltransferase and α1–3GlcNAc transferase involved in the B and A blood-group antigens, respectively, have also been studied.[210b]

Table 5. Relative rates of β1–4galactosyltransferase-catalyzed transfer of donor substrates.

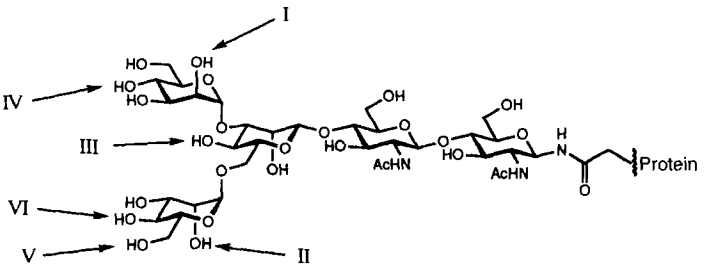
Donor substrates	k_{rel}	Ref.
UDP-Gal	100	[211a]
UDP-Glc	0.3	[210, 211a]
UDP-4-desoxy-Glc	5.5	[211a]
UDP-Ara	4.0, R = H 1.3, R = CH_3 0.2, R = CH_2F	[211a] [211b] [211b]
UDP-GalNAc	4.0	[210]
UDP-GlcNAc	0.00	[210]
UDP-GlcN	0.09	[210]
UDP-5-thio-Gal	5.0	[212]
UDP-2-desoxy-Gal	90	[173] [a], [205] [b]

[a] Generated in situ from 2-deoxygalactose with galactokinase/uridyltransferase [213]. [b] Generated in situ from 2-deoxyglucose with hexokinase/mutase/UDP-Glc pyrophosphatase/epimerase.

5.2.2. *Sialyltransferase (SiaT)*

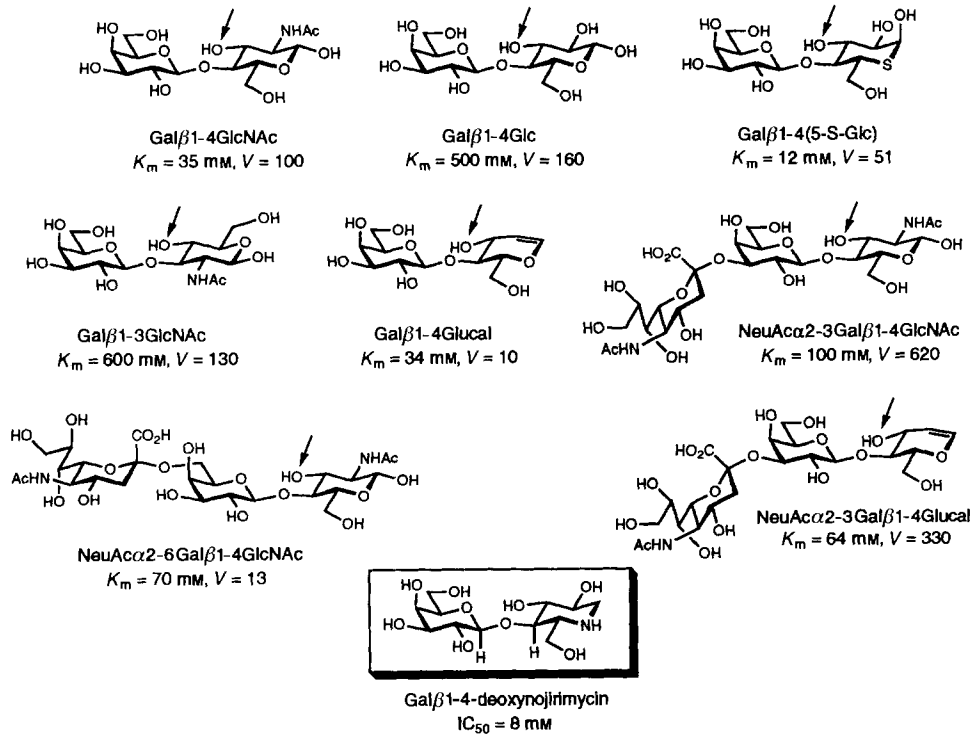
Several α2–6- and α2–3 sialyltransferases have been used for oligosaccharide synthesis.[214–216] These sialyltransferases generally transfer *N*-acetylneuraminic acid to either the 6- or 3-position of terminal Gal or GalNAc residues. The α2–8-sialyltransferase is involved in the synthesis of α-2,8-linked polysialic acids.[217] Some sialyltransferases have been shown to accept CMP-NeuAc analogs that are derivatized at the 9-position of the sialic acid side chain,[197–199, 218] such as those in which the hydroxyl group at C-9 is replaced with an amino, fluoro, azido, acetamido, or benzamido group. Analogs of the acceptors

Galβ1-4GlcNAc and Galβ1-3GalNAc in which the acetamido function is replaced by an azide, phthalimide, carbamate, or pivaloyl functionality are also substrates for the enzymes.[219] A recent synthesis of a G_{M_3} analog started with a disaccharyl ceramide derivative in which the fatty acid amide group was replaced with an azide group.[220] To incorporate sialic acid analogs into sialosides is, however, problematic because sialyltransferases are very specific for CMP-sialic acid.



5.2.3. *Fucosyltransferase (FucT)*

Fucosyltransferases are involved in the biosynthesis of many oligosaccharide structures such as blood-group substances and antigens associated with the cell surface and tumors. Fucosylation is one of the last modifications of oligosaccharides in vivo. Several fucosyltransferases have been isolated and used for in vitro synthesis.[221-224] For example, α1-3fucosyltransferase has been used to L-fucosylate the 3-position of the GlcNAc of *N*-acetyllactosamine and of sialyl α2-3*N*-acetyllactosamine to provide the Lewis^x and sialyl Lewis^x structural motifs, respectively.[179, 221] Several other acceptor substrates with modifications in the GlcNAc residue can also be fucosylated (Scheme 43).[179] Galβ1-4Glc, Galβ1-4Glucal, and Galβ1-4(5-SGlc) are all substrates. A similar enzyme, α1-3(4fucosyltransferase, has also been used for synthesis. This enzyme fucosylates either the GlcNAc 3-position of Galβ1-4GlcNAc or the GlcNAc 4-position of Galβ1-3GlcNAc to afford Lewis^x or Lewis^a, respectively.[221, 222] The corresponding sialylated substrates have also been employed as acceptors.[221]



The Lewis^a α1-4fucosyltransferase has been shown to transfer nonnatural fucose derivatives from their GDP esters. 3-Deoxyfucose and L-arabinose are transferred to Galβ-1-4GlcNAcβO-$(CH_2)_8CO_2CH_3$ at a rate of 2.3% and 5.9%, respectively, relative to L-fucose.[224] Furthermore, this enzyme will transfer a fucose residue that is substituted at C-6 by a very large sterically demanding group. In particular, a synthetic blood-group antigen was attached, and the resulting „oligosacharide" was transferred to an acceptor from its GDP derivative by fucosyltransferase.[225] This approach has been used to alter the antigenic properties of cell-surface glycoproteins.

5.2.4. *N-Acetylglucosaminyltransferase*

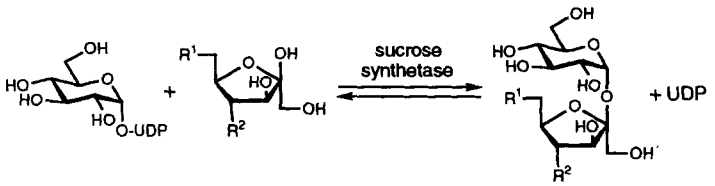
In vivo, the *N*-acetylglucosaminyl transferases control the branching pattern of N-linked glycoproteins.[226, 227] Each of the enzymes transfers a βGlcNAc residue from the donor UDP-GlcNAc to a mannose or other acceptor. The GlcNAc transferases I-VI, which catalyze the addition of the GlcNAc residues to the core pentasaccharide of asparagine glycoproteins as outlined in Scheme 44, have been identified and character-

Scheme 44. Specificity of GlcNAc transferases I-VI.

Scheme 43. Substrates and inhibitors for fucosyltransferase. The reason that Galβ1-4deoxynojirimycin is an inhibitor may be due to a hydrogen bond between the NH group of the inhibitor and the base in the enzyme that abstracts the 3-OH proton of the acceptor (indicated by an arrow).

ized.[226-228] These, as well as other GlcNAc transferases, have been exploited for purposes of oligosaccharide synthesis.[229, 230]

GlcNAc transferases have also been utilized to transfer nonnatural residues to oligosaccharides. In addition to transferring GlcNAc, *N*-acetylglucosaminyl transferase I from human milk catalyzes the transfer of 3-, 4-, or 6-deoxy-GlcNAc from its UDP derivative to Manα1-3(Manα1-6)ManβO-$(CH_2)_8CO_2CH_3$.[229] The 4- and 6-deoxy-GlcNAc analogs can also be transferred by GlcNAc transferase II; however UDP-3-deoxy-GlcNAc is not a substrate for this enzyme.[229] One of the many synthetic applications of GlcNAc transferases is the attachment of the terminal GlcNAc of GlcNAcβ1-4GlcNAcα dolichyl pyrophosphate, a substance employed in the study of oligosaccharyl transferase.[231a] A murine kidney GlcNAc transferase was used



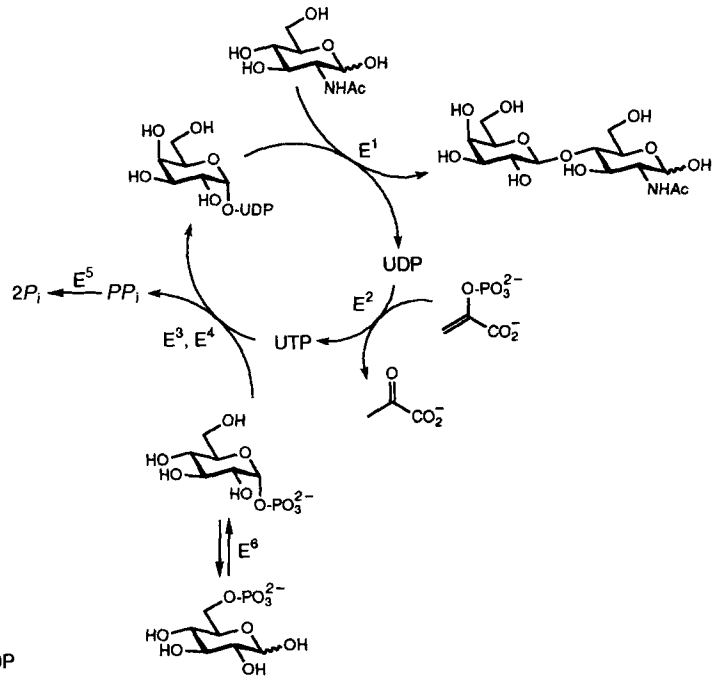
in the synthesis of a hexasaccharide containing sialyl Lewis^x. This enzyme catalyzes the transfer of GlcNAc to 6-OH of Galβ1-3GlcNAc.[231b]

5.2.5. *Mannosyltransferase*

Various mannosyltransferases have been shown to transfer mannose and 4-deoxymannose from their GDP adducts to acceptors.[232] The α1-2mannosyltransferase from yeast has been cloned and overexpressed in *E. coli* (about $1UL^{-1}$) and was employed to transfer mannose to the 2-position of various derivatized α-mannosides and α-mannosyl peptides to produce the Manα1-2Man structural unit.[233] A recent report indicates that mannosyltransferases from porcine liver accept GlcNAcβ1-4GlcNAc phytanyl pyrophosphate, an analog of the natural substrate in which the phytanyl moiety replaces dolichol.[234]

5.2.6. *Sucrose Synthetase*

The fructose derivatives 1-azido-1-deoxy-, 1-deoxy-1-fluoro-, 6-deoxy-, 6-deoxy-6-fluoro-, and 4-deoxy-4-fluorofructose have been used as glycosyl acceptors in the sucrose synthetase catalyzed synthesis of sucrose analogs (Scheme 45).[235] 6-Deoxy- and 6-deoxy-6-fluorofructose were generated in situ from the corresponding glucose derivatives under catalysis by glucose isomerase.[235] Because the reaction is reversible, the sucrose synthetase from rice was used for the preparation and regeneration of UDP-Glc. The enzyme also accepts TDP, ADP, and GDP.[236]

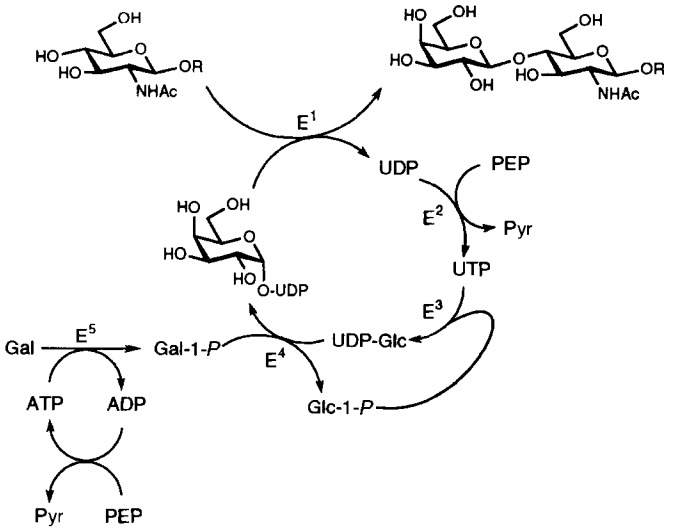


Scheme 45. Synthesis of sucrose analogs with sucrose synthetase. The system can also be used in the regeneration of UDP-Glc from sucrose and UDP. **a**: $R^1 = R^2 = OH$; **b**: $R^1 = F$, $R^2 = OH$; **c**: $R^1 = OH$, $R^2 = F$.

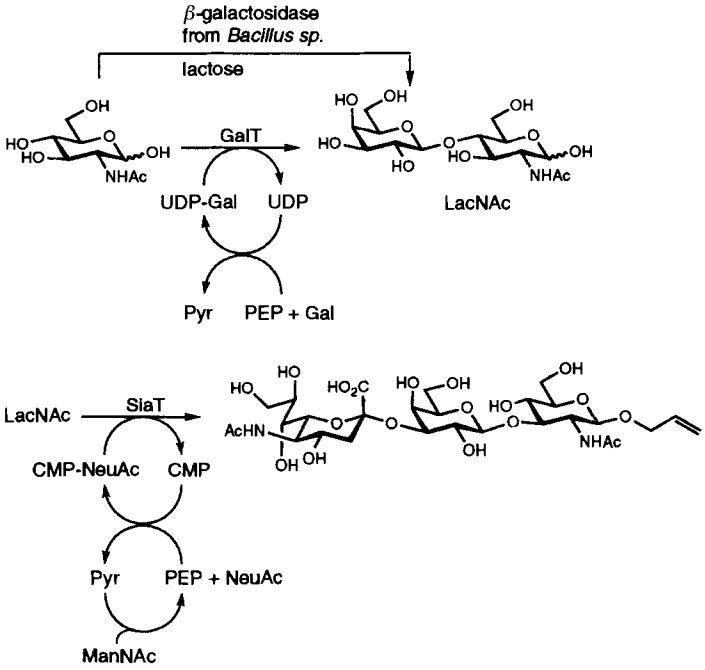
5.2.7. *Oligosaccharyltransferase*

As mentioned earlier, oligosaccharyltransferase catalyzes the transfer of an oligosaccharide consisting of two GlcNAc, nine mannose, and three glucose units from a dolichyl pyrophosphate intermediate to an Asn residue of a nascent peptide or protein.[137] The enzyme also transfers the minimal unit GlcNAcβ1-4GlcNAc from the corresponding dolichyl pyrophosphate donor or from a derivative in which the lipid component is truncated or simplified.[141] The minimal peptide that will serve as an acceptor is the tripeptide Asn-X-Ser/Thr. Oligosaccharyltransferase has been utilized for the in vitro synthesis of several peptides containing glycosylated Asn residues. The glycopeptides Bz-Asn(oligosaccharyl)-Leu-Thr-NH_2,[237] Bz-Asn-(GlcNAc$_2$)-Leu-Thr-NH_2,[238] and Ac-Asn(GlcNAc$_2$)-Leu-Thr-OCH_3/$NHCH_3$[140] were synthesized as well as glycosylated cyclic peptides such as Cys-Als-Asn(GlcNAc$_2$)-Cys-Thr-Ser-Ala.[140]

5.2.8. *In Situ Regeneration of the Cofactor*



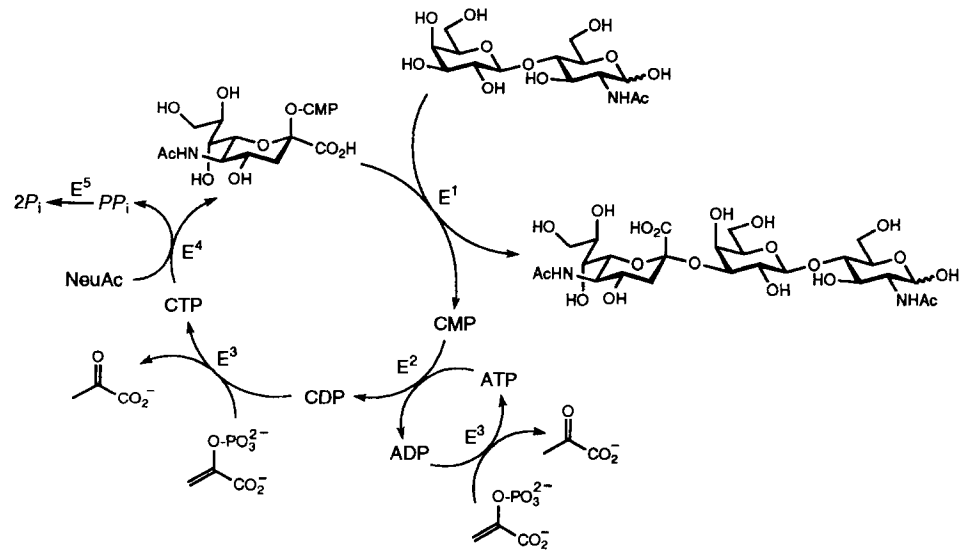
Though analytical- and small-scale synthesis with glycosyltransferases is extremely powerful, the high cost of sugar nucleotides and product inhibition caused by the released nucleoside mono- or diphosphates present major obstacles to large-scale synthesis. A simple solution to both of these problems is the regeneration of the sugar nucleotide in situ from the released nucleoside diphosphate. The first example of the use of such a strategy is the galactosyltransferase-catalyzed synthesis of *N*-acetyllactosamine.[161] (Scheme 46). A catalytic amount of UDP-Gal



Scheme 46. Galactosyltransferase-catalyzed glycosylation involving UDP-glucose epimerase with in situ regeneration of UDP-Gal and UDP-Glc. E^1 = β1-4galactosyltransferase, E^2 = pyruvate kinase, E^3 = UDP-Glc pyrophosphorylase, E^4 = UDP-Glc epimerase, E^5 = inorganic pyrophosphorylase, E^6 = phosphoglucomutase.

is initially used to glycosylate GlcNAc; UDP-Gal is regenerated from the product UDP and galactose with an enzyme-catalyzed reaction sequence that requires stoichiometric amounts of a phosphorylating agent. Several oligosaccharides have been prepared with routes based on this concept.[203] A second regeneration system for UDP-Gal, which is based on the use of galactose-1-phosphate uridyltransferase, has also been developed[213] and has been used in the preparation of analogs such as 2'-deoxy-LacNAc and 2'-amino-2'-deoxy-LacNAc (Scheme 47). A third regeneration method for UDP-Gal is based on sucrose synthetase catalyzed formation of UDP-Glc from sucrose and UDP.[236]

In situ cofactor regeneration offers several advantages. First, a catalytic amount of nucleoside diphosphate and a stoichiometric amount of monosaccharide can be used as starting materials rather than a stoichiometric quantity of sugar nucleotide, thus reducing costs tremendously. Second, product inhibition by the released NDP is minimized due to its low concentration



Scheme 47. Galactosyltransferase-catalyzed glycosylation involving galactose-1-phosphate uridyltransferase with in situ regeneration of UDP-Gal and UDP-Glc. in solution. And third, isolation of the product is greatly facilitated.

A regeneration system for CMP-NeuAc (Scheme 48) has also been developed.[192, 239] The UDP-Gal and CMP-NeuAc regeneration schemes can also be combined in a one-pot reaction (Scheme 49) and applied to the synthesis of sialyl oligosaccharides.[179] The development of these regeneration systems, as well as the more recent development of regeneration schemes or UDP-GlcNAc[240], GDP-Man,[233] and GDP-Fuc,[179] as well as UDP-GlcUA[183] should facilitate the more widespread use of glycosyltransferases for oligosaccharide synthesis. One example is the recent synthesis of sialyl Lewis^x (Scheme 50).[179]

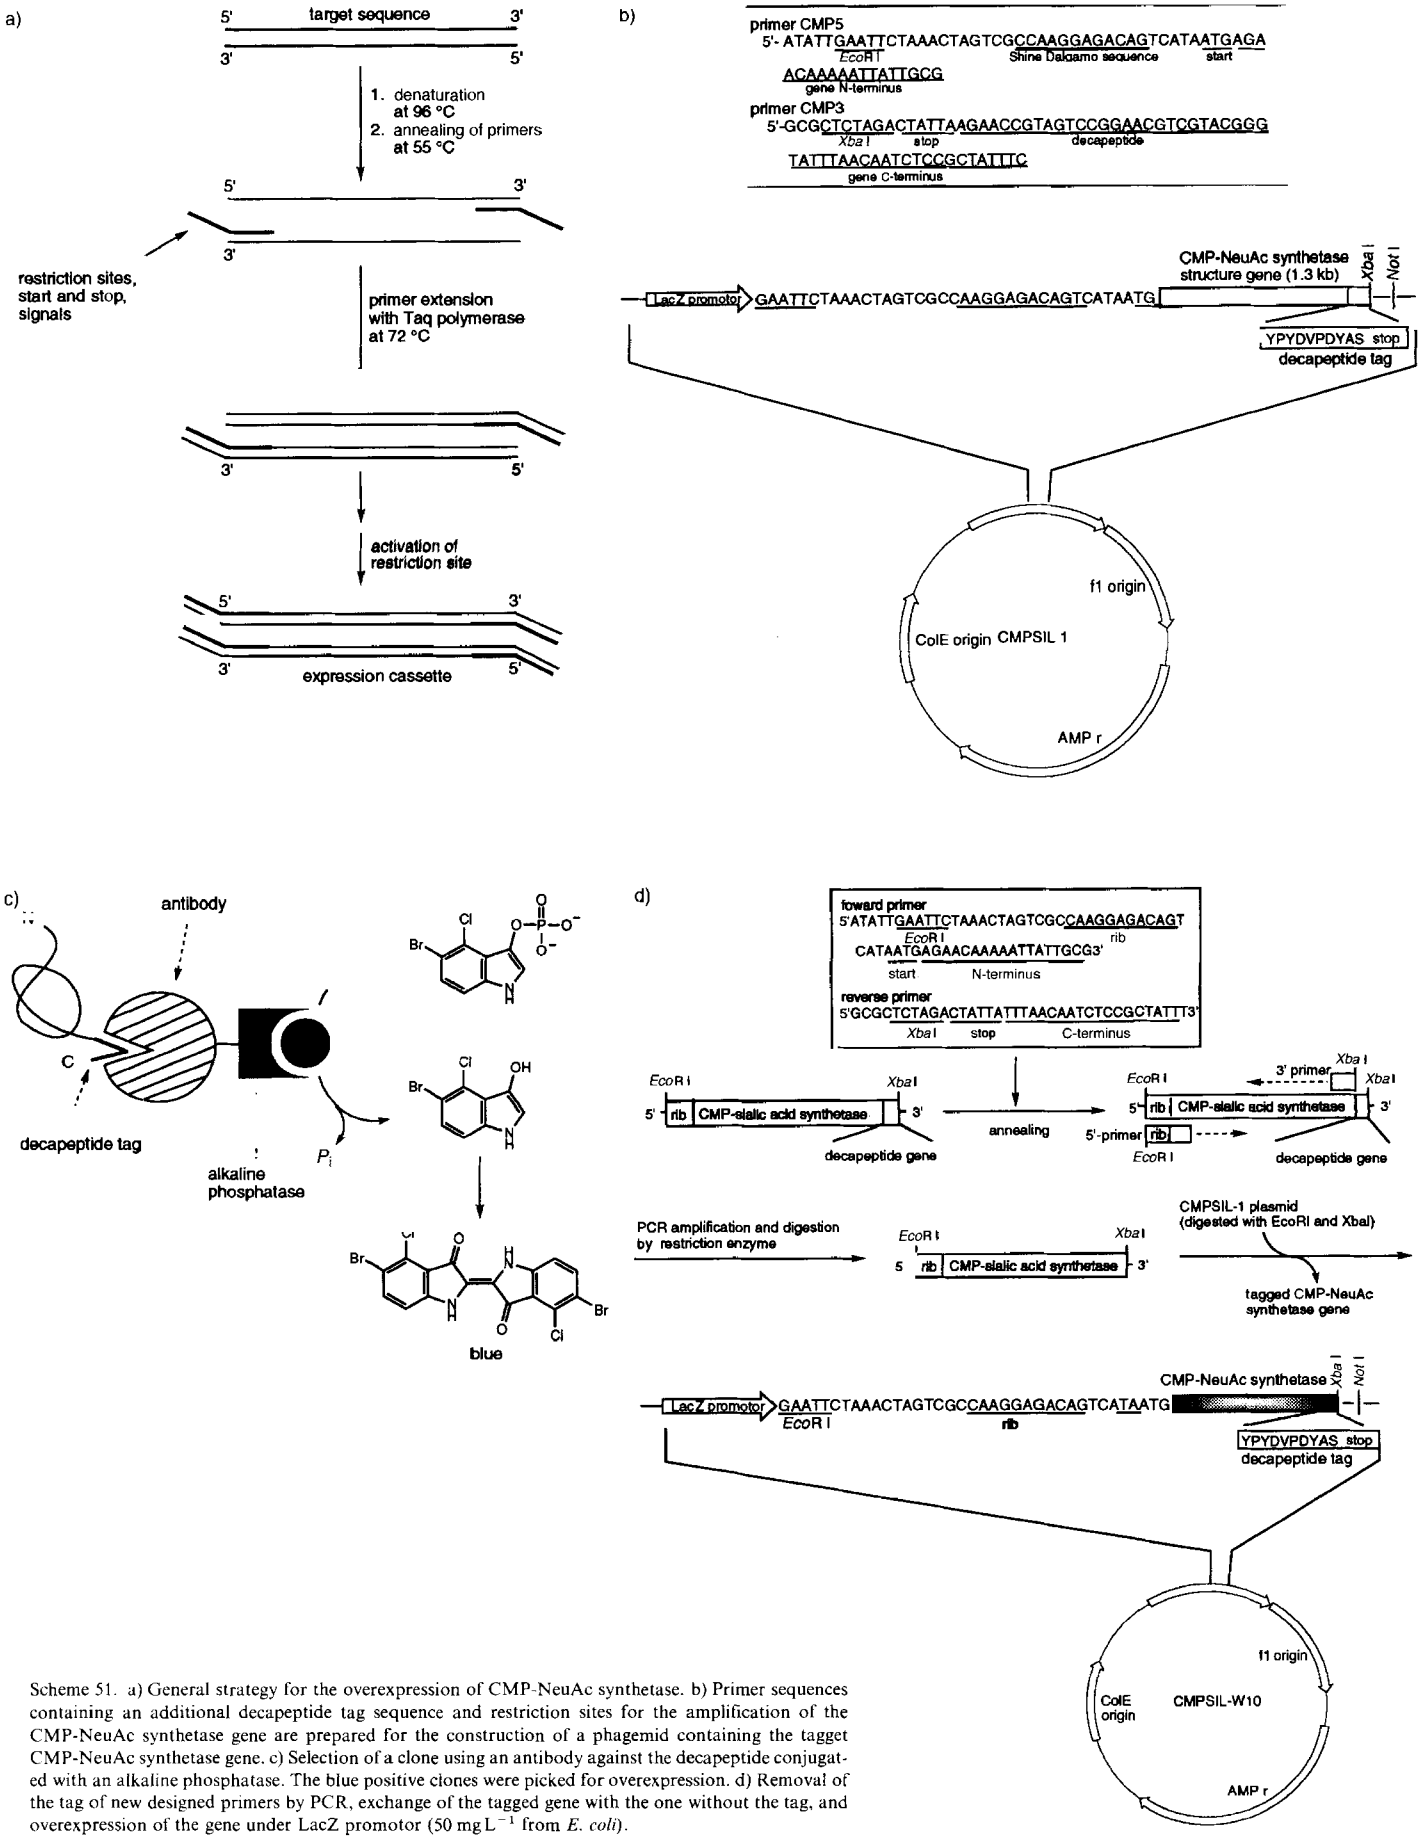
5.3. Cloning and Expression of Glycosyltransferases and Sugar Nucleotide Synthetases

Although many glycosyltransferases catalyze similar reactions and in many cases use the same donor substrate, there appears to be little sequence homology among the different transferases. There is, however, a significant homology between the same enzymes from different species. For instance, the protein sequence of β1-4galactosyltransferase from humans has an 86% identity with that of the enzyme from rat. The different glycosyltransferases do exhibit some similarity in that all the cDNA sequences determined to date encode regions consistent with a short N-terminal tail, a hydrophobic transmembrane sequence, a short stem sequence, and a large C-terminal catalytic domain.[244] In addition to the membrane-bound form of the glycosyltransferases, soluble forms of the enzymes have also been identified in various body fluids such as the blood, milk, and colostrum. Indeed, some of these enzymes have been isolated and purified from these fluids.[241-243] A comparison of the cDNA sequences of these soluble enzymes with the N-terminal protein sequence of the glycosyltransferases that have been sequenced suggests that the



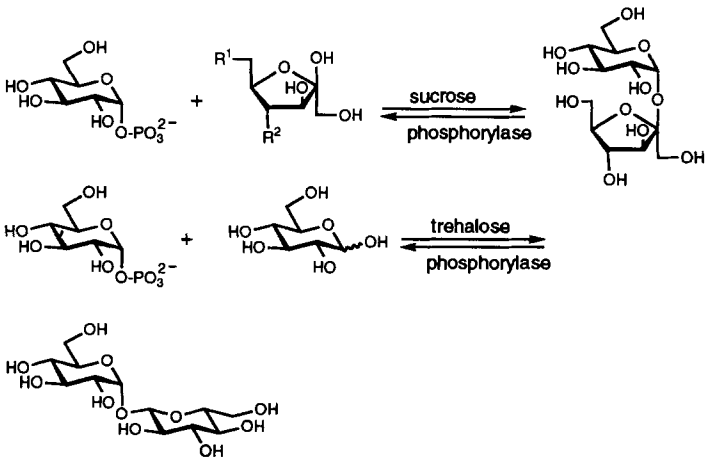
Scheme 50. Enzymatic fucosylation with in situregeneration of GDP-fucose.

stem region has been cleaved to release the large catalytic domain from the membrane. Presumably, this theme of signal sequence cleavage is typical for all the glycosyltransferases.[244]

The amount of the glycosyltransferase that can be isolated from a natural source is often limited by the low concentrations of these enzymes present in most tissues and body fluids. The purification of glycosyltransferases is further complicated by the relative instability of this group of enzymes.[11] For this reason, a great deal of interest has been directed toward the cloning of the glycosyltransferase genes into convenient expression systems. The general strategy involved in this procedure is outlined in Scheme 51a. The glycosyltransferase gene must first be identified and isolated from the mRNA pool by cloning of the cDNA to make a cDNA library. This library is then screened to identify the glycosyltransferase gene of interest among approximately 10^6 different sequences present in the library. Once identified, the gene is sequenced and a more complete cloning strategy is developed in order to incorporate the gene into an expression vector. This laborious path has successfully been practiced by several groups.[5, 244–253, 256–265] From various tissue sources cDNA is recovered, and, for example, the double stranded cDNA is ligated in λ phage through a convenient linker and packed into bacteriophages. The bacteriophages are then plated onto a lawn of *E. coli* and screened for the desired gene or gene product. The identification of the glycosyltransferase gene has most frequently been achieved by the hybridization of the gene to specific radiolabeled DNA probes.[245–248] Screening in this manner requires a previous knowledge of the gene sequence, information that in some cases may be obtained by extrapolation from a partial protein sequence or from the DNA sequence of the glycosyltransferase from a related source. Two other approaches have been used to screen glycosyltransferase cDNA libraries, both requiring successful transcription and translation of the gene product. In the cloning of the α2–6-sialyltransferase from rat liver, Weinstein et al. used polyclonal antibodies raised against the purified enzyme to screen the λ phages.[253] The other approach used by Larsen et al. alleviated the need for a previous knowledge of the sequence.[251] This method made use of the specificity of a lectin that recognizes the surface-expressed glycoconjugate product of the α1–3galactosyltransferase. The transfected cells were then panned in dishes coated with the lectin. The adherent cells were isolated and repanned for further purification. Each of these techniques makes use of libraries in which there are very few copies of the desired gene. A greater chance of success may be possible if the number of copies of the genes could be amplified. The introduction in 1985 of an in vitro amplification method based on the polymerase chain reaction (PCR) fulfilled this need.[254, 255] Of course, PCR (and Expression Cassette-PCR),[255] like the hybridization screening, requires a specific knowledge of the sequence.

Once identified, the genes are sequenced with standard procedures. An enlightened approach to the recloning of the gene into an expression vector is then used to develop an expression system. This recloning into expression systems has been performed with only a few of the glycosyltransferases. Toghrol et al. have inserted the mouse liver glucuronyltransferase gene into the yeast vector pEVP11 and expressed the enzyme in *Saccharomyces cerevisiae*.[245] The rat liver glucuronyltransferase, on the other hand, has been expressed in COS cells with the SV40 vector.[246] Bovine β1–4galactosyltransferase was cloned analogously.[247] A noteworthy approach toward the expression of the glycosyltransferase in *E. coli* has been developed to obtain human β1–4galactosyltransferase.[256] A unique *Rsr*II restriction site in the galactosyltransferase gene allowed the dissection of the sequence at the location of signal peptidase cleavage. The cohesive terminus was digested with Klenow fragment (the large subunit of the DNA polymerase I, which has a 3′ → 5′ exonuclease activity and cleaves the remaining bases at the restriction site), and the blunt end ligated to pIN-III-*omp*A_2[257] at *Eco*RI site that had also been treated with a Klenow fragment. Thus the code was generated for a fusion protein of the soluble form of galactosyltransferase with the *omp*A signal sequence (*omp*A = outer membrane protein A, an *E. coli* protein that controls secretion through its cleavable N-terminal signal sequence). Transcription and translation of this sequence in *E. coli* produced an active enzyme that was released into the periplasmic space. Purification and N-terminal sequencing of the enzyme verified the expresson of the soluble form of galactosyltransferase with an added N-terminal tail comprising three amino acids. The kinetic parameters of this enzyme appear to be identical to the isolated native enzyme. This system, however, only produced a very small amount of enzyme ($< 0.014\ U\ L^{-1}$). Though a 30-fold increase of productivity has been achieved with a modified *E. coli* host,[204] the level of productivity is still too low to be of practical synthetic value. More practical expression systems are perhaps those based on the baculo virus[179] and yeast.[258]

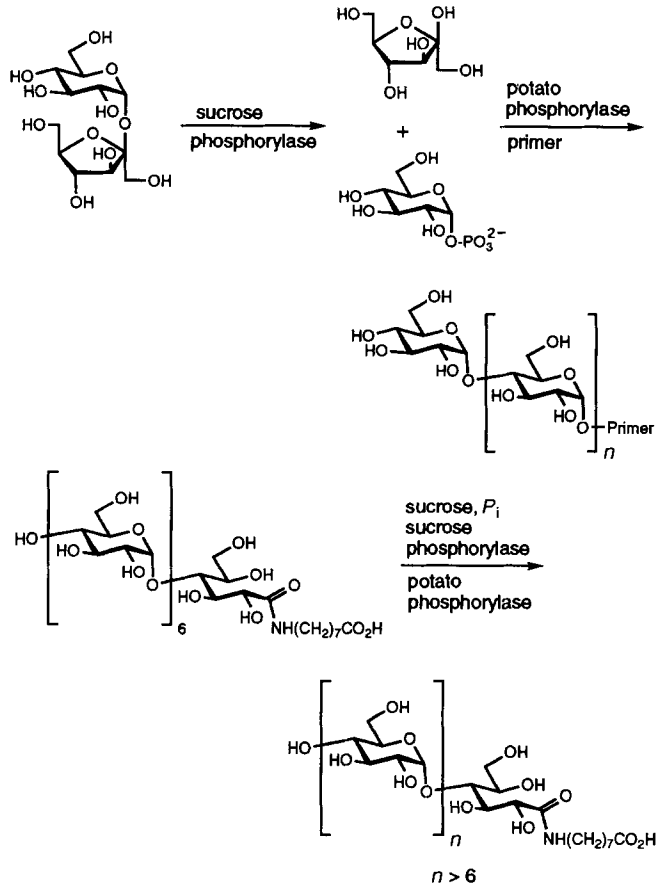
To date, very few glycosyltransferases have been cloned, expressed, and produced in quantities sufficient for enzymatic synthesis.[266] However, given the advantages of enzymatic synthesis of oligosaccharides over traditional schemes, research into the overexpression of glycosyltransferases will continue



Scheme 51. a) General strategy for the overexpression of CMP-NeuAc synthetase. b) Primer sequences containing an additional decapeptide tag sequence and restriction sites for the amplification of the CMP-NeuAc synthetase gene are prepared for the construction of a phagemid containing the tagget CMP-NeuAc synthetase gene. c) Selection of a clone using an antibody against the decapeptide conjugated with an alkaline phosphatase. The blue positive clones were picked for overexpression. d) Removal of the tag of new designed primers by PCR, exchange of the tagged gene with the one without the tag, and overexpression of the gene under LacZ promotor (50 mg L^{-1} from *E. coli*).

to flourish. Schemes 51b–51d describe the procedures used in the overexpression of CMP-sialic acid synthetase in *E. coli* ($\sim 50\,mg\,L^{-1}$).

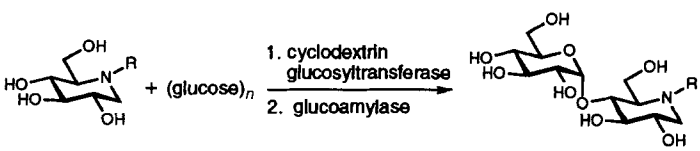
5.4. Non-Leloir Glycosyltransferases: Transfer of Glycosyl Donors from Glycosyl Phosphates and Glycosides



Oligosaccharides can also be prepared using non-Leloir glycosyltransferases. Phosphorolysis of polysaccharides is catalyzed by a group of these enzymes called glucan phosphorylases. The reaction is reversible and can be used in the synthesis of oligo- or polysaccharides. Two particularly important examples are the syntheses of sucrose and trehalose, catalyzed by sucrose phosphorylase[267] and trehalose phosphorylase[267] (Scheme 52). Examples of other enzymes of this class are those involved in synthesis of dextrans and levans.[268]

Scheme 52. Phosphorylase-catalyzed synthesis of sucrose and trehalose.

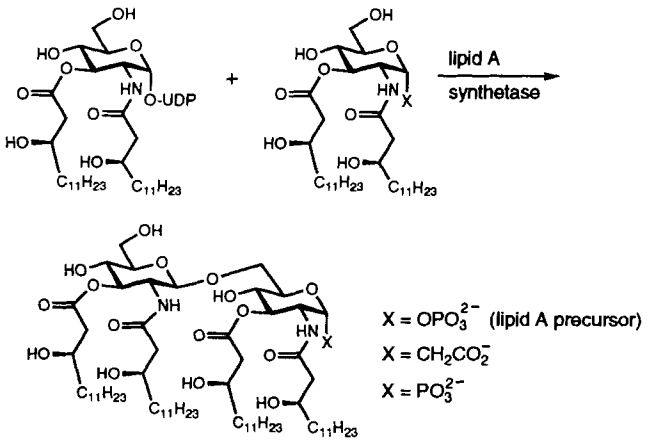
Non-Leloir transferases have also been used to synthesize a variety of polysaccharides. The synthesis of modified polysaccharides may provide materials with more desirable physical and biological properties than their natural counterparts. Approaches to influencing the characteristics of polymers include the control of genes encoding the enzymes responsible for their production, regulation of the activity of these enzymes, or the influence of their in vivo synthesis.[269] Potato phosphorylase [EC 2.4.1.1] has been used in vitro to prepare maltose oligomer,[159] and a family of linear and star- and comb-shaped polymers.[270]



Improvement of this system has recently been accomplished with the use of a coupled enzyme system in which glucose-1-phosphate is generated in situ from sucrose and inorganic phosphate catalyzed by sucrose phosphorylase.[160] The inorganic phosphate liberated by potato phosphorylase is used by sucrose phosphorylase to drive the formation of polymer, thereby increasing the yield. This coupled enzyme system also allows for regulation of the molecular weight of the polysaccharide product by control of the concentration of the primer. Nonnatural primers bearing functional groups can also be used to prepare tailor-made polysaccharides for further manipulation, for example, for attachment to proteins or other compounds (Scheme 53).

Scheme 53. Phosphorylase-catalyzed polysaccharide synthesis.

Cyclodextrin α1–4glucosyltransferase [EC 2.4.1.19] from *Bacillus macerans* catalyzes the cyclization of oligomaltose to form α-, β-, and δ-cyclodextrin, as well as the transfer of sugars from cyclodextrin to an acceptor to form oligosaccharides.[271, 272] The enzyme can also transform α-glucosyl fluoride into a mixture of α- and β-cyclodextrins and maltooligomers in almost equal amounts.[273] When immobilized on a silica gel support that was functionalized with glutaraldehyde, the enzyme was very stable, and no loss of activity was observed after four weeks at 4 °C. With an appropriate choice of acceptor, this type of enzymatic catalysis may provide a new route to cyclodextrin analogs and novel oligosaccharides.



Nonnatural sugar acceptors that are structurally similar to glucose are also substrates for cyclodextrin glucosyl transferase. With deoxynojirimycin as acceptor and cyclodextrin as donor, an oligoglucosyl deoxynojirimycin was produced, which was subsequently hydrolyzed by glucoamylase to give 4-*O*-α-D-glucopyranosyl deoxynojirimycin in approximately 60% yield (Scheme 54).[274] A number of N-substituted derivatives of deoxynojirimycin were also good substrates for the transferase,

Scheme 54. Synthesis of glycosyl *N*-alkyldeoxynojirimycin derivatives.

and the products can be degraded with glucoamylase to glucosyl aza sugars. One of these glucosyl aza sugars, 4-*O*-α-D-glucopyranosyl-*N*-methyldeoxynojirimycin, was reported to be a potent inhibitor of glucosidase.

A key step in the biosynthesis of lipid A is the glycosylation of the 6-position of a 2,3-diacylglucosamine-1-phosphate by the donor UDP-2,3-diacylglucosamine to produce a lipid A precursor. This transformation is catalyzed by the enzyme lipid A synthetase, which has been cloned and overexpressed.[275] It has been used for the *in vitro* synthesis of the lipid A precursor and analogs thereof. Some examples include C-glycoside[276] and phosphate[277] analogs (Scheme 55).

Scheme 55. Synthesis of lipid A analogs with lipid A synthetase.

5.5. Glycosidases and Transglycosidases

Glycosides may be synthesized with glycosidase catalysts under either equilibrium or kinetically controlled conditions.[13] Though quite easy to perform, the equilibrium approach provides poor yields generally not exceeding 15%. Also, the low yield of the desired product and the formation of side products generally make purification difficult.

Kinetically controlled synthesis relies on the trapping of a reactive intermediate generated from an activated glycosyl donor with exogenous nucleophiles to form a new glycoside bond.[13] Suitable glycosyl donors for this transglycosylation reaction include di- or oligosaccharides, aryl glycosides, and glycosyl fluorides. This reaction must be carefully monitored, and stopped when the glycosyl donor is consumed in order to minimize glycoside hydrolysis.

Yields in kinetically controlled synthesis generally range from 20 to 40%. Although addition of organic solvent might be expected to increase product yields, as in the equilibrium controlled approach, this effect generally has not been observed.

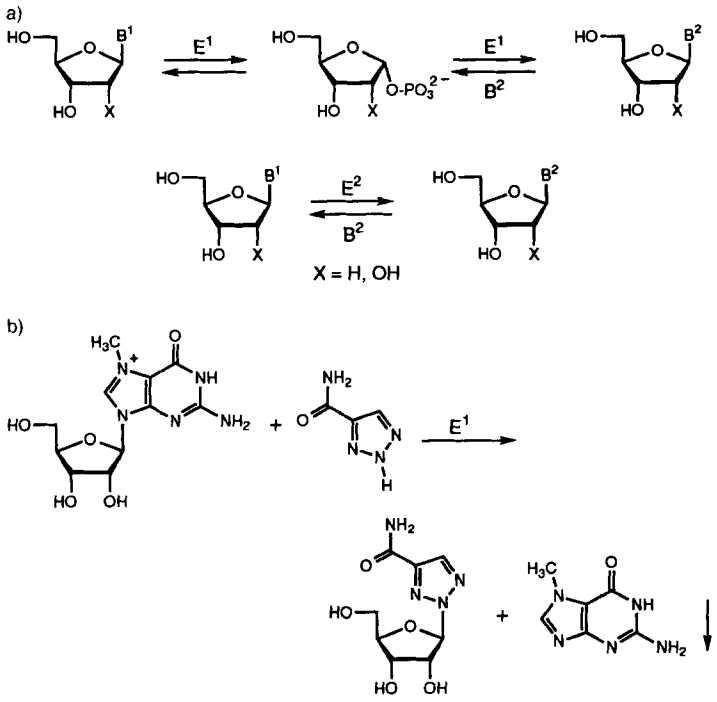
The kinetically controlled approach has primarily been applied to the glycosidases that give products with retention of configuration. However, an inverting glycosidase has been used with glycosyl fluorides as glycosyl donors to afford products having the configuration at the anomeric position opposite to that of the donor.[278] For example, the α,α-linkage of α-D-glucopyranosyl-α-D-xylopyranoside has been prepared utilizing β-glucosylfluoride and α-trehalase.[279]

In general, the primary hydroxyl group of the acceptor reacts preferentially over secondary hydroxyl groups to give a 1,6-glycosidic linkage. Some control of selectivity has been demonstrated by the selection of an appropriate dono/acceptor combination.[280] For example, the reaction catalyzed by α-galactosidase of α-Gal-OPh-*p*-NO_2 with α-Gal-OMe (or allyl α-galactoside) and β-Gal-OMe forms predominantly α-1,3 and α-1,6 linkages, respectively.[280a, b] The configuration of the anomeric center of the acceptor controls, to some extent, the position of glycosylation. This situation was also observed in the β-*N*-acetylgalactosaminidase reactions.[280c] α-gal-OPh-*p*-NO_2 acting both as donor and acceptor, forms referentially the α-1,3 linkage whereas the *ortho* nitrophenyl glycoside reacts in a similar fashion to form predominantly the α-1,2-linkage.[280a, b] With β-galactosidase, mainly the β-1,3-linked disaccharides were formed when benzyl or allyl β-galactoside was used as acceptor.[13, 280a, b] The use of glycals as acceptors has also been employed as a means of controlling selectivity,[281] giving the 1,3-linked glycoside as the major product when the 6-position was free or blocked.

One can also use glycosidases from different species to control the regioselectivity. For example, the β-galactosidase from testes catalyzes the formation of Galβ1–3GlcNAc from lactose or Galβ1–3GlcNAcβSEt[282] from either GlcNAc or GlcNAcβSEt. Minor products were then hydrolyzed by *E. coli* β-galactosidase, which preferentially hydrolyzes β-1,6-linked galactosyl residue. The overall yield of the β-1,3-linked disaccharides was around 10–20%. Syntheses of polysaccharides based on kinetically controlled glycosidase reactions have been accomplished, as examplified by the cellulase-catalyzed polymerization of β-cellobiosyl fluoride to form cellulose, with a degree of polymerization of greater than 22.[283a] The β-galactosidase from *Bacillus circulans* was used in large-scale synthesis of *N*-acetyllactosamine[283b] from lactose and GlcNAc. When this reaction was coupled with the sialyltransferase reaction in situ, a sialyl lactosamine was prepared[283c] (see Scheme 49), thus preventing the secondary hydrolysis of the galactosidase product.

Glycosyl transfer to non-sugar acceptors has also been demonstrated. These reactions are especially interesting with chiral, racemic, or *meso* alcohols, as some degree of diastereoselectivity due to the asymmetric microenvironment of an enzyme active site might be expected. Indeed moderate to exceptional diastereoselectivities[14] have been observed.

Transglycosidases are related to glycosidases in that they cleave glycoside bonds, but they differ in that they usually transfer the glycosyl moiety to another acceptor with a minimal amount of hydrolysis. Transglycosidases are thus useful catalysts for glycosylation. For example, a β-fructofuranosidase from *Antherobacter sp.* K-1 transfers fructose from sucrose to the 6-position of the glucose residues of stevioside and rubusoside.[284] Also, a sucrase from *Bacillus subtilis* catalyzes the reversible transfer of fructose from sucrose to the 6-hydroxyl of a fructose unit at the nonreducing end of a levan chain.[285] Several nonnatural sucrose derivatives have been prepared by taking advantage of this process.[286]



A transsialidase from *Trypanosoma cruzi* has been shown to transfer sialic acid reversibly to and from the 3-position of terminal β-Gal residues.[287] Chains terminating in α-linked galactose are not substrates. A number of oligosaccharides containing the

NeuAcα2-3Galβ substructure have been synthesized with this transsialidase.[288] Moreover, this enzyme has been shown to resialylate the terminal galactose units of the cell-surface glycoproteins and glycolipids of sialidase-treated erythrocytes.[289] and a galactoside.[290] Thus, the *T. cruzi* transsialidase potentially provides a useful alternative to α2-3sialytransferase.

5.6. Synthesis of Nucleosides

Nucleosides and their derivatives are ubiquitous in nature and are involved in a myriad of biochemical phenomena, most notably the storage and transfer of genetic information. Interest in this class of compounds has been stimulated by the efficacy of certain nucleosides as antiparasitic[291] (for example, 1-β-D-ribofuranosyl-1 *H*-pyrazolo[3,4-*d*]pyrimidin-4-one, allopurinol riboside) and antiviral (for example, 3'-azido-3'-deoxythymidine, azidovudine, AZT) agents.[292-293] Nucleosides have traditionally been prepared by various chemical methods.[294] These are multistep syntheses requiring protection and deprotection steps and glycosyl activation. Other problems include control of anomeric configuration, especially when preparing β-D-arabinofuranosyl- and 2'-deoxy-β-D-ribofuranosylnucleosides, and regiospecific C-N glycoside formation when there are several possible nucleophilic groups in the purine or pyrimidine base.

Two enzymatic methods have been used in the synthesis of nucleosides (Scheme 56a). Most enzymatic preparations of both natural and nonnatural nucleosides have been reported with nucleoside phosphorylases as catalysts.[295] These enzymes catalyze the reversible formation of a purine or pyrimidine nucleoside and inorganic phosphate from ribose-1-phosphate (R-1-P) and a purine or pyrimidine base. The equilibrium strongly favors nucleoside formation. Nucleoside synthesis has relied on the transfer of the ribose moiety of a readily available nucleoside to a different purine or pyrimidine base or analogs through the intermediacy of R-1-P. This work has been done primarily with isolated enzymes,[296] but whole cells have also been employed in a few cases.[297] The effects of deleterious hydrolases present in whole cells could be largely suppressed by conducting the reactions at 60 °C, a temperature at which the nucleoside phosphorylases maintain more than 70% of their original activity for three to five days.[297]

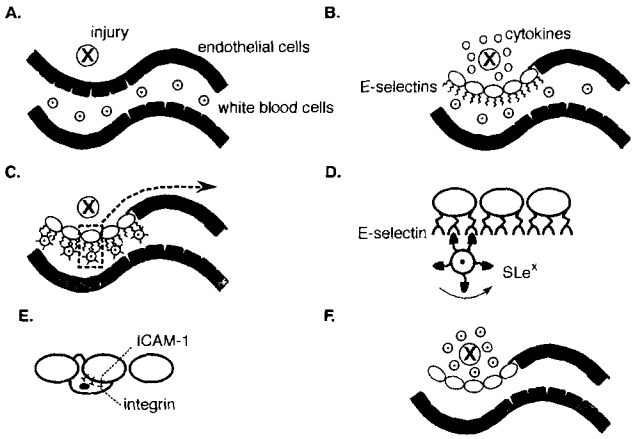
Scheme 56. a) Two strategies for enzyme-catalyzed nucleoside synthesis. E^1 = nucleoside phosphorylase, E^2 = transribosylase. Both E^1 and E^2 catalyze reversible reactions. b) When 7-*N*-methylguanosine is the donor, the reaction catalyzed by E^1 is irreversible.

Two basic strategies have generally been employed. The first involves isolation of R-1-P, which is prepared in good yield from a nucleoside in the presence of a high concentration of phosphate.[298] The isolated R-1-P is then used as the glycosyl donor in an enzymatic coupling reaction with added purine or pyrimidine bases or analogs. The second strategy involves a one-pot exchange of one nucleoside base for another in the presence of a catalytic amount of inorganic phosphate without isolation of R-1-P. The first strategy (isolation of R-1-P) is the most general, and almost any heterocycle that is a substrate for a nucleoside phosphorylase can be glycosylated by this method. The second strategy (in situ generation of R-1-P) is more limited. At best, it results in formation of an equilibium mixture of the substrate and the product nucleosides, from which the product must be isolated. In less favorable cases, the natural purine or pyrimidine base released from the glycosyl donor may be a potent competitive inhibitor with respect to the purine or pyrimidine analog, for which the enzyme has lower affinity. For example, because of competitive inhibition by hypoxanthine (K_m = 5.6 mM), 1,2,4-triazole-3-carboxamide (TCA, the aglycon component of virazole, K_m = 167 mM) cannot be glycosylated if inosine is the ribosyl donor and purine nucleoside phosphorylase (PNPase) the catalyst.[299] It was, however, possible to synthesize virazole by isolating of R-1-P and subsequently using it as the ribosyl donor.[299] An alternative way to circumvent the inhibition problems is to employ a pyrimidine nucleoside as the glycosyl donor and a purine (or purine analog) as the acceptor, since the released pyrimidine base does not inhibit the purine nucleoside phosphorylase.[300] By this method, both pyrimidine nucleoside phosphorylase and purine nucleoside phosphorylase are required.

Recently, direct purine-to-purine exchange reactions have been conducted without isolation of R-1-P with activated purine derivatives as the ribosyl donors.[301] The activated purine derivatives were prepared by 7-N-methylation of inosine and guanosine to provide derivatives that are excellent substrates for phosphorolytic cleavage by PNPase. The cleaved 7-*N*-methylpurines do not show any measurable product inhibition, and the equilibrium of the reaction greatly favors the product. The effectiveness of this approach was demonstrated by the one-pot synthesis of virazole from 1,2,4-triazole-3-carboxamide and 7-*N*-methyl guanosine (Scheme 56b).

The nucleoside phosphorylases accept a wide range of nucleoside analogs modified in both the base and glycosyl components, as substrates. Most of these reactions have been carried out in one step without isolation of the sugar phosphate, which has, however, been demonstrated to be an intermediate.

The use of nonnatural bases has met with much success with both natural and nonnatural glycosyl donors. However, a few limitations have been observed. For example, in the purine nucleoside phosphorylase catalyzed synthesis of certain imidazole[4,5-c]pyridine nucleosides (3-deazapurine nucleosides), the normally observed regiospecificity was lost, and a mixture of N-1 and N-3 glycosylated products was isolated. This problem was not encountered with purines, which retain the nitrogen at the 3-position: 2'-deoxyribosylation of unsubstituted purine gave only the N-9 glycosyl product.[300] Apparently either the N-3 nitrogen atom of the purine base or an appropriate substituent at C-6 is necessary for proper orientation of the base for regiospecific glycosylation.



Sugar-modified nucleosides can be synthesized from glycosyl donors prepared by chemical modification of readily available nucleosides such as uridine and cytidine. Good yields of arabino-[297] and 2'-amino-2'-deoxyribonucleosides[293] have also been obtained enzymatically, although that of the enzymatic synthesis of 3'-amino-2',3'-dideoxyribonucleosides is low.[302] This low yield may be due to competition of the two pyrimidine heterocycles for enzyme binding or to an overall decreased reaction rate caused by alteration of the 3'-position, which may be important in substrate binding by the enzyme.[303]

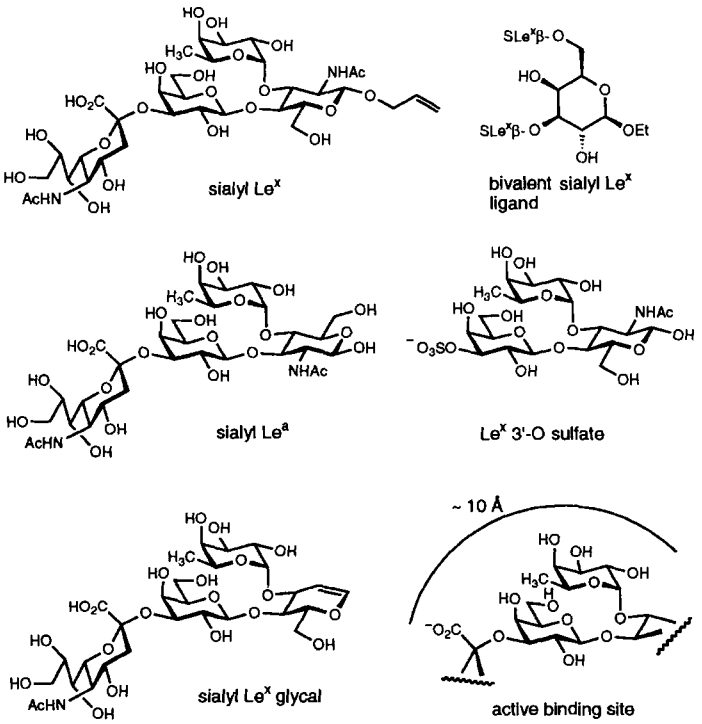
N-Transribosylases have been employed in the synthesis of nucleoside analogs.[295, 304] Two classes of transribosylases have been identified: type I enzymes catalyze the transfer of the sugar moiety between two purine bases, and type II catalyze the transfer between any two bases. Like nucleoside phosphorylases, transribosylases are stereospecific for the β-anomer of the nucleoside product. Thymidine and 2'-deoxycytidine are the best glycosyl donors, and a reasonable amount of variation in the acceptor bases is tolerated. The transribosylase from *L. leichmanii* has been used to prepare 2-chloroadenosine, an antileukemic and immunosuppressive nucleoside.[304c]

5.7. Silyl Lewis^x and Related Structures

Carbohydrate-mediated cell adhesion is an important event, which can be initiated by tissue injury or infection and is involved in metastasis.[10] One such adhesion process that was recently discovered is the interaction between the glycoprotein E-selectin (formerly called *e*ndothelial *l*eukocyte *a*dhesion molecule or ELAM-1), which is expressed on the surface of endothelial cells during inflammation and an oligosaccharide structure displayed on the surface of neutrophils. The ligand recognized by E-selectin has been identified to be the tetrasaccharide sialyl Lewis^x (SLe^x), which is present at the terminus of glycolipids displayed on the surface of neutrophils.[305] The adhesion process[10] is stimulated by signaling molecules (cytokines) or other inflammatory factors (for example, toxins, lipopolysaccharides, leukotrienes) that induce the production of E-selectins. After binding to the endothelial cells, the white blood cells roll along the surface of the endothelium. Further adhesion occurs by protein–protein interactions, mediated by integrins on white blood cells and a protein ligand containing the RGD (Arg-Gly-Asp) sequence (called *i*ntercellular *a*dhesion molecule-1, ICAM-1) on endothelial cells. The white blood cells are then able to squeeze through gaps between endothelial cells and enter the adjacent tissue to help repair injury (Scheme 57).

If too many white blood cells are recruited to the site of injury, normal cells can also be destroyed. This can occur in the condition of septic shock, in chronic inflammatory diseases such as psoriasis and rheumatoid arthritis, and in the reperfusion tissue

Scheme 57. Inflammation of tissue involves E-selectin-mediated cell adhesion. When tissue injury occurs (A), cytokines are released to stimulate synthesis of E-selection (B). Adhesion then occurs through interaction of E-selectins and SLe^x on the surface of leukocytes (C, D). As leukocytes roll along the surface of endothelial cells, further adhesion occurs through interaction between integrins on leukocytes and the ligand on the endothelial cells that contain the sequence Arg-Gly-Asp (RGD) (called ICAM-1) (E). The leukocytes reach the injury site through small openings between the endothelial cells (F).

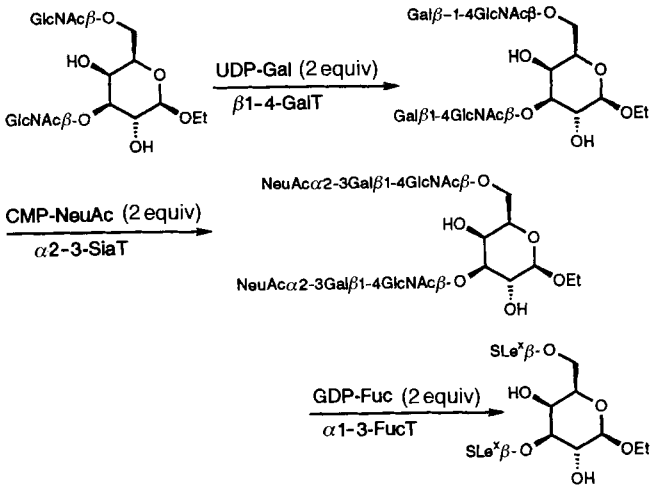


injury that occurs following heart attack, stroke, and organ transplant. High levels of sialyl Lewis^x have also been found on the surfaces of certain tumor and cancer cells (for instance, colon and lung cancer cells), which suggests that cancer cells may exploit this phenomenon of adhesion to metastasize after entering the blood stream.[10] In addition to E-selectin, two other carbohydrate-binding proteins, P- and L-selectin, also recognize sialylated ligands in cell-adhesion processes.

The discovery that the ligand for E-selectin is sialyl Lewis^x[305] provides new impetus for the development of therapeutic agents in the treatment of inflammation-related diseases and cancers. Since sialyl Lewis^x in solution competes with the white blood cells for binding to E-selectin, thus inhibiting the adhesion process, it may be useful as an anti-inflammatory to anticancer agent.[10] On the other hand, understanding the active conformation of sialyl Lewis^x recognized by E-selectin may also lead to the development of simple and easy-to-make inhibitors that are analogs or non-carbohydrate mimetics of sialyl Lewis^x with better bioavialability. Another approach is to inhibit the enzymes (such as the α1–3fucosyltransferase) associated with the biosynthesis of sialyl Lewis^x.

Considerable research has been directed toward the chemical synthesis of sialyl Lewis^x;[306–309] these syntheses tyically require multiple protection and deprotection steps, making large-scale production difficult. Enzymatic syntheses of sialyl Lewis^x based on glycosyltransferases proceed regio- and stereoselectively in aqueous solution, without the need for protecting groups.[179, 310–311] With the advances in recombinant DNA technology for the cloning and overproduction of enzymes and

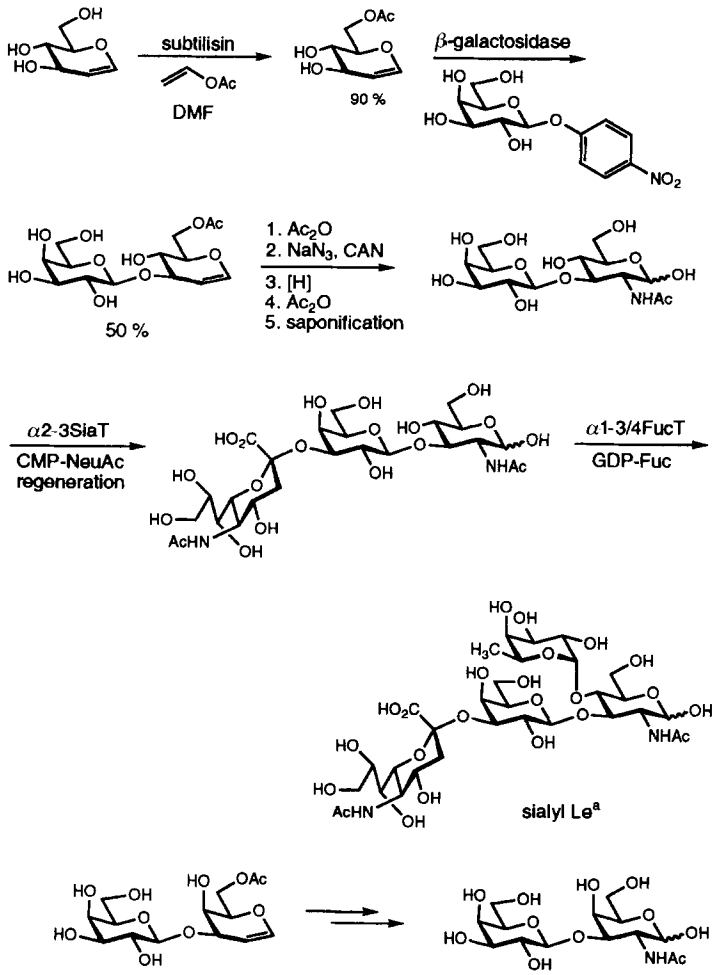
the development of sugar nucleotide regeneration, sialyl Lewis^x can now be produced in large quantities. (Cytel Co., San Diego, California, is producing SLe^x in kg quantities as a drug candidate for the treatment of reperfusion tissue injury.)



The enzymatic method has also been used for the synthesis of [^{13}C]Gal-1-labeled sialyl Lewis^x,[179] which was used for conformational analysis with NMR spectroscopy. In addition, sialyl Lewis^a (SLe^a),[179, 312] SLe^x glycal,[179] and Le^x-3′-sulfate[313] are also conformationally[179] similar to SLe^x and biologically as active (Scheme 58). The results of these studies indicate that the active binding domain of sialyl Lewis^x consists primarily of the galactose, fucose, and the carboxylate group of the sialic acid. The methyl group of the fucose is not essential, as the fucose residue can be replaced with arabinose.[314] The three hydroxyl groups of the fucose, however, are required.[314]

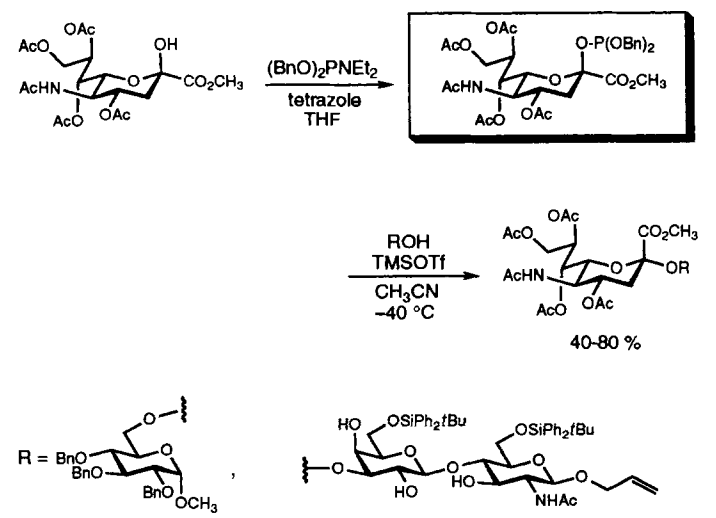
Scheme 58. Ligands for E-selectin and the minimum active binding site. Sialyl Lewis^a, sialyl Lewis^a, Le^x-3′-O-sulfate, and SLe^x glycal exhibit almost the same binding activity to E-selectin in vitro ($IC_{50} \approx 1-2$ mM). The three OH groups of Fuc are essential, while the CH_3 group is not required. Ion-spray mass analysis using the collision-induced decomposition technique indicated that the Ca^{2+} ions may be located in the Lewis^x moiety.

Further studies on the nature of ligand recognition by E-selectin revealed that a bivalent ligand consisting of two sialyl Lewis^x groups anchored onto ethyl β-galactoside by β-1,3- and β-1,6-linkages was five times better at blocking adhesion ($IC_{50} = 0.4$ mM) than monovalent SLe^x. This observation suggests the possibility of a multivalent ligand–receptor interaction.[314] All these activities were measured in vitro based on an enzyme-linked immunosorbant assay (ELISA). The level of in vivo activity of sialyl Lewis^x is, however, not very clear. The IC_{50} for protecting lung injury in rats appears to be, for example, about 1 μM.[315] While the structure of the E-selectin–ligand complex and the role of Ca^{2+} in the ligand binding are still not known, further experiments with defined multivalent ligands or mimetics with appropriate spacers should clarify the nature of E-selectin-mediated cell adhesion and may suggest new approaches to the discovery and development of antiadhesion molecules. Of particular interest is the development of non-carbohydrate molecules to mimic the topography of the sialyl Lewis^x binding region composed of carboxylate, galactose, and fucose.



The glycosidic bonds in SLe^x, SLe^x glycal, and Le^x can be formed enzymatically with glycosyltransferases. Introduction of a sulfate group to the 3′-position of Le^x with a sulfate-transfer enzyme coupled with regeneration of PAPS for large-scale process, however, has not been developed. The synthesis of the bivalent oligosaccharide ligand containing two SLe^x groups was very straightforward, starting with a chemically prepared trisaccharide followed by three glycosyltransferase reactions (Scheme 59).[314] Since the glycosyltransferase required for the

Scheme 59. Synthesis of a bivalent ligand containing two SLe^x groups. Two sugar residues are are incorporated in each enzymatic step.



synthesis of the Galβ1–3GlcNAc core unit of SLe^a is not readily available, this disaccharide was prepared chemoenzymatically from glucal by subtilisin-catalyzed acetylation followed by β-galactosidase-catalyzed galactosylation and azidonitration (Scheme 60).[150] The remaining glycosidic bonds were then formed with appropriate glycosyltransferases. Another SLe^x analog derived from SLe^x glycal was prepared by chloroperoxidase-catalyzed halohydration (Scheme 61).[316] This halogenated SLe^x may have the same activity as SLe^x, since the active conformation should not change. Although the halohydration is, in general, not stereoselective, the enzymatic halohydration of sialic acid glycal is regio- and stereoselective, giving 3-bromosialic acid with the bromide in the axial position. Presumably a bound hypobromite intermediate is involved.

It is noteworthy that though enzymatic synthesis of oligosaccharides is potentially useful for large-scale processes, the method is quite limited, as many oligosaccharide analogs cannot be prepared enzymatically. Synthesis of modified oligosaccharides thus requires the use of chemical glycosylation.[317] The scope and mechanism of recently developed glycosyl phosphites in glycosylation[318] has been examined in detail,[319] and the

method appears to be particularly effective for sialylation (Scheme 62) and fucosylation. Mechanistic study of the glycosylation reactions indicates that triflic acid is involved in the activation when trimethylsilyl trifluoromethanesulfonate (TMSOTf) is used in catalytic amounts (Scheme 63).[319]

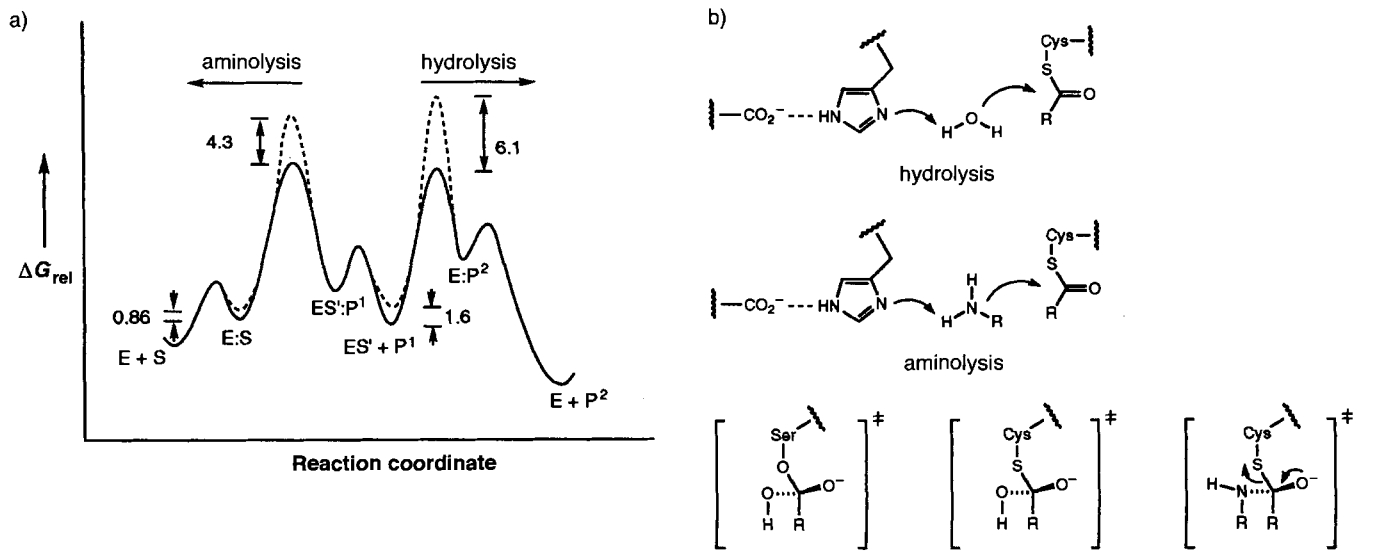
6. Glycopeptide Synthesis and Glycoprotein Remodeling

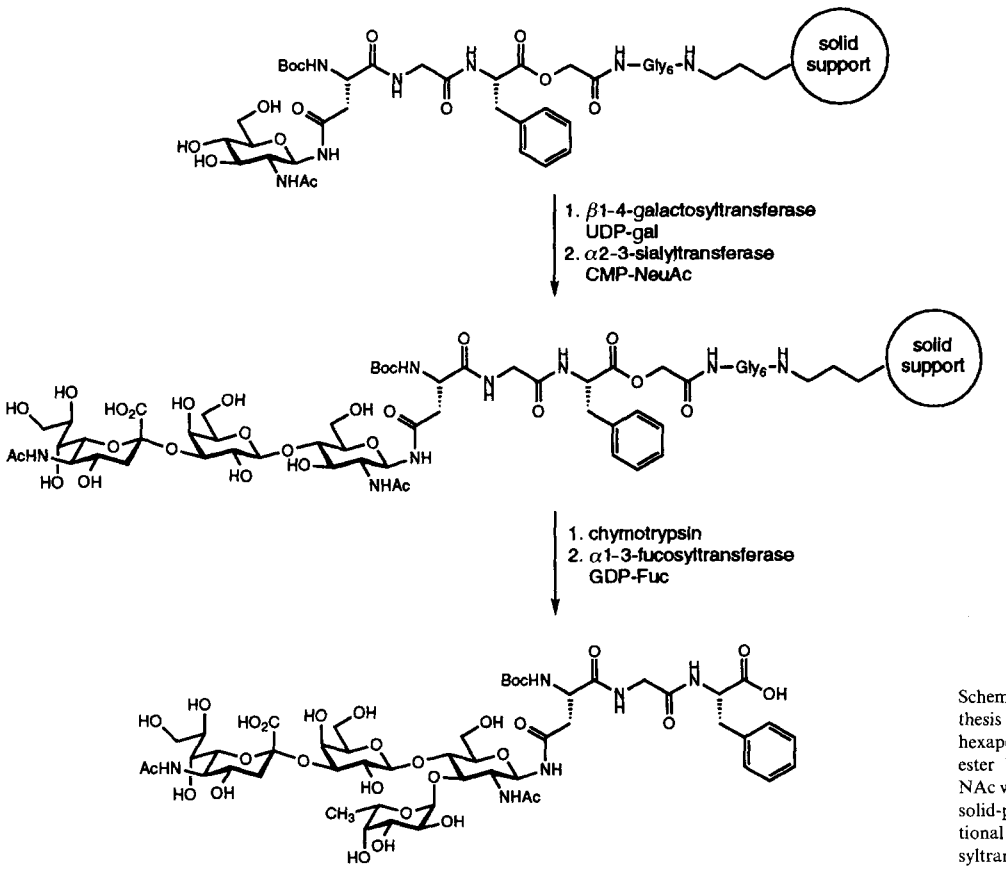
A number of the proteins of interest as human pharmaceuticals (tissue plasminogen activator, juvenile human growth hormone, CD4) are glycoproteins. There is substantial interest in developing methods that will permit modification of oligosaccharide



structures on these glycoproteins by removing and adding sugar units ("remodeling") and in making new types of protein-oligosaccharide conjugates.[320, 321] The motivation for these efforts is the hope and that modification of the sugar components of naturally occurring or nonnatural glycoproteins might increase serum lifetime and the solubility of the drug, decrease antigenicity, and promote uptake by target cells and tissues.

Enzymes are feasible catalysts for manipulating the oligosaccharide content and structure of glycoproteins. The delicacy and polyfunctional character of proteins and the requirement for high selectivity in their modification indicate that classical synthetic methods will be of limited use. The major obstacle to the widespread use of enzymes for glycoprotein remodeling and generation is the lack of availability of many of the glycosyl transferases that are plausible candidates and the uncertainty whether glycosyltransferases that probably act on unfolded or partially folded proteins in vivo will be active at the surface of a completely folded protein.

A useful method for glycopeptide synthesis incorporates glycosylamino acids into oligopeptides chemically[322] or enzymatically[323] and subsequently introduces additional sugars with glycosyltransferases. Enzymatic formation of peptide and glycoside bonds is quite effective, because both procedures can be carried out in aqueous solution, thus minimizing protection/deprotection steps in peptide synthesis. Glycosyl amino acids can be used as the P_2, P_3, P'_2, and P'_3 residue in subtilisin-catalyzed-glycopeptide segment condensation. Using a thermostable variant developed by site-directed mutagenesis in which the active-site Ser is converted to Cys, the enzymatic coupling of glycopeptide segments can be carried out efficiently at 60 °C in aqueous solution (Scheme 64).[323] The enzyme prefers aminolysis over hydrolysis by a factor about 10000, and kinetics studies indicate that the selectivity arises because the acyl–enzyme intermediate reacts more selectively with the amine nucleophile than the wild-type enzyme (Scheme 65).[323] Chemical synthesis of glycopeptides followed by enzymatic glycosylation, however,



Scheme 64. Synthesis of a glycopeptide with engineered subtilisins and galactosyltransferase. The thiosubtilisin mutant contains the following changes: Met50 → Phe, Asn76 → Asp, Gly169 → Ala, Asn218 → Ser, Ser221 → Cys.

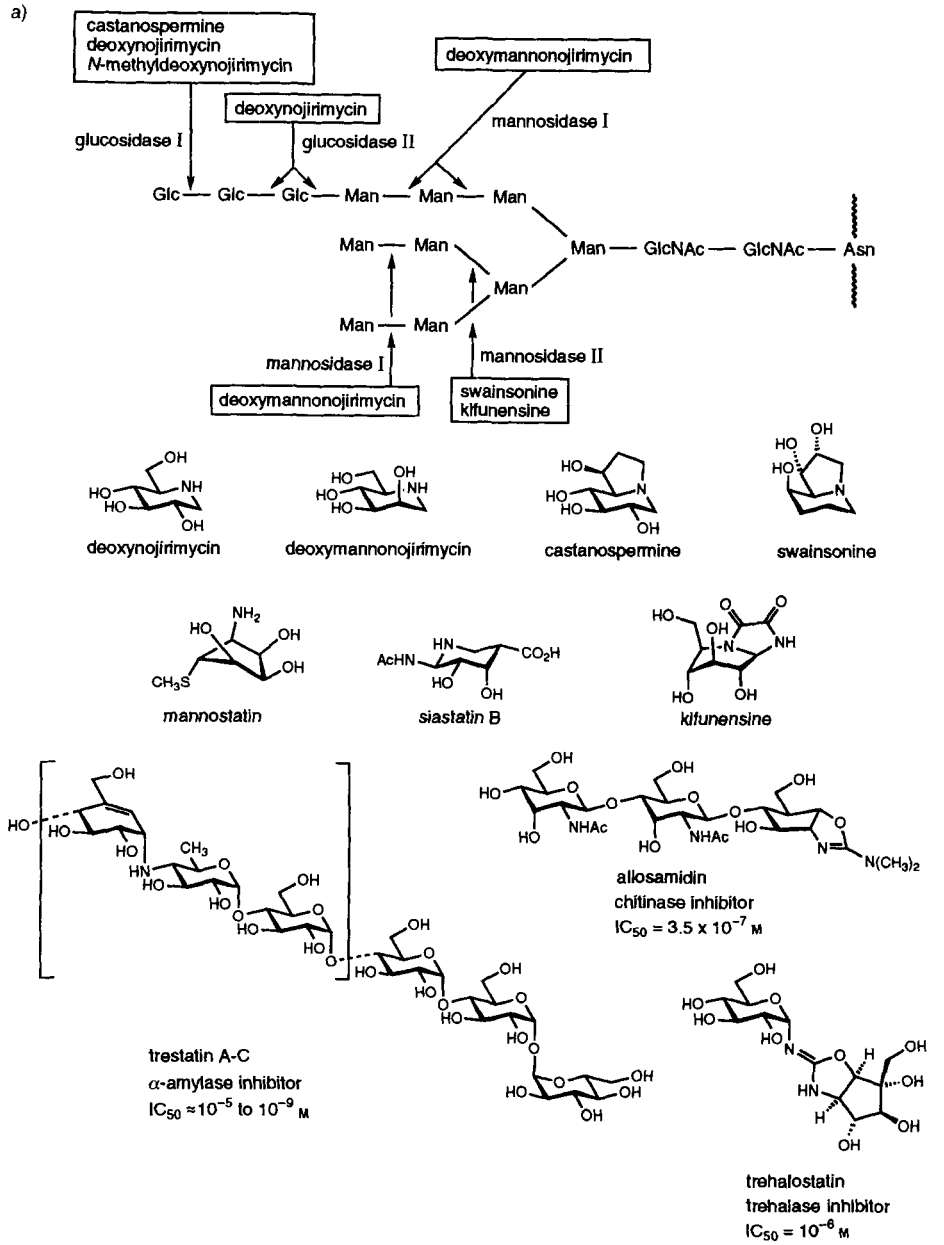
works very well on an aminopropylsilica support.[324] A key element in this strategy is the attachment of a proper acceptor–spacer group with a selectively cleavable bond. The method allows rapid iterative formation of peptide and glycosidic bonds in organic and aqueous solvents, respectively; the glycopeptides are released from the support enzymatically (Scheme 66).

charged transition-state structure is generated by general-acid- and general-base-catalysis, presumably from carboxylic acid and carboxylate residues in the active site of the enzyme. Compounds which resemble the transition-state structure of the glycosidic cleavage or glycosyltransfer reactions are therefore potent inhibitors of the enzyme. The aza sugars described previously seem to be inhibitors resembling the transition state, as they

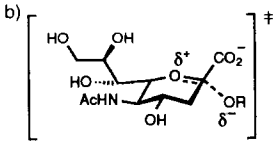


Scheme 66. Solid-supported chemoenzymatic synthesis of a glycopeptide containing SLe^x. The hexapeptide spacer (Gly_6), chymotrypsin-sensitive ester linkage, and oligopeptide-containing GlcNAc were attached to the support by conventional solid-phase synthesis (chemical coupling). Additional sugar residues were then added with glycosyltransferases.

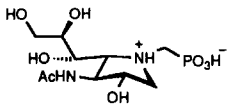
7. Inhibition of Glycosidases and Glycosyltransferases

Glycosidases and glycosyltransferases are important enzymes for the processing of various oligosaccharide-containing glycoproteins and glycolipids. The profound impact of these enzymes on life processes has made them desirable targets for inhibition.[15, 16] Glycoprocessing inhibitors have been used to treat diabetes and other metabolic disorders, and have been implicated in the blocking of infection, inflammation, and metastasis. Some representative examples of naturally occurring and synthetic inhibitors of glycosidases and glycosyltransferases are presented in Schemes 67 and 68.[325] The mechanisms of the reactions with glycosidases and to some extent with glycosyltransferases have been studied.[326] It is generally postulated that the reactions proceed through a half-chair (or twist-boat) transition state with substanial sp^2 character at the anomeric carbon. This positively

show potent inhibition activities. Both five- and six-membered aza sugars can be easily prepared by the aldolase reactions, and they can be considered as building blocks for the development of sequence-specific glycosidase or glycosyltransferase inhibitors. The synergistic inhibition of α1–3fucosyltransferase with the fucosyl-like five-membered aza-sugars and GDP (Scheme 69, see p. 542)[179] is of particular interest, as it provides a new direction in the design of glycosyltransferase inhibitors. Another interesting observation is that most naturally occurring glycosyltransferase inhibitors do not have he pyrophosphate moiety. Perhaps sugars (for instance, in tunicamycin) or peptides can be used to mimic the pyrophosphate–Mn^{2+} component of the sugar nucleotide in glycosyltransferase reactions. Other mimics of pyrophosphate–Mn^{2+} complexes may be useful as a linker between aza sugars and nucleosides for the development of aza sugar nucleosides as synthetic glycosyl-

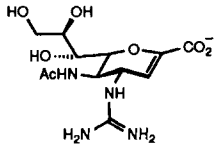


Scheme 67. a) Naturally occurring glycosidase inhibitors and their site of inhibition in the biosynthesis of glycoproteins [325a].



transferase inhibitors. The issue of stability and bioavailability associated with sugar-based inhibitors will have to be examined further if carbohydrates are to be drug candidates. The discovery that C-linked glycosides possess the same conformation as the parent O-linked glycosides[327, 328] is important, because C-linked glycosides may be metabolically stable. Similarly, C-linked aza glycosides, guanido-sugar-containing glycosides,[329] and O-linked carbocycles may have a desirable conformation and may be useful as sequence-specific endoglycosidase and glycosyltransferase inhibitors (Scheme 70, see p. 542). With regard to the preparation of inhibitors to block the multivalent interaction of receptors or enzymes with their ligands or inhibitors, the phospholipase D-catalyzed transphosphatidylation[330] may offer a new method for the preparation of multivalent inhibitors, as phospholipids tend to form a liposome by self-assembly (Scheme 71, see p. 543).

8. Future Opportunities



The pace of development of carbohydrate-derived pharmaceutical agents has, in general, been slower than that of more convenient classes of materials, undoubtedly partly because of the difficulties in the synthesis and analysis of carbohydrates. At least three areas of biology and medicinal chemistry have redi-

rected attention to carbohydrates. First, interfering with the assembly of bacterial cell walls[331] remains one of the most successful strategies for the development of antimicrobials. As bacterial resistance to the classical β-lactam antibiotics, the penams and cephams, becomes more widespread, there is increasing interest in disturbing with the biosynthesis of the characteristic carbohydrate components of the cell wall, especially KDO, heptulose, lipid A, peptidoglycans and related materials. Interest in cell-wall constituents is also heigtened by their relevance to vaccines and to starting point for the development of non-protein immunomodulating compounds. Second, cell-surface carbohydrates are central to cell–cell communication, cell adhesion, infection differentiation, and development. They may be relevant to abnormal states of differentiation, such as those

characterizing some malignancies. Synthesis of these cell-surface ligands on large scales by enzymatic or chemoenzymatic methods for therapeutic evaluation are beginning to be realized. The enzymes involved in the biosynthesis of these ligands also represent interesting targets for therapeutic development. Third, the broad interest in diagnostics has finally begun to generate interest in carbohydrates as markers of human health. In addition, there are a number of other possible applications of carbohydrates (for example, as dietary constituents, as antivirals, or as components of liposomes) that warrant attention. Enzymatic methods of synthesis will contribute to further research in all of these areas by rendering carbohydrates more accessible.

Scheme 71. Synthesis of phospholipid-inhibitor conjugates catalyzed by phospholipase D (PLD). They self-assemble into a liposome bilayer with numerous inhibitors on the surfaces (a simple system for the synthesis of polyvalent ligands and inhibitors). Examples shown are an azasugar, a nucleoside, RGD peptide (the ligand of integrin), and a sialic acid bound to a phospholipid (influenza hemagglutinin receptor).

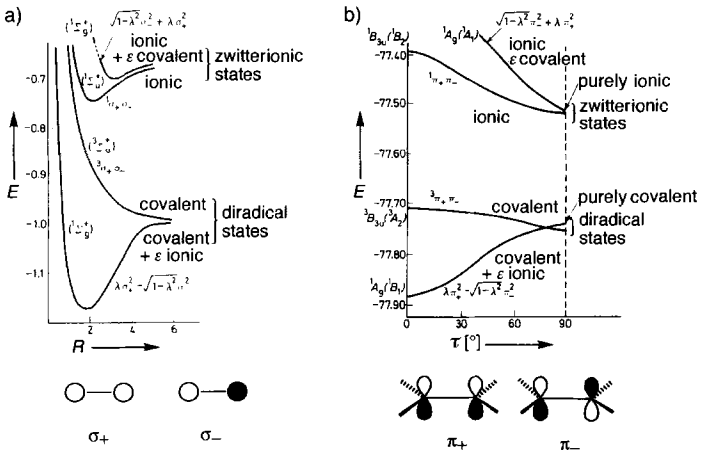
Direct Spectroscopic Evidence for a Hitherto Elusive "Zwitterionic" Excited State

Lutz H. Gade*

Direct experimental support for a theoretical concept in science is sometimes obtained in an area for which it was not originally proposed. The case we describe here is the simplest example of chemical bonding, the interaction of two electrons in weakly coupled orbitals on two atomic centers. As early as 1932 Mulliken analyzed the situation in the π-orbital domain of twisted ethylene[1] and a few years later the (related) electronic structure of the σ domain in "stretched" dihydrogen (i.e. an H_2 molecule in which the interatomic distance is increased well beyond its equilibrium value).[2] In both cases four electronic states are specified (Fig. 1): two low-energy "diradical" states



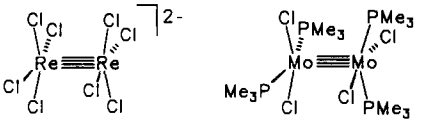


Fig. 1. The four electronic states of the $\sigma(1s)$- and $\pi(2p)$ manifolds in H_2 and ethylene, respectively. a) "Stretching" of H_2. VB description of the four states (atomic orbitals centerd on atoms A and B): $^1\Sigma_g^+ = {}^1[1s(A)1s(B)]$, $^3\Sigma_u^+ = {}^3[1s(A)1s(B)]$, $^1\Sigma_u^+ = {}^1[1s(A)1s(A) - 1s(B)1s(B)]$, $^1\Sigma_g^+ = {}^1[1s(A)1s(A) + 1s(B)1s(B)]$. b) "Twisting" of C_2H_4. In weakly coupled systems (H_2 at $R > 4a_0$; twist angle $\tau \approx 90°$) the four states may be clearly distinguished as either of diradical or zwitterionic nature (from ref. [3a]). E in Hartree, R in a_0.

(singlet and triplet) with the electrons in separate orbitals, and two higher energy "zwitterionic" singlet states.[3] The latter are derived from the symmetric and antisymmetric linear combination of wave functions representing the pairing of the two electrons in the two orbitals. It should be noted that these zwitterionic states do not have a net dipole moment in homosymmetric molecules. The fact that one of the states would represent the ground state in a real zwitterion is the reason for this potentially confusing terminology. However, in a polar environment (solution) these states may be subject to "sudden polarization" and display zwitterionic reactivity.[3]

Whereas the diradical states have been comprehensively studied over the past decades and provide the foundation for the description of the extensive organic chemistry of biradicals, the zwitterionic states have proved to be far more elusive (though invoked, for example, to explain the photoisomerization and cyclization of 1,3-dienes).[4] Recent studies of the solvent and substituent effects on the lifetime of the transient species generated by $\pi \rightarrow \pi^*$ excitation of alkenes have provided some indirect evidence for the existence of the postulated manifold of zwitterionic excited states.[5] However, its direct detection has to date not been achieved with these systems. The short lifetime and thus the transitory nature of the weak coupling, which is characteristic of the zwitterionic states during the stretching of bonds preceding dissociation or the twisting of bonds in isomerizations, is the main reason for this situation.

D. G. Nocera and co-workers have now reported the direct spectroscopic detection of the zwitterionic states in a weakly coupled two-electron two-orbital system.[6] As their object of study they chose the dinuclear complex **2** with a quadruple

1 **2**

metal–metal bond, which was first synthesized and characterized by F. A. Cotton et al.[7] What is it that almost predestines this particular compound for an investigation into the nature of the zwitterionic states? First of all, systems with a quadruple bond have a nontransitory weakly coupled set of orbitals virtually built into them: the δ and δ^* molecular orbitals derived from the d_{xy} metal orbitals. Their spatial arrangement is structurally reinforced by the σ and π bond framework which maintains their weak coupling. Secondly, the relatively bulky phosphane ligands sterically lock the system in its ground state conformation, and therefore the orientation of the d_{xy} orbital is

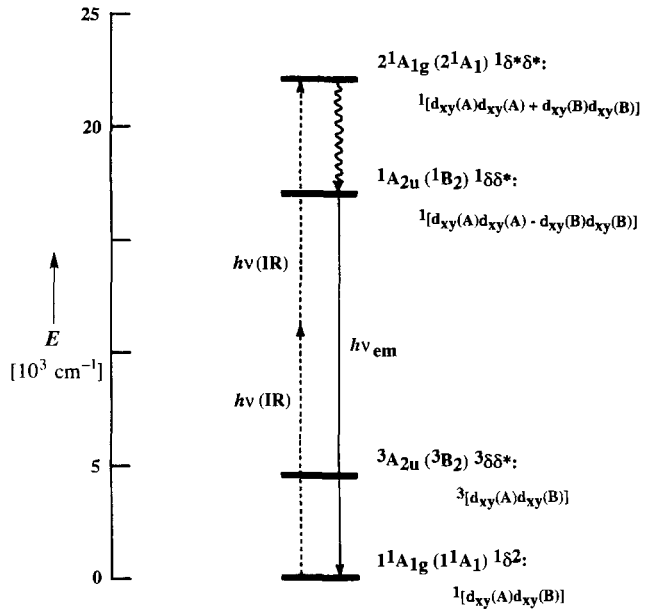
fixed. The choice of the PMe_3-substituted complex thus avoids complications arising from internal rotation about the metal–metal axis in an excited state of the molecule, as observed for instance for $[Re_2Cl_8]^{2-}$ (**1**) in solution. Finally, previous work performed in the groups of H. B. Gray,[8] F. A. Cotton,[9] and others[10, 11] has provided a reliable assignment of relevant bands in the UV/Vis absorption and emission spectra of several quadruply bonded compounds, which developed simultaneously with the theoretical understanding of the electronic structure[*] of these species.[12]

A qualitative energy level diagram showing the four-state δ manifold of M≡M complexes of D_{4h} symmetry (D_{2d} in the case of **2**) is displayed in Figure 2. The energy gap between the



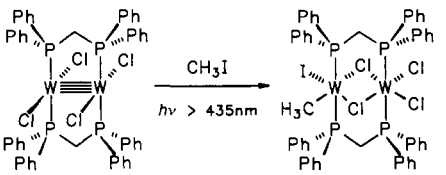


Fig. 2. A qualitative energy level diagram for the δ-δ* orbital manifold based on a valence bond model (orbitals centered on the two metal atoms A and B). The states are designated by their symmetry labels in D_{4h} and D_{2d} symmetries (the latter in brackets). The two-photon excitation (by absorption of two near-infrared photons) into the zwitterionic 2^1A_{1g} (2^1A_1) state is indicated, followed by internal conversion to the highly emissive $^1A_{2u}$ ($^1B_2$) state. The red fluorescence ($h\nu_{em}$) from this state was detected in the fluorescence experiment with two-photon excitation (adapted from ref. [6]).

ground state 1^1A_{1g} (1^1A_1) and the triplet state $^3A_{2u}$ ($^3B_2$) in **2** has been extrapolated recently from magnetic measurements[15] as well as from an elegant application of paramagnetic ^{31}P NMR spectroscopy to a series of related systems.[16] The low-frequency band in the UV/Vis spectra of the quadruply bonded dinuclear compounds corresponds to the excitation into the dipole-allowed zwitterionic $^1A_{2u}$ ($^1B_2$) state. In "sterically locked" complexes such as **2** relaxation into a twisted excited singlet state (as in **1**) is not feasible; the $^1A_{2u}$ ($^1B_2$) state therefore shows instantaneous and intense emission. The second zwitterionic excited singlet state corresponds approximately to a $(\delta^*)^2$ configuration (neglecting configuration interaction with the ground state 1^1A_{1g} (1^1A_1)) and is thus not allowed according to the selection rules for one-photon, electric-dipole transitions. Nocera and co-workers located this state in **2** by two-photon excitation fluorescence spectroscopy. Upon excitation into the 2^1A_1 state the system undergoes transition to $^1B_2$; the emission from the latter state is then detected. That the primary excited state is indeed populated by a two quantum transition was established by the dependence of the fluorescence intensity on the square of the incident excitation intensity.[17] The polarization ratio ($\Omega = I_{circ}/I_{lin} < 1$; circ, lin = circular and linear polarized irradiation) of the excitation fluorescence spectrum furthermore indicates that the excited state is indeed of $^1A_1$ symmetry,[18] as required for the second zwitterionic state of the investigated system. The small $2^1A_1 - {}^1B^2$ energy gap of 4800 cm^{-1} relative to the $^1B_2 - 1^1A_1$ gap of 17100 cm^{-1} indicates the very ionic nature of the doubly excited state 2^1A_1 (the authors give a preliminary estimate of 68%). With both zwitterionic states of the δ-δ* manifold now unambiguously located, the four-state structure of a weakly coupled two-electron two-orbital sytem has been established for the first time.

What is the significance of this study beyond the direct verification of an important model for chemical bonding dating back to the very beginning of quantum chemistry? For the inorganic photochemist it sheds new light on the potential photochemical reactivity of the metal–metal quadruple bond. The pairing of two electrons on one metal center and two "holes" on an adjacent one predisposes this type of system for multielectron reactivity. Recent investigations by the same group give first indications of such a reactive pattern, for instance, the two-electron photoreduction of CH_3I by $[W_2(dppm)_2Cl_4]$ [Eq.(a)].[19]

(a)

These recent developments have shown that the metal–metal quadruple bond continues to fascinate the chemical community even three decades after it was discovered by F. A. Cotton et al.[20]

[*] It should be mentioned in this context, however, that an "isolated δ-δ* manifold" model is entirely inadequate for a *quantitative* theoretical description of the δ-δ* photochemistry, as has been recently discussed by Bursten and Clayton [13] (and, previously, by others [14]). It should therefore be taken for what it is worth: a convenient approximation to the actual chemical bonding in dinuclear complexes with quadruple metal–metal bonds. The accurate calculations presented in ref. [12] include configuration interaction with states outside the δ-δ* manifold.

Conical Intersections and the Mechanism of Singlet Photoreactions

Martin Klessinger*

The reaction pathway of a nonadiabatic photochemical reaction begins on the potential energy surface of the excited state (S_1) in the Franck–Condon region or at a spectroscopic minimum of the reactant and ends at the product minimum on the ground-state surface (S_0). The two stages on the S_1 and S_0 surface are separated by a funnel[1] at which radiationless decay from the excited state to the ground state becomes possible (Fig. 1). For a long time it was believed that the funnels mostly correspond to surface crossings (or touchings) that are at least weakly avoided, but recent work has shown that for a great number of inorganic[2] and organic[3] systems the crossings are actually unavoided and correspond to true conical intersections.[4] Nowadays it appears that conical intersections are a common feature in most nonadiabatic singlet photoreactions.

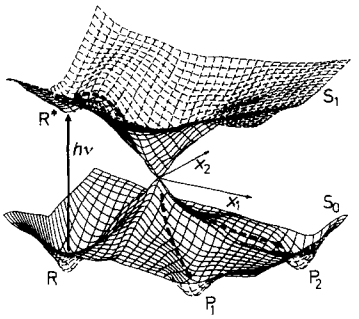

Fig. 1. Schematic representation of the potential energy surfaces of the ground state (S_0) and the excited state (S_1) of a nonadiabatic photoreaction of reactant R. Depending on the way the classical trajectories enter the conical intersection region, different ground-state valleys, which lead to products P_1 and P_2, can be reached.

A conical intersection is defined as follows: Two states, even if they have the same symmetry, intersect along an $(F-2)$-dimensional hyperline as the energy is plotted against the F nuclear coordinates ($F = 3N-6$).[5] While for any point of the $(F-2)$-dimensional intersection space the energies of the two states are the same, the degeneracy is lifted along the two remaining linearly independent coordinates $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. Thus, when the energy of the two states is plotted against these two geometrical variables (they are combinations of bond distances, angles, etc.), the corresponding energy surfaces have the shape of a double cone, as shown in Figure 1.

The gradient difference vector $\boldsymbol{x}_1$ is defined by Equation (a). In this direction the difference in the slopes of the upper and

$$\boldsymbol{x}_1 = \partial(E_0-E_1)/\partial\boldsymbol{q} \qquad \text{(a)}$$

the lower surface is largest. The nonadiabatic coupling vector $\boldsymbol{x}_2$ is given by Equation (b). This is the direction of nuclear dis-

$$\boldsymbol{x}_2 = \langle\Psi_0|\partial\Psi_1/\partial\boldsymbol{q}\rangle \qquad \text{(b)}$$

displacement that mixes the states two adiabatic wave functions at the cone point the best. If Ψ_0 and Ψ_1 are of different symmetries at the apex of the cone, $\boldsymbol{x}_2$ is the symmetry-lowering coordinate that permits them to mix. The vectors $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are often nearly orthogonal. The gradient of neither of the touching surfaces is zero at the tip of the cones, as it would be for a true stationary point. Rather, it is the projection of the gradient onto the $(F-2)$-dimensional subspace orthogonal to $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ that goes to zero when the geometry of the conical intersection is optimized. Therefore, in the F-dimensional space, gradient-based search routines will not recognize the bottom of the funnel as a minimum, although it represents the lowest energy point on that surface (unless the funnel is strongly tilted).

From a mechanistic point of view a conical intersection funnel plays a similar role in a photochemical reaction as the transition state in a thermal reaction.[3] Both describe the geometry of the "reactive conformation" of the system. For a thermal reaction, the transition state corresponds to the point of the

potential energy surface where the probability of passage from the reactant well to the product well is the largest. Similarly, in a photochemical reaction, a conical intersection represents the region of the excited-state surface where the probability of decay to the ground state is the largest. The initial motion after passage through a transition state is characterized by a single vector q_R (the normal coordinate of the imaginary vibrational frequency), that corresponds to the reaction path through the saddle point. In contrast, a conical intersection provides two linearly independent reaction-path directions x_1 and x_2. In the immediate vicinity of the apex of the cone the reaction path can follow any direction in the x_1, x_2 plane and may reach different reaction valleys that develop on the S_0 surface.

Thus, for a nonadiabatic photoreaction, the dynamics of nuclear motion can be described as shown schematically in Figure 1. After absorption of a photon, the system moves on the excited-state surface toward a funnel along classical trajectories following the bottom of valleys and possibly passing over barriers. In this region the energy separation between excited and ground state will be too large to allow a surface jump, until eventually the system enters the conical intersection region, where the energy gap is small and consequently the probability of a surface jump is large. The trajectories passing exactly through the tip of the cone proceed undisturbed. They follow the typically quite steep slope of the cone wall, thus converting electronic energy into energy of nuclear motion. The acceleration will often be in a direction close to the vector x_1. Trajectories that just miss the cone tip have some probability of staying on the upper surface, and some probability of jumping to the lower surface. In this latter case, an amount of energy equal to the height of the jump is converted into the component of motion in a direction given by the vector x_2 (nonadiabatic coupling). The determination of quantum yields of the various possible products requires the knowledge of the exact components of motion in the x_1 and x_2 directions. This, in turn, is available only from detailed dynamics calculations, which so far have been performed for simple model systems only.[6]

The most important consequence of the refinement of the original Oosterhoff model[7] is the fact that the $S_1 \rightarrow S_0$ decay does not occur at the "pericyclic minimum" (which, in fact, can be a transition state between two conical intersections, which might be equivalent by symmetry, cf. Fig. 2), but rather at geometries of lower symmetry.[3a] Efficient algorithms have been developed for locating the points of minimum energy within the $(F-2)$-dimensional intersection space and for determining the exact geometry at the conical intersections.[8] Geometries at which conical intersections are likely to occur may be predicted by means of simple models. From the two-electron—two-orbital model for biradicaloids,[9] for instance, it follows that certain perturbations δ that induce a splitting of those orbitals that are degenerate in the perfect biradical will lower the energy separation between the S_0 and S_1 states. For a value $\delta = \delta_0$ that is referred to as the critically heterosymmetric case this separation becomes zero, which results in a conical intersection.

Thus, for 90°-twisted ethylene the p orbitals are orthogonal and degenerate; the pericyclic geometry corresponds to a perfect biradical with a very large energy gap between S_1 and S_0. Replacement of one of the CH_2 groups by a more electronegative group transforms the perfect biradical into a heterosymmetric biradicaloid, and the 90°-twisted formaldiminium ion $CH_2{=}\overset{+}{N}H_2$ represents the critically heterosymmetric case. The energy gap is zero, and a conical intersection results.[10] In the case of the photochemical [2 + 2] cycloaddition, a rhomboidal distortion of the pericyclic geometry differentiates the otherwise degenerate energies of the localized nonbonding orbitals of the cyclobutadiene-like perfect biradical. This again decreases the energy gap, and eventually a conical intersection is reached (Fig. 2). The same conclusion is reached on the basis of a qualitative VB model that Bernardi, Olivucci, Robb and coworkers[11] developed for predicting and discussing the geometries of conical intersections and verified by ab initio calculations.[3a] For the photoreactions of butadiene[3j] they determined geometries of the conical intersection region that correspond to a distorted quasitetraradical, which is characterized by a combination of peripheral and diagonal interactions of the reactive orbitals (Fig. 3). The suggestion that the return to S_0 occurs through a conical intersection at a distorted pericyclic geometry involving diagonal interactions was first proposed on the basis of model calculations for H_4.[12] The various ways of recoupling the electrons of the tetraradical depicted in Scheme 1 demonstrate how different photoproducts may evolve from the same funnel.[3j,k]

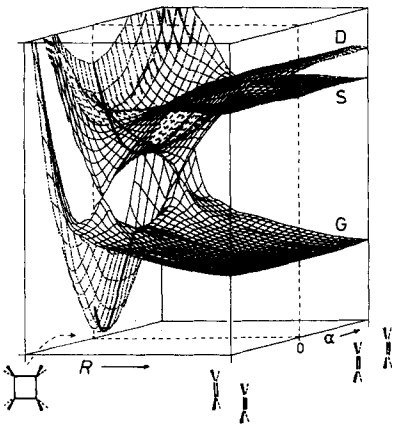

Fig. 2. Schematic representation of the potential energy surfaces of the singlet states for the photodimerization of ethylene, plotted as a function of the intermolecular distance R and the angle α that measures the deviation from the rectangular arrangement. G, S, and D label the surfaces described in the 2×2 CI model by the ground state, and the singly and the doubly excited configuration, respectively. The potential energy curves shown for $\alpha = 0$ correspond to the Oosterhoff model.

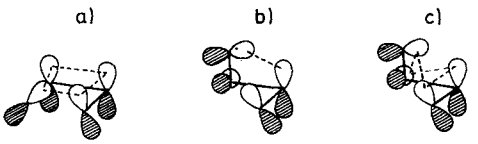

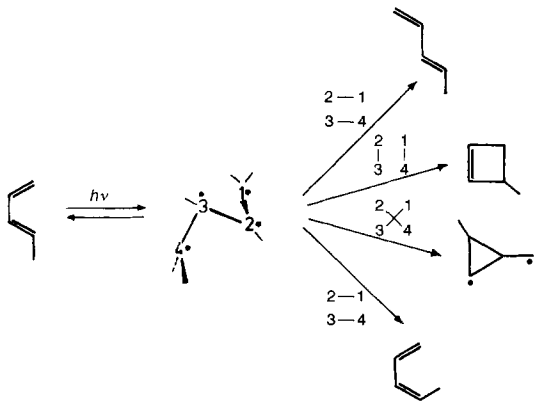

Fig. 3. π Orbital interactions in butadiene. a) Peripheral interactions along the perimeter at high-symmetry disrotatory pericyclic geometry; b) diagonal and c) peripheral interactions at the geometry of the conical intersection.

Recently, real conical intersections have been located by means of ab initio calculations for a large variety of photoreactions.[2,3] This demonstrates that the occurrence of this topological phenomenon, previously believed to be quite improbable, is

Scheme 1. Possible courses for the photoreaction of pentadiene after formation of the tetraradical intermediate.

more likely to be the rule than an exception.[13] Substituents may affect 1) the excited-state reaction pathway toward the funnel, 2) the geometrical structure at the conical intersection, and 3) the dynamics of the decay and the ground-state reaction path. First studies of substituent effects in butadiene photochemistry[31] and in photochemical [2 + 2] cycloaddition[14] suggest that all three effects may be important.

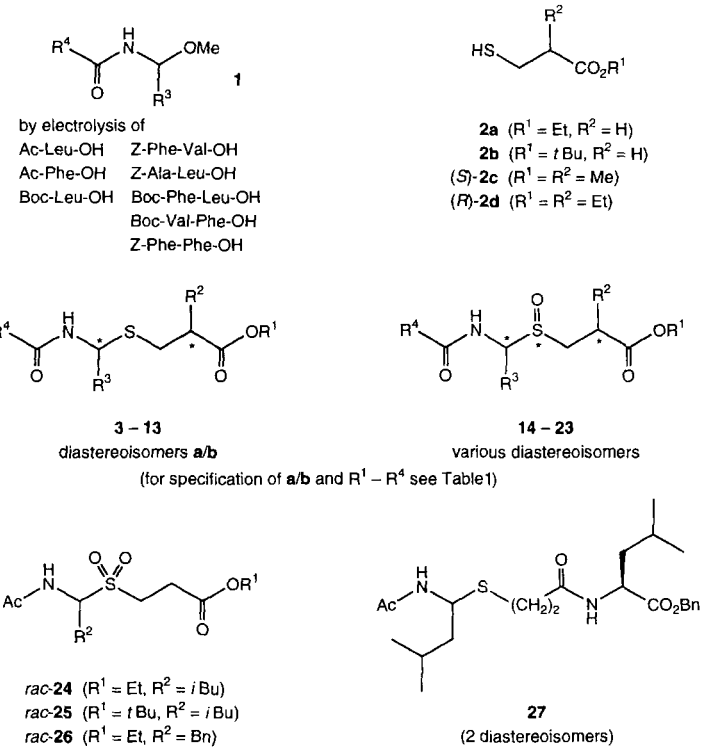
Synthesis of Ψ[SCH_2]-, Ψ[$SOCH_2$]-, and Ψ[SO_2CH_2]-Peptide Isosters*



Thimo Sommerfeld and Dieter Seebach*

Though α-aminophosphonamides (**A**) are stable building blocks in peptides and serve as analogues of tetrahedral intermediates of peptide cleavage,[1a] the sulfur derivatives **B** could not be synthesized until now, despite many attempts. The instability of α-aminosulfonamides can be explained by an elimination, as indicated in Scheme 1[1b] (cf. formation and cleavage of hydrogensulfite adducts of aldehydes and ketones). Obviously, this complication is not present in the β-aminosulfonic acid derivatives **C**.[2] We have now prepared new types of sulfur-containing peptide isosteres[3] of type **D** ($n = 0, 1, 2$), in which a subtle interplay between the donor ability of the RCONH group and the nucleofugality of the SO_nCH_2 group determines the stability (see **D** and Table in Scheme 1).

Scheme 1. Peptide analogues **A**–**D**, bearing phosphorus- and sulfur-containing groups in the backbone. The stability of the sulfur derivative **D** described herein depends upon the oxidation state at sulfur and upon the nature of the acyl group at nitrogen. RCO-Xaa represents an N-protected amino acid moiety and ROCO a carbamate protecting group; for examples see Scheme 2, Table 1, and Experimental Procedure.

As starting materials we used the *N,O*-acetals **1**, which are easily accessible from amino acids or N-protected peptides by anodic oxidative decarboxylation.[4] Lewis acid mediated substitution of MeO for RS in the acetals **1** by methyl, ethyl, or *t*-butyl β-mercaptocarboxylates **2**[5] to yield the sulfides **3**–**13** (**D**, $n = 0$) and subsequent oxidation with tetrabutylammonium peroxomonosulfate (TBA oxone)[6] led to the sulfoxides **14**–**23** (**D**, $n = 1$) and sulfones **24**–**26** (**D**, $n = 2$) (see Table 1 and Experimental Procedure). In addition to the peptide analogues **3**–**26**, which bear the sulfur-containing δ-amino acid residue at the C-terminus, we also prepared **27** with this moiety at the N-terminus.

Scheme 2. Building blocks **1** and **2**, and products **3**–**13** with sulfide structure, **14**–**23** with sulfoxide structure, and **24**–**27** with sulfone structure ("*N,S*-, *N,SO*-, and *N,SO*$_2$-acetal structure"). The conditions for transacetalization (**1** → **3**–**13**) and oxidation (**3**–**13** → **14**–**26**) are given in the text, in the Experimental Procedure, and in Table 1. Bn = benzyl.

The reaction of **1** with **2**, which involves *N*-acyliminium ions as intermediates, is best performed in CH_2Cl_2 at −78 °C with $BF_3 \cdot OEt_2$ as the Lewis acid. As with other nucleophiles,[4] this reaction is not diastereoselective. The epimeric sulfides (*N,S*-acetals) **7a**–**13a** and **7b**–**13b** were formed in ratios ranging from 4:3 to 1:2 and in yields usually exceeding 90%. They could be separated and purified by chromatography (though with heavy losses) or by recrystallization. In the subsequent oxidation step, oxone proved to be superior to other reagents tested: the reaction in CH_2Cl_2 stops at low temperature (−75 °C, 30–60 min) after formation of the sulfoxide. The sulfones[7] are formed under more "drastic" conditions (excess oxone, 1–2 h, −30 to −20 °C); however, only the N-acetyl derivatives **24**–**26** could be isolated in pure form, albeit in poor yields.

[a] Yield of crude product (by NMR spectroscopy). [b] Yield after chromatography. [c] Diastereoisomers separated by chromatography. [d] Separated by fractional crystallization. [e] Not separated, but pure according to elemental analysis after chromatography or precipitation. [f] M.p. 86 °C. [g] M.p. 88–89 °C. [h] Major product: m.p. 146–147 °C, $[\alpha]_D = +36.5$ ($c = 1$, MeOH). [i] For details see Experimental Procedure.

Often one of the two possible epimeric sulfoxides was formed very selectively (see last column in Table 1). The crude sulfides **3**–**13** (mostly oily products) were pure enough (**4**, **5**, **9**, and **11**) for the oxidizing step to the sulfoxides or were used after chromatography.[8] At least one of the stereoisomeric sulfoxides could be purified in each case and was characterized by elemental analysis, optical rotation, melting point, and IR, NMR, and mass spectra.[9] The access to *both* diasteroisomers could be advantageous for possible drug research with this novel type of peptide analogues. We have not yet been able to determine the configuration of the acetal and of the sulfoxide center in the products **7**–**23**. Since a chemical correlation is impossible, we are trying to grow single crystals of the solid compounds for X-ray analysis.

Experimental Procedure

12a, **12b**: To a solution of the *N,O*-acetal **1** (2.00 g, 4.62 mmol, from Z-Phe-Phe-OH, see Scheme 2) and the thiol **2c** (1.24 g, 9.24 mmol) in CH_2Cl_2 (40 mL) at −78 °C under argon was added $BF_3 \cdot OEt_2$ (0.580 mL, 4.62 mmol). After consumption of the starting material (about 30 min, monitoring with thin layer chromatography (tlc)) a saturated solution of $NaHCO_3$ (a few mL) was added. The solution was washed with saturated solutions of $NaHCO_3$ and NaCl, dried ($MgSO_4$), and the solvent was removed under reduced pressure. The sulfide (*N,S*-acetal) **12** (2.00 g, 81%) was isolated as a mixture of two epimers in a 1:1 ratio (**12a** and **12b**), which were separated by fractional crystallization (Et_2O/hexane).

22 (two diastereoisomers): A solution of 1.24 g (2.32 mmol) of the more readily crystallizing epimer **12a** (m.p. 131–132 °C, $[\alpha]_D = -47.6$ ($c = 0.9$, MeOH)) in CH_2Cl_2 (15 mL) at −78 °C was treated with a solution of tetrabutylammonium peroxomonosulfate (1.77 g, 2.55 mmol) in CH_2Cl_2 (10 mL). After about 30 min (tlc control), H_2O and EtOAc were added. The solution was extracted with H_2O (twice) and a saturated solution of NaCl, and dried with $MgSO_4$. After evaporation of the solvent, the sulfoxide **22** (epimer ratio 4:1) was isolated in quantitative yield. The epimers were separated by fractional crystallization. Major product: m.p. 124–125 °C, $[\alpha]_D = -83.6$ ($c = 1$, MeOH); minor product: m.p. 126–129 °C, $[\alpha]_D = +115.2$ ($c = 0.5$, MeOH).

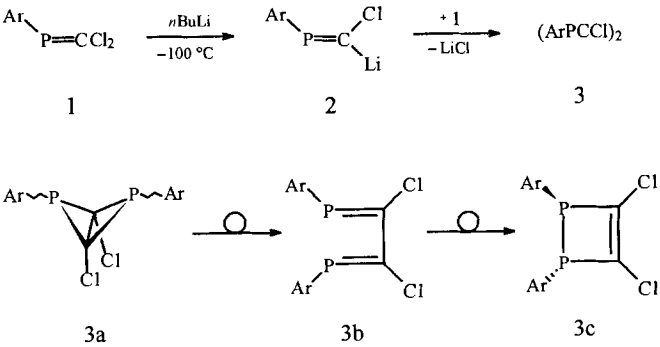
A P_2C_2 Four-Membered Ring with Unusual Bonding—Synthesis, Structure, and Ring Opening of a 1,3-Diphosphacyclobutane-2,4-diyl**

Edgar Niecke,* Andre' Fuchs, Fred Baumeister, Martin Nieger, and Wolfgang W. Schoeller

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday



The delocalization of six π electrons in a four-membered ring heterocycle of type **I** has been well documented for disulfur dinitride (A = N, B = S).[1, 2] Likewise for isoelectronic compounds of the types **II** and **III** (e.g. A = C; B = O, S **II** and A = C; B = N, P **III**, respectively) structures have been discussed which appear to allow a π delocalization.[2d, e, 3] However, the spectroscopic identification or even the isolation of

I II III

such species has to date[4] not been achieved owing to the energetically favored valence isomerizations (ring closure to the bicycle or ring opening[2d, e, 3]). We report here on the synthesis and structure of the first stable P_2C_2 heterocycle **III** (A = C, B = P), which can be considered as an opened form (orbital isomer[5a]) of the corresponding bicyclic system.[5b] In the context of investigations on carbenoids with P–C pπ bonding[6] we were interested in the reaction of the phosphanylidene carbenoid[7] **2** with aryl(dichloromethylene)phosphane[8] **1**, which could possibly provide a route to the only still unknown 2,4 isomer[10] in the series of diphosphabicyclobutanes.[9]

The reaction of **1** (Ar = 2,4,6-$tBu_3C_6H_2$) with *n*-butyllithium in the mole ratio 2:1 led to the product **3** with the desired composition (elemental analysis), which was isolated in good yield (63%) in the form of deep red crystals (Scheme 1). The symmetrical structure of the compound was confirmed by the chemical equivalence of the two phosphorus nuclei in the ^{31}P NMR spectrum both in solution and in the solid state (δ = 26.5; δ_{iso} = 26.1). However, the strong deshielding of the ^{31}P nuclei as well as the chemical shift of the ring carbon atoms in the olefinic region (δ = 98.8 J(C,P) = 51.5 Hz) of the ^{13}C NMR spectrum are not consistent with a 2,4-diphosphabicyclobutane **3a**. These findings indicate rather the presence of a 1,2-dihydro-1,2-diphosphete[11] (**3c**), which should be derived from valence isomerization from **3a** via a 1,4-diphosphabuta-1,3-diene (**3b**).[12]

Scheme 1. Ar = 2,4,6-$tBu_3C_6H_2$.

Thus, the result of a single-crystal structure analysis was the more surprising;[13] it shows the P_2C_2 unit of **3** in the crystal as a planar four-membered ring (∢ CPC 87.8(1)°, ∢ PCP 92.2(1)°), in which the substituents at the carbon and the phosphorus atoms each adopt a *trans* configuration (Fig. 1). The

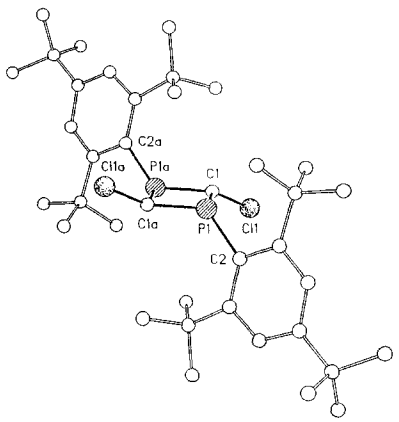


Fig. 1. Molecular structure of **3**. Selected bond lengths [pm] and angles [°]: C1–P1 174.9(3), P1-C1a 175.0(2), Cl1–C1 173.8(3), P1–C2 183.5(2); P1-C1-P1a 92.2(1), C1-P1-C1a 87.8(1), Cl1-C1-P1 127.6(2), Cl1-C1-P1a 127.5(2), C1-P1-C2 123.2(1), C1a-P1-C2 126.9(1).

pyramidalization at the phosphorus atoms (Σ 337.9°) is significantly more pronounced than at the carbon atoms (Σ 347.3°), however, small in comparison to 1,3-diphosphetanes (e.g. 293° in $(C_6H_5PCHNMe_2)_2$[15]). The P–C bonds, which are considerably shorter than a P–C single bond, are the same length within the error limits (174.9(3), 175.0(2) pm) and are similar to those in λ^3-phosphinines.[16] Longer P–C bonds occur in transition metal complexes of 1,3-diphosphacyclobutadienes,[17] for which likewise a delocalized π-electron structure is assumed. Furthermore, the different exocyclic bond angles at the phosphorus atoms (C1-P1-C2 123.2(1) and C1a-P1-C2 126.9(1)°) are worthy of note; they reveal the distortion of the molecular symmetry from C_{2h} to C_i. The exocyclic distances C–Cl 173.8(3), P-*ipso*-C 183.5(2) and also the bond angles and bond lengths in the aryl substituent show no peculiarities.

In order to determine the bonding in **3**, quantum chemical calculations on the parent structure, $(HP)_2(CH)_2$ **III**, were performed both at the MCSCF/DZP[19] and also at the MP2/6-31G(d,p) level[21] under complete geometry optimization. A MCSCF optimization of the geometry of **III** affords a singlet ground state with C_i symmetry. The singlet state with C_{2h} symmetry,[24] which lies higher in energy, is not a minimum on the

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

potential hypersurface. The corresponding structure can be considered as the transition state for a rearrangement of **III** into the 2,4-diphosphabicyclobutane system.[24] In contrast, ab initio calculations at the RHF level lead to ring-opened structures as energy minima.[2e]

The two dominant contributions to the CI wavefunction from the MCSCF calculation[19] for the ^1A_g state are found to be $\Phi(^1Ag) = 0.90|\pi_1^2\pi_2^2\pi_3^2\rangle - 0.40|\pi_1^2\pi_2^2\pi_4^2\rangle$. This corresponds to an occupation of the bonding π_3 orbital (HOMO) with 1.6 electrons. Thus, it follows that a considerable diradical contribution can be assigned to **III** (Fig. 2).[25]

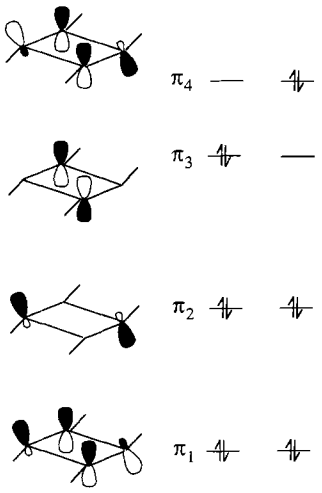

Fig. 2. Schematic representation of the π orbitals of **III**.

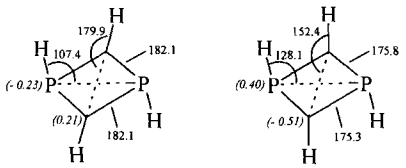
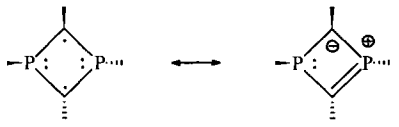
For the lowest lying triplet state (^3A_u), which according to a vibrational analysis[24] corresponds to an energy minimum, the geometry optimized MCSCF calculations give a structure with C_{2h} symmetry with only a small difference in energy of 5.5 kcal mol^{-1} to the ^1Ag state (after MRCI plus Davidson correction). A similar result is obtained from energy optimized MP2/6-31G(d,p) calculations, which afforded an energy difference (after MP4 correction[21]) between the ^1Ag and ^3A_u states of 7.4 kcal mol^{-1}. Figure 3 shows the geometries as well as the Mulliken populations for these two states. In contrast to the structure of the triplet state with mainly nonpolar P–C bonds, whose distances correspond approximately to those of normal P–C single bonds, the structure of the singlet state shows a stronger polar charge distribution in the ring. This leads, as is expected, to shorter P–C distances, which are in good agreement with the experimental values. The pyramidalization at the carbon atoms is likewise well reflected by the calculations, while the substituents at the phosphorus atoms as expected are more bent than those of the experimentally determined structure[26] (Fig 3).





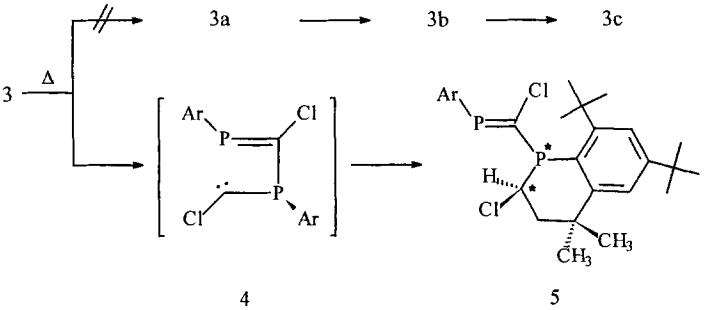


Fig. 3. Optimized geometries and Mulliken populations (left: ^3A_u state; right ^1A_g state).

The stabilization of the singlet state (^1Ag) can thus be explained by a conjugative interaction of the unpaired electrons at the carbon atoms with the nonbonding electron pairs of the phosphorus atoms. A planarization of all substituents, which would lead to perfect cyclic π conjugation as in the disulfur dinitride, however, is not achieved, above all because of the high inversion barrier at the phosphorus atom (42.7 kcal mol^{-1} in the phosphetane[27]). Therefore, **III** can on the one hand be considered as a delocalized π system and described by the diradical, **IIIa**, and dipolar limiting formula, **IIIb** (4 hybrids). On the other hand the heterocycle **III** can also be considered as an orbital isomer[5a] of the energetically poorer 2,4-diphosphabicyclobutane (– 36.9 kcal mol^{-1} relative to the *exo/endo* conformer of 2,4-diphosphabicyclobutane[28]).[29]

IIIa IIIb

In the case of compound **III**, a transannular C–C linkage leading to the formation of the bicycle is forbidden according to the Woodward–Hoffmann rules. In fact, on heating in toluene the thermally remarkably stable heterocycle **3** isomerizes not by ring closure to give the 2,4-diphosphabicyclobutane **3a** or to a thermodynamically more stable subsequent product (**3b**, **3c**), but by cleavage of the P–C bond to give the diphosphapropene **5**. A plausible intermediate of this reaction is the phosphanocarbene **4**,[31] which results from a ring opening and stabilizes by CH activation of an *ortho*-positioned *tert*-butyl group to give **5**. The carbene-analogous reaction behavior of such stabilized carbenes (λ^5-phosphaalkynes) is confirmed by a series of publications.[32]

4 5

We assume that the intramolecular ring closure **4** → **3** induced by the kinetically controlled reaction of the starting materials (**1**,**2**) is possibly the key for the successful verification of the P_2C_2 heterocycle **3**. Further investigations into the examination of this hypothesis and into the chemistry of this novel type of compound are in progress.[33]

Experimental Procedure

3: *n*BuLi (2.6 mL, 4.2 mmol of a 1.6 M solution in hexane) was added dropwise to a solution of 2,4,6-*t*Bu$_3$H$_2$C$_6$P=CCl$_2$ (3.0 g, 8.4 mmol) in THF (100 mL) at –100 °C. The resulting yellow reaction mixture was slowly warmed to room temperature, which caused a color change to dark red. Subsequently the solvent was removed in vacuum, the residue treated with pentane (ca. 50 mL), and the LiCl formed separated by filtration together with most of the product. The filter residue was extracted with pentane until it was colorless. Removal of the pentane in vacuum afforded 1.73 g (63%) **3** in the form of a dark red fine crystalline solid. M.p. 155–157 °C (decomp.). ^{31}P NMR (CH_2Cl_2, 303 K): $\delta = 26.5$. ^{31}P CP/MAS: NMR: $\delta_{iso} = 26.1$. ^{13}C NMR (CD_2Cl_2, 253 K): $\delta = 30.2$ (s, *o*-CC_3); 32.0 (s, *p*-CC_3); 33.7 (pseudo-t, $J(|C,P + C,P'|) = 9$ Hz, *o*-CC_3); 34.9 (s, *o*-CC_3); 38.0 (pseudo-*t*, $J(|C,P + C,P'|) = 4$ Hz, *o*-CC_3); 38.6 (s, *p*-CC_3); 98.8 (*t*, 51.5 Hz, CP_2); 122.5 (pseudo-t, $J(|C,P + C,P'|) = 13.8$ Hz, C3-aryl); 122.8 (s, C5-aryl); 124.1 (pseudo-t, $J(|C,P + C,P'|) = 34.4$ Hz, C1-aryl); 153.8 (s, C6-aryl); 157.4 (s, C4-aryl); 159.1 (pseudo-t, $J(|C,P + C,P'|) = 35.0$ Hz, C2-aryl). ^{1}H NMR (CD_2Cl_2, 253 K): $\delta = 1.26$ (s, 9H, *o*-*t*Bu-phenyl); 1.38, 1.77 (each s, 9H, *p*- and *o*-*t*Bu); 7.48, 7.51 (each s, br, *m*-H-phenyl). Rotation around the P–C(aryl) bond at about 303 K leads to an equivalence of the signals for the *o*-*t*Bu and *m*-phenyl protons. UV/Vis: $\lambda_{max}(\varepsilon) = 214$ (33000), 246 (26000), 356 (19000), 478 (900) nm. The mass spectrum of **3** is identical with that of the isomeric product **5**.

5: The heating of **3** (ca. 100 mg) in toluene to 100 °C led quantitatively to **5** in the form of two isomers **A** (70%) and **B** (30%) within 45 minutes. ^{31}P NMR (THF, 303 K): (A) $\delta = 306.4$, –3.1 (^2J(P,P) = 231 Hz, ^2J(P,H) = 22 Hz); [(B) $\delta = 281.2$, 4.5 (^2J(P,P) = 175.5 Hz]. ^{1}H NMR (C_6D_6, 303 K, selection: CH(Cl), CH_2): $\delta = 4.65$ (dddd, ^2J(P,H) = 22, ^3J(H,H) = 14, ^3J(H,H) = 3.5, ^4J(P,H) = 1.5 Hz, CHCl); [5.10 (dt, ^3J(H,H) = 9.5, ^2J(P,H) = ^3J(H,H) = 4 Hz, CHCl)]; 3.05 (td, ^2J(H,H) = ^3J(H,H) = 14, ^3J(P,H) = 5 Hz, CH_2); [2.55 (dddd, ^2J(H,H) = 14,

[21] Calculations at the MP2 and MP4 levels were carried out with the Gaussian-92/DTF program system, revision G.3 [22]. Both the singlet and the triplet states were geometry optimized at the MP2 level and subsequently calculated with regard to the electron correlation at the MP4SDTQ(fc)-level. The vibrational analyses (in harmonic approximation) show both states as minima on the energy hypersurface. For all triplet states the rule is $\langle s^2 \rangle = 2.07$, which shows a negligible spin contamination. The MP4 energies for the triplet sates were obtained by spin projection according to the PMP4 method [23].

[33] A further example of this new structure type was made accessible with the compound $(RPCAr)_2$ (R = Ar–P=C(Cl), Ar = 2,4,6-tBu$_3$C$_6$H$_2$): F. Baumeister, M. Nieger, E. Niecke, unpublished results.

A New Method for the Synthesis of Amphipolar Phosphorus-Containing Heterocycles**

Hans H. Karsch,* Eva Witt, Arnold Schneider, Eberhardt Herdtweck, and Maximilian Heckel

Dedicated to Professor Alfred Schmidpeter on the occassion of his 65th birthday

Diphosphinomethanides show a rich and varied coordination behavior towards main group elements and transition metals.[1] Oxidative coupling of these ligands with transition metals results in the formation of C–C, C–P and P–P bonds, and reduced metal complexes comprising the rearranged organophosphorus ligands have been isolated as intermediates.[2] Analogous redox reactions have been reported for some main group elements[3] and their compounds [for example, Eq. (a)].[2] In these examples antimony and bismuth trichloride are reduced

to afford the zerovalent metal and **2**, which contains two ylidic functions, whereas $AsCl_3$ yields compound **3** (arsenic bears an average oxidation state of + 0.5) in an analogous reaction. The latter compound is the first example of an intermediate containing a main group metal center in this type of reaction.[4]

$$MCl_3 + 3\ Li[C(PMe_2)_2(SiMe_3)] \xrightarrow[-3\ LiCl]{} M^0 + 1.5\ [(Me_2P)(SiMe_3)C{=}PMe_2{-}]_2 \quad (a)$$
M = Sb, Bi; 1; 2

$$4\ AsCl_3 + 12\ Li[C(PMe_2)_2(SiMe_3)] \xrightarrow[-12\ LiCl]{} \{\mu\text{-}[C(PMe_2)_2(SiMe_3)]As_2\}_2 + 5\ 2 \quad (b)$$
1; 3

As PCl_3 is even more difficult to reduce, we surmised that analogous reactions might provide a novel entry to reduced phosphorus compounds. Because both phosphino groups of the diphosphinomethanides can react, the formation of heterocyclic rings should be favored. Indeed, this concept can be applied in the synthesis of previously unknown heterocyclic rings that contain phosphorus as a ring member in the oxidation state +1 . However, the complicated course of reaction leads, in part, to completely unexpected results.

When PCl_3 reacts with **1** in toluene, the reaction sequence can be formulated as in Scheme 1. The crucial step in this sequence

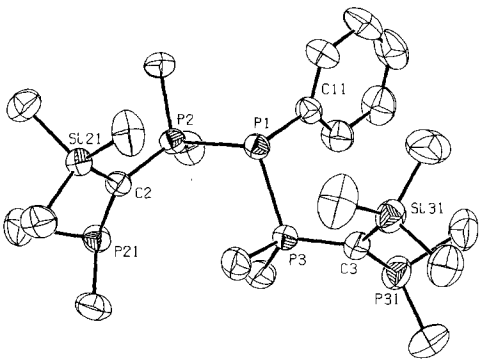
Scheme 1. The course of the reaction of PCl_3 with **1** in toluene.

is the oxidative "outer-sphere coupling"[5] of the terminal PMe_2 groups. Ring formation and concurrent reduction of the central phosphorus atom yields **5**, which is a derivative of the "pentaphosphacycloheptatrienyl cation"[6] and is a new bisphosphane-stabilized phosphanylium ion.[7] Accordingly, upon further reaction of **5** with **1**, the anionic diphosphinomethanide displaces the "double" ylide **2**, and lithium chloride is eliminated. In analogy to other eight-membered rings which, however, have been prepared by a different route,[8] the product **6** is formulated as a dimer.[9]

The following findings provide support for the reaction mechanism depicted in Scheme 1: Replacing the chloride leaving group by a phenyl group prevents the redox reaction and P–P bond formation. Thus the reaction yields **7** according to Equation (c). To the best of our knowledge, **7** is the first 1,3-bis(alkylidene)-1λ^5,3λ^5-triphosphane (that is, a double ylide in which the two λ^5 phosphorus atoms are connected by a λ^3 phosphorus

$$PhPCl_2 + 2\ Li[C(PMe_2)_2(SiMe_3)] \xrightarrow[-2\ LiCl]{} PhP[PMe_2{=}C(PMe_2)(SiMe_3)]_2 \quad (c)$$
1; 7

atom) and represents a new type of ylide–phosphane chelating ligand. An X-ray structure analysis of the yellow crystals of **7**[10] confirms the phosphane/ phosphorane character (Fig. 1). The central P1 atom is in a pyramidal environment; however, the sum over all angles (316.5°) is slightly larger than the standard



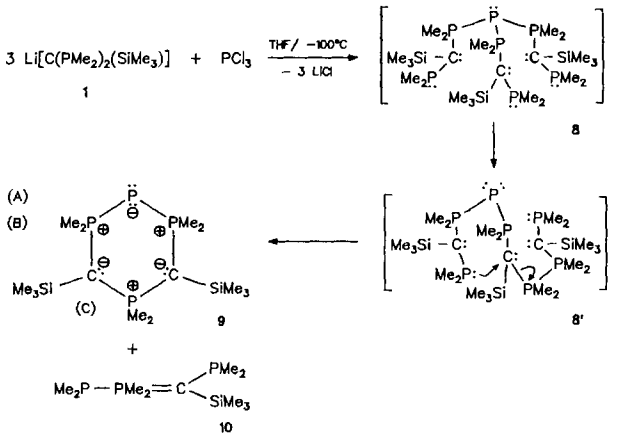


Fig. 1. Crystal structure of **7**. For clarity, hydrogen atoms were omitted. Selected distances [Å] and angles [°]: P1-P2 2.246(1), P1-P3 2.235(1), P1-C11 1.832(2), P2-C2 1.697(2), P3-C3 1.693(2), Si21-C2 1.855(2), P21-C2 1.793(2), Si31-C3 1.846(2), P31-C3 1.797(2); P2-P1-P3 107.9(1), C11-P1-P2 104.2(1), C11-P1-P3 104.4(1), P2-C2-P21 114.4(1), Si21-C2-P2 118.8(1), Si21-C2-P21 125.9(1), P3-C3-P31 112.7(1), Si31-C3-P3 121.7(1), Si31-C3-P31 124.6(1).

value. The distances for P1–P2 (2.246(1) Å) and P1–P3 (2.235(1) Å) are characteristic of single bonds, while the distances for P2–C2 (1.697(2) Å) and P3–C3 (1.693(2) Å) are typical of phosphorus ylides. The spatial arrangement of the P1 substituents is obviously dictated by their steric requirements.

The reaction between PCl_3 and **1** takes a completely different route when THF is used as solvent since, owing to the good solubility of **1** in THF, **1** is present in excess throughout the course of the reaction (Scheme 2). If one assumes that initially

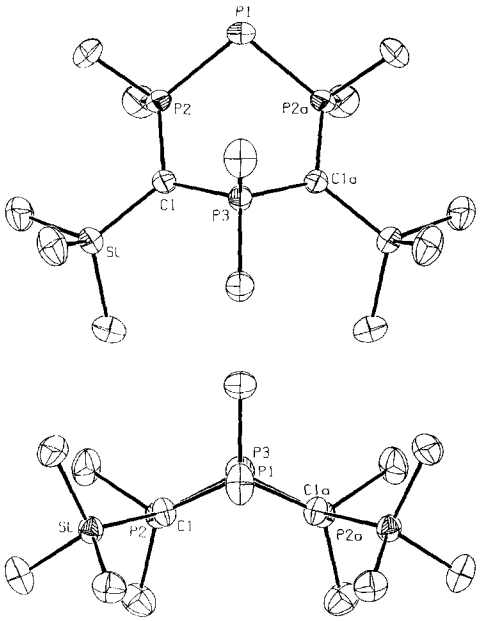
Scheme 2. The course of the reaction of PCl_3 with **1** in THF.

the substituted phosphane **8** is formed, though it cannot be detected, a reaction sequence similar to the one depicted in Scheme 1 becomes feasible. This "outer-sphere coupling" reaction requires the assignment of ten electrons to the central phosphorus, an unfavorable situation which is alleviated by cleavage of a P–P bond of the initially formed—in this case seven-membered—ring. Another cycle of P–C bond forming and breaking steps that are in principal well-known[2] concludes the redox process. The six-membered heterocycle **9** is afforded as colorless

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0558 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 5

crystals. In addition, ylide **10** and varying amounts of **2**, **6**, and $HC(PMe_2)_2(SiMe_3)$ are also formed.[12]

Compound **9** can formally be classified as the first example of a tetraphosphabenzene; however, its description as a $1\lambda^5,3\lambda^5,5\lambda^5,2\lambda^3$-tetraphosphinine is more appropriate. It was anticipated that the molecular structure would reflect[15] the structural characteristics of planar λ^3-phosphinines[13] and various λ^5-di- and triphosphinines.[14] Surprisingly, this is not the case: the molecular structure of **9** (Fig. 2) is characterized by a



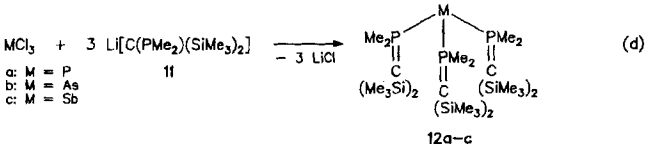


Fig. 2. Two views of the crystal structure of **9**. For clarity, hydrogen atoms were omitted. Selected distances [Å] and angles [°]: P1-P2 2.134(1), P2-C1 1.725(1), P3-C1 1.742(2), Si-C1 1.842(2); P2-P1-P2a 98.1(1), P1-P2-C1 116.4(1), P2-C1-P3 114.7(1), C1-P3-C1a 117.0(1), P2-C1-Si 122.0(4), P3-C1-Si 122.0(1).

pronounced folding (interplanar angle 127°) along the P1–P3 axis, which lies in a mirror plane. This structural feature supports the amphipolar (ylidic) principle.[17] As a result of its polar nature the P1–P2 bond (2.134(1) Å) is shortened, and the angle P2-P1-P2a is 98.08(3)°. All other distances and angles can also be interpreted in light of the aforementioned structural principle.

The successful isolation of analogs of the previously unknown isotetraphosphane/-phosphorane **8**[18] (that is, **12a–c**, which are $SiMe_3$-substituted instead of PMe_2-substituted [Eq. (d)][19, 20]) corroborates the earlier assumption (Scheme 2) that

8 is formed as an intermediate. At the same time it provides evidence for the decisive role of the terminal phosphino groups in the "outer-sphere coupling" process. These novel tris(P-ylide) derivatives (tris(alkylidenephosphoranyl)phosphane and its homologues)[21] **12a–c** form yellow crystals; **12b** is stable at room temperature.[22] The structure of **12b** (Fig. 3)[25] consists of an arsenic atom in a pyramidal environment surrounded by three phosphorus atoms (sum over all angles 316.8°). The As–P distances are in a range typical of single bonds. The ylidic nature of the P1–C1, P2–C2, and P3–C3 bonds is apparent from the characteristic shortening. The potential of **12a–c** as novel tripodal ligands is currently under investigation.

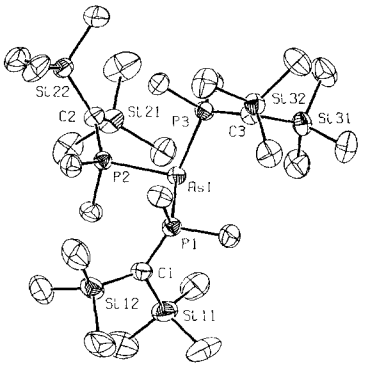

Fig. 3. Crystal structure of **12b**. For clarity, hydrogen atoms were omitted. Selected distances [Å] and angles [°]: As1-P1 2.383(1), As1-P2 2.386(1), As-P3 2.387(1), P1-C1 1.680(3), P2-C2 1.684(3), P3-C3 1.686(2), Si11-C1 1.858(3), Si12-C1 1.847(3), Si21-C2 1.849(2), Si22-C2 1.839(2), Si31-C3 1.860(3), Si32-C3 1.843(3); P1-As1-P2 104.8(2), P1-As1-P3 106.1(2), P2-As1-P3 105.9(2), As1-P1-C1 116.9(1), As1-P2-C2 117.0(1), As1-P3-C3 117.7(1), P1-C1-Si11 116.3(2), P1-C1-Si12 126.0(2), Si11-C1-Si12 117.1(1), P2-C2-Si21 116.4(1), P2-C2-Si22 126.8(1), Si21-C2-Si22 116.2(1), P3-C3-Si31 116.4(1), P3-C3-Si32 126.3(2), Si31-C3-Si32 116.9(1).

The unique cascade of bond forming and breaking reactions (P–P, P–C) described herein exemplifies how the properties of phosphinomethanides can be used for the directed synthesis of cyclic compounds with low-valent main group elements as constituents. During reaction design specific consideration has to be given to the following: The phosphinomethanide carbanion must be shielded by heteroelement substituents.[24] The cyclic redox reaction will only be initiated by a P–P bond formation involving terminal phosphino groups ("outer-sphere coupling") if good leaving groups are present that enable electrons to be transferred to the central atom. These conditions provide the framework for a broader application of this synthetic methodology.

Experimental Procedure

All reactions were conducted under anhydrous conditions in a nitrogen atmosphere. **7**: A solution of $PhPCl_2$ (0.3 mL, 2.23 mmol) in THF (8 mL) was slowly added dropwise at −78 °C to **1**[12] (1.05 g, 4.90 mmol) in THF (30 mL). The mixture was allowed to warm to room temperature and stirred for 3 h. The solvent was distilled off under vacuum, and the yellow residue was extracted twice with 35 mL portions of pentane. The pentane extracts were combined, and yellow crystals were afforded by slow evaporation of the solvent. The oily mother liquor was decanted, and the crystals were washed with a small amount of pentane. Yield: 0.41 g (35%). $^{31}P\{^1H\}$ NMR (C_6D_6, + 20 °C): ABB'CC' spin system, $\delta P_A = -27.59$, $\delta P_B = +16.28$, $\delta P_C = -38.76$, $J(P_AP_B) = 307.4$ Hz, $J(P_AP_C) = 15.0$ Hz, $J(P_BP_C) = 176.6$ Hz, $J(P_BP_{B'}) = 9$ Hz, $J(P_BP_{C'}) = 10$ Hz, $J(P_CP_{C'}) = 13$ Hz.

9: At −100 °C a solution of PCl_3 (0.168 mL, 1.93 mmol) in THF (20 mL) was slowly added to **1**[12] (1.24 g, 5.79 mmol) in THF (30 mL). The mixture was allowed to warm to room temperature and stirred for 12 h. Next, the solvent was removed under vacuum, and the residue extracted three times with 30 mL portions of pentane. The extracts were combined, and the pentane was removed under vacuum. On storage of the remaining yellow oil for 120 d at −10 °C colorless crystals of **9** precipitated. The oily supernatant was decanted, and the crystals were washed with a small amount of pentane. Yield: 0.24 g (32%). In addition to **9**, the supernatant contained **2**, **6**, and $HC(PMe_2)_2(SiMe_3)$, as shown by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$ NMR (C_6D_6, + 20 °C): AB_2C spin system, $\delta P_A = -140.36$ (m, $J(P_AP_B) = 348.3$ Hz, $J(P_AP_C) = 12.7$ Hz), $\delta P_B = +5.48$ (m, $J(P_BP_C) = 24.3$ Hz), $\delta P_C = +13.50$ (m).

12b: At −100 °C, $AsCl_3$ (0.21 mL, 2.53 mmol) was added by pipette to **11**·½ TMEDA [12] (2.38 g, 8.37 mmol) in THF (30 mL). The mixture was allowed to warm to room temperature and stirred for 2 h. The solvent was evaporated, and the residue was dried under vacuum and then extracted three times with 30 mL portions of pentane. The pentane extracts were combined, and the product precipitated as a yellow crystalline solid after concentration of the solution. Yield: 1.30 g (70.1%). $^{31}P\{^1H\}$ NMR (C_6D_6, + 20 °C): $\delta P = 13.51$ (s).

Cobalt-Containing Molecular Sieves as Catalysts for the Low Conversion Autoxidation of Pure Cyclohexane**

Dominic L. Vanoppen, Dirk E. De Vos,*
Michel J. Genet, Paul G. Rouxhet and Peter A. Jacobs

CoAPO molecular sieves have already been studied as solid acid catalysts,[1] but the incorporation of cobalt into aluminophosphate [2] and aluminosilicate structures [3] could also open a route toward heterogenization of cobalt autoxidation catalysis. The autoxidation of cyclohexane is an important bulk process,[4] which is currently carried out in the presence of small amounts of dissolved cobalt salts. Reactions proceed by a free radical mechanism, yielding primarily cyclohexyl hydroperoxide (cHHP). Cobalt ions accelerate the overall reaction as new radicals are generated by cHHP decomposition in a Haber–Weiss cycle. As the primary oxidation products are more susceptible to oxidation than the substrate, conversion must be kept low to obtain reasonable selectivities for the products cyclohexanol and cyclohexanone. Precipitation deactivates the homogeneous catalysts.[4] Besides the technical advantages of catalyst heterogeneity, the catalyst activity, stability, and selectivity are thus important factors to be considered in developing new heterogeneous catalysts for this process. We studied the autoxidation of cyclohexane in the presence of CoAPO-5 and CoAPO-11 molecular sieves, monitoring activity and selectivity by product formation and oxygen consumption. Overall cobalt distribution and coordination were studied by elemental analysis, X-ray photoelectron spectroscopy (XPS), and UV-Vis reflectance spectroscopy (DRS) to evaluate heterogeneity and stability. Isolation of the cobalt sites by incorporation into the molecular sieve framework seems to be critical for obtaining active and truly heterogeneous autoxidation catalysts. These solid catalysts show an improved stability and selectivity over the classical cobalt naphthenate catalyst.

CoAPOs are aluminophosphate molecular sieves in which a few percent of Al^{3+} centers is substituted by Co^{2+} centers. CoAPO-5 has AFI-topology with channels with 12-membered rings, while CoAPO-11 has AEL-topology with only 10-membered rings forming the channels. Figure 1 shows formation of

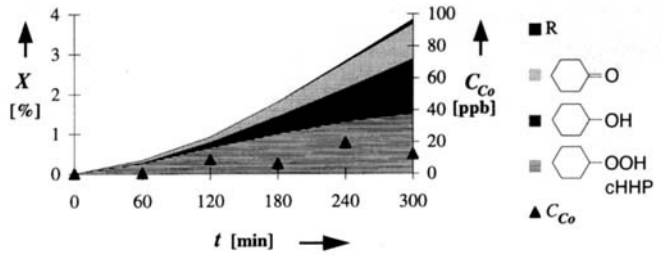

Fig. 1. Autoxidation of cyclohexane (75 mL) in the presence of 0.5 g CoAPO-5 (from gel with Co/(Co + Al) = 0.01) at 130 °C and 1 MPa O_2 initial pressure. Results were obtained in five independent reactions, by stopping reactions after 1, 2, 3, 4, and 5 h. Amount of products are expressed in % yield (X), calculated as (mmol product/mmol cyclohexane) × 100. R is the sum of caprolactone and acids detected. C_{Co} denotes concentration of dissolved cobalt.

products and evolution of free cobalt in a typical reaction. It is clear from Table 1 that the catalyst is truly heterogeneous, because the amount of dissolved cobalt is much lower than in homogeneous catalysis. Heterogenization of cobalt catalysis has

Table 1. Heterogeneity of autoxidation catalysis with CoAPO (75 mL cyclohexane, 1 MPa O_2 initial pressure, 5 h, 130 °C).

Catalyst	Conversion [%]	Dissolved [Co]
1) 0.5 g CoAPO-5 (0.01) [a]	3	12 ± 3 ppb
2) contribution from homogeneous catalysis [b]	–	7 ± 3 ppb
3) cobalt naphthenate	0.5	100 ppb
4) cobalt naphthenate	–	50 ppb

[a] The number in brackets denotes the Co/(Co + Al) ratio. [b] The reaction mixture is prepared by heating the mixture of 1) under N_2 for 5 h at 130 °C and filtering off the catalyst.

a dramatic effect on product distribution. With CoAPO-5, cHHP is a main product, whereas with a homogeneous catalyst it is only a minor one (Fig. 2). cHHP is an attractive primary

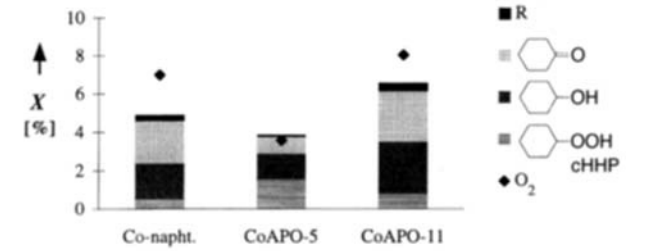

Fig. 2. Autoxidation of cyclohexane (75mL) in the presence of 0.5 g CoAPO-5, 0.5 g CoAPO-11 (from gels with Co/(Co + Al) = 0.01) or 33 ppm cobalt naphthenate (total amount of cobalt in all reactions is identical; 130 °C, 5 h, 1 MPa O_2 initial pressure). Products are expressed in % yield (X), as in Fig. 1. Oxygen consumption [(mmol O_2 consumed/mmol cyclohexane) × 100] was calculated from the difference in pressure at room temperature before and after reaction.

product, because ever more clean and convenient routes lead from it to cyclohexanol and cyclohexanone.[5] Furthermore CoAPOs yield higher selectivities for monofunctionalized products (Fig. 3).

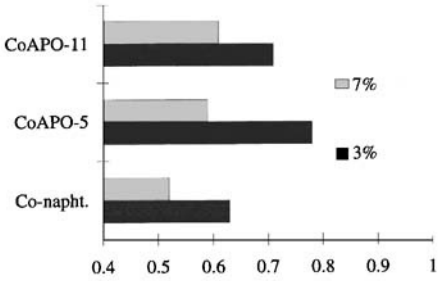

Fig. 3. Oxygen efficiency for monofunctionalization as a measure of the overall selectivity for monofunctionalization, calculated as (mmol cHHP + mmol cyclohexanone + 0.5x mmol cyclohexanol)/(mmol oxygen consumed). Reactions were stopped after consumption of 0.03 or 0.07 moles O_2 per mole cyclohexane (3 and 7% theoretical conversion to cyclohexanone or cHHP). Reaction mixtures and conditions were as in Fig. 2.

Quite unexpectedly since cyclohexane and its oxidation products are expected to diffuse only slowly into 10-membered ring channels,[6] CoAPO-11 molecular sieves exhibit higher catalytic activities than CoAPO-5. Lowering the cobalt content to zero (see Fig. 5) shows that in CoAPO-11, cobalt catalysis is superimposed on an effect of the molecular sieve itself, which promotes peroxide production. The mechanism behind this catalytic activity is still unclear, but may be related to enhanced hydroperoxide production observed in certain polar solvents[7] or in molecular sieve structures.[8]

The Co-naphthenate catalyst is deactivated by formation of precipitates, which seem to quench further reaction (Fig. 4). CoAPO catalysts are not deactivated, which we ascribe to immobilization of cobalt ions at framework positions. XPS and elementary analyses (Table 2) indeed indicate that the uniform

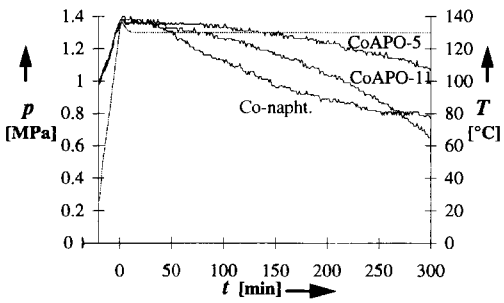

Fig. 4. Pressure decrease during autoxidation of cyclohexane in the presence of CoAPO-5, CoAPO-11, or cobalt naphthenate as a measure for oxygen consumption. Reaction mixtures as in Fig. 2. After reaction with cobalt naphthenate a purple precipitate could be filtered from the reaction mixture.

Table 2. Composition of catalysts from elemental analysis and XPS. XPS ratios were calculated from Al 2p and Co $2p_{3/2}$ lines.

Catalyst	Ratio Co/(Co + Al)					Co leached in reaction
	synthesis gel	bulk analysis	XPS			
			as synthesized	calcined + reduced with acetone	after reaction	
CoAPO-5	0.01	0.0096	0.008	0.006	0.008	0.07% [a]
CoAPO-11	0.01	0.0081	0.008	0.005	0.009	0.08% [a]
CoAPO-5	0.04	0.0363	0.016	0.016	0.014	0.15% [b]
CoAPO-5 0.04 with acetic acid as a promoter					0.129	0.08% [c]

[a] The reactions were stopped at 7% theoretical conversion (as in Fig. 3). [b], [c] The reactions were stopped after 5 h. [a], [b] DRS and XPS spectra gave no evidence for change in cobalt coordination.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0561 $ 10.00+.25/0

cobalt ion distribution is preserved during reaction in cyclohexane. These catalysts could be recalcined and reused at least four times without apparent loss of activity.

In contrast, a cobalt-exchanged zeolite Y in which the cobalt ions are highly mobile is catalytically inactive and even strongly inhibits reaction under conditions for spontaneous autoxidation (Table 3). The typical DRS features of exchanged cobalt ions disappear during reaction, which supports the hypothesis of quenching by cobalt clusters or precipitates.

Table 3. Inhibition of the autoxidation of cyclohexane (75 mL, 1 MPa O_2 initial pressure) by CoNaY.

Catalyst [a]	T [°C]	Conversion [%] (time)	Dissolved [Co]
0.5 g CoNaY (0.5)	130	– (5 h)	320 ppb
0.5 g CoNaY (1.5)	130	– (5 h)	260 ppb
–	145	3 (5 h)	–
0.5 g CoNaY (0.5)	145	– (5 h)	160 ppb

[a] The numbers in brackets denote the cobalt content in weight percent.

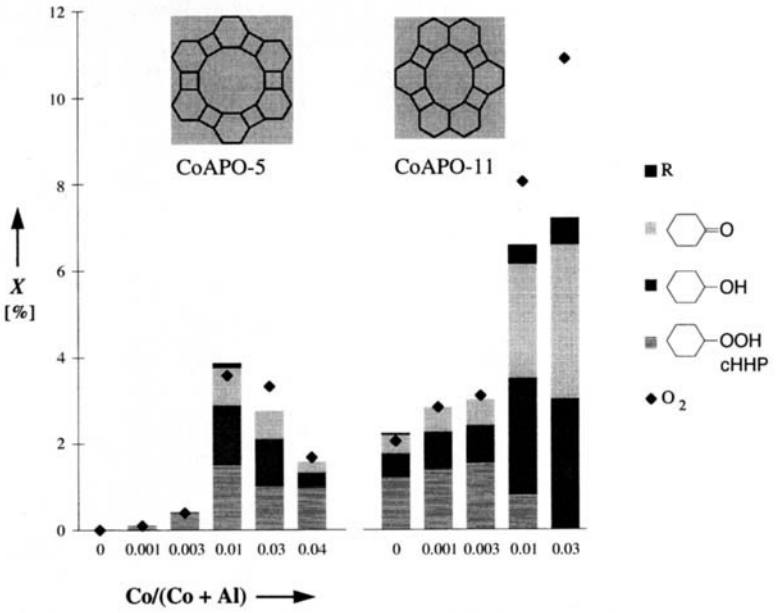

Fig. 5. Autoxidation of cyclohexane in the presence of CoAPO-5 or CoAPO-11 with different ratios of Co/(Co + Al). Reaction mixtures, conditions, notation, and calculation as in Fig. 2.

When acetic acid is used as a promoter,[9] the CoAPO molecular sieve seems to act as an inhibitor rather than as a catalyst (Table 4). XPS analysis after reaction in acetic acid indicates an eightfold increase of the cobalt signal (see Table 2) and splitting of the Co $2p_{3/2}$ line. Acid leaching of cobalt from its isolated sites and reprecipitation at the surface explains our observations. Clusters or precipitates again seem to quench the reaction.

Table 4. Autoxidation of cyclohexane (60 mL) with acetic acid (15 mL) as a promoter (1 MPa O_2 initial pressure).

Catalyst [a]	T [°C]	Reaction (time)	Dissolved [Co]
1) 0.5 g CoAPO-5 (0.04)	100	– (5 h)	820 ppb
2) –	130	all oxygen consumed (3.1 h)	–
3) 0.5 g CoAPO-5 (0.04)	130	all oxygen consumed (4.2 h)	110 ppb
4) test for contribution from homogeneous catalysis [b]	130	all oxygen consumed (1.1 h)	1700 ppb

[a] The numbers in brackets denote Co/(Co + Al) ratios. [b] The reaction mixture is prepared by heating the mixture of 3) under N_2 for 1 h at 130 °C and filtering off the catalyst.

Finally, a similar phenomenon is observed for CoAPO-5 in pure cyclohexane. Varying cobalt content (Fig. 5) shows that activity increases with increasing cobalt content at low loadings. Above a Co/(Co + Al) ratio of 0.01, higher leaching (up to 200 ppb) occurs, but no further increase in activity is observed. This can again be ascribed to a decrease in site isolation at higher cobalt content. Recent ^{31}P NMR studies indicate that CoAPO-11 displays a more uniform cobalt distribution than CoAPO-5 at high cobalt loadings.[10] This readily explains their different response toward increasing cobalt content (Fig. 5).

Therefore we conclude that site isolation is the key factor leading to active and truly heterogeneous catalysts. Adding acids or using catalysts with high cobalt content results in loss of this essential advantage.

Experimental

CoAPO molecular sieves were prepared by hydrothermal synthesis from gels with molar composition $2x\,Co(CH_3COO)_2 : 1\,P_2O_5 : (1-x)Al_2O_3 : 1.5\,Pr_3N : 40\,H_2O$ (CoAPO-5) or $2x\,Co(CH_3COO)_2 : 1\,P_2O_5 : (1-x)Al_2O_3 : 1\,Pr_2NH : 40\,H_2O$ (CoAPO-11) ($0 < x < 0.04$) in an autoclave under autogeneous pressure at 150 °C for 24 h (CoAPO-5) or 175 °C for 72 h (CoAPO-11). Gels were cooled during preparation. Crystallinity and cobalt incorporation were checked by X-ray diffraction and DRS (Varian Cary 5 with integration sphere). CoNaY was prepared by stirring NaY (PQ) in a dilute cobalt nitrate solution. All catalysts were calcined for about 12 h at 500 °C in a stream of oxygen prior to use. Autoxidation experiments were carried out in a 300 mL stainless steel Parr pressure reactor, passivated with a saturated sodium pyrophosphate solution [7].

Typical experiments used 0.5 g of catalyst and 75 mL of cyclohexane, and the headspace was filled with oxygen under a total pressure of 1 MPa, which allowed a conversion of approximately 10% [11]. The following products were detected by GC (CP-sil5 column, Chrompack): cyclohexanol, cyclohexanone, cHHP, caprolactone, and adipic, glutaric, succinic, caproic, valeric, and butyric acids. Deficiency in the oxygen mass balance can be ascribed to formation of esters that are invisible in GC. As cHHP partially decomposed upon injection, its concentration was estimated by double analysis, before and after reducing cHHP to cyclohexanol with Ph_3P [12]. For elemental analysis, reaction mixtures were extracted with 25 mL HNO_3 (1 N), and catalysts were dissolved in a HF solution. XPS studies were carried out on a SSX-100/206 Fisons spectrometer with a monochromatized Al X-ray source (analyzer pass energy 150 eV). Acquisition times of 3 h were needed to obtain acceptable signal-to-noise ratios. No charging effects were observed during accumulation.

Novel Structures from Tris(benzocyclobutadieno)cyclohexatriene: Triscyclopropanation and Trisoxacyclopropanation to the First [2.1.2.1.2.1]Hexaannulanes**

Debra L. Mohler, K. Peter C. Vollhardt,* and Stefan Wolff

In the triangular [4]phenylene **1** ("tris(benzocyclobutadieno)-cyclohexatriene"),[1] σ-strain and antiaromatic π-effects[2] combine to impose a cyclohexatrienic structure on the central ring, which manifests itself chemically in its unprecedented ring-opening to the corresponding cyclic triyne[1] and facile all-*cis*-hydrogenation.[3] We now report the direct methylenation and oxidation of the cyclohexatriene unit in **1** to give the surprisingly stable novel compounds **4** and **5**, incorporating the unknown, highly strained[4] all-*cis*-[2.1.2.1.2.1]hexaannulane[5] frameworks **2** and **3**, respectively.

1a, R = H
1b, R = $Si(CH_3)_3$ **2** **3**

Cyclopropanation of **1a,b** to the *cis*-tris-σ-homobenzenes **4a,b** was achieved under modified Simmons–Smith conditions (Scheme 1).[6, 7] The products are remarkably thermally stable, surviving prolonged heating to 200 °C (**4a**, C_6D_6) or 340 °C (**4b**, neat). They are also inert to (at least relatively mild) hydrogenolysis conditions (H_2, 1 atm, Pd, THF, 20 °C). Their symmetry is apparent from the NMR spectral data,[7] and their chemical shift values are, perhaps surprisingly, not unexpected.[1, 3, 5, 8] The methylene hydrogens are relatively strongly[8] deshielded,[7] most likely due to the presence of the benzene rings, although we cannot rule out a contribution arising from the all-*cis* fusion of the cyclopropane rings.[8h] In the series of all-*cis*-σ-homobenzenes, **4** is unique for its lack of perturbing substituents on the methylene bridges. This feature allows a comparison of the two C–H coupling constants (*exo*, *endo*). Surprisingly, not only are their values essentially equal to those of model fused cyclopropanes and the parent ring itself,[9] but they are also identical ($J = 161.2$ Hz)!

The novelty of the framework **4** prompted the determination of the X-ray structural details of **4b** (Fig. 1).[10] Unlike hexamethyl-*trans*-σ-trishomobenzene,[11] but like several 3,5,9-trisubstituted *cis*-σ-trishomobenzenes and hexahydro-**1a**[3] (and several hetero-σ-trishomobenzenes),[12] the central cyclohexane unit is planar, but exhibits considerably less bond-length alternation (1.541, 1.510 Å), mainly because of a pronounced shortening of the bond of the four-membered rings (from 1.599 to 1.541 Å). While such bond shortening has been interpreted previously as indicating conjugation between the three-membered rings,[11, 12] rehybridization effects to accommodate ring strain are more likely the dominant cause of this phenomenon.[13] Otherwise, the benzocyclobutene units resemble those of **1b**,[1a] 1,2-dihydro-4,5-bis(trimethylsilyl)-,[14] and 1,2-dihydrobenzocyclobutene in geometry.[15] Finally, the average dihedral angle between the central cyclohexane and the benzocyclobutene moieties is 132.3°, noticeably expanded from hexahydro-**1a**,[3] while that to the cyclopropane planes is 121.3°. The latter value is in remarkable agreement with that calculated for the unknown parent *cis*-σ-trishomobenzene,[16] thought to be unstable at ambient temperatures with respect to electrocyclic ring opening.[8h, 17] In **4** such a retrocyclization could proceed with triscyclopropane participation to give a trisbenzocyclobutadiene structure, or by trisbenzocyclobutane opening[3] to result in three linked cyclopropene units. Both isomerizations are estimated to be endothermic,[18a, b] and no other facile (and detectable) pathways of rearrangement are open to the molecules, which provides a rationale for their baffling thermal robustness.

The trioxaannulane framework of **5** was prepared as shown in Scheme 1[7] with 3,3-dimethyl-1,2-dioxacyclopropane (dimethyldioxirane).[19] It is stable up to its melting point (180 °C),

Ellipsoids are scaled to represent the 50% probability surface; hydrogen atoms are given as small spheres with arbitrary radius. Averaged selected distances [Å] and angles [°] (idealized C_{3v} symmetry): C1–C8 1.541, C8–C10 1.510, C8–C9 1.500, C1–C2 1.501, C2–C7 1.387, C2–C3 1.371, C3–C4 1.415, C4–C5 1.413; C2-C1-C8 87.2, C8-C1-C26 120.0, C26-C1-C27 59.7, C1-C2-C7 92.9, C3-C2-C7 122.4, C2-C3-C4 118.9, C3-C4-C5 119.6.

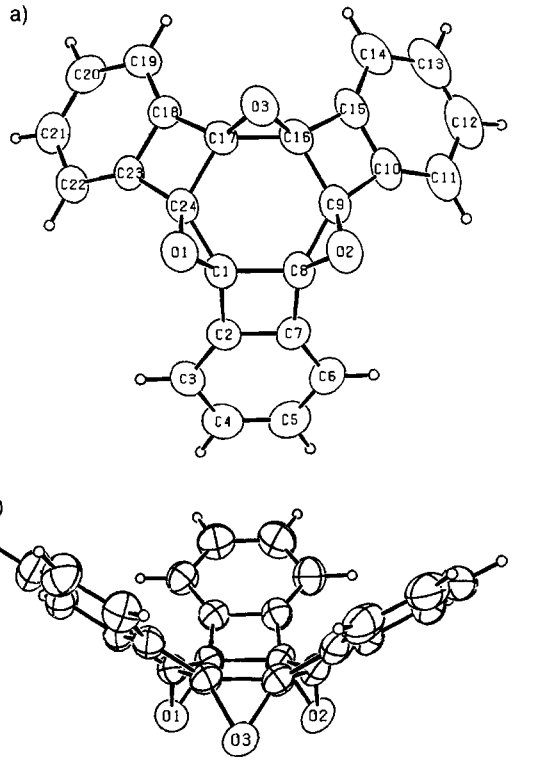

Fig. 2. View from above (a) and the side (b) of the molecular structure of **5**. Ellipsoids are scaled to represent the 50% probability surface; hydrogen atoms are given as small spheres with arbitrary radius. Averaged selected distances [Å] and angles [°] (for idealized C_{3v} symmetry): O1–C1 1.441, C1–C2 1.496, C1–C8 1.526, C1–C24 1.463, C2–C3 1.378, C2–C7 1.394, C3–C4 1.383, C4–C5 1.384; C1-O1-C24 61.0, C24-C1-O1 59.5, C2-C1-C8 87.5, C8-C1-C24 120.0., C1-C2-C7 92.5, C3-C2-C7 122.2, C2-C3-C4 115.6, C3-C4-C5 122.2.

when it slowly decomposes without a sign of internal ring opening, in this case not only for thermodynamic,[18a, c] but perhaps also kinetic reasons.[20] The ether bridges survived chromatography on silica gel, but not direct acid treatment (dilute aqueous CF_3CO_2H or HCl). Irradiation with a medium-pressure Hg lamp led to complete decomposition within minutes. Again, the symmetrical structure manifests itself in the simple signal pattern in the NMR spectrum,[7] in which the unusually large chemical shift of the central carbon atoms ($\delta = 76.3$) reflects the cumulative influence of the constituent parts of **5**.[20, 21]

The X-ray structural details of **5** are depicted in Figure 2.[22] The framework of **5** is similar to that of **4b** except that the bonds of the *cis*-trioxa-tris-σ-homobenzene unit are all shortened, while the bonds in the central, planar cyclohexane ring still alternate in length (1.526, 1.463 Å). The average dihedral angle between the cyclohexane ring and the benzocyclobutene planes is further expanded (relative to hexahydro-**1a** and **4b**) to 145.5°, while the three-membered rings point further inwards (114.5°). The structural changes on going from *cis*-benzenetrioxide[12b] to **5** are also instructive: the linkages between the oxacyclopropanes lengthen (1.488 to 1.526 Å) and the C–O bonds to the bridging oxygen atoms shorten (1.471 to 1.463 Å). The crown ether cavity is also clearly widened (dihedral angle change from 106.9° to 114.5°), thus lengthening the average O–O distance (2.82 Å to 3.15 Å) and providing new geometric constraints on the potential ability of the trisoxaface to function as a tridentate ligand for metals.[12d, e] This aspect is currently under investigation.

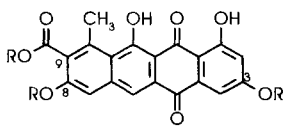
Biosynthetic Origin of the Oxygen Atoms of Tetracenomycin C**

György Udvarnoki, Christina Wagner, Reinhard Machinek, and Jürgen Rohr*

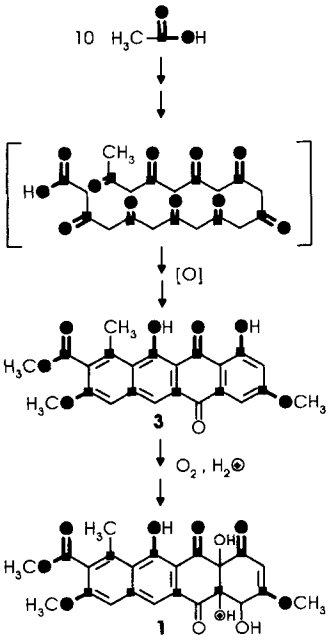


Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

There is currently great interest in the details of the polyketide biosynthetic pathway, one of nature's most important routes for forming a diversity of bioactive compounds.[1] For the past few years we have focused our attention on polycyclic, aromatic polyketides,[2–4] so-called type II polyketides.[5] Recent investigations of the sources of oxygen in the metabolites have provided novel insights, for example, unexpected deoxygenation steps before aromatization during the general assembly of these polyketides.[4] The tetracenomycins (e.g. tetracenomycin C (**1**)) and elloramycins (e.g. elloramycin A (**2**)) form a small, distinct group of tetracyclic, aromatic polyketides whose biosyntheses have been extensively studied.[6–12] Nevertheless, the oxygenation reactions, the last steps of the biosynthesis of tetracenomycin C (**1**)[9–12] from its immediate precursor tetracenomycin A_2 (**3**), are not well understood and are still subjects of debate. We describe here the biosynthetic sources of all the oxygen atoms of tetracenomycin C (**1**) and, to our knowledge, the first experimental proof in biosynthetic studies of an oxygen atom deriving from H_2O.

1 R = H
4 R = CH_3

2



3 R = CH_3
5 R = H

In a study using an $^{18}O_2$-enriched atmosphere Rickards et al.[12] showed that only three oxygen atoms in tetracenomycin X (**4**), a close relative of **1** produced by *Nocardia mediterranea*, derive from molecular oxygen, namely O-4, O-5, and O-12a. These findings seemed to be in contradiction to the general biosynthetic pathway for the tetracenomycins outlined by Hutchinson et al.[9] (see also Scheme 1) and to the results of our studies with blocked mutants,[11] since the oxygen atom attached to C-4a did not derive from atmospheric oxygen. If this

Scheme 1. Biosynthesis of tetracenomycin C (**1**).

oxygen atom is part of the acetate unit incorporated there, as one could assume from its position as well as from studies on related tetracycles bearing similar angular hydroxyl groups,[3, 13] then the biosynthesis of tetracenomycin C (**1**) does not proceed via aromatic intermediates such as tetracenomycin D_3 (**5**) and A_2 (**3**).[12, 14] Unfortunately, Rickards et al. did not resolve this ambiguity by carrying out additional feeding experiments, for example with ^{18}O-labeled acetate.

In a first series of experiments to find optimal incorporation conditions, we fed [1-^{13}C]acetate to a growing culture of *Streptomyces glaucescens* (strain Tü 49),[15] the producer of tetracenomycin C (**1**), and obtained sufficient incorporation rates (Table 1). The signal of the critical carbon atom C-4a, a broad singlet under standard NMR conditions, was not well enough resolved for possible detection of an ^{18}O upfield shift after labeling of 4a-OH. Systematic NMR studies with **1** finally yielded conditions under which C-4a gave rise to a sharp singlet (acetone as the solvent, $T = -30\,^{\circ}C$). After we completed the unambiguous assigment of the complete ^{13}C NMR spectrum of **1** (A in Table 1),[16] we approached the consequent feeding experiment with [1-^{13}C,$^{18}O_2$]acetate. The resulting samples of tetracenomycin C (**1**) showed ^{18}O upfield shifts of the expected magnitude for the signals of C-1, C-3, C-8, 9-C=O, 9-OCH_3, C-11, and C-12, but clearly not for C-4a (C in Table 1). Thus 4a-OH either derives from molecular oxygen, in contradiction to the earlier experiment,[12] or from water. Atmospheric oxygen has been proved to be the source for similar angular oxygen atoms in tetracyclines (tetracyclic aromatic polyketides structurally related to **1**).[17] Water has never been implicated as a source of oxygen atoms in studies on polycyclic, aromatic polyketides.

We examined this second, more attractive possibility by carrying out a fermentation of *Streptomyces glaucescens* (Tü 49) in 500 mL of $H_2{}^{18}O$ (10% ^{18}O). The resulting sample of **1**[18] showed an ^{18}O upfield shift for the signals of 3-OCH_3, C-4a, 8-OCH_3, and 9-OCH_3. The ^{18}O enrichments are about tenfold less than that obtained in the experiment with [1-^{13}C,$^{18}O_2$]acetate because of the tenfold lower ^{18}O enrichment of the labeled precursor (D in Table 1). The upfield shifts observed for the signals of the OCH_3 groups are surprising on first glance, but can be explained by partial ^{18}O exchange at the stage of the biosynthetic building blocks (acetate) and/or intermediates (e.g. tetracenomycin D_3 (**3**)). Nevertheless, this ^{18}O exchange is insignificant: the shifts are observable only for the signals of OCH_3 groups, which are much more intensive in the ^{13}C NMR spectrum than those of quarternary carbons. The oxygen atom linked at the quarternary C-4a, however, seems to stem directly from the ^{18}O-labeled water, because ^{18}O exchange is unlikely at this position. The ^{18}O enrichment of 4a-OH resulting from the experiment with the labeled water is by far the highest (D in Table 1).

Table 1. A: ^{13}C NMR data for tetracenomycin C (**1**); δ values relative to TMS in [D_6]acetone, −30 °C, 125.7 MHz, multiplicities from APT (*a*ttached *p*roton *t*est) and C,H-COSY experiments [a]. B: Specific incorporation rates [b] from the feeding experiment with [1-^{13}C]acetate. C: Upfield shifts ($\Delta\delta$ ^{13}C-^{18}O) in **1** obtained by feeding [1-^{13}C,$^{18}O_2$]acetate. D: Upfield shifts (ΔS ^{13}C-^{18}O) in **1** obtained from the fermentation in $H_2{}^{18}O$ (^{18}O enrichments in % [c]).

[a] The ^{13}C signals were further assigned through long-range C,H couplings (COLOC, HMBC) [25]. [b] Incorporation rates (± 1%) calculated according to Townsend, Scott, et al. [26]. [c] ^{18}O Enrichment = $[(I_{^{13}C-{}^{18}O}/I_{^{13}C-{}^{16}O} + I_{^{13}C-{}^{18}O})] \times 100\%$.

The findings described here (Scheme 1) are in agreement with all the results from earlier biosynthetic investigations on the tetracenomycins.[8–12] The studies were also aimed at comparing oxygenation steps in the biosynthesis of the tetracenomycins with those leading to other tetracyclic decaketides such as angucyclines and anthracyclines. Tetracenomycin C (**1**) is the first example among the polycyclic, aromatic polyketides requiring a molecule of H_2O to obtain its oxygen pattern. Thus, a novel enzymatic feature is implied, which is interesting for approaches to hybrid antibiotics through combination of the biosynthetic genes of the tetracenomycin producer *S. glaucescens* with related polyketide synthases of other producers of polycyclic, aromatic polyketides.[19, 20] For the oxygenation in the biosynthetic conversion of **3** into **1**, an epoxide intermediate such as **6** (Scheme 2) has to be assumed. It is unclear whether **6** is formed by two monooxygenases or only one dioxygenase; the latter possibility is in agreement with the suggested mechanisms found in oxygenation studies of aromatic compounds,[21a] as well as those proposed for the mode of action of vitamin K.[9c, 21b–e] This epoxide intermediate, however, would require an interesting, enzymatically controlled, but chemically unlikely "*cis* opening" to generate the stereocenters found in **1**.[6] Alternatively, the overall *cis* opening of the epoxide may result from an initial attack of an enzyme-bound SH group, which is then replaced by water in a S_N2-type reaction (Scheme 2).[22]

Experimental Procedure

Cultivation of the microorganism: *Streptomyces glaucescens* (Tü 49) was cultivated on slants (20% agar-agar, 10% malt extract, 4% glucose, 4% yeast extract, pH 7.0, adjusted before autoclaving) at 28 °C until sporulation occurred, then stored at 4 °C. The culture for the fermentations was innoculated directly from the slants and

Scheme 2. Details of the oxygenation in the biosynthetic conversion of **3** into **1**.

shaken on a rotary shaker (type Multitron, Infors AG, Switzerland) in ten 250 mL, triply baffled Erlenmeyer flasks, each filled with 100 mL of R2YENG medium [23] for 96 h at 30 °C and 250 rpm.

Isolation of tetracenomycin C (**1**): The combined cultures were treated with 300 mL of MeOH and celite and filtered. The combined culture filtrates were extracted with 1 L of ethyl acetate and the extract concentrated to dryness. The residue was dissolved in MeOH and chromatographed on a Sephadex LH 20 column (2.5 × 100 cm, MeOH). Yield ca. 20 mg of **1**.

Feeding experiments with labeled precursors: a) Feeding of sodium [1-^{13}C]acetate: The labeled substrate (750 g L^{-1} culture) was dissolved in 75 mL of sterile water and neutralized with 0.1 M HCl. One-sixth (12.5 mL) of this solution was distributed every eight hours (36 h to 76 h after inoculation) among ten Erlenmeyer flasks each containing 100 mL of the growing culture of *S. glaucescens* Tü 49. b) Feeding of [1-^{13}C,$^{18}O_2$]acetate (1 g L^{-1}): As in a); to avoid ^{18}O exchange with the solvent, the labeled material was added in portions (6 × 166 mg); each portion was dissolved in 10 mL of sterile water directly before the feeding and neutralized immediately with 5 N NaOH. c) Feeding of $H_2{}^{18}O$: The cultivation (500 mL culture) was carried out as above using $H_2{}^{18}O$ (10% ^{18}O) for the preparation of the medium and as the cultivation solvent.

Labeled compounds: [1-^{13}C]Acetate (99% ^{13}C) was obtained from Cambridge Isotope Laboratories (Cambridge, MA, USA) and $H_2{}^{18}O$ (97.9% ^{18}O, 10% ^{18}O) from Isotec Inc. (Miamisburg, OH, USA). [1-^{13}C,$^{18}O_2$]Acetate was synthesized from [1-^{13}C]acetate and $H_2{}^{18}O$ (97% ^{18}O) [24].

$ATh_{12}N_6X_{29}$ (A = Li... Rb; X = Cl, Br): A New Type of Thorium Cluster with a $Th_{12}N_6$ Core

Thomas P. Braun, Arndt Simon,* Fred Böttcher, and Fumio Ueno

The reduced halides of the rare earth elements exhibit a rich chemistry, in which discrete or condensed metal clusters play a major role.[1, 2] Primarily the 5d electrons are involved in metal–metal bonds in the clusters; the 4f electrons are much lower in energy. The possible participation of f electrons in the formation of metal–metal bonds is still in question. One prerequisite for this is significantly higher energies, as found in the 5f metals. We therefore started experiments to prepare reduced thorium halides as a "window towards the actinoids". Like the related element zirconium, thorium forms cluster compounds[3–5] if interstitial heteroatoms are allowed for stabilization. We have already reported on thorium cluster compounds with an octahedral Th_6Br_{15} unit,[6, 7] and we now describe compounds with the new cluster framework $Th_{12}Br_{29}$.

The phase $ATh_{12}N_6Br_{29}$ (A = Li... Rb) was first found for A = Li. However, complete structural characterization of the compound was not possible. The lithium atoms could not be localized by either X-ray crystallographic methods or by neutron diffraction on samples prepared with ^7Li. Later we found that these phases are also accessible with the heavier alkali metals sodium through rubidium as the A element. Even though these atoms could not be localized with X-ray methods either, they were essential in the preparations (introduced as bromides, azides, and also in elemental form). The presence of nitrogen was secured for single, selected crystals by using Nessler's reagent.[8] Whether nitrogen in these compounds can be replaced by neighboring elements was answered experimentally. Traces of oxygen (almost unavoidable) always lead to the formation of $ThOBr_2$ needles with an orange-red tinge caused by an excess of thorium. Apparently all of the oxygen present in the system is gettered by the formation of this compound. Use of carbon instead of nitrogen inhibits the formation of the cluster compound. These phases are also not formed when NH_4Br or ThH_2 are used as hydrogen sources, or when the reaction mixture is annealed in a H_2 atmosphere.

As the alkali metal atoms could not be localized in the bromides, we tried to prepare the chloride analogues with potassium and rubidium as the alkali metal. The desired compounds can indeed by synthesized, and the inclusion of the alkali metal atoms could be established by an X-ray structure analysis on a single crystal of $RbTh_{12}N_6Cl_{29}$.[9] Although the chlorides and the bromides belong to different crystal systems ($ATh_{12}N_6Cl_{29}$ are triclinic and $ATh_{12}N_6Br_{29}$ are orthorhombic), they are based on the same cluster units $Th_{12}N_6X_{41}$. The distances within the $Th_{12}N_6$ unit are also almost identical in both systems. Cyclic condensation of six nitrogen-centered thorium tetrahedra through common *cis* edges (i.e. every three tetrahedra share a common vertex) leads to formation of the new star-shaped cluster unit (Fig. 1). The thorium–thorium distances along the shared edges are shortened to 360 pm (as in thorium metal). As a consequence of the cyclic condensation, an octahedral void (compressed along the threefold axis) is formed inside the polyhedron. The $Th_{12}N_6$ unit is surrounded by a total of 41 halogen atoms divided into four groups:

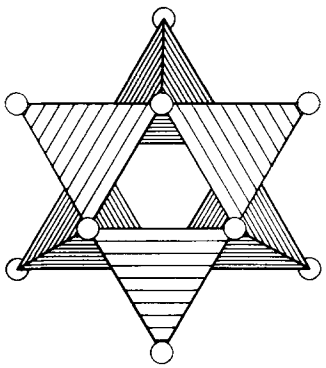

Fig. 1. Structure of the metal core of the $[Th_{12}N_6X_{41}]$ cluster: six nitrogen-centered thorium tetrahedra are joined though common *cis* edges.

1. One halogen atom is on either side of the basal plane of the central trigonal antiprism.
2. Another twelve halogen atoms surround these first halogen atoms in a close-packed fashion in the same planes.
3. A total of 18 halogen atoms are bound tripod-like in sets of three to the six peripheral thorium atoms.
4. The "waist" of the cluster contains nine additional halogen atoms, of which all nine are disordered in the case of the bromides, and three in the case of the chlorides.

Both the orthorhombic and the triclinic structure variant can formally be described by the connectivity scheme $ATh_{12}N_6X^i_{19}X^{i-a}_{4/2}X^{a-a}_{8/2}X^{a-a}_{6/3}X^{a-i}_{4/2}$. Following the treatment of octahedral cluster units by Schäfer and Schnering,[10] the outward singly bonded halogen atoms in the "tripod" positions are denoted as a, and all other halogen atoms bound to more than one thorium atom inside the cluster as i. With this formulation the two structure variants are differentiated only in the particular choice of the X^i positions used for the asymmetric $X^{i-a}_{4/2}$ link. The formation of the two structure variants in the solid can thus be attributed to subtle local variations in connectivity.

The arrangement of the metal and halogen atoms represents a section from the ZrCl-type structure.[11] If the interstitial nitrogen atoms in the tetrahedral voids are also considered, the arrangement is a section of the TbXH structure type.[12]

If we regard just the arrangement of the metal atoms, the new cluster type may be interpreted as a substitution variant of the octahedral M_6X_8 cluster type, in which some of the halogen atoms above the octahedral faces are replaced by additional metal atoms. Up to now only cluster compounds with one[13] or two faces[14–18] of more or less distorted octahedra capped by additional metal atoms were known. In comparison, six of these faces are capped in the star-shaped Th_{12} units.

If chemical bonds are considered in the simplest, purely ionic terms (i.e. $A^+(Th^{4+})_{12}(N^{3-})_6X^-_{29}$), two electrons (1 + 48 − 18 − 29 = 2) per cluster unit remain for occupying metal–metal bonding orbitals. According to Extended Hückel calculations[19] on the molecular unit $[Th_{12}N_6Cl_{41}]^{13-}$, the energetically distinct HOMO has symmetry class a_{1g} in the idealized point group $\bar{3}m$ (D_{3d}). Only the six inner thorium atoms contribute to this orbital with their 6d orbitals (Fig. 2). This six-center, two-electron bond stabilizes the entire cluster unit. The homonuclear bonds are thus confined to the central octahedron, whereas the nitrogen-centered tetrahedra best fit an ionic description. If one includes the Th 5f orbitals in the calculations, significant contribution of these orbitals to the metal–metal bonding HOMO results (at least on that level of the calculation). Hence these compounds are only obtained when the incorporation of the alkali metal atom provides an additional electron for the metal–metal bond. The structure analysis of $RbTh_{12}N_6Cl_{29}$ impressively demonstrates the inclusion of exactly one alkali metal atom. Even though the alkali metal atom is disordered over two positions, these positions can be localized easily. The occupation factors can be refined independently, and add up to a value of $x = 1.08(8)$ based on the formula unit $Rb_xTh_{12}N_6Cl_{29}$. In the final refinement these occupation factors were therefore constrained and refined together. The observed diamagnetism shows that these compounds are stoichiometric without a noticeable range homogeneity.

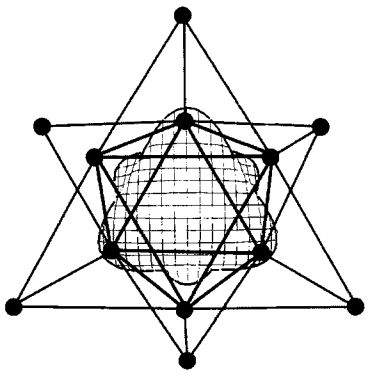

Fig. 2. Representation (ref. [20]) of the HOMO (a_{1g}) of the $[Th_{12}N_6X_{41}]$ cluster.

Experimental Procedure

The following preparation of $RbTh_{12}N_6Cl_{29}$ is representative for those of the other compounds: A Ta capsule containing 37.7 mg of Th (turnings), 700.1 mg of $ThBr_4$, 306.1 mg of Th_3N_4, and 30 mg of RbCl was sealed, protected from oxidation in a quartz ampule, annealed for 3 d at 680 °C, and then quenched. The samples obtained were single phase by X-ray crystallography (Guinier-Simon technique).

Polymers with Complexed Cyclobutadiene Units in the Main Chain: The First Example of a Thermotropic, Liquid Crystalline Organometallic Polymer**

Markus Altmann and Uwe H. F. Bunz*

Low molecular weight metallomesogens[1] were discovered some time ago and are now a topic of thorough investigation because of their optical and electronic properties.[2] In contrast, liquid crystalline, organometallic polymers have hardly been described. Among the few examples are the palladium/platinum alkyne polymers of Hagihara et al.[3] that have been known for several years and the more recent tricarbonylchromium-complexed polyaramides synthesized by Dembek et al.[4] In both cases the occurrence of lyotropic liquid crystalline phases is attributable to the rigid molecular structure (rigid rods) and thus to the shape anisotropism.[5]

In contrast to the conformationally flexible or bent diethynylated sandwich or half-sandwich complexes[6] the structure of the 1,3-diethynylcyclobutadiene metal complexes should make them suitable monomers for the construction of linear, stiff, organometallic polymers. Although in 1,3-diethynylcyclobutadiene(cyclopentadienyl)cobalt (**1**) a potential cyclobutadiene monomer is accessible on a gram scale,[7] no polymers with cyclobutadiene units in the main chain are yet known. In a preliminary experiment **1a** (R^1 = H) was stirred for 18 h with 1.0 equivalent of 1,4-dihexyl-2,5-diiodobenzene, 5 mol% of $[PdCl_2(PPh_3)_2]$, and CuI in diisopropylamine at room temperature.[8] Gel permeation chromatography (GPC) of the crude mixture, however, showed that a wide range of only low molecular weight products had been formed. On use of piperidine as base under otherwise identical conditions,[9] a yellow amorphous powder was obtained in 75% yield (see Table 1) after repeated precipitation of the dark reaction mixture into methanol and into pentane (see Experimental).

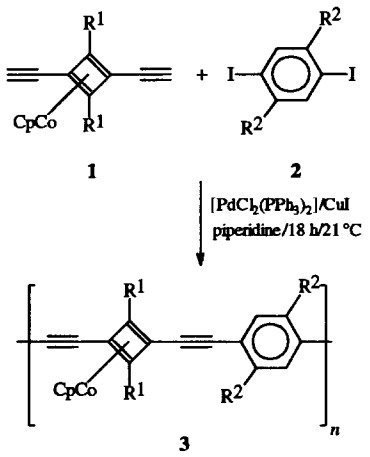

Table 1. Substitution patterns, yield, molecular weights, and average degree of polymerization $\bar{P}$ of the polymers **3a–e** after precipitation from methanol.

3	R^1	R^2	Yield [%]	M_n [10^3 gmol^{-1}]	M_w [10^3 gmol^{-1}]	$\bar{P}$
a	H	hexyl	75	3.66	19.4	18
b	$SiMe_3$	H	86	4.31	7.41	18
c	H	dodecyl	79	23.6	65.0	58
d	$SiMe_3$	hexyl	74	5.13	13.1	18
e	$SiMe_3$	dodecyl	79	4.91	20.1	12

Analytical GPC (chloroform) yielded a polydispersity of $M_w/M_n = 5.3$ (polystyrene as standard) for polymer **3a**; an M_n of 3660 gmol^{-1} was obtained. The ^{1}H NMR spectrum showed the expected resonances: Weak signals of end groups appear in the aromatic range at $\delta = 7.33$ and 7.64. The signal assigned to the ethynyl groups of the monomer has completely disappeared.

The polymers **3b** and **d** were prepared and purified in the same way as **3a** (for the synthesis of **3c** and **e**, see Experimental Procedure). The polymer **3c** has by far the highest molecular weight. After precipitation once from methanol and once from pentane, all the polymers form an intensely yellow amorphous powder, but take on an increasingly reddish tinge from **3a** through **3b** to **3d**. All polycondensates form strong, flexible and transparent films from solution. The physical data of **3a–e** are given in Table 2.

Rapid concentration of the solutions of **3a–e** in dichloromethane provides clear yellow films, which appear isotropic

Table 2. Physical data of **3a–e** [a].

3a: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3105, 2955, 2925, 2856, 2190; ^{1}H NMR ($CDCl_3$): δ = 0.93 (t, ^3J(H,H) = 3.0 Hz), 1.36 (br. s), 1.61 (br. s), 2.64 (br. s), 4.66 (s), 5.06 (s), 7.18 (s); ^{13}C NMR (CD_2Cl_2): δ = 19.02 (q), 23.14, 29.63, 31.04, 32.11, 34.43, (5 t), 55.85 (d), 64.62 (s), 81.67 (d), 89.33, 91.50 (2 s), 128.32, 142.21 (2 s), 132.14 (d).

3b: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3104, 2953, 2923, 2853, 2188; ^{1}H NMR (CD_2Cl_2): δ = 0.88 (br. s), 1.29 (br. s), 1.55 (br. s), 2.65 (br. s), 4.67 (s), 5.06 (s 22.95, 142.20 (2), 7.17 (s); ^{13}C NMR (CD_2Cl_2): δ = 15.71 (q), 24.52, 31.19, 31.38, 31.50, 31.54, 32.48, 33.76, 35.82 (8 d), 55.78 (d), 64.61 (s), 81.58 (d), 89.29, 91.45 (2 s), 122.95, 142.20 (2 s), 132.05 (d).

3c: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3015, 2962, 2898, 2192, 2127; ^{1}H NMR (CD_2Cl_2): δ = 0.37 (s), 4.97 (s), 7.27 (s), 7.11, 7.64 (2 d, ^3J(H,H) = 8.5 Hz (terminal group)); ^{13}C NMR (CD_2Cl_2): δ = −0.31 (q), 65.39, 76.08 (2 s), 77.11, 91.08 (2s), 81.68 (d), 123.66 (s), 130.94 (d).

3d: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3105, 2956, 2927, 2869, 2190, 2132; ^{1}H NMR (CD_2Cl_2): δ = 0.39 (s), 0.92 (br. s), 1.35 (br. s), 1.60 (br. s), 2.67 (br. s), 5.00 (s), 7.14 (s); ^{13}C NMR (CD_2Cl_2): δ = 0.04 (q), 14.64 (q), 23.47, 29.87, 31.29, 32.63, 34.66 (5 t), 66.24, 76.28 (2 s), 81.96 (d), 90.84, 93.93 (2 s), 123.61, 141.83 (2 s), 132.53 (d).

3e: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3105, 2955, 2925, 2845, 2190, 2128; ^{1}H NMR (CD_2Cl_2): δ = 0.38 (s), 0.89 (t, ^3J(H,H) = 6 Hz), 1.29 (br. s), 1.61 (br. s), 2.66 (br. s), 4.99 (s, 5H;), 7.14 (s, 2H;), 14.63 (q, 2C), 23.45, 30.12, 30.26, 30.46, 31.53, 32.70, 34.69 (7 d), 66.25, 76.26 (2 s), 81.96 (5 d), 90.86, 93.92 (2 s), 123.63, 141.84 (2 s), 132.53 (d).

[a] The ^{13}C and ^{1}H NMR spectra were recorded at 200 and 500 MHz, respectively.

(black) under crossed polarizers and display no birefringence. If, however, the films are obtained by slow evaporation of the solvent (dichloromethane or -ethane), *schlieren* textures and/or Maltese crosses are observed under crossed polarizers; that is, **3a–e** form lyotropic liquid crystalline phases. Only in the case of **3c** was an isotropic film formed exclusively, and no lyotropic phase was detected. The *schlieren* textures and Maltese crosses of **3a**, **b**, **d**, and **e** do not disappear when the solvent has evaporated. This is a consequence of the restricted mobility of the polymer after removal of the solvent, which probably indicates that the polymer has a frozen liquid crystalline structure.

Thermogravimetric studies on **3d** as representative polymer showed that decomposition begins at about 250 °C and reaches a maximum at 450 °C. An investigation of the phase behavior of **3d** by differential thermal analysis revealed that in the first heating curve an endothermic monotropic phase transition (0.42 kcal mol^{-1}) occurs at about 115 °C, and at 155 °C a structural change was observed. In the cooling curve and in a second heating curve, transitions could no longer be observed. On heating a thin isotropic film obtained by evaporating a solution of **3d** in dichloromethane under the polarizing microscope (in a pure nitrogen atmosphere) to 160 °C, *schlieren* patterns (Fig. 1) were observed within a few minutes.[10] These showed no change whatever up to 250 °C and did not disappear on cooling. Liquid crystalline **3d** could, however, not be converted into the isotropic melt, because at about 300 °C the sample started to decompose, accompanied by considerable darkening. Differential thermal analysis of **3e** gave only two endothermic transitions at 55 and 80 °C, which are probably caused by melting of the side chains; for **3e** a mesophase was not found on heating to above 250 °C.

To understand the phase behavior of **3d** better, we performed X-ray diffraction experiments. The initially precipitated polymer is almost X-ray amorphous. A diffractogram recorded at 180 °C supports the disappearance of all *crystalline* order. In a sample of **3d** prepared by slow evaporation of a solution in dichloromethane, the polymer is (partially) crystalline.[11] If this material is heated to 180 °C and studied by diffractometry, the X-ray reflections also disappear to a large extent. This behavior is consistent with the occurrence of a nematic liquid crystal,

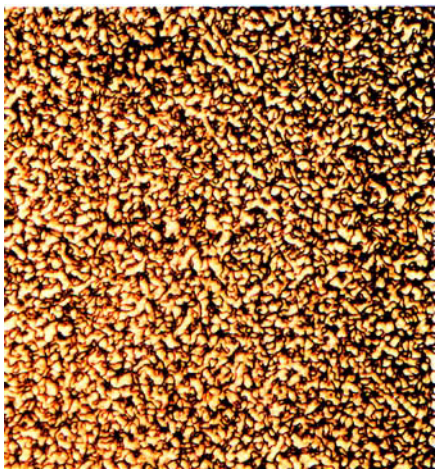

Fig. 1. Schlieren textures of **3d** in a film at 165 °C.

because the anticipated "nematic streak" is not always observable.[12]

We interpret the thermal behavior of **3d** in terms of melting of the side chains for the phase transition at 115 °C. The mobility of the main chain at this point does not appear large enough for the transition from the nonordered isotropic (or crystalline) phase to a liquid crystalline phase to take place. Only at about 160 °C, when the exothermic second phase transition takes place, does a pronounced *schlieren* texture form (Fig. 1).

Experimental Procedure

1 (0.60–1.0 mmol) was placed in a Schlenk tube with an equimolar amount of **2**, $[PdCl_2(PPh_3)_2]$ (5 mol%), and CuI. Under an inert atmosphere (N_2) dried piperidine (50 mL) was added. The initially clear yellow solution was stirred for 18 h at 21 °C, during which ammonium salts precipitated with concomitant darkening and increased viscosity. The mixture was worked up by filtering off the salts, removing the piperidine under reduced pressure, and dissolving the residue in chloroform. Methanol was then added till the polymer (yellow flakes) precipitated. By centrifugation and renewed dissolution and precipitation with pentane the polymers **3a**, **b**, and **d** can be isolated in pure state. Attempts to precipitate **3e** from pentane were unsuccessful. Instead **3e** was freed from low molecular impurities (M < 1000 g mol^{-1}) by GPC (chloroform). In the case of **3c** the precipitation from methanol yielded an insoluble product, and as for **3e** the purification had to be carried out by GPC (products with M < 1000 g mol^{-1} were discarded). The study of the phase transitions as well as the NMR spectroscopy was performed on the doubly precipitated polymers (**3a**, **b**, **d**).

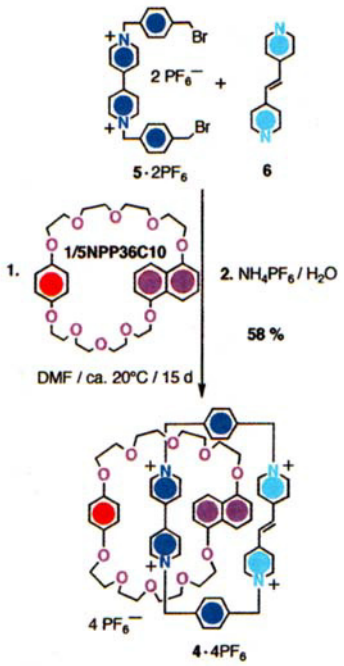
[11] Powder spectra: Siemens diffractometer D500, $Cu_{K\alpha}$ radiation; distances found 11.2, 7.1, 6.4, 5.1, 4.8, 4.3, and 3.7 Å. The reflection corresponding to the 11.2 distance is the most intense and probably represents the Co–Co distance in the chain. The 7.1 distance probably represents the interchain distance.

[12] A "streak" in the phase diagram is seen in the powder diffractogram as a pattern of unstructured scattering intensity with a sharp rise at small scattering angles. Although the integrated intensity of a streak can be very large, it is not necessarily observable on account of the large signal width.

Controlling Translational Isomerism in [2]Catenanes**

Peter R. Ashton, Lluïsa Pérez-García, J. Fraser Stoddart,* Andrew J. P. White, and David J. Williams

The recognition processes that lead to the self-assembly[1] of [2]catenanes[2] are controlled by the information stored in the molecular components which are constructed from "preprogramed" starting materials. This information[3] is trapped within the [2]catenanes molecules whose properties are quite different from those of their individual molecular components. The study of phenomena such as translational isomerism, a structural characteristic[4] of many of these intriguing molecules, may provide insight into the recognition processes that operate during their formation and subsequently in their molecular states. Furthermore, the control of the translational isomerism in catenanes is important in demonstrating their chemical properties and for predicting possible applications.[5] Some recent examples illustrate[6, 7] the progress that has been made already toward the construction of controllable catenanes and rotaxanes. In our own research laboratory, after the [2]catenane **1**-4PF_6 had been self-assembled,[2] the [2]catenane **2**-4PF_6 was also synthesized[8] by a template-directed approach in the belief that the different π-donating abilities of the 1,5-dioxynaphthalene unit and the hydroquinone ring would influence strongly the relative populations of the rapidly equilibrating translational isomers. In the event, the position of the equilibrium was found to be highly dependent on the dielectric constant of the medium in which the [2]catenane was dissolved.



Another way to exercise control over the translational isomerism is by using π-extended viologen units as building blocks in the construction of interlocked molecular structures. We recently reported on the self-assembly, characterization, and electrochemical properties of the [2]catenane **3**-4PF_6,[9] in which the macrocyclic polyether, bis-*p*-phenylene[34]crown-10 (BPP34C10), is encircled by a tetracationic cyclophane containing one bipyridinium and one bis(pyridinium)ethylene unit.[9] In the case of **3**-4PF_6, the translational isomer, in which BPP34C10 encircles the bipyridinium rather than the bis(pyridinium)ethylene unit, is by far the more predominant one in CD_3COCD_3 solution at low temperature. This selectivity is a consequence of the lower π-accepting ability of the π-extended viologen unit relative to that of the parent viologen unit.

By combining both strategies, that is, by altering the different binding abilities of *both* the π-donor and π-acceptor units in these catenated structures, we should be able to exercise more control over their translational isomerism. Thus, we have designed and self-assembled a [2]catenane in which *all four* building blocks, the two π-donor and two π-acceptor units, are different. Here, we describe the synthesis of the [2]catenane **4**-4PF_6, which incorporates 1/5NPP36C10, a macrocyclic polyether containing *one* hydroquinone ring and *one* 1,5-dioxynaphthalene unit, as the π-electron rich macrocycle and a tetracationic cyclophane incorporating *one* bipyridinium and *one* bis(pyridinium)ethylene unit as the π-electron deficient components. We report on the characterization of **4**-4PF_6 by fast atom bombardment mass spectrometry (FABMS), X-ray crystallography, and dynamic ^{1}H NMR spectroscopy.

The [2]catenane **4**-4PF_6 was self-assembled using a template-directing methodology (Scheme 1).[10] The instantaneous formation of a complex between 1/5NPP36C10 and **5**-2PF_6 was followed by stepwise alkylation of **6** to form the [2]catenane **4**-4PF_6, which was isolated in 58% yield after counterion exchange and crystallization. The reaction was carried out in dimethylformamide (DMF) in the dark with an excess of the macrocyclic polyether. Positive-ion FABMS of this new compound revealed[11] peaks at $m/z = 1567$, 1422, and 1277 characteristic of the successive loss of one, two, and three PF_6^- counterions, respectively, from the molecular ion of **4**-4PF_6.

Scheme 1. The template-directed synthesis of the [2]catenane **4**-4 PF_6.

The observation of peaks at $m/z = 836$ and 690, corresponding to the loss of one and two counterions, respectively, from the tetracationic cyclophane component of the [2]catenane, is characteristic[12] of the fragmentations of a [2]catenane by loss of one of its rings—in this case, the neutral crown ether.

The catenated structure of **4**-4PF_6 was confirmed by X-ray crystallography;[13, 14] suitable single crystals were grown by vapor diffusion of diisopropyl ether into an acetonitrile solution of the compound. The major point to note about the solid-state structure (Fig. 1) is that **4**-4PF_6 exists as only one isomer. The macrocyclic polyether is threaded through the center of the extended tetracationic cyclophane; the 1,5-dioxynaphthalene unit is positioned within the cavity of the tetracationic cyclophane, sandwiched between the π-electron deficient bipyridinium and bis(pyridinium)ethylene units;[15] the hydroquinone ring is located outside of the cavity alongside the bipyridinium component. The molecule has crystallographic C_2 symmetry about an axis passing through the centers of the ethylenic double bond, the 1,5-dioxynaphthalene ring, the bipyridinium unit, and the hydroquinone ring. The [2]catenane is stabilized further by a) T-type edge-to-face interactions between the 1,5-dioxynaphthalene and the *p*-xylyl spacers of the tetracationic cyclophane,[16] and b) weak C–H···O hydrogen bonding of the central oxygen atom in each polyether chain with both a *p*-xylyl hydrogen atom and one of the α-CH hydrogen atoms of the bipyridinium unit, at each "end" of the tetracation

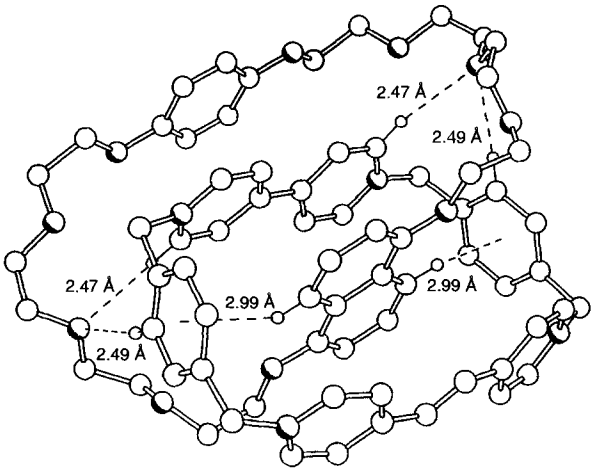

Fig. 1. The structure of the [2]catenane **4**-4PF_6 in the crystal; the additional stabilizing C–H···π and C–H···O interactions are shown.

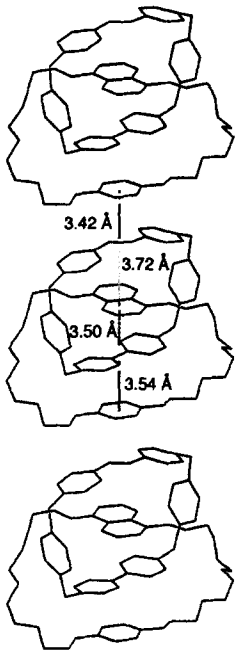
ic cyclophane (Fig. 1).[16] The incorporation of one extended viologen in place of the bipyridinium unit into one of the sides of the tetracationic cyclophane increases significantly its overall dimensions and alters its recognition properties. The length increases from 10.3 to 11.2 Å and the width from 6.8 to 7.2 Å.[17] The center of the 1,5-dioxynaphthalene unit lies closer to the bipyridinium unit (3.50 Å) than to the double bond (3.72 Å) of the π-extended viologen component (Fig. 2). In common with **1**-4PF_6, the [2]catenane **4**-4PF_6 forms extended polar stacks in the crystals. An interesting feature of this stack is that the double bond of the extended viologen component lies appreciably closer (3.42 Å) to the hydroquinone ring of an adjacent [2]catenane than to the 1,5-dioxynaphthalene unit within the [2]catenane (3.72 Å); indeed the separation is less than the intramolecular distance (3.50 Å) between 1,5-dioxynaphthalene and the bipyridinium units.



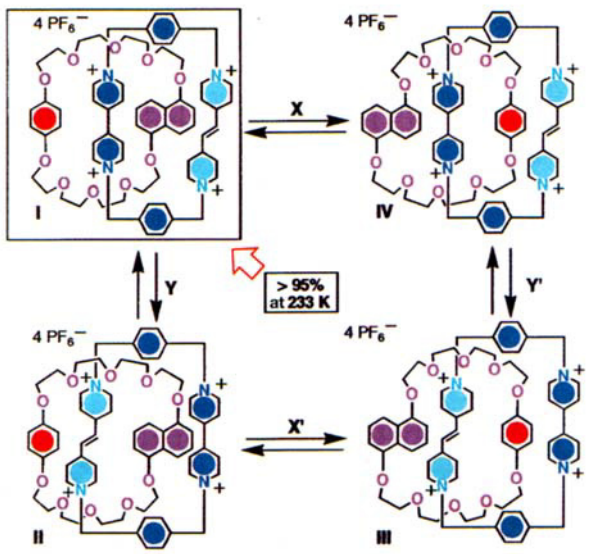


Fig. 2. Part of the extended polar stacks present in the crystals of the the [2]catenane **4**-4PF_6.

The [2]catenane **4**-4PF_6 consists of four different π systems, and therefore an equilibrium between four different translational isomers is possible (Scheme 2). Like [2]catenane **1**-4PF_6,[2] the new [2]catenane **4**-4PF_6 exhibits temperature-dependent ^{1}H NMR spectra.[18] However, the differences in the recognition processes between its components imbue the system with a high level of structural selectivity. One process (**X**/**X'**) is the equilibration of the π-electron rich hydroquinone ring and 1,5-dioxynaphthalene unit between positions either inside or alongside the tetracationic cyclophane. In the case of **4**-4PF_6, both in CD_3COCD_3 and CD_3CN solutions, ^{1}H NMR spectroscopic studies indicate that the circumrotation of 1/5NPP36C10 through the tetracationic cyclophane is already slow on the

Scheme 2. Equilibrium between the translational isomers (**I**–**IV**) of the [2]catenane **4**-4PF_6 in solution.

^{1}H NMR timescale at room temperature, in other words, the process **X/X′** is "frozen out" and the aromatic π-electron donors (hydroquinone and 1,5-dioxynaphthalene) do not interchange their positions. The equilibrium (Scheme 2) is predominantly in favor of the translational isomers **I** and **II**, where the 1,5-dioxynaphthalane ring occupies the position inside the tetracationic cyclophane. This conclusion may be drawn from the fact that the ^{1}H NMR spectrum at room temperature in CD_3COCD_3 shows three well-resolved signals at $\delta = 3.77$, 5.71, and 6.37 corresponding to the H-4/8, H-3/7, and H-2/6 protons, respectively, of the 1,5-dioxynaphthalene unit, and one well-resolved singlet at $\delta = 6.08$ for the hydroquinone ring protons. None of the chemical shifts for these signals undergo any changes at lower temperatures, at least down to −40 °C, indicating that the two types of aromatic rings do not interchange on the ^{1}H NMR timescale. At + 40 °C, the four aromatic signals are slightly broadened, indicating that process **X/X′** is starting to occur on the ^{1}H NMR timescale. At this temperature, saturation transfer experiments led us to identify some low-intensity broad resonances present in the ^{1}H NMR spectrum, corresponding to the averaged signals resulting from protons in the rapidly equilibrating translational isomers **III** and **IV**, where the hydroquinone unit is located inside the tetracationic cyclophane. Thus, irradiation of these weak signals at $\delta = 7.13$ and 7.36, corresponding, respectively, to H-3/7 and H-4/8 on the "alongside" 1,5-dioxynaphthalene unit indicated that they are undergoing exchange with a triplet at $\delta = 5.73$ and a doublet at $\delta = 3.68$, corresponding to the same protons on the "inside" 1,5-dioxynaphthalene unit in the rapidly equilibrating translational isomers **I** and **II**. Direct integration of these signals in the ^{1}H NMR spectrum at room temperature, where process **X/X′** has already been frozen out, gave an equilibrium ratio of 88:12 for the translational isomers **I** and **II** versus **III** and **IV**. The second dynamic process (**Y/Y′** in Scheme 2) exhibited by **4**-4PF_6 involves pirouetting of 1/5NPP36C10 around the tetracationic cyclophane. At room temperature, this process is fast on the ^{1}H NMR timescale. However, below −40 °C, it is frozen out and the major isomer detected is the translational isomer **I**, where the π-electron deficient bipyridinium unit is located inside the tetracationic cyclophane. This is indicated by the relative simplicity of the ^{1}H NMR spectrum, in which only four major signals are observed for the α-bipyridinium protons, two doublets, corresponding to the bipyridinium unit, and two doublets, corresponding to the bis(pyridinium)ethylene unit. This temperature-dependent behavior associated with process **Y/Y′** was accompanied by changes in the ^{1}H NMR signals arising from all the protons in the tetracationic cyclophane component of the [2]catenane. Thus, at −40 °C, the signal corresponding to the olefinic protons of the bis(pyridinium)ethylene unit in translational isomer **I** appears at $\delta = 6.60$, only $\Delta\delta = 0.10$ downfield relative to the analogous signal in the room-temperature spectrum. This observation confirms that this signal corresponds to translational isomer **I**, where the π-extended viologen resides alongside the polyether cavity. Once again, a saturation transfer experiment at −20 °C showed the existence of site exchange between a high-intensity signal at $\delta = 6.56$ (**I**) and a low-intensity signal at $\delta = 6.15$ (**II**). These signals are associated with site exchange of the olefinic protons of a bis(pyridinium)ethylene unit, alongside and inside the macrocyclic polyether. This is evidence for the population of both translational isomers **I** and **II** (Scheme 2). Integration of the signals at −40 °C gave a ratio of 95:5 for isomers **I** and **II**. Neither of the other two possible isomers (**III** or **IV**) were detected at this temperature. In solution at low temperatures [2]catenane **4**-4PF_6 exists almost exclusively as one amongst four possible translational isomers. This one isomer is precisely the same as that observed in the solid by X-ray crystallography.

The [2]catenane **4**-4PF_6 shows how the recognition processes operating between the components of interlocked molecular systems express themselves in the properties of the molecules—in this case, by controlling translational isomerism. This finding demonstrates the progress that is being made toward the construction of controllable [2]catenanes.

Experimental Procedure

4-4PF_6: A solution of **5** (53 mg, 0.06 mmol) in dry DMF (5 mL) was added to a solution of 1/5NPP36C10 (77 mg, 0.13 mmol) in dry DMF (4 mL). A deep red color was formed immediately, and a solution of **6** (13 mg, 0.07 mmol) in dry DMF (1 mL) was added. After the reaction mixture had been stirred at room temperature for 15 d, the suspension was poured in Et_2O (50 mL). The red solid was filtered off, washed with Et_2O (10 mL) and CH_2Cl_2 (10 mL), and then dried before being dissolved in H_2O (15 mL) and Me_2CO (5 mL). Then, a saturated aqueous solution of NH_4PF_6 was added, and the solution was left to stand for ca. 15 h, during which time purple crystals formed. The suspension was filtered off, and the crystals were washed with H_2O (2 × 3 mL) and then dried to give **4**-4PF_6 as a purple solid (65 mg, 58%), m.p. >300 °C; positive-ion FABMS: *m/z*: 1567 $[M - PF_6]^+$, 1422 $[M - 2PF_6]^+$, 1277 $[M - 3PF_6]^+$; ^{1}H NMR (300 MHz, CD_3CN): $\delta = 3.20$–4.30 (m, 32H), 3.37 (d, $J = 8.0$ Hz, 2H), 5.57 (dd, $J = 7.5$, 8.0 Hz, 2H), 5.61 (d, $J = 13.5$ Hz, 2H), 5.68 (s, 4H), 5.80 (d, $J = 13.5$ Hz, 2H), 6.09 (s, 4H), 6.10 (s, 2H), 6.26 (d, $J = 7.5$ Hz, 2H), 7.06 (d, 4H), 7.27 (br s, 4H), 7.88 (d, $J = 8.5$ Hz, 4H), 7.98 (d, $J = 8.5$ Hz, 4H), 8.73 (br s, 8H).

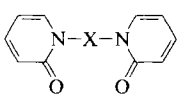
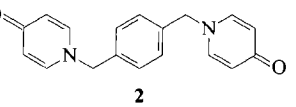
[15] The $OC_{10}H_6O$ axis of the 1,5-dioxynaphthalene unit is inclined by 34° to the equatorial plane of the tetracationic cyclophane as defined by the mean plane of its four methylene carbon atoms.
[16] The distances between H-4 and H-8 on the naphthalene rings and the centers of their immediately adjacent *p*-xylyl rings are 2.99 Å and the C–H···centroid angles are 143°. In the case of the C–H···O interactions between one of the *p*-xylyl hydrogen atoms and the central oxygen atoms of the polyether chains, the H···O distances are 2.49 Å and the C–H···O angles are 167°. For the C–H···O interactions between the α-CH hydrogen atoms of the bipyridinium unit and the same oxygen atoms of the polyether chains, the H···O distances are 2.47 Å and the C–H···O angles are 169°.
[17] The length is defined as the distance between the centroids of the two *p*-xylyl rings, and the width as the distance between the centers of the bond(s) linking the pyridinium rings.
[18] The ^{1}H NMR spectra were recorded on a Bruker AMX400 spectrometer operating at 400.13 MHz. All chemical shifts are referenced via the residual $CHD_2COCHCD_2$ or CHD_2CN signals to Me_4Si.



$[Mn(C_{18}H_{16}N_2O_2)_3](ClO_4)_2$: A Polymeric 34- and 68-Membered Metallacyclic Network Forming a Novel Woven Polycatenated Structure**

David M. L. Goodgame,* Stephan Menzer, Amanda M. Smith, and David J. Williams*



The past decade has seen the creation of many elegant interlocked molecular species, the most notable of which have been the catenanes, rotaxanes, and "knots" pioneered principally by Sauvage et al. and Stoddart et al.[1] Key factors in the development of this work have been the use of metal templating combined with appropriate ligand design, and the employment of noncovalent interactions as part of the synthetic strategy. An important feature of both these approaches has been the use of conformationally flexible components.

Concurrent with this has been the development of three-dimensional networks based primarily on linking metal centers with rodlike or other essentially rigid bridging components.[2] An occasional product of this latter work has been the formation of interpenetrating, adamantyl-like networks.[3] Interleaved, extended networks incorporating flexible bridging units are, however, rare.[4] We report here the discovery of an unusual, new, flexibly bridged, interpenetrating polycatenane.

We have recently been exploiting the conformational preferences of a series of extended-reach organic ligands of the general type **1** to create a range of two- and three-dimensional polymeric metallamacrocyclic networks.[5] Extending this work, we have

1

2

explored the effect of changing the position of the exocyclic O-donor group on the heterocyclic unit from *ortho* to the *para* position relative to the ring nitrogen, as in *N,N'-p*-phenylenedimethylenebis(pyridin-4-one) (**2**, *p*-XBP4). This has resulted in the formation, inter alia, of the polymer **3**.

$\{[Mn(p\text{-XBP4})_3](ClO_4)_2\}_n$ **3**

X-Ray analysis[6] of **3** shows that the crystal structure is based on a network of octahedrally coordinated Mn centers linked by *p*-XBP4 ligands (Fig. 1). There are two distinct ligand geometries (A and B) present in the structure in a 2:1 ratio. In A, one of the pyridone rings is essentially orthogonal to the central *p*-xylyl unit, whilst the other is in an "open book" conformation with respect to it. Bridges of this type link pairs of Mn centers, creating open 34-membered rings (Fig. 1). Within each 34-membered ring, adjacent pairs of *cis*-coordinated pyridone rings are held in a near coplanar arrangement by weak CH···O hydrogen bonds (H···O 2.33 and 2.48 Å) between the *ortho* CH group of one pyridone ring and the oxygen atom of its *cis*-coordinated neighbor.

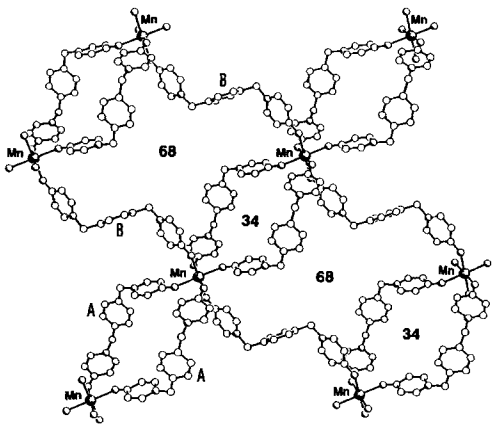


Fig. 1. Part of the network of 34- and 68-membered metallacycles, showing the ligand geometries A and B in **3**.

Ligands in arrangement B have the pyridone rings centrosymmetrically disposed but skewed to a position intermediate between an orthogonal orientation and an open-book conformation with respect to the *p*-xylyl spacer. These type B bridges serve to link pairs of the 34-membered rings, thus creating a set of 68-membered rings (Fig. 1). The manganese atoms within this network lie in the *ab* plane and are separated by two unit cell translations in both the *a* and *b* directions.

[**] This work was supported by the Science and Engineering Research Council and the Commission of the European Communities.

The fascinating feature of the structure of **3** is that it comprises not one, but two such networks interwoven one with the other (Fig. 2). Each network is displaced by one unit cell translation in the *a* or *b* direction with respect to the other; thus, the manganese atoms in one network reside in the centers of the 68-membered rings of the other and vice versa. In addition, ligands of conformation B in one network are threaded through the centers of the 34-membered rings of the other, thus forming a polycatenated sheet structure.

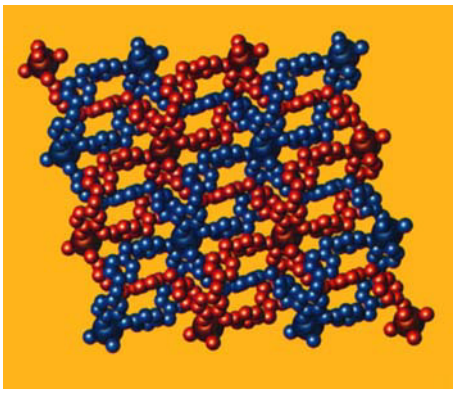

Fig. 2. Perspective view of the interwoven polycatenane structure of **3**. Manganese atoms are depicted as large spheres. The atoms of the individual networks are shown in red or blue.

The interpenetrating networks are stabilized by a combination of near parallel face-to-face and T-type edge-to-face $\pi-\pi$ interactions (Fig. 3). The face-to-face interactions are between the central *p*-xylyl ring (P) of the threading ligand (that is, type B) and one each (Q and Q′) of a pair of centrosymmetrically disposed pyridone rings of type A ligands, and also between the *p*-xylyl ring (T) of the type A ligand and the terminal pyridone ring (S′) of the thread.[7] The T-type interactions are between the pyridone ring (S) of the thread and the pyridone ring (R) of the type A ligand within the 34-membered ring.[7]

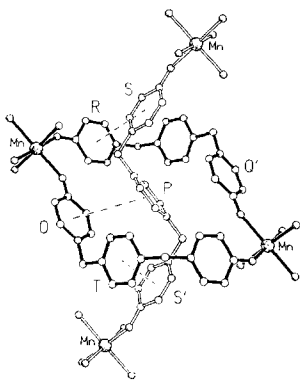

Fig. 3. The type B ligand is threaded through the center of one of the 34-membered rings. The face-to-face and edge-to-face interactions are indicated as broken lines. The ring P lies on a crystallographic center of symmetry.

The sheets have a pronounced corrugated cross section and adjacent sheets are positioned approximately ridge-to-ridge, creating channels within which the anions and acetonitrile solvate molecules are located. Studies by mass spectrometry (positive FAB to $m/z = 2500$) of solutions of **3** in water and in methanol showed that the polymer is broken up in these solvents. In each case the dominant species observed was (*p*-XBP4)H^+, and a much smaller peak assignable to (*p*-XBP4)$_2H^+$, but there was no conclusive evidence for oligomeric Mn-containing species under these conditions.

It is remarkable that such a complex, polycatenated structure is formed by **3** in preference to either the layered sheets of large ring metallacycles[8] or the three-dimensional networks of non-interpenetrating rings[9] we have observed previously with ligands of type **1**. The mechanism of the formation of the interpenetrating structure is manifestly complex, though it is possible that the aromatic–aromatic face-to-face and edge-to-face interactions may play an important templating role. Further studies are in progress to investigate the factors favoring the polycatenation process.

Experimental Procedure

Ligand **2**: Pyridin-4-one (0.02 mol) was treated with sodium butoxide (0.02 mol) in butan-1-ol (80 mL), α,α′-dibromo-*p*-xylene (0.01 mol) was added, and the mixture was heated at reflux for 6 h. After cooling, extraction with water (3 × 30 mL) gave the product as the crystalline tetrahydrate. Yield 45%: elemental analysis for $C_{18}H_{16}N_2O_2 \cdot 4H_2O$; found: C 59.39, H 6.43, N 7.77; calcd: C 59.33, H 6.64, N 7.69.

3: Dropwise addition of a solution of $Mn(ClO_4)_2 \cdot 6H_2O$ (0.033 mmol) in acetonitrile (4 mL) to a solution of **2** (0.1 mmol) in a mixture of acetonitrile (3 mL) and methanol (1 mL) yielded **3**. The precipitate that formed immediately was redissolved by addition of methanol (1 mL), and the resulting solution was allowed to evaporate slowly over concentrated sulfuric acid. Pale yellow crystals formed overnight and were collected by filtration, washed with cold acetonitrile, and air-dried. Yield 80%.

DNA–Carbohydrate Recognition: Design and Synthesis of an Eight-Base Sequence-Selective DNA-Binding Oligosaccharide**

K. C. Nicolaou,* Keiichi Ajito, Hironori Komatsu, Brian M. Smith, Tianhu Li, Miles G. Egan, and Luigi Gomez-Paloma

DNA-binding molecules, particularly those with sequence specificity, have considerable potential in chemistry, biology, and medicine.[1–7] Such molecules may provide the basis for further insights in the chemistry and structure of DNA, for the design and development of tools for molecular and cell biology, and for the development of antisense and gene therapies.[4–7] Following calicheamicin γ_1^I [8] as a lead, we have recently synthesized and studied the binding of a series of oligosaccharides to duplex DNA.[9–11] In these investigations[9, 10] oligosaccharide **1** (Scheme 1) emerged as the most potent and selective molecule, binding duplex DNA at TCCT sites with an affinity constant of $K_a \approx 10^6\ M^{-1}$. First synthesized in 1990 in our laboratory,[12] oligosaccharide **1** was recently shown by Crabtree et al.[13] to specifically inhibit transcription complexes. Appropriately designed oligomers of **1** should exhibit enhanced binding to duplex DNA in terms of potency and specificity. We now wish to report the design and chemical synthesis of the head-to-head dimer **2** (Scheme 1) of oligosaccharide **1**, which was designed to bind duplex DNA selectively at *TCCTXXAGGA* sequences.[14]

Scheme 1. Structures of calicheamicin γ_1^I oligosaccharides **1** (monomer, binds a TCCT site) and **2** (head-to-head dimer designed to bind a *TCCTXXAGGA* site). The tether is marked with an arrow.

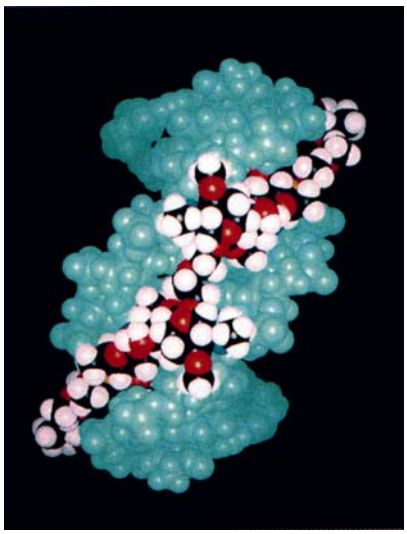

Fig. 1. Computer-generated model of dimer **2** bound to the minor groove of duplex DNA [GCA*TCCTATAGGA*TGC] along a *TCCTATAGGA* site.

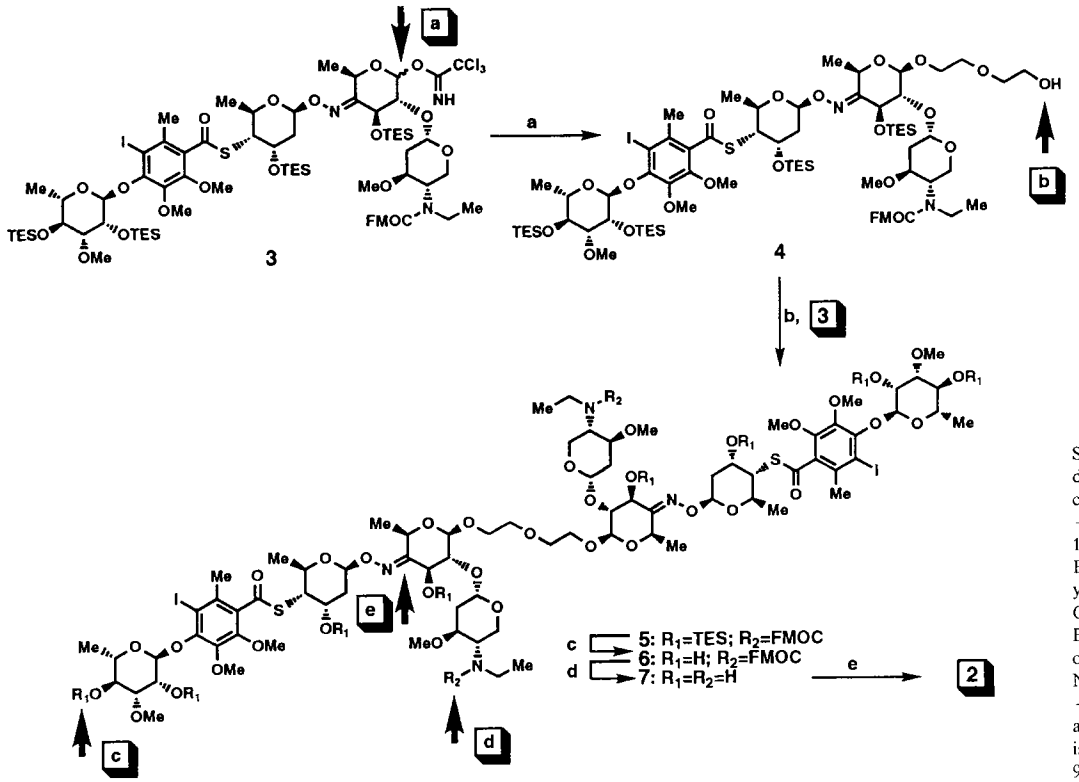
Based on the detailed interactions of oligosaccharide **1** with a TCCT site of a duplex 10-mer DNA as determined by NMR spectroscopy,[11, 15] and footprinting experiments,[9, 10, 16] and by using computer modeling, the head-to-head dimer **2** was designed to dock properly into the minor groove of duplex DNA along a *TCCTXXAGGA* tract. The five-atom tether $-CH_2CH_2OCH_2CH_2-$ was found, by computer modeling, to allow optimum fit of the two oligosaccharide domains into their respective binding sites. Figure 1 depicts a computer-generated model of dimer **2** bound to duplex DNA along its target *TCCTXXAGGA* tract.



The synthesis of the designed decacyclic oligosaccharide **2** was carried out from the previously reported[17] key intermediate **3** as summarized in Scheme 2.[18] Coupling trichloroacetimidate **3** with excess diethylene glycol in CH_2Cl_2 at $-78 \rightarrow -40\,^\circ C$ in the presence of $BF_3 \cdot Et_2O$ provided compound **4** in 69% yield together with its α anomer (**4'**, 11% yield). The chromatographically separated **4**[19] was then coupled with a second molecule of **3** under similar conditions to afford the dimeric compound **5**[19] in 59% yield (plus 18% recovered starting material **4**). Desilylation of **5** with HF · pyridine followed by removal of the 9-fluorenylmethoxycarbonyl (FMOC) group led to the polyhydroxyl intermediate **7**, via compound **6**, in 76% overall yield. Finally, $NaCNBH_3$ reduction of **7** catalyzed by $BF_3 \cdot Et_2O$ resulted in the formation of the targeted compound **2**[19] in 46% yield. The structure of **2** was secured by spectroscopic means, particularly ^1H NMR spectroscopy which defined the stereochemistry at the newly generated anomeric and N-bearing centers.

Preliminary NMR studies (variable-temperature, NOESY, TOCSY) on a 1:1 complex of dimer **2** with ds[GCA*TCCTATAGGA*TGC] DNA revealed binding in the minor groove along the *TCCTATAGGA* tract. The data are consistent with a

Synthesis of head-to-head dimer **2**. a) 4.0 equiv diethylene glycol, 0.5 equiv $BF_3 \cdot Et_2O$, CH_2Cl_2, $-78 \rightarrow -40\,^{\circ}C$, 4 h, 69% yield plus 11% α anomer; b) 2.0 equiv **3**, 0.3 equiv $BF_3 \cdot Et_2O$, CH_2Cl_2, $-78\,^{\circ}C$, 5 h, 59% yield plus 18% recovered **4**; c) HF · py, CH_2Cl_2, py, $-40 \rightarrow 0\,^{\circ}C$, 20 h; d) Et_2NH/THF (1/1), 25 °C, 3 h, 76% overall yield from **5**; e) 60 equiv NaCNBH$_3$, 26 equiv $BF_3 \cdot Et_2O$, CH_2Cl_2, $-60 \rightarrow -40\,^{\circ}C$, 2.5 h, 46% yield plus a number of other, not characterized isomers. TES = triethylsilyl; FMOC = 9-fluorenylmethoxycarbonyl.

model in which two complexes are present at low temperature corresponding to one tightly bound pentasaccharide unit and one loosely bound unit; at higher temperatures the two states interconnect.[20]

Footprinting experiments with **2** were complicated, presumably owing to the interference of the molecule with the endonuclease used (deoxyribonuclease I) and the apparent multifaceted binding of the sugar to duplex DNA. Competition experiments with calicheamicin γ_1^I, however, revealed strong, concentration-dependent inhibition of DNA cleavage by the dimer **2** as expected (Fig. 2). In comparison with monomer **1** (lanes 8–10, Fig. 2), dimer **2** (lanes 5–7, Fig. 2) appears to exhibit considerably higher binding affinity to DNA.

Preliminary in vitro experiments[21] also indicated strong inhibiton of binding for certain transcription factors to DNA and interference with in vivo gene expression, suggesting potential application for molecules such as **2** to gene regulation and therapy.[13]

Further studies are needed to determine more precisely the interaction of dimer **2** with DNA and its potential in DNA recognition and gene regulation. The design, synthesis, and evaluation of higher oligomers of **1** and their corresponding enediyne-containing relatives are in progress.

Keywords: DNA-binding molecules · DNA cleavage · molecular recognition · oligosaccharides

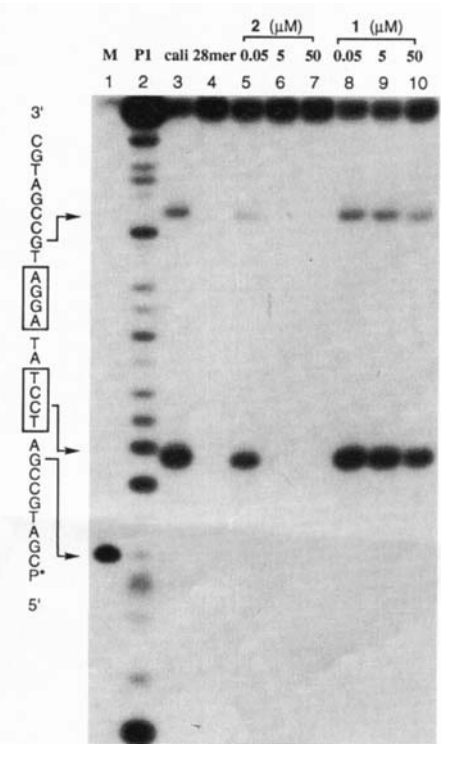

Fig. 2. Autoradiogram of denaturing polyacrylamide gel showing products of calicheamicin-induced DNA cleavage of [5'-^{32}P]-labeled, *TCCTATAGGA*-containing DNA duplex in the presence of oligosaccharides **1** and **2**. Lane 1: marker lane containing the products of DNA digestion with *Mbo* I restriction enzyme; lane 2: 28-mer ladder resulting from partial DNA digestion with nuclease P1; lane 4: [5'-^{32}P]-labeled 28-mer; lanes 3, 5–10: products of DNA cleavage with calicheamicin (250 nM) in the presence of varying concentrations of monomer **1** and dimer **2** (lane 3: no oligosaccharide, lane 5: 50 nM **2**, lane 6: 5 μM **2**, lane 7: 50 μM **2**, lane 8: 50 nM **1**, lane 9: 5 μM **1**, lane 10: 50 μM **1**). Methods: DNA cleavage by calicheamicin was performed as follows: The [5'-^{32}P]-labeled, *TCCTATAGGA*-containing DNA oligomer was incubated at 95 °C for 3 min and then cooled slowly to 25 °C over 1 h. An aliquot of the oligomer was added to a reaction mixture containing 20 mM NaCl, 30 mM Tris-HCl (pH 7.5), 10% DMSO (v/v), and varying concentrations of oligosaccharide **1** or **2** in a final volume of 40 μL, and the mixture was incubated at 37 °C for 20 min. Calicheamicin-dependent DNA cleavage was initiated by addition of 2 μL of 2-mercaptoethanol to attain a final concentration of 50 mM. Aliquots of 3 μL of reaction mixture were transferred to a dry, ice-cooled Eppendorf tube. An equal volume of gel loading buffer, containing 96% formamide, 7.5 mM Na_2EDTA 0.05% (w/v), bromophenol blue, and 0.05% (w/v) xylene cyanol, was added and the sample was stored at −70 °C until loading. Tris = tris(hydroxymethyl)aminoethane. DMSO = dimethyl sulfoxide, EDTA = ethylenediaminetetraacetic acid.

[20] The details of these NMR studies will be reported elsewhere in due course.
[21] We thank Drs. Peter Vogt and Chen Liu for their results. These and related studies will be reported in due course.

Spherical Cyclophosphazene Dendrimers to the Fifth Generation**

François Sournies, François Crasnier, Marcel Graffeuil, Jean-Paul Faucher, Roger Lahana, Marie-Christine Labarre, and Jean-François Labarre*

Dendrimers, that is, highly branched functionalized molecules formed by iterative reaction sequences, constitute a definite breakthrough into generations of new materials and are attracting considerable attention in organic, supramolecular, and polymer chemistry.[1] Only few of these macromolecules incorporate main group elements such as silicon,[2] germanium,[3] or phosphorus,[4] and only phosphorus dendrimers having charges within the cascade structure had been described[4] till very recently when two kinds of neutral phosphorus dendrimers were reported concomitantly by Majoral et al.[5] and by our group.[6, 7] Majoral's dendrimers have a structure resembling a cauliflower, with $SPCl_3$ as the core and possess 46 pentavalent phosphorus atoms and 48 terminal functions (aldehydic groups or phosphorus–chlorine bonds; molecular weight 11268 or 15381). His group is now synthesizing further generations having up to 384 functional groups (molecular weight 94146).[8]

Our dendrimers are spherical architectures which were designed from previously skillfully synthesized D_{3h} cyclophosphazene cores. Indeed, we recently reported[6, 7] pure cyclophosphazenic hexapodanes (termed sexapus because of the six tentacles, in analogy to an octopus) synthesized through a regiospecific peraminolysis of hexachlorocyclotriphosphazene ($N_3P_3Cl_6$) by long-chain diamines, $H_2N(CH_2)_nNH_2$ ($n \geq 6$), on ALPOT(50:11), that is, on alumina impregnated with a certain amount of potassium hydroxide.[9] These sexapus units are 3-dimensional polyfunctional cores suitable for generating spherical cyclophosphazene dendrimers (that is, resembling the structure of a dry dandelion flower and not of a cauliflower like Tomalia's dendrimers[1]). An attempt at the production of spheroid dendrimers belonging to carbon chemistry was recently made by

[**] On the Scent of Dandelion Dendrimers. Part 3. The authors are greatly indebted to the Université Paul Sabatier (ACRU 1993–1994) and the French Ministery of Education (66.71.50) for their generous financial support to this work. Sincere thanks are due to Dr. Suzanne Richelme who performed DCI/NH_3 and FAB measurements and to Dr. Alain Dall'Ava for ^{31}PNMR spectra. Part 2: [7].

Frechet[10] "through the linkage of two cauliflowers by their stumps", but such dendrimers are just spheroids and not, in a strict sense, spherical objects.

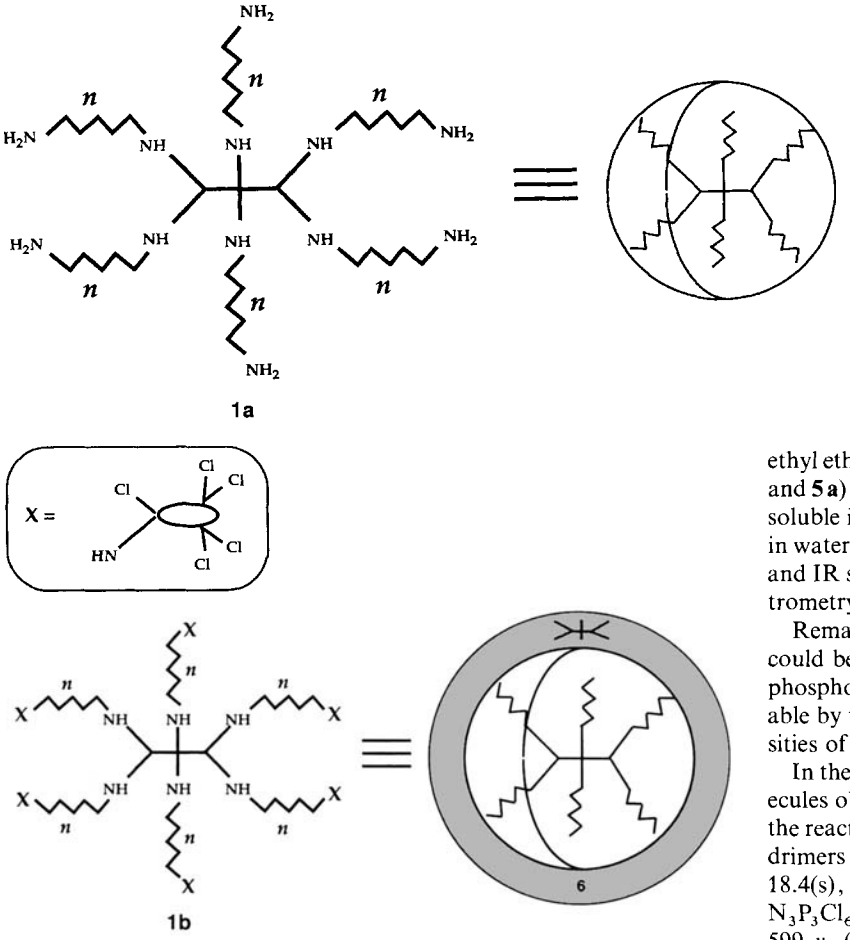
Scheme 1 shows that the amino end groups of tentacles in sexapus **1a** are accessible to further nucleophilic attacks. Our dendrimer design is based on a two-step process. In the first step $N_3P_3Cl_5$ flagstones (pentafunctional fans) are grafted at the end of each tentacle to give compounds **1b** (or generation 1) and in the second step the chlorine atoms of the $N_3P_3Cl_5$ flagstones are all substituted by a new set of long-chain diamines ($H_2N(CH_2)_n$-NH_2, $n \geq 6$) as linkers to give compounds **2a**. In other words, the linkage of such $N_3P_3Cl_5$ flagstones on sexapus cores leads to first-generation dendrimers, in which the number of linkers for further extension is multiplied by five with respect to the starting $N_3P_3Cl_6$ itself. Thus, every two-step procedure from **1b** yields a new generation. In this paper we report on the synthesis and structural characterization of such dendrimers from sexapus cores till the fifth generation (**5b**). Moreover, the chemical properties of dendrimers of the first (**1b**) and second (**2b**) generations were investigated to discover more about the point where steric congestion and/or loss of solubility will prevent further growth of the dendrimer.

The expected first-generation dendrimers **1b** are actually polybino structures,[11] and we demonstrated previously that the synthesis of such two-ring, bridged assemblies requires the use of polar solvents. In other words, toluene (which was used to obtain

Scheme 2. A general pattern for the step by step synthesis of dendrimers to the fifth generation. Left are the formula numbers, right the molecular weights M (for $n = 6$) of the first, second, third, and fifth generations, and in the middle the structural formulas of the added unit (top) and number of functionalities (bottom).

cores **1a**) is no longer the right solvent for reaction (a) and has to be replaced by diethyl ether. In addition, Et_3N was required

$$N_3P_3[HN(CH_2)_nNH_2]_6 + 6\,N_3P_3Cl_6 \longrightarrow N_3P_3[HN(CH_2)_nNH(N_3P_3Cl_5)]_6 + 6\,HCl \quad \text{(a)}$$



sexapus **1a** → **1b**

for scavenging hydrogen chloride. Incidentally, when ALPOT(50:11) is used, irrespective of the choice of solvent, no eluent can be found to remove the final products from the solid support.

Further elaboration to cascade molecules of the second (**2b**), third (**3b**), fourth (**4b**), and fifth generation (**5b**) is accomplished by repetition of the two-step procedure (Scheme 2). In each step, reactants are introduced in the correct stoichiometry. The only by-products are hydrogen chloride and the related hydrochlorides! All the compounds of the generations are stable and perfectly soluble in a wide variety of organic solvents (for example, chloroform, diethyl ether). All the intermediate compounds (**2a**, **3a**, **4a**, and **5a**) with amino groups at the periphery are no longer soluble in the organic solvents but are noticeably soluble in water. All the dendrimers were characterized by NMR and IR spectroscopy, and elemental analysis. Mass spectrometry (FAB or electron spray) was useful up to **2a**.

Remarkably, the construction of each generation could be easily followed by ^{31}P NMR spectroscopy: all phosphorus centers of each generation are distinguishable by their ^{31}P NMR chemical shifts and by the intensities of the different signals.

In the following we shall describe various cascade molecules obtained from sexapus **1a**, $n = 6$. Physical data of the reactants for the synthesis of the first-generation dendrimers **1b** are as follows: for the sexapus: $\delta(^{31}P) = 18.4$(s), m/z (MH^+) 826, $\nu(NH_2)$ 3410 cm^{-1} (br.); for $N_3P_3Cl_6$: $\delta(^{31}P) = 20.1$(s), m/z (MH^+) 345, ν_s (PCl) = 599, ν_{as} (PCl) = 520 cm^{-1}. Two days later both singlets at $\delta = 18.4$ and 20.1 had disappeared, and the signals of an A_2B system (peripheral PCl_2 and peripheral PClNH) to-

Scheme 1. Sexapus cores (**1a**), the precursors of dendrimers of the first generation (**1b**). Zigzag lines marked with n represent $(CH_2)_n$ chains within the -$HN(CH_2)_nNH_2$ tentacles. The central N_3P_3 ring has the bow-tie form proposed by R. A. Shaw.

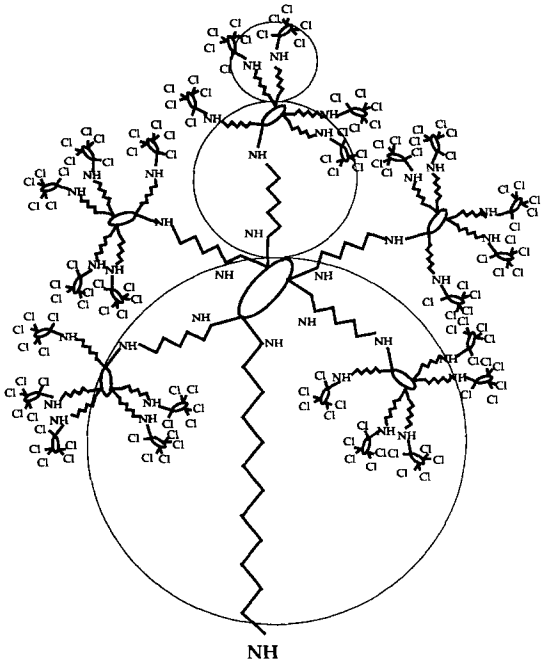
gether with the singlet of the phosphorus atoms from the core are revealed. Simultaneously, the symmetric and asymmetric PCl stretching modes from $N_3P_3Cl_6$ at 599 and 520 cm^{-1}, respectively, are replaced by modes at 589 and 513 cm^{-1}, which are characteristic for the first-generation dendrimers **1b**. Moreover, the NH_2 stretching frequency of the starting sexapus at 3410 cm^{-1} is no longer observed, but a unique N–H stretching frequency remains at 3234 cm^{-1}. In other words, ^{31}P NMR and FTIR spectroscopies are sufficient to characterize **1b**, $n = 6$.

The second-generation dendrimers **2b** are obtained through nucleophilic substitution of the 30 chlorine atoms of the first-generation **1b** by 30 diamino groups (leading to **2a**) and subsequent grafting of 30 $N_3P_3Cl_5$ moieties on the ends of the 30 new tentacles. Because this aminolysis on ALPOT(50:11) gave very poor yields ($\leq 25\%$), we chose Et_3N as scavenger for HCl and a polar solvent such as Et_2O. After 48 h the resulting light yellow syrupy oils, which are actually Et_2O-clathrates, are stirred (about 12 h) with large excess of *n*-heptane to afford the declathrated species as white powders.

The physical data for **2a** are as follows: $\delta(^{31}P) = 18.8$ (s, major signal), 19.3, 22.0 (each s, minor signals), $\nu_s(NH_2) = 3393\ cm^{-1}$, $\nu_{as}(NH_2) = 3333\ cm^{-1}$, $\delta(NH_2) = 1583\ cm^{-1}$.



The transformation from **2a** to **2b** occurs upon grafting 30 $N_3P_3Cl_5$ moieties on the ends of the 30 tentacles. Modifications to ^{31}P NMR and FTIR data are strictly identical to the ones we described above when comparing the spectra from the sexapus **1a** and the first-generation dendrimers **1b**, that is, replacement of a ^{31}P NMR singlet by an A_2B system together with emergence of $\nu_s(PCl)$ and $\nu_{as}(PCl)$ stretching frequencies.

The purity of the products at each step was checked by thin layer chromatography with toluene/CCl_4 (3:1) as eluent. A unique spot was observed till the third-generation **3b**, where a minor side-spot appeared. Apparently this impurity corresponds to an incompletely substituted species in which some amino end groups of **3a** do not react with the $N_3P_3Cl_5$ moieties. This assumption is supported by the fact that final products **3b** are not fully soluble in organic solvents (as any compound of any generation of type **b** should be); a small amount (less than 10% in weight) is insoluble in organic solvents but soluble in water (like any precursor of type **a**).

In other words, at the level of third-generation dendrimers **3b**, about 10% excess $N_3P_3Cl_6$ rather than the strict 1:30 stoichiometry is required to obtain the compounds quantitatively. Nevertheless, further precursors and generations of dendrimers from sexapus cores may be synthesized till the fifth generation, but the amount of impurities (that is, species not completely substituted) increases slowly but steadily with the size of molecules. An efficient approach for circumventing this difficulty is based on the following consideration: the three steps consisting of the successive graft of *n* linkers, *n* $N_3P_3Cl_5$ fans, and another 5n linkers are strictly identical to the graft of *n* sexapus molecules! In Scheme 2, compounds **5a**, which are precursors of **5b**, were synthesized from compounds **3b** in this way. Such a procedure sharply decreases the risk of generating impurities.

In our opinion, cyclophosphazene dendrimers are Unusual Fascinating Objects (UFOs!) built from "fractal" structures (Scheme 3) where the chaining (one diamino tentacle plus one $N_3P_3Cl_5$ fan) can be repeated ad libitum. The upper limit to these constructions will be given by mathematics[12] or chemistry or both.

The structures of compounds **1b**, **2a**, **2b**, and **3a** were calculated with the molecular modeling package MAD[13] on an IBM RISC 6000 station. The units $H_2N(CH_2)_6NH_2$ and $H_2N(CH_2)_6NHN_3P_3Cl_5$ were constructed and their structures minimized; in the conformational analysis a tree-searching algorithm[14] with an extended MM2 force field[15] and a Newton–Raphson minimizer was used. The force field was tuned with results from X-ray structure and electron diffraction analyses. Five iterations were then used to build the full molecule in which steric contacts are avoided (Fig. 1). Careful checking of these structures shows that the limitation of the growth of the dendrimers within the cyclophosphazene series will be more probably due to the progressive filling of the "holes" around the primitive core than to a saturation of peripheral sites as predicted by de Gennes.[12] It seems to us that this important point will have to be given more weight than the "external saturation of active sites on the periphery of the dendrimer" in the design of future dendrimers. Most recently we succeeded in purifying fourth and fifth generations by single SiO_2 column chromatography with *n*-hexane/diethyl ether (2/1) as the eluent and are attempting to obtain crystals of these dendrimers.

Scheme 3. The "fractal" structure of the third-generation dendrimers.

Experimental Procedure

The ^{31}P NMR spectra were recorded on a Bruker AC 200 Spectrometer with H_3PO_4 (85%) as external reference. DCI and FAB mass spectra were recorded on a Ribermag R1010-H Quadrupole Mass Spectrometer. Hexachlorocyclotriphosphazene (degree of purity $\geq 99.8\%$) was generously donated by Shin Nisso Kako Co. Fluka supplied us with the primary diamines (degree of purity $\geq 98\%$).

Alumina-supported potassium hydroxide: Potassium hydroxide (Prolabo Rectapur, 11 g) in H_2O (250 mL) was mixed with neutral alumina for chromatography (Fluka, type 207 C, 90–110 mesh, 50 g). After stirring for 5 min, the water was removed under reduced pressure. The resulting powder was further dried at 70 °C for 24 h in an oven. This reagent [termed ALPOT(50:11)] may be kept in a desiccator without loss of activity for several months.

Synthesis of **1a**: ALPOT(50:11) (150 g) was first impregnated with a solution of $N_3P_3Cl_6$ in toluene (11.96 g in 400 mL) and the solvent was immediately removed in vacuo at 25 °C to fix $N_3P_3Cl_6$ to the alumina surface. Second, this system was impregnated with a solution of the 1,6-diaminohexane (6 equiv. 24.16 g) in toluene (200 mL), and the solvent was immediately removed in vacuo as before. Washing of the solid support twice with 200 mL portions of toluene gave **1a**, $n = 6$ (15.75 g, 55.5%). ^{31}P NMR (81.015 MHz): $\delta = 18.3$ (s); DCI/NH_3 MS: *m/z*: 826 (MH^+), 710 ($M^+ - HN(CH_2)_6NH_2$), 594 ($M^+ - 2(HN(CH_2)_6NH_2)$); FAB-MS (glycerol/thioglycerol (80/20) as matrix): *m/z* 826, 710, 594, 498 (M^+-3 ($HN(CH_2)_6NH_2$)). Thus, aminolysis of $N_3P_3Cl_6$ by 1,6-diaminohexane on ALPOT(50:11) yields instantaneously the pure hexadangling (or hexapodane) sexapus **1a**, $n = 6$ as a hygroscopic microcrystalline white powder (m.p. 39 °C). Moreover, the persubstitution of the 6 Cl atoms of $N_3P_3Cl_6$ by tentacles is accompanied by a vanishing of both strong

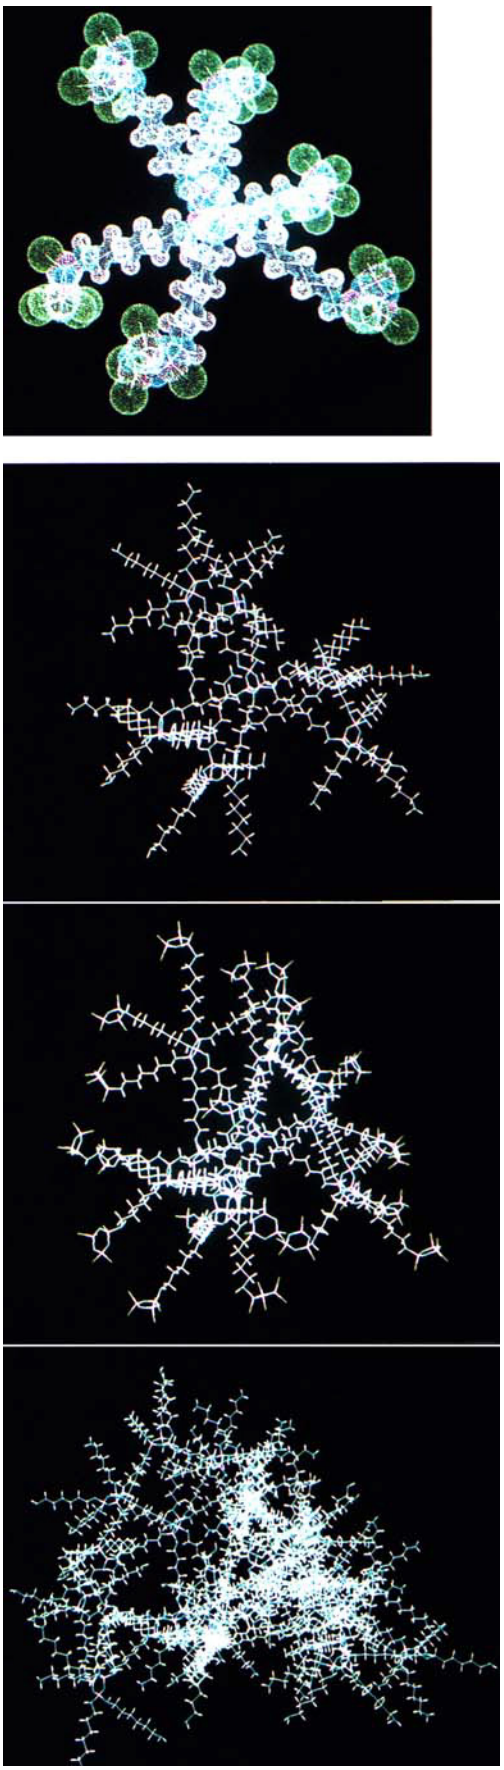

Fig. 1. From top to bottom: Structures of dendrimers **1b**, **2a**, **2b**, and **3a** from molecular modeling studies.

vibrational bands ν_s(PCl) and ν_{as}(PCl) of $N_3P_3Cl_6$ at 600 and 520 cm^{-1} and the emergence of ν(NH) bands at 3382 and 3319 cm^{-1}.

Synthesis of **1b**, $n = 6$: The reaction (a) was performed in Et_2O with Et_3N as HCl scavenger. The reaction was considered complete after 48 h when the singlet of **1a**, $n = 6$ in the ^{31}P NMR spectrum had disappeared. The product was soluble in $CDCl_3$. ^{31}P NMR (81.015 MHz): A_2B system (δ(PClNH) = 18.7 (t), $\delta(PCl_2)$ = 21.3 (d, ^2J(P,P) = 46.6 Hz), δ(P,core) = 22.0 (s). FAB-MS (*meta*-nitrobenzyl octyl ether (MNBE) as matrix): *m/z*: 2693 (M^+). We had to use MNBE instead of the more common glycerol/thioglycerol mixture as the matrix, because the 30 chlorine atoms of **1b**, $n = 6$ are substituted in situ by glyceryl and thioglyceryl groups, which led to molecules with masses much larger than 2000, beyond the threshold of response of the detector. The IR spectrum reveals an emergence of one ν(NH) band at 3234 cm^{-1} and no PCl band in the 400–600 cm^{-1} range.

Compounds **2a/2b**, **3a/3b**, **4a/4b**, and **5a/5b** with $n = 6$ were synthesized analogously to **1a** and **1b**, under the respective stoichiometric conditions. Average yields: **1a** → **1b** 90%, **1b** → **2a** 67%, **2a** → **2b** 75%, **2b** → **3a** 77%, **3a** → **3b** 80%, **3b** → **4a** 65%, **4a** → **4b** 92%, **4b** → **5a** 69%, and **5a** → **5b** 80%. The overall yield for the target molecule **5b** was thus 9%. However, in terms of molecular weights, 1 g of **1a** yields 199 g of **5b**.

Microanalytical data are not reported here, because the huge variations with respect to the carbon and chlorine content from one step to the next makes identification of each step unambiguous [6].

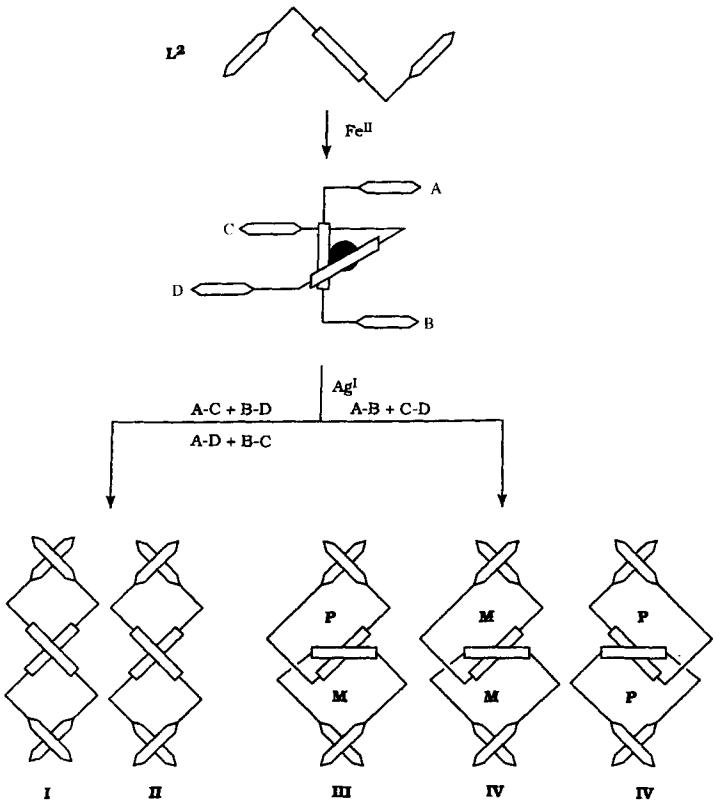
Formation of the First Isomeric [2]Catenates by Self-Assembly about Two Different Metal Ions**

Claude Piguet,* Gérald Bernardinelli, Alan F. Williams, and Bernard Bocquet

The control of molecular structures and topologies is a major goal in supramolecular chemistry,[1] and the self-assembly of tailored ligands with metal ions has been extensively used to produce organized architectures.[2-4] Double-helical,[2-5] triple-helical,[4, 6, 7] toroidal,[8] and cylindrical[9] homopolynuclear structures have been generated by the complexation of oligo(multidentate) ligands to two or more metal ions. The recent development of new segmental ligands with different binding units connected by suitable spacers[10] leads to programmed heteropolynuclear complexes where each metal ion occupies a coordination site corresponding to its stereochemical preferences.[11, 12] Thus, it was shown recently that ligand $\mathbf{L^1}$, containing both bi- and tridentate binding units (Scheme 1), reacts with a mixture of Fe^{II} and Ag^{I} ions to give the self-assembled heterodinuclear double-helical complex $[FeAg(\mathbf{L^1})_2]^{3+}$, where the Fe^{II} ion is pseudooctahedrally coordinated by the two tridentate units and the Ag^{I} center lies in the pseudotetrahedral site defined by the two remaining bidentate units.[11]



$\mathbf{L^1}$

$\mathbf{L^2}$

Scheme 1. Structures of the segmental ligands $\mathbf{L^1}$ and $\mathbf{L^2}$.

The ligand 1,1'-dimethyl-2,2'-bis(6-methylpyridin-2-yl)-5,5'-{pyridine-2,6-diylbis[(1-methyl-1*H*-benzimidazole-2,5-diyl)-methylene]}bis[1*H*-benzimidazole] ($\mathbf{L^2}$),[10] a logical extension of $\mathbf{L^1}$, similarly self-assembles with Fe^{II} and Ag^{I} ions in acetonitrile to give the heterotrinuclear complex $[FeAg_2(\mathbf{L^2})_2]^{4+}$, where the Fe^{II} center is pseudooctahedrally coordinated by the two tridentate binding units and each Ag^{I} ion is pseudotetrahedrally bound to two bidentate units.[11] Depending on which bidentate units bind to Ag^{I}, more than one organometallic macrocycle[13] may be envisaged leading to different topological isomers.[14] When the Ag^{I} ions are coordinated to bidentate units of different strands (A-D + B-C or A-C + B-D; Scheme 2), double-helical (**I**) or side-by-side (**II**) structures are expected; coordination of the Ag^{I} ions to the two bidentate units of the same strand (A-B + C-D) leads to the [2]catenates **III** and **IV**. In structures **III** and **IV** each organometallic macrocycle is itself helical and has either P or M helicity.[15] This leads to two isomers, the heterochiral, S_4-symmetric *meso* form **III** and the homochiral, D_2-symmetric **IV**, which exists as a pair of enantiomers (Scheme 2).

Scheme 2. Self-assembly of heterotrinuclear supramolecular complexes of $\mathbf{L^2}$ with Fe^{II} and Ag^{I} ions. ⬭ corresponds to a bidentate unit, ▭ a tridentate unit. **I** is a helical, D_2-symmetric structure, **II** a D_2-symmetric, side-by-side structure, **III** a S_4-symmetric (*P*,*M*)-[2]catenate, and **IV** D_2-symmetric (*M*,*M*)- and (*P*,*P*)-[2]catenates.

Crystallization of $[FeAg_2(\mathbf{L^2})_2](PF_6)_4$ gives dark violet crystals with two different morphologies, hexagonal prisms **A** and large pellets **B**, both of which were suitable for X-ray diffraction studies. The crystal structure of **A** corresponds to the formula $[FeAg_2(\mathbf{L^2})_2](PF_6)_4(CH_3OH)_{2.5}(H_2O)$ and shows it to be composed of the cation $[FeAg_2(\mathbf{L^2})_2]^{4+}$, four uncoordinated PF_6^- anions, and solvent molecules. The anions and solvent molecules are slightly disordered (see *Experimental Procedure*) but otherwise show no features of interest. The cation $[FeAg_2(\mathbf{L^2})_2]^{4+}$ adopts the [2]catenate structure and not the helix, and lies on a crystallographic C_2 axis passing through the three metal ions. The Fe^{II} center is coordinated by the two tridentate units of the two strands, while each Ag^{I} ion is pseudotetrahedrally bound to two bidentate units of one ligand, produc-

ing two helical interlocked organometallic macrocycles of opposite helicity (Figs. 1, 2) which correspond to the *meso*-(P,M) structure **III**. Figure 1 shows an ORTEP[16] stereoview of $[FeAg_2(\mathbf{L^2})_2]^{4+}$ perpendicular to the C_2 axis, and Figure 2 (left) gives a computer-generated representation[17] of the catenate structure in which the two macrocycles are shown in different colors. The intermetallic distances (Ag–Fe 8.156(3), 8.082(3) Å) are only slightly shorter than those reported for

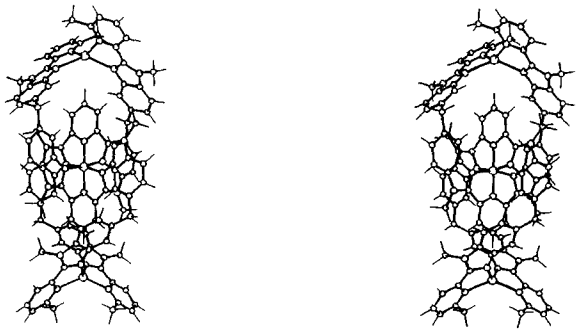

Fig. 1. ORTEP[16] stereoview of the heterochiral (*P*,*M*)-[2]catenate $[FeAg_2(\mathbf{L^2})_2]^{4+}$ perpendicular to the C_2 axis.

triple-helical complexes with similar ligands possessing the same diphenylmethane spacer (8.876(3) Å for a bis(tridentate) ligand[6] and 8.427(4) Å for a bis(bidentate) ligand[18]). This suggests that the catenate structure does not strongly constrain the spacers in $\mathbf{L^2}$. The meridionally coordinated tridentate units are roughly planar (see Table 2) and are maintained mutually perpendicular by pseudooctahedral coordination to the Fe^{II} center (dihedral angle between the mean planes of the aromatic tridentate units: 92.1(1)°). The Fe–N(py) bonds are slightly shorter than the Fe–N(bzim) bonds (py = pyridine, bzim = benzimidazole), but do not significantly deviate from the average value (1.918 Å) and are close to the reported values for $[Fe(\mathbf{L^3})_2]^{2+}$ ($\mathbf{L^3}$ = 2,6-bis(1*H*-benzimidazol-2′-yl)pyridine).[19]

As a result of the small average chelate angle of the bidentate units coordinated to the Ag^I ions (72.5°), the coordination spheres around the Ag^I centers may be best described as D_{2d}-distorted tetrahedrons.[20] However, a flattening along the C_2 axis of the molecule produces further distortions as exemplified by the large N(py)-Ag-N(py) and N(bzim)-Ag-N(bzim) angles (Table 1) and by the dihedral crossing angles between the planes defined by the two coordinated nitrogen atoms and the center Ag^I (81.3(3)° for strand a, 74.6(3)° for strand b; perfect tetrahedron: 90°). The Ag–N(py) bonds are slightly shorter than the Ag–N(bzim) bonds, as found for the Fe–N bonds, but the average value (2.311 Å) is close to the reported Ag–N bond length for the pseudotetrahedral complex $[Ag(tmbp)_2]^+$ (2.321 Å; tmbp = 4,4′,6,6′-tetramethyl-2,2′-bipyridine).[21] The twisting of the ligand required for the formation of the organometallic macrocycles is achieved by rotation about the C_{arom}-CH_2-C_{arom} bonds of the spacer, which places the aromatic benzimidazole planes connected to the methylene bridge in an approximately perpendicular arrangement (80.6(2) and 86.0(2)° for strands a and b, respectively; Table 2).

Table 1. Structural data for the *meso*-(P,M)-[2]catenate $[FeAg_2(\mathbf{L^2})_2]^{4+}$ **III**.

	Average	Minimum	Maximum
Bond length [Å]:			
Fe-N(py)	1.89(1)	1.88(1)	1.90(1)
Fe-N(bzim)	1.932(6)	1.928(6)	1.935(8)
Ag-N(py)	2.287(8)	2.281(8)	2.293(9)
Ag-N(bzim)	2.337(7)	2.331(9)	2.342(7)
Chelate angle [°]:			
N(bzim)-Fe-N(py)	81.3(3)	81.3(3)	81.4(4)
N(bzim)-Ag-N(py)	72.1(3)	71.7(3)	72.5(3)
Interligand angle [°]:

N(bzim)-Fe-N(py)	98.7(2)	98.6(2)	98.7(2)
N(py)-Ag-N(py)	139(3)	135.3(3)	143.8(3)
N(bzim)-Ag-N(bzim)	133.7(4)	133.3(3)	134.1(3)
N(py)-Ag-N(bzim)	125(1)	126.7(3)	124.1(3)

Table 2. Selected interplane angles between aromatic rings of ligand $\mathbf{L^2}$.

Ring 1 [a]	Ring 2	Angle [°]	
		strand a	strand b
pAg	bAg	18.0(3)	8.1(3)
bAg	bFe	80.6(2)	86.0(2)
bFe	pFe	8.2(3)	5.2(3)

[a] The pyridine and benzimidazole rings bound to the Fe and Ag centers are denoted p and b, respectively. Thus, bAg is the benzimidazole ring bound to an Ag ion.

The X-ray diffraction data of the large pellets **B** also shows the cation $[FeAg_2(\mathbf{L^2})_2]^{4+}$ and four uncoordinated PF_6^- anions. But significant disorder in the crystal, arising from the lacunar occupation of the anionic sites, limits refinement of the data to $R = 0.14$ (see *Experimental Procedure*). Nevertheless, the resolution is sufficient to show that in **B** the cation $[FeAg_2(\mathbf{L^2})_2]^{4+}$ adopts the homochiral [2]catenate structure **IV** with two interlocked organometallic macrocycles of the same helicity leading to a racemic mixture of (*M*,*M*) and (*P*,*P*) enantiomers. Figure 2 gives a computer-generated representation[17] of the two structures of $[FeAg_2(\mathbf{L^2})_2]^{4+}$ in **A** (**III**, left) and in **B** (**IV**, right) showing the diastereomeric relationship between them.

^{1}H NMR studies have shown that **A** and **B** give the same spectrum in acetonitrile.[11] Detailed NOE measurements have established an almost perpendicular arrangement of the benzimidazole rings connected to the methylene bridge,[11] which preclude the formation of the side-by-side complex **II**, but do not

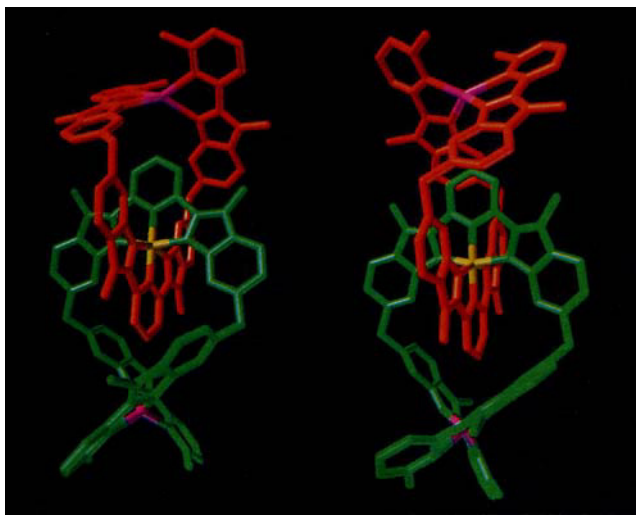

Fig. 2. VISP [17] representations of the two forms of $[FeAg_2(\mathbf{L^2})_2]^{4+}$, with the individual ligand strands of each complex in red or green. The heterochiral (*P*,*M*)-*meso* form **III** is shown on the left and the (*M*,*M*) enantiomer of the homochiral form **IV** on the right. Hydrogen atoms are omitted.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0583 $ 10.00+.25/0

allow the helicate (**I**) to be distinguished from the catenates (**III**, **IV**) in solution. However, the significant NOE effects observed between H_{23} and H_8, and H_{22} and H_8 (see Scheme 1) are only compatible with interstrand effects (H_{23a}–H_{8b}: 3.02–3.04 Å and H_{22a}–H_{8b}: 4.09–4.21 Å from the crystal structure of **III**) and demonstrate that the [2]catenate structure is maintained in acetonitrile for $[FeAg_2(\mathbf{L^2})_2]^{4+}$. The ^{1}H NMR spectrum at room temperature shows rapid exchange on the NMR timescale leading to an average D_{2d} symmetry for $[FeAg_2(\mathbf{L^2})_2]^{4+}$[11] and corresponding to a dynamic equilibrium between **III** and **IV**. This results from rapid interconversion of *P* and *M* helical enantiomers of each interlocked macrocycle on the NMR timescale ((*M*,*M*) ↔ (*M*,*P*) ↔ (*P*,*P*)). Cooling the sample to 240 K slows down the exchange processes, and the ^{1}H NMR spectrum shows the expected AB spin system for the diastereotopic protons H_{131} and H_{132}, in agreement with the catenate structures **III** and **IV**.[5]

In summary, the segmental ligand $\mathbf{L^2}$ reacts quantitatively with Fe^{II} and Ag^{I} in acetonitrile to give the first heteronuclear organometallic [2]catenate $[FeAg_2(\mathbf{L^2})_2]^{4+}$. As a result of the helicity of the organometallic macrocycles, both chiral (**IV**, (*P*,*P*) and (*M*,*M*)) and achiral (**III**, *meso* (*M*,*P*)) forms are found in the crystals, while rapid interconversion is observed in solution. This is, to our knowledge, the first self-assembly of a heterotrinuclear supramolecular complex. This new approach offers promising perspectives for the efficient synthesis of organized heteropolynuclear complexes with planned topologies and controlled physical properties.

Experimental Procedure

The ligand $\mathbf{L^2}$ [10] and the complex $[FeAg_2(\mathbf{L^2})_2](ClO_4)_4 \cdot 4H_2O$ [11] were obtained according to literature procedures. Crystals of $[FeAg_2(\mathbf{L^2})_2](PF_6)_4(CH_3OH)_{2.5}(H_2O)$ were obtained by vapor diffusion of methanol into a concentrated solution of $[FeAg_2(\mathbf{L^2})_2](ClO_4)_4 \cdot 4H_2O$ in acetonitrile containing a large excess of NBu_4PF_6. A dark violet hexagonal prism **A** ($0.15 \times 0.20 \times 0.26$ mm) was fixed on a quartz fiber with perfluoropolyether oil RS3000.

Crystal data for [2]catenate **III**: $FeAg_2C_{104.5}H_{108}N_{22}O_{3.5}P_4F_{24}$, $M = 2570.0$, monoclinic, $C2/c$, $a = 25.934(5)$, $b = 22.787(3)$, $c = 19.659(5)$ Å, $\beta = 107.79(1)°$, $V = 11\,062(4)$ Å^3 (by least-square refinement of 24 reflections ($35° \le 2\theta \le 50°$)), $Z = 4$, $\rho_{calcd} = 1.54$ g cm^{-3}, $F(000) = 5212$, $\mu(Cu_{K\alpha}) = 5.287$ mm^{-1}. Data collection and processing: Nonius CAD4 diffractometer, ω-2θ mode, scan width $= 1.2 + 0.15 \tan\theta$, scan speed 0.092° s^{-1}, $Cu_{K\alpha}$ radiation; $T = 200$ K; 5866 reflections measured ($4 \le 2\theta \le 100°$, $-25 < h < 25$, $0 < k < 22$, $0 < l < 19$), 5660 unique reflections (R_{int} for equivalent reflections = 0.043), of which 4174 were observable ($|F_o| > 4\sigma(F_o)$). Structure analysis and refinement: Data were corrected for Lorentz, polarization and absorption effects [22] (A^*min = 2.037, A^*max = 3.168). The structure was solved by direct methods using MULTAN 87 [23]; all other calculations used XTAL [24] system and ORTEP II [16] programs. Refinements (on *F*) were performed with full matrix, number of variables = 776. All non-hydrogen atoms were refined with anisotropic displacement parameters (89 atoms) except for one slightly disordered methanol molecule which was refined with isotropic displacement parameters. The cation $[FeAg_2(\mathbf{L^2})_2]^{4+}$ lies on a C_2 axis with Fe, Ag1, Ag2, N6a, N6b, C23a, C23b, H23a, and H23b in special positions 4e. Two hexafluorophosphate ions are found in special positions 4b and 4c (PF_6^- in position 4c is slightly disordered and refined with ten atomic positions for the fluorine atoms) and one in a general position. Final $R_w = 0.061$ ($\omega = 1$) for 776 variables and 4160 reflections. The mean shift/error on the last cycle was 0.003 and the maximum 0.14. Hydrogen atoms were placed in calculated positions and contributed to F_c calculations. The final Fourier difference synthesis showed a maximum of +0.83 and a minimum of −0.74 e Å^{-3}.

The crystal structure of the pellets **B** shows significant disorder and many attempts to solve it led to a final *R* factor of 0.14. At this level of resolution, solvent molecules are not observed. Four PF_6^- are in general positions with one anion showing a site occupancy of 0.5. The fifth hexafluorophosphate ion is in special position 2c. This statistical lacunar occupation of the anionic sites produces some disorder in the structure which explains the low ratio of observed reflections to number of variables.

Crystal data of [2]catenate **IV**: $FeAg_2C_{102}H_{86}N_{22}P_4F_{24}$, $M = 2471.4$, monoclinic, $P2_1/c$, $a = 13.1022(8)$, $b = 31.370(3)$, $c = 30.579(5)$ Å, $\beta = 95.976(5)°$, $V = 12\,500(2)$ Å^3 (by least-square refinement of 21 reflections ($33° \le 2\theta \le 47°$)), $Z = 4$, $\rho_{calcd} = 1.38$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 4.68$ mm^{-1}. Violet pellets ($0.07 \times 0.30 \times 0.36$ mm) fixed on a quartz fiber with perfluoropolyether oil RS3000. Data collection and processing: Nonius CAD4 diffractometer, ω-2θ mode, ω scan width $= 1.2 + 0.15 \tan\theta$, scan speed 0.092° s^{-1}, $Cu_{K\alpha}$ radiation; $T = 200$ K; 13071 reflections measured ($4 \le 2\theta \le 100°$, $-12 < h < 12$, $0 < k < 31$, $0 < l < 30$), 12778 unique reflections (R_{int} for equivalent reflections = 0.14) of which 6500 were observable ($|F_o| > 4\sigma(F_o)$). Structure analysis and refinement: Data were corrected for Lorentz, polarization, and absorption effects [22] (A^*min = 1.412, A^*max = 4.610). The structure was solved by direct methods using MULTAN 87 [23]; all other calculations used the XTAL [24] system and ORTEP II [16] programs. Refinements (on *F*) were performed with two block matrices, maximum number of variables = 1431). Final $R_w = 0.14$ ($\omega = 1$) for 1431 variables and 6469 contributing reflections. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ (UK), on quoting the full journal citation.

X-Ray Structure of a Self-Assembled Gelating Fiber**

Fredric M. Menger,* Yasuhiro Yamasaki, Kelly K. Catlin, and Taisei Nishimi

Almost seventy years ago, chemist Dorothy Jordan noted that "gels are easier to recognize than to define".[1] We will attempt a definition nonetheless: Gels are semi-rigid colloidal systems rich in liquid. Protoplasm ranks as the most widespread example of this peculiar state of matter. A gel is formed by a molecular network, often fibrous in nature, that entrains the dispersing medium within its capillary spaces. Most organic gelators are polymeric (for example, gelatin,[2] poly(acrylic acid),[3] and hyaluronic acid[4]), but small molecules (for example, cholesteryl 4-(2-anthryloxy)butanoate,[5] 5-hexadecyl-2,4,6-triaminopyrimidine,[6] *N*-octylgluconamide,[7] and arborols[8]) can induce gelation as well.

We have long been interested in a little-known but remarkable gelator, dibenzoyl-L-cystine (DBC).[9] Although most gels require 1–10% gelator, DBC in water rigidifies at concentrations

DBC: R = H
DTC: R = Me

as low as 2 mM (0.1%). While attempting to learn how such miniscule quantities of DBC manage to self-assemble into a macroscopic network, we performed an X-ray analysis of a gel "fiber". Structural data at the atomic level is virtually unavailable for gel networks, and it is only through good fortune that these data became accessible. But before giving the details, let us summarize the properties of acylcystines in water.

DBC forms a firm, translucent gel in a thermally reversible process at a concentration of 4 mM in ethanol (5%)/water. Ethanol was used because the DBC tends to crystallize from pure water. There is, clearly, a delicate balance between gelation and crystallization. The gelating properties are destroyed when the S–S linkage is replaced by CH_2CH_2 or CH=CH groups.[10] This implies that the CH_2-S-S-CH_2 dihedral angle[11] of about 90 °C plays a key role in the formation of the molecular network. Gels do not form from esterified DBC or at basic pH values, which suggests the presence of either a favorable -COOH/-COOH attraction or a deleterious $-CO_2^-/-CO_2^-$ repulsion. Addition of NaCl (0.1 M) softens the gels, whereas more than 10% dioxane induces crystallization.

Diacetyl-L-cystine fails to gelate in ethanol (5%)/water. Di-*n*-octanoyl-L-cystine (4 mM) forms only a soft and cloudy gel. The superior quality of the DBC gel leads us to suspect that aromatic $\pi-\pi$ stacking stabilizes the creation of fibers. This conclusion is appealing, because intermolecular hydrogen bonding between DBC molecules in water would seem too unfavorable to serve as the sole adhesive force. Water, of course, normally dominates at the hydrogen-bonding sites of solutes dissolved within it.

[**] This work was supported by the National Institutes of Health.

Assembly of DBC molecules appears to be a cooperative event much like the micellization of surfactants. This was affirmed by a primitive yet informative experiment in which 2.0×2.0 cm^2 squares of Parafilm were placed on the surface of aged DBC gels. Known weights were then positioned carefully at the center of a film until the film submerged. A plot of "supportable weight" vs. DBC concentration (not shown) gave a sharp break at 1.6 mM, a value that might be qualitatively regarded as the "critical gelation concentration".

Spin-lattice relaxation studies with ^{13}C NMR spectroscopy on DBC have shown that gelation has no apparent effect on T_1 values.[9] We interpreted this result as proof for two distinct states: a monomeric species that possesses normal T_1 values and a self-assembled state whose ^{13}C resonances are broadened to the point of non-observability by long correlation times. This conclusion was affirmed by examining ^1H NMR line-widths of DBC's methylene signal. No line-broadening was observed from 0.5 mM to 10 mM DBC, a concentration range spanning the fluid-to-gel transformation. Quantitative comparison of NMR peak areas with those of an internal standard (2 mM DSS) showed conclusively that in ethanol (5%)/water 15% monomer (with normal line-widths) coexists with 85% gelated material (whose signals disappear into the baseline). In ethanol (25%)/water, DBC contains 40% monomer and 60% aggregate, while in ethanol (50%)/water only 20% of the DBC exists in the fibrous state. The sharp monomer peaks also prove that monomer does not exchange with fiber on the NMR time scale. Thus, the DBC fiber, unlike the micellar aggregate, is a fairly static entity.

Definitive structural information became available when, unexpectedly, crystalline di(*p*-toluoyl)-L-cystine (DTC) precipitated from solution before the gel had a chance to set. X-ray quality crystals (m.p. 194.5–196 °C) were obtained by recrystallizing the solid from methanol/ethyl acetate. The perennial question, namely, whether the solid-state structure reflects the solution properties, must be cautiously answered in the affirmative for several reasons: a) According to one theory,[10] gelation is a type of incomplete crystallization (the gel is considered to be microcrystalline forms surrounded by water). Small perturbations in conditions or structure (in our case, the addition of a methyl group to the aryl ring of DBC) can tip the scale in favor of the crystalline state. b) Throughout our work with acylcystine gels, it was obvious that the gels are poised to transform into the crystalline state. Thus, as mentioned, DBC will crystallize from gels if 5% ethanol is not present in the water or if more than 10% dioxane is added to the water. Crystallization seems too commonplace and too abrupt to postulate a molecular reorganization from a gel fiber into an entirely different solid-state structure. c) The X-ray structure in Figure 1 shows a linear association of DTC molecules, as one would expect for a fiber-forming system. To our knowledge, this is the first picture of a self-assembled gel fiber at the atomic level.

The crystal structure has a linear backbone containing disulfide linkages with CH_2-S-S-CH_2 dihedral angles alternating between 87° and 99°. Self-assembly is stabilized by long hydrogen bonds between amide-NH and carboxyl-CO functionalities (N···O distances range from 2.9 to 3.2 Å). Intrafiber association between the carboxyl groups appears to play little role, because they are stacked one upon another rather than held in a coplanar orientation. Ionization of the carboxyl groups apparently destroys the gel because of electrostatic repulsion. The aromatic rings extend to one side of the backbone, and every other ring is tilted by 22°. Toluoyl methyl groups are spaced in a repeating sequence of 6.66 Å, 4.12 Å, 7.36 Å, and 3.96 Å. The gel fiber is, therefore, held together by a favorable backbone

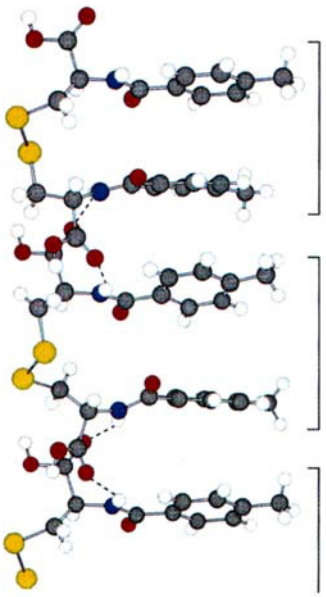

Fig. 1. X-ray crystal structure of di(*p*-toluoyl)-L-cystine (DTC). Red spheres represent oxygen, blue nitrogen, and yellow sulfur atoms. The dotted lines represent hydrogen bonds between amide-NH and carboxyl-CO functionalities. The N···O distances (and N-H-O angles) from bottom to top in the structure are 3.156 Å (130.4°), 3.172 Å (148.6°), 3.123 Å (148.0°), and 2.888 Å (135.2°).

orientation enhanced by hydrogen-bonding and $\pi-\pi$ stacking (or hydrophobic) interactions. This fortuitous blend of structural features accounts for the ability of acylcystines to gelate at remarkably low concentrations.

Figure 2 shows how two neighboring strands are held together by cooperative hydrogen bonding between carboxyl hydrogens and amide oxygens. The O···O distances are all about 2.6 Å in length. Single strands assemble into multi-filament fibers that we postulate can cause the gelation of aqueous solutions.[12]

The beautiful DNA-like structure of DTC in Figure 1 leads one to wonder whether acylcystines bearing nucleic acid bases instead of toluoyl groups would have self-replicative properties.[13]

Hexakis(trifluoromethyl)tetrazane**

Burkhard Krumm, Ashwani Vij, Robert J. Kirchmeier,* Jean'ne M. Shreeve,* and Heinz Oberhammer*

While no element can compete with carbon in the number of contiguous atoms in saturated chemical compounds, stable straight-chain species composed of other elements are known, especially if fluorine atoms, fluorinated groups, or other electronegative species are present in the molecule, for example $CF_3(O)_nCF_3$ ($n = 1-3$) and O_nF_2 ($n = 1, 2, 4$). Fluorinated N_n compounds do exist and do exhibit surprising hydrolytic, thermal, and chemical stabilities. In contrast, the hydrogen-substituted analogues such as diazane, triazane, and tetrazane are increasingly unstable with increasing chain length. While tris(perfluoro-

alkyl)amines $N(R_f)_3$[1-3] and tetrakis(perfluoroalkyl)diazanes $(R_f)_2NN(R_f)_2$[4,5] are well known, and their gas-phase structures determined, only recently have the synthesis and property characterization of per- and polyfluoroalkyl-substituted tetrazanes been reported.[5,6] All of the known fluorine-containing tetrazanes are relatively dense liquids of low volatility which solidify as glasses, precluding single-crystal X-ray structural analyses. As a consequence, the smallest, most symmetric perfluoroalkylated compound of this type, hexakis(trifluoromethyl)tetrazane (**4**), was selected for a structural study in the gas phase using electron diffraction (GED).[7]

Our synthesis of **4** differs from the one reported by Emeléus et al.[8] and provides a facile route to these N_4 compounds (Scheme 1). The conversion of the *N*-chloro-*N*-chlorodifluoro-

Scheme 1.

methyldiazane **1** to difluoromethylenediazane **2** is achieved by utilizing only a catalytic amount of chlorotrimethylstannane with benzonitrile as solvent. Chlorine is removed easily without the formation of side products. The intermediate trimethylstannyldiazane loses chlorotrimethylstannane at 25 °C and yields **2**. The chlorostannane again reacts with **1** with the evolution of Cl_2. The process continues until **1** is totally consumed. This is a convenient method for the preparation of perfluorinated difluoromethylenamines (or -azanes). The double bond can be chlorofluorinated with ClF to form *N*-chloro-*N*-trifluoro methyldiazane **3**. *N*-Chlorodiazanes are known to lose chlorine upon photolysis and dimerize to give tetrazanes.[9] In this way hexakis(trifluoromethyl)tetrazane (**4**) is obtained as a volatile, colorless liquid with considerable vapor pressure at 25 °C. Furthermore, this compound is air and water stable and does not decompose even at elevated temperatures. The ^{19}F NMR spectrum shows two broad signals for the terminal CF_3 groups, which are not equivalent at 25 °C. Another resonance at higher field for the CF_3 groups attached to the inner nitrogen atoms is split into a multiplet due to nonequivalent couplings to the outer CF_3 groups. In a variable-temperature NMR study the signals for the terminal CF_3 groups were found to coalesce at 58 °C. The features of the low-temperature NMR spectrum (−40 to −100 °C), which were reported earlier[10] for a solution of **4** in $CFCl_3$, could not be reproduced. Instead, we observed precipitation of the compound from solution upon cooling.

The radial distribution function (RDF) derived by Fourier transform of the experimental electron diffraction intensities is shown in Figure 1. A large number of molecular models with different torsional angles about the N–N bonds were tested. The models were evaluated according to two criteria: 1) no F···F contacts shorter than 2.5 Å (except within the CF_3 groups) and 2) agreement between calculated and experimental RDF. The RDF range 2.8–3.5 Å contains mainly C···F and F···F distances between adjacent CF_3 groups and N···F distances to CF_3 groups bonded to the neighboring nitrogen atom (e.g. from N1 to the CF_3 group of C2 or from N2 to the CF_3 groups of C1 and C1'). This RDF range can be reproduced only

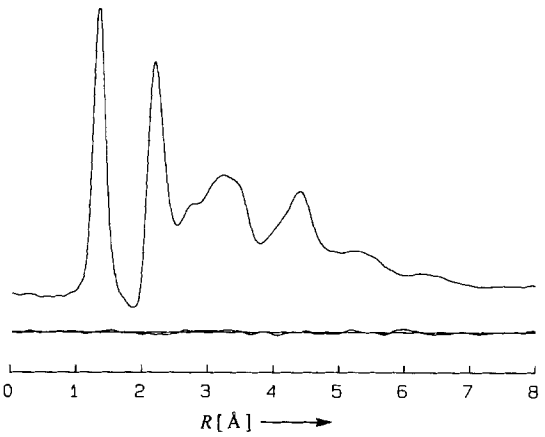

Fig. 1. Experimental radial distribution function for **4** and difference curve between experimental and calculated functions.

with models having planar or nearly planar coordination at all nitrogen atoms. The outer part of the RDF can be fitted satisfactorily only with models that have dihedral angles ϕ about the N–N bonds of close to 90° (for $\phi = 0°$ the lone pairs of electrons on adjacent nitrogen atoms are parallel).

The following constraints were applied in the least squares refinements: 1) local C_{3v} symmetry for the CF_3 groups, 2) local C_2 symmetry for the $(CF_3)_2N$ moieties, in other words the CF_3 groups are rotated about the N–C bonds in opposite directions, and 3) overall C_2 symmetry. The C_2 axis is perpendicular to the N2–N3 bond and bisects the dihedral angle ϕ(NNNN). Only mean values for the N–N and C–N bond lengths could be derived. The final results of the electron diffraction analysis are given in Table 1; the nitrogen-carbon skeleton of tetrazane **4** is

Table 1. Structure parameters of $[(CF_3)_2NN(CF_3)N(CF)_3N(CF_3)_2]$ (**4**) [a].

$(N-N)_{mean}$ [Å]	1.379 (11)	N1–N2–N3 [°]	116.4 (13)
$(N-C)_{mean}$ [Å]	1.438 (6)	N1–N2–C2 [°]	122.6 (15)

those of tetrakis(trifluoromethyl)diazane, which also has planar coordination at the nitrogen atoms ($\Sigma\alpha(N) = 359.5(26)°$), perpendicular nitrogen lone pairs ($\phi(lp-N-N-lp) = 88.4\ (40)°$), and an N–N bond length of 1.402(20) Å.[4] The unsaturated tetrazenes $R_2N-N=N-NR_2$ have planar nitrogen skeletons and *trans* configuration. The N–N single bonds are slightly longer (1.429(5) Å for R = H[11] and 1.394(5) Å for R = $SiMe_3$[12]) than those in the tetrazane **4** (1.379(11) Å).

Experimental Procedure

2: Diazane **1** (10 mmol) was condensed into 5 mL benzonitrile containing a catalytic amount of Me_3SnCl. The reaction mixture was stirred at 25 °C for 1 h before all volatile material was held over mercury for 5 h to remove chlorine. Distillation gave pure **2** as a colorless gas in quantitative yield, after passage through a trap at −90 °C. ^{19}F NMR ($CDCl_3$): $\delta = -65.2$ (d, $^5J(F,F) = 4.0$ Hz, 6F; $(CF_3)_2N$), −63.4 (d, $^2J(F,F) = 93.3$ Hz, 1F; N = C*F*F), −40.2 (d of sept, $^2J(F,F) = 93.3$ Hz, $^5J(F,F) = 4.0$ Hz, 1F; N = CF*F*); IR (gas): $\nu[cm^{-1}] = 1753$ (s, N=C), 1360 (s), 1326 (s), 1263 (s), 1220 (s), 982 (m), 959 (w), 734 (m); MS (EI): *m/z* (%): 216 (M^+, 7), 197 ($M^+ - F$, 6), 128 ($CF_3NN = CF^+$, 11), 109 (CF_3NNC^+, 2), 69 (CF_3^+, 100). Elemental analysis for $C_3F_8N_2$ (calcd/found): C 16.68/16.00, F 70.35/68.2.

3: Diazane **2** (5 mmol) and ClF (5.5 mmol) were condensed into a stainless steel reaction vessel and allowed to react for 12 h at 25 °C. Distillation through a −90 °C trap, in which $(CF_3)_2NN(Cl)CF_3$ condensed, gave the pure product as a colorless liquid in quantitative yield. ^{19}F NMR ($CDCl_3$): $\delta = -68.0$ (sept, $^5J(F,F) = 4.7$ Hz, 3F; $N(Cl)CF_3$), −61.4 (q, $^5J(F,F) = 4.7$ Hz, 6F; $(CF_3)_2N$); IR (gas): $\nu[cm^{-1}] =$ 1339(s), 1289 (s), 1265 (s), 1220 (s), 1178 (m), 1030 (w), 986 (m), 927 (w), 839 (w), 734 (m), 725 (m); MS (CI): *m/z* %: 270 (M^+, 1), 251 ($M^+ - F$, 15), 235 ($M^+ - Cl$, 16), 216 ($M^+ - ClF$, 50), 197 ($(CF_3)_2NN = CF^+$, 45), 148 ($CF_3NNCF_2H^+$, 38), 128 ($CF_3NN{=}CF^+$, 38), 109 (CF_3NNC^+, 11), 69 (CF_3^+, 100).

4: Diazane **3** (5 mmol) was condensed into a 100 mL quartz vessel and photolyzed for 5 h ($\lambda = 3000$ Å). Distillation of the contents gave tetrazane **4**, which was condensed in a trap at −80 °C, in 90% yield. ^{19}F NMR ($CDCl_3$): $\delta = 64.6$ (m, 6F; $NNCF_3$), −58.8, −60.3 (br., 12F; $(CF_3)_2N$); coalescence at 331 K, $\Delta G^* =$ 15.2 kcal mol^{-1}; IR (gas): $\nu[cm^{-1}] = 1347$ (m), 1312 (s), 1300 (s), 1284 (s), 1247 (m), 1201 (w), 1181 (w), 987 (m), 935 (w), 735 (m). IR- and mass spectral data were reported earlier [8].

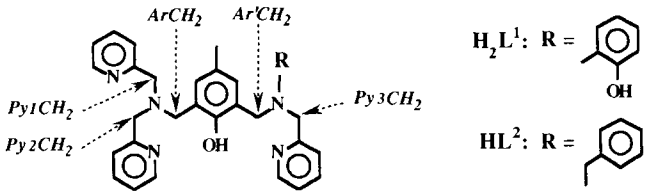
A Model of Semimet Hemerythrin; NMR Spectroscopic Evidence of Valence Localization in Bis(μ-carboxylato)(μ-phenolato)diiron(II,III) Complexes in Solution**

Wakako Kanda, William Moneta, Michel Bardet, Elisabeth Bernard, Noële Debaecker, Jean Laugier, Azzedine Bousseksou, Sylvie Chardon-Noblat, and Jean-Marc Latour*

Hemerythrin (Hr), a dioxygen carrier found in sipunculid worms and other marine invertebrates, is considered the prototype of non-heme proteins with a diiron active site.[1] Since the early 1980s the structures of four distinct forms of the protein have been solved by X-ray crystallography.[2] In the deoxy form, the two Fe^{II} ions are bridged by one hydroxy and two carboxylate groups. The coordination spheres of the two iron ions are quite different. One is bound by three histidine residues and is thus hexacoordinate; the other is bound by only two histidines, thus leaving a coordination site accessible to dioxygen and other substrates. Oxygenation of Hr leads to deprotonation of the bridging hydroxo ligands, resulting in a (μ-oxo)diiron(III) unit with a terminal hydroperoxo ligand linked to the bridging oxo ligand through a hydrogen bond. The hydroperoxo ligand can be replaced by anions (e.g. azide) leading to the corresponding met forms, which have been structurally characterized.[2] Apart from the $[Fe^{II}Fe^{II}]$ and $[Fe^{III}Fe^{III}]$ states, two mixed-valence forms $[Fe^{II}Fe^{III}]$ have been detected. These semimet hemerythrins are obtained either by oxidation of the deoxy form ($(semimet)_OHr$) or by reduction of the met form ($(semimet)_RHr$). No X-ray structures are available for the semimet forms yet, but EXAFS[3] and other spectroscopic methods[4] have revealed a Fe^{II} (μ-OH)Fe^{III} unit. NMR experiments on $(semimet)_RHr$ derivatives in solution have shown that the valence of the two ions is localized.[5] Kurtz et al.[6] and Solomon et al.[7] have proposed that the two semimet forms differ in terms of the location of the valences of the iron atoms in the ligand environment as illustrated in Scheme 1.



Scheme 1. Proposed structures of the semimet forms of hemerythrin. his = histidine, glu = L-glutamic acid, asp = L-aspartic acid.

Over the last decade, numerous μ-oxodiiron(III) complexes have been reported that mimic the physical properties of metHr.[8] However, in most cases the Fe^{III} ions are coordinatively saturated, and the compounds are not active catalysts. The one complex having the unsymmetrical structure of the Hr active site[9] exhibits some activity in hydrogen peroxide disproportionation. Fewer studies have focused on diiron(II)[10] and mixed-valence complexes.[11] Models of the semimet forms have been developed mostly by using ligands built on phenol-based ligands which mimic the hydroxo bridge of Hr. All the systems reported so far are coordinatively saturated and symmetrical. The latter feature results in delocalized valences for the two iron centers in solution at room temperature as shown by NMR experiments,[11] in contrast to the protein.

To model the structure and properties of hemerythrin and related proteins, we have synthesized new bridging ligands for diiron complexes (Scheme 2), which provide a phenolate and

Scheme 2. Structural formulas of ligands H_2L^1 (**1**) and HL^2 (**2**), and labeling of the methylene groups (see discussion of the NMR spectra).

other donor groups and mimic key features of the protein active sites. We recently reported on the structure of the $[Fe^{II}Fe^{III}]$ complex **1** with the ligand H_2L^1, which supplies one Fe ion with a terminal phenolate group (Scheme 2).[12] In this communication, we describe the synthesis and the structure of the first model of semimetHr that mimics the unsymmetrical histidine coordination of the protein active site, leaving a free coordination site on one iron center. In addition, variable-temperature NMR measurements show that the valences of the iron centers are localized in solution at room temperature as in $(semimet)_OHr$. Similar studies of complex **1** show that the valences are localized in the configuration found in $(semimet)_RHr$.

To mimic the active site of Hr we synthesized ligand HL^2, which provides three nitrogen donors to bind the first Fe center and only two for the second.[13] Reaction of HL^2 with two equivalents of $Fe(NO_3)_3 \cdot 9H_2O$ and one equivalent of disodium 1,3-benzenedipropionate (Na_2mpdp) affords a pale violet precipitate of **2** after addition of sodium tetraphenylborate. Recrystallization of the precipitate in acetonitrile/methanol furnishes dark purple crystals of **2** suitable for X-ray crystallography.[14] Elemental analysis and spectroscopic and magnetic studies show that **2** is a mixed-valence complex and support the proposed formulation.

$[Fe^{II}Fe^{III}L^2(H_2O)(mpdp)](BPh_4)_2 \cdot 2H_2O$ **2**

The structure of the cation of **2** is shown in Figure 1. The compound consists of discrete complex cations and tetraphenylborate counterions. The two iron ions are bridged by the phenolate oxygen atoms and two carboxylate groups from the mpdp ligand. The coordination sphere of Fe2 is completed by one tertiary and two pyridine nitrogen atoms, while that of Fe1 includes the oxygen atom of a water molecule in addition to one tertiary and one pyridine nitrogen atom. The Fe–Fe distance is 3.409 Å, which is close to that determined by EXAFS[3] for the

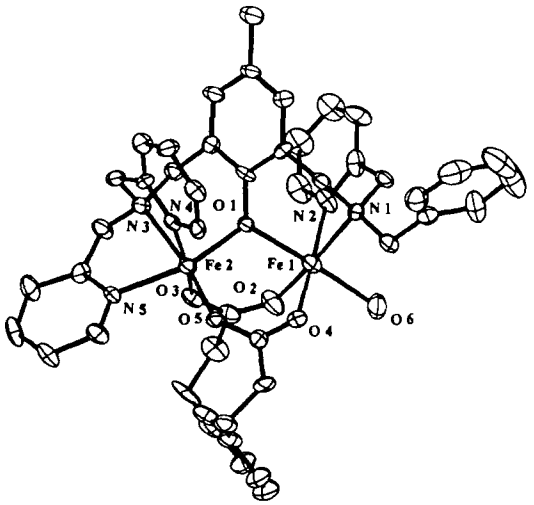

Fig. 1. Structure of the cation $[Fe_2L^2(mpdp)(H_2O)]^{2+}$ in the crystal of **2**. Important bond lengths [Å] and angle [°]: Fe1···Fe2 3.409(1), Fe1-O1 2.115(6), Fe1-O2 2.084(6), Fe1-O4 2.128(6), Fe1-O6 2.156(8), Fe1-N1 2.254(5), Fe1-N2 2.191(7), Fe2-O1 1.952(4), Fe2-O3 1.996(5), Fe2-O5 1.948(5), Fe2-N3 2.215(5), Fe2-N4 2.173(7), Fe2-N5 2.156(6); Fe1-O1-Fe2 113.9(2).

azide derivative of semimetHr (3.457 Å) and those found in other bis(μ-carboxylato)(μ-penolato)diiron(II,III) complexes.[11] The Fe-O-Fe unit is strongly asymmetric: the Fe2–O1 distance is 0.16 Å shorter than the Fe1–O1 separation. A similar trend is observed for the other metal–ligand distances and leads to the conclusion that the valences of the iron ions are localized. The Fe2 ion with the N_3O_3 coordination sphere, is in the +III oxidation state, while the Fe1 ion with the N_2O_4 coordination sphere is in the +II oxidation state. It is worth noting that this assignment is opposite to that for phenolate complex **1**, in which the terminal phenolate group stabilizes the Fe^{III} ion in the N_2O_4 site.

The valence localization of **2** in the solid state is supported by the Mössbauer spectra (80–300 K range). Two quadrupole split doublets are observed at 80 K with isomer shifts of 0.475(4) and 1.196(4) mm s^{-1} (relative to metallic iron at room temperature), splittings of 0.329(6) and 2.657(7) mm s^{-1}, and relative areas of 51(1) and 49(1)%, respectively. The first doublet is attributed unambiguously to the high-spin Fe^{III} center Fe2, while the second one corresponds to the high-spin Fe^{III} center Fe1. Similar Mössbauer parameters have been obtained for semimetHr.[1]

The electrochemical properties of **2** have been investigated in acetonitrile with 0.1 M tetrabutylammonium perchlorate. Cyclic voltammetry reveals a one-electron reduction at -0.36 V_{Ag/Ag^+} and an oxidation wave at about 0.5 V_{Ag/Ag^+}.[15] Since the latter wave overlaps with the oxidation wave of the tetraphenylborate anion, precise coulometric analysis is not possible. Spectroelectrochemical studies show that the reduction process is associated with the $[Fe^{II}Fe^{II}]/[Fe^{II}Fe^{III}]$ couple, and the oxidation with the formation of the Fe^{III}_2 derivative.

Both **1** and **2** have been characterized by ^{1}H NMR spectroscopy. Assignments of the signals were made by chemical substitution (replacement of mpdp by acetate), T_1 measurements, and COSY experiments, as well as by comparisons with spectra of related compounds.[10a, 11a, 16] Several features of **1** and **2** strongly suggest that the valences of the two Fe ions are also localized in solution on the NMR timescale and that the structure in solution is the same as that in the solid state.[17] These suppositions were established unambiguously through the use of variable-temperature NMR experiments. Figure 2a illustrates the dependence of the reduced chemical shift of the equatorial protons of the five methylene groups of complex **1**

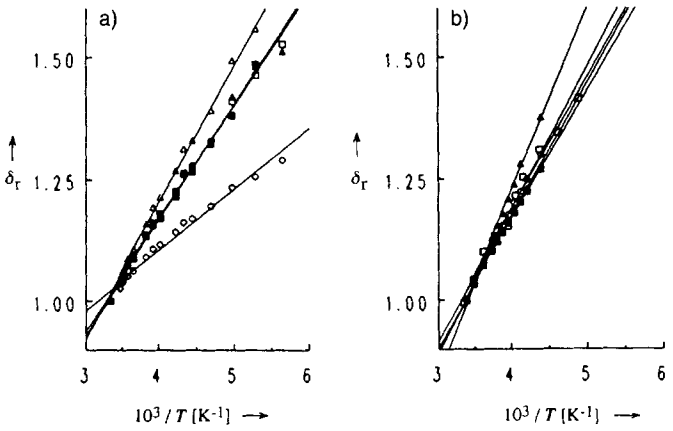

Fig. 2. Plot of the reduced chemical shift (δ_r is the ratio of the chemical shift at any temperature to the chemical shift at a reference temperature, here 293 K) versus the inverse of the temperature for the equatorial protons of complex **1** (a) and complex **2** (b); $ArCH_2$(eq) (□), Py1CH_2(eq) (△), Py2CH_2(eq) (○), Ar'CH_2(eq) (■), and Py3CH_2(eq) (▲).

with the inverse of temperature. (Equatorial protons are defined within the metallacycles by analogy with cyclohexane.) It is clearly seen that two protons, Ar'CH_2(eq) and Py3CH_2(eq), behave in the same manner, while the other three, $ArCH_2$(eq), Py1CH_2(eq), and Py2CH_2(eq), strongly differ. This behavior can be easily understood if the former protons are located in the vicinity of the magnetically isotropic Fe^{III} ion and the latter protons close to the magnetically anisotropic Fe^{II}. Examination of the corresponding plot for **2** (Fig. 2b) reveals that the same situation holds, but with opposite valences for the two Fe ions. These experiments demonstrate that the valences of the Fe centers in both complexes are localized in solution at room temperature and that in both cases the localization is the same as in the solid state: in **1** the Fe^{II} ion is in the N_3O_3 site, while in **2** it occupies the site accessible to the exogeneous ligand (a water molecule in the present case).

The similarity of the valence localization in **1** and **2** to that in $(semimet)_RHr$ and $(semimet)_OHr$, respectively, provides strong support for the Kurtz–Solomon hypothesis. Preliminary studies show that the terminal aqua ligand in **2** can be easily replaced, giving rise to very rich chemical behavior.

Experimental Procedure

To a solution of 0.2 g (0.38 mmol) of HL^2 in 6 mL of CH_3OH were added successively a solution of 0.31 g (0.76 mmol) of $Fe(NO_3)_3 \cdot 9H_2O$ in 3 mL of CH_3OH and a solution of 110 mg (0.38 mmol) of Na_2mpdp [18] in 5 mL of CH_3OH. The resulting violet solution was stirred for 4 h at room temperature. A solution of 0.53 g (1.52 mmol) of $NaBPh_4$ in 6 mL of CH_3OH was then added, and the mixture was stirred for roughly 15 h at room temperature. The pale purple precipitate that formed was filtered and recrystallized from acetonitrile/methanol to give dark purple crystals of **2** (0.32 g, yield 56%). The compound gave satisfactory elemental analysis and mass spectrum.

[17] The smaller spectral range ($\Delta\delta = 400$) of the NMR signals of delocalized complexes compared to the present compounds is indicative of an averaging of the signals caused by delocalization. The occurrence of signals with negative chemical shifts is characteristic of Fe^{II} complexes [10a, 16a]. The presence of true Fe^{II} ions is further supported by comparison with the spectra of heterobimetallic complexes [16b].

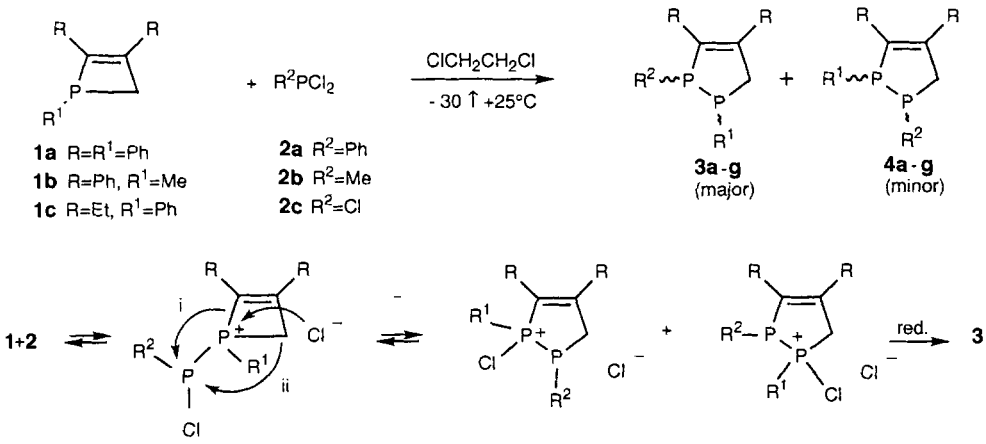
Synthesis of 1,2-Diphospholide Ions

Nicole Maigrot, Narcis Avarvari, Claude Charrier, and François Mathey*



To date, the 1,2-diphospholide ions are the only members of the polyphosphacyclopentadienide family that have not yet been synthesized.[1] Their preparation would permit the completion of a series of aromatic species that results from the successive replacement of sp^2-CH units in an aromatic hydrocarbon by isolobal sp^2-P units. No such complete series exists for any heteroatom.

Several literature reports suggest that, were they made, 1,2-diphospholide ions would be stable: Padma Malar[2] has calculated similar aromaticity indexes for the hypothetical $[1,2\text{-}C_3H_3P_2]^-$ and the known $[1,2,3\text{-}C_2H_2P_3]^-$ anion.[3, 4] Furthermore, two groups have described ferrocene derivatives containing η^5-1,2-diphospholyl ligands,[5, 6] and more recently a zwitterionic phosphole derivative has been reported.[7]

Our approach relies on a transposition of our preceding work on 1,2,3-triphospholide ions.[4] As a first step, we devised a

synthesis of the unknown 1,2-diphosphacyclopent-3-enes (Scheme 1). In essence, this comprised a formal insertion of phosphinidenes into 1,2-dihydrophosphetes (easily accessible from titanacyclobutenes and dihalophosphanes[8–10]), a process analogous to the reaction transforming phosphirenes into 1,2-dihydro-1,2-diphosphetes.[11] Our reasoning was that cyclic strain, which provides the driving force for the ring expansion of phosphirenes, is also significant in dihydrophosphetes. Our results are summarized in Tables 1 and 2.

The proposed mechanism is outlined in Scheme 1. The compound serving as the reducing agent is, very probably, the starting material itself. Indeed, when a mixture containing equimolar quantities of **1** and **2** reacts to completion, **1** disappears completely whereas **2** is still present. Hence, the theoretical yield of the reaction is limited to 50%, as is observed. The two first steps are probably reversible, since when starting materials are used in which $R^1 \neq R^2$, R^1PCl_2 and the corresponding insertion products can be detected by ^{31}P NMR spectroscopy at the end of the reaction. As shown in Table 1, the insertion preferentially takes place into the P–C(sp^2) bond of **1**, probably because of a favorable two-electron interaction between the LUMO of the C=C bond and the lone pair of the exocyclic phosphorus atom in the intermediate dihydrophosphete quaternary salt. The structures of **3** and **4** are easily established through the large ^2J(H,P) coupling (16–18 Hz) between one of the CH_2 protons and P1.

The reduction of the chloro derivatives **3e** and **3g** by lithium in THF yields the expected 1,2-diphospholide anions **6a** and **6b**,

respectively. The reaction proceeds via an intermediate anion **5**, whose P–Ph bond is still intact and which can be detected when R = Et ($\delta(^{31}P) = -133.8, +20.6$, ^1J(P,P) = 339 Hz). The preliminary formation of this partly delocalized anion precludes the cleavage of the P–P bond in the second step leading to **6**. The anions **6** are characterized by the low-field shifts of their ^{31}P NMR signals (δ = 152–206), their huge ^1J(P,P) couplings of roughly 440 Hz, and their sizeable ^2J(P,H) couplings of about

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0591 $ 10.00+.25/0

37 Hz. All these data are very characteristic of polyphospholide ions.[1] Further identification was achieved by the preparation of the 1,2-diphosphaferrocene **7** from **6b**.

Experimental Procedure

All the reactions were performed under argon, and the solvents were purified and dried by standard methods. For the synthesis of the initial titanacyclobutenes, see refs. [12, 13]. Dihydrophosphete **1a** was made as described in 65% yield [8–10]. **1b** appears to be unstable and has not been isolated: $\delta(^{31}P) = -19$. **1c** was recovered as a pale yellow oil in 20% yield: ^{31}P NMR (81.0 MHz, C_6D_6, H_3PO_4): $\delta = -10.6$; ^1H NMR (200 MHz, C_6D_6; TMS): $\delta = 0.92$ (t, $^3J(H,H) = 7.5$ Hz, 3H; Me), 0.98 (t, $^3J(H,H) = 7.5$ Hz, 3H; Me), 1.8–2.5 (m, 6H; $3CH_2$); ^{13}C NMR (50.0 MHz, C_6D_6, TMS): $\delta = 11.87$ (s, Me), 13.61 (d, $J(C,P) = 3.9$ Hz, Me), 21.73 (d, $^1J(C,P) = 10.8$ Hz, P-CH_2), 24.78 (d, $J(C,P) = 2.4$ Hz, C-CH_2), 27.52 (d, $J(C,P) = 7.5$ Hz, C-CH_2), 140.2 (d, $^1J(C,P) = 34.7$ Hz, sp^2-C), 145.85 (s, sp^2-C), 149.7 (d, $J(C,P) = 4.7$ Hz, sp^2-C).

3 (and **4**): $PhPCl_2$, $MePCl_2$, or PCl_3 (12×10^{-3} mol) was added dropwise to a solution of the corresponding dihydrophosphete **1** (12×10^{-3} mol) in 1,2-dichloroethane (25 mL) at $-30\,^\circ C$. The mixture was stirred and slowly warmed to room temperature. The reaction was stopped upon disappearance of **1** (^{31}P NMR). After evaporation of the solvent, the residue was chromatographed on silica gel (150 g, 60 mesh) with hexane/toluene (80/20) as the eluent. **3a**: pale yellow solid, m.p. 132 °C; **3b**: white solid, mixture of isomers; **3c**: white solid, m.p. 131 °C; **3d**: pale yellow oil; disulfide: m.p. 186 °C; **3e** and **3g** were not purified by chromatography but by thorough evaporation of the solvent and of the excess of PCl_3 under vacuum; **3f**: colorless oil. For ^1H NMR data see Table 2.

6: A solution of **3e** or **3g** (15×10^{-4} mol) in dry THF (5 mL) was stirred with lithium wire (5×10^{-2} g) at room temperature. For **6a**, the reaction was complete after 30 min. Dark brown solution: MS ($m/z = 253$ (M^-, 100%)); ^{31}P NMR: $\delta = 181.0$ (P1), 206.0 (P2), $^1J(P1,P2) = 444$ Hz, $^2J(P1,H) = 36.7$ Hz. For **6b**, the reaction required 4 d at 50 °C for completion. Brown solution: MS ($m/z = 157$ (M^-, 100%)); ^{31}P NMR: $\delta = 152.1$ (P1), 173.7 (P2), $^1J(P1,P2) = 436$ Hz, $^2J(P1,H) = 37$ Hz, $^3J(P2,CH_2) = 10.8$ Hz.

7: To the solution of **6b** was added solid NH_4Cl (8×10^{-2} g). The mixture was stirred for 1 h at room temperature, then $[Fe(\eta^6\text{-}1,4\text{-}Me_2C_6H_4)(\eta^5\text{-}C_5H_5)]^+PF_6^-$ [14] (0.56 g) was added. After additional stirring for 2 h, the solution was concentrated to 1.5 mL and chromatographed with hexane on silica gel. Compound **7** was recovered as a purple liquid in 25% yield. ^{31}P NMR (C_6D_6): $\delta = -34.5$ (P1), −9.9 (P2), $^1J(P1,P2) = 384$ Hz, $^2J(P1,H) = 36.5$ Hz, $^3J(P2,CH_2) = 10.6$ Hz; ^1H NMR (C_6D_6): $\delta = 1.03$ (t, $^3J(H,H) = 7$ Hz, 3H; Me); 1.17 (t, $^3J(H,H) = 7$ Hz, 3H; Me); 2.24 (m, 4H; $2CH_2$); 3.99 (s, 5H; Cp); 4.85 (d, $^2J(H,P) = 36.8$ Hz, 1H; P-CH); ^{13}C NMR (CD_2Cl_2): $\delta = 16.2$ (s, CH_3), 16.7 (s, CH_3), 23.0 (s, CH_2), 23.75 (d, $^2J(C,P) = 19$ Hz), 73.8 (s, Cp), 90.80 (d, $^1J(C,P) = 79$ Hz, P-CH), 99.7 (s, =C-CH), 101.3 (pt, P-C=).

[Bis{(η^5-pentamethylcyclopentadienyl)cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands**

Jörg J. Schneider,* Uwe Denninger, Oliver Heinemann, and Carl Krüger

Dedicated to Professor Günther Wilke on the occasion of his 70th birthday

In organometallic triple-decker complexes with bridging carbacyclic π-perimeters, the bridging ligands are bonded to each transition metal with either maximum hapticity or lower.[1] In the mixed triple-decker **1**[2]—the first with a bridging η^6-coordinate arene ligand—the aromatic benzene "middle deck" can be exchanged with other arenes such as toluene or mesitylene at temperatures above 100 °C, and yet retain the original triple-decker structure. To our knowledge, this is the only compound known to date with an antifacial coordinated arene bridge with which this can be achieved.

$[\{(\eta^5\text{-Cp})V\}_2\text{-}\mu\text{-}(\eta^6\text{:}\eta^6\text{-}C_6H_6)]$ **1**

We report here on the synthesis and structural characterization of cobalt triple-decker complexes with μ-η^4:η^4-bonded arene ligands, as well as on their unusual reactivity with respect to ligand exchange. During the course of our investigations into the synthesis of nonbridged $[(\eta^5\text{-}C_5R_5)Co]$ dimers (R = alkyl), we studied the reductive ligand release occurring in the reaction of $[(\eta^5\text{-Cp*})(acac\text{-}O,O')Co]$[3] with alkali metal. If the reaction is performed in solvents such as diethyl ether or THF, **2** is formed along with other substances.[4] The additional hydrido ligands presumably originate from the solvent. If benzene or methyl-substituted arenes such as toluene or *o*-, *m*-, and *p*-xylene are used as solvent, the reaction with alkali metal—typically in a batch of about 10 mmol—requires 10–14 days to go to completion instead of just one day in ethers. The reaction times can, however, be considerably reduced by prior activation of the alkali metal with ultrasound. Admittedly, undesirable side products such as $[(\eta^5\text{-Cp*})(\eta^6\text{-arene})Co]$ and $[(\eta^5\text{-Cp*})_2Co]$ (identified in the crude product by means of mass spectrometry and ^1H NMR spectroscopy) are then also formed. If the ultrasonic activation is not used, compounds with the composition **3** can be isolated by crystallization in about 40–60% yield.

$[\{(\eta^5\text{-Cp*})Co\}_3H_4]$ **2**

The compounds **3a–f** are brown solids, are stable for several months at 0 °C, and can be dissolved in aliphatic solvents and in diethyl ether without decomposition. The complexes react with aromatic solvents, however.

[{(η^5-Cp*)Co}$_2$-μ-(η^4:η^4-arene)] **3**

3a: arene = benzene
3b: arene = toluene
3c–e: arene = *o*-, m- bzw. *p*-xylene
3f: arene = cumene

The composition of the compounds of type **3** was confirmed by C, H, and Co elemental analyses, as well as by mass spectra in which the corresponding molecular ions were registered (admittedly only with low intensity). The most intensive signals in the mass spectra were attributed to the decomposition products of the complexes **3a–f**, such as the sandwich compound [(η^5-Cp*)$_2$Co] and the respective arene. The typical peak positions for the π-complexed arene were also found in the IR spectra. The positions of the resonance signals of the π-complexed arenes around δ = 3.19–2.70 in the ^{1}H NMR spectra of the compounds of type **3** identify them as diamagnetic complexes. With the exception of the signals of **3b**, all the signal groups in the ^{1}H NMR spectra of **3a** and **3c–f** are broadened. The temperature-dependence of the NMR spectra of **3b** as representative example was investigated: Down to 193 K both in the ^{1}H NMR and the ^{13}C NMR spectra, the typical splitting and coupling patterns that would be expected for a complex in solution with a time-averaged symmetrical μ-η^6:η^6-coordinate toluene ligand were observed. Neither the signals due to the arene and Cp* protons nor the signals due to the carbon atoms coalesce. This indicates a very low activation barrier to possible dynamic processes for **3b**. We first noticed the extraordinary behavior of the benzene derivative **3a** while taking a ^{13}C NMR spectrum at 27 °C. After several hours accumulation time of a spectrum of a freshly prepared sample of **3a**, signals from free benzene were observed, and the corresponding signals of the formally complexed benzene were missing. This indicated a ready exchange of the complexed benzene ligands with the deuterated [D$_6$]benzene used as solvent. In fact, if the NMR sample was worked up preparatively after two days, the corresponding [D$_6$]-**3a** was isolated quantitatively and characterized by NMR, IR, and mass spectroscopy. The signals from free arene were seen in the NMR spectra of the derivatives **3b–f** a short time after the samples had been prepared. This means that the aromatic middle-deck of these compounds is also as readily exchanged as that of **3a**. The arene ligand in compounds of type **3** is therefore apparently bonded in a labile fashion to both the {(η^5-Cp*)Co} units. Compound **3b** reacts with equimolar amounts of 1,3,5-cycloheptatriene or 1,3,5,7-cyclooctatetraene even at 20 °C within a short time to give the binuclear complexes **4**[5] and **5**.[6] The smooth exchange of the aromatic middle deck in **3b** under very mild reaction conditions is quite remarkable. The spectroscopic data and a crystal structure analysis[7] verified that the composition of compound **4** really does match that of the compound first prepared and characterized by Wadepohl. The smooth formation of **4** and **5** from **3b** without changing the binuclear structure, is observed even at room temperature; this argues against a dissociative mechanism for the ligand exchange in **3b**, that is, against the loss of a {(η^5-Cp*)Co} unit in the initial reaction step. Kinetic studies into the exchange process will be the subject of future investigations.

[{(η^5-Cp*)Co}$_2$-μ-(η^4:η^4-cycloheptatriene)] **4**

[{(η^5-CP*)Co}$_2$-μ-(η^4:η^4-cyclooctatetraene)] **5**

A conclusive decision in favor of one of the two conceivable structural variations of **3**, **A** and **B** (Fig. 1), was not possible from the existing preparative results and the spectroscopic data. Solid state CP/MAS ^{13}C NMR spectra of the arene derivatives **3b–f** also do not permit an unequivocal verdict on the structure, that is, on whether the {(η^5-Cp*)Co} units on the arene ligands are arranged synfacially or antifacially. In the case of **3b** for example, the signals in the arene region are broad at 83 K, but do correspond to those in the ^{13}C NMR spectrum of **3b** in solution as regards number and position. This would seem to indicate a distinct structural fluctuation—both in solution and in the solid. Such dynamic behavior in solids is not unusual and has already been confirmed for [Fe(CO)$_3$(η^4-C$_8$H$_8$)],[8] [Fe$_2$(CO)$_5$-μ-(η^8-C$_8$H$_8$)],[8] [Ru$_3$(CO)$_4$-μ-(η^8-C$_8$H$_8$)$_2$],[9, 10] and [Os$_3$(CO)$_8$(η^2-CH$_2$CH$_2$)-μ-(η^2:η^2:η^2-C$_6$H$_6$)],[11] by means of CP/MAS ^{13}C NMR experiments.

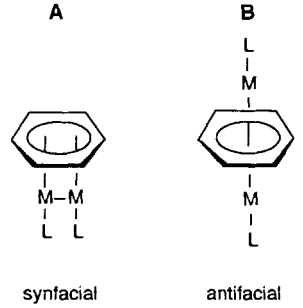

Fig. 1. Synfacial (**A**) and antifacial (**B**) coordination of two complex fragments to a bridging π-perimeter.

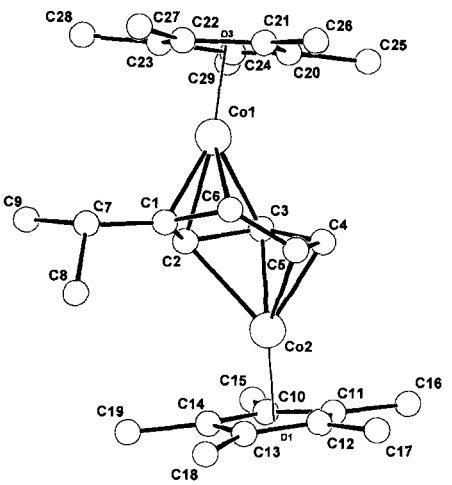
The molecular structure of **3f** in the crystal was determined by a single-crystal X-ray structure analysis (Fig. 2).[12] We assume that the derivatives **3a–e** have a similar structure. In **3f** the arene ligand bridges the two {(η^5-Cp*)Co} complex fragments in such a way that an antifacial arrangement of the two complex fragments results in a "slipped" triple-decker. Analogous structures can be found in the binuclear complexes of cyclooctatetraene (cot). An *anti*-μ-η^5:η^5 structure, comparable to that in **3f**, is present in [{(η^5-Cp)Rh}$_2$-μ-(cot)]$^{2+}$,[1d] [{(η^5-Cp)Fe}$_2$-μ-(cot)],[13] and [{(η^5-Cp)Ru}$_2$-μ-(cot)].[1e] Both the Co atoms in **3f** are η^4-bonded to the bridging arene ring. The C$_6$ arene system in **3f** is no longer planar, and a chair conformation results for the isopropylbenzene ligands. The bond angles C1-C6-C5 and C2-C3-C4 are 117.9(6) and 120.1(7)°, respectively. The atoms C2 and C3 of the isopropylbenzene ligand each bridge



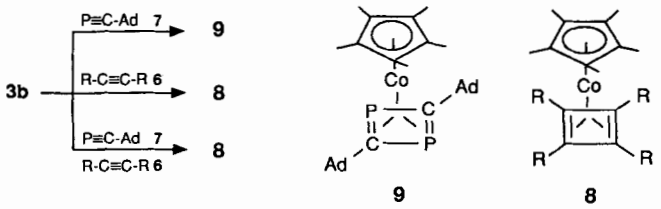


Fig. 2. Molecular structure of **3f** in the crystal. Hydrogen atoms not shown. Selected distances [Å] and angles [°]: Co1-C11.935(8), Co1-C3 2.1668(1), Co1-C2 2.062(7), Co1-C6 2.051(8), Co2-C2 2.255(8), Co2-C4 1.899(8), Co2-C3 2.053(8), Co2-C5 2.084(7), C1-C2 1.43(1), C3-C4 1.44(1), C5-C6 1.44(1), C1-C6 1.43(1), C2-C3 1.47(1), C4-C5 1.45(1), C7-C8 1.53(1), C7-C9 1.53(1); C6-C5-C4 116.3(7), C5-C4-C3 109.8(7) C6-C1-C2 110.0(7), C9-C7-C8 110.2(7).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0593 $ 10.00+.25/0

the metal atoms. The coordination of the arene ligand in **3f** thus corresponds to that of the cycloheptatriene in **4**[5, 7] and of the cot ligand in $[\{(\eta\text{-cot})Ti\}_2\text{-}\mu\text{-(cot)}]$.[1f, 1g] As is also the case in **4**, C2 and C3 are each bonded to both Co atoms through one longer and one shorter bond. In contrast to the corresponding bond in **4** (1.516(6)[5] and 1.492(9) Å[7]), however, the C2–C3 bond of 1.47(1) Å (in which both C atoms coordinate to both Co atoms) in **3f** is not significantly elongated. The antifacial μ-η^4:η^4 coordination, which was characterized here for the first time for arenes, is a novel mode of coordination for this important ligand type. Interestingly enough, for the heavier homologous element Rh, a closely related compound $[\{(\eta^5\text{-Cp})Rh\}_2\text{-}\mu\text{-}(\eta^3\text{:}\eta^3\text{-}C_6H_6)]$,[14] contains an arene that—in contrast to that in the Co complex **3f**—bridges the $\{(\eta^5\text{-Cp})Rh\}$ units in a synfacial fashion. The compound also contains a Rh–Rh bond.

We also investigated the reaction behavior of **3b** with respect to its participation in a possible dimerization or trimerization of alkyne **6** or λ^3-phosphaalkyne **7**[15] (Scheme 1). If solutions of

Scheme 1. Ad = adamantyl, R = phenyl.

3b in diethyl ether are treated with **6** or **7** at 20 °C (stoichiometry **3b**:**6**, **3b**:**7** 1:3) or 1:1 mixtures of the two alkynes (stoichiometry **3b**:**6,7** 1:1), the homo- and heteroalkyne components **6** and **7** are dimerized to form the corresponding cyclobutadiene complex **8** or diphosphacyclobutadiene complex **9**. The structure of **9** with a λ^3-1,3-diphosphete unit is confirmed by the crystal structure analysis[16] (Fig. 3). In the case of the reaction of mixtures of **6** and **7** with **3b**, only **8** is isolated. The product of a codimerization accompanied by the formation of a monophosphacyclobutadienecobalt(I) complex is not observed in this case. Nor is a cyclotrimerization of the λ^3-phosphaalkyne accompanied by the formation of triphosphinines observed.

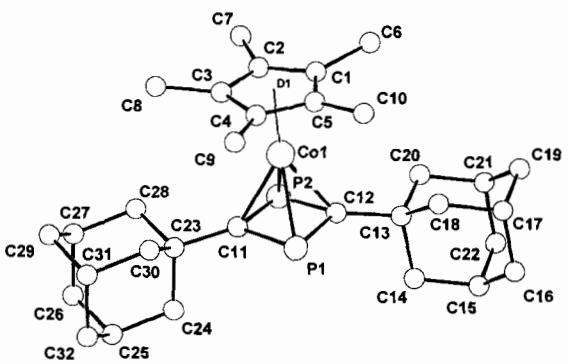

Fig. 3. Molecular structure of **9** in the crystal. Hydrogen atoms not shown. The asymmetric unit contains two independent molecules which do not differ significantly in their bonding parameters, however. For this reason, only molecule 1 is shown. Selected distances [Å] and angles [°]: Co1-C11 2.082(3), Co1-C12 2.082(3), Co1-P1 2.236(1), Co1-P2 2.253(1), C11-P1 1.795(3), C11-P2 1.792(3), C12-P1 1.787(3), C12-P2 1.789(3), C11-C23 1.505(4), C12-C13 1.509(4); P1-C11-C23 128.8(2), P1-C12-C13 128.9(2), P2-C12-C13 128.2(2), P2-C11-C23 128.8(2), P2-C12-P1 99.4(1), P2-C11-P1 99.0(1).

In conclusion, **3** demonstrates a remarkable reactivity with regard to ligand exchange and is also the first example for the exchange of the aromatic "middle deck" of a triple-decker at room temperature. Complex **3** thus seems to be a promising source of $[(\eta^5\text{-Cp*})Co]$ complex fragments and as a transfer reagent for these fragments in future studies.

Experimental Procedure

3a–f: $[(\eta^5\text{-Cp*})(\text{acac-}O,O')Co]$ (10 mmol) was dissolved in 100 mL of the particular arene concerned, and an equimolar amount of pieces of potassium metal were added. The surface of the potassium metal can be activated by ultrasound for a short period of time. The mixture was then stirred until the metal had dissolved completely (max. 2 weeks). During this time, the color of the reaction mixture changed from red to deep brown. A dirty-grey precipitate was also formed. Excess arene was then removed under vacuum, and the residue fully extracted with pentane. The extract was filtered, concentrated by removal of solvent under vacuum, and cooled to −78 °C to give the triple-decker complexes **3a–f** in crystalline form. Yield: 40–60%.

3a: MS (EI, 70 eV): *m/z* (%): 466 (5) [M^+], 386 (7), 329 (42), 192 (17), 78 (100), 51 (28); ^{1}H-NMR (200 MHz, 27 °C, [D$_6$]benzene): δ = 2.05 (s, 30H), 3.00 (s, 6H). – **3b**: MS (EI, 70 eV): *m/z* (%): 480 (30) [M^+], 386 (73), 329 (64), 92 (78), 91 (100); IR (KBr): $\tilde{\nu}$ = 730 (s, vw), 755 (vw), 775 (vw), 850 (vw), 990 (vw), 1020 (s), 1370 (vs), 1430–1470 (vs), 3020 cm^{-1} (vw); ^{1}H-NMR (300 MHz, 27 °C {−80 °C}, [D$_8$]THF): δ = 1.79 {1.77} (s, 30H), 1.57 {1.65} (s, 3H), 2.70 {2.21} (d, ^3J(H,H) = 4.6 Hz, 2H, 2.82 {2.36} (t, ^3J(H,H) = 4.6 Hz, 2H), 3.00 {3.32}(t, ^3J(H,H) = 4.6 Hz, 1H); ^{13}C-NMR (75.5 MHz, 32 °C {−80 °C}, [D$_8$]THF): δ = 10.9 {11.2} (q ^1J(C,H) = 126 Hz, 30H, Cp*), 20.6 {19.8} (q, ^1J(C,H) = 126 Hz, 3H, CH$_3$), 53.1 {50.5} (d, ^1J(C,H) = 167 Hz, *m*-C), 55.2 {51.3} (d, ^1J(C,H) = 166 Hz, *o*-C), 56.2 {60.8} (d, ^1J(C,H) = 172 Hz, *p*-C), 69.3 {74.3} (s, quart. C), 85.7 {86.3} (s, C_{Ring} on Cp*). – **3c**: MS (EI, 70 eV): *m/z* (%): 494 (34) [M^+], 386 (100) 329 (38), 300 (25), 192 (14), 133 (19), 106 (19), 91 (32); IR (KBr): $\tilde{\nu}$ = 770 (s), 795 (m), 860 cm^{-1} (vw); ^{1}H-NMR (200 MHz, 27 °C, [D$_6$]benzene): δ = 1.91 (s, 30H), 1.55 (s, 6H), 2.81 (s, 2H), 2.96 (s, 2H). – **3d**: MS (EI, 70 eV): *m/z* (%): 494 (33) [M^+], 386 (100), 329 (38), 300 (25), 192 (15), 133 (20), 106 (19), 91 (31); IR (KBr): $\tilde{\nu}$ = 840 (vw), 960 (vw), 1025 (s), 1375 (s), 1480 (s, br), 3020 cm^{-1} (vw); ^{1}H-NMR (200 MHz, 27 °C, [D$_6$]benzene): δ = 1.96 (s, 30H), 1.51 (s, 6H), 2.72 (s, 2H), 2.82 (s, 1H), 3.19 (s, 1H). – **3e**: MS (EI, 70 eV): *m/z* (%): 494 (4) [M^+], 386 (15), 329 (20), 106 (63), 91 (100); IR (KBr): $\tilde{\nu}$ = 680 (s), 850 (vw), 905 (vw), 1195 (vw), 3020 cm^{-1} (vw); ^{1}H-NMR (200 MHz, 27 °C, [D$_6$]benzene): δ = 1.97 (s, 30H), 1.63 (s, 6H), 2.71 (s, 4H). – **3f**: MS (EI, 70 eV): *m/z* (%): 508 (27) [M^+], 386 (88), 314 (100), 192 (41), 120 (25), 133 (28), 105 (93); IR (KBr): $\tilde{\nu}$ = 995 (s), 860 (m), 782 (m), 725 cm^{-1} (vw); ^{1}H-NMR (400 MHz, 27 °C, [D$_6$]benzene): δ = 1.02 (s, 1H), 1.32 (s, 6H), 1.98 (s, 30H), 3.0 (s, 2H), 3.05 (s, 1H), 3.20 (s, 2H). Single crystals of **3f** suitable for an X-ray structure analysis were obtained from a saturated diethyl ether solution of **3f** at −78 °C. Correct C, H, and Co elemental analyses were obtained for all the compounds **3a–f**.

[D$_6$]3a: **3a** (80 mg, 0.17 mmol) was dissolved in 5 mL [D$_6$]benzene and allowed to stand at room temperature for 2 days or at 0 °C for 1 week in a sealed NMR tube. The solvent was then fully removed and the residue analyzed. The yield was approximately quantitative. MS (EI, 70 eV): *m/z* (%): 472 (3) [M^+], 329 (6), 84 (100); ^{1}H-NMR (200 MHz, 27 °C, [D$_6$]benzene): δ = 2.01 (s, 30H); IR (KBr) $\tilde{\nu}$ = 2240 cm^{-1} (CD-Ring).

4: **3b** (120 mg, 0.25 mmol) was dissolved in 30 mL ether, and cycloheptatriene (0.026 mL, 0.25 mmol) added with continuous stirring. The mixture was stirred for 1 h, and all volatile components then removed under vacuum. The residue was taken up in pentane and filtered. Compound **4** crystallized at −30 °C in the form of brown crystals with a metallic luster. Yield : 84 mg (0.18 mmol, 72%). The C, H, and Co elemental analyses were correct. The spectroscopic data of **4** were identical with those in the literature [5].

5: **3b** (120 mg, 0.25 mmol) was dissolved in 30 mL ether, and cot (0.016 mL, 0.25 mmol) added while stirring. The mixture was stirred for 2 h, and the solution turned red. All volatile components were removed under vacuum, and the semicrystalline residue was dissolved in pentane and filtered. Compound **5**[16] crystallized at −30 °C in the form of red crystals. Yield: 82 mg (0.16 mmol, 64 %). The C, H, and Co elemental analyses were correct. MS (EI, 70 eV): *m/z* (%): 492 (100) [M^+], 386 (27), 329 (15), 297 (60), 243 (48), 133 (18); ^{1}H-NMR (200 MHz, 27 °C, [D$_8$]THF): δ = 3.0 (s, 8H), 1.42 (s, 30H); ^{13}C-NMR (50.32 MHz, 27 °C, [D$_8$]THF): δ = 91.45, 81.89, 9.13.

8, 9: **3b** (345 mg, 0.718 mmol) was dissolved in 50 mL ether and treated either with a) **6** (384 mg, 2.25 mmol), b) **7** (382 mg, 2.14 mmol), or c) **6** (122 mg, 0,68 mmol) and **7** (120 mg, 0.67 mmol) simultaneously. In each case the mixture was stirred for 12 h. In the case of a) and c), **8** precipitated as a yellow powder (230 mg, 0.42 mmol, 29%) as the reaction proceeded. The powder was purified sufficiently for analytical purposes by filtration and washing with pentane. In the case of b), the solvent was removed to give a viscous brown residue. This was dissolved in a small amount of ether, and **9** was obtained in the form of beige-brown crystals, which are suitable for

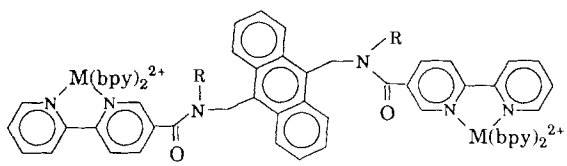
Electronic Energy Transfer in a Supramolecular Species Containing the $[Ru(bpy)_3]^{2+}$, $[Os(bpy)_3]^{2+}$, and Anthracene Chromophoric Units**

Peter Belser,* Roland Dux, Marcel Baak, Luisa De Cola,* and Vincenzo Balzani*

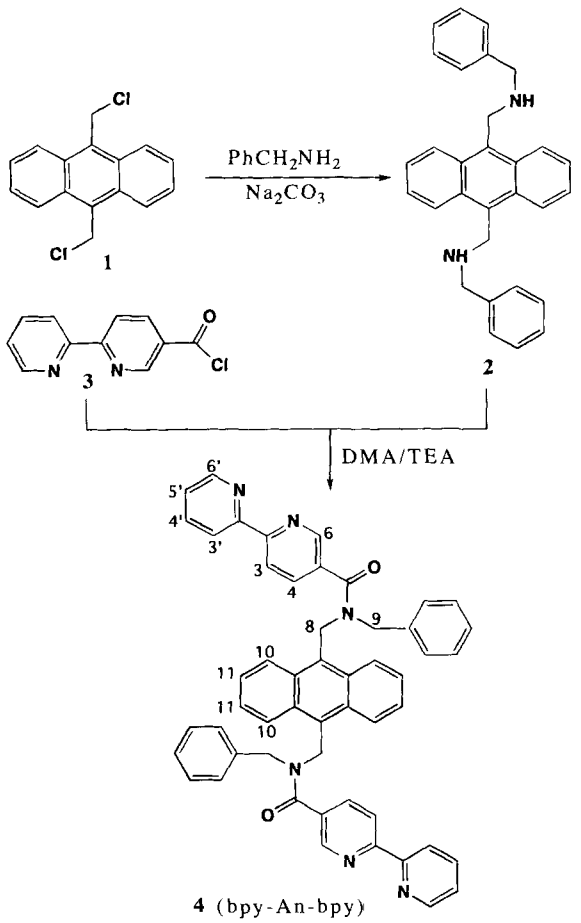


At the roots of supramolecular chemistry is the concept that supramolecular systems have the potential to achieve much more elaborate tasks than simple molecules:[1–6] while molecules can be involved in simple chemical *acts*, supramolecular systems can perform *functions*. In other words, supramolecular systems have the potential to behave as molecular devices. A particularly interesting class of molecular devices is that capable of using photons as energy or information inputs (photochemical molecular devices).[4, 7] An essential function in many photochemical molecular devices is electronic energy transfer.[4] The design of ordered supramolecular systems in which the path of electronic energy transfer can be synthetically predetermined and then switched by an external input is an important goal of current chemical research.[8]

Continuing our investigations on the study of energy transfer processes in supramolecular systems involving transition-metal complexes,[9, 10] we have designed and synthesized a three-component species in which i) energy transfer occurs in a predetermined direction and ii) its efficiency and rate can be strongly reduced as a consequence of a self-photosensitized reaction involving dioxygen.

The Ru-An-Os three-component system (Scheme 1) is made up of $[Ru(bpy)_3]^{2+}$- and $[Os(bpy)_3]^{2+}$-type units (indicated by

bpy-An-bpy



$[(bpy)_2Ru(bpy\text{-}An\text{-}bpy)Os(bpy)_2]^{4+}$	Ru-An-Os
$[(bpy)_2Ru(bpy\text{-}An\text{-}bpy)Ru(bpy)_2]^{4+}$	Ru-An-Ru
$[(bpy)_2Os(bpy\text{-}An\text{-}bpy)Os(bpy)_2]^{4+}$	Os-An-Os

Scheme 1. Structural formulas of the bpy-An-bpy bridging ligand and of its complexes. The abbreviations used to indicate the complexes are also shown.

Ru and Os, respectively; bpy is 2,2′-bipyridine), linked to the 9,10 positions of an anthracene (An) ring. This arrangement has been chosen so as to have a gradient for energy transfer along the Ru-An-Os sequence (see below).[11] The analogous homometallic Ru-An-Ru and Os-An-Os species have also been prepared, and their properties will be mentioned when necessary for comparison. Very good model compounds for the isolated Ru-based and Os-based units of Ru-An-Os are the previously investigated[12] Ru and Os complexes with two bpy ligands and a bpy ligand which carries an amido-type substituent in a 5′ position. For the An-based unit of Ru-An-Os, the model compound is the bpy-An-bpy free ligand used to prepare the dinuclear complexes (Scheme 2). This compound shows, as expected, the same absorption spectrum (above 350 nm) and the same fluorescence spectrum and lifetime of anthracene.

Scheme 2. The synthesis of the bpy-An-bpy bridging ligand. See *Experimental Procedure* for details.

The absorption spectrum of Ru-An-Os (Fig. 1) is exactly that expected for a 1:1:1 mixture of the corresponding model compounds, indicating that the electronic interaction between the three components of the supramolecular system is very small. The structured absorption around 350–400 nm is due to the anthracene unit, the broad band with maximum at 451 nm receives contributions from spin-allowed metal-to-ligand charge-transfer (CT) transitions of the Ru-based and Os-based components, and the broad tail above 500 nm is due to spin-forbidden CT transitions of the Os-based component.

Luminescence experiments (inset in Fig. 1) were carried out with 464 nm excitation, corresponding to an isosbestic point of the $[Ru(bpy)_3]^{2+}$ and $[Os(bpy)_3]^{2+}$ moieties. In order to discuss

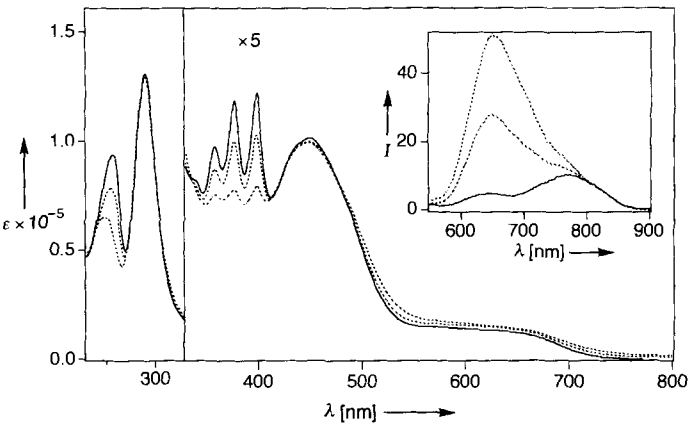

Fig. 1. Absorption and luminescence (inset) spectra in acetonitrile solution of Ru-An-Os (full line). The spectral changes caused by irradiation with visible light of aereated solution are also shown (dotted curves).

the results obtained (Table 1), reference will be made to the simplified energy level diagram of Figure 2. For deaerated acetonitrile solution, comparison with the behavior of the mononuclear model compound shows that the lifetime of the Ru-based emission of Ru-An-Os is extremely short. This indicates that in Ru-An-Os the ^{3}CT Ru-based excited state undergoes a quenching process. Quenching is confirmed by the fact that the intensity of the Ru-based luminescence band is extremely weak (about 0.5% that of the model compound). The quenching process involves energy transfer to the Os-based unit, as shown by a) the intensity of the Os-based 770 nm band, and b) the observation of a risetime, for the Os-based emission, which is close to the decay rate of the Ru-based luminescence. The rate constant for the quenching process can be calculated from the equation $k_{en} = 1/\tau - 1/\tau^{\circ}$, where τ and τ° are the luminescence lifetimes of the Ru-based moiety of Ru-An-Os and of the Ru model compound, respectively. From the values displayed in Table 1, k_{en} was calculated to be $4.7 \times 10^8\ s^{-1}$.

Table 1. Luminescence data [a].

	Deaerated solution [b]						Air-equilibrated solution			
	Ru-based			Os-based			Ru-based		Os-based	
	λ_{max} [nm]	τ [ns]	I_{rel} [c]	λ_{max} [nm]	τ [ns]	I_{rel} [c]	λ_{max} [nm]	τ [ns]	λ_{max} [nm]	τ [ns]
Ru model compound [d]	640	495	100	–	–	–	640	200	–	–
Os model compound [e]	–	–	–	770	18	100	–	–	780	14

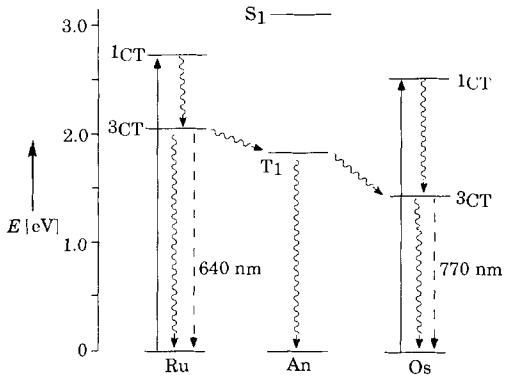

Fig. 2. Schematic diagram for the low-energy excited states of Ru-An-Os.

The occurrence of energy transfer from the Ru-based to the Os-based component of Ru-An-Os can be explained on the basis of the relative energy positions of the ^{3}CT levels of the two metal-containing units (Fig. 2). The structure of the supramolecular species, and the energy level diagram suggest that energy is first transferred from the ^{3}CT Ru-based excited state to the lowest triplet excited state of anthracene (T_1), which then transfers energy to the luminescent ^{3}CT excited state of the Os-based unit.[11] The experiments described below support this hypothesis. In air-equilibrated acetonitrile solutions the intensity of the luminescence of the Os-based unit is slightly weaker and the lifetime slightly shorter than in deaerated solutions. This is an expected result in view of the quenching effect of oxygen on the ^{3}MLCT excited state of Os^{II}-polypyridine compounds.[13]

Continuous irradiation with visible light of deaerated acetonitrile solutions of Ru-An-Os does not cause any change in the absorption and luminescence spectra. The energy absorbed by the Ru-based unit flows to the Os-based one, where it is dissipated by radiative and radiationless transitions. In air-equilibrated solutions, however, continuous irradiation causes a photoreaction, as shown by the progressive disappearance of the structured anthracene absorption in the 350–400 nm region (Fig. 1). A concomitant increase in the intensity of the Ru-based luminescence band at 640 nm is also observed (Fig. 1, inset). At the end of the photoreaction the lifetime of the recovered Ru-based emission is about 90 ns, that is much shorter than that of the model Ru compound (Table 1). These results indicate that in the photoreaction product the Ru-based luminescence is quenched with a rate constant of $0.6 \times 10^7\ s^{-1}$, a value about 80 times smaller than that found for Ru-An-Os. Although the experimental error is large because of the intense tail of the Ru-based luminescence, it is clear that the partial quenching of the Ru-based emission is still accompanied by sensitization of the Os-based luminescence (Fig. 1, inset). NMR measurements on the irradiated solutions indicate formation of an anthracene endoperoxide species as well as of other products where the anthracene aromaticity is no longer present.[14]

The results obtained in aerated solution can be interpreted by oxygen quenching of the Os-based ^{3}CT excited state of Ru-An-Os with formation of singlet oxygen [Eq. (a)], followed by attack of singlet oxygen on an anthracene ring to form an endoperoxide derivative [Eq. (b)],[15] which then may evolve[16] to give other products (indicated by Ru-X-Os) where the central ring of anthracene has lost its aromatic character [Eq. (c)].

$$Ru\text{-}An\text{-}(^3CT)Os + O_2 \longrightarrow Ru\text{-}An\text{-}Os + (^1\Delta)O_2 \quad (a)$$

$$Ru\text{-}An\text{-}Os + (^1\Delta)O_2 \longrightarrow Ru\text{-}An(O_2)\text{-}Os \quad (b)$$

$$Ru\text{-}An(O_2)\text{-}Os \longrightarrow Ru\text{-}X\text{-}Os \quad (c)$$

The very low quenching rate of the Ru-based excited state by the Os-based moiety in the photoproducts (where the anthracene aromaticity has been destroyed and, as a consequence, the T_1 level (Fig. 2) has been removed) indicates that the T_1 excited state of anthracene does play a role in the energy transfer process observed for Ru-An-Os.

In conclusion, electronic energy transfer from the Ru-based to the Os-based unit of Ru-An-Os takes place through the anthracene bridge with almost unitary efficiency and rate constant $4.7 \times 10^8\ s^{-1}$. When the aromaticity of the anthracene unit is destroyed by the self-photosensitized oxidation reaction, the rate constant and the efficiency of the energy transfer process from the Ru-based to the Os-based unit are strongly reduced.

Experimental Procedure

Benzyl[{10-(benzylaminomethyl)anthracen-9-yl}methyl]amine **2**: 9,10-Bis(chloromethyl)anthracene **1** [17] (4.21 g, 15.3 mmol) was added under stirring to anhydrous sodium carbonate (26 g, 0.245 mol) in benzylamine (250 mL, 2.29 mol). The mixture was stirred at room temperature for 8 h and the solid was filtered off. The excess of benzylamine was distilled from the filtrate. The remaining solid was dried in an oven at 80 °C for one day. For purification the residue was heated to reflux for 15 minutes in 6 M hydrochloric acid (75 mL) and the solid, which was formed after standing overnight, was filtered off. The solid was then stirred with sodium hydroxide (2 M solution, 200 mL) for 3 h. The clear solution was extracted with dichloromethane. The combined extracts were dried over magnesium sulfate. Evaporation of the solvent yielded **2** (5.93 g; 93%). ^{1}H NMR (300 MHz, [D$_6$]DMSO: δ = 2.5 (s, 2H, NH), 3.95 (s, 4H, CH_2), 4.53 (s, 4H, CH_2), 7.25–7.46 (m, 10H, CH_{ar}). FAB-MS: m/z = 416 (M^+), 310 (M^+ – benzylamine), 218 (M^+ – 2 benzylamine), 192 (anthracene–CH_2), 178 (anthracene). Satisfactory C, H, N, analysis for $C_{30}H_{28}N_2$.

9,10-Bis[2,2'-bipyridinyl-5-yl-carbonyl-(*N*-benzyl)aminomethyl]anthracene **4**: A mixture of amine **2** (1.62 g, 3.9 mmol) and triethylamine (TEA) (10 mL) in dimethylacetamide (DMA) (20 mL) was added to a stirred mixture of 2,2'-bipyridinyl-5-carbonyl chloride **3** [12] (2.18 g, 10 mmol) in DMA (50 mL). The mixture was stirred overnight and filtered. The organic layer was treated with 800 mL 5% $NaHCO_3$ solution. The precipitated solid was separated by centrifugation and dissolved in dichloromethane, washed with water, and dried over magnesium sulfate. Evaporation of the solvent yielded **4** (0.609 g; 20%). ^{1}H NMR (300 MHz, [D$_6$]DMSO, 100 °C): δ = 4.2 (s, 4H, CH_2(9)), 5.8 (s, 4H, CH_2(8)), 6.6–7.3 (m, 10H, benzyl), 7.42 (ddd, 2H, CH(5')), 7.64 (dd, 4H, CH(11)), 7.90 (ddd, 2H, CH(4')), 7.97 (dd, 2H, CH(4)), 8.17 (dd, 4H, CH(10)), 8.33 (ddd, 2H, CH(3')), 8.37 (dd, 2H, CH(3)), 8.66 (ddd, 2H, CH(6')), 8.73 (dd, 2H, CH(6)). FAB-MS: m/z = 803 ($M^+ + Na^+$), 597 (M – bpy–CO), 492 (M – bpy–CONH–benzyl), 391, 310, 218, 204 (CH_2–anthracenediyl–CH_2), 183 (bpy–CO), 156 (bpy), 149, 113, 71. Satisfactory C, H, N analysis for $C_{52}H_{40}N_6O_2$.

The metal complexes were prepared by using [M(bpy)$_2$Cl$_2$] (M = Ru, Os) and the bpy-An-bpy ligand in refluxing methoxyethanol. Upon addition of an excess of NH_4PF_6, the PF_6^- salts of the complexes were precipitated and purified as previously described [12].

Characterization of the metal complexes: Ru-An-Ru. ^{1}H NMR (300 MHz, [D$_6$]DMSO, 90 °C): δ = 3.85 (s, 4H, CH_2(9)), 5.67 (s, 4H, CH_2(8)), 6.49–6.55 (m, 4H, benzyl), 7.2–7.42 (m, 6H, benzyl), 7.3–7.8 (m, 26H, ar.), 7.9–8.2 (m, 16H, ar.), 8.5–8.8 (m, 12H, CH(3,3')). FAB-MS: m/z = 2074 ($M^+ - O_2 - PF_6$), 2042 ($M^+ - PF_6$), 1898 ($M^+ - 2PF_6$), 1754 ($M^+ - 3PF_6$), 1339, 1051. Satisfactory C, H, N, analysis for $C_{92}H_{72}F_{24}N_{14}O_2P_4Ru_2$.

Os-An-Os. ^{1}H NMR (300 MHz, [D$_6$]DMSO, 90 °C): δ = 3.85 (s, 4H, CH_2(9)), 5.67 (s, 4H, CH_2(8)), 6.4–6.55 (m, 4H, CH(benzyl)), 6.9–7.2 (m, 6H, CH(benzyl)), 7.3–7.8 (m, 26H, CH(5,5',6,6',11)), 7.7–8.0 (m, 16H, CH(4,4',10)), 8.5–8.8 (m, 12H, CH(3,3')). FAB-MS: m/z = 2386 (M^+ + Na), 2221 ($M^+ - PF_6$), 2073 ($M^+ - 2PF_6$), 1141, 1038, 750. Satisfactory C, H, N, analysis for $C_{92}H_{72}F_{24}N_{14}O_2Os_2P_4$.

Ru-An-Os. ^{1}H NMR (300 MHz, [D$_6$]DMSO, 100 °C): δ = 3.85 (s, 4H, CH_2(9)), 5.66 (s, 4H, CH_2(8)), 6.4–6.55 (m, 4H, CH(benzyl)), 6.9–7.2 (m, 6H, CH(benzyl)), 7.2–7.7 (m, 26H, CH_{ar}), 7.7–8.2 (m, 16H, CH(4,4',10)), 8.5–8.8 (m, 12H, CH(3,3')). FAB-MS: m/z = 2299 (M^+ + Na), 2133 ($M^+ - PF_6$), 1988 ($M^+ - 2PF_6$). Satisfactory C,H,N, analysis for $C_{92}H_{72}F_{24}N_{14}O_2OsP_4Ru$.

The equipment used to measure the absorption spectra, emission spectra, and luminescence lifetimes have been previously described [12].

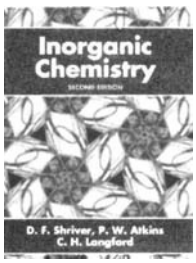
World of Light

Chemistry and Light. By *P. Suppan.* Royal Society of Chemistry, Cambridge, 1994. 295 pp., paperback £ 19.50.—ISBN 0-85186-814-2



Anyone who maintains awareness of publications in the area of photochemistry knows that the subject is currently undergoing a renaissance in the form of monographs, reviews, and original papers (and thus also in research and development). However, in contrast to the wealth of publications on specific topic areas, there has up to now been a shortage of more comprehensive up-to-date general introductions to photochemistry. To help remedy that gap we now have this book by Suppan, which needs to be evaluated and compared with that edited by H. G. O. Becker: *Einführung in die Photochemie* (Deutscher Verlag der Wissenschaften, 1991).

Suppan's book begins with a short introduction (Chapter 1) in which photochemical reactions are compared with reactions in the absence of light and with thermal excitation. In Chapter 2 the author briefly discusses the various interactions between light and matter (photochemical, photoelectric, and electrooptical phenomena), then in Chapter 3 moves on to a more detailed treatment of excited states. Aspects covered here include absorption and emission spectra, potential diagrams and orbital diagrams, transitions from excited states, quenching, photophysical phenomena, and medium (solvent) effects. Chapter 4 deals at considerable length with the chemistry of excited states, covering not only "conventional" photoreactions but also inorganic photochemistry, chemiluminescence, and photochemistry in organized systems. In Chapter 5 ("Light and Life") the author discusses photosynthesis, phototaxis, photochemical damage to nucleic acids and proteins, and some examples from the photomedical field and bioluminescence. Chapter 6 ("Light in Industry") relates photochemistry to practical applications, discussing photographic processes, photopolymerizations, photochemical syntheses, photochromic phenomena, and the photochemistry of the atmosphere. Chapter 7 is of special importance for the experimentalist, with descriptions of laboratory techniques and equipment, including light sources, filters, lasers, and methods for studying luminescence and flash photolysis. Chapter 8 gives a brief survey of "Frontiers in Photochemistry", including time-resolved photolysis and spectroscopy, supramolecular photochemistry, and "hole-burning" experiments.

The book is clearly written, the figures are of high quality, and the text has been carefully checked and well printed. It is well suited for use as an introduction to the subject. A criticism is that some important topical aspects of the interactions between light and matter are omitted or only touched on briefly, including photovoltaic phenomena, photoelectrochemistry, sensitization of semiconductor electrodes and semiconducting colloids, solar photochemistry, renewable solar energy systems, photodynamic cancer therapy, and diagnostics. The Appendix explains band-gaps in semiconductors, but it is only with difficulty that one finds any reference to these in the main text. Also there are no tables listing photophysical properties of sensitizers. Not enough literature references are given, and no recent monographs on the subject are mentioned. However, despite these criticisms *Chemistry and Light* is a carefully written account of the fundamentals of photochemistry. If confronted with the choice between Suppan's book and that by Becker mentioned earlier, I would advise in favor of Becker, which contains more practical examples and data on compounds and reactions. It is more experimentally orientated and contains many more references to the primary literature.

Inorganic Chemistry. (Second edition). By *D. F. Shriver, P. W. Atkins* and *C. H. Langford.* Oxford University Press, Oxford, 1994. 819 pp., paperback £ 19.50.—ISBN 0-19-855396-X

The perennial questions when writing a textbook on inorganic chemistry are: what blend of theory and experimental facts to employ and, in a text of finite size, does one want an assemblage of basic knowledge or an emphasis on the latest developments? Further, from the user's point of view—how well is the theory applied to rationalize experimental knowledge? In this book the first two-fifths is devoted to theoretical principles and the remainder to mainly descriptive chemistry. The other questions are elaborated upon below.

In this second edition, apart from alterations to the text (expansion and refinement), there has been a reorganization of the material so that the book is now divided into three parts: "Foundations", "Systematic Chemistry of the Elements", and "Advanced Topics". New problems/exercises and more literature references have been added. Each chapter includes a summary of key points and ends with a list of further reading and a set of exercises (solutions in the Appendix) and advanced problems.

As an aid to learning, key concepts are in bold type when first introduced. Moreover, worked problems are included throughout the text, followed by a similar problem for the reader to consider. A rather wide left-hand margin is employed; this is filled with illustrations and annota-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995* *0570-0833/95/0505-0599 $ 10.00+.25/0*

tions to figures. This works well in most cases, although occasionally the figure is out of synchronization with the text. In fact the entire book is extremely well illustrated with a whole gamut of molecular orbital diagrams, figures, schemes, structures, spectra, and equations.

The "Foundations" section follows the traditional treatment: atomic and molecular structure, molecular shape and symmetry, structure of solids, acids and bases, metal complexes, redox. Part 2 ("Systematic Chemistry of the Elements") begins with a new chapter on the metals, followed by chapters on hydrogen and its compounds, main-group organometallic compounds, boron and carbon groups, nitrogen and oxygen groups, and halogens and the noble gases.

Part 3 ("Advanced Topics") covers effectively all aspects of transition metal chemistry, with chapters on electronic spectra of complexes, reaction mechanisms of d-block complexes, d- and f-block organometallic compounds, structures and properties of solids, and bioinorganic chemistry. The book ends with a series of appendices and a formula and subject index.

All the material that one would wish to cover in two years of undergraduate inorganic chemistry courses is contained in this one text. Part 2 is a balance of basic knowledge and the latest experimental results (e.g. buckminsterfullerene complexes, p. 482): the latter should serve to stimulate the enthusiasm of students. Excellent use is made of line drawings of molecular structures. A positive effort has been made to apply the theoretical principles (in particular molecular orbital theory) in the latter part of the book.

My negative comment is that on reading the book I experienced a sense of overcompression of the material in some sections, as if the authors have tried to reduce the text to a minimum number or words. The end result of being too brief is that these sections strike me as difficult for the student to assimilate. A slight amplification would greatly facilitate understanding. This runs contrary to the preface, which states that the writing and refinement of the text was undertaken with the advice of students and instructors.

Let me illustrate this with some selected examples, of which there are many. Chapter 1 on atomic structure is a brief summary with no more depth than a general chemistry text. It is too brief for anyone without knowledge of the subject to understand. Students reading a course on inorganic chemistry would already have had a general chemistry course and this material will be familiar. The aim is thus not clear. Is it to refresh the reader's memory or to provide a more detailed treatment than an introductory text? The former aim may be achieved, but not the latter. To cite two specific instances, the Uncertainty Principle (p. 12) merits only one-third of a page, and the radial distribution functions are shown only for hydrogen 1s, 2s, and 2p orbitals (the latter two in the form of a problem).

Similarly, the chapter on molecular structure describes UV photoelectron spectroscopy (PES) rather briefly (p. 65). A slight amplification would greatly enhance understanding; e.g. on page 67 it is stated that the "vibrational structure in the photoelectron spectrum can be very helpful in assigning the origin of the spectral line", but the authors fail to adequately explain how this can be used to make assignments. It is left for the reader to do this, and to relate the sample PES of dinitrogen (p. 66) to the molecular orbital energy level diagram three pages later.

Concerning the actual text, what is different is the rather frequent use of the first person plural (we, us), more than is generally found in chemistry books. There are several instances in the text of a loose colloquial style, e.g. on page 249: "and, although avoiding the pairing *penalty*, will have an energy higher by Δ_o"; page 240: "this *trick*, which is called the template effect".

In summary though, the positive aspects of the book far outweigh the foibles of style and layout. Students at all levels of inorganic chemistry will profit from a perusal of this text which describes the subject as it is in the 1990s.

Structure and Properties of Polymers. (Series: Materials Science and Technology, Vol. 12.) Edited by *E. L. Thomas*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 786 pp., hardcover DM 430.00, $ 325.00.—ISBN 3-527-26825-1/0-89573-700-0

The series to which the volume *Structure and Properties of Polymers* belongs is intended to cover a wide range of topics in materials science and to serve both as a work of reference and for systematic study. Thus each chapter should treat its subject in greater detail than an encyclopedia but more concisely than a monograph. The series is intended for a broad readership, and is also suitable for the reader who wants a survey of recent developments in a related field.

The book covers a very wide range of subjects, giving an overview of all the topic areas in modern polymer physics. Polymer structure and elasticity, followed by viscoelastic, rheological, dielectric, and optical properties, are treated in 13 chapters. Three further chapters are devoted to high-strength polymer fibers, polymer surfaces and interfaces with other materials, and crazing and fracture.

The book begins with a chapter by L. J. Fetters and E. L. Thomas on the synthesis of model polymers, covering even very recent published work in this area. Chapter 2, by F. T. Gentile and U. W. Suter, deals with amorphous polymers and gives a good review of structural models (static atomistic modeling), including a detailed description of the model proposed by Theodoru and Suter. The diffusion of small molecules in glassy polymers is also treated. I particularly liked the chapter by B. Lotz and J. C. Wittmann on the structure of polymer single crystals, covering nearly every aspect of their formation, structure, properties, and deformational behavior. Experimental methods for studying polymer single crystals are only touched on briefly, but despite that the chapter is a mine of information for the interested reader. In contrast the following chapter by P. J. Barham on crystallization and morphology devotes much space to experimental methods (scattering techniques, microscopy, spectroscopy, calorimetry), while also not neglecting the fundamentals (nucleation and crystallization, structural types, models). Chapter 5, by M. Ballauff, is concerned with liquid crystal polymers, currently a topic of great interest. This is written in a clearly understandable way, and can be read as an introduction to the physics of liquid crystal polymers. Chapter 6 (T. Hashimoto) deals with the structure of polymer blends. Although one cannot expect an exhaustive coverage of this enormous field in a chapter of 41 pages, the treatment is far from superficial. Phase diagrams, the formation of microphases, and spinodal segregation in two-component systems are well described and discussed.

Next come several chapters that are mainly concerned with the mechanical properties of polymers: "Elastic Properties of Crystalline Polymers" (D. T. Grubb), "Rubber Elasticity" (R. Ullmann), "Viscoelastic Properties" and "Rheological Properties" (both by M. Doi), and "Elastic Deformation of Polymers" (B. Christ). Together with the later chapters "High-Strength Polymer Fibers" (H. Jiang, W. W. Adams, and R. K. Eby)

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0505-0600 $ 10.00+.25/0

and "Crazing and Fracture of Polymers" (I. Narisawa and A. F. Yee), these articles provide much more than a mere overview of these important areas of polymer physics. As well as the fundamentals they include details of methods of measurement and theoretical models, such as the Takayanagi model for mechanical behavior, the Mooney–Rivlin model for rubber elasticity, and the Rouse model.

The two chapters on dielectric properties (G. Williams) and optical properties (W. Knoll) contain a wealth of information, but this is presented in a readable style. The second of these also touches on the highly topical areas of optical fibers and optoelectronics. As the authors of the chapter on "Polymer Surfaces and Interfaces with Other Materials" (M. Tirrell and E. E. Parsonage) themselves point out, it was not possible here to cover all aspects of this broad field. The chapter concentrates on solid polymers and omits, for example, interactions with solvents, surfaces with adsorbates, and swelling phenomena.

On the whole the authors of this book seldom go into great detail. The reader who wishes to make a thorough study of a special area may regret this, but on the other hand those who wish to obtain an overview are spared the trouble of working through lengthy derivations. Despite being the work of 22 authors, the volume is surprisingly homogeneous; the unifying hand of the editor is evident throughout. It can be recommended not only for specialists but certainly also for students interested in this field, especially advanced and post-graduate students of polymer physics.

Structure–Property Relations in Polymers. Spectroscopy and Performance. (Series: Advances in Chemistry, Vol. 236.) Edited by *M. U. Urban* and *C. D. Craver*. American Chemical Society, Washington, D.C., 1993. 832 pp., hardcover $ 139.95.—ISBN 0-8412-2525-7

The book *Structure–Property Relations in Polymers* contains a selection of papers from the 200th National Meeting of the American Chemical Society (Washington, D.C., 1991), covering applications of Fourier transform (FT) infrared and Raman spectroscopy, fluorescence spectroscopy, and mass spectrometry in the polymer field. The preface announces the aim of bridging the gap between the molecular data yielded by these spectroscopic methods and specific macroscopic properties. It aims to serve the needs of both newcomers to polymer spectroscopy and experienced specialists. This is an ambitious objective, but in my view some of the contributions achieve it very well.

The 35 articles are arranged in six chapters; as well as bringing a degree of order to the topic areas, this in part gives the book some of the qualities of a monograph.

The first chapter, "Fundamental Aspects of the Spectroscopy of Polymers", is concerned with basic principles and recent developments in FT infrared and Raman spectroscopy, fluorescence spectroscopy, and mass spectrometry. Although intended as an introduction to the principles of these techniques, it also covers some recent developments, such as the use of multivariate data processing in polymer analysis.

The chapters that follow deal with the applications of the above methods to problems in polymer physics. Thus the second chapter is concerned with crystalline polymers and copolymers. Data from Raman spectra on the internal and longitudinal vibrational modes can be used in the structural analysis of crystalline polymers or in studying topotactic changes during solid-state polymerization. Interesting results from the application of FTIR spectroscopy to the analysis of phase behavior and the study of molecular interactions in polymer blends are also described. The use of near-IR spectroscopy for the quantitative analysis of a series of 25 thermoplastics is described in an interesting paper by H. F. Howell and J. K. Davis.

Chapter 3 deals with polymer surfaces and interfaces. The topics discussed include the role of surface-active agents in latex technology, and measurements on thick films. L. J. Fina contributes a very interesting article on the modeling of concentration gradients on polymer surfaces. Also worth special mention is an article by M. B. Mitchell on the technique of diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy and its applications. Coatings are becoming ever more important in plastics technology, and the contribution by M. Claybourn and P. H. Turner describing FTIR and FT Raman measurements on coatings is therefore well worth reading. Other topics of special interest are FT Raman studies of dyes and the recording of Raman spectra during emulsion polymerization.

The chapter entitled "Spectroscopic Studies of Polymers in Solution and Polymer Networks" contains eight articles. Among the subjects discussed are metachromasy in dye–polyelectrolyte solutions, intermolecular association of polymers in water, photochemical and degradation reactions in polymers, and polymer–monomer interactions. Interesting applications of PALS (position annihilation lifetime spectroscopy) measurements for investigating changes of the in-situ free volume in polymer networks are described.

Chapter 4 consists of four contributions describing combinations of two or more techniques, such as FTIR with photoacoustic measurements, and differential thermoanalysis with thermogravimetric analysis.

The final chapter, "Polymer Analysis and Surface Modifications", is concerned with surface analytical methods such as SPI-SALI (single-photon ionization–surface analysis by laser ionization), SIRIS (sputter-initiated resonance ionization spectroscopy), SALISA (surface analysis by laser ionization of sputtered atoms), and pulsed radiofrequency plasma discharge spectroscopy. Applications of these techniques in areas such as inorganic polymer synthesis and polymer surface studies are described. Also interesting is the determination of the molecular mass of organic compounds by the K^+IDS (K^+ ionization of desorbed species) technique.

This volume is certainly a mine of information for the specialist, and can also be recommended for readers with interests in infrared spectroscopy.

Probing Protein Structure and Function with an Expanded Genetic Code

Virginia W. Cornish, David Mendel, and Peter G. Schultz*

A general biosynthetic method has been developed which makes it possible to site-specifically incorporate unnatural amino acids with novel properties into proteins. In this approach the codon encoding the amino acid of interest is replaced with the "blank" nonsense codon UAG by oligonucleotide-directed mutagenesis. A suppressor tRNA that recognizes this codon is generated by run-off transcription and then chemically aminoacylated with the desired unnatural amino acid. Addition of the mutagenized gene and the aminoacylated suppressor tRNA to an in vitro extract capable of supporting protein biosynthesis generates a mutant protein containing the unnatural amino acid at the specified position. This methodology has recently been used to study the stability, specificity, and catalytic properties of a number of proteins. In these studies amino acids and analogues possessing altered hydrogen-bonding, electronic, and steric properties and unique backbone conformations have all been site-specifically incorporated into proteins. In addition, photoactivatable amino acids, isotopically labeled amino acids, and amino acids bearing biophysical probes have been inserted site-specifically. This chemistry increases our ability to carry out detailed physical organic studies on this important class of macromolecules.

Keywords: amino acids · mutagenesis · proteins

1. Introduction

Proteins are at the crossroads of virtually every biological process, including signal transduction, catalysis, gene regulation, and the immune response. Yet we still understand little about the mechanisms whereby these biopolymers, composed of twenty simple building blocks, carry out their remarkable range of functions. One important tool for probing the forces that govern protein structure and folding, biomolecular recognition, and catalysis is site-directed mutagenesis. This method makes it possible to substitute a specific amino acid in a protein with any of the other nineteen common amino acids.[1, 2] However, in contrast to studies of small molecules for which analogues with virtually any structural changes can be synthesized, changes in protein structure at a given site are limited to the common amino acids. Ideally, one would like to tailor the steric or electronic properties of an amino acid in a protein to address a specific structure–function question. Desired changes might include modifying the acidity, nucleophilicity, hydrogen-bonding, or hydrophobic properties of an amino acid side chain; altering or restricting the protein backbone conformation; or introducing biophysical probes such as spin labels or isotopic labels at a specific position within a protein. The possibility of substituting such unnatural amino acids, beyond those specified by the genetic code, would greatly expand our ability to manipulate and study protein structure and function and may allow for the generation of new proteins with novel properties.

A number of methods can be used to incorporate unnatural amino acids into proteins. Solid-phase peptide synthesis, particularly recent advances in the segment synthesis-condensation approach,[3] has allowed for the synthesis of small proteins ($\leq$12 kDa) containing novel amino acids in milligram quantities.[4–11] Protein semisynthesis, in which a synthetic peptide is ligated to a protein fragment to produce a full-length protein, has been used to incorporate unnatural amino acids into proteins.[12, 13] This approach is complicated by the need to cleave the protein specifically at the peptide ligation site and by difficulties in coupling the protein and peptide termini selectively. Chemical modification also has been used to introduce a variety of unnatural side chains into proteins including cofactors, spin labels, and oligonucleotides.[14–20] In this method, however, substitutions are largely restricted to simple derivatives of reactive amino acid side chains (e.g. lysine, cysteine, tyrosine) on the protein surface. Alternatively, biosynthetic methods that employ chemically modified aminoacyl-tRNAs have been used to incorporate a number of biophysical probes into proteins synthesized in vitro.[21, 22] This approach is limited, though, because mutations are restricted to derivatives of the natural amino acids and the modified amino acid is substituted at multiple sites. Furthermore, both the modified and natural amino acids are incorporated at the site of interest because of

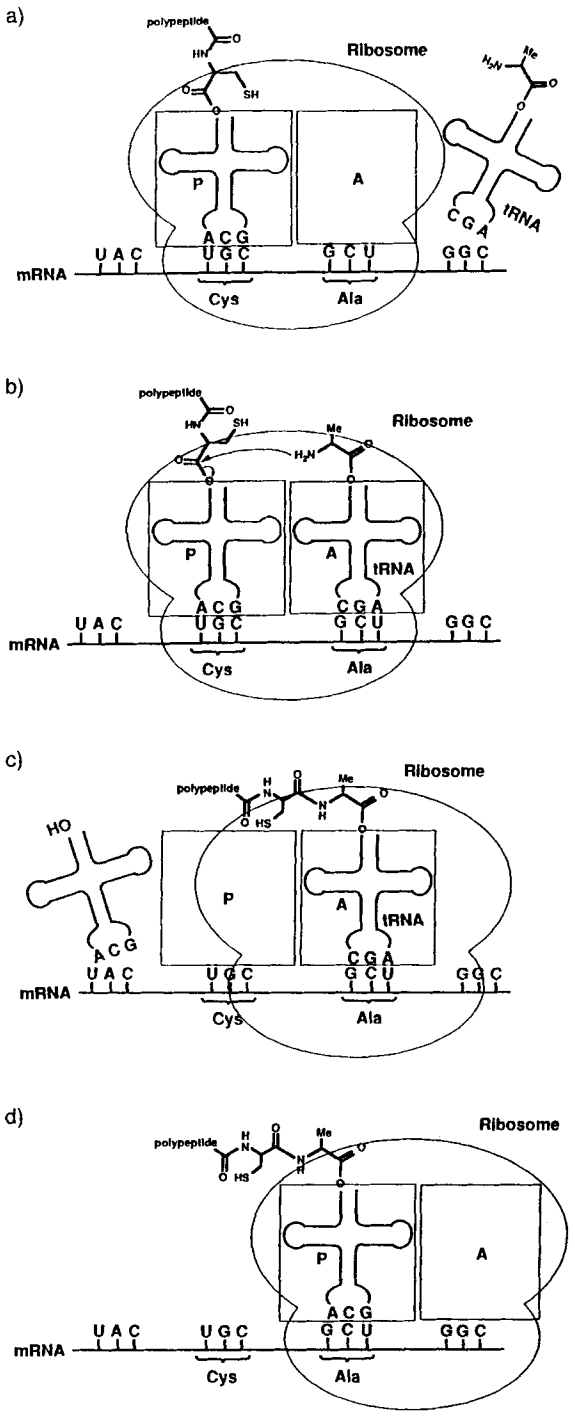
difficulties in removing endogenous aminoacyl-tRNA from the in vitro extract.

Recently, a biosynthetic approach has been developed which for the first time makes possible the site-specific incorporation of a large variety of unnatural amino acids into proteins.[23-25] In this article we describe the methodology as well as its current scope and limitations. In addition, applications are described in which the substitution of unnatural amino acids with novel electronic, steric, and biophysical properties into proteins has provided new insights into the mechanisms of enzymatic catalysis, protein stability, and biomolecular recognition.

2. The Methodology

2.1. Design Considerations

The ability to incorporate unnatural amino acids site-specifically into proteins depends on the following observations: 1) Although three stop codons (UAA, UAG, and UGA) exist, only one is required for the termination of protein synthesis (Scheme 1), leaving two "blanks" in the genetic code (Scheme 2).[26,27] 2) Suppressor tRNAs, tRNAs that insert one of the common amino acids in response to a stop codon, function efficiently in vivo and in vitro.[28] 3) Anticodon–codon recognition is independent of the amino acid at the acceptor stem of the tRNA (the adaptor hypothesis).[29,30] 4) The translational machinery shows relatively broad substrate specificity.[31,32] In light of these facts, the following strategy was developed (Scheme 3). The codon for the amino acid of interest is replaced with the stop codon UAG through standard oligonucleotide-directed mutagenesis.[33] A suppressor tRNA that recognizes this codon is chemically acylated with the desired unnatural amino acid. Addition of the mutagenized gene or mRNA and the aminoacylated suppressor tRNA to an in vitro extract capable of supporting protein biosynthesis generates a mutant protein containing the unnatural amino acid at the desired position.[23,24] The development of this methodology requires the generation of the requisite suppressor tRNA, a general method for acylating the tRNA with unnatural amino acids, and the synthesis of sufficient protein in vitro for meaningful mechanistic or structural studies.

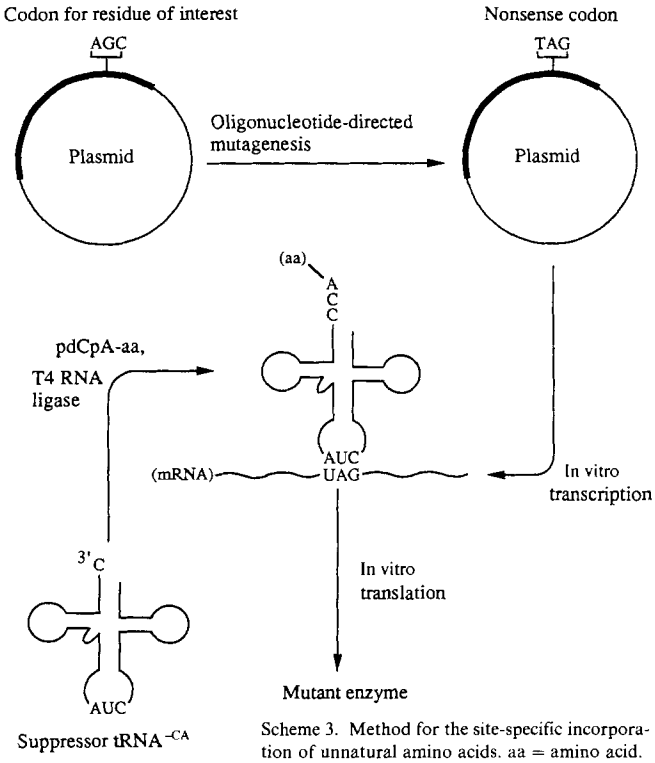


2.2. The Suppressor tRNA

The facile incorporation of an unnatural amino acid into a protein requires a tRNA that is recognized by the protein biosynthetic machinery sufficiently well to suppress a stop codon with high efficiency. This suppressor tRNA, however, cannot be a substrate for any of the aminoacyl-tRNA synthetases present in the in vitro protein synthesis extract. If the suppressor tRNA were recognized by any of the aminoacyl-tRNA synthetases, the tRNA could be subject to proofreading (deacylation of the noncognate amino acid) and/or aminoacylation with one of the common twenty amino acids. This recognition would result in either low suppression efficiencies or incorporation of a common amino acid, as well as the desired unnatural amino acid, in response to the stop codon.

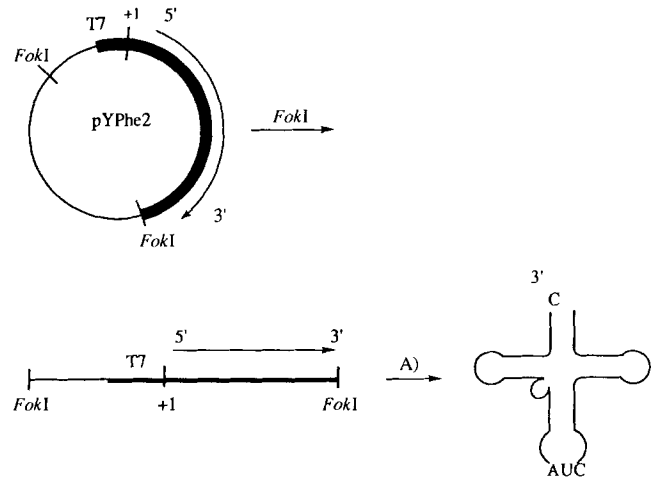
We initially chose to construct an amber suppressor tRNA (a tRNA that recognizes the stop codon UAG) derived from yeast phenylalanyl-tRNA in which residues 34 to 37 have been replaced by 5′-CUAA-3′[34] (in accord with Yarus' rule).[35-37] This suppressor tRNA is known to function efficiently in vitro[34] and is likely to be a poor substrate for the *E. coli* aminoacyl-tRNA synthetases.[38] Alternatively, a suppressor tRNA derived from *E. coli* $tRNA^{Gly}$[39] has been used to suppress UAG codons in short peptides in a rabbit reticulocyte translation system.[25] Both suppressor tRNAs can be readily prepared in relatively large quantities by run-off transcription (Scheme 4).[40,41] Even though these tRNAs are produced in vitro and likely do not contain modified bases,[42] both incorporate unnatural amino acids efficiently and exhibit little readthrough (incorporation of any amino acid other than the desired unnatural amino acid in response to the UAG codon) at optimal Mg^{2+} concentrations.

Peter G. Schultz was born in 1956 in Cincinnati, Ohio, and did both his undergraduate and graduate work at the California Institute of Technology. His thesis work resulted in the design of the first synthetic sequence-selective DNA cleaving molecules. In 1985, after postdoctoral studies at the Massachusetts Institute of Technology, he joined the faculty of the University of California at Berkeley, where he is currently a Professor of Chemistry, a Principal Investigator at the Lawrence Berkeley Laboratory, and an Investigator of the Howard Hughes Medical Institute. His research interests span organic chemistry, molecular biology, and immunology. His research focuses on the study of mechanisms of molecular recognition and catalysis in biological systems and applications to the design of molecules with novel biological (and medicinal) function. His group has contributed to the development of catalytic antibodies, DNA binding proteins, peptides, and oligonucleotides, RNA compounds, and unnatural biopolymers such has oligourethanes and oligosulfones. He has developed methods for the incorporation of unnatural amino acids in proteins and for the manipulation of enzyme specifity through chemical and biological mutagenesis. Schultz has received many awards including the Waterman Award of the National Science Foundation, the Pure Chemistry Award of the American Chemical Society, the Young Investigator Award of the Protein Society, and the Wolf Prize in 1994.



Scheme 1. Schematic representation of protein biosynthesis: a) binding of the aminoacyl-tRNA to the ribosomal complex; b) peptide bond formation; c) dissociation of the deacylated tRNA; d) ribosome translocation.

2.3. Aminoacylation of the tRNA



With the suppressor tRNA in hand, a general method for acylation of the tRNA with any unnatural amino acid had to be developed. Enzymatic aminoacylation of the tRNA with aminoacyl-tRNA synthetases is not general because of the high specificity of these enzymes.[43, 44] Direct chemical acylation is probably not practical owing to the large number of reactive sites in the tRNA. Consequently, a modification of a two-step

method originally developed by Hecht et al.[45] was used in which the dinucleotide pCpA is chemically acylated with a N^{α}-protected amino acid and then enzymatically ligated to a truncated tRNA ($tRNA^{-CA}$ missing the terminal dinucleotide pCpA at the 3′-acceptor stem) (Scheme 5).[46] The truncated suppressor tRNA can be generated directly by run-off transcription of a *Fok*I linearized plasmid encoding the tRNA gene.[41]

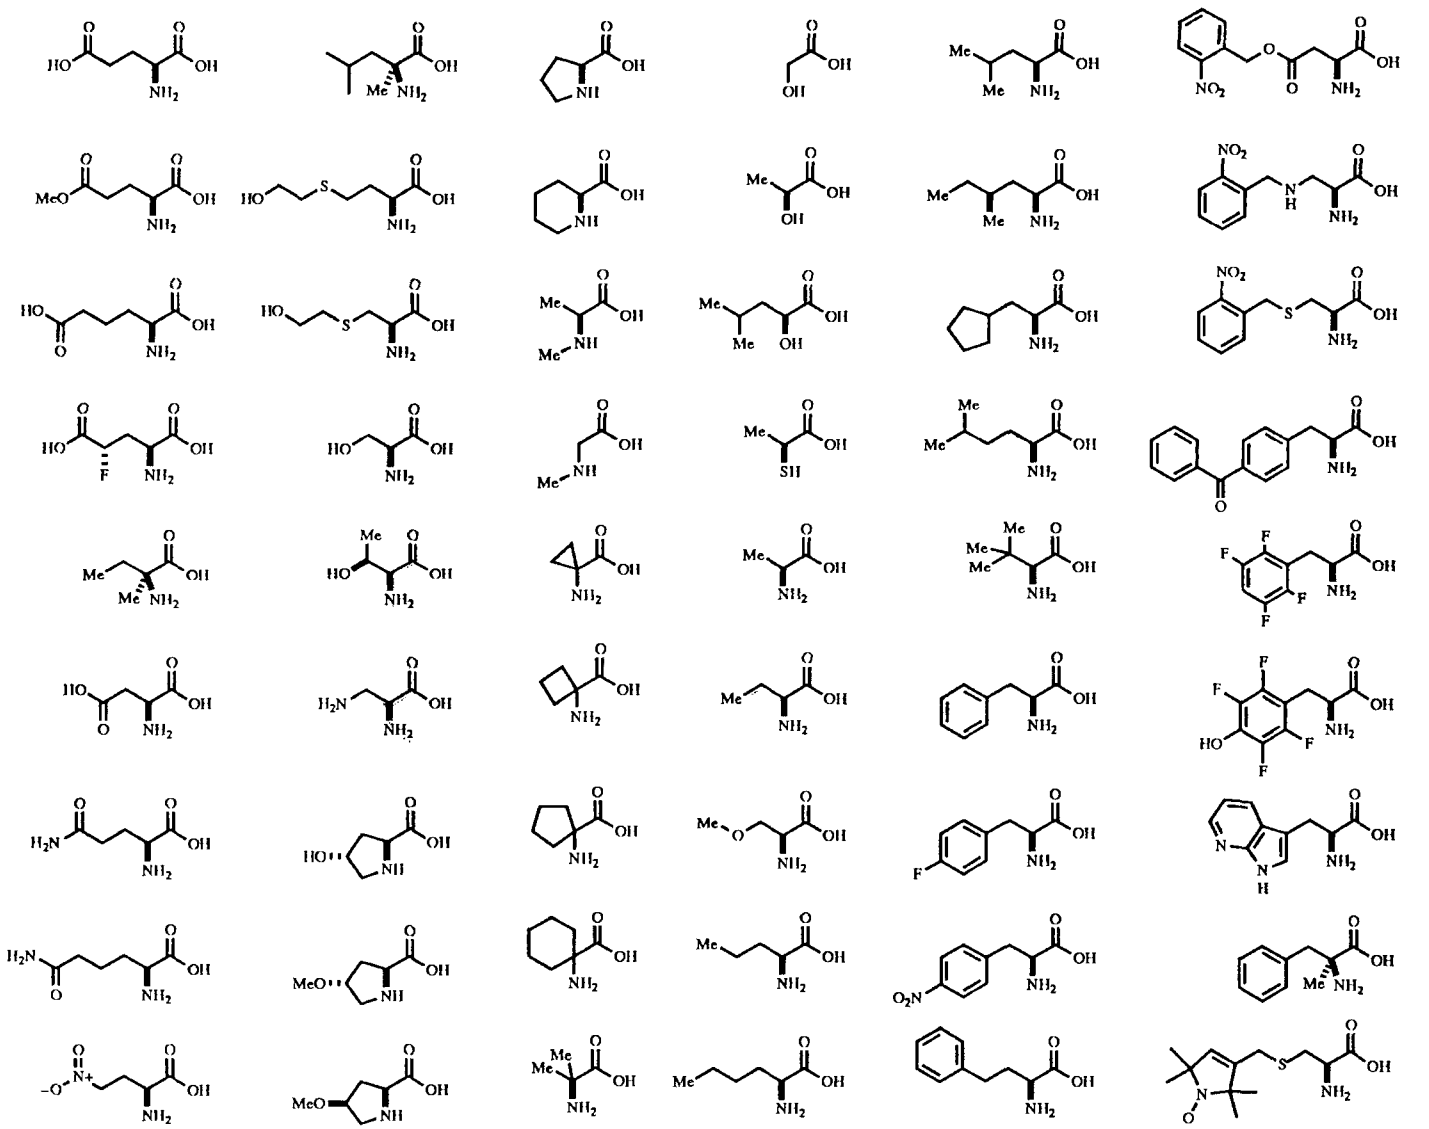
Scheme 5. Strategy for the chemical aminoacylation of $tRNA^{Phe}_{CUA}$. R = amino acid side chain.

Acylation of the dinucleotide is complicated by side reactions including diacylation and acylation of the exocyclic amino groups of the bases which result in low yields of the desired product. Moreover, the aminoacyl tRNA linkage itself is relatively unstable in the pH range (7–8) required for efficient T4 RNA ligase function.[47, 48] We found that the cyanomethyl ester of an amino acid reacts selectively with the 2′,3′-hydroxyl groups of the ribose to give the monoacylated product, obviating the need to protect the dinucleotide prior to aminoacylation (Scheme 6).[49] In addition, deoxycytidine was substituted for cytidine in the dinucleotide, significantly simplifying the synthesis and eliminating another 2′-OH group without affecting biological activity. The α-amino group of the amino acid and any reactive side chains are protected as the nitroveratryloxy (NVOC) carbamate, ester, or ether[50, 51] prior to acylation of the dinucleotide. These protecting groups can be removed photochemically from the intact aminoacyl-tRNA (after ligation) in high yield under mildly acidic conditions which prevent deacylation of the aminoacyl-tRNA.[49] For light-sensitive amino acids the biphenylisopropyloxycarbonyl (BPOC) group can be used; the BPOC group is cleaved with mild acid from the aminoacyl-pdCpA prior to ligation to $tRNA^{-CA}$.[25, 49] This aminoacylation protocol is relatively straightforward, proceeds in high yield (both the aminoacylation and ligation reactions), and is applicable to amino acids with a wide variety of side chains.[48, 24] Nevertheless, the generation of a nonspecific "aminoacyl tRNA synthetase", either a lipase, mutagenized synthetase, or a catalytic antibody, could significantly simplify this step.[52–54]

Scheme 6. Simplified acylation of pdCpA using an amino acid cyanomethyl ester. R = amino acid side chain, X = protecting group.

2.4. In Vitro Protein Synthesis

Proteins are synthesized in vitro because no general methodology exists for introducing large quantities of the aminoacylated suppressor tRNA into intact, dividing cells.[55] We currently use an *E. coli* in vitro transcription/translation protein synthesis system.[56, 57, 24] This system consists of an *E. coli* S-30 extract which contains all of the proteins and RNAs required for transcription and translation. Nucleotide triphosphates, bacterial tRNAs, phosphoenolpyruvate, pyrophosphatase, a variety of salts (Mg^{2+} and Ca^{2+} concentration can significantly affect protein yields) and cofactors, and the DNA encoding the gene of interest are added to this S-30 extract to reconstitute protein synthesis in vitro. Typically the gene of interest is placed under a strong T7 or bacterial RNA polymerase promoter. The in vitro reaction can be carried out on scales ranging from 30 μL to 5 mL. The requisite S-30 can be prepared reasonably on a 2 L scale, the suppressor tRNA on a 30 mg scale, the aminoacyl-pdCpA on a 0.2 mmol scale, and the plasmid on a 12 mg scale. A major limitation of in vitro protein synthesis remains the relatively small quantities of protein that can be obtained. Regardless of whether the protein is synthesized from plasmid DNA using an *E. coli* transcription/translation system or from mRNA using a rabbit reticulocyte translation system, protein yields greater than $100\,\mu g\,mL^{-1}$ generally have not been achieved.[24] Many factors are known to affect protein expression levels in vivo, such as the strength of the RNA polymerase promoter, the particular ribosome-binding site, codon usage, and mRNA stability and secondary structure.[58, 59] Unfortunately, in vitro protein yields do not necessarily correlate with those obtained in vivo, and we have found no simple and general rules for ensuring high protein expression in vitro.

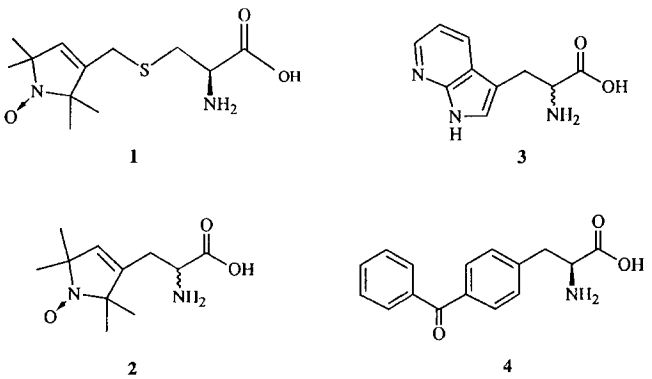


2.5. Scope of the Methodology

The relatively broad substrate specificity of the elongation factors and peptidyl transferase suggested that a wide variety of amino acids could be incorporated into proteins.[31, 32] This is in fact the case—over seventy amino acids have been incorporated at more than twenty sites in a variety of proteins by using the

above methodology (Scheme 7). Conformationally restricted amino acids (e.g. 2,4-methanoproline (not shown), cyclopropylglycine, and α-methyl-L-leucine), amino acids with spin labels and photoaffinity labels as side chains, amino acids with altered pK_A values and hydrogen-bonding properties, "caged" amino acids, α-hydroxy acids, and amino acids with unusual steric properties (e.g. *tert*-butylglycine) have all been incorporated into proteins. Suppression efficiencies can vary widely depending on the nature of the amino acid, ranging from 100% for substitution of L-norleucine for Gln 28 in 434 repressor[60] to 10% for incorporation of α-methyl-L-leucine in T4 lysozyme.[61] Although the suppression efficiency of a given amino acid cannot be predicted a priori, several trends emerge when the identities of the amino acids tested are correlated with their suppression efficiencies.[61, 62] In general, large hydrophobic amino acids such as *p*-benzoyl-L-phenylalanine are inserted with higher efficiency than small amino acids such as alanine and glycine, or charged amino acids such as homoglutamate or ornithine. This correlation is in agreement with reports that large, hydrophobic amino acids such as Trp and Phe bind more tightly to the *E. coli* elongation factor EF-Tu than do other natural amino acids such as Ala, Glu, and Lys.[63]

The stereochemistry of an amino acid also affects suppression efficiency. Although L-amino acids and some α,α-disubstituted amino acids such as α-aminoisobutyric acid (AIB) and cyclopentylglycine can be incorporated into proteins, D-amino acids do not seem to be accommodated by the translational machinery.[61] These stereochemical requirements are in agreement, for the most part, with previous studies on the affinity of a variety of unnatural aminoacyl-tRNAs for *E. coli* EF-Tu and the ribosome.[31] Interestingly, previous experiments, in which the ability of an aminoacyl-tRNA or aminoacyl-CpA to bind to the *E. coli* ribosomal A-site and participate in peptide elongation was studied, suggested that achiral amino acids like AIB could not be used as substrates by the *E. coli* protein biosynthetic machinery.[64–66]



A variety of backbone mutations are accomodated by the translational machinery.[67] *N*-Methyl-L-phenylalanine (rabbit reticulocyte), *N*-methylglycine (*E. coli*) and *N*-methyl-L-alanine

Scheme 7. Examples of amino acids and analogues that have been successfully incorporated into proteins.

(*E. coli*) are site-specifically incorporated into proteins, whereas *N*-ethyl-L-alanine is not.[68] Pipecolinic acid, the six-membered version of proline, is accepted by the *E. coli* system, whereas the ring-contracted proline analogues aziridine-2-carboxylic acid and azetidine-2-carboxylic acid are not. (This may stem from chemical instability rather than from discrimination by the biosynthesis machinery.) However, Tirrell and others[69, 70] have reported the successful biosynthetic incorporation of L-azetidine-2-carboxylic acid into polypeptides. Other types of backbone replacements for α-amino acids that have been examined include β- and γ-amino acids such as β-alanine, γ-aminobutyric acid, and longer variants[71] as well as dipeptides and dipeptide mimetics.[72] To date, attempts to incorporate these amino acids using either *E. coli* or rabbit reticulocyte lysate systems have proven unsuccessful.

The precise structure of an amino acid also influences its suppression efficiency dramatically. For example, even though the spin-labeled amino acids **1** and **2** both contain the 1-oxyl-2,2,5,5-tetramethylpyrrolidine group (Scheme 8), only **1** could

Scheme 8. Structure of biophysical probes tested for incorporation into T4L.

be incorporated in vitro.[62] In addition, suppression efficiencies may vary with the nature of the in vitro protein synthesis system (prokaryotic vs. eukaryotic). While L-4′-(3-trifluoromethyl-3*H*-diazirin-3-yl)phenylalanine was incorporated poorly (<10% efficiency) when an *E. coli* in vitro transcription/translational system was used,[73] the same amino acid was inserted with higher efficiency (>40%) in a rabbit reticulocyte in vitro extract.[74] Finally, in contrast to in vivo results,[35–37] there appears to be little correlation between the codons adjacent to the UAG codon and suppression efficiencies.[62] As more unnatural amino acids are substituted into proteins, this methodology should provide additional insights into the specificity of the translational machinery and the factors governing in vitro suppression efficiency.

2.6. Future Work

Future work will focus on broadening the scope of the methodology by increasing protein yields, by minimizing the effect of the amino acid identity on suppression efficiency, and by developing ways to introduce more than one amino acid into a protein at a time. Efforts to improve protein yields will require improvements in in vitro protein synthesis. Higher protein yields may be achieved by using in vitro systems derived from other sources[55] or alternative approaches such as continuous flow in vitro systems.[75] Alternatively, since the *E. coli* transcription/translation system is active at 37 °C for about only one hour, protein expression levels may be increased by using other lysates such as lysed spheroplasts, capable of supporting protein synthesis for longer periods of time.[76, 77]

Suppression efficiencies may be improved by 1) altering nucleotides in the tRNA molecule involved in tRNA recognition by the elongation factors, the ribosome, or the aminoacyl-tRNA synthetases; 2) utilizing suppressor tRNAs from different species (here tRNA must be "engineered" to eliminate recognition by the corresponding aminoacyl-tRNA synthetase); 3) deleting release factor-1 (*E. coli*), which competes with the suppressor tRNA for recognition of the UAG codon, from the in vitro extract;[78] or 4) modifying the specificity of elongation factor EF-Tu. One would also like to be able to produce proteins containing several unnatural amino acids. A single unnatural amino acid can be incorporated at more than one position in a protein simply by introducing several UAG codons in the coding sequence.[79] Preliminary efforts to insert different amino acids into the same protein have focused on using the other nonsense codons,[80] infrequently occurring codons,[81] or a 65th codon composed of nonstandard nucleotides.[82]

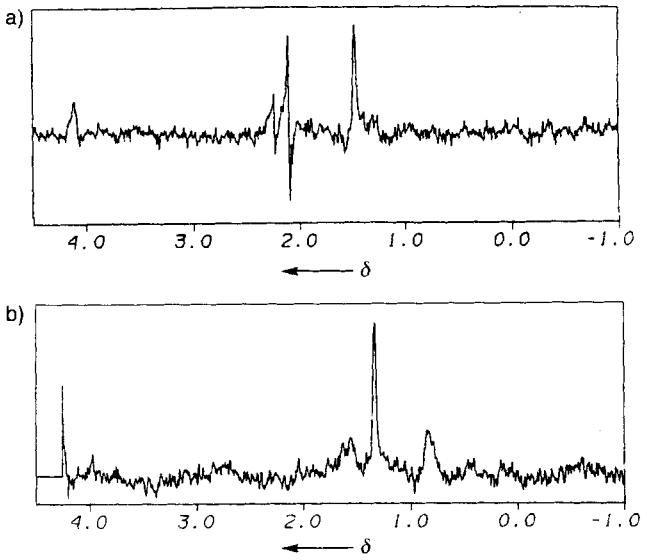
3. Applications

In this section, several applications of the methodology are discussed to illustrate both the scope of the methodology and the kinds of questions that can be addressed when unnatural amino acids can be incorporated into proteins. These examples include the site-specific incorporation of biophysical probes into proteins, the construction of photocaged proteins, and studies of protein stability, enzyme mechanism, and signal transduction.

3.1. Biophysical Probes

Several amino acids that can serve as biophysical probes have been incorporated into proteins through unnatural amino acid mutagenesis (Scheme 8). A novel spin-labeled amino acid **1**, an unnatural fluorescent amino acid **3**, and an efficient cross-linking agent **4** were all introduced site-specifically at several external and internal positions in T4 lysozyme (T4L) with reasonable efficiency.[62] By taking advantage of recent loop-gap resonator technology, the ESR spectrum of approximately 10 μL of a 1 μM solution of purified T4L containing the spin-labeled amino acid **1** was measured. Replacement of one of the tryptophans in T4L by 7-azatryptophan (**3**) resulted in a red shift in the fluorescent emission maxima. In addition, amino acids that form active nitrene, carbene, and ketyl radicals have been successfully incorporated into *ras* p21 and T4L at specific positions.[62, 83] Photoaffinity probes can in principle be used to identify key components involved in complex biochemical processes, for example signal transduction and gene activation.

With considerably more effort, a sufficient quantity of purified T4L specifically labeled at site Ala82 with [^{13}C]Ala was produced. The proton resonances of the labeled residue were observed selectively, in both the native and denatured states, by using ^{13}C-decoupled ^{1}H NMR spectroscopy (Fig. 1).[84] Finally, enough staphylococcal nuclease (SNase) containing the unnatural amino acid homoglutamate at position Glu43 was obtained for determination of the mutant protein's structure by X-ray crystallography to a resolution of 2.4 Å.[85] The ability to incorporate probes capable of detecting local structure and dynamics into proteins site-specifically should allow for more precise studies of protein folding and stability, conformational changes in proteins, and the interaction of proteins with other proteins, small molecules, and membranes. For example, it should be possible to carry out site-specific spectroscopy on both the folded and unfolded states of proteins, compare denaturation curves for various regions of a protein, and probe local structural changes that occur during protein translocation.



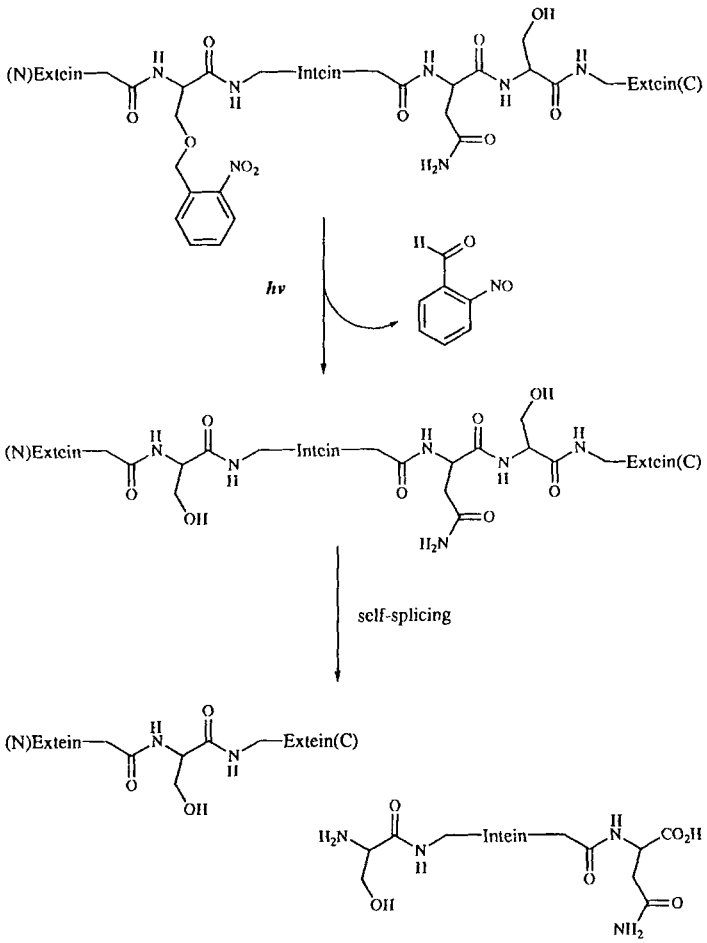


Fig. 1. a) ^{13}C-Decoupled ^{1}H NMR spectrum of the T4L variant Ala82 → [^{13}C]Ala; b) ^{13}C-decoupled ^{1}H NMR spectrum of the denatured form of the same sample.

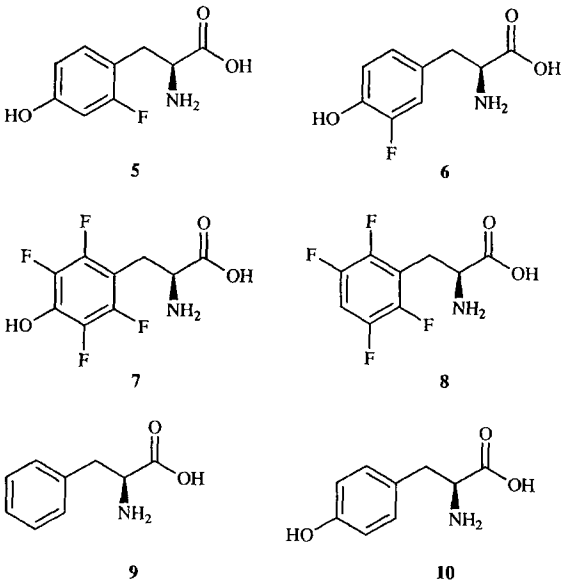
3.2. "Caged" Proteins

Low molecular weight "caged" substances, inactive precursor molecules that can be rapidly activated by photolysis, are useful tools for biochemical studies.[86, 87] Mutagenesis with unnatural amino acids provides a unique approach to the construction of photocaged proteins. For example, the unnatural amino acid *ortho*-β-nitrobenzylaspartate was substituted for the active-site residue Asp20 in T4L.[88] Since Asp20 is essential for catalytic activity, the resulting protein was inactive. Removal of the protecting group by photolysis of the intact, modified protein restored full catalytic activity.

In a second example, a serine residue thought to be involved in the self-splicing reaction of the protein Vent DNA polymerase was replaced by *O*-nitrobenzylserine (Scheme 9).[89] The resulting caged polymerase did not undergo the self-splicing reaction, allowing the full-length protein to be isolated. Photolysis of the unspliced protein resulted in loss of the nitrobenzyl protecting group and subsequent protein splicing. This result demonstrates unequivocally that protein splicing occurs at the posttranslational level. The ability to construct caged proteins of this sort should make possible a broad range of time-resolved experiments relevant to catalytic mechanism, biomolecular recognition, and protein folding.



Scheme 9. Photoactivated self-splicing of Vent polymerase using a caged serine analogue. The mechanism of the protein self-splicing mechanism is not known.

3.3. Protein Stability

Mutagenesis with unnatural amino acids has been used to make defined mutations in proteins in the hope of gaining a more precise picture of the forces governing protein stability.[90, 91] An outstanding issue in the literature on protein stability and folding is the role of hydrogen bonding. Although hydrogen bonds are clearly important in determining the secondary and tertiary structure of proteins,[92, 93] the magnitude of their contribution to protein stability has been difficult to assess.[94, 95] Stabilization values for hydrogen bond formation determined from studies with mutants, in which one member of a hydrogen-bonded pair is deleted, vary considerably depending upon the nature and local environment of the hydro-

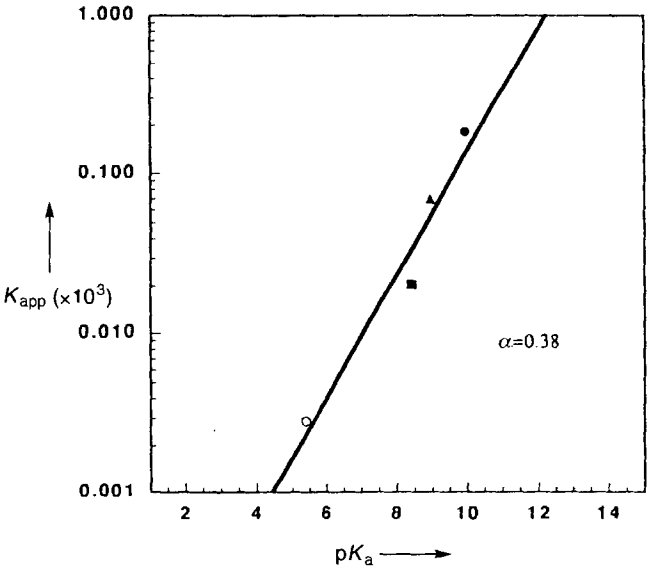
gen bond.[90, 96] Moreover, a concern in all such studies with mutants is the possibility of introducing additional destabilizing interactions by leaving an unpaired hydrogen bond donor or acceptor and/or altering local solvation and packing interactions (e.g. a Glu-Phe versus a Glu-Tyr pair).

In an effort to determine the degree to which side-chain hydrogen bonding stabilizes the folded state of proteins while minimizing the steric and electronic perturbations associated with deleting one member of a hydrogen-bonded pair, Tyr 27 in staphylococcal nuclease (SNase) was replaced with a number of isosteric, fluorinated tyrosine analogues, including 2-fluorotyrosine (**5**), 3-fluorotyrosine (**6**), and tetrafluorotyrosine (**7**) as well as 2,3,5,6-tetrafluorophenylalanine (**8**) and phenylalanine (**9**) (Scheme 10).[97] These mutants were designed to examine

Scheme 10. Structures of the amino acids with altered hydrogen-bonding properties substituted for Tyr 27 in SNase.

the effect of increasing the strength of the Tyr 27–Glu 10 hydrogen bond on protein stability. Denaturation studies of the corresponding mutants revealed a unique free energy correlation between stability constant K_{app} ($\alpha = 0.38$) and the pK_a of the hydroxyl group in the tyrosine analogue in position 27 (Fig. 2). Indeed, substitution of Tyr (pK_a ca. 10) with tetrafluoro-L-tyrosine (pK_a ca. 5) increased the stability of SNase by 2.3 kcal mol^{-1}. This experiment provides strong evidence that side-chain intramolecular hydrogen bonds can preferentially stabilize the folded state of a protein relative to the unfolded state in water. In addition this study effectively extends the use of substituent effects in physical organic chemistry from small molecules to proteins.

A series of mutations were also made in T4L to examine the role of backbone hydrogen bonding in determining protein stability.[68] The surface amino acid Ala 82 in T4L was replaced with its hydroxy isostere lactic acid (Fig. 11). Ala 82 is at a break between two helices with the NH group and side chain exposed to water. The Ala 82 → lactate mutation effectively substitutes a good hydrogen-bond acceptor, the amide carbonyl group, with



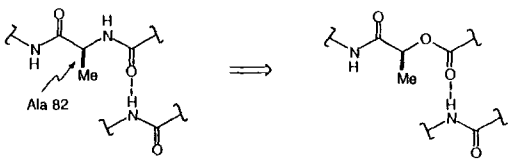


Fig. 2. The relation between the pK_a of the residue at position 27 (Tyr **10** and Tyr analogues **5**–**7**) and the stability (K_{app}) of the SNase. ● = **10**, ▲ = **5**, ■ = **6**, ○ = **7**.

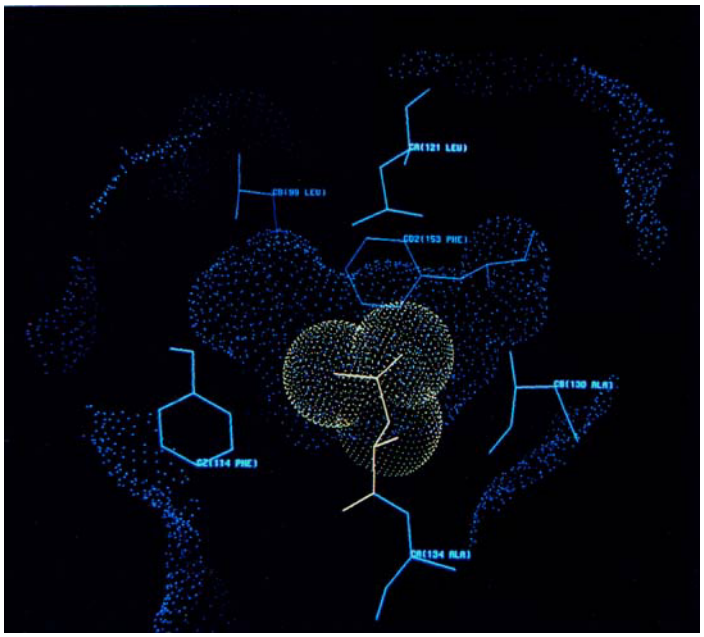
a considerably weaker hydrogen-bond acceptor, the ester carbonyl group.[98] Because both esters and amides exist mainly in the *trans* conformation,[99] the destabilization caused by this substitution (decrease in the melting temperature T_m by 3.7 °C (1.0 kcal mol^{-1})) provides evidence that backbone amide hydrogen-bonding interactions do in fact help to stabilize proteins.

Scheme 11. Substitution of Ala 82 in T4L with lactic acid.

In an examination of the importance of packing interactions in the core of a protein,[100–103] replacements were made for Leu 133 which lies along the edge of the largest cavity in the interior of T4L (Fig. 3).[104] Previous attempts to stabilize T4L by increasing the packing density of the hydrophobic core by means of a Leu 133 → Phe or Ala 129 → Val mutation had been unsuccessful, as both mutations disrupt neighboring residues.[104] However, incorporation of the unnatural amino acid (*S,S*)-2-amino-4-methylhexanoic acid (**11**) and (*S*)-2-amino-3-cyclopentylpropanoic acid (**12**), both of which were designed to fill the cavity with minimal strain, stabilizes T4L, increasing the protein's melting temperature by 1.9 °C (0.6 kcal mol^{-1}) and 4.3 °C (1.24 kcal mol^{-1}), respectively.[105] This result demonstrates that amino acids that increase the bulk of buried hydrophobic residues without concomitant introduction of strain can increase protein stability significantly. As there is little difference in surface area between **12** and **11** (Δsurface area = 0.9 Å^2), the difference in stability between the two mutants likely reflects the fact that the cyclic amino acid **12** loses less conformational entropy upon folding than does the acyclic amino acid **11**. Consequently, side-chain conformational



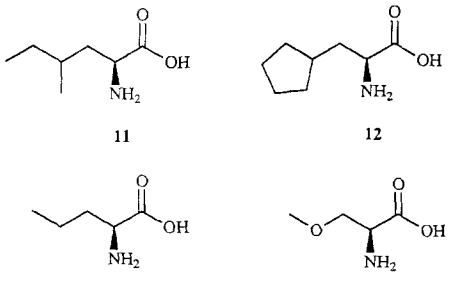


Fig. 3. Graphic representation of the van der Waals surfaces (yellow) of the side chains of Leu 133 in T4L.

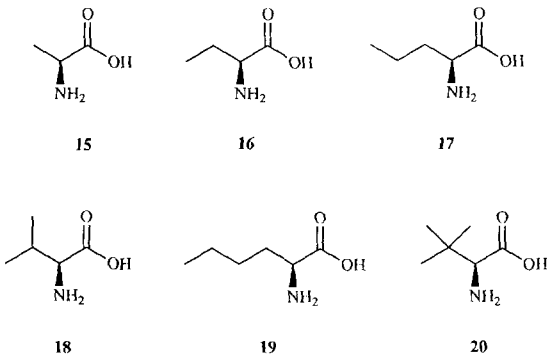
entropy, as well as packing interactions, plays an important role in determining protein stability.

In a second example, substitution of norvaline (**13**) and *O*-methylserine (**14**) (Scheme 12) for Leu 133 allowed for a measurement of the effect of modifying side-chain hydrophobicity in the absence of changes in packing interactions or side-chain entropy.[105] In this case it was found that the difference in the stabilities of the two mutant enzymes relative to that of wild-type T4L corresponds to the difference in the partitioning ratios of the respective *N*-acetyl amide derivatives in octanol–water. This correlation provides further evidence that these partitioning ratios give an accurate measure of solvation effects.



11 **12** **13** **14**

Scheme 12. Structures of the amino acids substituted for Leu 113 in T4L.

In another experiment, systematic removal of methyl and methylene groups from the Leu 133 side chain was found to lead to a stepwise decrease in protein stability.[105] However, the change was nonlinear; $\Delta\Delta G$ became increasingly large with decreasing side-chain surface area. This trend is reflected accurately in the semiquantitative estimates of the $\Delta\Delta G$ values and results from the net effect of changes in the hydrophobic, entropic, packing, and cavity energy terms.

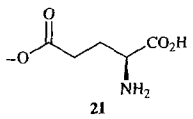
The effects of incorporating β-branched amino acids were examined by comparing the stabilities of mutant proteins containing the series of branched and linear amino acids **15**–**20** (Scheme 13), at two surface-exposed sites in the middle of two

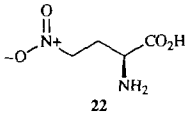
15 **16** **17** **18** **19** **20**

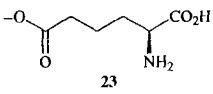
Scheme 13. β-Branched and linear amino acids incorporated at sites 44 and 68 in T4L.

α-helices in T4L.[106] The natural β-branched amino acids valine, isoleucine, and threonine are thought to destabilize α-helices. In known protein structures these amino acids occur infrequently in α-helices relative to amino acids such as leucine, and they destabilize α-helical peptides and protein α-helices.[107–113] For example, when a series of linear and branched amino acids were incorporated into an α-helical peptide, the β-branched amino acids were found to be destabilizing relative to the linear and γ-branched amino acids.[114] Substitution of *tert*-butylglycine (**20**) for *n*-butylglycine (**19**) or alanine (**15**) destabilizes the peptide by 0.9 kcal mol^{-1}; however, the same substitution either destabilizes T4L by 0.7 kcal mol^{-1} ($\Delta T_m = 2.6\,^{\circ}C$) (site 44) or stabilizes the protein by 0.3 kcal mol^{-1} ($\Delta T_m = 1.0\,^{\circ}C$) (site 68). This difference illustrates the difficulty in delineating simple rules as to which factors stabilize or destabilize proteins given the influence of context effects. In addition, the stabilities and simulated structures of the *tert*-butylglycine mutants have provided insight into the effects of β-branched side chains on α-helix stability in proteins.

The results described underscore the difficulty in interpreting mutagenesis data when more than one property of an amino acid is altered at once. The ability to precisely alter the structure of an amino acid should allow us to better dissect the individual contributions of hydrophobicity, packing, entropy, and cavity formation on protein stability. We are currently extending these studies to hydrogen bonding, and π–π and π–ion interactions in protein interiors.







3.4. Enzyme Mechanisms

Mutagenesis with unnatural amino acids also is being used to probe the catalytic mechanisms of the enzymes staphylococcal nuclease, aspartate aminotransferase, methionine aminopeptidase, and ribonucleotide reductase. The enzyme staphylococcal nuclease (SNase) accelerates the hydrolysis of phosphodiester bonds in nucleic acids some 10^{16}-fold over the rate of the uncatalyzed reaction. This enzyme has been the subject of many struc-

tural, mechanistic, and mutagenesis studies aimed at understanding how enzymes can achieve such extraordinary rate enhancements.[115-119] Based on these studies it has been suggested that general base catalysis contributes significantly to the catalytic efficiency of this enzyme. Specifically, it is thought that Glu43 in SNase acts as a general base to activate a water molecule for attack on the phosphodiester backbone of DNA. Glu43 is known to be important for catalysis, because replacement by the natural amino acids Asp and Gln results in a significant loss in activity.[120]

Surprisingly, substitution of Glu43 with either homoglutamate **23** or the nitro analogue (*S*)-4-nitro-2-aminobutyric acid (**22**), which is both isoelectronic and isosteric to glutamate but a much poorer base, yielded mutant enzymes with kinetic constants similar to those of wild-type SNase under normal assay conditions (Table 1).[85] The pH dependence of the catalytic

Table 1. Catalytic efficiences of wild-type staphylococcal nuclease and mutants Glu43 → (*S*)-4-nitro-2-aminobutyric acid and Glu43 → homoglutamate. V_{max} = maximum reaction rate (measured based on the absorption at 260 nm, A_{260}), K_M = Michaelis constant.

Amino acid	V_{max} ($\mu g^{-1} min^{-1}$)	K_M(DNA) ($\mu g mL^{-1}$)	K_M(Ca^{2+}) (μM)
 **21**	6.7±0.7	8±3	320±30
 **22**	3.0±0.5	26±8	470±40
 **23**	5.2±0.2	10±2	290±30

efficiencies of these mutants (the pH profiles of the mutants with nitroglutamate **22** and homoglutamate **23** suggest that the nitronate anion is not formed) and the crystal structure of the homoglutamate43 mutant (Fig. 4) suggest that Glu43 may not be acting as a base, but rather may play a structural role, serving as a bidendate hydrogen-bond acceptor to fix the conformation of the neighboring loop. Independent studies by Gerlt et al., in which the loop adjacent to Glu43 was deleted from SNase, have led to the same conclusion.[121]

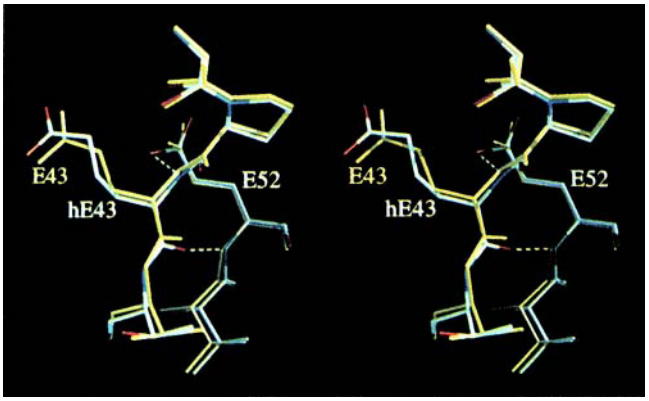


Fig. 4. Comparison of the positions of the side chains of Glu43 and homoglutamate43 as determined by X-ray crystallography for the apo wild-type and homoglutamate43 mutant proteins, respectively (stereoplot).

3.5. Cellular Signal Transduction

Mutagenesis with unnatural amino acids has been used to probe the role of *ras* p21 in cellular signal transduction pathways. Mammalian proteins encoded by the *ras* genes are thought to function as regulators of various signal transduction processes involved in cell growth and differentiation.[122-125] The chemical basis for signal regulation involves cycling of the protein between the inactive guanosine diphosphate (GDP) bound state and the active guanosine triphosphate (GTP) bound state (Fig. 5). Point mutations that result in a decrease in

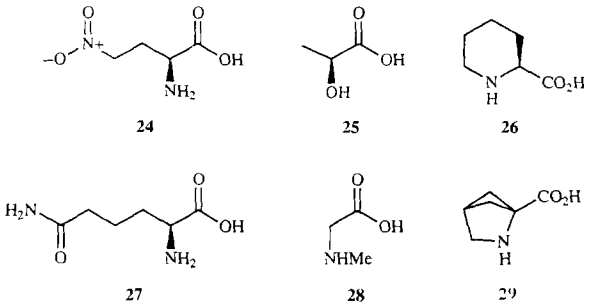

Fig. 5. Model of *ras* p21 with bound GTP [138].

the intrinsic GTPase activity of *ras* p21 or of the GTPase activity stimulated by GTPase activating protein (GAP) are associated with approximately 30% of human cancers.[123, 126-129] In order to better understand the molecular basis by which mutations in *ras* p21 lead to switch inactivation, we have substituted residues in loop L4 (the switch II region), loop L2 (the switch I region), and loop L1 (the phosphate binding loop) with a series of unnatural amino acids.[130-132]

Mutations at Gln61 are among the most common that lead to impaired intrinsic GTPase activity. This residue lies in loop L4 of *ras* p21, a region that undergoes conformational change upon GTP/GDP exchange.[133-140] On the basis of biochemical studies and the three-dimensional X-ray crystal structures of the GTP-, Gpp(CH_2)p-, and Gpp(NH)p-bound forms of *ras* p21, it has been proposed that Gln61 is critical for γ-phosphate binding

and catalysis.[133-141] Specifically, it has been proposed that the γ-carboxamide of Gln 61 either polarizes a water molecule (175) for attack on the γ-phosphate or stabilizes the incipient pentacoordinate transition state. In order to test these mechanistic hypotheses, we replaced Gln 61 with the isoelectronic, isosteric nitro analogue **24** and with homoglutamine **27** (Scheme 14).[130]

Scheme 14. Structures of some unnatural amino acids used to probe the switch function of *ras* p21.

Whereas seventeen natural mutants at position 61 have reduced GTPase activity and are not activated by GAP, both unnatural mutants had GTPase activity similar to that of the wild-type protein and were activated by GAP. The fact that these mutants retained activity suggests that residue 61 plays some other role in catalysis, perhaps serving to distort the bound GTP toward the transition state geometry.

Mutations at Gly 12 of *ras* p21 also result in impaired intrinsic GTPase activity and are commonly associated with oncogenic activation.[123, 142] Gly 12 occurs in a highly conserved type II β-turn, [Gly 11-X-X-X-Gly-Lys-(Ser or Thr)], a phosphate-binding loop found in many nucleotide-binding proteins.[143, 144] Mutation of Gly 12 to any common amino acid other than proline results in diminished GTPase activity.[142] To more fully understand the role of Gly 12 mutants in switch function, we inserted a number of unnatural amino acids and analogues at this site, including lactic acid (**25**, Lac), pipecolic acid (**26**, Pip), and *N*-methylglycine (**28**, MeGly) (Scheme 14).[130] The protein containing pipecolic acid (**26**) at position 12, which was expected to have a much more negative torsion angle ϕ than Gly 12, displayed GTPase activity similar to that of wild-type ras. The *N*-methylglycine (**28**) mutant also had comparable activity (N^{α}-methyl substitution also decreases ϕ values). Whereas the Ala 12 mutant had reduced GTPase activity, the variant with isosteric lactic acid (**25**), in which the backbone amide linkage is replaced by an ester linkage, had normal GTPase activity. The fact that only mutants that can adopt unusual backbone conformations are active suggests that a conformational change in loop L1 may relieve unfavorable side-chain interactions at position 12 in the transition state. However, even though the Pro 12, Pip 12, Lac 12, and MeGly 12 variants had intrinsic GTPase activity similar to that of wild-type *ras* p21, they were not activated by GAP. Moreover, the Gly 13 → Thr, Gly 13 → allothreonine, and Gly 13 → Ser proteins, which have intrinsic GTPase activity two to three times that of wild-type *ras* p21 (attributable to the β-hydroxyl group), were not activated by GAP and were not transforming in a germinal vesicle breakdown assay with *Xenopus laevis* oocytes. One interpretation of these results is that loop L1 can adopt two or more conformations in solution and that its positioning by one or more effector proteins modulates GTPase activity and onocogenic activation. The unusual backbone structures of the Gly 12 and Gly 13 mutants may prevent switch function.

In a third mutagenesis experiment the role of Pro 34 in loop L2 function was probed. The most significant difference between the GTP- and GDP-bound forms of *ras* p21 is in this region (residues 32–40).[133-140] It has been proposed that Pro 34, which is conserved in *ras* p21 and close to the active site, may play a role in controlling the conformation of loop L2, perhaps through a *cis–trans* isomerization of the Pro 34 amide bond.[137] In order to examine the structural and mechanistic role of this residue more precisely, Pro 34 was replaced with 2,4-methanoproline (**29**) (Scheme 14), which is strongly biased toward the *trans* configuration by virtue of the C_{α} substitution.[131] The fact that this mutant has intrinsic and GAP-activated GTPase activity comparable to that of the wild-type protein strongly suggests that the *cis–trans* isomerization of Pro 34 does not play a key role in signal transduction. Similar substitutions may be useful in probing the role of backbone isomerization in protein folding pathways.

4. Conclusion

The ability to incorporate unnatural amino acids into proteins site-specifically makes possible detailed physical studies on this important class of organic compounds. Mutations can be made to probe the precise nature of the contribution of an individual amino acid to protein structure or function, often without dramatic losses in activity. This methodology should provide new insights into and perhaps challenge assumptions about the nature of protein structure and function. In addition, it may be possible to generate mutant proteins with novel functions. The remaining goals are increasing the quantities of protein obtainable and finding ways to bypass the specificity of the protein biosynthetic machinery so that more diverse amino acid structures can be incorporated to further add to the power of this approach.

Y. Ohashi (ed.)

Reactivity in Molecular Crystals

1993. XII, 348 pages. Hardcover. DM 198.00.
ISBN 3-527-29098-2

Do you need to design syntheses that are
- highly selective
- fast
- enantioselective with quantitative enantiomeric yield?

This book describes in detail how best to exploit the enormous synthetic potential of solid state reactions. Written by leading experts, it provides in depth information on
- the theoretical and physico-chemical approach to solid state reactions
- solid-to-solid organic reactions
- stereoselective solid state photoreactions
- reactivity and crystal structure

An ideal companion to Bürgi and Dunitz's *Structure Correlation*, this book will be highly useful to synthetic organic chemists, stereochemists, crystallographers, and solid-state chemists.

Preparative Solid-State Chemistry with High-Power CO_2 Lasers**

Sönke Möhr and Hanskarl Müller-Buschbaum*

The establishment of solid state chemistry as an independent field, which also has had a stimulating effect on material sciences, is a consequence of the experimental skill of chemists. The development of new methods led to an abundance of new compounds, the characteristic properties of which are linked with the solid state. The reaction temperature plays an important role in the synthesis of solid compounds; therefore, it is not surprising that a large number of the newly developed experimental techniques involve methods which can produce high temperatures on the open-ended temperature scale. Since the development of the CO_2 laser, the solid-state chemist has an excellent heat source available, and with the power available today the range of high temperatures possible has been extended considerably. A way is now open for producing metastable, "entropy-supported" high-temperature compounds and substances with anomalous oxidation states and with macroscopic defects.

Keywords: high-temperature reactions · laser chemistry · metastable compounds · solid-state chemistry

1. Introduction

In 1917, when Albert Einstein postulated the theoretical principles of the modern LASER (*L*ight *A*mplification by *S*timulated *E*mission of *R*adiation),[1] the interactions between light and material known at the time, that is, absorption and spontaneous emission, were supplemented by stimulated emission. Almost forty years later Gordon, Zeiger, and Townes[2] developed the first MASER (*M*icrowave *A*mplification by *S*timulated *E*mission of *R*adiation), taking into account the results of Basov and Prokhorov[3] on the amplification of electromagnetic radiation. From then on the development of the laser advanced more and more rapidly, culminating in the construction of the first flash-light pumped ruby laser by Maiman[4] in 1960. In the meantime, the number of types of laser has become so large that they are now divided into categories such as solid-state, liquid, and gas lasers. The original acronym LASER has now become the term "laser" which is used for the characterization and the use of a method, or, to refer to an apparatus which produces a characteristic radiation.

A broad spectrum of application arises from the large number of laser types, ranging from modulation techniques in information technology (glass fibers, scanners), metrology and surface testing (interferometry), and material processing, to coagulation of body tissues in medicine. The laser has also become important in chemistry. Numerous review articles[5–9] and monographs[10–12] have been published on the subject. It is, however, apparent that optical and spectroscopic applications of the laser for analytical purposes are of primary interest. There are only a few examples from the domain of molecular chemistry on the use of lasers in chemical synthesis, and in preparative solid-state chemistry they are also only used sporadically.

About 15 years ago we began our first experiments to introduce the CO_2 laser available then (with continuous-wave power up to about 500 Watt) into preparative solid-state chemistry.[13, 14] Since then articles have been published describing syntheses at normal pressure, under increased oxygen pressure, and under reducing conditions. Here we review applications of the CO_2 laser technique to date (lasers of medium power) and then report on new ways of using high-power lasers.

2. The Application of Medium-Power CO_2 Lasers for the Synthesis of New Solids

2.1. Synthesis at Normal Pressure in a Defined Gas Atmosphere

In a review article on the crystalline chemistry of lanthanoid oxides[15] published in 1981, methods of producing high temperatures in chemical laboratories were summarized. These differ not only in the method, but above all, in the efficiency of energy transfer to the solid substances. According to Reed,[16–18] hot flames and laminar argon plasmas transfer 0.2 $kWcm^{-2}$, direct current electric arcs transfer 16 $kWcm^{-2}$, but electron beams and lasers can transfer 10^3 $kWcm^{-2}$. Thus, it is evident that the CO_2 laser, developed by Patel,[19] and subsequently improved by admixture of nitrogen and helium,[20, 21] is

an unusually efficient source of radiation for heating solid materials.

The first reports on the use of CO_2 lasers for preparative purposes appeared in 1979.[13] The laser activity is based on the fact that the emission at 10.6 μm, which lies in the infra-red region, is absorbed by almost all substances, and by conversion of radiated energy into warmth they can be heated to high temperatures. This technique uses the same principle as that of a solar furnace, that is, the emitted radiation of a CO_2 laser is focused onto the sample, as shown in Figure 1. Here, the horizontally produced laser light is deflected into the vertical by a silicon mirror and then focused by KCl lenses of varying focal length. The sample can be heated simply in air or, as shown in Figure 1, in any chosen gas atmosphere. High-temperature reactions in a defined gas atmosphere are carried out in sealed quartz tubes, which, contrary to the principle of a Liebig condenser, are flushed with gas from top to bottom. This direction of flow hinders vapor deposition on the plane-parallel polished KCl window, which is connected to the quartz tube by O rings. The sample irradiated in this way (e.g. tablets of pressed oxide mixtures) absorbs the total energy in a relatively thin layer; this causes a steep temperature gradient from top to bottom because of the poor heat conduction in ceramic materials. The distribution of temperatures in the vertical direction depends on the radiation profile of the particular type of laser used.

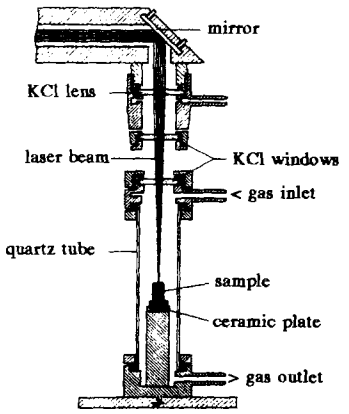

Fig. 1. Schematic representation of the method of working with medium-power CO_2 lasers under a defined gas atmosphere.

The first experiments using radiation energy from a CO_2 laser for the synthesis of new solids were carried out nearly twenty years ago. These involved, for example, the preparation of the following compounds: $La_2Ti_2O_7$,[22] $CaFe_6Al_6O_{19}$,[23] monoclinic $SrAl_2O_4$,[24] $Sr_6Nb_{34}O_{91}$,[25] $Ba_4FeTa_{10}O_{30}$,[26] $MBeLn_2O_5$ with M = Ca and Ln = La, Y;[27] Sr/La,[28] Sr/Sm; Ba/La,[29] Eu^{II}/Eu^{III}; Ca/Pr,[30] Ga/Gd; Ba/Nd,[31] Ca/Eu; Sr/Gd; Eu/Sm,[32] Eu/Gd; (Ca,Sr)/Sm; (Ba,Ca)/Nd; (Ba,Sr)/Nd,[33] $Ba_6Dy_2Al_4O_{15}$[34] and $Ba_6La_2Fe_4O_{15}$.[35] All substances were obtained as single crystals by recrystallization of molten oxide mixtures.

2.2. Synthesis Using High Oxygen Pressure

During a series of syntheses at high temperatures ($T > 1900\,°C$) the partial thermal decomposition of stable oxides was observed. Less stable oxides, for example those of transition metals in higher oxidation states, extensively decompose at high temperatures, so that chemical syntheses at high temperatures are not possible. For instance, Ag_2O, $Au_2O_3 \cdot xH_2O$, and HgO are particularly sensitive to heating, and therefore cannot be used in experiments with the CO_2 laser. In order to reduce the thermal decomposition of such substances or to shift the decomposition equilibrium towards the oxides, the work was carried out under high oxygen pressure. In this way the compounds given in Table 1 were successfully synthesized by conventional autoclave methods. The list shows that there is an upper temperature limit of around 700 °C for the stainless steel autoclaves used. At higher temperatures the oxy-

Table 1. Summary of the syntheses of oxometalates under increased oxygen pressure.

Hanskarl Müller-Buschbaum was born in 1931 in Wallendorf in the Thüringer Wald. He studied chemistry and physics at the University of Grifswald, gaining his doctorate in 1960 under the supervision of H. Witzmann for research on UV-excited borate luminophores. He then joined the research staff at Siemens in Munich, where he carried out research work on hard superconductors. In 1962, he continued his academic career at the University of Münster with Wilhelm Klemm and in 1965 he joined Rudolf Hoppe at the University of Giessen where he gained his habilitation in 1966 for work on the generation of high temperatures with the low-pressure/high-frequency plasma burner and its application in high-temperature solid-state reactions. In 1969 he accepted the offer of a professorial chair for inorganic chemistry at the University of Kiel. His main research interests focus on solid-state chemical reactions at high temperatures using high frequency plasma discharges and the synthesis of metastable materials with the CO_2 laser technique.

gen-filled autoclaves themselves or their seals burn out from the inside. This problem led to the idea of heating the sample under increased oxygen pressure using laser irradiation, that is, the extent of the local heating is limited to exactly the size of the sample, which is, of course, small. For this purpose, autoclaves were constructed with KCl windows transparent to CO_2-laser radiation, which allowed the transfer of energy to the sample without the autoclave itself being heated to a considerable extent. Figure 2 shows the design of such an autoclave as used in combination with CO_2 laser techniques. The laser radiation is focused onto the sample through a KCl window sealed with indium and silver rings. The laser beam can be centered, and the course of the reaction can be monitored through a separate observation window. With this method it was possible to reduce the thermal decomposition of NiO at high temperatures to such an extent that single crystals of $SrNiO_2$[55] could be obtained from a reaction with SrO.

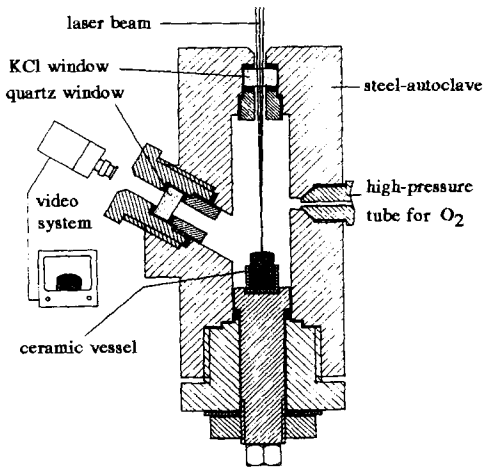

Fig. 2. Schematic representation of an autoclave for syntheses under oxygen pressure using CO_2 lasers.

However, this apparently simple method is restricted by the limited resistance to pressure of the KCl window, which, at pressures above 2000 bar and the simultaneous load of irradiation by the CO_2 laser, begins to deform so that the laser beam can no longer be focused. The energy density reaching the sample is then too low, and no high-temperature reactions under increased oxygen pressure can be carried out. A remedy for this problem is a cascade technique with several pressure stages so that each individual KCl window is only subjected to a maximum of 1000 bar. Unfortunately, this is experimentally very demanding, and the development had to be discontinued for financial reasons.

2.3. Synthesis of Metastable Compounds

In Section 2.1 it was mentioned that the energy irradiated onto the sample is absorbed in a thin layer. This causes the surface of the sample to heat up much more intensely than the deeper layers, and the resulting steep temperature gradient may lead to inhomogeneities in the composition of the reaction products and to demixing of the starting components. This effect is a limiting factor in the use of the CO_2 laser technique for preparative reactions under equilibrium conditions. However, the vertical and horizontal temperature gradient may also be an advantage for the synthesis of metastable compounds. The latter are only stable at high temperatures and are only formed in a relatively small range of temperatures which is very difficult to regulate precisely and is often even unknown. Within the temperature gradient of an irradiated tablet there exists an optimal range of temperatures for the synthesis of metastable compounds. When the sample is rapidly cooled from the high-temperature range after the reaction has taken place, the metastable compounds may be "frozen in" and can then be investigated at room temperature. The following compounds were synthesized in this way: $SrCr_2O_4$,[56] α-$CaCr_2O_4$,[57] $Ca_2Sc_6O_{12}$,[58] $SrCa_2Yb_{10}O_{18}$, $SrCa_2Lu_{10}O_{18}$,[59] $BaSrCaTm_{22}O_{36}$,[60] $Ba_2SrLu_{22}O_{36}$,[61] $Ba_2SrLn_6O_{12}$ (Ln = Yb, Tm),[62] $BaCa_2Ln_{10}O_{18}$ (Ln = Er, Yb;[63] Ln = Tm, (Tm,Sc)),[64] $BaSr_2Ln_6O_{12}$ (Ln = Y, Er, Tm),[65] $Sr_3Ln_4O_9$ (Ln = Nd,[66] La,[67] Pr, (La,Sm)[68]), $BaCa_2Y_6O_{12}$, $CaMg_3Y_8O_{16}$,[69] $BaNi_2M_8O_{15}$ (M = In,[70] (In,Sc)[71]) and $Mn_2Zn_3Ta_6O_{20}$.[72]

2.4. Synthesis of High-Temperature Modifications

In addition to pressure-stabilized and metastable compounds, high-temperature modifications of oxides have also been prepared. For example, it is interesting that the low-temperature modification of $Co_3(AsO_4)_2$[73, 74] is transformed on heating with a CO_2 laser to a high-temperature modification H-$Co_3(AsO_4)_2$,[75] the crystal structure of which is isotypic to that of $Cu_3(AsO_4)_2$.[76]

There were indications that a high-temperature modification existed of the low-temperature orthorhombic modification of $CaTa_2O_6$.[77] Preliminary experiments indicated a perovskite structure of the formula $CaTaO_3$,[78] containing tantalum in the unusual oxidation state IV. Later investigations revealed a small, cubic unit cell filled with one formula unit of $Ca_{0.5}TaO_3$.[79] Here, tantalum shows the expected oxidation number Ta^V, but the question of how $Ca_{0.5}$ can be interpreted in the small perovskite cell remained unanswered. Our experiments using the CO_2 laser technique produced larger single crystals, an X-ray analysis of which revealed a doubling of the lattice constants and a lowering of the symmetry. The elucidation of the structure gave a unit cell with eight times the volume in which only half of the calcium sites are occupied.[80] The unusual thermal ellipsoids of oxygen in the small unit cell disappear when these leave their special positions in the large unit cell.

Lanthanoid oxometalates of the composition Ln_2TiO_5 show a characteristic type of structure for compounds containing large lanthanoid ions, which was first found for La_2TiO_5[81] and then confirmed with Nd_2TiO_5[82] and Eu_2TiO_5.[83] High-temperature modifications were found for Ln_2TiO_5 with Ln = Gd, Dy, Er, Yb, and Lu,[84, 85] the structures of which remained, at first, unknown. Subsequently, the high-temperature modifica-

tion of Dy_2TiO_5[86] was synthesized by the CO_2 laser technique and its structure was elucidated by X-ray analysis. H-Dy_2TiO_5 crystallizes as a cubic pyrochlore ($Dy_2Ti_2O_7$) from which formally one TiO_2 unit has been removed, causing cation and anion defects to appear.

2.5. Syntheses of Low- and Mixed-Valent Oxometalates

2.5.1. Syntheses by Reduction with Hydrogen at High Temperatures

One advantage of the CO_2 laser technique (Fig. 1) is that it is possible to carry out reactions at high temperatures in a hydrogen atmosphere, that is, under reducing conditions. If the oxides are heated by CO_2 laser irradiation until the melting point is reached, on the upper surface of the tablet a liquid droplet is formed which is normally held together by surface tension. This droplet can be heated well above the melting point by further absorption of energy; thus, when this hot melt comes into contact with a hydrogen atmosphere, reduction reactions can occur which are not possible at lower temperatures for thermodynamic reasons ($\Delta G > 0$). At high temperatures (2000–3000 °C) the product $T\Delta S$ of the Gibbs–Helmholtz equation often reaches values which can compensate for a positive reaction enthalpy, thus reversing the sign of ΔG.

Reductions in superheated melts under these conditions are "self-crucible methods", that is the substrate is at the same time either the crucible material or the support for the superheated melt. Reductions with hydrogen at high temperatures led to a series of interesting compounds of the composition $MV_{10}O_{15}$ with M = Ba[87] and Sr[88] as well as $MCr_{10}O_{15}$ with M = Sr, Ba.[89] In these compounds vanadium and chromium are partially reduced to V^{III} and Cr^{II}, respectively. The low oxidation states of vanadium and chromium are indirectly confirmed in $SrNi_2Cr_8O_{15}$[90] and $BaNi_2Cr_8O_{15}$;[91] in $BaNi_2In_8O_{15}$[92] and $BaNi_2In_4Sc_4O_{15}$[93] Ni^{II} and In^{III} were assigned to face-sharing octahedra. $BaVO_{2.5}$[94] also belongs to the group of reduced high-temperature oxides containing vanadium in the oxidation state III.

2.5.2. Synthesis by Comproportionation

Metal oxides can also be reduced by metals. An elegant method is the comproportionation of oxides with metals as introduced by Ehrlich[95] with great success for the synthesis of low-valent titanium oxides. Experiments with medium-power CO_2 lasers only had a limited success in this area. For instance, in this way it was possible to heat SrO, Nb_2O_5, and Nb metal under the exclusion of oxygen and to synthesize $Sr_7Nb_2^{IV}Nb_4^{V}O_{21}$;[96] however, a considerable amount of the radiated energy was reflected by the niobium metal so that the desired high temperatures could not be reached. This provided the stimulus for the use of more powerful lasers and the development of a technique which is particularly suitable for reactions of oxides in the presence of metal melts.

3. Employment of High-Power CO_2 Lasers for Solid-State Synthesis

3.1. Apparatus for Solid-State Synthesis in a Defined Gas Atmosphere

The methods described in Section 2.5 for the reduction of oxides by hydrogen or by metals result in a high thermal load and destruction of the inert gas apparatus. A different design for the apparatus was required to cope with the radiated heat from the sample and the laser radiation reflected by metallic components. The primary objectives are the protection of the experimentalist from the invisible radiation, the protection of the radiation inlet port and the observation window from the high heat of radiation and finally, the handling of hot gases.

A new unit for the sample was constructed for solid-state reactions using high-power CO_2 lasers (power >1200 W; Fig. 3). The reaction chamber (I) made from an aluminum alloy

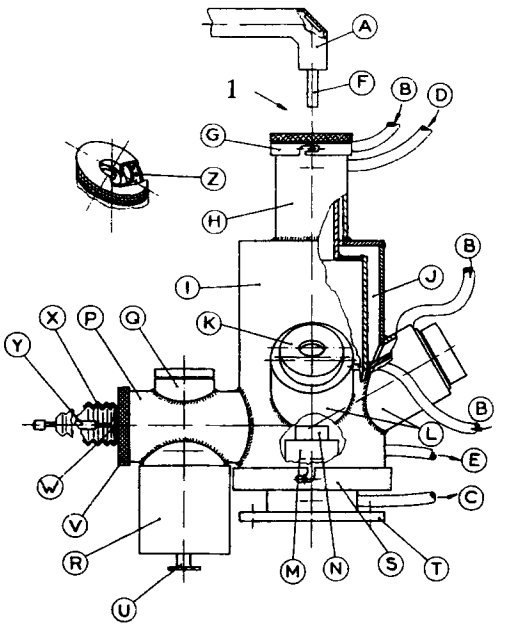

Fig. 3. Cross-section of the double-walled reaction chamber for high-temperature reactions with high-power CO_2 lasers. A = tilted mirror for deflecting the laser beam, B = gas inlet, C = gas outlet, D = cooling water inlet, E = cooling water outlet, F = protective tube against laser radiation, G = fastening device for the KCl window, H = upper part of the reaction chamber, I = reaction chamber, J = water cooling system, K = observation window, L = observation ports, M = sample holder, N = crucible, P = access port, Q = observation window, R = Dewar flask, S = base of the reaction chamber, T = cross-table, U = vacuum flange, V = holder for the manipulator, W = ball-and-socket joint, X = rubber sleeve, Y = manipulator, Z = partial view showing the tangential gas inlet at the windows.

(AlMg7) is double-walled. The inner and outer aluminum walls are kept at a uniform temperature by a water cooling system (J) (inlet at (D), outlet at (E)). The high thermal conductivity of the metal casing as well as the cooling system (J), which constantly removes the heat reaching the inner wall by heat radiation and convection, ensure that even for long reaction times the thermal load of all the components remains low. In order to allow the reaction to be monitored visually and the sample to be subjected to laser radiation, there are four ports in the reaction chamber (I). At three of these openings there are double-walled ports (L)

which are also joined to the cooling system (J). They are mounted in such a way that the reaction can be monitored under an observation angle of 60°. The tube (H) serves as an inlet for the radiation beam. The fourth opening in the the reaction chamber contains a separate quenching device (P). The first three ports mentioned have transparent windows.

The horizontal window is made of a plane-parallel ground KCl single crystal, and is connected by a bayonet joint (G) and O rings to the tube (H). To protect this KCl window against vaporized material, gas is allowed to flow (B) into the reaction chamber from twelve jets (Z) positioned tangentially to the laser axis. This gas flushes away vapors of oxides, suboxides, and metals from the window area. The turbulence of vaporized material observable in the larger chamber (I) is entrained by the spiraling flow of gas as it passes from (H) to (I). In this way the observation windows are also protected from condensing material.

The two observation windows are made of BK-7 (from Dr. Korth/Merck, Kiel-Altenholz), a special glass that has its absorption maximum at 10.6 μm which matches the radiation used here. This prevents the escape of scattered radiation. The spacing of 13 cm between the windows and the heated sample has been chosen so that the direct radiation does not lead to their destruction. The rotatable rings (K), each equipped with two filters (polarizer/analyzer), allow fine adjustment of the brightness during observation of the sample. As in the radiation inlet tube (H), each window is protected by a spiraling flow of gas into the reaction chamber by the pierced ring channels (Z) and gas supply lines (B), which also prevents condensation on the windows.

Finally, the sample can be moved through the port (P) by using the manipulator (Y) during the reaction, or, at the end of a high-temperature reaction, it can be thermally quenched by liquids in a Dewar flask (R). The quenching procedure can be monitored through the observation window (Q). The hot gases are removed from the reaction chamber through the gas outlet (C).

The whole apparatus can be lined up with the laser beam by a cross-table (T). The sample crucible (N) stands on a corundum block (M) and may also be observed on a monitor during the reaction. Figure 4 supplements the cross-section and shows the experimental setup with the beam entering vertically.

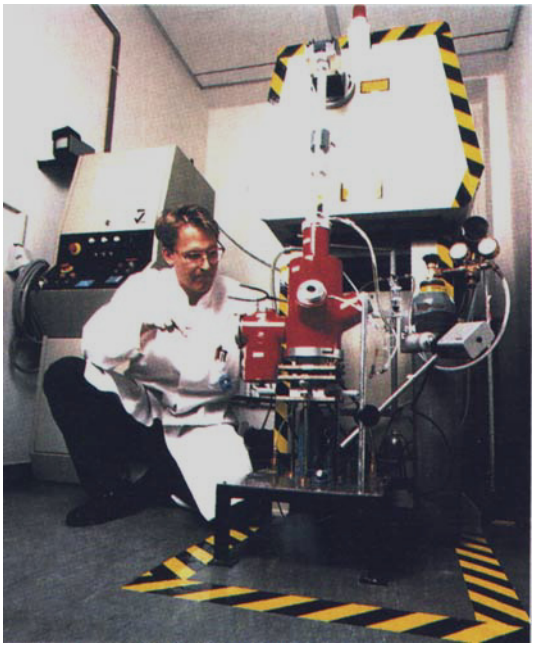

Fig. 4. View of the whole apparatus, with user terminal (left) and CO_2 laser (in the background).

3.2. Measurement of the Reaction Temperature

The sample temperature is measured pyrometrically and only refers to the surface temperature. Pyrometric measurement of temperature presupposes that the sample behaves as a black body. According to Kirchhoff's law the relationship between emitted and absorbed radiation at constant wavelength and constant temperature equals the intensity of the black body radiation [Eq. (a)].

$$I_{(\lambda,T)}A^{-1}_{(\lambda,T)} = I(\text{black body})_{(\lambda,T)} \quad \text{(a)}$$

According to the Stefan–Boltzmann law of radiation the intensity $I(\text{black body})_{(\lambda,T)}$ is proportional to T^4, and the wavelength of the maximum energy λ_m is inversely proportional to the temperature of the black body. This means that with monochromatic measurement of the sample temperature (red filter in the pyrometer), the errors in the measurement becoming increasingly large as the temperature rises. Deviations of a "gray body" from a black body can be corrected with an acceptable accuracy for "visible" wavelengths using Equation (b)[97] [T = temperature of the sample, T_S = temperature of the black body, A = absorption capacity of the sample, λ = wavelength at which the measurement is undertaken, C = constant from Planck's theory ($\equiv$ 1.439 cm K[98])].

$$1T^{-1} = 1T_S^{-1} + \lambda C^{-1} \ln A_{(\lambda,T)} \quad \text{(b)}$$

Figure 5 shows a series of curves calculated with this relationship for several values of the absorption coefficient A at wave-

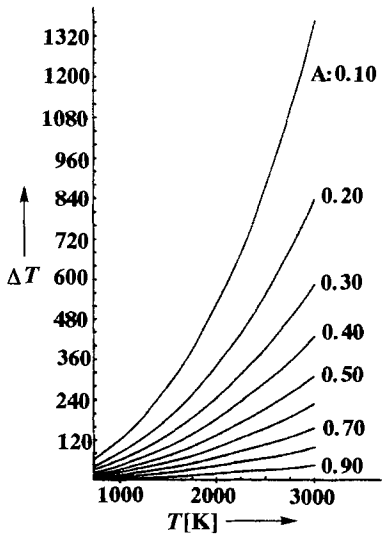

Fig. 5. Plot of the temperature difference as a function of the temperature to be measured for substances with different absorption coefficients (A); wavelength: 0.65 μm.

length $\lambda = 0.65$ μm. It is evident that measurement of the surface temperature for weakly absorbing substances at high temperatures is very inaccurate.

The situation is completely different when the CO_2 laser technique is used for measurement of temperature. Here, the irradiation energy is invisible to the visual pyrometric measurement; that is, each substance appears to have an absorption coefficient of $A = 1.0$, so that the temperature is read off along the abscissa of Figure 5. The inherent brightness observed for the sample is therefore characteristic of its surface temperature.

3.3. Examples of High-Temperature Reactions with High-Power CO_2 Lasers ($P > 1200$ W)

Within the framework of a dissertation[99] and using the apparatus described in Section 3.1, a hitherto unknown high-temperature modification of TiO[100] isotypic with tungsten carbide was synthesized at about 3000 °C.

Above 2600 °C an oxotitanate of the formula $Ba_2Ti^{III}_{12}Ti^{IV}O_{22}$[102] was obtained, which has a new type of structure with face-sharing $Ti^{III}_2O_9$ double-octahedra. Futhermore, for the first time it was possible to substitute Ti^{III} ions by other trivalent cations (here Cr^{III}) in $Ba_2Ti_6O_{12}$ at high temperatures;[103, 104] thus, single crystals of $Ba_2Ti_4CrO_{13}$[105] were investigated by X-ray structure analysis.

The oxides TiO_2 and Y_2O_3 reacted with titanium metal in an argon atmosphere above 2800 °C to give a $TiYO_{2.1}$ phase[101] containing Ti^{II}/Ti^{III} and Y^{II}. The X-ray structure analysis indicates the presence of a defect pyrochlore structure similar to that of the $Ti_{0.5}DyO_{2.5}$[86] phase. Finally, the oxoniobate $BaNb_3O_6$,[106] was synthesized at 2900 °C in the apparatus described. This mixed-valent compound shows open polyhedra not only for Nb^{II} and Nb^{IV} ions but also for Ba^{II} ions.

All the experiments were carried out in a borate-free $(BN)_x$ crucible. In order to avoid reactions with the walls of the crucible, it is important to have information on the vertical and horizontal temperature profiles in the sample. The thermal expansion has been measured for austenite heated up to 2000 °C.[107] However, the temperature profiles of oxides have not been determined, so the dimensions of the crucible must be chosen so that the maximum temperatures reached lie within the sample and do not reach the walls of the crucible.

The profile of the beam of the high-power laser used is also important (VFA 1200, BAASEL Lasertechnik GmbH, D-82319 Starnberg, Germany). The transverse electromagnetic ground mode (TEM_{00}) has an intensity profile which can be described by a Gaussian distribution curve. Since the peak sharpness is proportional to the width of the emitted beam of rays, it follows that for the beam diameter of 15 mm used, no thermal equipartition can exist horizontally in the reaction area. Samples of sufficient diameter and height lead to comparable results and avoid a reaction with the walls of the $(BN)_x$-crucible.

4. Summary and Outlook

High-temperature reactions with the CO_2 laser technique can be used to synthesize new solids, which seemed, until recently, to be inaccessible. This applies particularly to high-temperature reactions under defined gas atmospheres and to the combination of high pressures *and* high temperatures.

Kinetics no longer play a role in the formation of new compounds at high temperatures. Thermodynamics, in particular entropy, is the determining factor for the existence of new compounds and phases. The properties of all the metastable, "entropy-supported" substances described are largely unknown, because experimental techniques still have to be developed which can investigate these substances within the range of their thermodynamic stability.

In addition to the well-known methods for preparing and stabilizing compounds with metal ions in extremely low oxidation states, there is now this new method for syntheses at high temperatures, which has led to the formation of new high-temperature modifications and entropy-supported substances with low oxidation states. Compounds with disordered phases having deficits in subdomains or in the anionic and cationic part of the crystal structure are just beginning to be explored and will bring about a reconsideration of structures in terms of fragmented polyhedra instead of well-defined and complete coordination polyhedra. At present we can only speculate on the physical properties that may arise from such macroscopic defects.

The powerful CO_2 lasers can, with imaginative use of their high-power densities, extend the potential of known techniques—in particular high-pressure/high-temperature reactions between solids or recrystallization of compounds from melts unter extreme pressures. Interesting, partly because only very small amounts of substance are heated locally, are high-temperature syntheses in strong magnetic fields; these are already possible from the experimental point of view. One area still to be investigated is the interaction between strongly heated vapors of metals and compounds with melts or solids.

These few examples show that owing to the advantages associated with the production of high temperatures in a very small area, this method can expect a wide range of applications with interesting results.

We would like to thank the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie for their support with valuable materials. A special thanks is due to Herr Organista (Kiel) from the Deutscher Verband für Schweißtechnik for the complicated welding of the double-walled reaction chamber as well as to the workshops of the Institut für Anorganische Chemie for producing the component parts and the final processing.

Direct On-Line Coupling of Capillary Electrophoresis and ^{1}H NMR Spectroscopy

Klaus Albert*

Capillary electrophoresis[1, 2] (CE) as a new separation technique in addition to high-performance liquid chromatography (HPLC) is becoming more and more popular. In contrast to conventional electrophoresis techniques, capillary electrophoresis has the big advantage that due to the use of capillaries with internal diameters of 25–75 μm Joule heat occurring during an electrophoretic separation dissipates to the lattice. Separation in capillary electrophoresis is based on the different electrophoretic mobilities in an electric field of the charged molecules to be separated. At voltages ranging from 10–50 kV and currents ranging from 10–50 μA, a CE separation takes place within 5 to 30 minutes. The high efficiency of the separation has aroused a lot of interest in the CE separation technique for applications in the field of biopolymers (peptides, proteins, oligonucleotides) and in the field of naturally occurring compounds. One mode of CE is micellar electrokinetic capillary chromatography (MECC), in which charged micelle-inducing surfactants are added to the electrolyte creating a pseudo-stationary phase. In this way neutral molecules can also be separated.

CE separations are carried out in open- or gel-filled fused-silica capillaries (30–80 cm overall length) at flow rates in the nanoliter per second range. Both ends of the capillary are immersed in buffer reservoirs, the electric field is generated by a high-voltage power supply connected to two electrodes immersed in the buffer reservoirs (Fig. 1). The separation depends on the strength of the electric field, the temperature, the buffer composition, the pH value, the ionic strength, the viscosity, and the surface characteristics of the capillary used. The amount of compound required lies between the pg and ng range. The simplest way of injecting the probe is performed hydrostatically by raising the sample vial at the inlet end of the capillary.

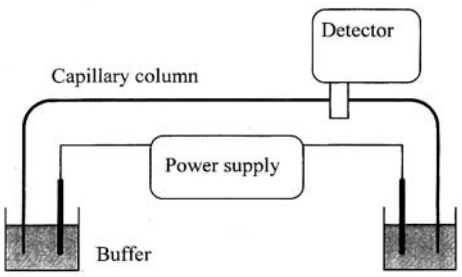

Fig. 1. Schematic diagram of a capillary electrophoresis instrument.

Detection using UV/Vis-photometers is performed in an on-column mode by directly using the capillary as detection cell. One of the most powerful methods for structure elucidation of separated compounds is on-line coupling of CE and electrospray mass spectrometry. For instance, this technique was used for characterization of peptides and proteins in the mass range of several kilodaltons[3] for characterization of oligonucleotides,[4] and for the analysis of plant pigments.[5, 6] An unequivocal structural assignment of separated compounds however can only be performed with the additional use of NMR spectroscopy.

NMR spectroscopy shows two severe disadvantages with respect to its practical application: The low sensitivity with respect to other investigation techniques neccessitates a large amount of sample, and the investigated samples should be pure otherwise the overlap of sample and impurity signals could lead to misinterpretations. Despite the insensitivity of NMR spectroscopy, first experiments to directly couple HPLC and NMR spectroscopy were already carried out in the 1980s.[7–9] However, HPLC–NMR coupling[10–12] as well as the coupling of supercritical fluid chromatography (SFC) with NMR spectroscopy[13] have only recently been applied more widely as labor- and time-saving methods.

In practice two different investigation techniques are performed. In the on-line continuous-flow mode the chromatographic separation is continuously monitored by recording ^{1}H NMR spectra with a minimal time resolution of eight s. The detection limit for a compound of low molecular weight (300 Dalton) is about 500 ng on a 600 MHz NMR instrument equipped with a 120 μL flow cell. In the stopped-flow mode two-dimensional assignment experiments can be performed with inverse ^{1}H{^{13}C}-continuous-flow probes. A big advantage of the coupling of separation techniques such as HPLC and SFC with ^{1}H NMR spectroscopy is the possibility of displaying the chromatogram as a contour plot. Here, ^{1}H NMR chemical shifts are plotted versus the retention times of the chromatographic separation. The introduction of a second dimension, the ^{1}H NMR chemical shift, enables a clear and accurate assignment of the signals even of overlapping peaks in contrast to conventional UV registration. Thus, the main disadvantages associated with chromatography, that is large amounts of substance and large detector volumes, are compensated.

Special continuous-flow probes have been developed for HPLC–NMR and SFC–NMR coupling, which differ from conventional NMR probes mainly with respect to the arrangement of the NMR measuring coil (Fig. 2). In contrast to conventional NMR probes (Fig. 2a), the coil is directly fixed to the glass tube of the continuous-flow cell (Fig. 2b). Thus the ratio of coil

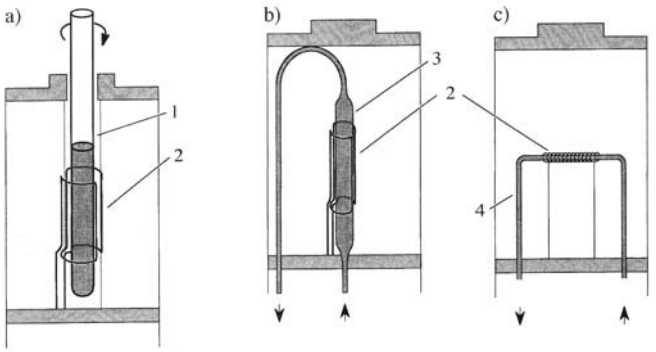

Fig. 2. Different arrangements of NMR probes. a) Conventional probe with rotation of the NMR tube. b) Continuous-flow probe for HPLC–NMR and SFC–NMR coupling. c) Probe for CE–NMR coupling. The arrows show the flow direction of the eluent. 1 = NMR tube (5 mm diameter); 2 = transmitter/receiver coils; 3 = flow cell; 4 = flow capillary.

volume to sample volume, the so-called filling factor, is improved resulting in an improved signal sensitivity. The disadvantage of this design lies in the fact that the NMR tube cannot be rotated. An alternative approach is shown in Figure 2c. Here, the NMR detection coil is positioned perpendicular to the magnetic field of the cryomagnet; this solenoid measuring coil assembly may lead to increased NMR signal sensitivity with respect to the double-saddle coil measuring assembly shown in Figure 2b. The disadvantage of the solenoid coil design is the difficulty of eliminating magnetic field inhomogenities, because the shim systems used for the homogenization in cryomagnets are optimized parallel to the rotation axis of the NMR tube (in z-direction parallel to magnetic field lines) and not in the perpendicular (x, y) direction. The volume required for measurement in a conventional NMR tube (5 mm diameter) is about 250 µL, the detection volumes employed in HPLC–NMR and SFC–NMR coupling are in the range of 40–120 µL.

The use of nanoliter volume sample cells to couple capillary electrophoresis with ^{1}H NMR spectroscopy was recently reported from Sweedler et al.[14, 15] for the first time. The NMR detection cell was built by wrapping a microcoil around a fused silica capillary (75 µm inside diameter) this creates a detection volume of 5 nL. With a capillary (outside diameter 350 µm), NMR signal line widths in the order of 7 to 11 Hz could be obtained. According to the authors the detection limit of 35 ng arginine can be reached within a measuring time of one minute. They report an on-line CE–NMR separation of arginine, glycine, and cysteine at an injection level of 20 nL and compound concentrations of 0.7–0.8 M. The absolute injected amount is in the 1–4 µg range.

The different parameters contributing to the NMR signal line width are discussed by the authors in detail. In addition to the effect of solution flow and the electrophoretic current-induced magnetic field, mainly susceptibility variations caused by the design of the microcoil used influence the resolution of the NMR signals. It is interesting to note that the authors observe a reduction in NMR signal line width as a function of current. With the 5 nL-measuring cell at a voltage of 6 kV and a current of 15 µA, a minimum in NMR signal line width of 12 Hz is found. Susceptibility variations of the measuring coil severely affect the NMR signal half width. By varying the coil diameter a reduction in NMR signal line width from 200 Hz to values lower than 20 Hz can be obtained. But a further increase of NMR resolution to values in the range of a few Hz for the observation of ^{1}H spin coupling constants is impossible. It is considered that a improved coil design will help to further reduce line widths.

Taking into account the NMR resolution and sensitivity values described by the authors, it is clear that the main development is due to the fact that NMR detection is performed in the nanoliter volume range. The practical benefit of the described CE–NMR coupling may be considered from different viewpoints. Due to the loss of stereochemical information one of the most important reasons to perform on-line coupling experiments using NMR spectroscopy as a detection technique is no longer applicable. A further argument is the application range of the described separation. CE is mainly used for the separation of biopolymers. NMR spectroscopic investigation of biopolymers is only possible in the stopped-flow mode. In analogy to HPLC–NMR and SFC–NMR coupling, a practicable CE–NMR on-line technique should enable the use of both techniques with a NMR resolution of 1–2 Hz comparable to routine acquisition conditions.

Sweedler et al. have shown that coupling of CE and NMR is possible using nanoliter-NMR detection cells. The described method of miniaturization must be continued to derive a NMR resolution under the described measuring conditions which is close to values attainable by conventional acquisition systems. When this goal is reached, further development of NMR instruments will take place with respect to the complete automation of NMR spectra acquisition.

The Three-Dimensional Structure of Hammerhead Ribozymes**

Georg Sczakiel*

Ribonucleic acids (RNA) that can catalyze chemical reactions[1] have been the subject of intensive research ever since their discovery some thirteen years ago. Ribozymes—RNA molecules with a defined base sequence and three-dimensional structure—recognize certain RNA-sequences (substrates) in a base-specific manner and cleave a defined phosphoester bond of a defined base triplet. In naturally occurring ribozymes this step is essential, as for instance in the reproduction (replication) of certain satellite RNAs and viroids.[2] In these cases, the ribozyme and substrate sequences are found on the same RNA strand, leading to an intramolecular, in-*cis* cleavage. However, ribozymes can also act intermolecularly (in-*trans* cleavage),[3] with the result that they can be tailored to cleave any desired substrate RNA selectively, thereby inactivating it biologically. This explains the great importance that molecular biologists and biochemists attach to this class of substances today, and that in the long term makes therapeutic applications in vivo conceivable.[4]

One of the best studied ribozymes is the so-called hammerhead ribozyme,[5] which was first found in the avocado sunblotch viroid (ASBVd).[6] This natural system's genome is formed during replication as a covalently linked multimer, and the ribozyme activity serves to cleave it into unit lengths by an intramolecular reaction (in-*cis* cleavage). Recognition of the substrate RNA with the cleavable sequence motif (a base triplet) takes place by specific base interactions between the ribozyme and substrate strands (Fig. 1). Together with the complementary sequences of the substrate RNA, these 5′ and 3′ sequences of the ribozyme form Helices I and III of the hammerhead, and can therefore be understood as antisense sequences. The so-called catalytic domain formed between them consists of the structural components Helix II, the adjacent uridine turn, and the cleavable base triplet. These structural and functional domains together make up the catalytically active hammerhead, which can cleave the target domain only if metal ions such as Mg^{2+} ions are present. At least one Mg^{2+} ion is involved in the cleavage of the phosphodiester bridge between C17 and $A_{1.1}$ upstream of the cleavable base triplet ($G_{16.2}$, $U_{16.1}$ and C17; Fig. 1). This takes place by nucleophilic attack of the oxygen atom of the 2′-hydroxy group; release of the 5′-hydroxy group then proceeds via an intermediate with a trigonal–bipyramidal arrangement of the oxygen atoms around the central phosphorus atom, yielding a cyclic 2′,3′-phosphodiester and a free 5′-hydroxy group (Fig. 2). The crucial role of the 2′-hydroxy group is emphasized by the fact that a deoxyribose at the cleavage site prevents the cleavage reaction.[7]

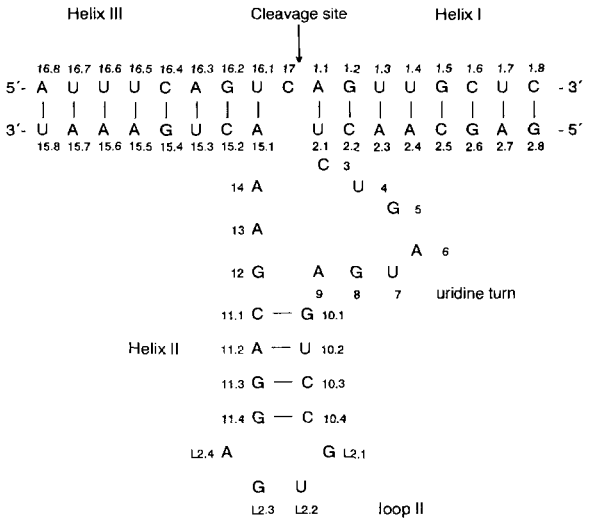

Fig. 1. Schematic diagram of the hammerhead with the nomenclature introduced by Hertel et al. [21].

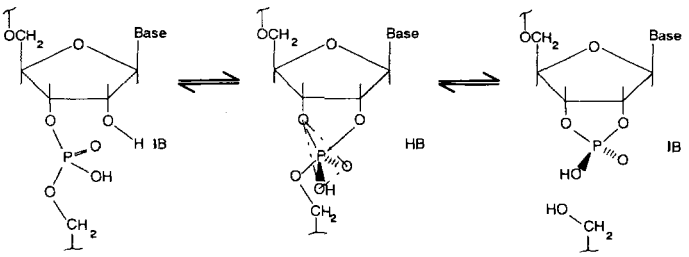

Fig. 2. Simplified reaction mechanism of the hammerhead ribozyme-mediated hydrolysis of the phosphodiester bond of RNA [5].

Recently, two independent groups have constructed three-dimensional structural models for the hammerhead ribozyme.[8, 9] The research group of F. Eckstein in Göttingen used chemical synthesis to produce ribozyme–substrate complexes, which were labeled on one of the three helices with a fluorescein group as fluorescence donor and on a second helix with a rhodamine group as acceptor. The ribozyme-mediated cleavage was prevented by introducing a 2′-deoxycytidine at the cleavage site. With this molecule fluorescence energy transfer (FRET) measurements could be made, and determination of energy transfer efficiencies permitted calculation of the distances between the donor and acceptor groups coupled to the helices. From these data, a structure proposal for the hammerhead ribozyme was worked out.[9] At the same time, the group of D. B. McKay in Boulder (USA) published the X-ray structure of a crystallized ribozyme–substrate complex.[8] In this study, the substrate strand consisted entirely of deoxyribonucleic acid (DNA) instead of RNA, so that the cleavage reaction could not take place. The structure determined in the crystal was remarkably consistent with the structural proposal of Eckstein et al., even though the latter was arrived at by a completely different method. The crystal

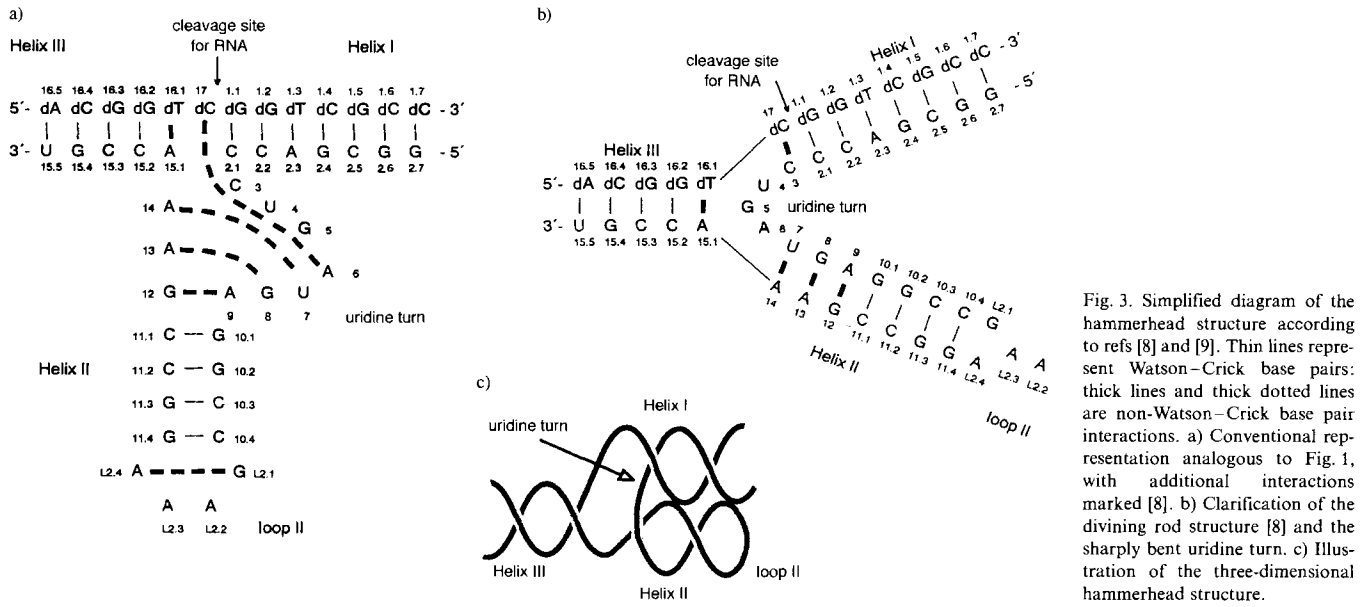

Fig. 3. Simplified diagram of the hammerhead structure according to refs [8] and [9]. Thin lines represent Watson–Crick base pairs: thick lines and thick dotted lines are non-Watson–Crick base pair interactions. a) Conventional representation analogous to Fig. 1, with additional interactions marked [8]. b) Clarification of the divining rod structure [8] and the sharply bent uridine turn. c) Illustration of the three-dimensional hammerhead structure.

structure also yields information about unexpected and nonconventional interactions between components of the hammerhead, which permit and explain the three-dimensional structure.

In previous structural models the three helices of the hammerhead were assumed to adopt a two-dimensional T-shaped structure (Fig. 3a). In the two new proposed structures the helices are almost collinear, leading to a sort of divining rod form (Fig. 3b). Helix III and Helix II are almost coaxial[8] or at a slight angle to each other,[9] whereas the axis of Helix I is collinear with that of Helix III but somewhat displaced from it (Fig. 3c). This implies that Helix II and Helix I are either arranged collinearly[8] or like a divining rod[9] (Fig. 3c). In addition to the Watson–Crick base pairs, several other interactions between the three helices (all of which are present in the A-form) are worth noting. The most remarkable of these is the extension of the otherwise short Helix II by three further base–base interactions close to the junction of the three helices (Fig. 3). Helix II is further stabilized by the interactions in loop II (5′-GAAA-3′), a so-called tetraloop.[10] A homopurine base pair (G–A) is formed in this loop, which allows stacking of the remaining two purines (A,A). A very similar loop structure is formed by the GAGA-loop (5′-GAGA-3′) of ricine-binding RNA, which was recently characterized by NMR studies.[11] The Helix II/loop II unit is therefore a significant component with regard to the structure and stability of the hammerhead. Compared to older structural models, helices I and III must be expanded by one base–base interaction in each case (C–C in helix I and A–U in helix III). The non-Watson–Crick pairing between A15.1 and dT16.1 is notable here. One marked result of the additional interaction and the configuration of all three helices is the very sharp angle of the uridine turn between helix I and helix II, whose structure corresponds almost exactly to that of the uridine turn in the anticodon loop and pseudouridine loop of yeast $tRNA^{Phe}$. This structural element receives additional stabilization from hydrogen bonds between the N3-atom of U4 and the *pro*-S_p-phosphate oxygen atom of U7, as well as between the 2′-OH group of U4 and the N7-atom of A_6. A further essential hydrogen bond is formed between the 2′-OH group of G5 in the uridine turn and the 2′-OH group of $C_{15.2}$ in Helix III. The importance of the 2′-OH group of G5 for the activity of the hammerhead ribozyme can also seen in the fact that exchange of arabinose for ribose in this position almost completely removes activity.[12]

Metal ions such as Mg^{2+}, Mn^{2+}, or Ca^{2+} are a necessary component of catalytically active hammerheads, though Mg^{2+} ions are usually used in vitro. The hammerhead ribozyme is therefore often regarded as a metalloenzyme.[13] When the oxygen atoms on the prochiral phosphodiester bridge which serves as substrate were exchanged for sulfur atoms, evidence was found that the *pro*-R_p-oxygen atom is coordinated to a Mg^{2+} ion (Fig. 4). No candidate for this coordination can be discerned in the crystal structure, though at another position in the structure a Mn^{2+} or Cd^{2+} ion is bound to the *pro*-R_p-phosphodiester oxygen atom of A9 as well as N7 of $G_{10.1}$ (presumably via an H_2O molecule). Pley et al. also discussed the possibility that a helix element at the end of Helix II (5′-$G_8A_9G_{10.1}$-3′) and 3′-$A_{14}A_{13}G_{12}$-5′) can bind an additional metal ion, a theory which is supported by activity studies with sulfur derivatives.[8] A simplified model for the participation of magnesium in ribozyme-mediated cleavage is illustrated in Figure 4 (from ref. [5]). Although a Mg^{2+} ion could be involved as magnesium hydroxide in the abstraction of the 2′-OH hydrogen atom, it is assumed that a second Mg^{2+} ion supports the cleavage of the P–O bond (Fig. 4). According to Sawata et al., the second Mg^{2+} ion could act directly as a Lewis acid at the leaving oxygen atom, and thereby play a role in the chemical step of the cleavage.[15] Independently of this, however, Mg^{2+} ions could have a structure-stabilizing function in the hammerhead. For example, it was recently shown with RNA-modifying reagents

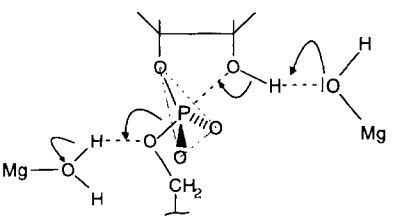

Fig. 4. Possible participation of Mg^{2+} ions in ribozyme-catalyzed cleavage.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0606-0644 $ 10.00+.25/0

in solution that the three-dimensional structure of the hairpin ribozyme is clearly influenced and stabilized by the presence of Mg^{2+} ions.[16] Nonconventional base–base interactions also play a large role in substrate binding by the hairpin ribozyme.

Previous biochemical analyzes of the hammerhead ribozyme generally aimed to find correlations between directed chemical substitution of single functional groups or atoms and changes in cleavage activity by kinetic measurements. Conclusions were then drawn about the functional and to a lesser extent the structural significance of the changes made.[17] The effects of chemical and structural changes on measured kinetic parameters are largely due to changes in the transition state of the cleavage reaction, and cannot be accounted for in either X-ray analysis or during FRET measurements in solution. Packing effects in the crystal can also affect the RNA structure found and alter it compared to the solution structure. To a certain extent, therefore, deviations between biochemical data and the presented structures must be accepted, and do not detract from the quality of the structure determination. A more dependable structural model for the hammerhead will require the structural elucidation of further hammerhead ribozymes in the crystal and in solution. In this connection it seems relevant to ask why previous attempts to determine the hammerhead structure by NMR methods have obviously not been as successful. One conceivable cause for this is that the actual structure of the hammerhead in solution differs greatly from that assumed up till now. Thus, for example, in the highly concentrated solutions that are required for NMR studies not only 1:1 complexes of ribozyme and substrate might exist, but also multimers with higher mass and in addition a changed three-dimensional structure. This would not be surprising, if one remembers that during nondenaturing gel electrophoresis in the concentration range above 100 nM many RNA species produce several defined bands, which coalesce to a single band under denaturing conditions. However, the above, somewhat critical remarks should not detract from the fact that the majority of previous findings are in agreement with the two published three-dimensional structures, and may be explained with their assistance.

The three-dimensional hammerhead structure also affords a significantly better basis for discussions of previously unexplained observations. For example, the hydrolysis rate constants measured for catalytic antisense RNA (that is, hammerhead ribozymes with long-chain antisense flanks or long-chain substrate strands (more than 50 bases)) are a factor ≥ 100[18] smaller than those for short-chain ribozymes and substrates (less than 40 bases), which afford values for k_{obs} of around $1\,min^{-1}$. This value appears somewhat slow for an unhindered SN_2 reaction (see Fig. 2). This has encouraged speculation that the angle or flexibility between the three helices of the hammerhead or the configuration of the active site may have a decisive influence on the cleavage activity. One could thus imagine that an extreme extension of the ribozyme strand or the substrate strand (or both) could lead to negative effects on the exact configuration of the catalytic domain and the activity associated with it. The observation that a shortening of Helix III to the innermost Watson–Crick base pair ($N_{1.1}$–$N'_{2.1}$) does not affect the activity[19] is also in agreement with the structural model; the more distant base pairs are required neither for structural nor for functional reasons.

Our understanding of the structure and function of the hammerhead ribozyme has been clearly improved by the two studies presented, with their independent but concurring structure proposals. Numerous findings can be ordered and discussed on this basis. For chemists, the hammerhead ribozyme is now becoming ever more interesting. For application-oriented biochemists and molecular biologists, manageable models are emerging, with whose help medicinally relevant hammerhead ribozymes can be better designed and modified. In principle, it should be possible to produce just as broad a range of chemical modifications with synthetic ribozymes as in the area of antisense-oligonucleotides.[20] The structural elucidation of the hammerhead ribozyme certainly also contributes to our understanding of the biochemistry and biological importance of other active ribonucleic acids, which in the last few years have expanded the horizons of the conceivable and the feasible.

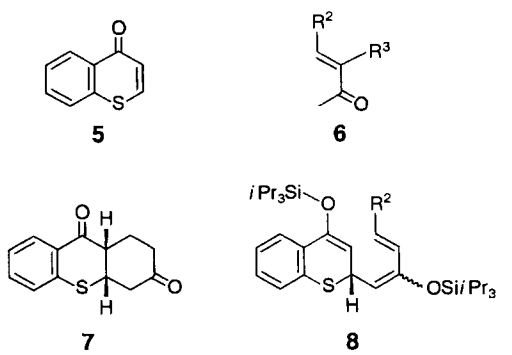
Sequential Transformation of Benzothiopyrylium Salts to Diastereoselectively Annulated Benzothiopyranones**

Uwe Beifuss,* Henning Gehm, Mathias Noltemeyer, and Hans-Georg Schmidt

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

S-containing heterocycles are versatile synthetic building blocks that can be transformed by ring-contraction reactions, ring-opening reactions, or desulfurization.[1] Furthermore, S-heterocycles such as thioxanthenes are important both for pharmacological research[2a–c] and as dyes.[2d–j] In contrast to N- and O-containing heterocycles, only few methods are known for the stereoselective formation of S-containing heterocycles.[3] Whereas simple nucleophilic additions to C-2 and C-4 of 1-benzothiopyrylium salts have been described, stereoselective syntheses with 1-benzothiopyrylium salts have not been investigated to date.[4, 5] Using a novel method we were able to achieve the highly diastereoselective synthesis of annulated benzothiopyranones *rac*-**4** by the sequential reaction[6] of 4-silyloxy-1-benzothiopyrylium salts **1** with 2-silyloxy-1,3-butadienes **2** (Scheme 1).

Scheme 1. Diastereoselective sequential transformation of 4-silyloxy-1-benzothiopyrylium salts **1** with 2-silyloxy-1,3-butadienes **2** to diastereoselective annulated benzothiopyranones *rac*-**4** (R^1, R^2, R^3 see Table 1, only one enantiomer is shown).



For this purpose, 4*H*-1-benzothiopyran-4-one (**5**)[7] is allowed to react with trialkylsilyl trifluoromethanesulfonates[9]—in analogy to the corresponding O-alkylation with methyl 2-nitrobenzenesulfonate[8]—to form **1** in situ and is then treated with **2** to obtain *rac*-**4** with formation of up to three stereogenic centers (Table 1). The 2-silyloxy-1,3-butadienes **2**[10] can either be used as such or can be prepared in situ by treating the respective methyl vinyl ketone **6** with a trialkylsilyl trifluoromethanesulfonate.[9]

Table 1. Results of the diastereoselective sequential transformations of 4-silyloxy-1-benzothiopyrylium salts **1** with 2-silyloxy-1,3-butadienes **2**.

[a] Salts **1** were formed in situ from **5** and the appropriate trialkylsilyl trifluoromethanesulfonate. [b] Butadienes **2** were formed in situ from the required methyl vinyl ketone **6** and trialkylsilyl trifluoromethanesulfonate. [c] All transformations were performed at reflux in CH_2Cl_2. [d] All compounds were identified by their ^1H NMR, ^{13}C NMR, UV, and mass spectra. The elemental analyses are consistent with the calculated values (see also Table 2). [e] The yields are given for the analytically pure compounds. [f] The by-products **8f–i** were separated from **4f–i** by flash chromatography on silica gel (ether/petroleum ether $^1/_4$–$^1/_8$). [g] **4a** could not be isolated without decomposition upon chromatographic purification on silica gel (ether/petroleum ether 1/8). The yield is based on diketone **7**, which was obtained after acidic hydrolysis of **4a** (10% H_2SO_4, THF, 23 °C, 30 min) and subsequent flash chromatography on silica gel (ether/petroleum ether 1/1).

The transformation of **1a–c** with the unsubstituted 2-silyloxy-1,3-butadienes **2a–c** results exclusively in the highly diastereoselective formation of the *cis*-fused products *rac*-**4a**-*rac*-**4c**. The highest yield of the annulation product is obtained in the reaction of **1c** with **2c**. The trimethylsilyl enol ether *rac*-**4a** cannot be isolated without decomposition, but only as a mixture with its hydrolysis product, the diketone *rac*-**7**.

[**] This work was supported by the Fonds der Chemischen Industrie and the Universität Göttingen. H. G. thanks the Fonds der Chemischen Industrie for a doctoral fellowship. We thank Professor Tietze for his generous support and continuous interest.

The transformations of **1c** with the 4-substituted and the 3,4-disubstituted 2-silyloxy-1,3-butadienes **2d**–**k** are specially noteworthy, since of the four possible diastereomers only the all-*cis* diastereomers *rac*-**4d**-*rac*-**4k** are formed with high diastereoselectivity in these reactions (Table 1). The 4-methoxy, 4-aryl, 4-heteroaryl, and 3,4-disubstituted cyclic compounds were converted into *rac*-**4d**-*rac*-**4k** in 68–91% yield. In the reactions of **2f**–**i**, by-products *rac*-**8f**-*rac*-**8i** were isolated in 3–15% yield.

The *cis*-configuration of the ring fusion in *rac*-**4a**-*rac*-**4k** is supported by the vicinal coupling between 4a-H and 9a-H in the ^{1}H NMR spectra, which is found to be J = 3.2 Hz for *rac*-**4c** (Table 2). The relative configuration at C-1 in *rac*-**4d**-*rac*-**4k** was determined by crystal structure analysis of *rac*-**4e**.[11] It is remarkable that the coupling constants ^3J (1-H, 9a-H) of up to J = 7.5 Hz in *rac*-**4d**-*rac*-**4k** are relatively high for the *cis* fusion between 1-H and 9a-H.

The formation of *rac*-**4** can be explained by a sequential 1,2- and 1,4-addition. We presume that the first step of this reaction sequence is an intermolecular 1,2-addition of the silyl enol ether functionality in **2** to the C=S$^+$ bond in **1**, forming the intermediate *rac*-**3**. The resultant Michael system subsequently undergoes an intramolecular 1,4-addition to the silyl enol ether functionality to give *rac*-**4**. The observed complete diastereoselectivity in the transformation of **1** and **2** to *rac*-**4** can be explained with the transition state structure depicted in Figure 1.

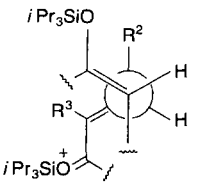

Fig. 1. Newman projection of the transition state structure for the reaction of **1** and **2** to *rac*-**4**.

An alternative to the proposed sequential mechanism is an intermolecular Diels–Alder reaction. The two-step mechanism of the reaction is supported by several experimental observations: In the transformation of **1c** with **2f**–**i**, products *rac*-**8f**-*rac*-**8i** that can be derived from the intermediates *rac*-**3f**-*rac*-**3i** are formed in yields of 3–15% (Table 1).

Furthermore we were able to obtain the 1,2-adduct *rac*-**9e** by treating **5** with **2e**.[12] This adduct reacts with 2,6-lutidinium triflate and triisopropylsilyl trifluoromethanesulfonate (TIPSOTf) to yield the all-*cis* product *rac*-**4e** in a highly diastereoselective intramolecular 1,4-addition, the same product that is formed in the one-pot synthesis of **1c** with **2e**. Regardless of the mechanism, the reactions of the 4-silyloxy-1-benzothiopyrylium salts and the 2-silyloxy-1,3-butadienes introduced herein provide a preparatively simple and highly diastereoselective access to annulated benzothiopyranones. Currently we are investigating whether the double activation of benzothiopyranones as 4-silyloxy-1-benzothiopyrylium salts can be applied in the synthesis of 2,3-*trans*-substituted 2,3-dihydro-4*H*-1-benzothiopyran-4-ones.

[a] All compounds gave correct elemental analyses or high-resolution mass spectrometric data (**8f**).

Experimental Procedure

Trialkylsilyl trifluoromethanesulfonate (1.5 mmol, 1.5 equiv) was added to 4*H*-1-benzothiopyran-4-one (**5**, 1.0 mmol) by syringe under argon, and the reaction mixture was heated at 70 °C for 1 h without stirring. Subsequently the mixture was allowed to cool, dichloromethane (2 mL), 2,6-lutidine (2.0 mmol), trialkylsilyl trifluoromethanesulfonate (0.6 mmol, 0.6 equiv), and a solution of the α,β-unsaturated ketone **6** (1.3–1.5 mmol) in dichloromethane (2 mL) were added consecutively, and the mixture was heated to reflux. After complete conversion (monitored by TLC), the reaction solution was allowed to cool, then 10 mL of an ice cold 5% sodium hydrogencarbonate solution was added, and the mixture quickly extracted with ice cold dichloromethane (three 10 mL portions). The complete workup must

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0606-0648 $ 10.00+.25/0

be performed under argon. After drying the combined organic layers over sodium sulfate and removing the solvent, the crude product was obtained, which was purified by flash chromatography on silica gel (50 g). Subsequent recrystallization provided compounds **4** in analytically pure form.

Structure Determination in the Twilight Region Between Monolayers and 3-D Crystals; a Grazing Incidence X-Ray Diffraction Study of Nanocrystalline Aggregates of α,ω-Docosanediol at the Air–Water Interface**

Jaroslaw Majewski, Ron Edgar, Ronit Popovitz-Biro, Kristian Kjaer, Wim G. Bouwman, Jens Als-Nielsen, Meir Lahav, and Leslie Leiserowitz*

The understanding and control of three-dimensional (3D) crystal nucleation is of fundamental importance in pure and applied sciences. Direct observation of primarily formed, structured aggregates that may eventually lead to macroscopic crystals is therefore essential. From the crystallographic point of view, such nuclei present a challenge as a result of the complex diffraction patterns caused by limited repeat in certain directions and by imperfect order.

Previously certain amphiphiles and bolaamphiphiles[1] were shown to aggregate spontaneously into multilayered crystalline structures when spread at zero surface pressure on the water or formamide surface; their packing arrangements were not determined.[2–4] Here we report the application of grazing incidence synchrotron X-ray diffraction (GID) for the determination of the packing arrangements of crystalline aggregates of the bolaamphiphile α,ω-docosanediol ($HO(CH_2)_{22}OH$, C_{22} diol) which is spread more than one layer thick on the water surface.[3] This experimental approach has three unique virtues. Confining the layer to a water surface imposes physical boundary conditions to the molecules, which supports self-aggregation by reducing the number of degrees of freedom and allows formation of stable clusters. Moreover, in the GID experiment the penetration of X-ray beam is limited almost to the surface layer, which effectively eliminates background from the subphase.[5] Finally, it proved possible to examine by GID the effect of inhibition of growth of multilayer crystallites leading to a monolayer phase, which was achieved by the use of auxiliary molecules present in the spreading solution.

The long-chain diols $HO(CH_2)_nOH$ were chosen for study by GID in view of their ice-nucleating properties[6] and the possibility of elucidating the crystal structure if the interchain packing properties and hydrogen-bonding requirements were also taken into account. The GID data from the C_{22} diol were measured at 70, 100, 200% of the surface coverage necessary for a monolayer,[7, 8] with no detectable surface pressure. The Bragg reflections in the GID powder pattern of C_{22} diol are shown in Figure 1a. The q_z widths of the z component of the Bragg reflections, the Bragg rods, (shown in Fig. 1b) correspond to crystallites with an average thickness of two layers.[9] The positions of the two Bragg peaks at $q_{xy} = 1.52$ and $1.72\ \text{Å}^{-1}$ ($q_{xy} = 2\pi/d$, where d is the spacing between scattering planes) lead to a rectangular cell with $a = 5.04$ Å and $b = 7.30$ Å; thus the two reflections are indexed as {1,1} and {0,2} respectively. These cell dimensions are characteristic evidence of a herringbone

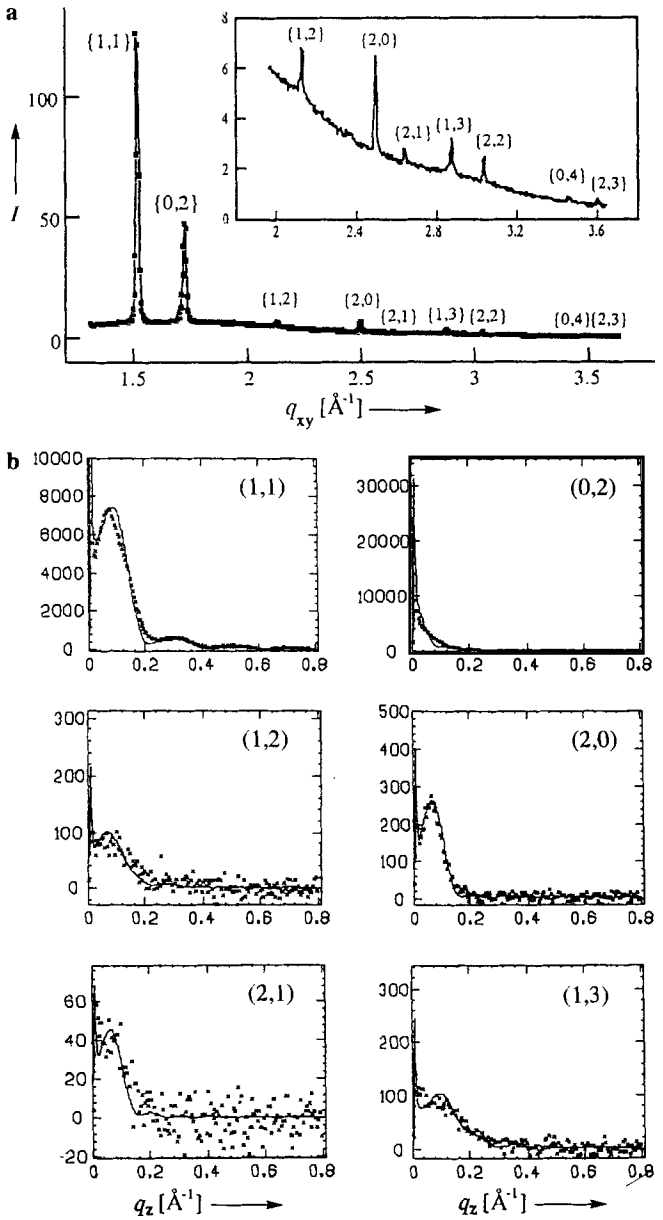

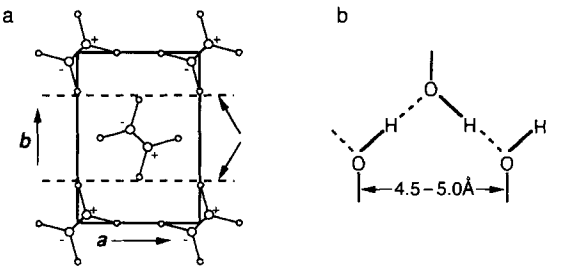

Fig. 1. a) The Bragg reflections in the GID powder pattern of the C_{22} diol on water, measured at 200% coverage (assuming monolayer formation). The inset shows an expanded view of the higher order reflections. The reflections were obtained by scanning along the horizontal scattering vector q_{xy} and integrating the intensity along the vertical scattering vector q_z. I in 1000 counts. b) Observed (×) and calculated (full line) intensity profiles of the z component of the Bragg reflections (Bragg rods) of the C_{22} diol (six of the nine Bragg rods are shown), obtained by recording the intensity distribution along q_z while integrating across the appropriate Bragg peak in q_{xy}. The fit was calculated for the molecular packing arrangement of the bilayer shown in Fig. 3 and described in the text. In each case the ordinate represents the relative intensity.

motif[10] of hydrocarbon chains in an all-*trans* conformation, generated by glide symmetry in the unit cell.

The intensity profiles of the Bragg rods show that the molecular chains are aligned almost perpendicular to the water surface, which is in agreement with the cell dimensions. The observation that the Bragg rod for the {0,2} reflection peaks at $q_z \approx 0$ Å^{-1} and that the {1,1} and {2,0} reflections both peak at $q_z \approx 0.08$ Å^{-1} indicate that the chains are slightly tilted along the a direction. Consequently the molecules within an ab layer must be related by an a glide[11] forming the herring-bone motif (Scheme 1a). In such an arrangement, the hydrocarbon chain

Scheme 1. a) Glide plane along a (dashed lines indicated by arrows) and the resulting herringbone pattern of the C_{22}-diol layers. For an explanation of the representation of the molecule, see legend of Figure 2 and the text. b) Definition of the repeat distance of hydrogen bonds.

axes must be parallel to one another and lie halfway between the neighboring glide planes to ensure good packing.[12] The molecular centers for the bottom layer are thus positioned at $x,y = (0,0)$ and $(1/2,1/2)$. A reasonable starting model of a second layer that would produce a strong {0,2} reflection would require the chain axes of the bottom and top layers to line up when viewed along the a axis. Consequently, the centers of the molecules of the second layer must also lie halfway between the neighboring a glide planes as for the first layer. Therefore the a glide planes coincide for the two layers as they would in a regular 3D crystal; the y coordinates of the centers of the two molecules in the top layer are 0 and 1/2. To fix the interlayer separation and the layer offset along the a direction we take advantage of the hydrogen bonding requirements. The repeat distance in an O–H···O chain motif involving OH groups varies from 4.5 to 5.0 Å (Scheme 1b); such an arrangement may be achieved by centers of inversion or twofold axes in space groups $P2_1/a$ and $A2/a$, respectively[13] (Fig. 2).

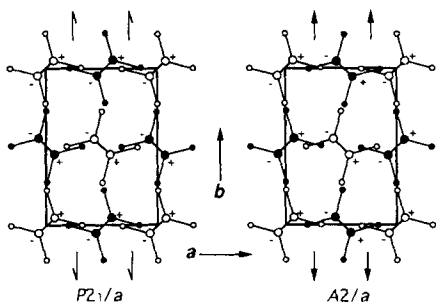

Fig. 2. Schematic views along the molecular axis showing the packing arrangements of two layers of the C_{22} diol in space groups $P2_1/a$ and $A2/a$. For convenience, only the hydrogen atoms of the chain and the two oxygen atoms are depicted. The open and filled circles represent the lower and upper layer respectively. The plus (+) and minus (−) signs at the oxygen atoms mark their difference in height within each layer. In space group $P2_1/a$ the a glide planes intersect the b axis at $y = 1/4$, 3/4 as shown in Scheme 1a. The crystallographic centers of inversion ($\bar{1}$) coincident with the molecular centers of inversion lie halfway between the glide planes. The twofold screw axes (2_1, →), which lie at $z = 0$, are generated by the combination of the a glide and $\bar{1}$ symmetry elements. The two neighboring molecular layers are related by translation along the c axis (which is not necessarily perpendicular to the ab plane in space group $P2_1/a$). In space group $A2/a$, the two neighboring molecular layers (each of which contains a 2_1 axis as in $P2_1/a$) are related by twofold axes (2, ⟶) at $z = 1/4$. Note that the space group symbol A specifies molecular translation of neighboring layers along the diagonal $1/2(b + c)$.

The corresponding molecular models for two layers were generated,[14] their X-ray structure factors calculated,[16] and the models refined by adjusting the relative positions of the layers along the a axis to fit the observed Bragg rod data[17] and best

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0606-0650 $ 10.00+.25/0

satisfy hydrogen-bonding geometry. The latter constraint also enabled us to fix the absolute orientation of the molecular chain about its long axis; only one of the two possible azimuthal angles gave reasonable interlayer O–H···O hydrogen bonding.[18] Furthermore, the intralayer *a* glide plane was allowed a minor relaxation by leaning the *a* glide planes by an angle δ away from the plane perpendicular to the water surface[19] to obtain the best fit of the Bragg rod profiles. The packing arrangement for this bilayer of symmetry slightly relaxed from $P2_1/a$ is shown in Figure 3, and the corresponding Bragg rod fit

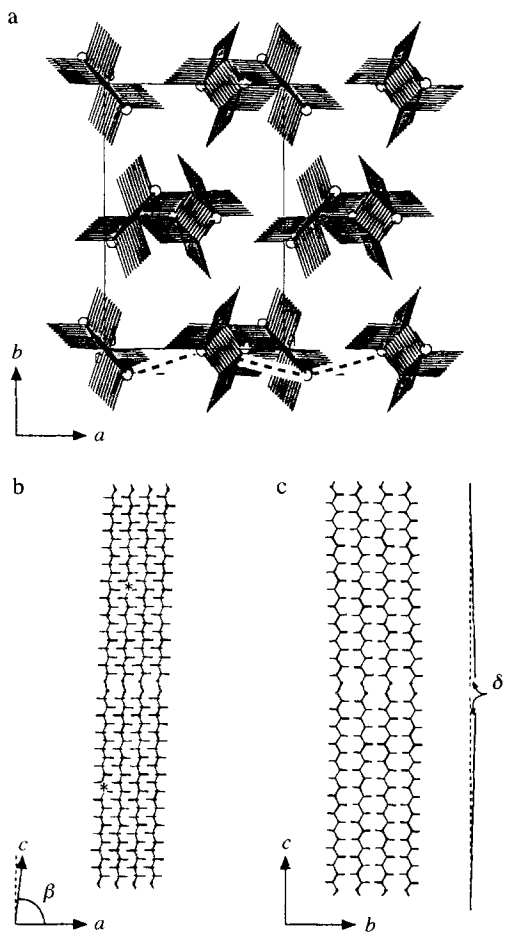

Fig. 3. Bilayer packing arrangement of the molecular model of C_{22} diol in a pseudo $P2_1/a$ space group. a) View perpendicular to the *ab* plane. Dashed lines show the hydrogen-bonding pattern along the *a* axis. The calculated distances between the hydrogen-bonded oxygen atoms are 2.5 and 3.4 Å. These two values can easily be brought to a satisfactory hydrogen-bonding mean of approximately 2.9 Å by minor adjustments in molecular tilt, rotation about the molecular axes, or conformation. b) View along the *b* axis. The length of the *c* "axis" is given by the distance separating the two asterisks placed on the molecular centers of two molecules in the top and bottom layers. c) View along the *a* axis. The layers were made to lean in opposite directions by an angle δ for the best fit to the Bragg rod data.

in Figure 1 b.[20, 21] In this model structure the two layers are related by a "pseudo-translation" axis *c*, with unit cell dimensions $a = 5.04$ Å, $b = 7.30$ Å, $c = 30.2$ Å, $\alpha = 90°$, $\beta = 84°$ and $\gamma = 90°$.

Inhibition of multilayer formation was accomplished by introducing 10% of the monoalcohol $C_{24}H_{49}OH$ into the initial solution and spreading the material for 100% monolayer coverage. The idea was to use an amphiphilic additive that might mix with the host matrix through favorable lateral interactions, but might hinder the interlayer interactions and thereby inhibit multilayer buildup (Fig. 4). Two major phases,[22] a mono- and a multilayer (α and β respectively), now appear in the X-ray scattering intensity map $I(q_{xy}, q_z)$. These two phases have overlapping {1,1} reflections but resolved {0,2} reflections that are easily assigned to their appropriate phase by the widths of their corresponding Bragg rods and q_{xy} positions. The calculated occupancy of the two phases indicates that only about 15% of the coverage is attributable to the double layer; the rest is occupied by monolayer.[23]

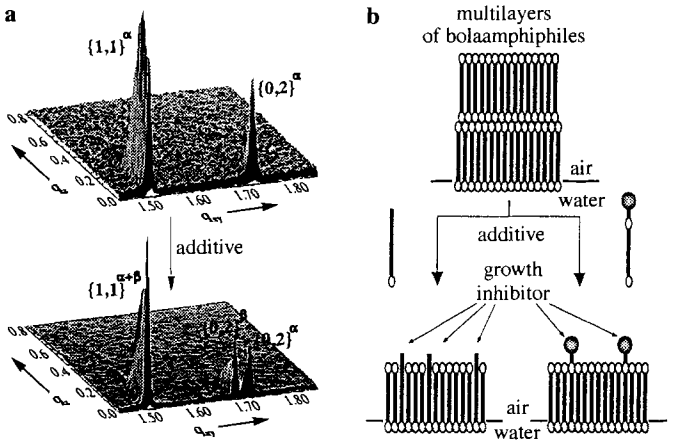

Fig. 4. a) Two-dimensional intensity distribution $I(q_{xy},q_z)$ of the diffraction pattern of 100% surface coverage of pure C_{22} diol (top) and C_{22} diol containing 10% of $C_{24}H_{49}OH$ (bottom) on the water subphase (also spread for 100% surface coverage), as a function of the horizontal (q_{xy}) and vertical (q_z) scattering vectors. Only the {1,1} and {0,2} Bragg rods are depicted. The α and β phases are bilayer and monolayer structures, respectively. b) Scheme showing inhibition by the two kinds of additive of bilayer formation (top) of C_{22} diol yielding monolayer (bottom).

The GID pattern of the C_{22} diol was also measured with $HO(CH_2)_{22}OCH_2C_6H_5$ as additive. This additive was far more effective than $C_{24}H_{49}OH$, by virtue of the bulky phenyl group: only 5% almost completely inhibited multilayer formation.

In this report we have demonstrated the use of GID, complemented by molecular packing and hydrogen-bonding considerations, for the determination of the probable "space groups" and molecular packing arrangement of the crystalline aggregates, only a few layers thick.[24] Clearly, the film formed comprises islands of bilayer in equilibrium, presumably with pure water surface, in the range of surface coverage from 70% to 200%. We cannot however, rule out the presence of minor amounts of multilayer and monolayer material. The bilayer islands have an average translational coherence length in the range of 400–1000 Å. A relaxation of crystal symmetry, commonly observed by means of GID in amphiphilic monolayers, is also found in the bilayer systems, although the extent and the causes thereof, in terms of possible influence of the water subphase, requires further investigation.

The analysis of this structure has also allowed a determination of the absolute orientation of the diol chains; such configurations for monolayers of simple chainlike molecules are almost impossible to ascertain from analysis of the GID data. In spite of the meager amount of diffraction data compared to that from 3D crystals, the derived models were based on very few assumptions. We may state that the layer structure is unambiguously determined by the unit cell dimensions and the interlayer hydrogen-bonding requirements. However, an ambiguity arose in fixing the interlayer structure, yielding two possible arrangements, both of which could be fitted to the *z* component of the Bragg data.

[7] The GID measurements were performed at the BW1 wiggler beamline at HASYLAB, DESY, Hamburg, Germany, on a liquid surface diffractometer. A beam of wavelength 1.35 Å was incident at a grazing angle slightly below the critical angle for total external reflection. This geometrical configuration enhances surface sensitivity. The footprint of the X-ray beam on the water surface was 5 × 50 mm. The backgound level of scattering was reduced by a He atmosphere inside the trough. Detection of both the horizontal (q_{xy}) and vertical (q_z) components of the diffracted beam was done by a vertical oriented position-sensitive detector (q_z resolution) mounted behind a Soller collimator giving q_{xy} resolution. The bolaamphiphiles were spread at room temperature from 5×10^{-4} M chloroform solution over the Millipore-filtered water contained in a Langmuir trough mounted on the diffractometer. GID measurements were performed after cooling of the subphase to 5 °C. More experimental details are given in Ref. [12].

[8] The GID pattern for 70, 100, and 200% surface coverage were essentially the same, differing only in intensity and thus in the number of observable peaks.

[9] Two layers are found by GID in contrast to the two to five layers of the C_{22} diol observed after deposition on mica, by atomic force microscopy [2]. We may reconcile this difference by bearing in mind that the multilayers are prepared under dynamic conditions away from equilibrium, and so slight changes in temperature, pressure, and support may lead to structural differences.

[10] D. M. Small in *Handbook of Lipid Research, Vol. 4*, Plenum, New York, **1986**.

[11] The *b* glide is ruled out since it would lead to a crisscrossed arrangement of chain axes and so to a poor packing, which has not yet been observed. Moreover, such a packing would not fit the Bragg rod profiles.

[12] F. Leveiller, D. Jacquemain, L. Leiserowitz, K. Kjaer, J. Als-Nielsen, *J. Phys. Chem.* **1992**, *96*, 10380.

[13] The inversion centers and twofold axes are crystallographically correct for the molecular chains, but only statistically correct for the hydroxyl hydrogen atoms in the hydrogen-bonding chain (Scheme 1b), which must be disordered as in the 3D crystal structures of hexagonal ice [15a], methanol [15b], $C_{16}H_{33}OH$ [15c], and $C_{24}H_{49}OH$ [15d]. A completely ordered O–H···O hydrogen-bonded system with identical O–H···O repeat along the hydrogen-bond chain axis *a* may be achieved with a twofold screw axis parallel to *a*. Such an arrangement would yield the commonly observed orthorhombic space group *Pcab*, but was found not to fit the GID data, which requires all the chains axes to be tilted in the same direction vis-a-vis the *a* axis.

[14] The best fit of the calculated Bragg rod intensity profiles to the observed data was obtained for an interlayer offset along the *a* axis of 3.3 Å and an interlayer separation of 30 Å. Furthermore, modeling with one or three layers yielded calculated Bragg rods with shapes distinctly different from those of the observed data.

[17] Model structures made up of one or three layers did not fit the observed Bragg rod data satisfactorily. We also note that for the given grazing incidence geometry the intensity of the X-ray beam falls off exponentially with depth of penetration of a value I_0/e (where I_0 is the intensity of the incident beam) for the depth $\Lambda \approx 90$ Å. If the thickness of the multilayer crystallites is less than 2 Λ, the shape of the Bragg rod is barely affected by the limited penetration depth. Furthermore the shape of the two-dimensional contour of the diffracted intensity $I(q_{xy},q_z)$ of the various reflections (not presented here) show that the *ab* plane of the multilayer crystallites are primarily parallel to the water surface. There is, however, some tendency for deviation therefrom. If such a spread of crystalline misorientation from the plane of water surface is pronounced, it would give rise to an apparent broadening of the Bragg rods along q_z, which would have to be treated in a detailed analysis (K. Kjaer, W. G. Bouwman, unpublished work).

[18] For a chainlike hydrocarbon molecule the limited number of observable peaks in the GID data does not allow one to differentiate between two structures differing in orientation by 180° about the long molecular axis unless other criteria are introduced.

[19] This reduction in crystal symmetry was found to be necessary for a good fit to the GID data of monolayer structures of several amphiphilic molecules on water [12, 15d]. In the multilayer C_{22}-diol structure the lean angles for the first and second layers were in opposite directions. In the refined structure the molecular chains are tilted by 1.5° along the *a* axis and leaned by 1.5° along the *b* axis.

[20] In this packing the center of inversion and twofold axes relating the two layers in the two space group are lost. Moreover, the relaxation of the $P2_1/a$ (or $A2/a$) symmetry is also manifested by the presence of an observed but very weak symmetry-forbidden {1,0} reflection.

[21] The results for symmetry relaxed from $A2/a$ are very similar to that for $P2_1/a$ and so are not shown here.

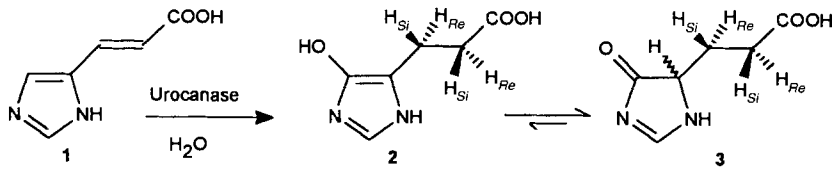
[22] In addition to α and β phases a minor γ phase exhibiting two very weak Bragg rods was observed. Their intensities were approximately one hundredth those of the major phases. The q_{xy}, q_z positions of these two Bragg rods indicate a rectangular unit cell of dimensions $a = 5.08$ Å, $b = 8.73$ Å. Modeling yielded multilayer (trilayer) structure with the molecules tilted by about 30° from the vertical in the *b* direction.

[23] The intensity profiles of the {0,2} and {2,0} (not shown in Fig. 4a) reflections of monolayer phase α were used to derive a model of its structure. The calculated intensity contribution of this model structure was subtracted from the intensity profile of the unresolved {1,1} reflection. The remaining intensity profile together with the resolved {0,2} reflection of the β phase was well fitted to the calculated structure of the bilayer previously determined (Fig. 3). The unit cell of the monolayer was found to differ slightly from that of the double layer: $a = 5.0$, $b = 7.43$ Å.

[24] A detailed determination of the multilayer structure would also benefit from atom–atom potential energy calculations as carried out on the amphiphilic monolayer structures [12].

[25] The structures of the C_{16}, C_{23}, and C_{30} diols will be reported elsewhere.

On the Mechanism of Action of Urocanase: Observation of the Enzyme-Bound NAD^+–Inhibitor Adduct by ^{13}C NMR Spectroscopy**



Carsten Schubert, Herbert Röttele, Manfred Spraul, and János Rétey*

Urocanase (E.C. 4.2.1.49) catalyzes the second step in the degradation of histidine in most cells (Scheme 1) and contains a tightly bound NAD^+ which is essential for catalytic activity.[1, 2] NAD^+ is supposed to function as an electrophilic catalyst and forms a transient covalent adduct with the imidazole ring of the substrate, urocanic acid (**1**).[3] According to the mechanism postulated by us,[3–5] the unusual addition of water leading to 5′-hydroxyimidazolepropionic acid **2** occurs in a chemically

plausible manner. Intermediate **2** is in a spontaneous equilibrium with imidazolonepropionic acid **3**.[6]

Recently we determined the structure of an NAD^+–inhibitor adduct, which is formed on urocanase and is most likely analogous to the transient NAD^+–substrate adduct, by measuring the one-bond ^{13}C-^{13}C coupling constants.[5] Because of its instability the double ^{13}C-labeled adduct had to be stabilized by oxidation while still bound to the enzyme and was subsequently separated from the enzyme.[4, 7]

Here we report on our direct observation of the native adduct in the enzyme-bound state for which we used difference ^{13}C NMR spectroscopy. To enhance the relevant ^{13}C signals both position 4 of the prosthetic NAD^+ and position 5′ of the inhibitor were enriched with ^{13}C. In a first experiment we applied urocanase containing (4-^{13}C)NAD^+ (99% ^{13}C). In the 150 MHz ^{13}C NMR spectrum the enzyme-bound (4-^{13}C)-NAD^+ gives rise to a broad signal at $\delta = 146$ (Fig. 1). After

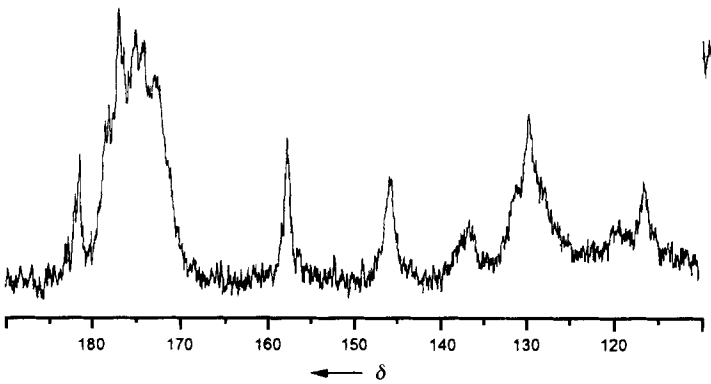

Fig. 1. Low-field portion of the 150 MHz ^{13}C NMR spectrum of the (4-^{13}C)NAD^+-containing urocanase. The broad signal at $\delta = 146$ stems from the C-4 atom of the nicotinamide moiety (99% ^{13}C). Approximately 120 mg (0.99 μmol) of urocanase in 2 mL of 50 mM K_2HPO_4 buffer, pH 7.5, H_2O/D_2O 8:1, 10 mm NMR tube, ^1H broadband decoupled, line broadening = 10 Hz, $T = 300$ K, 30 000 transients.

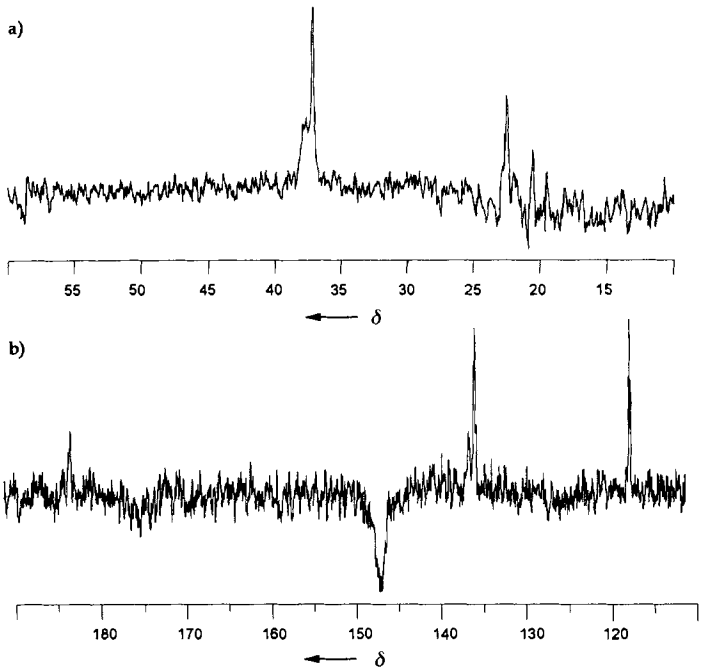
addition of unlabeled imidazolepropionic acid in tenfold excess (fivefold excess with respect to the active sites) the signal at $\delta = 146$ largely disappears, while at the same time a new, likewise broad signal at $\delta = 37.7$ arises. This indicates that practically all active sites are occupied by the inhibitor and is most clearly seen in the difference spectrum (Fig. 2). Besides the sharp ^{13}C NMR signals of the excess unbound imidazolepropionic acid, one observes the signal of the ^{13}C-4 atom of the enzyme-bound (4-^{13}C)NAD^+–imidazolepropionate adduct (**4** or **4a**; Scheme 2) at $\delta = 37.7$. For comparison: The C-4 atom of NADH **5** resonates at $\delta = 21.9$, whereas that of C-4 phosphorylated dihydropyridine derivative **6** appears at $\delta = 78.7$.[8]

In a further experiment, in which instead of NAD^+ now the inhibitor, imidazolepropionic acid, was labeled with ^{13}C in the 5′ position, the observation of the enzyme-bound adduct was confirmed, and the chemical shift of the C-5′ atom was determined. In the difference spectrum (Fig. 3) two ^{13}C NMR signals are observed in the region between $\delta = 80$ and $\delta = 120$, namely at $\delta = 117$ and at $\delta = 87.5$ for the free and the bound (5′-^{13}C) imidazolepropionic acid, respectively. The large highfield shift of the C-5′ signal indicates that the imidazole ring in the enzyme-bound adduct is not aromatic; in other words the adduct has structure **4a**.



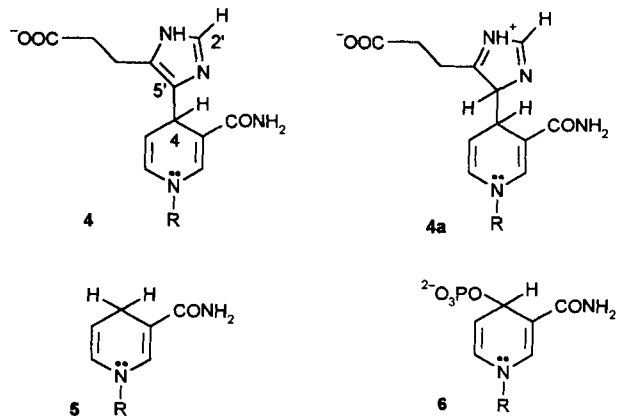


Fig. 2. ^{13}C NMR difference spectrum of (4-^{13}C)NAD^+-containing urocanase (after – before) addition of 9.9 μmol of imidazolepropionic acid. a) High-field portion, b) low-field portion. The broad signal at $\delta = 37.7$ arises from the enzyme-bound (4-^{13}C)NAD^+–imidazolepropionate adduct.

Scheme 2. Possible structures of the enzyme-bound NAD^+–imidazolepropionate adduct **4** and **4a** and structures of NADH **5** and of the NAD–4-phosphate adduct **6**. R = adenosine diphosphate ribosyl.

The preference of **4a** over **4** at the active site can be explained by an ionic interaction of a negatively charged group of the enzyme and the positively charged nitrogen atom of the imida-

$[R_3Si-arene]^+$ σ Complexes in the Gas Phase**

Fulvio Cacace,* Marina Attinà, and Simonetta Fornarini

The report by Lambert et al.[1] that an R_3Si^+ ion that is not coordinated to the anion and only weakly to the solvent exists in the solid $[Et_3SiB(C_6F_5)_4 \cdot$ toluene$]$ has stirred a controversy, mainly focused on the role of toluene.

Schleyer et al.,[2] in agreement with Olah et al.,[3] argue that the compound is actually a salt of the arenium ion $[Et_3Si \cdot$ toluene$]^+$, that is, a σ complex of type **1**. According to Pauling,[4] in the compound studied by Lambert et al.[1] a covalent bond does exist between the Si atom and the *para* C atom of toluene molecule, despite their large separation (2.18 Å), and a significant fraction of the positive charge of Et_3Si^+ is transferred to the aromatic ring. Reed et al.[5] recognize the existence of a covalent interaction between the Et_3Si group and the toluene molecule and assign the adduct the structure of a π complex with an sp^2 carbon (**2**), rather than of the σ complex **1** with an sp^3 carbon.

Discrimination between the above structures is difficult, since it is necessarily based on certain critical parameters such as the Si-C-C_{para} angle, whose values deduced from crystal structure analysis happen to be intermediate between those expected for unperturbed ions **1** and **2**. Indeed, the intrinsic structural features of the ions in the crystal lattice are affected by interactions with neighboring molecules, which detracts from the generality of the conclusions and may account for their inconsistency with the results of theoretical calculations on free, unperturbed species found exclusively in the gas phase.[6]

We have addressed the problem by investigating in the gas phase the same $[R_3Si$-arene$]^+$ adducts studied in the solid state by the radiolytic technique[7] and by the FT-ICR (ICR = ion cyclotron resonance) mass spectrometry. The reaction sequence shown in Scheme 1 in which B denotes a gaseous base or nucleophile was used.

$$R_3Si^+ + C_6X_5R^1 \longrightarrow [R_3Si{-}C_6X_5R^1]^+ \quad (I)$$

$$[R_3Si{-}C_6X_5R^1]^+ + B \longrightarrow R_3SiB^+ + C_6X_5R^1 \quad (II)$$

$$[R_3Si{-}C_6X_5R^1]^+ + B \longrightarrow R_3SiC_6X_4R^1 + BX^+ \quad (III)$$

(R = Et, *i*Pr; R^1 = X, CX_3; X = H, D)

In the radiolytic experiments, the *i*-$C_3H_7^+$ ions from the γ irradiation of gaseous mixtures containing C_3H_8 as the bulk component react with R_3SiH to give R_3Si^+ ions, which react with toluene according to (I) to yield $[R_3Si{-}C_7H_8]^+$ adducts. The latter, efficiently deactivated by thermalization in the dense gas, undergo reactions (II) or (III) or both with the bases and nucleophiles present in the system, yielding neutral products that are analyzed by GC/MS.[7] The composition of typical systems and the yields of the products, expressed by their G_{+M} values (molecules formed per 100 eV), are reported in Table 1. In the absence of added bases, only cymenes are formed from

Table 1. Gas-phase trialkylsilylation of toluene [a].

the direct alkylation of toluene by $i\text{-}C_3H_7^+$; the yields of silylated products are negligible. Formation of *m*- and *p*-trialkylsilyltoluenes can only be observed when nitrogen bases such as Et_3N or pyridine are added to the gas.

Such observations can be explained by the presence of oxygenated nucleophiles that are either invariably in the system as adventitious impurities (H_2O), or formed by the radiolysis (H_2O, CH_2O, CH_3OH, $(CH_3)_2CO$, etc.), or deliberately added ($(CH_3O)_3PO$). These nucleophiles exclusively promote desilylation (II),[8] thus preventing formation of neutral silylated products. The addition of strong bases such as Et_3N or pyridine has two opposite effects. On one hand it allows formation of silylated products by deprotonation (III). On the other, the base efficiently intercepts the charged electrophiles $i\text{-}C_3H_7^+$ and R_3Si^+ and depresses the yields. This accounts for the peculiar dependence of the silylation yields on base concentration, normally characterized by a maximum that is observed at pyridine pressures of 0.5–1.5 Torr under the experimental conditions typical for analogous radiolytic reactions.[8b, 8c, 8d] The ionic character of the silylation process is demonstrated, inter alia, by the negligible yields of products unless an appropriate base was deliberately added, which ruled out contributions from neutral, radiolytically formed reactive species, such as radicals and excited molecules. The radiolytic results indicate that at least a fraction of the $[R_3Si\text{–}C_6X_5R^1]^+$ adducts react with the base according to reaction (III), which is typical of ions having the σ complex structure **1**.

In the FT-ICR MS approach, a typical experiment involves formation of Et_3Si^+ ions by ionization of Et_3SiH and their reaction with C_6D_6, introduced by a pulse valve. In this way a benzene pressure of about 10^{-5} Torr is obtained, albeit for only 5×10^{-3} s, which allows partial collisional stabilization of the $[Et_3Si\text{–}C_6D_6]^+$ adducts from reaction (I).[9] Following removal of C_6D_6, all ions except the adduct are ejected by repeated, low-power radiofrequency pulses. This isolation procedure is designed to be as fast and mild as possible to minimize losses of $[Et_3Si\text{–}C_6D_6]^+$ ions and reduce their unintentional off-resonance excitation. In this way $[Et_3Si\text{–}C_6D_6]^+$ ions that are sufficiently thermalized to prevent extensive fragmentation are isolated. The reaction of the isolated $[Et_3Si\text{–}C_6D_6]^+$ cations with the neutral species present in the cell (Et_3SiH, Et_3N, and traces of adventitious water) gives a complex pattern of products (Fig. 1). Products $[Et_3SiNEt_3]^+$ and Et_3ND^+ of both processes (II) and (III) are detected. The other charged products have been shown by control experiments to arise from the reactions of Et_3Si^+, initially formed by the fragmentation of a minor fraction of excited $[Et_3Si\text{–}C_6D_6]^+$ adducts, or from the reactions of the latter with Et_3SiH.

The above FT-ICR MS results are significant, since in the first place they demonstrate directly the individual steps of the reaction sequence (I)–(III). Furthermore, insight into the structure of $[Et_3Si\text{–}C_6D_6]^+$ adducts is provided by applying a general criterion whose validity has been recently verified in the specific case of aromatic silylation:[8c] π complexes such as **2** react exclusively according to ligand exchange (II), whereas σ complexes such as **1** can undergo both reactions (II) and (III). According to this criterion, the FT-ICR MS experiments indicate that σ complex **1** must be formed from reaction (I), since D^+ transfer from $[Et_3Si\text{–}C_6D_6]^+$ to Et_3N does occur. The concurrent Et_3Si^+ transfer can be traced either to the presence of the π complex **2**, and/or to the fact that **1** not only reacts according to (III) but also according to (II).

In conclusion, the actual isolation of the silylated neutral products from radiolytic reactions and the mechanistic insight from FT-ICR mass spectrometry provide compelling evidence

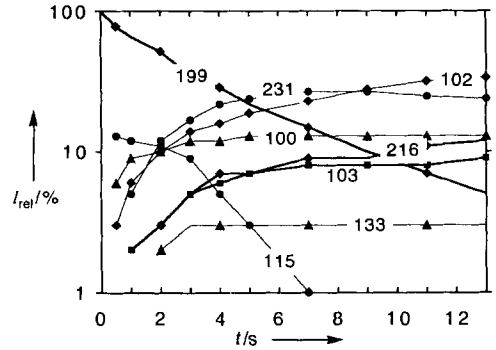

Fig. 1. Plot of the logarithm of the normalized intensities of the most intense peaks in the ICR mass spectrum as a function of the reaction time. Total pressure in the cell 1.5×10^{-8} Torr, Et_3N partial pressure 4×10^{-9} Torr, temperature 300 K. *m/z*: 199 $[Et_3SiC_6D_6^+]$, 100 $[Et_3N-H^+]$, 102 $[Et_3NH^+]$, 103 $[Et_3ND^+]$, 216 $[Et_3NSiEt_3^+]$, 133 $[Et_3SiOH_2^+]$, 231 $[Et_3SiEt_3SiH^+]$.

for the existence of σ complexes **1**. This is particularly relevant to the current debate on the structure of $[R_3Si\text{–arene}]^+$ adducts, since the gas phase is the only medium where free cations, unperturbed by environmental factors, can exist.[8, 10] Nevertheless, the present results do not rule out the existence of π complex **2**, for example, as species in equilibrium with the corresponding σ complex **1**.

Experimental Procedure

The gaseous samples for the radiolytic experiments were prepared in sealed glass vessels by described procedures[7] using commercial research grade products, Et_3SiH, iPr_3SiH, $(MeO)_3PO$, Et_3N, iPr_2NEt, pyridine, toluene, [D_8]toluene, benzene, and [D_6]benzene from Aldrich Chimica and CH_4, C_3H_8, and O_2 from Matheson Gas Products. The irradiations were carried out at 80 °C in a ^{60}Co 220 γ-cell from Nuclear Canada. The total dose was 1×10^4 Gy. The solution of the radiolytic products in cyclohexane was analyzed by GLC-MS on a fused silica column 50 m long with 0.2 mm inner diameter and coated with a 0.5 μm cross-linked methylsilicone film. A Hewlett Packard 5890 gas-chromatograph and a HP 5970B mass selective detector with internal standard ($PhSiMe_3$) calibration was used. The ICR MS experiments were performed with a Bruker Spectrospin Apex TM 47e FT-MS instrument equipped with an external ion source, a cylindrical (60 mm length, 60 mm diameter) "infinity" cell and a 4.7 T superconducting magnet. Duplicate experiments were performed with an EXTREL FTMS 2001 mass spectrometer, equipped with an Odissey Data Station and a FTMS autoprobe.

[6] For example, the C-Si-C angle in the Et_3Si group in **1**, R = Et, is not 120° as expected for a free Et_3Si^+ ion but an average of 114° according to the crystal structure analysis. This difference has been traced to the interaction of the ion with the "distant" toluene molecule; see ref. [1].

A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1′-Ferrocenedithiolato Complexes**

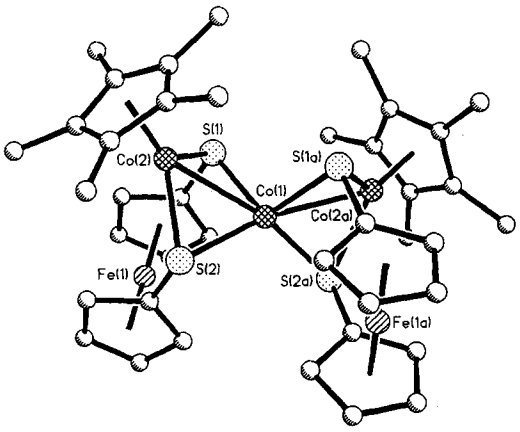
Max Herberhold,* Guo-Xin Jin, and Arnold L. Rheingold

Tricobalt complexes with either bridging sulfido or organothiolato ligands generally contain a closed Co_3 triangle;[1] well-known examples include $[\{Co(CO)_3\}_3(\mu_3\text{-}S)]$,[2] $[\{CpCo\}_3(\mu_3\text{-}S)(\mu_3\text{-}L)]$ (μ_3-L = S,[3,4] CO,[3,4] CS,[5] CNR (R = C_6H_{11}, C_6H_4Me-4)[6]), $[\{Co[\mu_2\text{-}(SCH_2)_2C_6H_4]\}_3(\mu_3\text{-}S)]^{2-}$,[7] and $[\{Co(CO)\}_3(\mu_2\text{-}SEt)_5(\mu_2\text{-}CO)]$.[8] We now report on the first complex of this kind in which an open tricobalt skeleton is present.

The binuclear, chloro-bridged complex $[(Cp^*CoCl_2)_2]$[9] reacts with the dilithium derivative of 1,1′-ferrocenedithiol, $[fc(SLi)_2]$, in tetrahydrofuran to give the violet, paramagnetic tricobalt compound **1**.

$[Co\{Cp^*Co(\mu_2\text{-}S_2fc)\}_2]$ **1**

The molecular structure of **1** has been established by a single-crystal X-ray structure analysis[10] (Fig. 1). Only the two terminal cobalt atoms of the Co_3 backbone in **1** have retained their Cp* ring. The two Co–Co bonds (2.584(1) Å) are each supported by a symmetrically bridging 1,1′-ferrocenedithiolate ligand. The four sulfur atoms surround the central cobalt atom Co(1) in a distorted tetrahedral arrangement; this coordination geometry is also observed in complexes such as $[Co_2(SiPr)_2(\mu_2\text{-}SiPr)_3]$.[11] The Co–S bond lengths in **1** are in the normal range: 2.275(2) Å (average) at the central Co(1) atom, 2.220(2) Å (average) at the terminal Co(2) atoms. Cobalt–iron interactions are clearly absent (Fe···Co(1) 3.893 Å, Fe···Co(2) 4.062 Å). The cyclopentadienyl rings of the 1,1′-ferrocenedithiolato ligands are arranged parallel and eclipsed with a ring–ring distance of 3.29 Å.



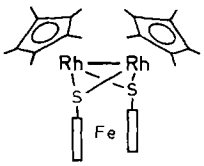


Fig. 1. Crystal structure of **1**. Selected distances [Å] and angles [°]: Co(1)-Co(2) 2.584(1), Co(2)-Cp*(center) 1.689, Co(1)-S(1) 2.278(2), Co(1)-S(2) 2.272(2), Co(2)-S(1) 2.213(2), Co(2)-S(2) 2.227(2), S(1)-S(1a) 3.780, S(2)-S(2a) 3.868, S(1)-S(2) 3.346; Co(2)-Co(1)-Co(2a) 137.9(1), Co(1)-Co(2)-Cp*(center) 149, S(1)-Co(1)-S(2) 94.7(1), S(1)-Co(2)-S(2) 97.8(1), S(1)-Co(1)-S(1a) 112.1(1), S(1)-Co(1)-S(2a) 120.2(1).

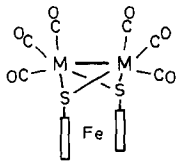
The Co–Co distances in **1** are found in the range expected for single bonds. Comparable Co–Co bond lengths were reported, for example, for $[\{CpCo(\mu\text{-}StBu)\}_2]$ (2.467(1) Å),[12] $[Co_2(CO)_6(\mu\text{-}S)_2]^{2+}$ (2.498(9) Å),[13] $[\{Cp'Co\}_3(\mu_3\text{-}S)_2]^{n+}$ (n = 0: two 2.48 Å (average), one 3.17 Å; n = 1: two 2.49 Å (average), one 2.87 Å; n = 2: three 2.52 Å (average)),[14] $[\{Co(CO)\}_3(\mu_2\text{-}SEt)_5(\mu_2\text{-}CO)]$ (2.552 Å (average)),[8] and $[\{Co(CO)_3\}_3(\mu_3\text{-}S)]$ (2.637 Å (average)).[2]

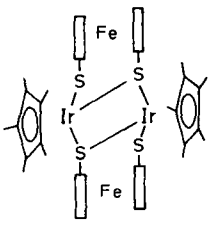


Surprisingly, the related reaction between $[(Cp^*RhCl_2)_2]$[15] and $[fc(SLi)_2]$ in THF [Eq. (a)] leads preferentially to a dirhodium complex **2**, which is similar to the known hexacarbonyl(1,1′-ferrocenedithiolato)diiron and -diruthenium compounds, **3**[16] and **4**,[17] respectively.

$$[(Cp^*RhCl_2)_2] + 2[fc(SLi)_2] \xrightarrow[-78\,^\circ C,\ -4\,LiCl]{THF} \underset{\mathbf{2}}{[Cp^*_2Rh_2(\mu_2\text{-}S_2fc)]} + [(fcS_2)_n] \quad (a)$$

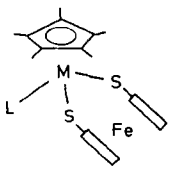
$[Cp^*_2Rh_2(\mu_2\text{-}S_2fc)]$

2



$[M_2(CO)_6(\mu_2\text{-}S_2fc)]$

3: M = Fe
4: M = Ru



The formation of **1** and **2** from $[(Cp^*MCl_2)_2]$ (M = Co, Rh) involves redox processes during which the metal center is partially reduced by $[fc(SLi)_2]$. The 14-electron fragments $[Fe(CO)_3]$/$[Ru(CO)_3]$ and [Cp*Co]/[Cp*Rh] of **1**–**4** are isolobal.[18] Complexes **2**–**4** each contain a M_2S_2 tetrahedrane framework and obey the 18-electron rule.

If the metal atoms are formally assigned the oxidation state ±0 and the ligands are considered as neutral building blocks (e.g. Cp* as a five-electron ligand), the 1,1′-ferrocenedithiolato group, $[S_2fc]$, acts as a six-electron ligand in **1**–**4**. On the other hand, the iridium compound **5** contains two four-electron $[S_2fc]$ ligands, but no metal–metal bond.[19] Compound **5** is generated in low yield (2–5%) by the reaction of $[(Cp^*IrCl_2)_2]$[15] with $[fc(SLi)_2]$; a more attractive route (70–80%) to **5** is the sulfur-induced triphenylphosphane abstraction from the mononuclear

$[Cp^*_2Ir_2(\mu_2\text{-}S_2fc)_2]$

5

$[Cp^*M(L)(S_2fc)]$

6a: M = Rh (L = PMe_3)
6b: M = Ir (L = PPh_3)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. W. Bronger, Aachen, for the magnetic measurements. Abbreviations: Cp = η^5-C_5H_5; Cp′ = η^5-C_5H_4Me; Cp* = η^5-C_5Me_5; fc = 1,1′-ferrocenediyl ($[Fe(C_5H_4^-)_2]$); fcS_2 = 1,1′-ferrocenedithiolato, ($[Fe(C_5H_4S)_2]$).

precursor $[Cp^*Ir(PPh_3)(S_2fc)]$ (**6b**).[19] In the very stable 18-electron complexes **6a** and **6c** [S_2fc] functions as a two-electron ligand. The dimeric structure of **5** has been confirmed by an X-ray crystal structure analysis for the selenium analogue, $[Cp^*_2Ir_2(Se_2fc)_2]$.

In summary, the 1,1′-ferrocenedithiolato unit [S_2fc] is a versatile ligand system which may function as a two-electron (in **6a** and **6b**), four-electron (in **5**), or six-electron donor (in **1**–**4**) and which may act as either chelating or bridging ligand.

Experimental Procedure

1: A green solution of $[(Cp^*CoCl_2)_2]$ [9] (0.42 g, 0.80 mmol) in THF (20 mL) and an orange solution of $[fc(SLi)_2]$ (0.45 g, 1.1 mmol) in THF (100 mL) were combined at −78 °C. The color of the homogeneous mixture changed to violet. The solution was stirred for 3 h at room temperature. After removal of the solvent, the residue was separated by column chromatography on silica gel (Merck, Kieselgel 60). Elution with pentane/CH_2Cl_2 (1:2) gave **1**. Recrystallizion from $CHCl_3$/toluene/hexane mixtures at −25 °C gave violet microcrystals of **1** (0.15 g, 30.1%, m.p. 248 °C). EI-MS (70 eV): prominent peaks at *m/z* (%): 943 (100) [M^+], 808 (10) [$M^+ - Cp^*$], 636 (48) [$Cp^*_2Co_2(S_2fc)^+$], 501 (22) [$Cp^*Co_2(S_2fc)^+$], 442 (42) [$Cp^*Co(S_2fc)^+$]; strong peaks due to the ferrocene oligomers (*m/z* 370 [Fc_2^+], 554 [Fc(fc)Fc$^+$], 738 [$Fc(fc)_2Fc^+$]) were also observed. The effective magnetic moment was found to be 5.6 μ_B at room temperature; it decreases with decreasing temperature to reach 3.4 μ_B at 6 K [20].

2. The reaction of $[(Cp^*RhCl_2)_2]$ [15] (0.24 g, 0.38 mmol) with $[fc(SLi)_2]$ (0.31 g, 0.76 mmol) in THF (130 mL) was started at −78 °C and then continued for 4 h at room temperature. Chromatography over silica (with CH_2Cl_2/hexane mixtures for elution) gave several bands; isolation of the first (violet) zone which follows [FcH] and recrystallization from hexane or pentane gave violet crystals of (**2**) (0.12 g, 41%, m.p. 168 °C). ^{1}H NMR ($CDCl_3$): δ = 1.99 (s, C_5Me_5, 30H), 3.74, 4.39 (vt, fc, 4 + 4H); EI-MS (70 eV): *m/z* 723 (100%) [$M^+ - H$].

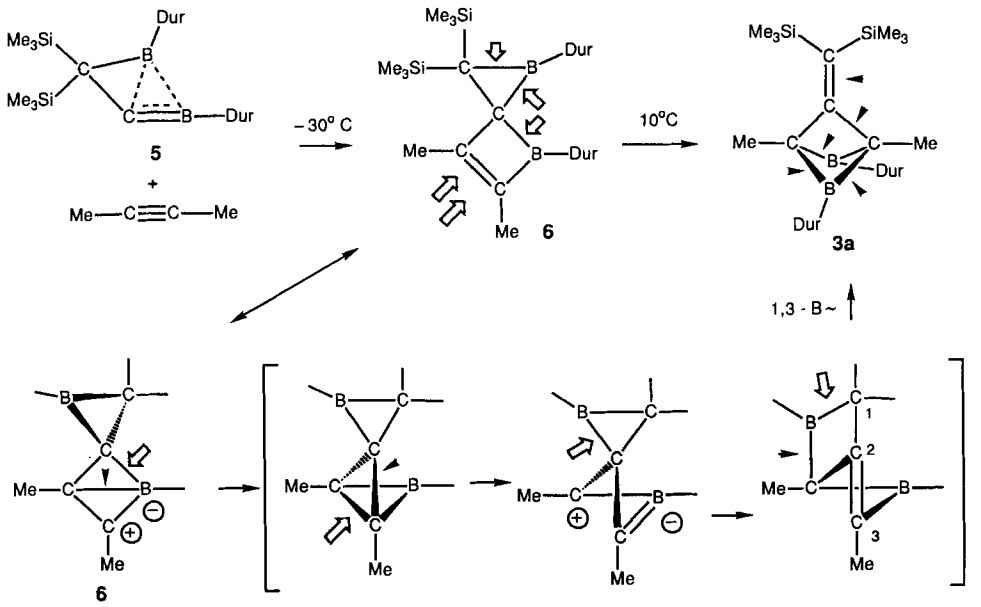
Heteroatom-Substituted Bicyclo[1.1.1]pentanes with Two Boron Atoms as Electron-Deficient Centers**

Matthias Menzel, Christine Wieczorek, Sigrid Mehle, Jürgen Allwohn, Heinz-Jürgen Winkler, Markus Unverzagt, Matthias Hofmann, Paul von Ragué Schleyer, Stefan Berger, Werner Massa, and Armin Berndt*

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

The dicarbapentaboranes(5) (**1**)[2] are the only known bicyclo[1.1.1]pentane derivatives[1] with boron atoms as electron-deficient centers. Here we report on the synthesis, X-ray crystal structures, and NMR data of the 2-methylene (**3a**) and 2-sila (**4a**) derivatives of diborabicyclo[1.1.1]pentane **2**. In addition, we computed the geometries and the chemical shifts of the unsubstituted (u) parent compounds **2u**, **3u**, and **4u** by ab initio methods to rationalize the observed properties of **3a** and **4a**.



1,4-Diboraspiro[2.3]-hex-5-ene **6** can be obtained from methyleneborane **5**[3] and 2-butyne at −30 °C. It isomerizes to **3a** in less than one hour at 10 °C. A plausible[4] reaction mechanism involving low energy intermediates[5] is given. (The bonds marked in Scheme 1 with open arrows and black arrowheads are broken and formed, respectively).

The X-ray crystal structure[6] of **3a** (Fig. 1) shows a surprising feature: the C2–B4 distance (188.3 pm) is significantly shorter than the C2–B5 distance (197.7 pm) even though higher

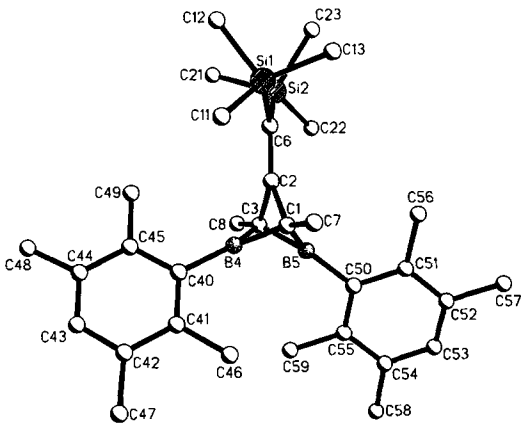
Scheme 1. Synthesis of **3a** starting from **5** and proposed mechanism for the isomerization **6** → **3a**. The open arrows mark the bonds to be broken in the next step, the black arrowheads the bonds that formed in the last step. Dur = 2,3,5,6-tetramethylphenyl.



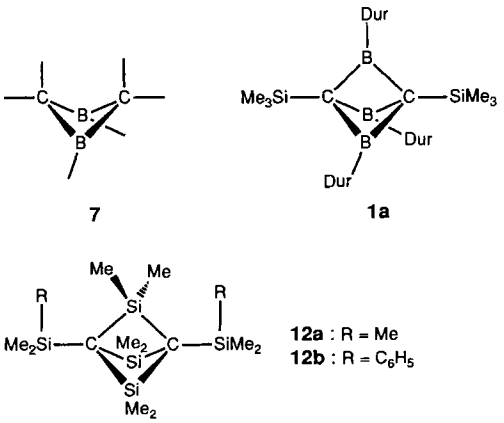


Fig. 1. Crystal structure of **3a**. Relevant distances [pm] and angles [°] (in addition to Table 1): C1-B4 153.9(3), C3-B4 160.9(4), C1-B5 157.5(3), C3-B5 154.1(4), C1-C2 156.4(4), C3-C2 152.9(3), C1 · · · C3 217.4(4), C2-C6 136.4(3); C1-B4-C3 87.3(2), C3-B5-C1 88.4(2), C1-C2-C3 89.2(2), B4-C1-C2 74.7(2), B4-C3-C2 73.7(2), B5-C1-C2 78.1(2), B5-C3-C2 80.1(2); C1-C2-C6-Si1 −23.6(3), C1-C2-C6-Si2 156.6(2)

symmetry is possible. In contrast, in the ^{13}C NMR spectrum of **3a** signals of only one kind of duryl group were observed even at −80 °C. Hence, the boron atoms are equivalent in solution according to NMR spectroscopy. The boron chemical shift for **3a** ($\delta(^{11}B) = 34$) is far from the usual range for 1,3-diboretanes **7** ($\delta(^{11}B) = 82 \pm 2$[7]) but close to that of dicarbapentaborane(5) **1a** ($\delta(^{11}B) = 21$).

The MP2(fc)/6-31G* geometry[8] **3u** (Fig. 2), like that of **3a**, exhibits a short (170.7 pm, C2–B4) and a long (208.1 pm, C2–B5) carbon–boron distance. The C_{2v} structure **3u*** with equal distances for C2–B4 and C2–B5 (188.4 pm) is 3.0 kcal mol^{-1} higher in energy than **3u** and is the transition structure for the rapid exchange of the chemical environments of the boron atoms in **3u**.[10] GIAO-MP2/tzpdz calculations[9] (Fig. 2) gave boron chemical shifts of $\delta(^{11}B) = 6.2$ (B4) and 34.9 (B5) for **3u**. The average value, 20.6, is in accord with the experimental value $\delta(^{11}B) = 34$, when the effects of the different substituents are taken into account (compare $\delta(^{11}B) = 1.9$ for **1u**[2] and 21 for **1a**). The C=C bond in **3u** hardly influences the strong shielding

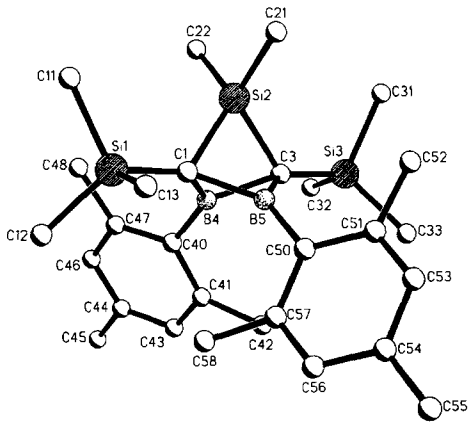
Table 1. Computed (**2u**, **3u**, **4u**) and experimental distances (**3a**, **4a**) [pm] and chemical shieldings of framework atoms.

	2u (X = C2)	**3u** (X = C2)	**3a** (X = C2)	**4u** (X = Si)	**4a** (X = Si)
X-B4	178.4	170.7	188.3(3)	224.0	223.2(6)
X-B5	217.3	208.1	197.7	224.0	225.2(6)
B4-B5	190.7	193.1	194.9(3)	186.2	187.6(6)
$\delta(^{13}C1,C3)$	72.0	76.8	91.7	82.2	98.6
$\delta(^{11}B4)$	10.9	6.2	34	39.2	46
$\delta(^{11}B5)$	40.0	34.9	34	39.1	46
δ(X)	−1.4	101.4	124.2	−140.4	−99.6
$\delta(^{13}C6)$	–	106.8	80.2	–	–

of the boron atoms.[11] The GIAO-MP2 $\delta(^{11}B)$ NMR shifts of **2u** (10.9 (B4) and 40.0 (B5)) are only about 5 ppm larger than those of **3u**. The lowest energy structure of **2u** (C_s), like **3u**, has a short C2–B4 distance (178.4 pm) and a long C2–B5 distance (217.3 pm). The C_{2v} symmetry form, **2u***, a transition structure with equal C2–B distances (201.1 pm), is 3.2 kcal mol^{-1} higher in energy than **2u**. Strong hyperconjugation between the strained C1–C2,C3 bonds and B4 and between the B4–C1,C3 bonds and B5 results in the strong boron shieldings in **3u** and **2u**. Analogous interactions of a boron atom with four neighboring strained C–B bonds give rise to the strong boron shielding in dicarbapentaborane **1** (see above). This was shown by means of an NBO analysis[12] involving a second-order perturbative estimation of donor–acceptor interactions. In addition, in **3u** π-electron density is transferred from the C2–C6 bond to B4, and there is back donation from the B4–C1,C3 bonds into the C2–C6 π^* orbital. Analogous but weaker interactions take place in **2u**, where C-H σ and σ^* orbitals act as donors and acceptors, respectively.

Hence, the nonclassical characteristics of **1** are not changed when one boron atom is replaced by an sp^2 (**3**) or an sp^3 (**2**) carbon atom. In the related 2-sila-4,5-diborabicyclo[1.1.1]-pentanes **4**, the nonclassical character of **1** is also conserved to a large extent. Borataalkyne **8**[13] reacts with chlorodimethylsilane to give **4a**, probably via intermediates **9**–**11** (Scheme 2). The crystal structure of **4a** is shown in Figure 3.[6] Important distances and the chemical shifts of the framework atoms are listed with those calculated for **4u** in Table 1. The experimental distances of **4a** differ little from those computed for **4u**. The chemical shift of the boron atoms in **4a** (δ = 46) lies *between* the values of classical 1,3-diboretanes **7** and the nonclassical dicarbapentaboranes **1**. The chemical shifts computed for **4u**, $\delta(^{11}B)$ = 39.1 and $\delta(^{29}Si)$ = −140.4, agree with the experimental values of **4a** (see Table 1), as long as the substituent effects are taken into account. Note the strong shielding of the bridging silicon atom in **4a**, $\delta(^{29}Si)$ = −99.6. The Si atoms in the $SiMe_2$ bridges in trisilabicyclo[1.1.1]pentanes **12a**, **b**[14] form C1-Si-C3 angles (79.5°) comparable to those in **4a** (75.4°), but the ^{29}Si chemical shifts of −4.9 (**12a**) and 31.9 (**12b**) differ. Therefore, the small angle at the Si2 atom of **4a** is not the source of the strong shielding.[15] No unusual chemical shifts are observed in bicyclo[1.1.1]pentanes, either.[17]



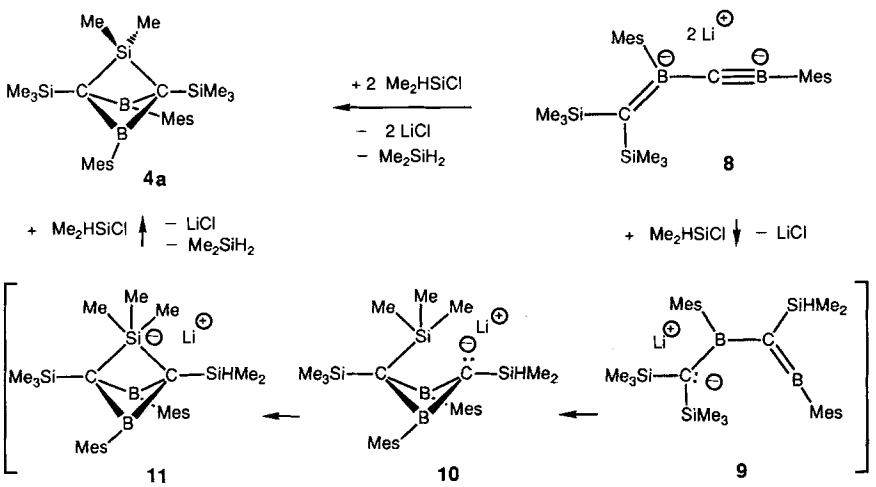


Fig. 3. Crystal structure of **4a**. Relevant distances [pm] and angles [°] (in addition to Table 1): C1-B4 158.3(6), C3-B4 159.9(6), C1-B5 159.2(6), C3-B5 156.9(7), C1-Si2 189.4(5), C3-Si2 189.3(4), C1···C3 231.7(6); C1-B4-C3 93.4(4), C3-B5-C1 94.4(4), C1-Si2-C3 75.4(2), B4-C1-Si2 78.6(3), B4-C3-Si2 79.2(3), B5-C1-Si2 80.6(3), B5-C3-Si2 80.1(3).

The strong shielding of framework atoms in heterobicyclo[1.1.1]pentanes is apparently due to the presence of electron-deficient centers. The second-order perturbative estimation of donor–acceptor interactions with NBO analysis[12] revealed that hyperconjugation of the C–B bonds in **4u** and in **1u** is equally strong. However, there are twice as many C–B bonds per boron atom in the latter. The hyperconjugation in **4u** is significantly weaker, because Si–C bonds are not as effective as C–B bonds as hyperconjugative donors. 2-Sila-4,5-diborabicyclo[1.1.1]pentanes **4** differ from dicarbapentaboranes(5) **1** only in the magnitude of the nonclassical interactions. These sila derivatives **4** are the simplest[18] examples of heterodicarboranes. Physical data for **1a**, **3a**, **4a**, and **6** are listed in Table 2.

Scheme 2. Synthesis of **4a**. Mes = 2,4,6-trimethylphenyl.

Experimental Procedure

6 and **3a**: 2-Butyne (0.18 g, 3.25 mmol) was added dropwise to a solution of **5** (1.49 g, 3.25 mmol) in 30 mL of pentane cooled to −78 °C. After the mixture had warmed to −30 °C, all volatile components were removed under high vacuum, and the pale yellow solid **6** was dissolved in 50 mL of pentane with cooling. The pale yellow suspension was warmed to 7 °C and stirred at this temperature until a clear red solution formed. The volatile material was removed under vacuum, the resulting yellow residue taken up in hexane at 0 °C, and the solid that precipitated removed by filtration through a D4 frit. **3a** crystallized from hexane at −30 °C as yellow cubes.

4a: Chlorodimethylsilane (2.0 g, 21.2 mmol) was added dropwise to a solution of **8** (4.19 g, 7.07 mmol) in 50 mL of diethyl ether cooled at −20 °C. The mixture was kept at −10 °C for 2 h and then stirred and

Table 2. Selected physical data for compounds **1a**, **3a**, **4a**, and **6**.

1a (colorless crystals): m.p. > 200 °C, yield: 69%. – ^{1}H NMR (500 MHz, $CDCl_3$, −30 °C): δ = −0.03 (s, 18H, $SiMe_3$), 2.15, 2.23 (each s, each 18H, *o*- and *m*-CH_3), 7.03 (s, 3H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): δ = −1.3 (6C, $SiMe_3$), 20.4, 20.9 (each 6C, *o*- and *m*-CH_3), 127.0 (2C, CB_2), 131.5, 133.5, 136.4 (total of 15C, *o*-, *m*-, *p*-C), 132.4 (br., 3C, *i*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 21

3a (yellow crystals): m.p. 62 °C, yield: 75%. – ^{1}H NMR (400 MHz, $CDCl_3$, −40 °C): δ = 0.24 (s, 18H, $SiMe_3$), 1.97 (s, 6H, CH_3), 2.20, 2.34 (each s, total of 24H, *o*- and *m*-CH_3), 7.15 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, CD_2Cl_2, −60 °C): δ = 3.9 (q, 6C, $SiMe_3$), 12.6 (q, 2C, CH_3), 19.4, 19.9 (each q, 8C, *o*- and *m*-CH_3), 80.2 (s, 1C, ^1J(C, Si) = 58 Hz, CSi_2), 91.7 (s, 2C, CB_2), 124.2 (br.s, 1C, $=CC_2$), 132.6 (d, 2C, *p*-C), 133.8, 136.7 (each s, each 4C, *o*- and *m*-C), 142.5 (br.s, 2C, *i*-C); ^{11}B NMR (96 MHz, pentane, 10 °C): δ = 34

4a (colorless crystals): m.p. 165 °C, yield: 73%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.01 (s, 18H, $SiMe_3$), 0.39 (s, 6H, $SiMe_2$), 2.22 (18H, *o*- and *p*-CH_3), 6.75 (s, 4H, *m*-H), ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 0.3 (q, 6C, $SiMe_3$), 5.0 (q, 2C, $SiMe_2$), 21.0 (q, 2C, *p*-CH_3), 23.4 (q, 4C, *o*-CH_3), 98.6 (s, 2C, CB_2), 128.0 (d, 4C, *m*-C), 133.9 (br.s, 2C, *i*-C), 137.6 (s, 2C, *p*-C), 140.1 (s, 4C, *o*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 46; ^{29}Si NMR (79 MHz, $CDCl_3$, 25 °C): δ = −11.0 (s, 2Si, $SiMe_3$), −99.6 (s, 1Si, $SiMe_2$)

6 (pale yellow solid): yield: quantitative by NMR spectroscopy. – ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): δ = 2.3, 2.9 (each q, each 3C, $SiMe_3$), 13.6, 15.8 (each q, each 1C, CH_3), 19.2 (br.), 19.3 (br.), 19.6 (br.), 19.8 (br.), 20.1 (br.), 20.3 (each q, 8C, *o*- and *m*-CH_3), 24.6 (s, 1C, CSi_2), 51.2 (br.s, 1C, CB_2), 130.3, 132.7 (each d, each 1C, *p*-C), 131.0, 133.0, 133.3, 136.3 (each s, 6C, *o*- and *m*-C), 138.1 (br.s, 1C, *i*-C), 144.0 (br.s, 2C, *o*-C of Dur on three-membered ring), 155.8 (s, 1C, $=CC_2$), 164.5 (br.s, 1C, =CB)

warmed to 25 °C for another 10 h. The volatile components were removed under vacuum, the residue was treated with pentane, and the the lithium chloride was removed with a D4 frit. The pentane soluton was concentrated and cooled to −20 °C to yield 2.5 g of **4a** as fine needles.

[5] The triple bond of 2-butyne is cleaved during the reaction with **5** by insertion of two B-Dur fragments and one $C{=}C(SiMe_3)_2$ moiety. Similar insertions were reported for the reaction of alkynes with B_4H_{10}: M. A. Fox, R. Greatrex, M. Hofmann, P. von R. Schleyer, *Angew. Chem.* **1995**, *106*, 2384–2386; *Angew. Chem. Int. Ed. Engl.* **1995**, *33*, 2298–2300, and references therein.

[6] X-ray structure analyses were conducted with a four-circle diffractometer (CAD4, Enraf-Nonius) with $Cu_{K\alpha}$ radiation (λ = 154.178 ppm) at −80 °C. The structures were solved by direct methods and refined with full matrix against the F_o^2 data employing the SHELXL-93 system (**3a**) or against the F_o data with the SHELXTL-plus (**4a**) system. Anisotropic temperature factors were used for all non-hydrogen atoms. **3a**. $C_{32}H_{50}B_2Si_2$, crystal dimensions 0.5 × 0.3 × 0.3 mm^3, triclinic, space group $P\bar{1}$, Z = 2, a = 880.4(2), b = 1190.0(2), c = 1600.7(3) pm, α = 88.73(3), β = 88.97(3), γ = 79.88(3)°, V = 1650.3 × 10^{-30} m^3, ρ_{calcd} = 1.031 g cm^{-3}; total of 5259 reflections collected in ω-scan mode up to 2θ = 150°; 5120 out of 5123 independent reflections used in subsequent calculations after LP correction; no absorption correction (μ = 10.8 cm^{-1}). The hydrogen atoms were considered in the calculations to be „riding" on their bonding partners in groups with common isotropic temperature factors. Final wR_2 = 0.1622 and R = 0.050 for 3825 reflections with $F_o > 4\sigma(F_o)$. The maximum residual electron density was 0.27 e Å^{-3}. **4a**: $C_{28}H_{46}B_2Si_3$, crystal dimensions 0.5 × 0.3 × 0.6 mm^3, monoclinic, space group $P2_1/c$, Z = 4, a = 1337.6(5), b = 1347.9(2), c = 1779.2(7) pm, β = 106.81(2)°, V = 3070.6 × 10^{-30} m^3, ρ_{calcd} = 1.057 g cm^{-3}; total of 4544 reflections collected in ω-scan mode up to 2θ = 110°; 3256 (with $F_o > 3\sigma(F_o)$) out of 3849 independent reflections used in subsequent calculations after LP correction; no absorption correction (μ = 14.1 cm^{-1}). All hydrogen atoms could be localized by difference Fourier synthesis and were considered in the calculations as riding on their bonding partners in groups with common isotropic temperature factors. Employing weights of $w = 1/\sigma^2(F_o)$ resulted in R = 0.063 and wR = 0.058. The maximum residual electron density was 0.50 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-58797.

The method was implemented in ACESII: ACESII, an ab initio program system by J. F. Stanton, J. Gauss, J. D. Watts, W. J. Lauderdale, R. J. Bartlett, Quantum Theory Project, University of Florida, 1991 and 1992. tzpdz stands for "triple zeta plus polarization" basis sets for heavy atoms and "double zeta" basis sets for hydrogen atoms: A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571–2577.

[10] The notably different NMR shifts of the C atoms in the C=C bonds in **3a** and **3u** are likely to be due to the trimethylsilyl substituents, which induce a negative partial charge at C6 (stabilized by the α-Si effect) and a positive partial charge at C2. IGLO(II′) computations for **3u′** (two SiH_3 substituents at C6) show significant shielding of C6 ($\delta(^{13}C)$ = 95.0) and deshielding of C2 ($\delta(^{13}C)$ = 142.2) relative to the data computed for **3u** at the same level ($\delta(^{13}C)$ = 112.5 (C6) and 118.0 (C2)). The difference $\Delta\delta(^{13}C)$ (C2,6) is 47 ppm for **3u′**, close to the experimental difference of 44 ppm. **3u′** was too large for GIAO-MP2/tzpdz computations.

[11] Siebert et al. reported strong shielding for the boron atom of a 3-methylenboretane derivative: M. Enders, H. Pritzkow, W. Siebert, *Angew. Chem.* **1992**, *104*, 628–629; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 606–607.

Silicon-Bridged Macrocycles—Synthesis of Sila-calixarenes**

Burkhard König,* Martin Rödel, Peter Bubenitschek, and Peter G. Jones

Specific recognition on a molecular level requires close correspondence between the shape of the receptor and the substrate molecule, or between lock and key in the image of Emil Fischer.[1] Macrocyclic structures can provide the necessary preorganization of the host for the inclusion process, and therefore most artifical receptors are cyclic molecules.[2] Carbon is the common bridging element in natural and synthetic macrocycles, such as porphyrins or calixarenes. However, carbon does not contribute to the binding properties of these ligands, while elements such as silicon, tin, or phosphorus can serve as additional coordination sites.[3] We describe here the facile synthesis of silicon-bridged macrocycles, including the first silacalix[4]arene, from readily available starting materials.

Furan, thiophene, and *N*-methylpyrrole, **1a–c**, are deprotonated in the 2- and 5-position by treatment with two equivalents *n*BuLi/TMEDA/KO*t*Bu (1/1/1) (TMEDA = *N*,*N*,*N*′*N*′-tetramethyl-1,2-ethanediamine) in hexane.[4] Slow addition of a solution of Me_2SiCl_2 in hexane gave the macrocyclic tetramers **2a–c**[5] and hexamers **3a–b** in yields up to 35% (Scheme 1, Table 1). The fast reaction of the organolithium compounds with Me_2SiCl_2 enabled the synthesis of the cyclic structures at organolithium concentrations of 10^{-2} M.

Scheme 1. Macrocyclization of heterocyclic dianions with Me_2SiCl_2; **a**, X = O; **b**, X = S[4]; **c**, X = NMe. a) 2.1 equiv *n*BuLi/TMEDA/KO*t*Bu (1/1/1) hexane, 2 h, −90 to 25 °C; b) 1.0 equiv Me_2SiCl_2, slow addition. For **2b** see also ref.[5].

All macrocycles, with the exception of **3a**, are high melting, crystalline solids, readily soluble in nonpolar organic solvents. The X-ray structure analysis of **2b** (Fig. 1)[6] displays crystallographic inversion symmetry and a 1,3-*anti* arrangement of the thiophene units in the crystal, similar to its known carbocyclic analogue tetrathiaporphyrinogene.[7]

While the hexa- and tetrameric structures of thiophene and furan were obtained in nearly equal amounts, the silaporphyrinogene **2c** was the single isolated cyclic structure from *N*-methylpyrrole. Macrocycles with ring sizes other than four or six in the reaction mixtures could be detected only in traces by mass spectrometry.

Table 1. Selected spectroscopic data [a] of **2a,c**, **3a**, **3b**, **5**, **6**, **8**, and **9**.

2a: Colorless crystals, m.p. 115 °C; ^{1}H NMR: δ = 0.53 (s, 24H), 6.65 (s, 8H); ^{13}C NMR: δ = −3.18 (+), 120.38 (+), 161.83 (C_{quat}); MS (70 eV): *m/z* (%): 496 (100) [M^+].

2c: White solid, m.p. 295 °C; ^{1}H NMR: δ = 0.44 (s, 24H), 3.00 (s, 12H), 6.41 (s, 8H); ^{13}C NMR: δ = −1.93 (+), 35.53 (+), 119.69 (+), 136.40 (C_{quat}); MS (70 eV): *m/z* (%): 548 (20) [M^+], 492 (100).

3a: Oil; ^{1}H NMR: δ = 0.55 (s, 36H), 6.68 (s, 12H); ^{13}C NMR: δ = −3.08 (+), 121.03 (+), 161.85 (C_{quat}); MS (70 eV): *m/z* (%): 744 (10) [M^+], 207 (100).

3b: White solid, m.p. 290 °C; ^{1}H NMR: δ = 0.62 (s, 36H), 7.33 (s, 12H); ^{13}C NMR: δ = 0.00 (+), 136.54 (+), 143.81 (C_{quat}); MS (70 eV): *m/z* (%): 840 (100) [M^+].

5: Colorless crystals, m.p. 106 °C; ^{1}H NMR: δ = 0.52 (s, 6H), 1.20 (s, 18H), 3.65 (s, 6H), 6.70 (m, 2H), 7.30 (m, 4H); ^{13}C NMR: δ = −1.70 (+), 31.55 (+), 34.05 (C_{quat}), 55.05 (+), 108.95 (+), 125.72 (C_{quat}), 127.18 (+), 133.33 (+), 142.36 (C_{quat}), 162.28 (C_{quat}); MS (70 eV): *m/z* (%): 384 (40) [M^+], 369 (100) [M^+−Me].

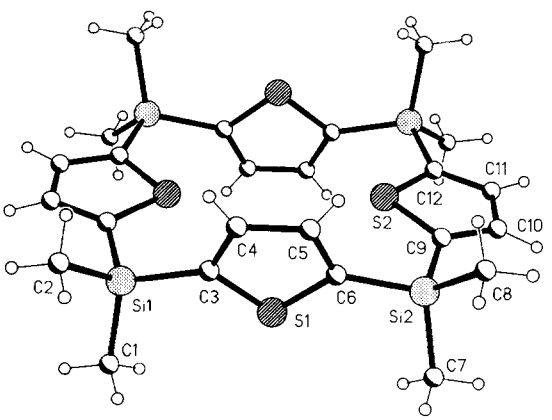
8: Oil, ^{1}H NMR: δ = 0.59 (s, 6H), 3.52 (s, 6H), 3.83 (s, 6H), 7.00 (m, 6H); ^{13}C NMR: δ = −0.65 (+), 56.20 (+), 60.82 (+), 114.65 (+), 124.64 (+), 127.79 (+), 133.29 (C_{quat}), 152.60 (C_{quat}), 154.49 (C_{quat}); MS (70 eV): *m/z* (%): 332 (11) [M^+], 225 (100).

9: Colorless crystals, m.p. 280 °C; ^{1}H NMR: δ = 0.63 (s, 24H), 3.58 (s, 24H), 6.57 (s, 8H); ^{13}C NMR: δ = −1.22 (+), 59.43 (+), 130.45 (+), 135.15 (C_{quat}), 157.02 (C_{quat}); MS (70 eV): *m/z* (%): 776 (40) [M^+], 57 (100).

[a] ^{1}H NMR: 400 MHz, $CDCl_3$, TMS; ^{13}C NMR: 100 MHz, $CDCl_3$; the multiplicity of the ^{13}C NMR signals was determined by the DEPT technique and quoted as (+) for CH_3 and CH, and (−) for CH_2 and C_{quat} for quaternary carbon atoms.



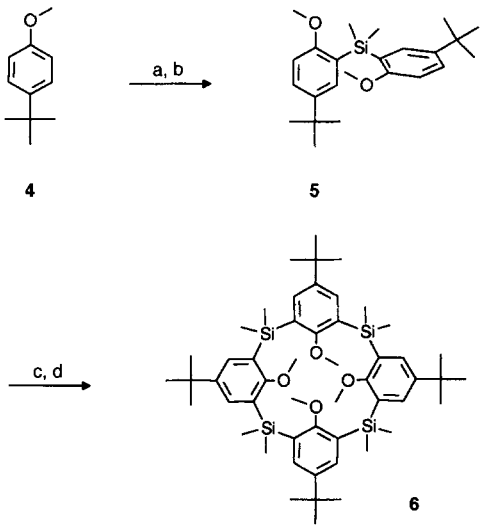


Fig. 1. Crystal structure of **2b**. Selected bond lengths [pm] and angles [°]: Si1–C3 185.7(2), S1–C3 172.5(2), C3–C4 136.8(2), C4–C5 141.8(2); C6-Si2-C9 107.56(7), (S1-C3-C6)-(S2-C9-C12) 98.7.

Methoxy groups have a strong *ortho* directing effect in the lithiation of aromatic rings.[8] However, the stabilization is insufficient to allow the formation of dianions. Therefore a stepwise procedure is necessary to obtain cyclic structures from *para-tert*-butylmethoxybenzene and Me_2SiCl_2 (Scheme 2). Monolithiation of **4** followed by reaction with Me_2SiCl_2 gave the crystalline dimer **5**, which was characterized by X-ray structure analysis.[6] Bislithiation of **5** was achieved with two equivalents *n*BuLi/TMEDA at room temperature and subsequent slow addition of one equivalent Me_2SiCl_2 yielded the *para-tert*-butylsilacalix[4]arene (**6**) in 16% isolated yield. The simple ^{1}H NMR spectrum of **6** indicates conformational mobility at room temperature in solution. At lower temperatures the signals significantly broaden, but defined conformers, as in the case of the carbocyclic

Scheme 2. Synthesis of the silacalix[4]arene **6**; a) 1.1 equiv *n*BuLi/TMEDA (1/1), 12 h, room temperature; b) 0.5 equiv Me_2SiCl_2; c) 2.1 equiv *n*BuLi/TMEDA (1/1), 12 h, room temperature; d) 1.0 equiv Me_2SiCl_2.

analogue *para-tert*-butylcalix[4]arene,[9] are not observed. The longer silicon–carbon bridges in **6** facilitate the rotation of the aromatic units.

1,2-Dimethoxybenzene (**7**) was converted to the dimer **8** and cyclized to macrocycle **9**[10] by the same procedure (Scheme 3, Table 1). Octa-methoxysila[1.1.1.1]paracyclophane (**9**) is, like **6**, a mobile compound at room temperature. A separation of the NMR signals is observed at $-90\,^{\circ}C$, indicating that the rotation of the aromatic rings or the *pseudo*-rotation of the *gem*-methyl groups becomes slow, on NMR time scale.[11]

Scheme 3. Synthesis of the sila[1.1.1.1]paracyclophane **9**; a)–d) see Scheme 2.

The reaction of bis-lithiated aromatic and heteroaromatic species with dichlorosilanes is a simple route to stable silicon-bridged macrocycles. Preliminary results with $PhPCl_2$ and Me_2SnCl_2 as electrophiles have also shown that other elements such as phosphorus or tin can substitute for silicon. The synthetic scope of the reaction and the good solubility of the silicon-bridged macrocycles in nonpolar organic solvents might lead to new synthetic receptors with additional coordination sites for the inclusion and the transport of ions or neutral guest molecules.

Experimental Procedure

2b, **3b**: *n*BuLi (1.26 mL, 10 M in hexane) was added to thiophene (504 mg, 6.0 mmol) and TMEDA (1.9 mL, 12.6 mmol) in dry hexane (300 mL) under nitrogen; the mixture was stirred for 30 min at room temperature and heated to reflux for an additional 30 min. Me_2SiCl_2 (730 µL, 6.0 mmol) in dry hexane (50 mL) was slowly added by syringe (5 mL h^{-1}), the mixture was stirred for an additional hour, poured into water (300 mL), the organic layer was washed with two portions of water, dried over $MgSO_4$, and evaporated in vacuo. The crude product was chromatographed on silica gel with CCl_4 (or petroleum ether:ether 8:1) as eluent to yield fraction I: 154 mg (18%) **2b**[5]; fraction II: 146 mg (17%) **3b**.

5: A mixture of *para-tert*-butylmethoxybenzene **4** (16.4 g, 100 mmol), TMEDA (16.4 mL, 110 mmol), and *n*BuLi (11 mL, 10 M) in ether (200 mL) was stirred at room temperature for 12 h, Me_2SiCl_2 (6 mL, 50 mmol) was added and the reaction mixture was stirred for additional 1 h. Usual workup, filtration through silica gel and recrystallization from *n*-heptane, yielded 16.15 g (84%) **5** as large crystals.

6: *n*BuLi (1.3 mL, 10 M in hexane) was added to a solution of **5** (2.3 g, 6.0 mmol) and TMEDA (2.0 mL, 13.4 mmol) in hexane (300 mL) under nitrogen and the mixture was strirred for 12 h at room temperature. Me_2SiCl_2 (0.73 mL, 6.0 mmol) in hexane (50 mL) was added over 7 h by syringe, the reaction mixture was poured into water (300 mL), and the organic layer was washed with water, dried, and evaporated in vacuo. Chromatography on silica gel (petroleum ether, 5% ether) gave 442 mg (16%) **6**.

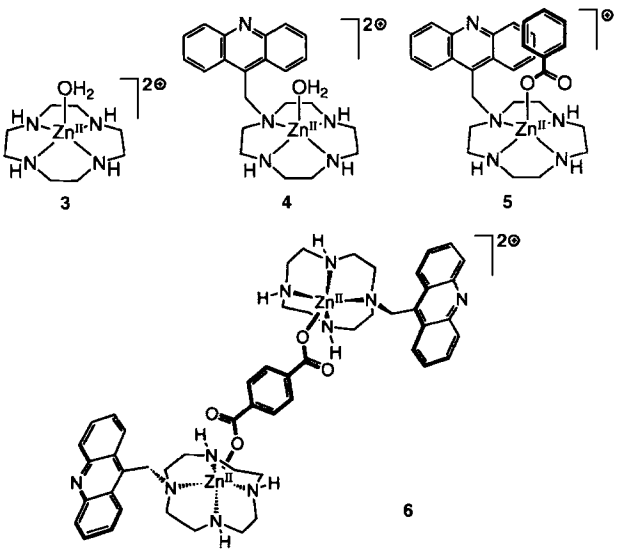
Molecular Recognition of Terephthalic Acid by Supramolecular Self-Assembly of an Acridine-Pendant Cyclen–Zn^{II} Complex**

Eiichi Kimura,* Takuya Ikeda, Mitsuhiko Shionoya, and Motoo Shiro

Selective molecular recognition of anionic substrates is of current interest. One classic example of a receptor is the cationic macrocyclic polyammonium compound that binds with phthalate (*o* isomer) to form complex **1** more strongly than with isophthalate (*m* isomer) or terephthalate (*p* isomer) due to more favorable electrostatic and hydrogen bonding interactions.[1] More recently, cryptate **2** was reported; here the substrate terephthalate dianion, which fits in the cavity, is bound by multiple hydrogen bonding, electrostatic, and hydrophobic interactions within a macrobicyclic polyammonium cryptand.[2]



1

2

Another supramolecular approach to the selective molecular recognition of anions could involve the formation of aggregates by self-assembly of two or more molecular subunits through noncovalent interactions. If the binding partners are sufficiently complementary, the subunits might spontaneously build up an ordered aggregate.

In the context of our work on zinc(II) complexes of cyclen (**3**) and its acridine-pendant derivative **4**, which were initially designed for selective recognition of thymine and its derivatives,[3] we have found that **4** has a fairly strong affinity for the benzoate anion.[4] It yields a 1:1 complex **5** with a stability constant of log $K = 2.25 \pm 0.05$ in aqueous solution (K = [**5**]/([**4**][anion]) [M^{-1}], ionic strength $I = 0.10$ ($NaNO_3$), 25 °C). Complex **4** (10 mM) interacts with terephthalic acid (5 mM) in an aqueous solution containing ClO_4^- (25 mM) at pH 8.4 [25 mM TAPS buffer (TAPS = *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid)] to form a crystalline precipitate of **6** immediately in high yield (90% based on terephthalic acid).

3 4 5

6

The isolated complex **6** comprises two Zn^{II} complexes **4** and one terephthalate dianion. It was characterized by ^1H NMR (in [D_6]DMSO) and IR spectroscopy ($\tilde{\nu} = 1599\ cm^{-1}$ (COO^-), 1360 (COO^-)) and elemental analysis.[5]

We initially suspected this 2:1 complex of having pronounced intramolecular π (guest)-π (host) stacking interactions. However, the X-ray crystal structure analysis of **6**·BF_4^-·ClO_4^-·$3H_2O$[6] (Fig. 1), showed more complex interactions. The zinc(II) ion

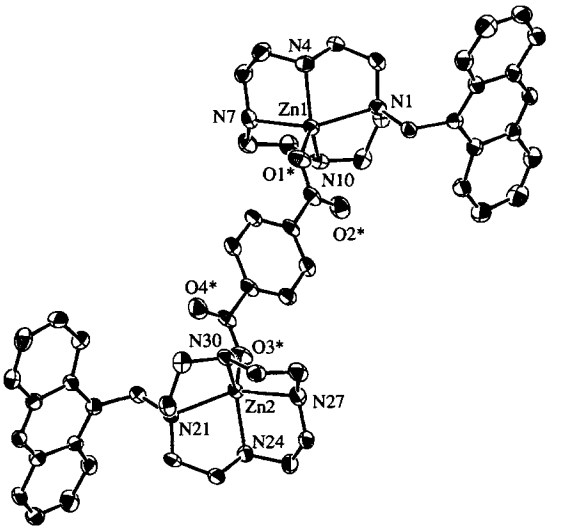


Fig. 1. An ORTEP plot (30 % probability ellipsoids) of **6**·BF_4^-·ClO_4^-·$3H_2O$. The perchlorate anion, the tetrafluoroborate anion, and the three water molecules are omitted for clarity. Selected bond lengths [Å] and angles [°]: Zn1–O1* 1.946(7), Zn2–O3*, 1.906(7), Zn1–N1 2.283(7), Zn1–N4 2.096(6), Zn1–N7 2.184(8), Zn1–N10 2.099(8), Zn2–N21 2.296(6), Zn2–N24 2.105(6), Zn2–N27 2.184(8), Zn2–N30 2.093(8); O1*-Zn1-N1 119.8(3), O1*-Zn1-N4 110.3(3), O1*-Zn1-N7 101.3(3), O1*-Zn1-N10 117.4(3), O3*-Zn2-N21 116.7(3), O3*-Zn2-N24 113.4(3), O3*-Zn2-N27 104.7(3), O3*-Zn2-N30 113.9(3).

resides in a distorted square-pyramidal environment, coordinated by four nitrogen atoms of the cyclen subunit and an oxygen atom of the terephthalate carboxylate anion (O1*–Zn1 1.946(7), O3*–Zn2 1.906(7) Å). In the crystal structure, the intercomplex array is more interesting (Fig. 2). The counterions (ClO_4^- and BF_4^-) lie in middle between two zinc(II) complexes,

and contribute greatly to the neutralization of the repulsive cationic charges. Two of the three water molecules lie in the vicinity of each zinc(II) ion and the third in that of a counterion. It is assumed that all molecules in a unit cell, that is two zinc(II) complexes, one terephthalate dianion, one ClO_4^- ion and one BF_4^-, and three water molecules, participate in the stabilization of this complex. Furthermore, the intermolecular interactions between the two acridine groups (at the closest interplane contact of 3.78 Å) and between an acridine group and the ethylene unit of a cyclen ring (closest contact 3.40 Å) form a well-organized chainlike aggregate **7** (Scheme 1). The pronounced stability of this supramolecular compound may be responsible for its extremely low solubility in water. Attempts to determine the stability constant of this 2:1 complex by potentiometric pH titration were unsuccessful, since the 2:1 complex precipitated immediately upon addition of the titrant.

It became apparent that the tendency of **6** to self-assemble into the supramolecule **7**, which is insoluble in water, may permit terephthalate to be separated efficiently from its isomers phthalate and isophthalate. The 2:1 complexes of phthalate and isophthalate with **4** were prepared as described for terephthalate. Both complexes remained in aqueous solution and scarcely precipitated out. We then tested the separation in the following way: 0.4 mL of an aqueous solution of $4 \cdot 2NO_3^-$ (20 mM)[8] was added to 0.4 mL of a solution containing the *o*, *m*, *p* isomers (each 10 mM) at pH 8.4 (25 mM TAPS buffer, 25 mM $NaClO_4$, 25 °C); immediate precipitation occurred. After 6 hours, the mixture was centrifuged and 0.54 mL of the upper solution layer was withdrawn and treated with D_2O (0.06 mL, 0.3% sodium [2,2,3,3-D_4]3-(trimethylsilyl)propionate). The ^1H NMR spectrum of this solution showed that the *p* isomer had almost completely disappeared, while most of the *o* (>95%) and *m* (>90%) isomers remained. According to the ^1H NMR spectrum in [D_6]DMSO of the collected precipitates, the major component (80%) was the *p* isomer **6**; a minor component (8%) comprising the 2:1 complex of **4** and isophthalate (*m* isomer) (the resulting composite; *p*:*m*:*o* = 10:1:0). The best separation of terephthalate from the *m* and *o* isomers with **4** (*p*:*m*:*o* = 15:1:0) was achieved when 5% CH_3CN was added to the above test solution.

We conclude that **4** selectively separates terephthalate as insoluble crystals from a mixture of terephthalate and its isomers phthalate and isophthalate, not because its 2:1 complex **6** has a particularly high stability constant, but because it is additionally stabilized by self-assembly into an ordered aggregate **7**. Metal complexes with aromatic pendants should also be useful for the molecular recognition of other anionic molecules in aqueous media.

[8] The compound was prepared by a modified procedure [3b], using $Zn(NO_3)_2 \cdot 6H_2O$ instead of $Zn(ClO_4)_2 \cdot 6H_2O$.

Coupling of Endothermic Thermal Cracking with Exothermic Oxidative Dehydrogenation of Ethane to Ethylene Using a Diluted SrO/La_2O_3 Catalyst

Vasant R. Choudhary,* Balu S. Uphade, and Shafeek A. R. Mulla

Presently ethylene is produced by the thermal cracking of ethane, ethane–propane mixtures, or naphtha.[1] This process is endothermic and hence energy intensive, and also produces large quantities of coke. Recently efforts have been made to convert ethane to ethylene by catalytic oxidative dehydrogenation of ethane.[2–8] Although the oxidative dehydrogenation [Eq. (a)] is moderately exothermic, it can become highly hazardous and difficult to control because the combustion of ethane [Eqs. (b) and (c)] is highly exothermic. A small increase

$$C_2H_6 + 0.5\,O_2 \longrightarrow C_2H_4 + H_2O + 25.1\ \text{kcal mol}^{-1} \quad \text{(a)}$$

$$C_2H_6 + 3.5\,O_2 \longrightarrow 2\,CO_2 + 3\,H_2O + 341.5\ \text{kcal mol}^{-1} \quad \text{(b)}$$

$$C_2H_6 + 2.5\,O_2 \longrightarrow 2\,CO + 3\,H_2O + 206.6\ \text{kcal mol}^{-1} \quad \text{(c)}$$

in the conversion of ethane to CO and CO_2 results in a large increase in the released reaction heat. Also, high ethane conversion coupled with high space velocity causes the release of a large amount of heat in a small catalyst zone. Because of these problems, the removal of heat from the reactor becomes very difficult, and the process can become uncontrolled owing to the formation of hot spots in the reactor. The conversion of ethane to ethylene in an energy-efficient (without applied energy) and safe manner is of great importance. In this communication we show that the endothermic cracking of ethane can be coupled with its oxidative dehydrogenation. The two reactions are carried out simultaneously in the presence of steam and limited O_2, by using a supported catalyst having high thermal/hydrothermal stability, SrO/La_2O_3/SA 5205, diluted with an inert solid. In this way ethane can be converted to ethylene efficiently and safely with high conversion and selectivity, and without coke formation. Our results reveal that by manipulating reaction conditions, particularly the temperature and the C_2H_6/O_2 ratio in the feed, this process can be made almost thermoneutral, mildly endothermic, or mildly exothermic, thus requiring little or no external energy.

Our results are summarized in Figures 1 and 2. The plots show the effects of the reaction temperature and the C_2H_6/O_2 mole ratio in the feed on conversion, selectivity, ratio of ethane conversion by cracking to ethane conversion by oxidation, net heat of reaction ΔH_r, and energy input to the reactor furnace. The coupled process is catalyzed by a supported catalyst with the composition SrO (17.3 wt%)/La_2O_3 (17.9 wt%)/SA 5205 diluted uniformly with the support SA 5205. This support is inert and porous (porosity: 50%), has a low surface area ($<0.01\ m^2 g^{-1}$), and consists of mainly Al_2O_3 (86.1 wt%) and SiO_2 (11.8 wt%). The net heat of the reaction is estimated by subtracting the heat of formation of the components in the feed (at the reaction temperature) from that of the components in the product stream.

The coupled process requires little or no external energy because the heat produced in the exothermic reactions is used instantly in the simultaneous endothermic reactions. Further,

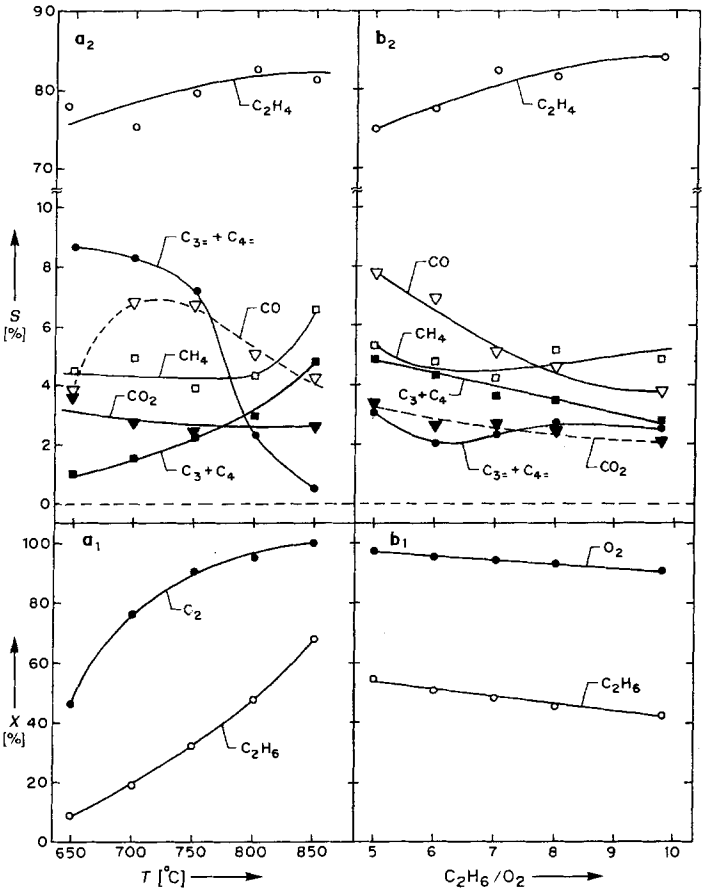

Fig. 1. Influence of a) reaction temperature and b) C_2H_6/O_2 mole ratio in feed on conversion and selectivity in the coupled process (T = reaction temperature, X = conversion, S = product selectivity). a) C_2H_6/O_2 mole ratio in feed = 7.0, b) T = 800 °C; C_2H_6/steam mole ratio = 1.0 and total space velocity = 35 100 cm^3 per g of diluted catalyst per h; ratio support/catalyst (wt/wt) = 2.0.

because the catalyst is dilute, longer residence times are possible for the slow noncatalytic reactions (particularly the thermal cracking of hydrocarbons). Heat removal from the reactor is also simplified since the heat transfer area of the reactor is increased.

The ratio of the conversion of ethane by endothermic cracking to that by exothermic oxidation (obtained from the feed and product compositions and reactions stoichiometry) increases with increasing reaction temperature and also with the C_2H_6/O_2 ratio. Consequently, the net heat of reaction (or the reaction endothermicity) also increases. The energy input to the reactor furnace for the coupled process (at different reaction conditions) relative to the energy input required in the absence of any reaction to maintain the same temperature is quite consistent with the net heat of reaction ΔH_r at the different reaction conditions. These observations clearly demonstrate the occurrence of simultaneous endothermic cracking and exothermic oxidative reactions and also the energy saving in the coupled process.

The overall process is thought to involve a complex series of catalytic surface reactions and noncatalytic reactions in the gas-phase. We suggest that the reaction is initiated on the catalyst (which also shows high activity/selectivity for the oxidative coupling of methane[9]) by formation of ethyl radicals from the surface reaction of ethane with adsorbed or lattice oxygen [Eq. (d)].

$$C_2H_6 + [O] \longrightarrow C_2H_5^{\cdot} + [OH] \quad \text{(d)}$$

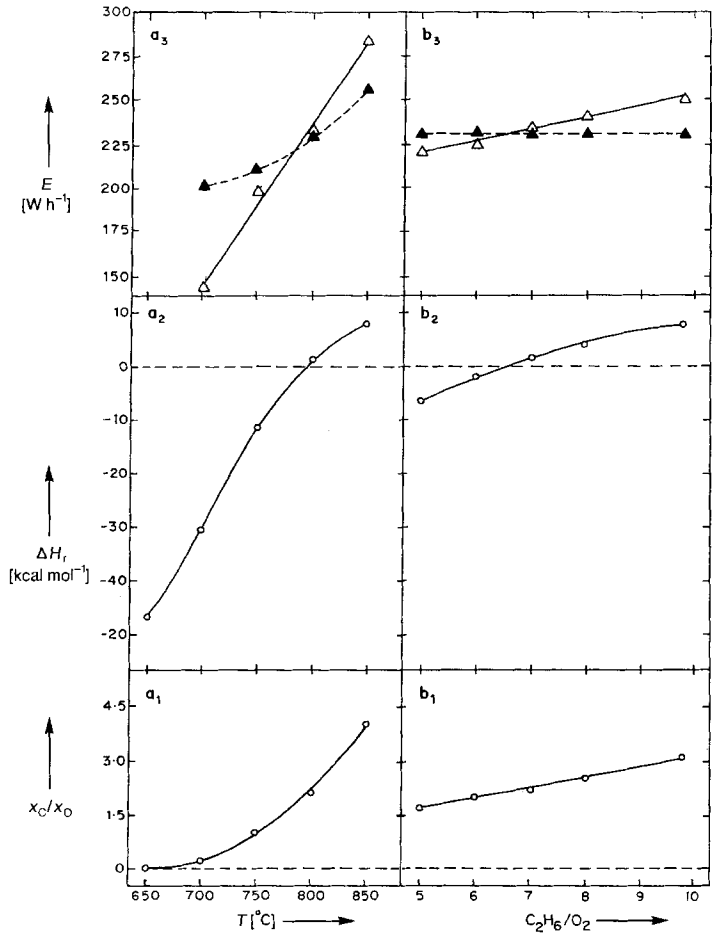

Fig. 2. Influence of a) reaction temperature and b) C_2H_6/O_6 mole ratio in feed on the relative conversion x_C/x_O of ethane by its cracking and oxidation reactions, on the net heat of reaction ΔH_r and energy input E to reactor furnace with (Δ) or without reaction (▲). T = reaction temperature. x_C = conversion of ethane by thermal cracking reactions, x_O = conversion of ethane by oxidation reactions.

(2 [OH] + 0.5 O_2 → H_2O + [O]; [OH] and [O] represent surface- or lattice-bound OH and O species, respectively.) The ethyl radicals desorb in the gas phase, and their subsequent homogeneous reactions lead to the formation of ethylene and longer chain hydrocarbons [Eqs. (e)–(h)].

$$C_2H_5^{\cdot} \longrightarrow C_2H_4 + H^{\cdot} \quad (e)$$

$$C_2H_6 + H^{\cdot} \longrightarrow C_2H_5^{\cdot} + H_2 \quad (f)$$

$$2\,C_2H_5^{\cdot} \longrightarrow C_4H_{10} \quad (g)$$

$$C_4H_{10} \longrightarrow \text{cracking products} \quad (h)$$

At higher temperatures the reaction should also be initiated by the formation of ethyl radicals from ethane [Eq. (i)]. The thermal decomposition of ethyl radicals [Eq. (e)] and ethane [Eq. (i)] is highly endothermic (ΔH_r = 36.4 and 100.6 kcal mol^{-1}, respectively). Since reaction (i) has a high activation energy (89.0 kcal mol^{-1})[10], it is predominant only at higher temperatures and lower concentrations of O_2. The thermal decomposition of ethyl radicals is also expected to be more predominant under these conditions. The results are quite consistent with these expectations. At higher oxygen concentrations ethyl radicals are also expected to be formed [Eq. (j)] and converted to ethylene [Eq. (k)] in the gas phase.

$$C_2H_6 \longrightarrow C_2H_5^{\cdot} + H^{\cdot} \quad (i)$$

$$C_2H_6 + O_2 \longrightarrow C_2H_5^{\cdot} + HO_2^{\cdot} \quad (j)$$

$$C_2H_5^{\cdot} + O_2 \longrightarrow C_2H_4 + HO_2^{\cdot} \quad (k)$$

Ethyl radicals may also undergo catalytic oxidative conversions [Eqs. (l) and (m)].

$$C_2H_5^{\cdot} + [O] \longrightarrow C_2H_4 + [O] \quad (l)$$

$$C_2H_4 + [O] \longrightarrow \text{combustion products (CO, } CO_2 \text{ and } CH_4) \quad (m)$$

The coupled process is thus very complex and involves a large number of homogeneous free radical reactions[10,11] in addition to catalytic reactions, depending upon the process conditions. Nevertheless, the process is very simple to conduct. The addition of steam in the feed is found to prevent formation of tarlike product and coke in the process.

The coupled process can be operated with a very low net heat produced or consumed and consequently with a low adiabatic increase or decrease in temperature. Thus further development may lead to a simple adiabatic reactor with very low capital and operating costs. Further work is required for understanding the nonisothermal behavior of such a reactor for the process and the complex reaction mechanism.

Experimental Procedure

The supported catalyst [SrO (17.3 wt%)/La_2O_3 (17.9 wt%)/SA 5205] was prepared by impregnating a commercial catalyst support SA 5205 (Norton Co., USA), crushed to 22–30 mesh size particles, first with lanthanum nitrate (GR LOBA) and then with strontium nitrate (extra pure, LOBA) by using the incipient wetness technique. After each impregnation the resulting particles were dried at 90 °C for 16 h and then calcined in static air at 900 °C for 4 h. The ethane conversions were conducted at atmospheric pressure in a continuous-flow tubular quartz reactor (i.d.: 5 mm) packed with 0.3 g of the diluted catalyst (catalyst diluted by uniformly mixing 0.1 g of the supported catalyst and 0.2 g of the support having the same particle size) and having a very low dead volume. The C_2H_6/steam mole ratio in the feed was 1.0 and total space velocity of the feed (measured at 0 °C and 1 atm) was 35100 cm^3 per gram of diluted catalyst per hour. The reactor was kept in a constant temperature zone of a tubular furnace (dia.: 2.0 cm). The energy input to the furnace, with and without reaction (at the same temperature and ambient conditions) was measued with an energy meter. The reaction temperature was measured with a Chromel-Alumel thermocouple in the diluted catalyst bed. The reactor effluent gases were cooled to 0 °C to remove water. The feed and products were analyzed by on-line gas chromatography. The error in C, H, O balances was less than 5%.

^{31}P CP/MAS NMR Spectroscopy of Transition Metal Phosphane Complexes: "*J*-Recoupling" between Chemically Equivalent ^{31}P Nuclei in Polycrystalline Compounds of the Type *trans*-[$(PR_3)_2MX_2$], M = Pd, Pt**

Elke Klaus and Angelika Sebald*

Spectroscopic properties of transition metal complexes are of fundamental interest in many branches of chemistry. In the case of Pd- and Pt-phosphane complexes, NMR spectroscopy in solution has for a long time been widely and successfully used for the investigation of structural and bonding properties.[1] The increasingly widespread availability of high-resolution solid-state NMR techniques, such as cross-polarization magic angle spinning[2] (CP/MAS) NMR provides an additional source of information, which may not be readily available from solution-state NMR or single-crystal X-ray studies. The ^{31}P nucleus, in particular, has become a popular CP/MAS target as it is usually straightforward to obtain ^{31}P MAS and CP/MAS NMR spectra of polycrystalline solids. This is also documented by a large, ever increasing number of publications dealing with CP/MAS NMR spectroscopy of this nucleus in transition metal phosphane complexes.[3] We report here on ^{31}P CP/MAS NMR spectra of square-planar Pd^{II} and Pt^{II} complexes of the type *trans*-[$(R_3P)_2MX_2$], M = Pd, Pt, in which the two phosphorus atoms are crystallographically equivalent. The two phosphane ligands R_3P in such complexes constitute a homonuclear ^{31}P spin pair. The solid-state NMR properties of homonuclear spin pairs under MAS conditions have recently been a major focus of much theoretical and experimental work.[4] We will show that for compounds of the type *trans*-[$(R_3P)_2MX_2$] seemingly minor, unimportant chemical modifications can completely alter the MAS NMR properties of the ^{31}P spin pair and that, therefore, reliable interpretation of such routinely available ^{31}P CP/MAS spectra must fully consider all orientation-dependent interactions within the ^{31}P spin pair.

Our ^{31}P CP/MAS NMR results on compounds *trans*-[$(R_3P)_2MX_2$] **1** (M = Pd) and **2** (M = Pt) are summarized in Table 1, in which the respective ^{31}P shielding tensor components are also listed. The general Hamiltonian operator for a homonuclear spin pair, such as the two ^{31}P nuclei in **1** and **2**, can be defined as in Equation (a), where $\mathcal{H}_Z$ is the Zeeman interaction,

$$\mathcal{H} = \mathcal{H}_Z + \mathcal{H}_{CS} + \mathcal{H}_J + \mathcal{H}_{DD} \qquad (a)$$

$\mathcal{H}_{CS}$ is the chemical shielding, $\mathcal{H}_{DD}$ is the homodipolar and $\mathcal{H}_J$ is the indirect homonuclear spin-spin coupling (*J* coupling). $\mathcal{H}_{CS}$, $\mathcal{H}_{DD}$, and $\mathcal{H}_J$ are orientation dependent with respect to the static magnetic field $\boldsymbol{B}_0$. If we refer to rapidly and isotropically reorienting molecules (as in non-viscous solutions), $\mathcal{H}_J$ and $\mathcal{H}_{CS}$ are averaged to their isotropic values J_{iso} and δ_{iso}, respectively, whereas $\mathcal{H}_{DD}$ is averaged to zero. In solution our pair of chemically equivalent ^{31}P nuclei in **1** and **2** is an A_2 spin system, giving rise to one single ^{31}P resonance: both ^{31}P nuclei have the same isotropic chemical shift $\delta(^{31}P)$; the isotropic *J*-coupling $^2J(^{31}P,^{31}P)$ is present but not observable since the intensity of the two outer transition lines is zero.[5] This "solution NMR" behavior is precisely what we find in the ^{31}P CP/MAS spectra of compounds **1a**, **2a**, **2c**, and **2d**: one sharp ^{31}P resonance flanked by ^{195}Pt satellites due to $^1J(^{195}Pt,^{31}P)$ for compounds **2** at all magnetic field strengths B_0 of 2.4–11.7 T and for MAS frequencies ranging from 0.8–12 kHz. A typical example, the ^{31}P CP/MAS spectrum of **2d** for two different MAS frequencies, is shown in Figure 1. It is extremely tempting to consider this ^{31}P CP/MAS behavior as typical for chemically equivalent ^{31}P spin pairs in crystalline solids, in analogy to the A_2 spin system in solution. In fact, the opposite is true: for a ^{31}P spin pair in solids very special circumstances are required to produce this appearance analogous to the A_2 spin system in solution.[4a] These special circumstances and the more general case of a chemically equivalent ^{31}P spin pair in the solid state will be discussed in the following.

Table 1. ^{31}P CP/MAS NMR results for the complexes **1** and **2** [a].

Komplex	δ_{iso} [b]	$^1J(^{195}Pt,^{31}P)$ [Hz]	$^2J(^{31}P,^{31}P)$ [Hz]	σ_{11}	σ_{22}	σ_{33}	η [c]
trans-[$(PEt_3)_2PdCl_2$] **1a**	18.3			16	5	−76	0.2
trans-[$(PnBu_3)_2PdCl_2$] **1b**	10.9		537	16	9	−57	0.2
trans-[$(PEt_3)_2PtCl_2$] **2a**	13.0	2393		60	−4	−95	0.8

	35.0	3112					

[a] All ^{31}P CP/MAS NMR spectra were obtained on Bruker MSL 100, MSL 300, or MSL 500 NMR spectrometers, using standard probes. Experimental parameters: recycle delays 2–10 s, contact times 0.3–1.5 ms, MAS frequencies 0.8–12 kHz. δ_{iso} and $^1J(^{195}Pt,^{31}P)$ were determined from fast spinning experiments. [b] Relative to external H_3PO_4 ($\delta = 0$). [c] Haeberlens notation [6] is used to report shielding tensor components: $\delta_{iso} = -\sigma_{iso}$; $|\sigma_{33} - \sigma_{iso}| \geq |\sigma_{11} - \sigma_{iso}| \geq |\sigma_{22} - \sigma_{iso}|$; $\eta = (\sigma_{22} - \sigma_{11})(\sigma_{33} - \sigma_{iso})^{-1}$.

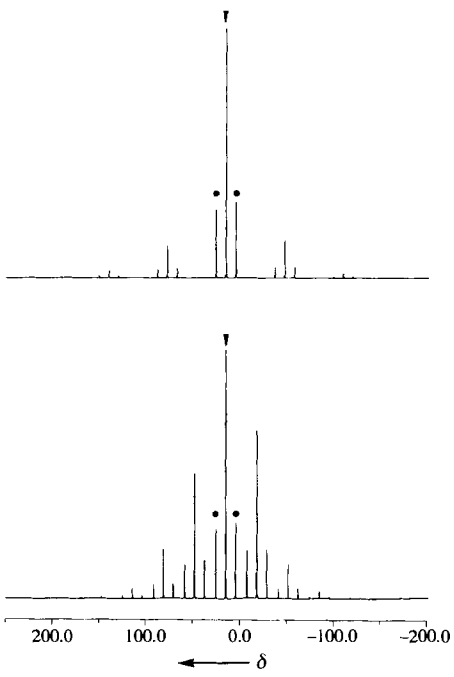

Fig. 1. 121.5 MHz ^{31}P CP/MAS NMR spectrum of **2d** at MAS frequencies of 7.6 kHz (top) and 4 kHz (bottom). The isotropic resonance is marked by an arrow, the ^{195}Pt satellites by a black dots.

Let us consider a spin pair in one single crystallite in a rigid powder sample. Furthermore, let us ignore the influence of anisotropy in J and the dipole–dipole interaction DD in the following explanation. In solid-state NMR, every single spin in a different orientation with respect to $\boldsymbol{B}_0$ will give rise to a distinct resonance line. If two chemically equivalent nuclei in a spin pair lead to only one single resonance for *every* possible orientation of the crystallite with respect to $\boldsymbol{B}_0$, these two nuclei are said to be magnetically equivalent.[4f, 6] This is possible only if the symmetry element connecting the two chemical shielding tensors of the two nuclei happens to be an inversion center. Within this symmetry requirement, there is no crystallite orientation possible which would lead to an instantaneous chemical shift difference δ_{CSA} for the spin pair.[4c, f] Hence, the intensity of the outer transitions due to J-coupling is zero for all orientations, and we observe the same spectral features in the solid state (one sharp resonance) as for the A_2 spin system in solution. Apparently, this symmetry criterion, that is the presence of an inversion center, is fulfilled for our solid compounds **1a**, **2a**, **2c**, and **2d**. Note that in all four cases the magnetically equivalent ^{31}P spin pair is produced by a pair of Et_3P ligands.

Let us consider next the more general case of a pair of chemically equivalent nuclei where the two shielding tensors are connected by a symmetry operation other than a center of inversion. Now there will be orientations of the crystallite with respect to $\boldsymbol{B}_0$ for which the two nuclei will give rise to two distinct resonances; the two nuclei are no longer magnetically equivalent, but will still display an identical isotropic chemical shift. The difference in the instantaneous chemical shift δ_{CSA} for certain orientations is the reason why in the solid state it is possible to observe J-coupling between chemically equivalent nuclei.[4c] In practice we do not work with single crystals but with polycristalline powders under MAS conditions. We observe this "J-recoupling" phenomenon[4c, f] in the ^{31}P CP/MAS NMR spectra of compounds **1b** and **2b**. In both cases the pair of chemically equivalent, but magnetically nonequivalent ^{31}P nuclei is produced by a pair of nBu$_3$P ligands! The effects of different magnetic field strengths B_0 and MAS frequencies on the J-recoupling pattern in the ^{31}P CP/MAS NMR spectra of **1b** are illustrated in Figure 2.

MAS leads to the well-known high-resolution spinning sideband patterns where the anisotropic interactions are not completely averaged but scaled, depending on the MAS frequency. Under MAS the nuclear spin Hamiltonian becomes periodically time-dependent. At $t = Nt_R$ (where t_R is the rotor period and N an integer), it can be described by an effective Hamiltonian consisting of an average Hamiltonian operator plus higher order correction terms as developed by Maricq and Waugh [Eq. (b)–(d)].[7] Our discussion will only include the first order cor-

$$\mathcal{H}_{eff} = \mathcal{H}^{(0)} + \mathcal{H}^{(1)} + \mathcal{H}^{(2)} + \ldots . \qquad \text{(b)}$$

$$\mathcal{H}^{(0)} = \frac{1}{t_R}\int_0^{t_R} \mathcal{H}(t)\,dt \qquad \text{(c)}$$

$$\mathcal{H}^{(1)} = \frac{-i}{2t_R}\int_0^{t_R} dt_2 \int_0^{t_2} [\mathcal{H}(t_2), \mathcal{H}(t_1)]\,dt_1 \qquad \text{(d)}$$

rectionterm. After inserting the time-dependent terms $\mathcal{H}_{eff}$ can be described according to Equation (e),[7, 4f] where K is a complex expression depending on DD, δ_{CSA}, and the MAS frequency

$$\mathcal{H}_{eff} = \omega_{iso}(I_{1z} + I_{2z}) + \omega_J I_1 \cdot I_2 - iK\frac{I_{1+}I_{2-} - I_{1-}I_{2+}}{2} \qquad \text{(e)}$$

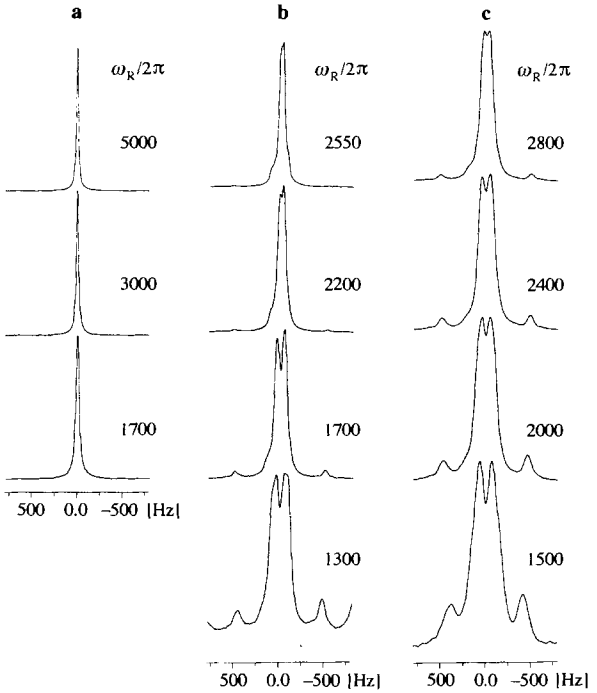

Fig. 2. ^{31}P CP/MAS NMR spectra of **1b** at different magnetic field strengths and different MAS frequencies. Only the isotropic region is shown. Note the interplay of B_0 (a) 40.5 MHz, b) 121.5 MHz, c) 202.5 MHz) and ω_R and the increasing intensity of the J-recoupling pattern with decreasing MAS frequencies. MAS frequencies $\omega_R/2\pi$ in Hz are given for each spectrum.

ω_R ($K \sim \omega_R^{-1}$, $\sim\delta_{CSA}$, $\sim$DD). The transition frequencies and their relative intensities are readily obtained from Equations (f)–(i),[7, 4c, f] where $D = [K^2 + \omega_J^2]^{1/2}$.

$$\omega_1 = \omega_{iso} + 1/2(D + \omega_J) \qquad P_1 = 1 - \frac{\omega_J}{D} \qquad \text{(f)}$$

$$\omega_2 = \omega_{iso} + 1/2(D - \omega_J) \qquad P_2 = 1 + \frac{\omega_J}{D} \qquad \text{(g)}$$

$$\omega_3 = \omega_{iso} - 1/2(D - \omega_J) \qquad P_3 = 1 + \frac{\omega_J}{D} \qquad \text{(h)}$$

$$\omega_4 = \omega_{iso} - 1/2(D + \omega_J) \qquad P_4 = 1 - \frac{\omega_J}{D} \qquad \text{(i)}$$

Here we only quote the final result; the full mathematical treatment can be found in the literature.[7, 4f] Equations (f–i) are identical with those for an AB spin system in solution, with two important exceptions: an AB spin pair in solution has two distinct chemical shifts ω_A, ω_B, and the corresponding mixing term has a different form ($D_{solution} = (1/2\,(\omega_B - \omega_A)^2 + w_J^2)^{1/2}$).[5] For an A_2 system in solution ($\omega_A = \omega_B$) it is obvious that P_1 and P_4 would be zero. In the solid state the mixing term D depends on K and, thus, on DD, δ_{CSA}, and ω_R. If δ_{CSA} or DD is zero, the mixing term D_{solid} takes the form of the mixing term $D_{solution}$ ($\delta_{CSA} = 0$ is what we observe in the ^{31}P CP/MAS spectra of **1a**, **2a**, **2c**, and **2d**). Figures 2 and 3 show how the anisotropic term K influences positions and intensities of the four transitions as a function of B_0 and ω_R for the case of magnetically nonequivalent spins (such as in **1b**, **2b**). The two internal parameters DD and δ_{CSA} are differently influenced by $\boldsymbol{B}_0$: δ_{CSA} is proportional to B_0, while DD is solely dependent on the internuclear distance between the two spins. Figure 3 also demonstates how $|^2J(^{31}P,^{31}P)|$ can be extracted from a series of ^{31}P CP/MAS NMR spectra. This procedure has also been used to determine

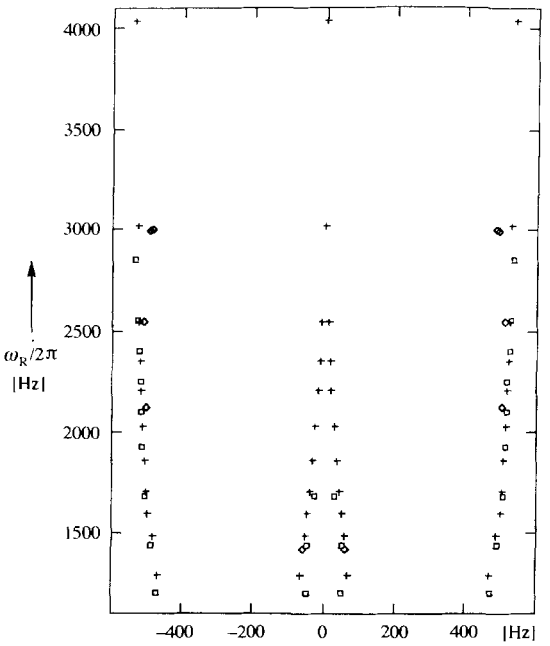

Fig. 3. Plot of relative positions of ^{31}P NMR resonances of **1b** versus $\omega_R/2\pi$ [Hz]. The symbols +, ◇, and □ refer to MSL 300, MSL 100, and MSL 500 data, respectively (for the latter two ω_R is scaled to allow for one common ω_R axis). Note that $|^2J(^{31}P,^{31}P)|$ in this case (and for **2b**) is given by alternate transitions 1,3 and 2,4, respectively, which is not possible for a solution-state AB spin system [4f,5].

$|^2J(^{31}P,^{31}P)|$ for solid $[(Ph_3P)_2Hg(NO_3)_2]$.[4f] Not only is it possible to obtain $|J_{iso}|$ for such pairs of chemically equivalent nuclei, the anisotropic perturbation term K also offers possibilities to determine relative chemical shielding tensor orientations from powder samples, a point which only recently has received attention.[8, 9]

The correct interpretation of routine ^{31}P CP/MAS NMR spectra of transition metal phosphane complexes generally requires careful consideration of the solid-state NMR properties of homonuclear spin pairs, including measurements over a wide range of ω_R and, if possible, at more than one B_0 strength. A, chemically speaking, minor modification such as replacing Et_3P by nBu_3P in otherwise homologous compounds can lead to expressedly different ^{31}P CP/MAS NMR properties (see also Table 1, compounds **2d, e**: the replacement of Et_3P for Ph_3P leads us from a magnetically equivalent pair to an even chemically inequivalent ^{31}P spin pair). Finally, it is well known from solution NMR spectroscopy that strongly coupled subsets of complex spin systems leave their complex footprints in the weakly coupled parts of such spectra.[5] The ^{195}Pt nucleus in compounds of the type *cis*- or *trans*-$[(R_3P)_2PtX_2]$ forms the X-part in a complex solid-state ABX spin system,[10] the homonuclear ^{31}P AB part and its complex ^{31}P CP/MAS behavior will also be mirrored in ^{195}Pt CP/MAS NMR spectra of such compounds.

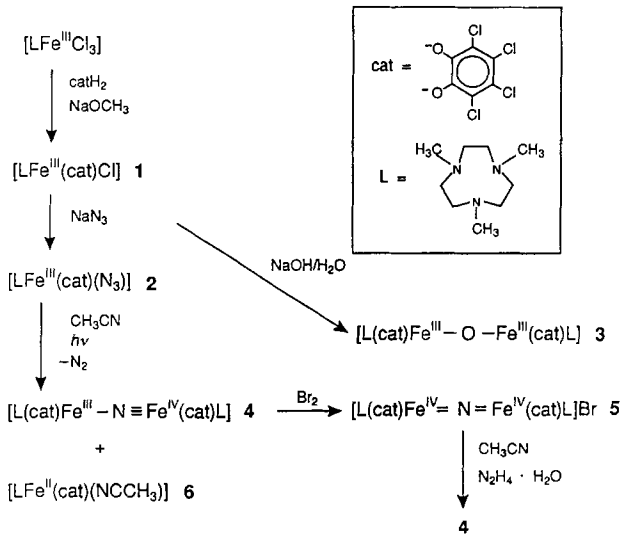
μ-Nitridodiiron Complexes with Asymmetric $[Fe^{IV}\equiv N-Fe^{III}]^{4+}$ and Symmetric $[Fe^{IV}=N=Fe^{IV}]^{5+}$ Structural Elements**

Thomas Jüstel, Thomas Weyhermüller, Karl Wieghardt,* Eckhard Bill, Marek Lengen, Alfred X. Trautwein, and Peter Hildebrandt

Dinuclear μ-nitridodiiron complexes with porphyrin or phthalocyanine ligands can be prepared in good yields by the thermolysis[2] or photolysis[3] of the corresponding mononuclear azidoiron(III) complexes, with the concomitant loss of N_2.[1-11] The resulting compounds contain a symmetric, linear[4] $[Fe=N=Fe]^{4+}$ moiety, in which both Fe ions are formally in the oxidation state + 3.5.[5] These complexes exhibit an ESR-active, $S = 1/2$ ground state[6] that results from the intramolecular antiferromagnetic coupling of a low-spin $Fe^{III}(d^5)$ and a low-spin $Fe^{IV}(d^4)$ center. As the Mössbauer spectra, even at low temperatures, show only *one* quadrupole doublet with isomer shifts ranging from $\delta = 0.08-0.18$ mm s^{-1},[7] these complexes belong to class III in the Robin and Day classification scheme,[8] with complete delocalization of the excess electron.[5] These complexes can be electrochemically[9] as well as chemically[10] oxidized to yield compounds containing a $[Fe^{IV}=N=Fe^{IV}]^{5+}$ unit; these compounds, however, have not yet been structurally characterized. They exhibit a diamagnetic ground state ($S = 0$) due to the strong antiferromagnetic coupling of two Fe^{IV} ($S = 1$) ions. Further oxidation leads to coordinated porphyrin π-radical cations.[11] μ-oxo bridged porphyrin,[12] phthalocyanine,[12] and porphycene and corrole[13] complexes with $[Fe^{III}$-O-$Fe^{III}]^{4+}$, $[Fe^{3.5}$-O-$Fe^{3.5}]^{5+}$, and $[Fe^{IV}$-O-$Fe^{IV}]^{6+}$ structural units have also been reported, the latter group only recently.



The planar, tetradentate dianions of porphyrins, phthalocyanines, and porphycenes, all of which have an N_4 donor set, enforce the low-spin configuration of the Fe^{III} and Fe^{IV} centers in complexes containing these ligands. We have examined, whether a similar chemistry, but with a high-spin configuration, can be developed by employing weaker, redox-inactive, neutral ligands containing O and N donor atoms. For this purpose, we

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

used 1,4,7-trimethyl-1,4,7-triazacyclononane, L, and tetrachlorocatechol, $catH_2$, as ligands.

The synthesis of the complexes **1**–**6** is summarized in Scheme 1. The reaction of $[LFe^{III}Cl_3]$ with tetrachlorocatecholate in anhydrous methanol yields dark green microcrystals of complex **1**.[14] Its chloro ligand can be replaced with an azido ligand by the reaction with NaN_3 in acetone, leading to the green compound **2**. The hydrolysis of **1** in acetone with $NaOH/H_2O$ leads to the dinuclear complex **3**, which contains a linear $[Fe^{III}$-O-$Fe^{III}]^{4+}$ unit. Photolysis of an ice-cooled solution of **2** in anhydrous, argon-purged acetonitrile, using a quartz Hg immersion

Scheme 1. Preparation of complexes **1**–**6**.

lamp, leads under loss of N_2 to black crystals of **4**, which can be recrystallized from dichloromethane. Workup of the reaction solution under an inert N_2 atmosphere yielded microcrystalline $\mathbf{6}\cdot 2H_2O$. Depending on the residual oxygen and moisture in the solvent employed, complex **4** is contaminated by small amounts of **3**.

The stoichiometry of the reaction $3\ \mathbf{2} \rightarrow \mathbf{4} + \mathbf{6} + 4N_2$ was verified by quantitative volumetric determinations of the N_2 formed during the reaction: per equivalent of **2**, 1.30 ± 0.2 equivalents of N_2 are formed (theoretical value: 1.33). The bromine oxidation of **4** in dichloromethane results in green-black crystals of the salt **5**. As **3**, present as a contaminant of **4**, cannot be oxidized by bromine, it remains in solution after the precipitation of **5**. Subsequent reduction of **5** with $N_2H_4\cdot H_2O$ in acetonitrile yields pure **4**.

The X-ray crystal structure analyses[15] of $\mathbf{3}\cdot 2$toluene, **4**, and $\mathbf{5}\cdot CH_3CN$ (Fig. 1 and Table 1) confirm the dinuclear nature of these species. All iron atoms are coordinated in a distorted octahedral fashion by a facially bound triamine and a didentate catecholato ligand; the sixth coordination site is occupied by the oxo bridge in **3** and the nitrido bridge in **4** and **5**, respectively. The dinuclear complexes display C_i symmetry, that is the bridging nitrogen atom in **4** and **5** and the bridging oxygen atom in **3** are located on a crystallographic center of symmetry.

Upon examination of the distribution of the total and residual electron density in the three Fe-X-Fe structural units (Fig. 2), it is apparent that only in **3** and **5** is the Fe-X-Fe unit indeed linear and symmetric. It was possible to calculate two statically disordered positions for the bridging nitrogen atom in **4**, using a split atom model (with occupancy factor of 0.5, on either side of

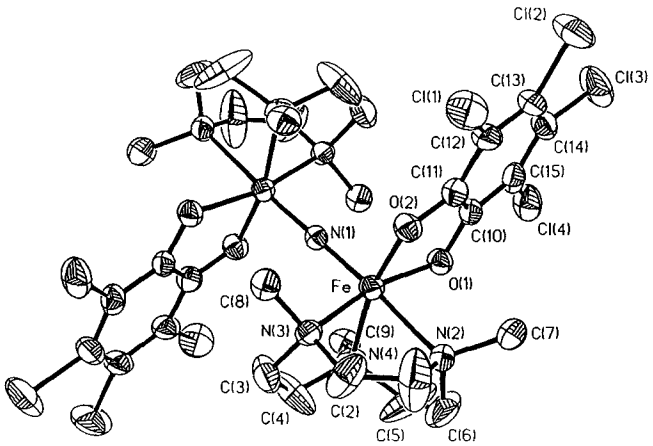

Fig. 1. Structure of the monocation of **5** in the crystal. The structures of the neutral complexes **3** and **4** are very similar and are not shown. In all cases, the oxygen and nitrogen atoms of the oxo or nitrido bridges, respectively, are situated on a crystallographic center of symmetry. Important structural parameters of **3**–**5** are given in Table 1.

Table 1. Comparison of the structural data of complexes **3**–**5**.

Complex	3	4	5
Fe-X/Å [a]	1.804(1)	1.495(7)	1.703(1)
		1.976(7)	
$Fe-O_{cat}$/Å	1.996(4)	1.960(3)	1.912(4)
	1.992(4)	1.978(3)	1.913(4)
$Fe-N_{trans}$/Å [b]	2.379(5)	2.356(4)	2.195(6)
$Fe-N_{cis}$/Å [b]	2.198(6)	2.129(3)	2.048(5)
	2.225(5)	2.137(3)	2.039(5)
O-C/Å	1.325(7)	1.329(5)	1.342(7)
	1.324(7)	1.323(4)	1.328(8)
Fe-X-Fe/°	180	180	180

[a] $X = O^{2-}$ in **3** and $X = N^{3-}$ in **4**, **5**. [b] $Fe-N_{amine}$ bond lengths in the *trans* or *cis* positions to the Fe–X bond.

the center of symmetry). This implies that the Fe-N-Fe unit in **4** is *asymmetric*, with a short Fe≡N bond of 1.50(1) and a long Fe–N distance of 1.98(1) Å.[16] Due to the disorder of the asymmetric $[Fe^{IV}\equiv N-Fe^{III}]^{4+}$ moiety in the unit cell, the $Fe-N_{amine}$ and $Fe-O_{cat}$ values for **4** given in Table 1 represent only the average values for the LFe^{III}(cat) and LFe^{IV}(cat) units. The crystal structure of **4** provides the first indication that in **4** the valencies are localized.

It is remarkable that the corresponding O–C and C–C bond lengths of the coordinated catecholato ligands are identical for all three structures within experimental error, indicating that they are independent of the formal oxidation state of the iron centers.

The cat^{2-} ligand is bound in all three complexes **3**, **4**, and **5** as catecholate dianion.[17] It is interesting to compare corresponding bond lengths in **3**, containing a $[Fe^{III}$-O-$Fe^{III}]^{4+}$ unit, and **5**, with a $[Fe^{IV}=N=Fe^{IV}]^{5+}$ moiety. The $Fe-O_{cat}$ distances in **3** are 0.082 Å longer than those found in **5**, while the $Fe-N_{amine}$ bonds *cis* to the bridging atom are even 0.168 Å longer in **3** than in **5**. The *trans* $Fe-N_{amine}$ bond in **3** is 0.184 Å longer than the one found in **5** (Table 1). These large differences in bond lengths can be understood when looking at the electronic configuration of the iron centers: in the LFe^{III}(cat) unit, a high-spin configuration is present ($S = 5/2$), with two half-filled e_g^* orbitals, while in the LFe^{IV}(cat) unit a low-spin configuration ($S = 1$) with *empty* e_g^* orbitals is present. It is remarkable that the apparent (i.e., averaged) $Fe-O_{cat}$ and *cis*-$Fe-N_{amine}$ distances in **4** correspond to the arithmetic mean of the equivalent

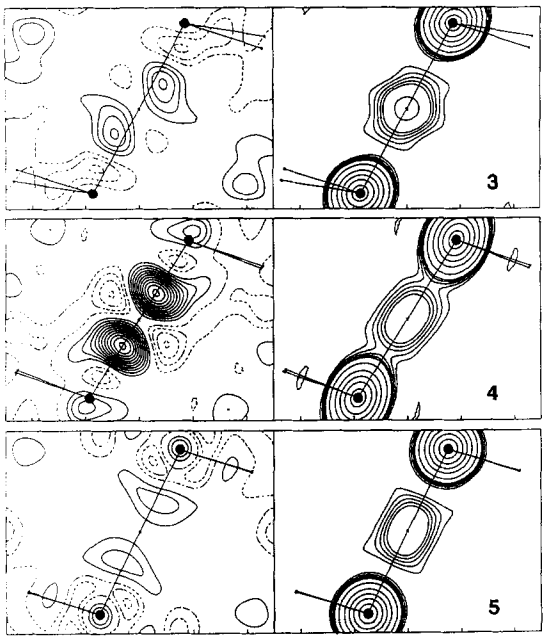

Fig. 2. Calculated contour maps of the residual electron density ($F_o - F_c$; left side) and the observed total electron density (F_o; right side) for the Fe-X-Fe moieties in the crystal structures of **3**–**5**. The plane shown is located between the catecholate oxygen atoms, it contains the iron atoms as well as the bridging oxygen and nitrogen atoms. The calculated values F_c were obtained after refinement for the structures had converged, using anisotropic temperature factors for the LFe(cat) units, while the bridging O atoms in **3** and the bridging N atoms in **4** and **5** were given isotropic temperature factors, as they are located on a crystallographic center of symmetry. The gradients for the electron density are as follows: left side: —— 0.1 e Å^{-3}; – – – −0.1 e Å^{-3}; right side: (going inward) 1, 2, ... 5 e Å^{-3}, going further inward 10, 20, ... 50 e Å^{-3}. (● = Fe atoms)

distances in **3** and **5**. The oxo bridge in **3** and the nitrido bridge in **5** exert a strong *trans* effect on the *trans*-Fe–N_{amine} bond ($\Delta[(Fe-N_{amine})_{trans}-(Fe-N_{amine})_{cis}]$: 0.17 Å in **3** and 0.22 Å in **5**).

Measurements of the molar magnetic susceptibilities (Faraday balance) yielded effective magnetic moments for the mononuclear complexes **1** and **2** that are characteristic for octahedral high-spin iron(III) complexes ($S = 5/2$) (Table 2), while the mononuclear species **6** was found to have a high-spin Fe^{II} configuration ($S = 2$). Complex **3** exhibited strongly temperature-dependent magnetic moments (4–298 K, SQUID magnetometer), which could be fitted without problems with the isotropic Heisenberg-Dirac-vanVleck model ($H = -2J\,\vec{S}_1 \cdot \vec{S}_2$, $S_1 = S_2 = 5/2$, $g = 2.0$ (fixed)), and a paramagnetic impurity of 2% ($S = 5/2$)), yielding $J = -90 \pm 4\ cm^{-1}$. Compound **3** therefore contains two high-spin Fe^{III} ions, which are antiferromagnetically coupled by a superexchange mechanism (oxo bridges), resulting in an $S = 0$ ground state.[12] Analogous measurements on **4** yielded a temperature-independent magnetic moment μ of 3.8 μ_B per dinuclear complex in the temperature range 50–300 K. Below 50 K, μ decreased to 2.8 μ_B at 3.0 K due to the zero-field splitting ($D_{3/2} = 13 \pm 4\ cm^{-1}$). Hence **4** has an $S = 3/2$ ground state resulting from strong antiferromagnetic coupling between a high-spin Fe^{III} ($S = 5/2$) and a low-spin Fe^{IV} ($S = 1$) center ($|J| > 150\ cm^{-1}$). The X-band ESR spectrum of **4** in dichloromethane at 10 K (Fig. 3) confirms the $S = 3/2$ ground state. The zero-field splitting was determined from the temperature dependence of the signal (3.0–40 K) to be $16 \pm 5\ cm^{-1}$, which is in good agreement with the value determined by susceptibility measurements. Complex **5** is diamagnetic even at 298 K ($S = 0$ ground state), indicating very strong

Table 2. Selected physical data for the complexes **1**–**6**.

1: IR: ν(Fe–O_{cat}) 564, ν(C–O_{cat}) 1250 cm^{-1}; UV/Vis (CH_3CN): λ_{max} (ε, M^{-1}cm^{-1}) = 304 (7800), 460 (1640), 704 nm (2400); magnetic moment (293 K): $\mu_{eff} = 5.8\ \mu_B$; ESR (X-band, DMSO, 10 K): rhombic signal $g_x = 5.7$, $g_y = 6.5$, $g_z = 2.0$; rhombicity $E/D = 0.017$.

2: IR: ν(Fe–O_{cat}) 563, $\delta(N_3)$ 640, $\nu_s(N_3)$ 1345, ν(C–O_{cat}) 1245, $\nu_{as}(N_3)$ 2069 cm^{-1}; UV/Vis (CH_3CN): λ_{max} (ε) = 306 (8600), 411 (3300), 680 nm (2500); magnetic moment (293 K): $\mu_{eff} = 5.7\ \mu_B$; ESR (X-band, acetone, 10 K): rhombic signal $g_x = 5.6$, $g_y = 6.5$, $g_z = 2.0$; rhombicity $E/D = 0.019$.

3: IR: ν_{as}(Fe-^{16}O-Fe) 817, ν_{as}(Fe-^{18}O-Fe) 777 cm^{-1}; resonance Raman (excitation at 407 and 483 nm; acetone): ν_s(Fe-^{16}O-Fe) 354, ν(Fe–O_{cat}) 544 cm^{-1} (both bands do not exhibit an isotope effect when the bridging O atom is labeled with ^{18}O); UV/Vis (CH_3CN): λ_{max} (ε) = 260 (16.3×10^3), 304 (14.3×10^3), 491 nm (5.0×10^3); cyclic voltammetry (0.10 *M* [N(*n*Bu)$_4$]PF_6, acetone): reversible one-electron oxidation at $E_{1/2} = +0.42$ V vs. Fc^+/Fc, irreversible reduction (1e) at −1.10 V.

4: MS (FAB): *m/z* (%): 960 (0.65) [M^+]; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 328 (16.9×10^3), 423 (4900), 442 (sh), 876 nm (300); resonance Raman (excitation at 413 nm, CH_2Cl_2): strongest band at 911.3 cm^{-1} ν(Fe-^{14}N-Fe) or at 884.2 cm^{-1} for the ^{15}N-labeled complex; cyclic voltammetry (0.10 *M* [N(*n*Bu)$_4$]PF_6, CH_2Cl_2): reversible one-electron oxidation at $E_{1/2} = +0.55$ V vs. Fc^+/Fc, irreversible one-electron reduction at −0.61 V. The electronic spectrum of **4** exhibits an intervalence band at 876 nm ($\varepsilon = 300\ M^{-1}cm^{-1}$), which is not found in the spectra of **3** and **5**.

5·CH_3CN: MS (FAB): *m/z* (%): 960 (100) [M^+]; resonance Raman (acetone): excitation at 413 nm: strongest band at 407 cm^{-1} ν_s(Fe-N-Fe), which does not show an isotope effect upon ^{15}N labeling; excitation at 520 nm: strongest band at 568 cm^{-1} ν(Fe–O_{cat}) (IR: 570 cm^{-1}); UV/Vis (CH_3CN): λ_{max} (ε) = 228 (5.5×10^4), 267 (8.9×10^4), 316 (3.3×10^4), 523 (2.2×10^3), 617 (1.7×10^3), 770 nm (1.1×10^3); ^{1}H NMR (400 MHz, CD_3NO_2) of the PF_6^-·toluene salt of **5**: δ = 7.15 (m, aromatic toluene protons), 3.41 (s, 6H; CH_3), 2.4–3.2 (m, 12H; N-CH_2-CH_2-N), 2.25 (CH_3, toluene), 1.95 (s, 3H, CH_3).

6·$2H_2O$: MS (FAB): *m/z* (%): 473 (5) [M^+]; IR: ν(C≡N) 2197 cm^{-1}; UV/Vis (CH_3CN): λ_{max} (ε) = 520 (820); magnetic moment (293 K): $\mu_{eff} = 5.0\ \mu_B$.

intramolecular antiferromagnetic coupling ($|J| > 200\ cm^{-1}$) between two low-spin Fe^{IV} ($S = 1$) ions.

The Mössbauer spectrum of solid **4** at 77 K is composed of three subspectra (Table 3; Fig. 4). The weak doublet at $\delta = 0.48$ mm s^{-1} is identical to that found for **3** and can therefore by attributed to the contamination by the μ-oxodiiron(III) compound. The two other doublets are of equal intensity, but exhibit very different isomer shifts. The signal at $\delta = 0.52$ mm s^{-1} is typical for octahedrally coordinated high-spin Fe^{III}, while the doublet at $\delta = 0.09$ mm s^{-1} is characteristic for octahedrally coordinated low-spin Fe^{IV}—it is also found for complex **5** containing the $[Fe^{IV}=N=Fe^{IV}]^{5+}$ unit. The isomer shifts confirm the formulation of **4** as a mixed-valent $Fe^{III}Fe^{IV}$ complex, with localized valences on the time scale of Mössbauer spectroscopy (10^{-7} s).[19] These results contrast strongly to those obtained for the porphyrin and phthalocyanine complexes known so far, which contain a symmetric, electronically delocalized $[Fe^{3.5}=N=Fe^{3.5}]^{4+}$ structural unit and an $S = 1/2$ ground state.

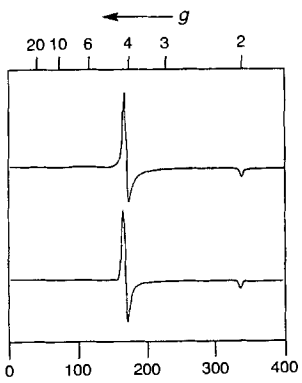

Fig. 3. X-band ESR spectra of **4** in CH_2Cl_2 at 10 K. Upper trace: experimentally obtained spectrum (9.4325 GHz; 20 μW/40 dB, modulation frequency: 100.0 kHz, modulation amplitude 1.00 mT); lower trace: simulated spectrum, having $g_x = 3.985$, $g_y = 4.140$, $g_z = 1.999$, rhombicity parameter $E/D = 0.013$. The ordinate axis is in arbitrary units of dX''/dB.

Complex **4** belongs therefore to class II (maybe even only to class I) in the Robin–Day scheme for mixed-valent compounds.[8] This stems presumably from the large Franck–Condon energy bar-

Experimental Procedure

1: $catH_2$ (0.30 g) and sodium methanolate (0.13 g) was added to a suspension of $LFeCl_3$ (0.30 g) [18] in anhydrous methanol (30 mL). The mixture was heated to reflux for 4 h. Upon cooling to 20 °C, dark green microcrystals of **1** formed. Yield 0.43 g (94%).

2: A solution of **1** (0.30 g) and NaN_3 (0.40 g) in anhydrous acetone (150 mL) was heated to reflux for 6 h. Upon cooling to −25 °C, green crystals of **2** formed. Yield 0.27 g (90%).

3: An aqueous NaOH solution (6 mL, 0.10 M) was added with intense stirring to a suspension of **1** (0.30 g) in acetone (100 mL). The mixture was subsequently stirred for 3 h at 20 °C and filtered. The filtrate was placed in an open container and left undisturbed for 24 h. Red crystals of **3** formed during this period. Yield 0.26 g (93%). Recrystallization from acetone/toluene (1:1) led to single crystals of **3**·2toluene.

4: A solution of **2** (0.10 g) in anhydrous acetonitrile (200 mL) was irradiated for 5 h with a quartz Hg immersion lamp. The solution was kept at 0 °C and argon was bubbled through the mixture throughout the process. During the irradiation, black crystals of **4** precipitated, which were recrystallized from CH_2Cl_2. Yield 0.40 g (42%). This material is contaminated to varying degrees by **3**, depending on the residual water and oxygen contents.

5: Br_2 (0.50 mL) was added dropwise with stirring to a solution of **4** (0.10 g) in dry CH_2Cl_2 (50 mL). After the mixture had been stirred for 3 h at 20 °C, black-green crystals formed, which were recrystallized from acetonitrile/toluene (1:1): **5**·CH_3CN; yield 0.80 g (74%). The reduction of **5** (0.50 g) in acetonitrile (50 mL) using $N_2H_4\cdot H_2O$ yielded pure, crystalline **4**.

6: The photolysis of **2** led to the nearly quantitative precipitation of **4**, due to its extremely low solubility in CH_3CN. The resulting solution was subjected to filtration, after which the solvent was removed by rotary evaporation under an N_2 atmosphere. The gray-black residue was dissolved in a deoxygenated 1:1 mixture of acetone/toluene. Slow evaporation of this solution led to the precipitation of violet crystals of **6**·$2H_2O$. Yield 40% (based on **2**).

All compounds yielded satisfactory elemental analyses for C, H, N, Cl, and Fe.

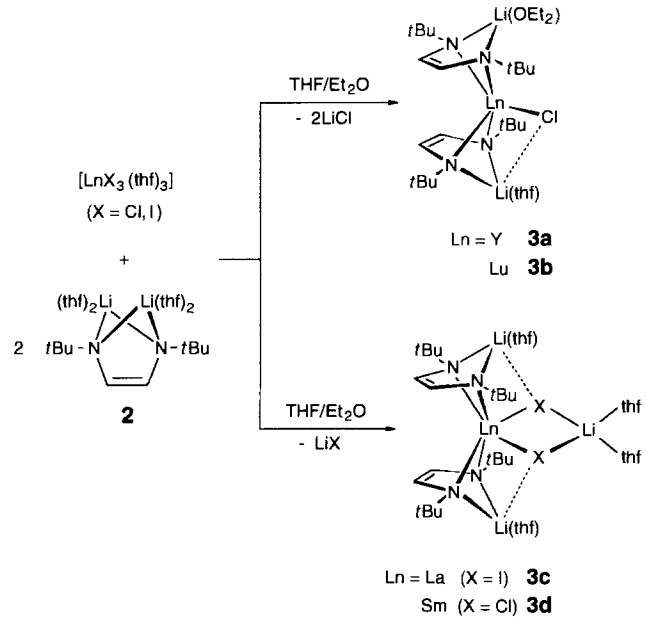
Lanthanoid Complexes with [(dad)Li] Ligands—New Starting Materials for Organolanthanoid Chemistry**

Helmar Görls, Bernhard Neumüller, Annett Scholz, and Joachim Scholz*

In contrast to transition metal compounds, for which the 18-e$^-$ rule generally enables one to make a reliable statement about the relative stability, the steric saturation of the metal atom plays a decisive role for the stability of the organolanthanoid compounds. For this reason, pentamethylcyclopentadienyl (Cp*) and cyclopentadienyl ligands (RCp) with bulky substituents R[1] or other known Cp equivalents employed in transition metal chemistry such as tritox (**A**), silox (**B**), scorpionate (**C**), or benzamidinate ligands (**D**) are an essential prerequisite for the preparation of most organolanthanoid compounds.[2] These ligands are also advantageous from a preparative point of view since their use frequently leads to highly soluble compounds.



In connection with the application of 1,4-diaza-1,3-diene ligands in organometallic chemistry, it has been shown that the sterically very demanding *N,N'*-bis(*tert*-butyl)glyoxaldiimine **1** (dad) can also shield reactive centers of the molecule.[3] Furthermore, as the dianion (enediamide) it is capable of stabilizing transition metals in high oxidation states.[4] However, in lanthanoid chemistry little has been made of these useful properties: To date very few lanthanoid–dad complexes are known and in these **1** occurs almost exclusively as a radical anion.[5]

(*t*Bu)N=CHCH=N(*t*Bu) **1**

We report here on the synthesis and the structure of lanthanoid complexes in which **1** is bound as a dianion to lanthanoid ions and [(dad)Li]$^-$ units assume the function of Cp ligands. Furthermore, these novel lanthanoid–dad complexes offer an alternative to cyclopentadienyllanthanoid halides, the most commonly used starting materials in lanthanoid chemistry, because of their simple method of preparation and their good solubility.

The lithium–dad compound **2** is particularly suitable for the transfer of the dad dianion $\mathbf{1}^{2-}$ to the lanthanoid ion (Scheme 1). Compound **2** forms quantitatively in the reaction of **1**, which is readily accessible from *tert*-butylamine and glyoxal, with 2 molar equivalents of lithium in THF.[6] The subsequent reaction of

Scheme 1. Synthesis of the new complexes **3**.

2 with the lanthanoid halide–THF adducts $[YCl_3(thf)_3]$, $[LaI_3(thf)_3]$, $[SmCl_3(thf)_3]$, or $[LuCl_3(thf)_3]$, each in the mole ratio 2:1, leads to orange to red-brown solutions, from which the new lanthanoid complexes can be isolated as pale yellow (**3a** and **3b**), shiny yellow (**3c**), and black-red crystals (**3d**) in 75–95% yields after separation of the lithium halide and recrystallization from diethyl ether. As expected, the complexes **3a–d** decompose very rapidly in air; however, under an argon atmosphere they can be stored indefinitely and are thermally stable. Furthermore, it is remarkable that the new complexes are readily soluble in both diethyl ether and THF as well as in aromatic and aliphatic hydrocarbons.

Simple NMR spectra containing only one set of signals for the dad ligand indicate that **3a–d** are highly symmetrical. In the ^{13}C NMR spectra, the signal of the azomethine-C atom shifted to high field relative to that of the free ligand **1** confirms that the two heterodienes are bound as dianions to the lanthanoid ion (**1**: $\delta = 158.14$; **3a–d**: $\delta = 111.61-118.36$). Thus, the chemical shifts of the azomethine-C atoms of **3a–d** are remarkably very similar to those of the lithium–dad compound **2** ($\delta = 113.79$).[6b]

The results of the X-ray crystal structure analyses of **3b** and **3d** show that contrary to the NMR data, and evidently depending on the radius of the lanthanoid ion, two different types of complex exist.[7] Single crystals of **3b** form on cooling of a saturated solution of the compound in diethyl ether; Figure 1 shows the results of the structure analysis. The Lu atom forms the center of a coordination polyhedron generated by the Cl and the four N atoms of the two dad ligands. The four N atoms bridge the Lu with two Li atoms; the two (LuN_2Li) rings formed are twisted by 89.7(1)° with respect to each other and are linked to each other through the Lu center. The two dad ligands show

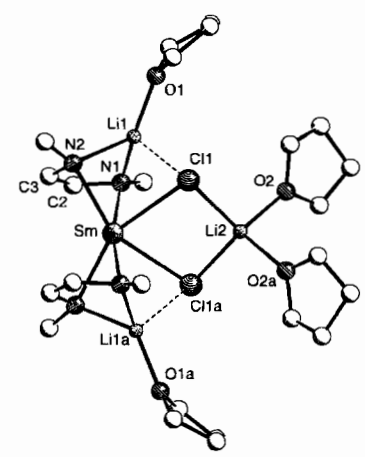
a "long-short-long" sequence of the N–C=C–N bond lengths typical for an enediamide structure. Short distances between the olefinic C atoms C1 and C2 and the metal centers Li1 and Lu, which are arranged on the opposite sides of the *cis*-configurated dad dianion (N1–C1=C2–N2), in particular, emphasize its bridging function. These distances lie in the range of usual Li–C and Lu–C bonds and indicate an intensive π interaction; thus, this dad dianion is formally coordinated η^4 to both metals.[9] Overall a structure motif results which was observed very recently for a Yb compound[5c] and is also comparable with that of the dilithium–dad compound [{Li(thf)$_2$}$_2${N(Me-4-C$_6$H$_4$)C(Ph)=C(Ph)N(Me-4-C$_6$H$_4$)}] reported by us a short while ago.[8] In the case of the second dad dianion a π interaction simply occurs between the C3–C4 double bond and Li2.

Remarkably, on recrystallization of **3b** from diethyl ether only the molecule of THF coordinated to the Li1 atom is substituted by diethyl ether. The reason for this is presumably the additional contact of the Cl atom with Li2 (Li2–Cl 2.429(9) Å), which leads to a tetrahedral coordination of Li2 and thus makes the replacement of THF at this Li atom kinetically more difficult.

The structure of **3d** differs from that of **3b** significantly in that the central Sm atom achieves the coordination number six by the addition of one molecule of LiCl; thus, overall the Sm atom is surrounded in a distorted octahedral fashion by four N and two Cl atoms (Fig. 2).[7] The two Cl atoms bridge the Sm atom with the Li2 atom, which is coordinatively saturated by two molecules of THF. Thus, overall, the molecular structure of **3d** is very similar to those of many bis(pentamethylcyclopentadienyl)lanthanoid halides [Cp$^*_2$Ln(μ-X)$_2$ML$_2$] **E** (Ln = lanthanoid; X = Cl, Br, I; M = Li, Na, K; L = Et$_2$O, THF, dme).[10] Evidently, the formation of this characteristic structure type for **3c** and **3d** is favored by the larger ionic radius of Sm^{3+} (0.964 Å) and La^{3+} (1.061 Å) relative to that of Y^{3+} (0.892 Å) and Lu^{3+} (0.848 Å).[11] Important structure elements of **3b**, however, are also present in **3d**; for example, the interaction of the Sm atom with the π-electron system C2=C3 of the dad ligand (Sm–C2 2.681(6), Sm–C3 2.654(6) Å) and the threefold coordination of the Li centers Li1 and Li1a. The latter is undoubtedly attributed to the spatial demand of the *tert*-butyl groups of the dad ligands, which prevents that more than one molecule of THF can be coordinated to these Li atoms.[12]

E

The low symmetry of the molecule structure of **3b** leads to the conclusion that the simple NMR spectra of this compound are simulated by a rapid molecular dynamic at room temperature. In fact the sharp singlets of the dad ligands in the ^{1}H NMR spectra ([D$_8$]THF) of **3a–d** coalesce on lowering the temperature at which the sample was measured and each singlet splits into two signals of equal intensity. An inversion of the folded metallacyclic five-membered ring M(NC=CN), like that which has been observed for many dad complexes of electron-deficient transition metals (Scheme 2, top[13]), can be ruled out as a reason for this dynamic behavior. First, the Li atoms block the swinging of the five-membered ring about the N,N′ axis, and second, even with a rapid inversion of both heterodiene ligands in **3a** and **3b**, the signals would be nonequivalent because of the differing influence of the Cl atom. Therefore, we assume that the [(dad)Li] units undergo a rotation or at least an oscillation at the complex core (Scheme 2, bottom). According to preliminary investigations, the energy barrier of this exchange process is 44.5(±1) kJ mol^{-1} for **3a** and 54.6(±) kJ mol^{-1} for **3b**.



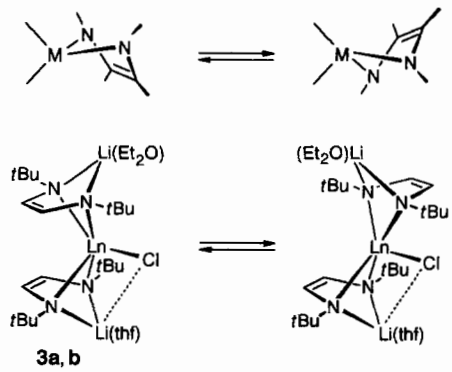


Fig. 2. Molecular structure of **3d** in the crystal. Only the quaternary C atoms of the *tert*-butyl groups are shown for clarity. Selected bond lengths [Å], bond, torsion, and interplanar angles [°]: Sm1-N1 2.482(4), Sm1-N2 2.420(5), Sm1-C2 2.681(6), Sm1-C3 2.654(6), Sm1-Cl1 2.878(2), Sm1-Li1 2.986(8), Li1-N1 2.08(1), Li1-N2 2.10(1), Li1-Cl1 2.50(1), Li2-Cl1 2.338(8), Li1-O1 1.93(1), Li2-O2 1.99(1), N1-C2 1.393(7), N2-C3 1.390(8), C2-C3 1.366(9); Cl1-Sm1-Cl1a 77.76(4), N1-Sm1-N2 68.2(2), N1-Sm1-N1a 169.7(1), N1-Sm-N2a 117.1(2), Cl1-Li2-Cl1a 101.2(5), Sm1-Cl1-Li2 90.5(2), O2-Li2-O2a 95.4(6), N1-C2-C3 120.2(6), N2-C3-C2 119.4(6), N1-Sm1-Cl1 81.7(1), N2-Sm1-Cl1 81.3(1); (Sm1,N1,N2)(Sm1,N1a,N2a) 67, (Sm1,N1,N2)(N1,N2,C2,C3) 77; N1-C2-C3-N2 0.0(1).

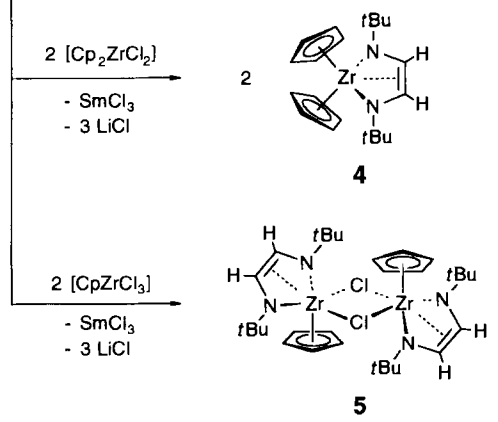

Scheme 2. Top: Inversion of the folded, five-membered metallacycle in dad complexes; bottom: postulated rotation or oscillation process in **3a, b**.

Owing to their structural relationship with the cyclopentadienyllanthanoid halides, the new lanthanoid–dad complexes **3a–d** are of interest as starting materials in organolanthanoid chemistry. Thus, not only can the halogen atoms be substituted by organic groups or other ligands, but also the Li atoms can be replaced by other metals. In this way **3a–d** open a route to new

3d

lanthanoid multinuclear complexes. However, in these reactions it must be noted that the complexes **3** under certain conditions, like the lithium–dad compound **2** itself, act simply as a dad transferer: for example, the reaction of **3d** with $[Cp_2ZrCl_2]$ or $[CpZrCl_3]$ leads smoothly to the formation of the complexes **4** and **5**, respectively.[14]

Experimental Procedure

All reactions were carried out in thoroughly dried and degassed solvents under an argon atmosphere.

3a: $[YCl_3(thf)_3]$ (3.72 g, 9.04 mmol) was added to a solution of **2** [prepared from **1** (3.04 g, 18.08 mmol) and lithium (0.251 g, 36.16 mmol) in THF (100 mL)] at −78 °C and stirred. The reaction mixture was allowed to warm slowly to room temperature and stirred for a further 24 h. Subsequently the solvent was removed under vacuum, and the residue was extracted with diethyl ether (100 mL). Pale yellow crystals of **3a** precipitated from the extract at −20 °C (yield 5.16 g, 92% based on $[YCl_3(thf)_3]$, correct elemental analysis). ^{1}H NMR (300 MHz, [D$_8$]THF, 20 °C): δ = 5.50 (s, 4H; NCH=), 3.62 (m, 4H; OCH_2CH_2), 3.38 (q, 4H; OCH_2CH_3), 1.78 (m, 4H; OCH_2CH_2), 1.14 (s, 36H; CMe_3), 1.12 (t, 6H; OCH_2CH_3); ^{13}C NMR (75 MHz, [D$_8$]THF, 25 °C): δ = 113.02 (dd, ^1J(C,H) = 160.6 Hz, ^2J(C,H) = 8.4 Hz; NCH=), 66.25 (t, ^1J(C,H) = 139.1 Hz; OCH_2CH_3), 53.23 (s; CMe_3), 32.00 (q, ^1J(C,H) = 123.0 Hz; CMe_3), 15.62 (q, ^1J(C,H) = 125.5 Hz; OCH_2CH_3).

3b: $[LuCl_3(thf)_3]$ (3.25 g, 6.53 mmol) was added to a solution of **2** [prepared from **1** (2.20 g, 13.06 mmol) and lithium (0.181 g, 26.12 mmol) in THF (100 mL)] at −78 °C and stirred. The workup of the reaction mixture was carried out as for **3a**. Yield 3.60 g of pale yellow crystals of **3b**, 78% based on $[LuCl_3(thf)_3]$, correct elemental analysis. Crystals suitable for an X-ray crystal structure analysis were obtained by recrystallization from diethyl ether. ^{1}H NMR (300 MHz, [D$_8$]THF, 20 °C): δ = 5.55 (s, 4H; NCH=), 3.62 (m, 4H; OCH_2CH_2), 3.38 (q, 4H; OCH_2CH_3), 1.78 (m, 4H; OCH_2CH_2), 1.14 (s, 36H; CMe_3), 1.11 (t, 6H; OCH_2CH_3); ^{13}C NMR (75 MHz, [D$_8$]THF, 25 °C): δ = 111.61 (dd, ^1J(C,H) = 161.7 Hz, ^2J(C,H) = 8.3 Hz; NCH=), 66.18 (t, ^1J(C,H) = 139 Hz; OCH_2CH_3), 53.41 (s; CMe_3), 31.73 (q, ^1J(C,H) = 123.7 Hz; CMe_3), 15.72 (q, ^1J(C,H) = 125.5 Hz; OCH_2CH_3).

3c: $[LaI_3(thf)_3]$ (8.16 g, 11.09 mmol) was added in portions to a solution of **2** [prepared from **1** (3.73 g, 22.18 mmol) and lithium (0.308 g, 44.36 mmol) in THF (150 mL)] at −78 °C and stirred. The workup of the reaction mixture was carried out as for **3a**. Yield 8.34 g of bright yellow crystals of **3c**, 75% based on $[LaI_3(thf)_3]$, correct elemental analysis. ^{1}H NMR (300 MHz, [D$_8$]THF, 20 °C): δ = 5.40 (s, 4H; NCH=), 3.63 (m, 16H; OCH_2CH_2), 1.78 (m, 16H; OCH_2CH_2), 1.18 (s, 36H; CMe_3); ^{13}C NMR (75 MHz, [D$_8$]THF, 25 °C): δ = 115.88 (dd, ^1J(C,H) = 157.2 Hz, ^2J(C,H) = 9.4 Hz; NCH=), 68.21 (t, ^1J(C,H) = 144.6 Hz; OCH_2CH_2), 53.81 (s; CMe_3), 33.66 (q, ^1J(C,H) = 123.6 Hz; CMe_3), 26.29 (t, ^1J(C,H) = 132.1 Hz; OCH_2CH_2).

3d: $[SmCl_3(thf)_3]$ (12.00 g, 25.37 mmol) was added in portions to a solution of **2** [prepared from **1** (8.54 g, 50.74 mmol) and lithium (0.704 g, 101.48 mmol) in THF (200 mL)] at −78 °C and stirred. The workup of the reaction mixture was carried out as for **3a**. Yield 20.90 g of black-red crystals of **3d**, 95% based on $[SmCl_3(thf)_3]$, correct elemental analysis. Crystals suitable for an X-ray crystal structure analysis were obtained by recrystallization from diethyl ether. ^{1}H NMR (300 MHz, [D$_8$]THF, 20 °C): δ = 6.36 (br.s, 4H; NCH=), 3.61 (br.m, 16H; OCH_2CH_2), 1.76 (br.m, 16H; OCH_2CH_2), 1.18 (br.s, 36H; CMe_3); ^{13}C NMR (75 MHz, [D$_8$]THF, 25 °C): δ = 118.36 (NCH=), 68.21 (OCH_2CH_2), 57.67 (CMe_3), 29.92 (CMe_3), 26.31 (OCH_2CH_2); (−60 °C): δ = 121.56 (NCH=), 108.18 (NCH=), 67.42 (OCH_2CH_2), 57.48 (CMe_3), 56.02 (CMe_3), 31.24 (CMe_3), 30.07 (CMe_3), 16.30 (OCH_2CH_2).

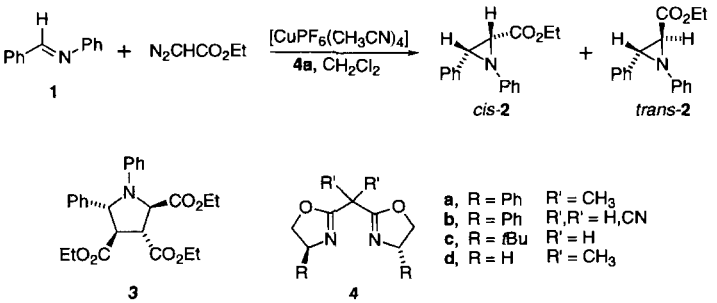
Carbenoid Transfer to Imines: A New Asymmetric Catalytic Synthesis of Aziridines**



Karl B. Hansen, Nathaniel S. Finney, and Eric N. Jacobsen*

Aziridines are versatile precursors for the synthesis of unnatural amino acids and other nitrogen-containing compounds of biological importance.[1] However, the use of aziridines as chiral building blocks in synthesis has been somewhat restricted because their preparation in optically active form typically requires multiple-step transformation of available starting materials. Quite recently, asymmetric metal-catalyzed nitrene transfer to olefins has emerged as the first direct method for the enantioselective synthesis of aziridines from prochiral substrates [Eq. (a), path a).[2] In principle, the catalytic asymmetric transfer of carbenes to imines represents a complementary alternative for the preparation of these compounds [Eq. (a), path b).

Among the potential advantages of the latter approach are the synthetic accessibility of imines and diazocarbonyl compounds, the high reaction efficiency (the only by-product being nitrogen), and the inherent convergence associated with coupling two potentially complex fragments. Although the synthesis of aziridines by metal-mediated reaction of imines with carbenes has some limited precedent,[3] asymmetric variants have not been developed. We report herein the first successful application of this strategy to the catalytic synthesis of aziridines in optically active form.

The transition metal catalyzed transfer of diazocarbonyl-derived carbenes to imines was investigated by employing the readily prepared *N*-benzylidene aniline (**1**).[4] A range of established protocols for asymmetric catalytic carbene transfer was examined, including systems based on Cu, Rh, and Ru.[5] Of these, it was found that copper(I) salts, in association with bis(-dihydrooxazole) ligands, were most effective in catalyzing aziridination reactions.[6] Thus, treatment of **1** with ethyl diazoacetate in the presence of copper(I) hexafluorophosphate $[Cu(PF_6)(CH_3CN)_4)]$[7] and **4a–c** resulted in the formation of enantiomerically enriched aziridine **2** as a mixture of two diastereomers, and racemic pyrrolidine **3** (Scheme 1, Table 1).[8, 9]

Scheme 1. Synthesis of aziridines **2**; only one enantiomer of is shown.

Table 1. Spectroscopic data for *cis*-**2**, *trans*-**2**, and **3**.

The aziridination reaction proved to be quite sensitive to the electronic properties of the substrate imine (Scheme 2). The methyl-substituted imine **5a** underwent aziridination with increased diastereoselectivity but reduced yield, while reaction of chloro-substituted imine **5b** led to exclusive formation of the corresponding pyrrolidine in low yield (Table 3). Incorporation of an electron-donating group in the aniline-derived portion of the imine resulted in slightly lower aziridine yield but improved enantio- and diastereoselectivity. Efforts to extend this aziridination methodology to other classes of imines have not yet been fruitful.[12]

The following observations, in conjunction with the formation of racemic pyrrolidine, allow the deduction of a plausible mechanism for this reaction. Treatment of **1** with excess ethyl diazoacetate led to increased yield of **3**, at the expense of aziridine formation. Treatment of **1** with a single equivalent of ethyl diazoacetate in the presence of two equivalents of diethyl fumarate similarly afforded **3** as the exclusive product. When dimethyl fumarate was employed instead, the corresponding 2-carboxyethyl-3,4-bis(carboxymethyl)pyrrolidine was formed. Thus, aziridine and pyrrolidine appear to arise from a common intermediate which is siphoned off to pyrrolidine in the presence of fumarate.[13] We propose that this intermediate is an azomethine ylide: azomethine ylides generated in the absence of transition metals and dipolarophiles are known to undergo intramolecular cyclization to form aziridines;[14] further, there is precedent for the formation of ylide intermediates by the attack of a heteroatom lone pair on a metallocarbene, and these ylides are known to react with dipolarophiles such as fumarates.[15, 16]

The generation of aziridine in optically active form indicates that its formation is mediated by the copper–bis(dihydrooxazole) complex. In contrast, the formation of racemic **3** suggests that pyrrolidine arises from the azomethine ylide by a path that is not metal mediated, and that the azomethine ylide thus exists as an equilibrating mixture of metal-complexed and uncomplexed forms. That the two forms equilibrate is evidenced by the suppression of aziridine formation accompanied by enhanced pyrrolidine formation in the presence of added dipolarophile. An important consequence of the generation of free azomethine ylide is that it can, in principle, form racemic aziridine as well as pyrrolidine. While there can be no direct observation of racemic aziridine formation under these conditions, we note the following. First, there is some variability (±5%) of the enantiomeric excesses of *cis*- and *trans*-**2** formed under the standard conditions. In general, lower enantiomeric excesses of **2** are accompanied by increased formation of pyrrolidine. Second, performing the reaction in a less polar solvent system (CH_2Cl_2:hexanes), which should suppress dissociation of the ylide from the copper–bis(dihydrooxazole) complex, results in an increase in the enantiomeric excess of isolated *cis*-**2** (53% *ee*).

The evidence outlined above is summarized by the mechanism depicted in Scheme 3. Thus, we propose that a transient bis(dihydrooxazole)copper carbene complex is generated and reacts either with diazoester to form a mixture of diethyl maleate and fumarate[13] or with the imine nitrogen lone pair to form a metal-complexed azomethine ylide. The complexed ylide may then undergo intramolecular ring closure to form aziridine enantioselectively, or it may reversibly dissociate from the metal–ligand complex. In its dissociated state, the free azomethine ylide can either undergo either dipolar cycloaddition with diethyl fumarate to generate racemic pyrrolidine or intramolecular cyclization to form racemic aziridine.

This work illustrates for the first time that the chemistry of azomethine ylides can be influenced by a transition metal complex; in the process, it outlines an extremely direct strategy for the synthesis of enantiomerically enriched *N*-aryl aziridines and, accordingly, of *N*-aryl amino acids. On the basis of the mechanistic analysis provided above, the development of a highly effective catalyst for enantioselective aziridination is predicted to

Scheme 3. Proposed reaction mechanism for the copper-catalyzed aziridination of imines with diazocarbonyl compounds; only one enantiomer is shown.

require a catalyst system for which azomethine ylide dissociation is completely suppressed. This may be attainable simply by judicious ligand design; however, it is possible that a fundamentally different metal–ligand system will be required. In this context, it is compelling to note the potential similarities between metal complexes of azomethine ylides and π-allyl ligands, especially in light of the recent marked advances in asymmetric catalysis with π-allyl complexes.[17]

Experimental Procedure

Representative procedure for the aziridination of **1**: A solution of **1** (0.113 g, 0.625 mmol, 1.000 equiv), **4a** (0.031 g, 0.094 mmol, 0.150 equiv, Aldrich), and $[CuPF_6(CH_3CN)_4]$ [7] (0.023 g, 0.063 mmol, 0.100 equiv) in CH_2Cl_2 (2.50 mL) containing 4 Å molecular sieves was stirred under nitrogen at room temperature for 10 min. Ethyl diazoacetate (2.50 mL, 0.25 M in CH_2Cl_2, 0.625 mmol, 1.000 equiv) was added by syringe pump over 12.5 h, and the solution was allowed to stir 1 h after the addition was complete. The crude reaction mixture was filtered through a plug of basic alumina (Brockmann, Activity I), eluting with CH_2Cl_2, and analyzed by GC and ^{1}H NMR after addition of a known quantity of internal standard (acetophenone). Alternatively, the reaction mixture could be purified directly by chromatography on silica gel (gradient elution, hexanes → 2% ethyl acetate in hexanes → 4% ethyl acetate in hexanes; R_f (10% ethyl acetate in hexanes): 0.50 (*cis*-**2**), 0.65 (*trans*-**2**).

Titanium-Induced Zipper Reactions**

Alois Fürstner,* Arne Ptock, Holger Weintritt, Richard Goddard, and Carl Krüger

The low-valent titanium-induced coupling of carbonyl compounds to alkenes, generally referred to as the McMurry reaction,[1] has recently found two important extensions. First, the restriction to aldehydes and ketones as the only starting materials has been overcome. Second, a new approach to aromatic heterocycles based upon the reductive cyclization of oxoesters or oxoamides has witnessed a substantially broader structural scope and made a realm of differently substituted furans, benzo[b]furans, pyrroles, and indoles readily accessible from simple precursors (Scheme 1).[2–5]

In addition to this new branch of applications, the experimental setup of McMurry reactions has been markedly simplified. In contrast to the established two-step procedure (i.e. preparation of the activated titanium prior to the addition of the carbonyl compound) we have been able to devise a substantially

Scheme 1. Low-valent titanium [Ti] induced reductive oxoester (X = O) or oxoamide (X = NR, R = H, alkyl, tosyl) cyclization reactions under "instant" conditions [3–5]. The rational for the site-selective preparation of [Ti] depicted in this Scheme does not imply an exclusive chelate formation. Other types of complexation between the substrate and the titanium species may also occur [5].

[**] This work was supported by the Volkswagen Stiftung and the Fonds der Chemischen Industrie.

shorter one-step protocol. Although this "instant" method essentially comprises heating a mixture of the respective substrate, $TiCl_3$, and Zn in one pot, the complexation of the Lewis acidic $TiCl_3$ to the substrate ensures that the active titanium species is formed within the coordination sphere of those carbonyl groups to be coupled (Scheme 1). We now report that this "site-selective metal activation" results in an amazing and unprecedented chemo- and regioselectivity in the reductive cyclization of polycarbonyl compounds.

Substrate **1a** is readily prepared from commercially available 2-amino benzophenone and oxalyl chloride. If a mixture of **1a**, $TiCl_3$, and zinc dust in an inert solvent (DME or MeCN) is heated to refux until TLC shows complete conversion of the substrate, the 2,2'-biindolyl **2a** is formed exclusively (Table 1, entries 1,2).[7] Neither conventional McMurry coupling of both the ketone groups of **1a**, nor formation of 2-quinolones upon reaction of the ketones with the distal amides,[6] nor intermolecular coupling processes interfere with this domino two-by-two ketoamide cyclization. The X-ray structure of **2a** is shown in Figure 1.[8] Comparison with entry 3 in Table 1 proves that the "instant" protocol rivals the best of the conventional two-step procedures that use preformed titanium–graphite as coupling agent.[9]

From a previous investigation on the reductive indole synthesis we concluded that the electronic properties of the keto group in oxoamides of the constitution shown in Scheme 1 (X = NR) determine the rate of titanium-mediated cyclizations.[5] As a rule substrates with R^1 = aryl react faster than those with R^1 = alkyl. We prepared the unsymmetrical oxalic acid diamide **1b** in order to probe this conclusion. While it affords the respective 2,2'-biindole **2b** in high yield on prolonged heating with $TiCl_3$ and Zn in DME (entry 4), the monoindole derivative **3** is in fact obtained in 60% isolated yield if the instant coupling is stopped after a reaction time of 4 h (entry 5). This result not only nicely fits our anticipated mechanism, but is also one of the extremely rare examples in which an unprotected keto group survives the exposure to low-valent titanium.[10]

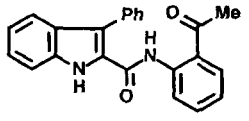
[a] With preformed titanium–graphite ($C_8K/TiCl_3$ = 2/1) [9] as the reagent. [b] The product slowly decomposes when kept in solution.



Using di- or triacid chlorides instead of oxalyl chloride for the N-acylation of the parent 2-acylaniline derivatives allows the incorporation of spacers between the indole rings. Compounds **4a**, **b** and **6** cyclized readily in a completely chemo- and regioselective way (entries 6–8 in Table 1). The stability of the products formed turned out to be dependent on the substituent R at C-3 of the indole units. Derivatives with R = Ph are completely stable, while those bearing a methyl group may suffer oxidative degradation.[11, 12] It is also worth mentioning that several of

the starting materials used in this study are highly insoluble in all common (NMR) solvents. Although we could not obtain high-resolution ^{13}C NMR spectra of compounds **1a,b** and **4** and had to characterize them by magic angle spinning (MAS)-^{13}C NMR,[13] they nevertheless react rapidly to the di- or triindolyl compounds under "instant" conditions.

The results summarized above prompted further extensions. Benzisoxazole **9a** was chosen as an appropriate starting material for the formation of linear indole oligomers of defined length with head-to-tail linked heterocyclic units. Compound **9a** is obtained in multigram amounts by nucleophilic attack of benzyl cyanide anion on nitroarene **8**.[14] As its benzisoxazole entity is a 2-aminoketone surrogate, an iterative sequence of 1) reductive scission of the N–O bond followed by 2) acylation gives rise to oligooxoamides ready for titanium-induced ring closure. This is illustrated by compounds **12** and **16**, prepared as depicted in Schemes 2 and 3.

Upon heating a suspension of substrate **16**, $TiCl_3$, and Zn in DME (0.02 M), this polyfunctional compound undergoes a titanium-induced zipper reaction with the exclusive formation of quaterindole **17** in 80% isolated yield, despite its numerous options for other intra- as well as intermolecular coupling processes. Likewise, the carbonyl groups in substrate **12** reacted strictly pairwise, always a ketone with its proximate amide, to give product **13** in 86% isolated yield. Taking these results and the high functional group compatibility of the instant ring closure[5] into account, even longer, monodispere oligomers and other substitution patterns in the products should be accessible in a similar way.[15] We are presently pursuing this option.

Scheme 2. Synthesis of the terindole **13** with head-to-tail linkage. a) $C_6H_5CH_2CN$, NaOH, MeOH, 0 °C (3 h) → room temperature (16 h), 41–75% [15]; b) $SOCl_2$, toluene, reflux, 1 h, 84%; c) MeOH, pyridine, reflux, 3 h, 76%; d) Fe dust, HOAc/H_2O (100/1), 55–60 °C, 1 h, 88%; e) 1) **9b**, CH_2Cl_2, pyridine, DMAP cat., room temperature, 72%; 2) Fe dust, HOAc/H_2O (100/1), 55–60 °C, 2 h, 94%; f) 1) **9b**, CH_2Cl_2, pyridine, DMAP cat., 2 h, room temperature, 96%; 2) Fe dust, HOAc/H_2O (100/1), 55 → 110 °C, 5 h, 72%; 3) benzoyl chloride, pyridine, CH_2Cl_2, DMAP cat., 3 h, room temperature, 92%; g) $TiCl_3$ (8 equiv), Zn dust (16 equiv), DME, reflux, 86%.

Scheme 3. Synthesis of the quaterindole **17** with head-tail-tail-head linkage. a) 2-aminobenzophenone, CH_2Cl_2, pyridine, DMAP cat., room temperature, 24 h, 81%; b) Fe dust, HOAc/H_2O (100/1), 55–60 °C, 1 h, 93%; c) oxalyl chloride (0.5 equiv), CH_2Cl_2, pyridine, DMAP cat., 2 h, room temperature, 70%; d) $TiCl_3$ (10 equiv), Zn dust (20 equiv), DME, reflux, 2.5 h, 80%.

Experimental Procedure

A suspension of **1a** (200 mg, 0.45 mmol) [16], $TiCl_3$ (282 mg, 1.83 mmol), and zinc dust (239 mg, 3.66 mmol) in DME (30 mL) was heated to reflux under Ar for 3 h. The mixture was allowed to cool to ambient temperature, filtered through a short pad of silica, and the insoluble residues were washed with ethyl acetate (50 mL in several portions). The combined filtrates were evaporated and the residue chromatographed (SiO_2) with hexane/ethyl acetate (10/1) as eluent. Thus, product **2a** was obtained as pale yellow crystals (140 mg, 81%). M.p. 232–233 °C; ^1H NMR (200 MHz, $CDCl_3$): $\delta = 7.95$ (bs, 2H, NH), 7.64–7.30 (m, 12H), 7.21–7.04 (m, 6H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 135.86$ (s), 134.37 (s), 130.23 (d), 128.98 (d), 127.77 (s), 127.11 (d), 125.97 (s), 123.11 (d), 120.39 (d), 119.38 (d), 115.88 (s), 110.87 (d); MS (70 eV): *m/z* (%): 385 (35), 384 (100) [M^+], 192 (10).

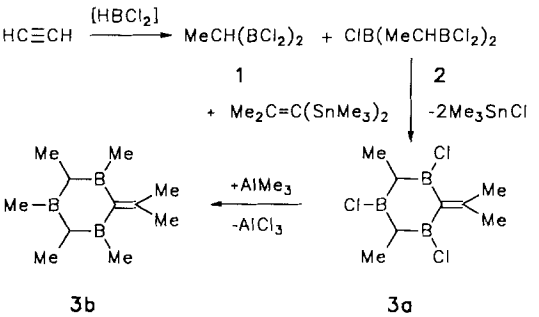
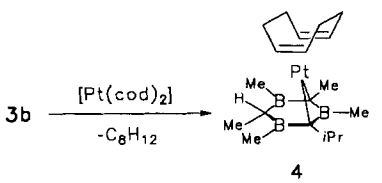
A μ-η^6:η^6-1,3,5-Triboratabenzenebis(cyclopentadienylcobalt) Triple-Decker Complex**



Thomas Deforth, Hans Pritzkow, and Walter Siebert*

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday



Derivatives of boratabenzene **A**[1] and diboratabenzenes **B**,[2] **C**,[3] and **D**[4] belong to a class of six-membered boron–carbon heterocycles. Neither metal complexes nor the free trianions of the possible triboratabenzene isomers **E**–**G** were yet known. The *arachno* framework of the trianions themselves could possibly undergo two-electron oxidation with formation of the anionic *nido* clusters 2,3,4- and 2,3,5-tricarbahexaborane.[5, 6] Deprotonation of 1,3,5-triethyl-2,4,6-trimethyl-1,3,5-triboracyclohexane[7] or 1,3,5-tris(dimethylamino)-1,3,5-triboracyclohexane[8] could be a suitable method to produce **F**. Here, we present another strategy for the formation of metal complexes of the triboratabenzene **F** via 2-isopropylidene-1,3,4,5,6-pentamethyl-1,3,5-triboracyclohexane (**3b**). An η^2 interaction of a CpCo complex fragment (Cp = C_5H_5) with the exocyclic double bond in **3b** results in a metal-induced hydrogen migration and an η^6 complexation of the ring. Addition of a further CpCo fragment provides the triple-decker **6**.

1,1-Bis(dichloroboryl)ethane (**1**),[10] and bis(1-dichloroborylethyl)chloroborane (**2**) as side product, are formed by the hydroboration of acetylene with $HBCl_2$[9] at -60 °C.[11] Ring closure of **2** through a tin–boron exchange reaction with 1,1-bis(trimethylstannyl)isobutene results in 1,3,5-trichloro-2-isopropylidene-4,6-dimethyl-1,3,5-triboracyclohexane (**3a**). Subsequent methylation with $AlMe_3$ provides **3b**. Compounds **1**–**3** are air-sensitive liquids. Compounds **2** and **3** each have two chiral centers and are found as a mixture of diastereomers. They are seen in the ^1H and ^{13}C NMR spectra as two sets of signals with the same coupling pattern. Since the isomers could not be separated, an unambiguous assignment was not possible.

In order to investigate the ligand characteristics of **3b**, it was first allowed to react with $Pt(cod)_2$ (cod = 1,5-cyclooctadiene). The spectroscopic data for the resulting yellow solid does not show η^2 complexation to the exocyclic double bond, but rather is consistent for the σ complex **4** with two Pt–C bonds. The ^1H NMR spectrum shows the corresponding coupling pattern for the transformation of the isopropylidene to the isopropyl group by 1,4-hydrogen migration from a MeCH unit to the exocyclic C atom. The small up-field shift of the ^{11}B NMR signals suggests a weak interaction between the platinum atom and the boryl groups; this is confirmed by a crystal structure analysis.[12]

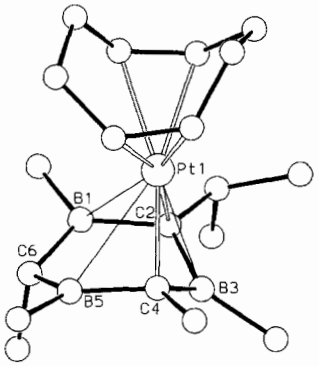
Figure 1 shows the C_3B_3 heterocycle in a boat conformation with σ bonds Pt–C2 and Pt–C4, and long interatomic Pt–B distances. The coordination around platinum is approximately square planar. Also in solution there is no agostic Pt-H-C6 interaction resulting in the formation of an 18 VE complex.



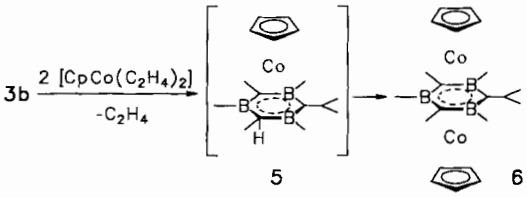


Fig. 1. Molecular structure of **4** in the crystal. Selected bond distances [Å] and angles [°]: Pt1-C2 2.163(6), Pt1-C4 2.111(6), Pt1-B1 2.593(7), Pt1-B3 2.449(7), Pt1-B5 2.658(7), B1-C2 1.563(9), C2-B3 1.556(9), B3-C4 1.551(9), C4-B5 1.542(9), B5-C6 1.590(9), C6-B1 1.572(8); C6-B1-C2 119.6(5), B1-C2-B3 116.5(5), C2-B3-C4 108.6(5), B3-C4-B5 116.4(5), C4-B5-C6 119.4(5), B5-C6-B1 110.3(5).

A 1,4-hydrogen migration in **3b** induced by a CpCo fragment is expected to produce the reactive 18 VE complex **5**. This analog of cyclopentadienylcobalt-2,3-dihydro-1,3-diborole complexes[14] could then be built up to a triple-decker complex with a CpCo unit. At room temperature the reaction with $[CpCo(C_2H_4)_2]$, accompanied by evolution of ethylene, provides the olive-green triple-decker complex **6** and a red compound **5′**, whose constitution is not yet clear.[15] The ^1H NMR spectrum of paramagnetic **6** shows broadened signals in the range

$\delta = +10 - -50$. Oxidation with $AgBF_4$ results in the diamagnetic 30 VE $\mathbf{6}^+$ BF_4^-, whose triple-decker structure is confirmed by NMR spectroscopy. Appearance of a septet and a doublet signalizes, as in the case of **4**, the transformation of the isopropylidene group in **3b** into the isopropyl substituent. The ^{11}B NMR shift of $\delta = 19$ indicates a bifacial coordination of the 1,3,5-triboratabenzene to the CpCo complex fragments.

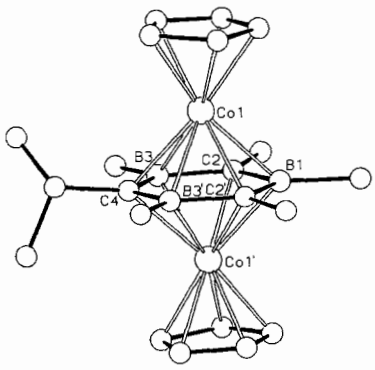

Fig. 2. Molecular structure of **6** in the crystal. Selected bond distances [Å] and angles [°]: Co1-B1 2.200(5), Co1-C2 2.129(5), Co1-C2′ 2.151(5), Co1-B3 2.229(6), Co1-B3′ 2.220(5), Co1-C4 2.217(5), B1-C2 1.519(8), C2-B3 1.545(9), B3-C4 1.521(7); C2′-B1-C2 113.4(6), B1-C2-B3 125.7(5), C2-B3-C4 116.2(3), B3-C4-B3′ 122.8(6).

The crystal structure analysis of **6** confirms that both Co atoms are η^6-bonded to the planar C_3B_3 ring (Fig. 2). As expected, the Co–Co distance of 3.14 Å is shorter than in the analogous 31 VE triple-decker complexes[16] (3.30 Å) with the smaller 2,3-dihydro-1,3-diborolyl bridging ligand (C_3B_2 ring). The B–C distances within the ring have approximately the same value (1.519(8)–1.545(9) Å).

Our results prove that the 3e-ligand C_3B_3 is incorporated into the triple-decker complexes **6** and $\mathbf{6}^+$, where this triboratabenzene **F** is stabilized by the cationic CpCo fragments. We postulate the intermediate **5** for the formation of **6**, which has not yet been detected.

Experimental Procedure

2: Trimethylsilane (0.4 mmol) in hexane (100 mL) was added dropwise to a solution of BCl_3 (0.4 mmol) in hexane (100 mL) at −78 °C under a continuous stream of acetylene (in situ synthesis of $HBCl_2$ [17]). After the solution had warmed to room temperature and the hexane solvent had been removed, **1** (23% yield, b.p. 65 °C/50 Torr) and **2** (10% yield, b.p. 100 °C/50 Torr) were isolated by distillation. **2**: ^1H NMR (200 MHz, C_6D_6): $\delta = 2.32$ (br. q, 2H, CH), 2.12 (br. q, 2H, CH), 1.07 (d, 6H, $^3J(H,H) = 6.33$ Hz, CH_3), 1.00 (d, 6H, $^3J(H,H) = 6.50$ Hz, CH_3); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 42$ (br., CH), 13.66 (CH_3), 13.34 (CH_3); ^{11}B NMR (64.2 MHz, C_6D_6): $\delta = 74$ (1B), 61 (2B); EI-MS: *m/z* (%): 266 (0.5) [M^+], 231 (3.8) [$M^+ - Cl$].

3a: **2** (18 mmol) and $Me_2C{=}C(SnMe_3)_2$ [18] (19 mmol), each in toluene (25 mL), were simultaneously added with stirring to toluene (50 mL) within 2 hr at −50 °C. The solution was allowed to warm to room temperature overnight, and the solvent and Mg_3SnCl were removed (5 Torr) over one day. Subsequent distillation (36 °C/0.005 Torr) provided **3a** in 91% yield. ^1H NMR (200 MHz, C_6D_6): $\delta = 1.94$ (s, 6H, $C(CH_3)_2$)), 1.85 (s, 6H, $C(CH_3)_2$)), 1.36 (d, 6H, $^3J(H,H) = 6.06$ Hz, $CHCH_3$), 1.31 (d, 6H, $^3J(H,H) = 6.05$ Hz, $CHCH_3$), 1.10 (br. q, 2H, CH); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 173.2$ ($C(CH_3)_2$), 165.9 ($C(CH_3)_2$), 44 (br., CH), 28.6 ($C(CH_3)_2$), 27.5 ($C(CH_3)_2$), 12.1 ($CHCH_3$), 11.9 ($CHCH_3$); ^{11}B NMR (64.2 MHz, C_6D_6): $\delta = 71$ (1B), 69 (2B); EI-MS: *m/z* (%): 248(51) [M^+], 219 (54) [$M^+ - Cl$].

3b: A solution of $AlMe_3$ (7.0 mmol) in pentane (20 mL) was added dropwise to **3a** (7.0 mmol) in pentane (20 mL) at −50 °C. Warming to room temperature, removing the solvent, and distillation provided **3b** (85% yield, b.p. 35 °C/0.1 Torr). ^1H NMR (200 MHz, C_6D_6). $\delta = 2.38$ (br. q, 2H, $CHCH_3$), 2.18 (br. q, 2H, $CHCH_3$), 1.78 (s, 6H, $C(CH_3)_2$), 1.75 (s, 6H, $C(CH_3)_2$), 1.33 (d, $^3J(H,H) = 6.0$ Hz, 6H, $CHCH_3$), 1.29 (d, $^3J(H,H) = 6.0$ Hz, 6H, $CHCH_3$), 0.95 (s, 6H, BCH_3), 0.91 (s, 6H, BCH_3), 0.72 (s, 3H, BCH_3), 0.61 (s, 3H, BCH_3); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 144.9$ ($C(CH_3)_2$), 129.2 ($C(H_3)_2$), 50 (br., CH), 48 (br., CH), 26.9 ($C(CH_3)_2$), 26.5 ($C(CH_3)_2$), 13.8 ($CHCH_3$), 12.2 ($CHCH_3$), 8.3 (br., BCH_3); ^{11}B NMR (64.2 MHz, C_6D_6): $\delta = 82$ (1B), 80 (2B); EI-MS: *m/z* (%): 188 (6) [M^+], 173 (5) [$M^+ - CH_3$], 158 (3) [$M^+ - 2CH_3$].

4: A solution of **3b** (1.5 M) in benzene (0.8 mL) was added by a syringe to a solution of $Pt(cod)_2$ (1.0 mmol) in benzene (15 mL) and stirred for 12 h. After removal of the solvent, column chromatography (Al_2O_3, deactivated with 6% H_2O) of the yellow residue with hexane eluent provided **4** in 33% yield, m.p. 65 °C. ^1H NMR (200 MHz, C_6D_6): $\delta = 4.1-5.0$ (m, 4H, CH_{cod}), 2.99 (m, 1H, $CHCH_3$), 1.99 (s, $^3J(Pt,H) = 25.5$ Hz, 3H, CH_3), 1.7–1.15 (m, 8H, $CH_{2,cod}$), 1.47 (d, $^3J(H,H) = 6.77$ Hz, 3H, $CHCH_3$), 1.31 (d, $^3J(H,H) = 6.86$ Hz, 3H, $CHCH_3$), 1.11 (d, 3H, $CHCH_3$), 1.08 (s, 3H, BCH_3), 0.89 (s, 3H, BCH_3), 0.86 (s, 3H, BCH_3), 0.62 (q, $^3J(H,H) = 7.67$ Hz, $J(Pt,H) = 23.2$ Hz, 1H, $CHCH_3$); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 100.54$ (CH_{cod}), 97.58 (CH_{cod}), 96.86 (CH_{cod}), 95.20 (CH_{cod}), 33.84, 30.80 ($CH_{2,cod}$), 29.93 ($CH_{2,cod}$), 29.23 ($CH_{2,cod}$), 27.72 ($CH_{2,cod}$), 26.33, 25.22, 18.97, 18.89, 7.5 (br.), 6.7 (br.); ^{11}B NMR (64.2 MHz, C_6D_6): $\delta = 62$ (2B), 52 (1B); EI-MS: *m/z* (%): 490 (100) [M^+].

6: A solution of **3b** (1.5 M) in benzene was added to $CpCo(C_2H_4)_2$ (1.8 mmol) in pentane (10 mL) by syringe and the mixture stirred for 12 hr. Removal of the solvent and subsequent chromatographic workup (Al_2O_3, deactivated with 6% H_2O) with hexane as eluant provided red **5′** (23% yield, b.p. 22 °C) and olive-green **6** (8% yield, m.p. 78 °C). **5′**: ^1H NMR (200 MHz, C_6D_6): $\delta = 4.44$ (s, 5H), 1.24 (br. s, 9H), 0.77 (br. s, 9H), −0.1 (br. s, 3H;); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 83$ (br.), 80.8, 14.9, 0 bis −7 (several broad signals); ^{11}B NMR (64.2 MHz, C_6D_6): $\delta = 28.6$ (1B), 11.8 (2B); EI-MS: *m/z* (%): 311 (43) [$M^+ + 1$]. **6**: EI-MS: *m/z* (%): 435 (62) [M^+], 311 (100) [$M^+ - CpCo$],189 (36) [Cp_2Co^+], 124 (13) [$CpCo^+$]; CV (DME, $Bu_4N^+PF_6^-$): $E^0 = -0.22$ (rev. ox), −1.24 (rev. red.), −2.41 (irrev. red.).

$\mathbf{6}^+$: Oxidation of **6** with equimolar $AgBF_4$ in Et_2O produces dark green $\mathbf{6}^+BF_4^-$ (95% yield, m.p. >200 °C decomp.). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 4.69$ (s, 10H, C_5H_5), 3.67 (sept., 1H, $CHCH_3$), 2.67 (s, 6H, $CHCH_3$), 1.64 (d, $^3J(H,H) = 7.03$ Hz, 6H, $CH(CH_3)_2$), 1.43 (s, 3H, BCH_3), 1.31 (s, 6H, BCH_3); ^{13}C NMR (50 MHz, CD_2Cl_2): $\delta = 81.9$ (C_5H_5), 37.7 (CH), 26.6 (CH_3), 25.1 (CH_3), 3 (br. BCH_3); ^{11}B NMR (64.2 MHz, CD_2Cl_2): $\delta = 19.0$ (BF_4^-); FD^+-MS: *m/z* (%): 435 (100) [M^+].

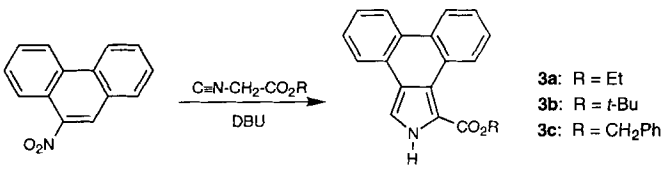
Tetraphenanthro[9,10-*b*:9,10-*g*:9,10-*l*:9,10-*q*]-porphyrin, a New Highly Conjugated Porphyrin System**

Timothy D. Lash* and Bennett H. Novak

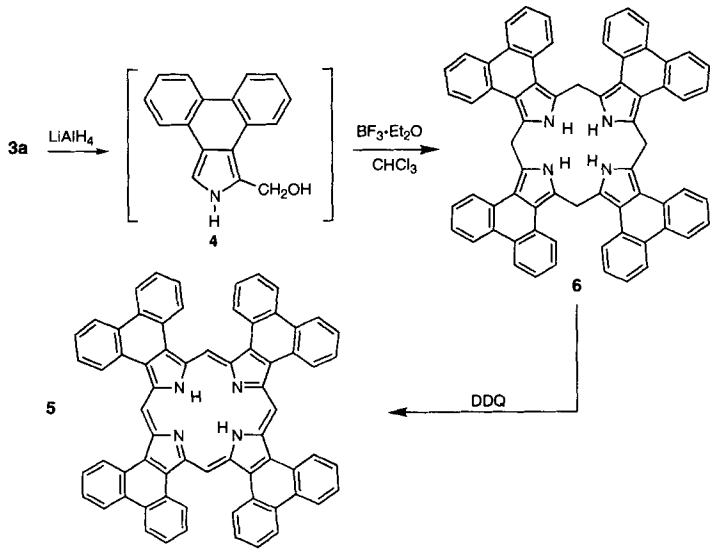
Porphyrins have a remarkable number of important functions in nature (hemes, chlorophylls, etc.), and have many unusual structural and chemical properties. Although porphyrins have been extensively studied by organic chemists for well over a century, structural variants of porphyrins[2] such as porphycene[3] were only discovered relatively recently.[4] In addition, many symmetrically substituted porphyrin systems of theoretical and potentially practical significance have yet to be described.[5] In our recent work, we have been interested in developing synthetic routes to new highly conjugated porphyrin systems.[1, 6, 7] This has led to the first syntheses of mono-[1, 6] and dinaphthoporphyrins.[7] These studies were initially stimulated by our ongoing interests in porphyrin geochemistry,[8, 9] and by the suggestion that porphyrin structures embedded in graphite-like matrices were present in the kerogen fractions of mature organic-rich sediments.[10] These systems are structurally related to phthalocyanines (**1**) and naphthocyanines (**2**), and hence may have value in numerous material science applications.[11] In addition, red-shifted porphyrin-like chromophores are being investigated as photosensitizers in photodynamic therapy.[12]



1

2

The synthesis of novel porphyrins bearing polycyclic arene units is dependent upon the availability of suitably substituted pyrrolic precursors. Recently, we reported that 9-nitrophenanthrene underwent a "Barton–Zard" type of pyrrole condensation[13] with isocyanoacetates to give the corresponding phenanthropyrroles **3a–c** in excellent yields (Scheme 1).[14, 15] The novel tetracyclic compound **3a** has now been utilized to prepare the first example of a tetraphenanthroporphyrin.



Scheme 1. Synthesis of phenanthropyrroles from 9-nitrophenanthrene. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

Reduction of **3a** with lithium aluminum hydride under mild conditions gave the corresponding alcohol **4** and subsequent treatment of **4** with boron trifluoride etherate in chloroform, followed by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), afforded tetraphenanthro[9,10-*b*:9,10-*g*:9,10-*l*:9,10-*q*]porphyrin (**5**) in 13% yield (Scheme 2). Initially, we attempted the cyclotetramerization of **4** in refluxing pyridine/acetic acid,[9b, 16] but this resulted in the formation of no detectable porphyrin product. This was attributed to the steric crowding in this unusual porphyrin system. Milder conditions have been successfully used to prepare crowded porphyrin structures,[17] and this suggested that the methodology developed by Lindsey et al. for the preparation of *meso*-tetrasubstituted porphyrins[18] might give reasonable results for our system. Reaction of **4** in dichloromethane with boron trifluoride etherate as the acid catalyst afforded, after dehydrogenation with DDQ, a rather impure sample of porphyrin **5**. However, when the solvent was switched to chloroform, as mentioned above, the required heptadecacyclic porphyrin was obtained in good yield. Commercially available chloroform contains approximately 0.8% ethanol and it is probable that this is largely

Scheme 2. Synthesis of tetraphenanthro[9,10-*b*:9,10-*g*:9,10-*l*:9,10-*q*]porphyrin **5**.

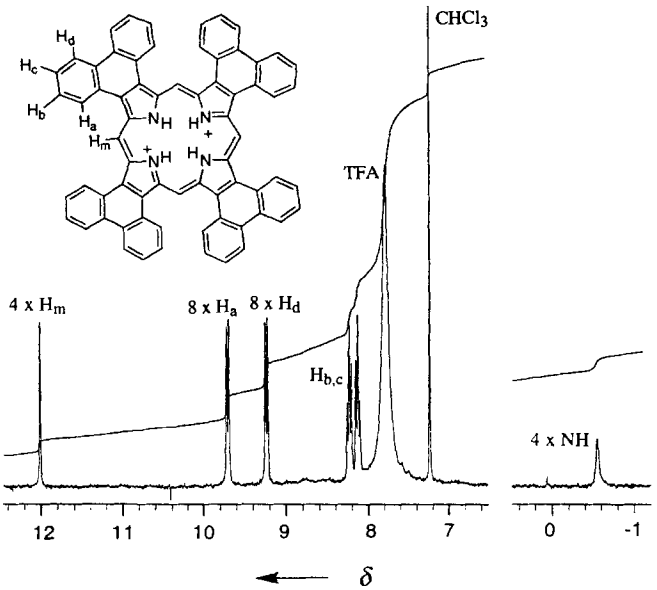

Fig. 2. 300 MHz ^{1}H NMR spectrum of **5** in trifluoroacetic acid/deuteriochloroform.

responsible for the improved results (see ref. [18b]). It seems likely that porphyrinogen **6** is the initially formed product and subsequent dehydrogenation with DDQ then led to **5**.

Porphyrin **5** was isolated as a dark green powder and was virtually insoluble in most organic solvents. In trifluoroacetic acid (TFA)/chloroform, the diprotonated form of **5** gave green solutions, and the electronic spectra showed dramatically red-shifted absorption bands compared to those of any previously reported porphyrin structure (Fig. 1). The Soret band was observed near 480 nm and two bathochromically shifted Q bands were observed at 615 and 668 nm. In neutral solvents, the electronic spectra for **5** showed very broad, ill-defined absorption bands. The ^{1}H NMR spectrum of **5** in trifluoroacetic acid/deuteriochloroform (Fig. 2) is consistent with the proposed structure of this highly symmetrical porphyrin dication and shows four separate sets of signals corresponding to the four distinct types of phenanthrene protons. These protons were only slightly deshielded relative to those of phenanthropyrrole **3a**, apart from the protons that protrude towards the *meso* bridges. This suggests that the major macrocyclic ring current involves the internal porphyrin 18 π-electron pathway. Although the phenanthrene protons labeled H_a in Figure 2 and the adjacent *meso* protons (H_m) are significantly deshielded, the signals of the latter appearing at $\delta = 12$, this appears to be primarily due to the steric congestion in this structure. The ^{13}C NMR spectrum for **5** in trifluoroacetic acid/deuteriochloroform showed only nine signals, which confirms the highly symmetrical nature of this 68 carbon system. Fast atom bombardment (FAB) mass spectrometry for **5** gave the expected $[M + H]^+$ peak at $m/z = 911$.

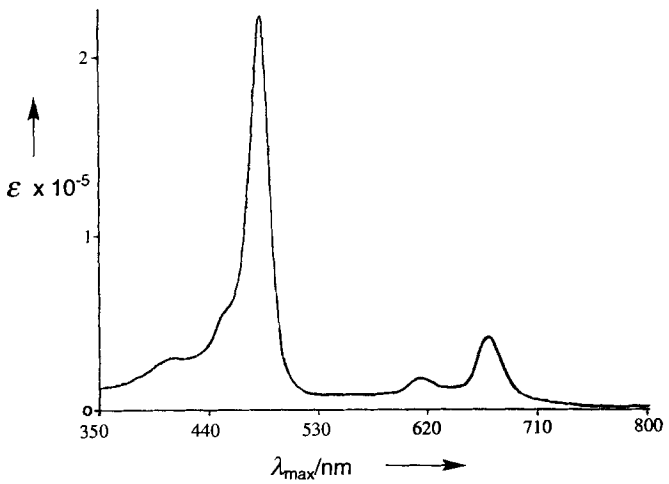

Fig. 1. Electronic absorption spectrum of **5** in 1% trifluoroacetic acid/chloroform.

Tetraphenanthroporphyrin **5** is one of the most highly conjugated porphyrin systems described to date and represents a potentially fascinating structure for further study. The results described here suggest that this methodology could make whole classes of new highly conjugated porphyrin systems available.

Experimental Procedure

5: A solution of phenanthropyrrole **3** (0.500 g, 1.73 mmol) in THF (50 mL) was added dropwise over a period of 20–30 min to a stirred mixture of lithium aluminum hydride (0.130 g, 3.425 mmol) in THF (50 mL), while the temperature of the mixture was maintained at 0 °C with the aid of a salt-ice bath. The mixture was stirred for an additional 1 h, water was added, and the organic phase separated. The aqueous layer was extracted with chloroform (2 × 50 mL), and the combined organic solutions were washed with water (50 mL) and dried over sodium sulfate. The solvent was evaporated on a rotary evaporator; the temperature of the water bath was maintained at 25–30 °C. The residual oil was taken up in chloroform (125 mL), the air was purged with nitrogen and boron trifluoride etherate solution in dichloromethane (68 µL, 2.5 M) was added. The resulting pale blue mixture was stirred in the dark at room temperature for 1 h. DDQ (0.290 g, 1.277 mmol) was added in a single portion, and stirring was continued for a further 1 h. The mixture was washed with water (50 mL), 5% sodium bicarbonate solution (50 mL), and water (50 mL), and the solvent evaporated under reduced pressure. The dark residue was recrystallized twice from chloroform/methanol to give the tetraphenanthroporphyrin **5** as a dark green powder. Selected physical and spectroscopic data for **5**: m.p. > 400 °C; UV/Vis (1% TFA/$CHCl_3$): λ_{max} [nm] (lgε) = 482 (5.35), 615 (4.26), 668 (4.63); UV/Vis (benzene): λ_{max} [nm] = 430, 650, 704; IR (KBr): ν = 3300, 3077, 3030, 1566, 1428, 1210, 1166, 967, 866, 812, 759, 714, 672, 616, 533 cm^{-1}; ^{1}H NMR (300 MHz, TFA/$CDCl_3$): δ = −0.55 (4H, br, 4 × NH), 8.13 (8H, t), 8.24 (8H, t), 9.24 (8H, d, 8.3 Hz), 9.71 (8H, d, J = 8.2 Hz) (32 × phenanthrene-H), 12.01 (4H, s, 4 × *meso*-H); ^{13}C NMR (TFA/$CDCl_3$): δ = 101.37 (*meso*-CH), 125.06, 126.90, 127.33, 129.56, 129.68, 129.75, 133.80, 139.55; HRMS (FAB): calculated for $C_{68}H_{38}N_4$ + H: m/z 911.3175; found: 911.3168. Correct C, H, N analysis for $C_{68}H_{38}N_4 \cdot 2H_2O$.

Topochemical Reaction Control in Solution**

Henning Hopf,* Helmut Greiving, Peter G. Jones, and Peter Bubenitschek

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

The photodimerization of cinnamic acid in the solid state is a classic example of topochemical reaction control: the correlation of the product configuration with the packing of the starting material in the crystal lattice.[1, 2] Products can form only if a given distance between the reactants is not exceeded; for the [2 + 2] cycloaddition of cinnamic acids the reactants can be separated by at most 360–410 pm (α- and β-cinnamic acid). Greater intermolecular separations such as those in the so-called γ structures of the cinnamic acids (>470 nm) result in photostability.[2] For application of topochemical principles in solution—an attractive prospect, for example, for stereocontrolled synthesis—a stable structure in solution must be found to replace the crystal lattice as an ordering principle. In this context [m.n]cyclophanes are especially suitable, as we have shown recently in studies on cinnamophane **1**.[3] This bis(cinnamic acid) is sterically fixed because of the alkano bridges (distance between the olefinic double bonds 350 pm[3]) and on irradiation reacts quantitatively both in the solid state and in solution to give the cyclobutane **2**. The quantum yield of 0.84 (methanol, −90 °C) for this reaction is the highest ever measured for the dimerization of a cinnamic acid derivative.[3]

Scheme 1. Synthesis of [*n*]ladderanes from pseudo-geminal-substituted [2.2]paracyclophanepolyenes; a) DIBAL-H, Et_2O, N_2, $-80 \rightarrow 0$ °C; b) MnO_2, CH_2Cl_2, N_2, room temperature; c) NaH, $(EtO)_2P(O)CH_2COOEt$, THF, N_2, room temperature.

The controlling effect of the cyclophane framework is not so surprising, since the reacting groups of **1** are directly attached to the framework. We wondered therefore whether extension of the double bond system, which would necessarily increase its flexibility, would reduce the control exerted by the cyclophane spacer. For this purpose compound **1** was reduced with diisobutylaluminum hydride and the resulting diol oxidized with MnO_2 to afford the dialdehyde, which was treated with ethyl diethylphosphonoacetate in a Wittig–Horner chain extension. Diester **3**, obtained in an overall yield of 55%, has an all-*trans* structure based on spectroscopic data.[4] Irradiation of **3** (ethanol, 150 W Hg high-pressure lamp, 30 min, room temperature, Pyrex) afforded phane **4** in >90% yield. The structure of **4**, which contains three annelated cyclobutane rings, was confirmed by spectroscopic[5] and crystallographic data.[6] With even longer pseudogeminal substituents stereocontrol is still not lost, as proved by the photoreaction of the deep-yellow bis(triene)diester **5**, which was prepared from **3** by procedure described above.[7] Irradiation of **5** in methanol in a Pyrex apparatus with a 450 W Hg high-pressure lamp for 60 min at room temperature furnished the colorless [5]ladderane **6** (83% yield);[8] spectroscopic data unequivocally showed **6** to be a higher homologue of **4**.[9] The structure was confirmed by a crystal structure analysis (Fig. 1).[10].

The four-membered rings in **6** are planar to within 1 pm; the interplanar angles are between 112 and 114°. The absolute torsion angles about the six chain bondsC18-C19-C20-C21 and C27-C28-C29-C30 lie in the range from 178 and 180°. The first bond between the chains, C17–C26, is very long (162.6(3) pm);

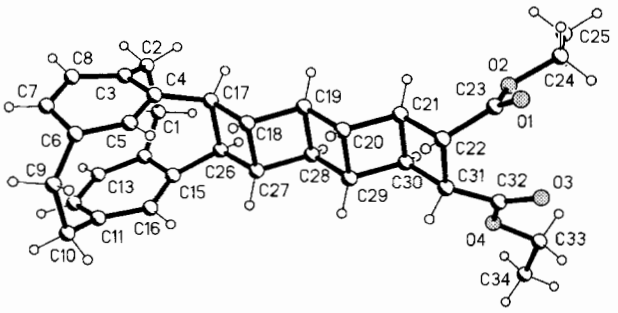

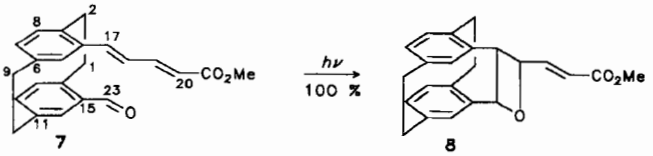

Fig. 1. Crystal structure of [5]ladderane **6**.

the others can be considered to be somewhat extended single bonds (156.4–157.7 pm). The corresponding distances in **4** are very similar.

The polycycloaddition of **5** is reversible. Ladderane **6** can be heated (180 °C) or irradiated (λ = 270 nm, methanol) to regenerate bis(triene) **5**; thus this pair of isomers is a new photochromic system.

The reaction of the phosphonate with an excess of the dialdehyde obtained from **1** affords monoester **7**. A methyl pentadienecarboxylate group is located directly above the formyl substituent in **7**, providing ideal conditions for an intramolecular Paterno–Büchi reaction. Indeed, irradiation of **7** (ethanol, 150 W Hg high-pressure lamp), room temperature, Pyrex) furnishes the expected oxetane **8** in quantitative yields.[11, 12]

The examples described here may usher in the use of [m.n]-phanes as spacer elements. Aside from the obvious potential of introducing other photo- and thermoactive substituents in the pseudo-geminal positions in [2.2]paracyclophanes, substituents can also be introduced in pseudo-*ortho* positions in these molecules, thus leading to a pseudo-dihedral angle of 60°. To what extent the reactivity would be reduced in this structural variation remains to be seen. Another open question is the effect of increasing the distance between the reacting substituents by extending the phane bridges.[13] It will never be possible to adjust the distance between the substituents or functional groups with infinite variability, but this ideal may be better approximated by using phanes as "set screws" rather than other rigid spacers. In addition, when other aromatic subunits are used in the cyclophanes in place of the benzene rings, other pseudo-dihedral angles besides 0 and 60° are possible. Thus, phane spacers should allow the deliberate positioning of substituents in three-dimensional space.

The Synthesis and Crystal Structures of $RbC(SiMe_3)_3$ and $CsC(SiMe_3)_3 \cdot 3.5C_6H_6$: A One-dimensional Ionic Solid and an Ionic Solid with a Molecular Structure**

Colin Eaborn, Peter B. Hitchcock, Keith Izod, and J. David Smith*

Little is known about the structures of alkylrubidium and -cesium derivatives.[1, 2] The unsolvated methyl compounds crystallize with ionic lattices comprising Rb^+ or Cs^+ ions and pyramidal Me^- ions.[1] Pentamethyldiethylenetriamine (pmdta) derivatives MR(pmdta) form linear polymers (R = CPh_3, M = Rb, Cs)[3] or dimers (R = $CH(SiMe_3)_2$, M = Rb),[4] and the yellow tris(trimethylsilyl)silyl compounds crystallize as dimeric toluene solvates.[5]

We have now shown that tris(trimethylsilyl)methylrubidium (**1**) and -cesium (**2**) may be obtained by metalation of $HC(SiMe_3)_3$ with the now readily available methylmetal derivatives[1] (prepared in situ in a slightly modified version of the original synthesis,[6] from methyllithium and the ether-soluble alkali metal 2-ethylhexoxides). Although both compounds are exceedingly air and moisture sensitive, crystals suitable for X-ray diffraction studies were obtained.

$RbC(SiMe_3)_3$ **1** $CsC(SiMe_3)_3$ **2**

We first determined the structure of the Cs derivative **2**, obtained as a yellow benzene solvate $\mathbf{2} \cdot 3.5(C_6H_6)$. The results[7] show that each Cs^+ ion is coordinated to the central carbon atom of the neighboring anion (Fig. 1) and to three benzene molecules η^6, leading to a quasi-tetrahedral arrangement. In addition, molecules of uncoordinated benzene are found in the lattice. The benzene is easily lost in vacuum, suggesting that it is weakly bound. The Cs–C1 bond length in $\mathbf{2} \cdot 3.5C_6H_6$ (332.5(12) pm) is very similar to that in the complex $CsCPh_3 \cdot$pmdta (334.8(4) pm)[3], and the distances from the Cs ion to the C atoms of the benzene rings (mean 381(2) pm) are similar to those in the toluene solvates $CsSi(SiMe_3)_3 \cdot 1.5$PhMe (mean 380(2) pm)[5] and $Cs[Al_7O_6Me_{16}] \cdot 3$PhMe (364–394 pm).[8]

The average distances of the Cs ion to the centers of the benzene rings of 358 pm are somewhat shorter. The mean Si-C1-Si angle (117.3(5)°) is much larger than the ideal value for a tetrahedron. This shows that the Cs–C1 bond is highly ionic,[9] with charge delocalized in such a way that the inner Si–C1 bonds are shortened. In contrast, the D-C-D angles in $NaCD_3$ and KCD_3, measured at 1.5 K, are 105–106°.[11]

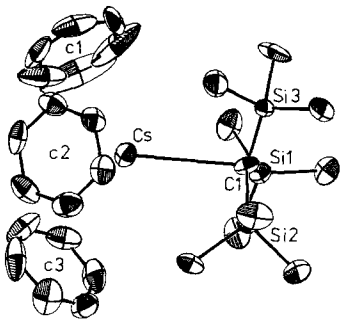

Fig. 1. Molecular structure of $\mathbf{2} \cdot 3.5C_6H_6$; 0.5 mol of lattice benzene omitted (50% vibrational ellipsoids). Significant bond lengths [pm] and angles[°]: Cs–C1 332.5(12), Cs-c_1 (c: centroid of benzene ring) 343.3, Cs-c_2 350.7, Cs-c_3 379.0, C–Si 181.7(11),* Si–Me 188.6(13);* c_1-Cs-c_2 99.4, c_1-Cs-c_3 107, c_2-Cs-c_3 93.0, Cs-C1-Si1 99.3(4), Cs-C1-Si2 97.0(4), Cs-C1-Si3 102.5(4), Si-C1-Si 117.3(5).* Me-Si-Me 103.0(3)*. The values marked with an * are mean values.

We had earlier found[10] that tris(trimethylsilyl)methylpotassium crystallized from benzene as a solvent-free one-dimensional ionic solid with chains of alternate K^+ ions and planar $[C(SiMe_3)_3]^-$ ions. It was thus of interest to determine whether the structure of the rubidium compound **1** was like that of the potassium or the cesium analogue. The structure of **1** was found to resemble that of the potassium derivative, but the planar anions are significantly distorted from C_3 symmetry (Fig. 2).[11] Whereas in the potassium compound each K^+ interacts with the central carbon atom and six methyl groups (three from the anion on the left and three from that on the right, thus preserving the threefold symmetry), the Rb^+ ion is apparently large enough to interact with eight methyl groups from the adjacent anions. Two methyl groups, one at C9, involved in the interaction with the cation, and one at C4, which is not, are forced into the space between Si1 and Si3, thus opening the Si-C-Si angle from the ideal value of 120° to 126°.

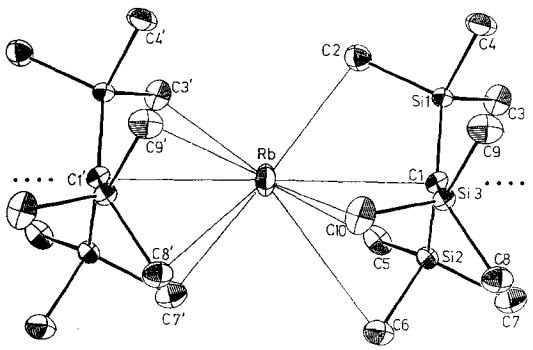

Fig. 2. The molecular structure of **1**. Selected bond lengths [pm] and angles [°]: Rb–C1 329.1(7),Rb–C1' 328.7(7), Rb–C2 327.8(9), Rb–C3' 358.6(6), Rb–C5 365.3(8), Rb–C6 364.3(8), Rb-C7' 342.8(8), Rb–C8' 355.1(9), Rb–C9 377.2(9'), Rb–C10 328.4(7), C–Si 181.5(7),* Si–Me 188.0(8);* C1-Rb-C1 177.7(2), Rb-C1 Rb''177.7(2), Si1-C1-Si2 116.5(4), Si1-C1-Si3 126.6(4), Si2-C1-Si3 116.8(4), Me-Si-Me 102.9(4),* C1-Si-Me 115.4(4). The values marked with an * are mean values.

In compounds $XC(SiMe_3)_3$, the Si-C-Si angles can be readily distorted from the ideal tetrahedral value in response to the steric and electronic requirements of the group X.[9] The significant distortion of the planar CSi_3 skeleton in **1** from C_3 symmetry is of a type not previously observed. The structures of **1** and **2** show that the more polarizable alkali metal ions interact with

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0606-0687 $ 10.00+.25/0

both methyl groups and benzene molecules. It would be of interest to know whether the M···Me interactions involve H or C atoms, but so far the X-ray data do not provide clear evidence on this point. Similar M···Me interactions are found in $[Yb\{C(SiMe_3)_3\}_2]$[12] and several related compounds. The $M^+\cdots(C_6H_6)$ interactions are strong enough when M = Cs to break the ionic $(M^+R^-)_n$ chains formed when M = K[10] or Rb; thus, individual ion pairs are separated by benzene solvate molecules, and the packing diagram looks like that for an organic compound in which interactions between molecules are weak.

Experimental Procedure

1: A solution of MeLi (13.6 mmol) in Et_2O (8 mL) was added to a cold (−10 °C) solution of 2-ethylhexoxyrubidium (2.92 g, 11.14 mmol) in Et_2O (30 mL). The solution was allowed to warm until the onset of effervescence (C_2H_4 evolution) showed that MeRb had begun to form. The solution was then cooled to −10 °C. $HC(SiMe_3)_3$ (14.8 mmol) was added and the mixture was stirred for 2 h at −10 °C and for a further 12 h during which time it slowly reached room temperature. The solvent was removed in vacuum and the residue was washed with light petroleum (3 × 30 mL) then extracted with benzene. The extract was evaporated and the residue was recrystallized from benzene/heptane to give colorless needles of **1** (2.26 g, 64%). The compound was too air and moisture sensitive for satisfactory C and H analysis; ^{1}H NMR (C_6D_6, chemical shifts relative to $SiMe_4$, 25 °C) δ = 0.32 (s, Me_3Si); ^{13}C NMR: δ = 6.89 (CSi_3), 8.36 (Me_3Si); ^{29}Si NMR: δ = −11.1.

2: CsR was made similarly from 2-ethylhexoxycesium (1.74 g, 6.38 mmol), MeLi (6.4 mmol) and $HC(SiMe_3)_3$ (6.0 mmol) in ether (30 mL) at −78 °C. The mixture was stirred for 0.5 h then allowed to warm slowly to room temperature during 1 h. The solvent was removed in vacuum, and the residue washed with light petroleum (3 × 30 mL) and then recrystallized from benzene to give extremely moisture-sensitive pyrophoric pale yellow plates of the benzene solvate $2\cdot 3.5C_6H_6$. ^{1}H NMR (C_6D_6, 25 °C): δ = 0.35 s, Me_3Si). ^{13}C NMR: δ = 8.22 (Me_3Si), 9.80 (CSi_3); ^{29}Si NMR: δ = −13.5.

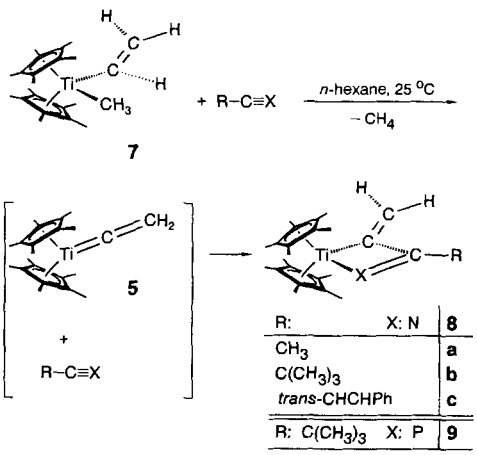
Synthesis and Structure of 1-Aza- and 1-Phospha-2-titanacyclobut-4-enes**

Rüdiger Beckhaus,* Isabelle Strauß, and Trixie Wagner

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday



Oxatitanacyclobutanes[1] and azatitanacyclobutenes[2] are discussed as intermediates in reactions of carbenoid titanium compounds with carbonyl compounds or nitriles, respectively. The high electrophilicity of the metal center has to date prohibited the isolation and characterization of **1** and **3**; spontaneous ring opening affords either carbonyl olefination (**1** → **2**),[3] or products of intermediately formed vinylimido species **4** corresponding to the reaction of **3** → **4**.[2b, 4]

1 **2** **3** **4**

The first stable and structurally characterized 1-oxa-2-titanacyclobutanes with a planar four-membered ring [5] were isolated by reaction of the permethylated titanocene vinylidene fragment $[Cp^*_2Ti{=}C{=}CH_2]$ (**5**) with heterocumulenes;[6] compound **5** may be obtained from $[Cp^*_2TiC(=CH_2)CH_2CH_2]$ (**6**) or $[Cp^*_2Ti(CH_3)(CH{=}CH_2)]$ (**7**) after elimination of ethylene or methane, respectively. Subsequently we report on the advantages associated with the use of **5** instead of $[Cp_2Ti{=}CH_2]$ intermediates in the preparation of azatitanacyclobutenes **3**. Furthermore, encouraged by the synthesis of the first 1-phospha-2-rhodacyclobut-4-ene by Binger et al.[7] we studied the reactivity of **5** towards the phosphaalkyne *t*Bu–C≡P.

The reaction of solutions of **7** in *n*-hexane with acetonitrile, pivalonitrile, cinnamonitrile, or 2-*tert*-butyl-1-phosphaacetylene[8] at room temperature led almost quantitatively to the prod-

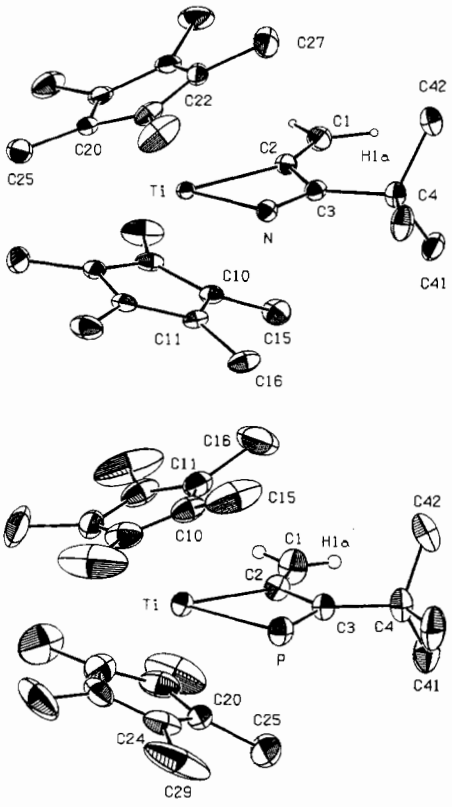
[**] This work was supported by the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. G. E. Herberich for his continuing interest and Prof. Dr. P. Paetzold for a sample of *t*BuCP (Technische Hochschule Aachen). Stimulating discussions with Prof. Dr. R. H. Grubbs (California Institute of Technology) are gratefully acknowledged.

ucts **8a–c**, and **9**, respectively, (Table 1) and its isomer **9′**(NMR spectroscopic determination). The complexes **8b** and **8c** were isolated as red ashlars or needles in 53% and 38% yield, respectively. Purification of **8a** was prevented by its low tendency to crystallize. The isomer **9** was obtained as brown ashlars in 35% yield. The mass spectra of **8b**, **8c**, and **9** exhibit the peaks expected for the molecular ions.

The two different chemical shifts for the protons of the *exo*-methylene group in the ^{1}H NMR spectra appear to be a particularly characteristic feature of these new complexes and similar metallacycles (δ = 4.98, 6.04 (**8a**); 4.87, 6.25 (**8b**); 5.05, 6.36 (**8c**); 3.49, 5.45 (**9**)).[9] Moreover the chemical shifts of the ring carbon atoms in the ^{13}C NMR spectra are consistent with a σ-Ti-bonded sp^2 carbon atom and a C=N or C=P carbon atom not bonded to a metal (δ = 195.0, 146.9 (**8a**); 184.5, 157.4 (**8b**); 192.6, 146.0 (**8c**); 194.1, 195.8 (**9**)). A metal-bonded λ^3 phosphorus atom in **9**[7, 10] is indicated by its high downfield shift in the ^{31}P{^{1}H} NMR spectrum (δ = 549).

The structures of **8b** and **9** in solution determined by NMR spectroscopy have been confirmed by X-ray crystal structure analyses[11] (Fig. 1). The structures show planar heterotitanacyclobutenes. The alternating bond lengths of the sequences C1-C2-C3-X (X = N, P) are comparable to a conjugated π-bond system, similar to that of free butadiene.[12]

Furthermore the interatomic distances (Ti–X and C–X; X = N, P) and the small angles (Ti-X-C) prove the existence of an sp^2 hybridized X atom with a noncoordinated lone pair.[13]



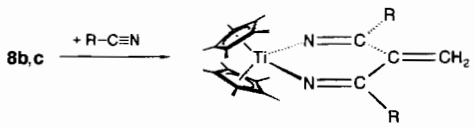


Fig. 1. Molecular structure of **8b** (top) and **9** (bottom) in the solid state. Selected bond lengths [Å] and angles [°] (Cp(1) and Cp(2) represent the centers of the Cp* ligands of the titanocene fragment; values in square brackets correspond to the parameters of **9**: X = N(**8b**), P (**9**)): Ti–Cp(1) 2.1055(5) [2.1053(9)], Ti–Cp(2) 2.1048(5) [2.1029(9)], Ti–X 2.017(2) [2.504(2)], Ti–C(2) 2.134(2) [2.161(5)], C(2)–C(1) 1.337(3) [1.326(8)], C(2)–C(3) 1.485(3) [1.473(7)], X–C(3) 1.290(3) [1.701(5)]; Cp(1)-Ti-Cp(2) 140.0(1) [139.4(2)], C(2)-Ti-X 67.85(8) [68.2(1)], Ti-X-C(3) 94.5(1) [81.1(2)], X-C(3)-C(2) 113.2(2) [111.6(3)], C(3)-C(2)-Ti 84.4(1) [99.1(3)], C(1)-C(2)-Ti 145.4(2) [133.1(4)].

Thus, the reactivity of [$Cp_2Ti{=}CH_2$]-based consecutive products observed by Doxsee et al. (that is the rearrangement (**3** → **4**)[2, 4]) can be regarded as a consequence of the participation of the nitrogen lone pair in the bonding to the titanium center, leading to the widening of the Ti-N-C angle and subsequent opening of the azatitanacyclobutene ring (→ **4**).[14] In contrast, because of the higher basicity of the permethylated cyclopentadienyl ligands, the electrophilicity at the titanium center is reduced in complexes **8** and **9**. An excess of nitrile and higher temperatures favor the insertion of another nitrile molecule into **8b** and **8c** to give **10a** and **10b**, respectively (**10a**: 64% yield).

10a : R = $C(CH_3)_3$
10b : R = CHCHPh

Whereas end-on coordination dominates in nitrile complexes,[15] phosphaalkyne ligands prefer side-on coordination due to the π character of their HOMO (i.e. the π-n separation is greater for phosphaalkynes than for nitriles).[16] After initial coordination of the nitrile (**A**), cycloaddition takes place via a suprafacial arrangement **B** to give **8**.

In the synthesis of **9**, an isomeric compound **9′** (corresponding to **C**) was detected in solution by NMR spectroscopy, but this has not yet been isolated (**9′**: ^{31}P{^{1}H} NMR: δ = 2.09 (s); ^{1}H NMR: δ = 6.66 (d, $^3J_{(H,P)}$ = 30 Hz, 1H, =CH_2), 5.80 (d, $^3J_{(H,P)}$ = 50 Hz, 1H, =CH_2), 1.60 (s, 30H)). The experimental

A B X: N, P C

data for **9** are consistent with initial η^2 coordination, thus demonstrating the alkyne-like behavior of the phosphaacetylene. Further investigations will be necessary to establish whether higher regioselectivities can be achieved by the use of bulkier RCP derivatives.

Experimental Procedure

8b: Pivalonitrile (0.22 mL, 2 mmol) was added dropwise to a solution of **7** (0.72 g, 2 mmol) in *n*-hexane (50 mL) at −20 °C and the reaction mixture was stirred for two hours at room temperature. The solvent was removed at 0–10 °C and **8b** was obtained as crude product. Recrystallization from *n*-heptane yielded 0.42 g (53%) **8b** as red ashlars or needles.

Analogous procedures afforded the compounds **8a** and **8c**, as well as **9** by using 2-*tert*-butyl-1-phosphaacetylene (60% in hexamethyldisiloxane). Treatment of complex **7** with 10 equivalents of pivalonitrile for four days afforded complex **10a** in 44% yield as red ashlars or needles from a solution of **10a** and **8b**.

Deformation of Polymethine Structures by Intermolecular Interactions**

Lars Dähne* and Günter Reck

Intermolecular interactions in polymethine dye systems have been the subject of great interest in recent years in the context of nonlinear optical processes,[1] energy transfer,[2] and conversion of solar into electrical energy.[3] Symmetrical polymethine dyes are characterized by maximal delocalization and therefore high polarizability of the linear π-electron system (Scheme 1, mesomer-

Scheme 1. Structural models of the 1,7-bis(dimethylamino)heptamethinium salts **1**-X.

ic structure **1b**). The formal single and double bonds are of equal length in the frontier structure **1a**, whereas the π-electron density alternates on the C atoms of the chain.[4] The polarization of the π system in the direction of the frontier structure **1a** should feasible through intermolecular interactions with anions lying asymmetrical to the methine chain.[5]

A bond lengths alternation of 6 pm was calculated on the basis of Coulombic interactions for the 1,7-bis(dimethylamino)heptamethinium ion BDH^+ **1**, if the anion is removed to 400 pm away from one of the terminal nitrogen atoms.[5] The bond lengths alternation is defined as the difference between the single and double bond lengths [Eq. (a)] and could reach a maximum value of 10.5 pm in the case of localized bonds.

bond lengths alternation = (N1/C1 + C2/C3 + C4/C5 + C6/C7 − C1/C2 − C3/C4 − C5/C6 − C7/N2)/4 (a)

N/C = lengths of the bonds

The bonds of the methine chain of **1** are arranged symmetrically with respect to the C4 atom in solution and are not affected by counterions.[6] In contrast to pure inorganic anions[7] tetraarylborate ions form contact ion pairs with bis(indoleninyl) trimethinium cations in aqueous solution.[8] These ion pairs undergo electron transfer reactions on electronic excitation.[9] A new type of ion pairs called penetrated ion pairs forms, if the aryl groups are very large (e.g. 4-(1-triptycyl)phenyl-).[10]

We have examined the interactions between the BPh_4^- ion and the BDH^+ dye **1** which serves as a model compound of the class of cyanine dyes. ^1H NMR measurements on **1**-BPh_4 show that the signals of the methine-H atoms are shifted to higher fields in contrast to other BDH^+ salts (Table 1). The vicinal coupling constants remain the same however.

Table 1. Chemical shift of the ^1H NMR signals of BDH^+X^- (1-X); measured at acetone with 500 MHz.

	1/7-H	2/6-H	3/5-H	4-H	N-CH_3	N-CH_3
1-ClO_4	7.706	5.874	7.390	6.256	3.166	3.362
1-BF_4	7.702	5.874	7.390	6.256	3.166	3.362
1-BPh_4	7.514	5.815	7.279	6.224	3.089	3.262
difference	0.188 (0.192)	0.059	0.111	0.032	0.077	0.100

The shift of the signal of **1** to higher field is caused by the ring current effect of closely adjacent phenyl groups of BPh_4^- ions which are associated with the cation. The stronger interference at the H1/H7 and H3/H5 atoms suggests the fixation of counterions on the side of positivated methine-C atoms (Scheme 1). This association does not change the structure of the polymethine chain in the temporary average, since the bond order and the symmetry of **1** are conserved.

For a cation–anion association the optical spectra of the salts of **1** should differ in accordance with the dissociation properties of the solvent (Table 2). Similar to other cyanine dyes[8], 1-BPh_4 forms ion pairs in water. The π-π* transition energy of the ion pairs is shifted by $\Delta E = 2650\ cm^{-1}$ to the red relative to the free molecule. This value is significantly higher than the shift of the hitherto examined bis(indoleninyl)trimethincyanine dyes ($\Delta E = 1196\ cm^{-1}$).[8] In solvents with high dielectric constant, the light absorption of the dye is not affected by the anion; the ions are completely dissociated. Apparently no associates are present in acetone either. The reason may be the substantially lower concentration in the optical measurements compared to the NMR experiments. In solvents with lower dielectric constant, the transition energy depends on the anion and is for 1-BPh_4 slightly lower than for 1-ClO_4. Compared to the other spectra the long wave UV/Vis absorption band for both salts is strongly broadened.

Table 2. UV/Vis data of two 1-BPh_4 and 1-ClO_4 in solvents of different polarity [a].

Solvent	ε_0	1-BPh_4			1-ClO_4		
		λ_{max}	ε	$\omega_{1/2}$	λ_{max}	ε	$\omega_{1/2}$
H_2O	80.0	507/583	[b]	[b]	507.0	187500	1353
MeOH	32.7	508.8	181210	1324	507.2	188300	1324

$CHCl_3$	4.8	515.2	149500	1370	511.4	156200	1433
C_6H_6	2.3	514.8	130200	1446	508.4	117500	1608

[a] λ_{max} in nm; ε in L $mol^{-1}\,cm^{-1}$, half width $\omega_{1/2}$ in cm^{-1}. [b] Ion pair.

Also in the solid state the BPh_4^- anion influences the dye cation considerably. The higher melting point of 1-BPh_4 (197 °C) compared to other salts of this dye (162–178 °C), the low solubility in water as well as changes in the IR spectrum (KBr) point to special interactions.

The results of the X-ray structure analysis of 1-BPh_4 shows that the bond lengths of the polymethine chain alternate in these crystals (Table 3).[14] The bond lengths alternation was calculated to be 1.22 pm [Eq.(a)],[15] which corresponds to a shift of the symmetrical mesomeric structure **1b** in the direction of the frontier structure **1a** by 12%.

Table 3. Bond lengths in the polymethine chain in crystals of 1-BPh_4.

Bond	length [pm]	Bond	length [pm]
N1-C1	131.4 (short)	C4-C5	137.4 (short)
C1-C2	138.5 (long)	C5-C6	138.6 (long)
C2-C3	137.6 (short)	C6-C7	136.7 (short)
C2-C4	139.0 (long)	N2-C7	131.9 (long)

In the hitherto examined **1**-X crystals[7] (X = Cl^-, ClO_4^-, BF_4^-) no bond lengths alternation of **1b** was found. To determine the reason for this difference, the molecular environment of the polymethine chain in the **1**-X salts was examined on the basis of X-ray structural data.[7] In the chloride and perchlorate salts the anions are located symmetrically with respect to the polymethine chain. Hence a polarization of the π-electron system could not occur. In contrast, the anions are unsymmetrically oriented in the tetrafluoroborate and tetraphenylborate salts of **1**.

An estimate was made of the asymmetry of the Coulomb forces caused by anions acting on the π-electron system of the dye. Here it was assumed that the heptamethine chain is a rodlike dipole limited by nitrogen atoms, and the anions are point charges. Taking into consideration all anions within a distance of 1000 pm from the nitrogen atoms, the relative difference of the forces acting at the ends of the dipole amounts to $\Delta F_{Coul} = 4.9 \times 10^{-11}$ N and 14.8×10^{-11} N for the two different molecule sites in the 1-BF_4 crystal and to only $\Delta F_{Coul} = 1.6 \times 10^{-11}$ N in 1-BPh_4.

In spite of the conspicuously higher asymmetry of the force field at 1-BF_4, a polarization of the π-electron system does not exist. Therefore the Coulomb forces between anion and cation cannot be the deciding factor for the electron polarization. The BPh_4^- ion acts as a π ligand forming η^6-arene complexes with electron-rich fragments of metal complexes.[11] The association between uncharged merocyanine dyes and benzene is also based on interactions between the π-electron systems.[12]

Figure 1 shows the phenyl rings of the BPh_4^-, which are in the vicinity of the polymethine chain. At the "left-hand" side of the molecule the influence of the anions is noticeably higher because of their larger number and the shorter distance of the phenyl rings from the methine chain. The polarization of the methine

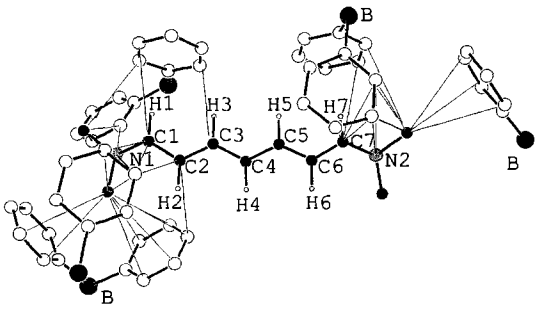

Fig. 1. Volume segment in crystals of the 1-BPh_4 (for simplification phenyl rings, whose carbon atoms are more than 400 pm away from the methine chain, have been omitted; thin lines denote intermolecular distances less than 380 pm)

π-electron system caused by electron-rich phenyl rings leads to a positivation of this side and therewith to the deformation of the molecular structure. Vice versa a polarization of the anions is also probable, in which the phenyl rings in the vicinity of the cation **1** should show a significantly higher electron density. We assume therefore, that inductive forces between the easily polarizable π-electron systems of the cations and anions dominate in the distortion of the polymethine structure.

The deformation of the polymethine chain is also conceivable as an effect of an aggregation of dye molecules. Such aggregates were observed in other crystals of **1** in which the distances between the cations amounted to only 348 pm.[7] In 1-BPh_4, the dye cations exist however as dimers (Fig. 2). A mutual polarization of the methine chains could be excluded, because of the comparatively large distance of 471 pm between the molecule plains and because of the head-to-head arrangement of the more positively charged ends of the polymethine chains.

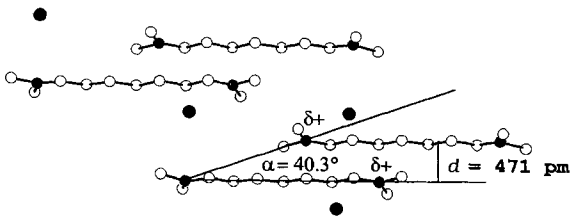

Fig. 2. Structure of the polymethine dimer in the crystal.

The bathochromic shifted UV/Vis absorption band found for ion pairs in aqueous solution cannot be explained by the observed distortion of the π-electron system, because a disturbance of the symmetrical polymethine system should shift the optical transition to higher energy. As for bis(indoleninyl)trimethine cyanine BPh_4 complexes,[8] it was concluded from optical data that the ion pairs should exist as dimers. This model is confirmed in an excellent manner by the crystal structure (Fig. 2). In agreement with the theory of molecular excitons of Kasha et al.[13] the dislocation angle of $\alpha = 40.3°$ between the dye molecules leads to the observed bathochromic shift of the transition energy.

A calculation of the ring current effect on the basis of the crystal structure results in graduations of the high-field shift of the methine protons qualitatively similar to those obtained in the ^1H NMR measurement in acetone (see Table 1). The calculated values are however two-to-three times larger and do not reflect the symmetry of **1** found in solution. In contrast to the aqueous solution, the anions are associated more weakly in organic solvents, because of the absent hydrophobic forces. Therefore, fluctuating motion of anions causes averaging of the NMR signals and broadening of the optical absorption band.

To summarize, the first experimental evidence has been obtained for the deformation of a symmetrical polymethine system caused by intermolecular interactions. The determining forces are not, as first assumed, Coulomb relations between anions and cation or dipole–dipole interactions between the cations, but an induction of charge shift in the easily polarizable π-electron systems of anion and cation by electrostatic interactions. All polymethine dyes possess as the principal structural element a π-electron system similar to that of the investigated model compound. Therefore it may be assumed that such polarization will also occur for other polymethine dyes with corresponding arrangement of tetraarylborate anions in the solid state. However the polarization should be less pronounced for polymethines with smaller π-electron systems (tri-, pentamethines) and with shielding end groups (e.g. indoleninyl).

Experimental Procedure

1-BPh_4: A solution of $NaBPh_4$ (2.32 g, 7.00 mmol) in water (400 mL) was added dropwise to a solution of 1-Cl (1.43 g, 5.00 mmol) in methanol (50 mL) at room temperature. The product which was sparingly soluble in water was filtered, washed, and recrystallized from dry acetone. This afforded 2.30 g (92%) of red prismatic crystals of 1-BPh_4. M.p. 196–197 °C; correct C,H,N analysis; MS: (FAB^+): *m/z* 179 (23)[M^+], (FAB^-): *m/z* 318, 319, 320 (5, 14, 5)[M^-]; UV/Vis data were obtained following dilution of a concentrated standard solution in acetone. Therefore, each stated solvent contains 0.1 vol.% acetone.

A Non-Peptidic Ion Channel with K^+ Selectivity

Yasutaka Tanaka, Yoshiaki Kobuke,* and Masahiro Sokabe

The sequence analyses of several channel proteins have defined the molecular basis of ion channels through the identification of several associated subunits in the biological membrane and a central ion-conducting pore.[1] Site-directed mutagenesis has further clarified the pore mechanism.[2] Stable and simple synthetic molecules that can transport ions across the membrane by means of a channel mechanism have also attracted much attention, and some non-peptidic channel mimics have been reported.[3] However, the detailed characterization of these molecules at the single-channel level as reported for natural channels is presently lacking. In principle measurement of the single ion channel current is required to establish the channel mechanism.[4] We have demonstrated that a chimeric pore of molecular aggregates with an oligoether ion pair showed a single ion channel current. A few kinds of channels having corresponding conductance levels seem to reflect different aggregation numbers.[5] Here we report on the structurally well-defined macrocyclic amphiphile **1a**, which forms channels having single ion channel currents and only one type of the channel conductance. This is the first example of an artificial ion channel that recognizes, monovalent cations and displays selectivity for K^+ ions.

1a : R= $CH_3(CH_2)_{16}$
1b : R = $CH_3(CH_2)_{10}$

Condensation of resorcinol with octadecanal under acidic conditions afforded the amphiphilic cyclic tetramer **1a** whose alkyl chains are similar in length to the lipid used in this study.[6] The ^1H NMR spectra of **1a** indicated that the molecule has fourfold symmetry; the alkyl chains are arranged in an all-axial, all-*cis* configuration (like **1b**).[7] After incorporation into planar soybean lecithin bilayers, **1a** exhibited the typical characteristics of a single ion channel: a stable and constant conductance (6.1 ± 0.8 pS) at various voltages with transitions between open and closed states in a membrane separating two 0.5 M KCl solutions (Fig. 1).[8] The symmetry in the channel current with respect to the voltage reversal across the membrane (Fig. 2) suggests the existence of a symmetric channel structure. Since a stable conductance was not observed in the absence of **1a**, neither leakage nor artifact currents can satisfactorily account for these observations. In contrast, use of **1b**, which has shorter

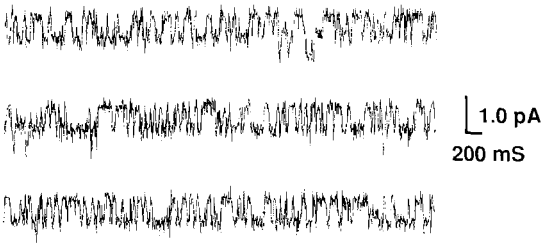

Fig. 1. Typical records of single-channel currents for soybean lecithin membranes containing **1a**; −74.4 mV in 0.5 M KCl solutions.

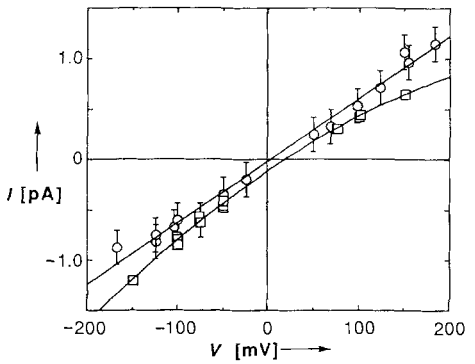

Fig. 2. Current-to-voltage relationship of membranes under the same conditions as in Figure 1 (○) and between two solutions (□) one containing 50 mM KCl and 450 mM NaCl, and the other 450 mM KCl and 50 mM NaCl.

alkyl chains, did not produce stable channel currents, showing that only when the amphiphile has alkyl tails capable of spanning half the membrane thickness can it form a stable channel structure. The conductance observed with **1a** remained constant during more than 90% of current records with variations in the molar ratio of **1a** to lipid between 1:200 and 1:3000. This is in marked contrast to the observation of several conductance levels for the molecular aggregate channels including synthetic peptides,[5, 9] where the different levels were assigned to the action of different sized aggregates. These results may also signify that monomeric **1a** penetrates nicely a single lipid layer of the bilayer. The cavity formed by the four resorcinol rings, which is extended by the four alkyl chains in **1a**, excludes the entry of lipid molecules and thus provides the channel pore for the passage of ions. Water molecules may also occupy the channel and coordinate to ions passing through the pore. On the assumption that the cavity formed by **1a** recognizes the positioning of another molecule of **1a** in the other half of the bilayer, a tail-to-tail dimer of **1a** forms (Fig. 3) and thus gives rise a symmetric transmembrane channel similar to the Gramicidin A channel.[10] In accordance with this dimer model, channel activities were not observed when **1a** was added to only one side of the lipid membrane, probably because such a bulky amphiphile does not flip-flop easily.

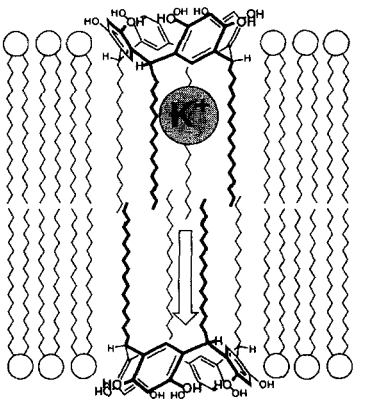

Fig. 3. Hypothetical structure of a channel formed by **1a** in lipid bilayers.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0606-0693 $ 10.00+.25/0

Under the conditions of single-salt gradients (0.5 M KCl/0.1 M KCl), the channel formed by **1a** showed a reversal potential of 35.9 mV, indicating that it has a distinct selectivity for cations over anions. The permeability ratio P_{K^+}/P_{Cl^-} of 20, calculated with the Goldman–Hodgkin–Katz equation,[4] is comparable to those observed for natural cation channels. Similar reversal potential measurements under gradients of K^+ and Na^+ ions revealed that the channel discriminates K^+ from Na^+ ions with a permeability ratio P_{K^+}/P_{Na^+} of roughly 3 (Fig. 2). In contrast, Rb^+ ions blocked the K^+ ion current: the solution containing K^+ and Rb^+ ions (0.05 M KCl, 0.45 M RbCl/0.45 M KCl, 0.05 M RbCl) provided no stable channel currents in 20 independent measurements. When the biionic solution was exchanged for 0.5 M KCl solutions, K^+-driven currents appeared immediately. Thus, the channel formed by **1a** shows maximum selectivity for K^+ ions like naturally occurring K^+ channels, but behaves differently from the latter one with respect ot the passage of Rb^+ ions.

Selectivity of ion permeation through membrane channels is determined primarily by the narrowest region of the channel pore termed the selectivity filter. The relation between the electric field strength at the filter and the dehydration energy of the permeating ion determines the extent of dehydration.[4] The selectivity mechanism in voltage-gated K^+ channels has been discussed in detail. It is generally accepted that the K^+-selective filter consists of an "aromatic cage" formed by four tyrosine residues, which provides a weak electric field allowing complete dehydration of K^+ ions but not of Na^+ ions. Consequently, the K^+ ions can pass through the filter but not the Na^+ ions. The π electrons of the aryl groups probably contribute to the lowering of the potential barrier for passage of K^+ ions through attractive π–cation interactions.[11] This mechanism may also explain the selectivity observed in **1a** channels. The narrowest section of the ion conducting pore in **1a** comprises the four resorcinol rings with a weak electric field. The section is thought to be just large enough to allow naked K^+ ions ($r = 1.33$ Å) to pass but not the slightly larger Rb^+ ions ($r = 1.47$ Å). According to molecular dynamics simulations, the size of this opening in **1a** resembles that of the pore of *p-tert*-butyl-calix[4]arene-tetraamide, which permits the passage of K^+ ions but not Cs^+ ions ($r = 1.69$ Å).[12]

We have described here the first example of selective ion-transport through a membrane bilayer by means of a channel mechanism with a simple and stable synthetic molecule. In a membrane bilayer dimers of **1a** reproduce the essential biological properties of a single ion channel. This simplest model of a single ion channel may offer insight into the origins of ion selectivity in ion channels.

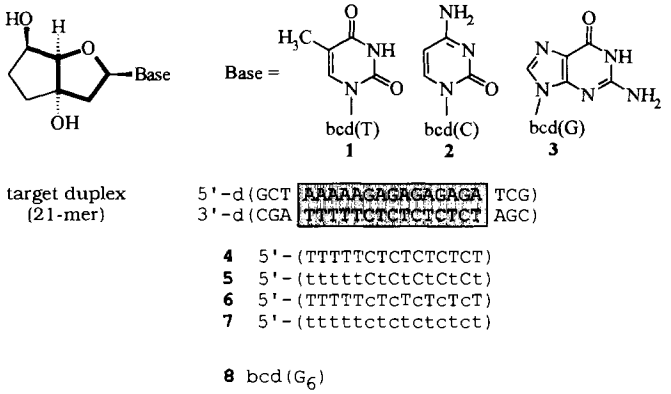
Triple-Helix Formation of Oligodeoxynucleotides Containing [(3′*S*,5′*R*)-2′-Deoxy-3′,5′-ethano-β-D-ribofuranosyl]nucleosides ("Bicyclo-deoxynucleosides")**

Martin Bolli and Christian Leumann*

In memory of Rolf Scheffold



High-affinity, sequence-specific recognition of single- and double-stranded RNA and DNA by oligonucleotide analogues is important for the selective control of gene expression.[2] The formation of triple helices either from a DNA duplex or of double helices from an RNA single strand represents a way to interfere with transcription in DNA, and translation in RNA.[3] Two structural motifs in triple helices have been identified to date; they differ in the composition of the base triple and the strand polarity. In the py–pu:py motif the third strand consisting only of pyrimidine bases is paired to the Hoogsteen side of the purine strand in a parallel fashion, forming T–A:T and C^+–G:C base triples.[4] In the pu–pu:py motif the third strand is purine-rich and paired in an antiparallel orientation to the Hoogsteen side of the purine strand of the Watson–Crick duplex and exhibits G–G:C, A–A:T, and T–A:T base triples.[5] Both motifs require strandwise separation of purine and pyrimidine bases. Within the py–pu:py motif, stronger triplex formation with single-stranded nucleic acids was observed by reducing the molecularity of association with circular or hairpin-forming oligonucleotides.[6] DNA analogues that exhibit stronger binding to double-helical DNA comprise oligonucleotides with modi-

[**] Nucleic Acid Analogues with Restricted Conformational Flexibility in the Sugar–Phosphate Backbone, Part 4. This work was supported by the Swiss National Science foundation. Part 3: [1]

fied sugar and base moieties,[7] or phosphate replacements,[8] or both.[9] A remarkable increase in the binding efficiency of the third strand is observed with oligonucleotides containing dinucleoside units that are linked by a conformationally constrained acetal group.[10]

We recently described the design and the synthesis of novel nucleoside analogues ("bicyclonucleosides", Scheme 1).[1, 11] The main structural features of the bicyclonucleosides are a conformation of the furanose unit restricted to the 2'-*endo*/1'-*exo* range

Scheme 1. Top: Structures of the nucleoside analogues bicyclothymidine (bcd(T), **1**), bicyclodeoxycytosine (bcd(C), **2**), and bicyclodeoxyguanosine (bcd(G), **3**) and the duplex target sequences for T_m analysis of third-strand binding. Bottom: Sequences **4**–**7** for triple-helix formation (t = bcd(T) = **1**, c = bcd(C) = **2**, T and C = natural deoxynucleosides thymidine and 2'-deoxycytidine).

and a preferential equatorial orientation of the secondary hydroxyl group in the carbocyclic ring.[11a, c] Prominent properties of decanucleotides of bicyclodeoxyadenosine are strong duplex formation with the RNA complement poly(U) and about a 20-fold increase (relative to the natural equivalent) in third strand binding with the corresponding DNA complement.[1, 11b] We now report on the triple-helix-forming properties of mixed-sequence oligonucleotides (**4**–**7**) containing bicyclothymidine (**1**) and bicyclodeoxycytidine (**2**) with a natural 21-mer DNA target duplex, as well as the complex-forming properties of a hexanucleotide of bicyclodeoxyguanosine (**3**) with the RNA polymer poly(C) within the py–pu:py structural motif (Scheme 1).

The synthesis of bicyclonucleosides and the corresponding cyanoethylphosphoramidite building blocks for oligonucleotide chain extension has been reported earlier.[1, 11a] The assembly of the oligonucleotides **4**–**8** was performed by automated solid-phase synthesis in analogy to the procedure already developed for bicyclo-DNA on a 1 μmol scale. The synthesis is completely compatible with that of natural DNA and proceeded in average coupling efficiencies of 98% per elongation cycle.[12] After detachment from the solid support and removal of the base and phosphate protecting groups, the crude oligomers were purified by ion exchange HPLC. In representative cases further analysis was performed by mass spectrometry.[13]

Triple-helix formation of the oligomers **4**–**7** with the 21-mer DNA target duplex was monitored by recording UV-melting curves at pH 6.0 and 6.5 for 200 mM NaCl and 1 M NaCl, respectively. The corresponding T_m and hyperchromicity data are summarized in Table 1. Figure 1 shows the melting curves of the triplexes of **4**–**7** with the target duplex at pH 6.0 and 1 M NaCl.[15] In all cases two well-separated transitions are observed. Those at higher temperature correspond to dissociation of the target duplex 21-mer, and those at lower temperatures to the

Table 1. T_m values [°C] and hyperchromicity [%] (in parentheses) of the dissociation of the third strand **4**–**7** from UV-melting curves (260 nm). Triplex concentration 0.9–1.1 μM in 10 mM NaH_2PO_4.

Strand	pH 6.0		pH 6.5	
	200 mM NaCl	1 M NaCl	200 mM NaCl	1 M NaCl
4	40.8 (8)	42.8 (10)	30.9 (6)	32.1 (9)
5	47.5 (7)	52.2 (10)	40.8 (3)	40.9 (8)
6	24.3 (6)	29.2 (9)	15.4 (3)	17.9 (8)
7	27.4 (2)	31.0 (7)	18.0 (2)	20.3 (5)

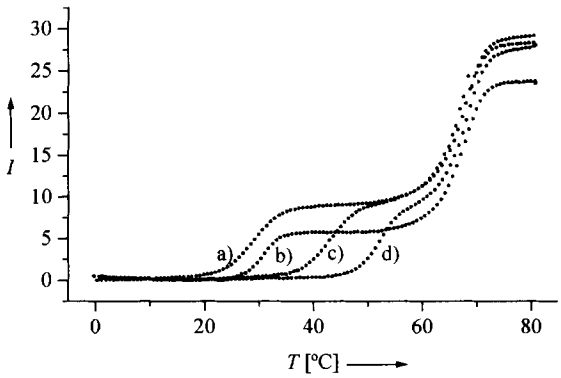

Fig. 1. UV-melting curves (λ = 260 nm) of **6** (a), **7** (b), **4** (c), and **5** (d) with the duplex target sequence (10 mM NaH_2PO_4, 1 M NaCl, pH 6.0. Triplex concentration 0.9–1.1 μM. T_m of target duplex 71 ± 1 °C.

melting of the triplex into single strands **4**–**7** and the target duplex. In all experiments the stability of the target duplex remained invariant as expected ($T_m \approx 71$ °C). However, large differences in the efficiency of triple-helix formation as a consequence of the nature of the bicyclic nucleosides were observed. By replacement of all 2'-deoxycytidine nucleosides in the third strand by bicyclodeoxycytidine **2**, a decrease in T_m of 2.7 °C per modification (mod.) occurs relative to the control sequence **4**. This contrasts with an increase in T_m of 1 °C/mod. when thymidine is replaced by the bicyclic analogue **1**. The completely bicyclic sequence **7** binds to the duplex with the same affinity as the sequence containing only bicyclodeoxycytidine (**6**). In this case the hyperchromicity is significantly lower than in the others, most probably due to incomplete base pairing with the target sequence over the whole oligonucleotide length.

The melting curves a) and c) in Figure 1 and the corresponding hybridization curves are superimposable at the applied temperature gradient (0.5 K min^{-1}) and therefore represent equilibrium binding. In the case of b) and d), melting and hybridization curves are different, the latter reflecting a broader transition with T_m at lower temperatures.[12] This behavior indicates slower triple-helix formation with increasing numbers of bicyclodeoxynucleosides. Kinetics of triple-helix formation is also dependent on the salt concentration.[17] Increasing the amount of NaCl in the buffer from 200 mM to 1 M (pH 6.0) reduces the extent of hysteresis of the melting and hybridization curves. A concomittant increase in triple-helix stability is observed in all cases investigated.[16a]

While negligible differences in pK_a between the nucleobase in **2** and 2'-deoxycytidine are expected, the decrease in binding efficiency observed with **6** relative to **4** is more likely to be due to differences in conformation of the two protonated cytosine nucleosides. NMR investigations on triple-helical natural DNA structures within the py–pu:py motif provided evidence for different conformational preferences of protonated cytidine and

thymidine residues in the Hoogsteen third strand, the former occurring preferentially in a 3′-*endo* and the latter in a 2′-*endo* conformation.[18] Bicyclonucleosides, however, show strong preference for the 1′-*exo*/2′-*endo* sugar conformation irrespective of the nature of the base.[11] The observation that the stability of oligonucleotides containing bicyclodeoxynucleosides is lower for bicyclodeoxycytidine containing **6** and higher for bicyclothymidine containing **5** is in agreement with the NMR data and provides additional evidence that the preferred conformation of the third strand backbone in DNA triplexes with the py–pu:py motif is heterogeneous.

To investigate the potential of duplex and triplex formation of oligomers of bicyclodeoxyguanosine we measured T_m data of mixtures of hexamer **8** with the RNA complement poly(C) (base stoichiometry C:G = 2:1) at different pH values between 5.5 and 8.3. In contrast to the analogous experiments in the bcd(A)/poly(U) series,[11b] the bcd(G)/poly(C) system allows easy differentiation of whether the pyrimidine strand pairs to the Watson–Crick or the Hoogsteen side of the purine strand simply by varying the pH. From the plot of T_m vs. pH in Figure 2 it becomes

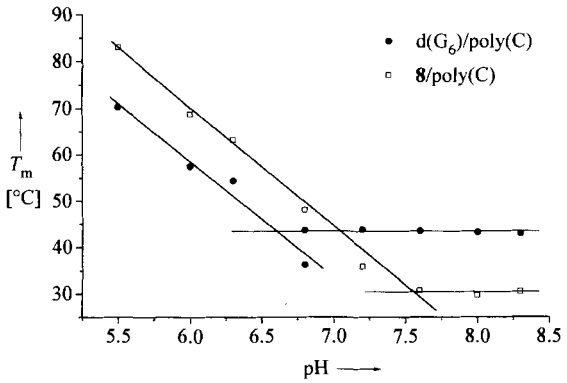

Fig. 2. T_m values from UV-melting curves (λ = 280 nm) of **8** and d(G_6) with poly(C) (ratio C:G = 2:1) in 150 mM NaCl/10 mM NaH_2PO_4 as function of pH. Overall base concentration 33.8–40 μM. Individual T_m values (λ = 250 nm) for triplex → duplex and duplex → single strand transitions were obtained at pH 6.8 in the case of d(G_6)/poly(C).

clear that the melting temperature is independent of proton concentration above pH 7.6 in both pairing systems d(G_6):poly(C) and **8**:poly(C), thus indicating only (charge-neutral) Watson–Crick base pairing. The corresponding T_m data (30 °C for **8**:poly(C) and 43 °C for d(G_6):poly(C)) clearly demonstrate an energetic advantage for the Watson–Crick duplex d(G_6):poly(C). Below pH 6.5 in both systems a linear increase in T_m as a function of pH is observed, which is due to triple-helix formation involving protonated cytosine bases. Comparison of the T_m data of d(G_6):poly(C) and **8**:poly(C) shows that at a given pH triplex formation is energetically favored in the latter case ($\Delta T_m \approx 12$ °C). This demonstrates that bicyclooligonucleotide **8** favors Hoogsteen binding and disfavors Watson–Crick binding of its RNA complement relative to its natural analogue. As a consequence, triplex formation of poly(C) with **8** is already observed about 0.5 pH units higher than in the reference system. This leads to higher overall complex stability for **8**:poly(C) than for the reference system below pH 7.1.

The results presented here clearly demonstrate that bicyclothymidine **1** can be used advantageously for the preparation of high-affinity, triple-helix-forming oligonucleotides within the py–pu:py motif. There is a considerable potential to increase triple-helix stability further by using oligonucleotides containing **1** in combination with nonnatural, base-modified deoxycytidine substitutes or with 2′-O-alkylated cytidine derivatives.[19] The fact that oligomers of bicyclodeoxyguanosine (and possibly also bicyclodeoxyadenosine) show increased acceptor properties at the Hoogsteen binding site is unprecedented for sugar-modified oligonucleotide analogues and might lead to analogues that form strong Hoogsteen base-paired duplexes or triplexes with pyrimidine-rich RNA.

Handy for Genetic Engineering

Introduction to Molecular Cloning Techniques. By *G. Lucotte* and *F. Baneyx*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. 298 pp., hardcover DM 79.00, $ 49.00.—ISBN 3-527-89613-9/1-56081-613-9

For anyone who has even a passing acquaintance with the subject, the title of this book must inevitably provoke the reaction: "What? yet another book on molecular cloning techniques?" One thinks immediately of the existing standard works in this field: laboratory manuals such as "Maniatis" and *Current Protocols*, and reference sources such as the *Parat Encyclopedic Dictionary of Genetics*, to name only those that are probably most familiar. The book reviewed here does not fit into either of these categories. Instead, as explained on the dustcover, it is intended for students and laboratory technicians concerned with microbiology, molecular biology, genetics, biotechnology, and chemical engineering. Thus it aims to introduce the reader to selected problems of genetic engineering, and is a mixture of textbook and laboratory manual. In each of the 23 chapters a short theoretical introduction is followed by a series of simple experiments and exercise problems. Throughout the book these are concerned exclusively with the commonest host organism, the prokaryotic *Eschericia coli*, despite the fact that many other such "domesticated animals", such as baculoviruses and yeasts, are nowadays used as standard organisms in genetics laboratories. However, this restriction seems to me to be entirely in keeping with the declared aims of this little book, even though it was not strictly necessary. Compared with the usual works on the subject the book has the considerable advantage of being compact and convenient to handle.

It consists of six parts whose contents vary from one to seven chapters, together with several appendices, answers to the exercise problems, a bibliography arranged according to chapters, and an index. Part 1 describes the host organism *E. coli* and introduces the relevant nomenclature. Part 2 introduces restriction enzymes and the techniques of methylation and electrophoresis. Part 3 deals with cloning vectors such as phages and plasmids, including the isolation of plasmid-DNA, the transformation of *E. coli* by plasmid-DNA, and in-vitro DNA packaging. Part 4 is concerned with the preparation of DNA and RNA from tissues or gels, the isolation and characterization of mRNA, electrophoresis of RNA, in-vitro protein synthesis, tissue-specific concentration of mRNAs, and the preparation of cDNA by reverse transcription. Part 5 deals with cloning techniques such as ligation and the cloning of cDNA fragments by elongation with homopolymers or synthetic sequences. Part 6 is concerned with libraries of genomes, cDNAs, and cosmids. Throughout the book the literature of the 1970s and 1980s is covered.

The appendices are very useful and practically orientated, and can also be used in everyday laboratory work. They include tables of bacterial strains and restriction enzymes, examples of isoschizomers, methylation patterns, and descriptions of several enzymes and vectors which could otherwise only be found by laborious searching through catalogs or original publications. Unfortunately though, some of the tables are badly set out. For example, in the detailed table of restriction enzymes, instead of the entries being listed according to the enzyme abbreviations, as would have been logical, they are arranged alphabetically according to the host organisms from which they originate. Would a reader who is not a microbiologist know, for example, that the enzyme *Aor* I comes from the organism *Acetobacter aceti* sub. *orleansis*? Appendices 13 and 14 describe the enzymes RNase A and DNase I respectively, with RNase A being given, absurdly, a whole page with only two and a half lines. A similar situation occurs with DNase I and RNase H. Here more detail was needed if the descriptions were to be included at all; otherwise it would have been better to omit these appendices. The structure of the index is not always consistent. For example, under the entry "Vector" one reads "See bacteriophage cloning vectors; plasmid cloning vectors", but neither of these appears in the index. Is this meant to refer to Chapter 6 with the title "Bacteriophage cloning vectors"? If so, what about the second reference?—There is no chapter or section entitled "Plasmid cloning vectors". Instead of sending the reader on an odyssey in search of these, it would have been more helpful to give actual page-numbers. This applies especially to the vectors described in Appendices 8–10 (the base sequence and restriction map for the vector pBR322, and the structure of the pUC vectors).

Defects such as these do, of course, detract from the usefulness of the book as a quick reference source for use in the laboratory. However, it can be thoroughly recommended for the readership mentioned above and for interested non-specialists as a convenient and concise introduction to molecular cloning techniques.

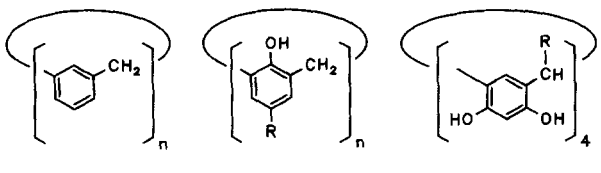
Calixarenes, Macrocycles with (Almost) Unlimited Possibilities

Volker Böhmer

The condensation reaction between *p-tert*-butylphenol and formaldehyde leads in a single step to good yields of cyclic oligomers in which, depending on the reaction conditions, either four, six, or eight phenol units are joined by methylene bridges. The beakerlike shape of the most stable conformation of the tetramer has led to their being given the name "calixarenes" (calix = chalice). Resorcinol can undergo condensation in a similar manner with a variety of aldehydes to afford cyclic tetramers with the same basic structure (the resorcarenes). In both cases the reaction does not require the use of dilution techniques, so that large quantities of product can be readily obtained. In addition, the parent compounds can be modified in various ways, in particular at the phenolic hydroxy groups or the phenyl residues; these approaches can be used separately or in combination. Calixarenes are thus ideal starting materials for the synthesis of various types of host molecules and can also act as building blocks for the construction of larger molecular systems with defined structures and functions. Their potential applications range from use as highly specific ligands for analytical chemistry, sensor techniques and medical diagnostics to their use in the decontamination of waste water and the construction of artificial enzymes and the synthesis of new materials for nonlinear optics or for ultrathin layers and sieve membranes with molecular pores.

Keywords: calixarenes · host-guest compounds · metacyclophanes · resorcarenes · supramolecular chemistry

1. Introduction



The name calixarenes was introduced by Gutsche[1] for the cyclic oligomers which are obtained from the condensation of formaldehyde with *p*-alkylphenols under alkaline conditions.[1, 2] The use of this word ("calix" means "beaker" in Latin and Greek) was suggested in particular by the shape of the tetramer, which can (and generally does) adopt a bowl- or beakerlike conformation which indicates the possibility of the inclusion of "guest" molecules.

Cyclic tetramers of this type had been described (or postulated[3a]) before and in some cases synthesized by defined reaction sequences.[3b] Most of these attempts were made with the goal of understanding the formation and properties of phenol-formaldehyde condensates on the basis of defined oligomeric model compounds. However, it required a point of view different from that of the polymer chemist to put this class of substances into the perspective of their present importance. Pedersen's discovery of the crown ethers stimulated the development of those areas of research known today as host–guest chemistry, inclusion compounds, or even supramolecular chemistry; the importance of the "cyclic oligonuclear phenolic compounds" was thus seen in a completely different light.

The condensation of resorcinol with aldehydes (but not with formaldehyde) under acidic conditions also leads to cyclic tetramers, and here again the initial structural postulates date back to the 1940s.[1] It is thus only logical to denote these compounds, which are also [1.1.1.1]metacyclophanes, as calixarenes, since nomenclature is normally based on the basic skeleton of a class of substances.

In what follows the name calix[*n*]arenes will generally be used for 1_n-metacyclophanes (general formula **I**), regardless of whether the phenolic hydroxy groups are intraannular (*endo*) or extraannular (*exo*) or whether individual units bear any phenolic OH groups at all. Although this review will deal primarily with calixarenes derived from phenol (calixarenes of type **II**), important results concerning calix[4]arenes derived from resorcinol (calixarenes of type **III**) will also be discussed. The term "resorcarenes" will be used to distinguish calixarenes of type **III**

I **II** **III**

Scheme 1. **I**: Calix[*n*]arenes or 1_n-metacyclophanes, **II**: Calix[*n*]arenes of phenol (or calixarenes in the narrow sense). The hydroxy groups are in the *endo* position. **III**: Calix[4]arenes derived from resorcinol or resorc[4]arenes. The hydroxy groups are in the *exo* position.

from those of type **II**. Compounds will also be referred to in which the methylene bridges or the phenol units are replaced by other related structural elements. However, orthocyclophanes such as the cyclotriveratrylenes or cryptophanes[4] and other macrocycles containing phenol building blocks will not be dealt with here.

2. Syntheses

2.1. One-Pot Procedures

The interest which calixarenes have aroused in the last ten years[5] is due in the main to their ready availability. Multigram amounts can be obtained on a laboratory scale in a relatively simple manner starting from cheap starting materials; in this calixarenes differ from many other synthetic macrocycles.

It is mainly thanks to the work of Gutsche that today the reaction conditions for the direct "one-pot synthesis" of calixarenes **1** with four, six, or eight *tert*-butylphenol units are known very exactly.[1, 6] Condensation of *tert*-butylphenol with formaldehyde under alkaline conditions (NaOH, KOH) leads in one step to the tetra-,[6a] hexa-,[6b] or octamer[6c] in yields (after recrystallization) of about 50, 85, and 63%, respectively.

1a–e (n = 4–8)

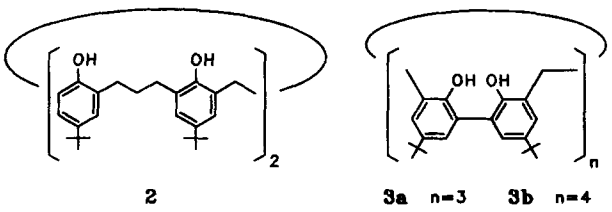
The reaction conditions determine which calixarene is formed.[7] The optimum amount of base for the formation of the tetramer and octamer appears to lie at about 0.03 mole NaOH per mole *tert*-butylphenol, the tetramer requiring higher temperatures (diphenyl ether, reflux) than the octamer (xylene, reflux). Considerably larger amounts of base (0.4 mole KOH per mole *tert*-butylphenol) favor the formation of the hexamer.

This ready availability of the calixarenes is quite amazing, since during this reaction either 8, 12, or 16 covalent bonds are newly formed in a defined manner. No other example is known in polymer chemistry in which four, six, or eight molecules of two different bifunctional starting materials form almost solely *one* cyclic tetra-, hexa-, and octamer, respectively. These cyclic compounds are in fact much more readily available than the corresponding linear oligomers.

Even though (at least in the case of *tert*-butylphenol) the synthetic conditions are known relatively exactly, many questions still remain with regard to the reaction mechanism. While various steps in the reaction between phenols and formaldehyde are well understood[1, 8] (and such steps must occur several times during the formation of the calixarenes), the reasons for the formation of particular calixarenes are virtually unknown. It is remarkable that macrocycles with an even number of phenol units are formed preferably[7] (cf. Table 1). There is a considerable amount of evidence that the calix[4]arene is the thermodynamically most stable product (it can for example be obtained from calix[6]- or calix[8]arene under basic conditions), while calix[8]arene is formed under kinetic control. In contrast, a template effect has been suggested as an explanation for the formation of calix[6]arene.[9a] Gutsche proposed an intramolecular reaction for the conversion of calix[8]arene into calix[4]arene.[1] However, experiments with a mixture of labeled and unlabeled calix[8]arene as the starting material show a rapid statistical distribution of the label in the tetramer.[9b] The conversion of calix[6]arene into calix[4]arene also argues against an intramolecular "constriction process".

More concisely, the ready availability of the calixarenes applies only when *p-tert*-butylphenol is used as the starting material. While the results for *p-tert*-pentylphenol are similar[10] (although the yields are somewhat lower), the formation of the hexamer starting from *p-tert*-octylphenol [*p*-(1,1,3,3-tetramethylbutyl)-phenol] has been mentioned,[11] but not yet described in detail. *p*-Adamantylphenol apparently yields only the octamer (71%). Calixarenes with an odd number of building blocks (5,[8] 7,[12] and even 9[11] and greater[9b]) have also been obtained from *p-tert*-butylphenol by direct condensation, but the yields are considerably lower. However, the formation of a tetramer has not yet been described starting from either *p*-phenylphenol or from *p-n*-alkylphenols (including *p*-cresol). Calix[7]arenes can

Volker Böhmer was born in 1941 in Rauscha near Görlitz and studied chemistry at the Universität Mainz. He received his doctorate in 1969 under the supervision of Prof. H. Kämmerer for work on phenolic multinuclear compounds as supports for synthetic matrix reactions. With the exception of a stay as a guest lecturer at the university in Le Mans (1976/77) he has remained loyal to the Universität Mainz. He has played a major role in the development of the Department for Teacher Trainees in Chemistry, where he is now Academic Director. His research interests are defined oligomers and particularly calixarenes. He is the author of approximately 130 publications, of which more than 50 have been concerned with calixarenes.



be obtained, however, from *p*-cresol and *p*-ethylphenol.[13] One reason for these confusing results certainly lies in the different solubilities of the various compounds which partly precipitate during the synthesis. Table 1 contains a survey of the "one-pot" syntheses presently known.

Table 1. Yield [%] of calix[*n*]arenes in one-pot syntheses starting from *p*-substituted (R) phenols. Values in parentheses refer to chromatographically isolated products. References are given in square brackets.

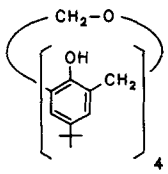
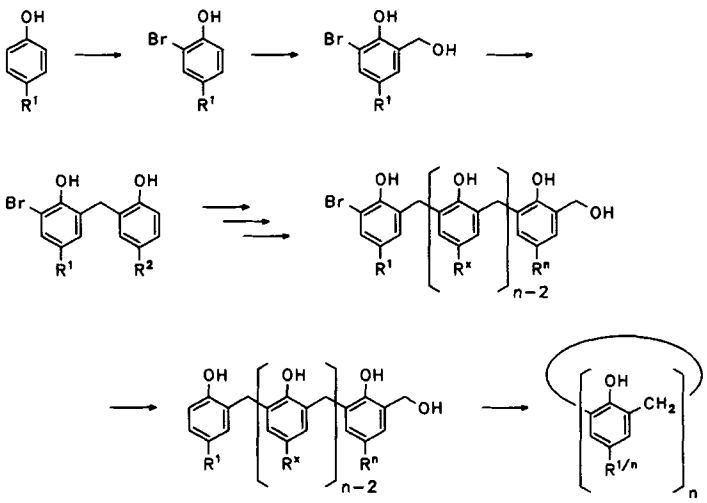
Results obtained in recent years suggest that the one-pot conditions (condensation with formaldehyde in the presence of alkali metal hydroxides in nonpolar solvents) are also applicable when diphenols are used as starting materials; this could open the way to a variety of interesting macrocycles. Thus, for example 1,3-bis(2-hydroxy-5-*tert*-butylphenyl)propane can undergo reaction with formaldehyde in the presence of NaOH to give the cyclic dimer **2** in 90% yield.[21] In contrast, the reactions of 2,2'-dihydroxy-5,5'-di-*tert*-butylbiphenyl lead to either the cyclic trimer (**3a**) or the tetramer (**3b**) in about 50% yield,



2 **3a** n=3 **3b** n=4

depending on the size of the alkali metal cation present,[22] while the relatively rigid macrocyclic diphenol **4** can be converted to the cyclic dimer **5**.[23]

4 **5**

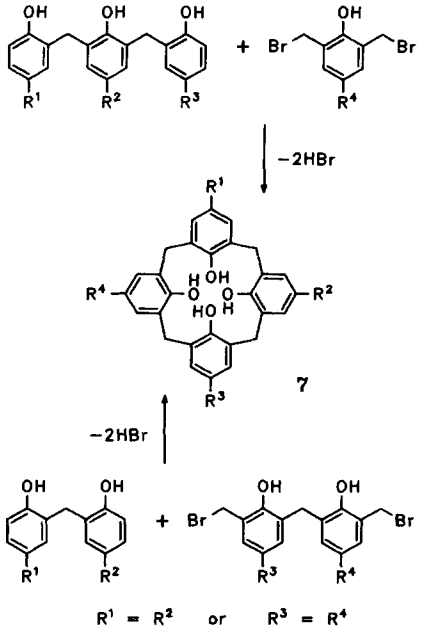


Condensation with formaldehyde under alkaline conditions can also lead to products with dimethylene ether bridges. The "dihomooxacalix[4]arene" **6** was identified at an early stage as one of the possible products of the one-pot reaction.[1] Macrocycles with several CH_2-O-CH_2 bridges can however be more readily prepared by the elimination of water from doubly hydroxymethylated phenols or from oligomers.[24a–c] Macrobi- and -tricyclic compounds with CH_2-O-CH_2 bridges have been obtained from the corresponding functionalized phenol ether derivatives by Williamson synthesis.[24d]

6

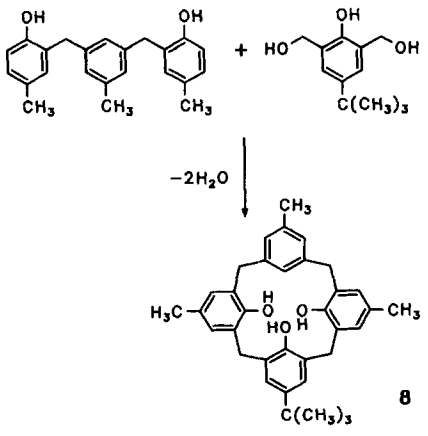
2.2. Stepwise Syntheses

The calixarenes obtained from a one-pot synthesis necessarily have the same substituent in all the *p*-positions. Calixarenes with different substituents can be obtained by the stepwise synthesis described by Hayes and Hunter[25] and further optimized by Kämmerer, Happel et al.[26] This stepwise synthesis starts from an *o*-bromo-*p*-alkylphenol and uses a series of alternating hydroxymethylation and condensation steps to build up a linear oligomer with a hydroxymethyl group at one end; this can then be cyclized under dilution conditions after the other *o*-position has been freed by dehalogenation (Scheme 2).



Scheme 2. Stepwise synthesis of calix[*n*]arenes (x = 2 to n–1).

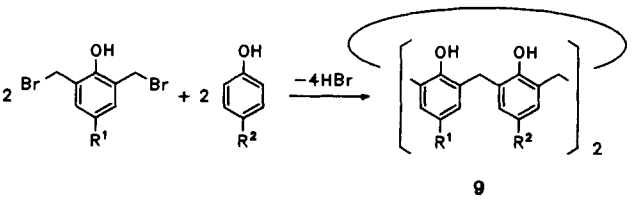
The yields obtained in the cyclization step are generally very good, but because of the large number of steps the synthesis is complicated and the overall yield low. In addition the number of possible substituents in the *p*-position compatible with the synthetic steps involved is limited.



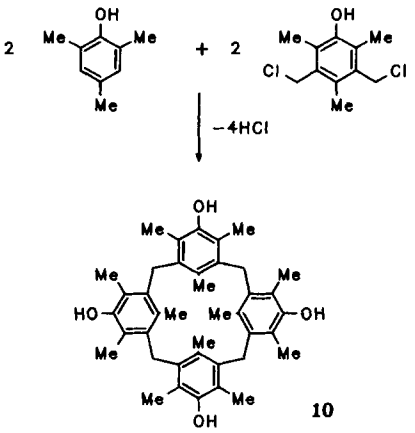
In special cases a shorter approach to linear, monohydroxymethylated tetramers has been described;[27] however, the stepwise synthesis[28] appears at present to be generally of only historical interest (see Section 2.6). But, even today it would probably be the primary choice for the synthesis of calixarenes which are built up from different alkylphenol units, and the calix[5]arenes prepared by this strategy are still the only known examples of this type.[26b,f]

2.3. Fragment Condensation

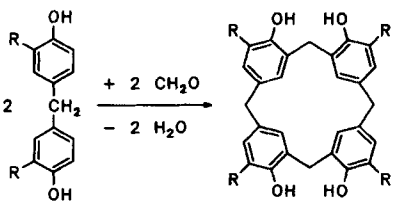
While the last step in the stepwise synthesis involves the cyclization of *one* linear starting molecule in *one intra*molecular reaction step, it is also possible to prepare (in particular) calix[4]arenes from two (or more) fragments, that is the cyclization step is preceded by (at least) one *inter*molecular condensation step. Condensations using the "3 + 1"[29] and "2 + 2"[30] principles have been used for the synthesis of a range of calix[4]arenes **7**; substituents such as COOR, NO_2, N=N-Ph, and halogen can be present in the *p*-position.[29c, 31]



Compounds with substituted bridges (Ar-CHR-Ar; Ar denotes aryl throughout the text)[31] and those with *m*-substituted phenol units have also been prepared in this way.[32] The best yields (up to 35%) have so far been obtained in dioxane in the presence of $TiCl_4$; however, the optimum conditions for the reaction and the workup differ in each case. For example, the trihydroxycalixarene **8** was obtained in dioxane by using sulfuric acid as the catalyst.[33a]

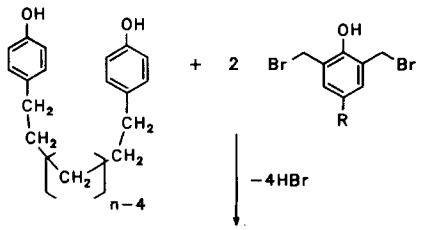


It also appears feasible to prepare calix[5]- and calix[6]arenes in this manner (i.e., according to the "3 + 2" or "3 + 3" principle); however, only one example of the synthesis of a calix[6]arene has so far been described.[29c, 34] Apparently the conditions for the synthesis ($TiCl_4$/dioxane) lead to the cleavage of Ar-CH_2-Ar bonds, since "3 + 3" experiments led among other products to calix[4]arenes, while a calix[5]arene was obtained as a by-product in the preparation of **8**.[33b]

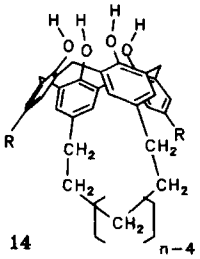


The tendency for the formation of calix[4]arenes observed in the presence of $TiCl_4$ can be applied in the "2 × 1 + 2 × 1" synthesis, which was used to obtain calix[4]arenes **9** with two alternating building units (including 4-chloro-3,5-dimethylphenol) in about 10% yield.[35]

The calix[4]arene **10** with extraannular hydroxy groups was formed in considerably better yield (60%) from the condensation of mesitol with chloromethylated mesitol in nitromethane using $SnCl_4$ as the catalyst.[36] Complications, which again appear to be due to the cleavage of Ar-CH_2-Ar bonds, are observed when other chloromethylated arenes are used.



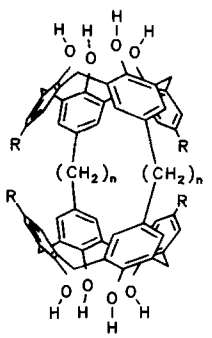
p-Linked dimers **11** can be treated with paraformaldehyde in xylene to give calix[4]arenes **12** with four *exo*-hydroxy groups[37] in yields upto 35% (**12a**).[37b] The possibility of forming a new intramolecular hydrogen bond between the OH groups appears to play an important role in the formation of the product, since **12** is for example not formed from the *o*-bridged dimer isomeric to **11**, in which such hydrogen bonds are already present.[38] In addition, the yield decreases to 5% in the case of **12b**.[38b] The stepwise synthesis can also be used to prepare calix[4]arenes of type **12** which contain different substituents in the *o*-positions.[38a]



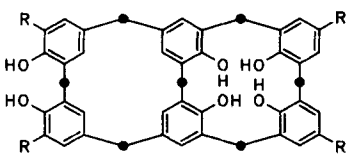
11 **a** R = $C(CH_3)_3$ **12**
b R = CH_3

2.4. Bridged, Double, and Annelated Calixarenes

When the phenol used in the "2 × 1 + 2 × 1" synthesis of **9** is replaced by a *p*-linked diphenol **13** (α,ω-bis(4-hydroxyphenyl)alkane), it is possible to prepare calix[4]arenes such as **14** in which two opposite *p*-positions are bridged by an aliphatic chain.[39]

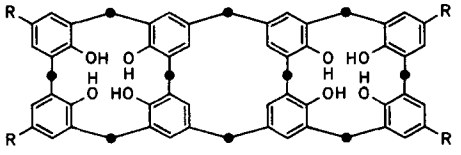


13



14

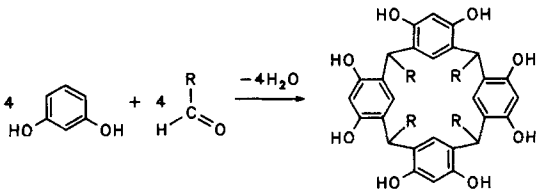
The synthesis of compounds **14**, with yields up to 34%,[40] has so far been realized for chain lengths $n = 5-16$ and the substituents R = Me, *t*Bu, alkyl, or cycloalkyl, phenyl, and chlorine. The byproducts can include double calix[4]arenes such as **15** in which two calix[4]arene units are linked by two aliphatic bridges.[41]



15

When a dimer is replaced in the "2 + 2" synthesis by a calix[4]arene of type **12** with two or four free *o*-positions, it is possible to obtain compounds in which either two (**16**) or three (**17**) calix[4]arene units are linked in a similar manner to the benzene rings in naphthalene or anthracene ("annelated calixarenes").[37b] A further extension of these annelated structures appears possible.

16

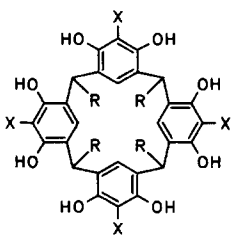


• = CH_2

17

2.5. Resorc[4]arenes

Because of its greater reactivity resorcinol affords no defined condensation products with formaldehyde. Cyclic tetramers can however be obtained by acid-catalyzed condensation with other less reactive aldehydes.[1] Larger cyclic oligomers have so far not been observed. The situation is complicated by the fact that for **18** because of the different relative configurations at the bridges (-CHR-) four diastereomers are possible which may be classified as *rccc*, *rcct*, *rctt*, and *rtct*.[42]



18

In 1980, Högberg[43] isolated the two isomers with the *rccc* and *rctt* configurations from the condensation between resorcinol and acetaldehyde or benzaldehyde; these are also formed with other aldehydes.[44] The *rcct* compound was later isolated in a few cases.[45] The fourth possible isomer (*rtct*) apparently occurs in very small amounts and has only been isolated by chromatography.[45c,d]

Conditions have however been found under which the all-*cis* isomer (*rccc*) can be obtained in good to excellent yields from a variety of aldehydes[45e] such as acetaldehyde,[43a] heptanal,[45a] dodecanal,[44a] dodecenal,[46] 3-oxopropanesulfonic acid (in the form of its cyclic acetal),[47] benzaldehyde[43b] (and substituted benzaldehydes including 4-formylbenzo[15]crown-5[48]), thiophene-,[44b] and ferrocenecarboxaldehyde.[49] The *rctt* isomer is often formed under kinetic control[43b] and is converted after longer reaction times into the thermodynamically more stable *rccc* isomer. The formation of Ar-CHR-Ar bonds must therefore be at least partially reversible. This isomerization, which is useful for preparative purposes, cannot always be realized, and the formation of the *rcct* and *rctt* isomers from pure *rccc* has also been observed.[45b]

It appears certain that the intramolecular hydrogen bonds between the OH groups of neighboring resorcinol units is the main cause of the preferred formation of the cyclic tetramer and, in combination with the preferred axial arrangement of the groups R (cf. Section 3.2.3), also for the preferred formation of the *rccc* isomer. Neither resorcinol monomethyl ether[45b] nor resorcinols which bear substituents such as NO_2 or COOH in 2-position afford the cyclic tetramer,[44a] since these (also generally deactivating) substituents are in competition with the OH–OH hydrogen bonds. On the other hand, compounds **19** were

19a X = OH
19b X = Alkyl
20 R = H, X = Alkyl

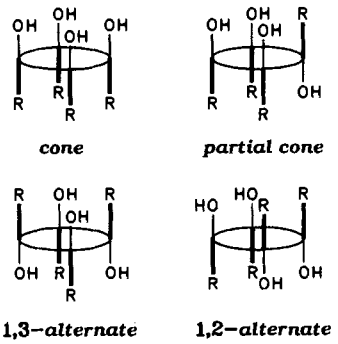
obtained with pyrogallol[50] and with 2-alkylresorcinols.[44a] Since 2-alkylresorcinols have only two reactive *ortho*- or *para*-positions (with respect to the hydroxy groups) they can also react with formaldehyde to give calix[4]arenes **20** with methylene bridges.[51]

It should be mentioned that cyclic tetramers have also been obtained (as their octamethyl ethers) from esters of 2,4-dimethoxycinnamic acid by treatment with BF_3,[52] a method which opens up a new and interesting route to resorcarenes.

2.6. Other Related Macrocycles

The descriptive quality of the name calixarene has been responsible for its recent use for other similar macrocycles. Some examples follow.

The closest relatives of the calixarenes derived from phenol are cyclic tetramers in which up to four methylene bridges are replaced by sulfur bridges.[53] With the exception of the tetrathio compound they were all obtained by stepwise syntheses from linear oligomers.[53b]



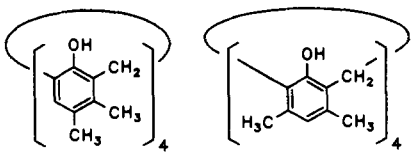
Macrocycles with $-CH_2-NR-CH_2-$ bridge(s) have been referred to as azacalixarenes (e.g. hexahomotriazacalix[3]arene) in analogy to the "dihomooxacalixarene" **6** and similar compounds.[24] "All-homocalixarenes", that is macrocycles in which all the methylene bridges are replaced by ethylene bridges,[55] have been obtained by Vögtle et al. from bisbromomethylated anisoles by Müller-Röscheisen cyclization,[55a, b] while Tashiro et al. have synthesized similar compounds via the corresponding CH_2-S-CH_2-bridged macrocycles by using "traditional" procedures known from cyclophane chemistry.[56] [3.3.3.3]Metacyclophanes with anisole building blocks were prepared in a similar manner.[57]

The phenol building blocks have also been exchanged for other structures.[55b, 58] Recent examples include calixarenes derived from furans,[59a,b] calix[3]indoles,[59c] and calix[4]naphthalenes.[59d, e] It is a moot point as to whether the names used are suitable in all cases, but further developments of this kind can be expected. Thus, for example, cyclic tetramers with Pt-bridged uracil units also show structural analogies to cali[4]arenes.[60]

3. The Conformations of the Parent Compounds

One of the most fascinating aspects of calixarenes lies in the variety of conformations which they can assume; these result from the (more or less) free rotation about the σ bonds of the Ar-CH_2-Ar groups.

In the case of calix[4]arenes, the relative orientations of the phenol units shown in Scheme 3 can in principle be assumed. Gutsche has introduced the terms "*cone*", "*partial cone*", "*1,2-alternate*", and "*1,3-alternate*", which are generally accepted today, to these basis conformations.[61a] They differ with respect to the position of the phenolic OH groups (and the *p*-positions) with respect to the molecular plane (here easily defined by the C atoms of the methylene bridges). A reference plane of this type is also clearly defined in the case of the calix[5]arenes, but not for larger oligomers: the conformations of the latter have been described in the literature in a correspondingly bewildering manner.[61b]



Scheme 3. The four basic conformations of a calix[4]arene; compare also Figs. 1 and 3.

3.1. Structures in the Crystal

3.1.1. *Calixarenes of Type II*

All crystal structures of calix[4]arenes with free OH groups so far reported,[62] including those of compounds containing different phenolic units,[63] have shown that the calixarene adopts the *cone* conformation, since the latter is stabilized by intramolecular hydrogen bonds between the hydroxy groups.[64] The arrangement of the molecules in the crystal lattice and the possible inclusion of guest molecules are not particularly important in this context (Fig. 1). This is the case even when a considerable deformation of the *cone* conformation is caused by the presence of one[65] or two[66] *m*-methyl groups per phenol unit and the resulting steric constraints.

However, while in the *p-tert*-butylcalix[4]arene **1a** (the toluene complex of which exhibits C_{4v} symmetry[67]) the four phenol units are twisted by an angle of 123° with respect to the reference plane, compounds **21** and **22** contain two phenol units which are nearly orthogonal to the reference plane while the two others are twisted out-

21 **22**

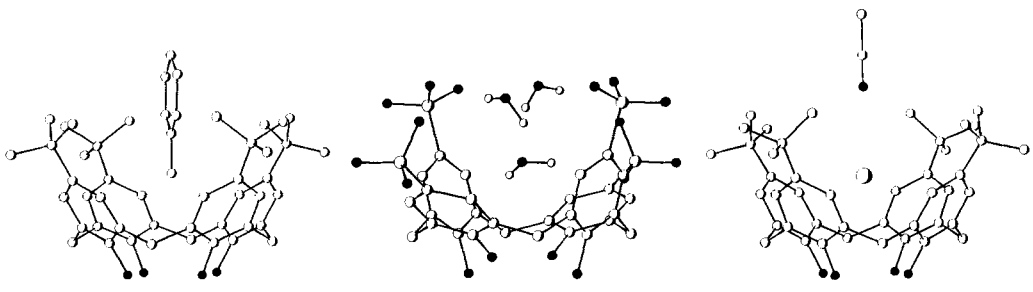


Fig. 1. Calix[4]arenes in the *cone* conformation (according to X-ray structure analyses). Oxygen and nitrogen atoms are black, hydrogen atoms in general not shown. Left: *tert*-butylcalix[4]arene **1a** with included toluene [67]; middle: *p*-sulfonic acid derivative with OH-π-bonded water as guest [68]; right: cesium salt of **1a** with the Cs^+ ion in the molecular cavity [69].

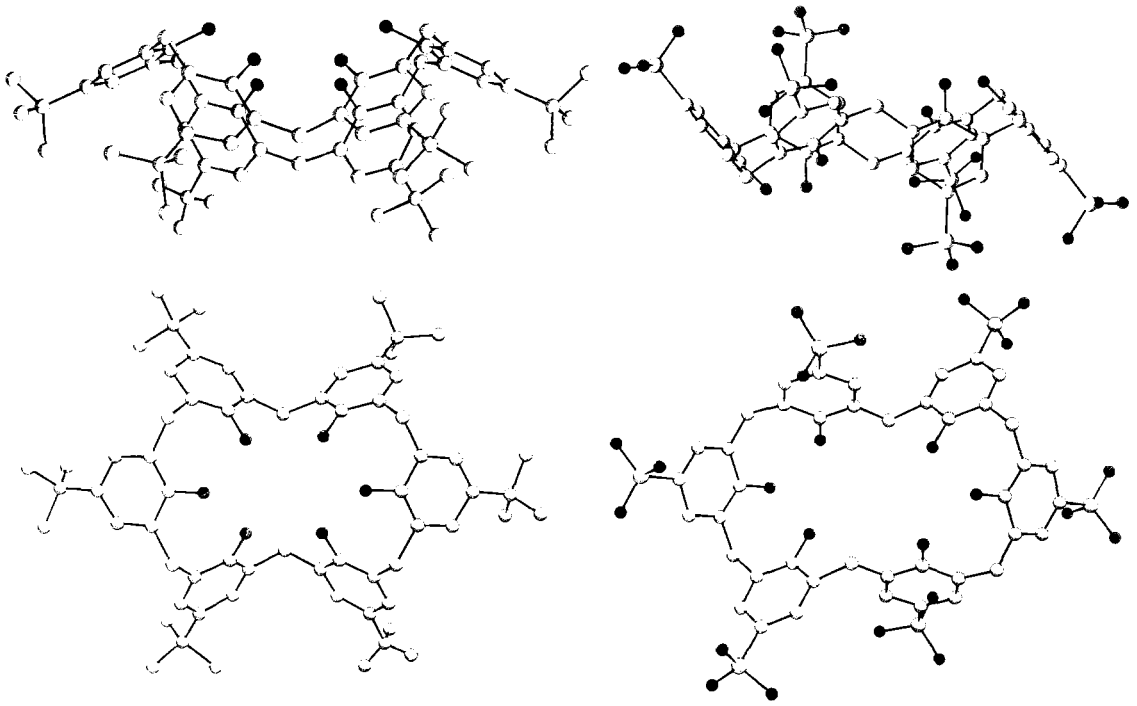

Fig. 2. Two typical conformations of calix[6]arenes in the crystal, seen from two different perspectives (oxygen atoms are black, hydrogen atoms not shown). Left: *tert*-butylcalix[6]arene [72b]; right: calix[6]arene-*p*-sulfonic acid (sodium salt) [72c].

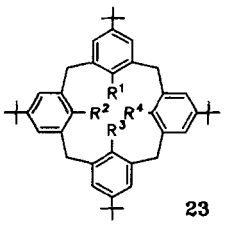
wards. In other words, two opposite phenol units are almost parallel, while the other two are almost orthogonal to one another. A similar deformation of the *cone* conformation in the bridged calix[4]arenes **14** is caused by the aliphatic chain linking the opposite *p*-positions; this deformation increases with decreasing chain length.[39b, c, 70]

All the known crystal structures of calix[5]arenes[71] also show a *cone*-like molecular conformation, which is in turn determined by intramolecular hydrogen bonds between the phenolic OH groups. The distances between neighboring O atoms are however on average somewhat larger than in the calix[4]arenes.

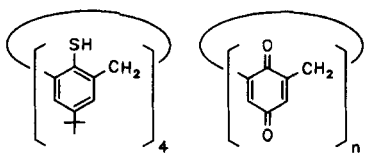


In calix[6]arenes[72] two completely different conformations have so far been observed in the crystalline state: a) all the OH groups are on one side of the molecule, the methylene bridges being arranged in a boat-shaped manner; b) groups of three neighboring OH functionalities are present on the opposing sides of the molecule (see Fig. 2). These two arrangements, each of which then contains the maximum number of intramolecular hydrogen bonds, can be visualized by joining together two three-quarter fragments of a calix[4]arene either in the same or in the opposite sense.

A simple visualization of this type is no longer possible for the calix[7]-[73] or calix[8]arenes.[74] An unequivocal description of their conformations makes use of the two torsional angles about the Ar-CH_2 bonds, which should always be reported.[75]

3.1.2. *Other Aspects*

The importance of the intramolecular hydrogen bonds for the conformation of calix[4]arenes with *endo*-OH groups becomes clear when **22** is compared with **10**, which exists in the 1,3-*alternate* conformation[36] (neighboring dipoles are arranged in an opposing manner). An additional methyl group in the *p*-position of each phenolic unit would certainly not play a decisive role in determining the conformation of **22** but would make the two compounds regioisomers which can formally be interconverted by the exchange of these *p*-methyl groups for the OH groups. In contrast, a *cone* conformation was found for **12a** with two intramolecular hydrogen bonds between the *exo*-OH groups, a stabilization, which would also be possible in the 1,2-*alternate* conformation.[38a]



The influence of the hydrogen bonds also becomes clear when the structures of calix[4]arenes with less than four *endo*-OH groups are considered. While the aminodiphenol **23h**[76c] still exists in the *cone* conformation, the diphenol **23b** and the OH-

23

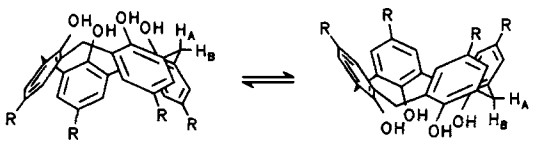
g	NH_2	OH	NH_2	OH
h	H	OH	NH_2	OH

free compound **23e** take up the 1,3-*alternate* conformation.[76] Removal of the *tert*-butyl groups from **23e** leads to the parent compound, which exists in the crystalline state in a "chair" form in which opposing benzene rings are coplanar.[77] The tetrathiocalix[4]arene **24**,[78] analogous to **1a**, exists in the 1,3-*alternate* conformation, while the tetraquinone **25a** takes up a *partial cone* conformation.[79]

24 **25a–c** (n=4–6)

3.1.3. *Resorcarenes*



The few known crystal structures of the parent compounds with free OH groups are those of all-*cis* isomers,[80] the configuration of which is thus confirmed.[44a] The molecules always exist in the *cone* conformation in which the groups at the bridging C atoms are arranged in an axial manner. Intramolecular hydrogen bonds between the OH groups of neighboring resorcinol units also provide a stabilizing factor, although not all the intramolecular hydrogen bonds possible are formed, for example when hydrogen bonds to included solvent molecules exist.[44a] In the known examples the macrocycle does not have an exact fourfold symmetry, even in the recently described tetraanions of some ammonium salts;[81a] however, C_4 symmetry has been found for a tetra(di-*n*-propylaminomethyl) derivative.[81b]

3.2. The Structure in Solution

3.2.1. *Calix[4]arenes of Type II*

Calix[4]arenes always exist in the *cone* conformation also in solution.[1] This is clear from the ^{1}H NMR spectrum, which for example in the case of the *tert*-butylcalix[4]arene **1a** shows singlets for the hydroxy, the aromatic, and the *tert*-butyl protons. The four methylene groups are also equivalent, but the two protons of each CH_2 group are nonequivalent in the *cone* conformation. Thus, at low temperatures a pair of doublets is observed with a coupling constant of 12–14 Hz typical of geminal protons.

These signals become broader when the temperature is increased and eventually collapse to form a sharp singlet at higher temperatures. This can best be explained in terms of a rapid exchange between the two opposed (but identical) *cone* conformations, in which the OH groups pass through the interior of the macrocycle, the originally equatorial proton becoming axial and vice versa. Thus the NMR spectrum shows only an "averaged" signal.

Scheme 4. Ring inversion of *p*-substituted calix[4]arenes.

The energy barrier for the ring inversion can be derived from the temperature-dependence of the ^{1}H NMR spectra.[1, 26a, f, 82] Typical values are collected in Tables 2–4; they show that the substituent in *p*-position has almost no influence on the energy barrier. The latter, however, decreases when a nonpolar aprotic solvent such as $CDCl_3$ or benzene is replaced by a polar solvent such as pyridine. This is not surprising, since the inversion requires that the hydroxy groups pass through the ring, so that the cyclic arrangement of the hydrogen bonds is temporarily interrupted or at least loosened. Solvents which can break hydrogen bonds will thus lead to a decrease in the energy barrier.

Little is known about the mechanism of this *cone*-to-*cone* rearrangement. Two limiting cases appear possible:[1] a) a stepwise conversion through the sequence *cone* → *partial-cone* → 1,3-*alt*ernate/1,2-*alt*ernate → *partial-cone* → *cone*; b) a concerted conversion involving only one single transition state. Computer simulations (molecular dynamics) suggest the *partial cone* and *alternate* conformations as possible intermediates.[84]

While the ^{1}H NMR spectrum of **21** provides no evidence for deviation from fourfold symmetry (C_{4v}) even down to the lowest temperatures studied (−130 °C),[85] **22** (which has eight methyl groups in *m*-positions) exhibits two signals at −80 °C for both the

aromatic protons and the methyl groups.[66] Thus, as in the crystal, the conformation with the lowest energy has C_{2v} symmetry.

The conformational conversion from C_{2v} to C_{2v} occurs by ring inversion (route a) and not by pseudorotation (route b); this follows from the equal values of the energy barriers for the coalescence of the signals for CH_3 and ArH on the one side and the CH_2 groups on the other.[66] This energy barrier is however nearly 5 kcal mol^{-1} lower than that for example for **1a**. If the same energy level is assumed in all cases for the (energetically highest) transition state, this indicates a higher energy level (because of the "loosened" hydrogen bonds) for the C_{2v} conformation, which may generally be involved in the conformational interconversion.

3.2.2. *Larger Calixarenes of Type II*

As in the case of calix[4]arenes, the ^{1}H NMR spectra of all other calixarenes exhibit a singlet for the methylene protons in solution when the temperature is sufficiently high (e.g. 50 °C). At lower temperatures (e.g. −40 °C) this singlet splits into *one* pair of doublets for calix[5]arenes, while in the case of calix[6]- and calix[7]arenes *three* and *seven* pairs are observed, respectively.[86] Remarkably, calix[8]arenes also give rise to only *one* pair of doublets at low temperatures.[87] Apparently the intramolecular hydrogen bonds stabilize a highly symmetrical conformation with a regular "up and down" arrangement of the phenol units in which all the methylene bridges are equivalent, while the environment of the protons is similar to that in calix[4]arenes. The higher cyclic oligomers again adopt very unsymmetrical conformations.[9b]

The number of signals indicates that the calix[6]arenes have a conformation with a plane of symmetry, a center of symmetry, or a twofold axis. In the case of a calix[6]arene with two different phenol building blocks in an alternating arrangement, which from its molecular structure contains a threefold axis, the result is that at low temperatures a completely unsymmetrical conformation is observed.[88]

The lower barrier to the ring inversion for the calix[5]-, calix[6]-, and calix[7]arenes (see Table 3), as determined from dynamic NMR spectra, corresponds to the greater flexibility to be expected for the larger rings. Surprisingly the temperature dependence of the signals for the methylene protons of the calix[8]arenes in $CDCl_3$ corresponds very closely to that found for the calix[4]arenes.[82a, 87] The greater flexibility of the "eight-membered" ring is only noticeable in a solvent such as pyridine which breaks down the hydrogen bonds; here only a singlet is observed for the methylene protons at the lowest temperatures studied (−90 °C).

3.2.3. *Other Calix[4]arenes*

The calix[4]arenes **10** and **24** exhibit only a singlet for the methylene protons across a large temperature range. It is thus logical to assume a fixed 1,3-*alternate* conformation for these molecules, as is found in the crystalline state,[36, 78a] although this result could also be explained on the basis of a completely flexible molecule. In contrast, 1_4-metacyclophanes such as **23e** which bear no OH groups[1, 77] and calix[4]arenes of type **12** with *exo*-hydroxy groups are indeed flexible. Energy barriers for calix[4]arenes with only two or three *endo*-OH groups and for calix[4]arenes which contain NH_2 groups rather than OH groups can be found in Table 4.

There have been few studies on the conformations of resorcarenes in solution.[89] Because of their lower solubility their octaesters have normally been studied;[43b] however, these ester groups introduce additional steric effects.[90] The *rccc* isomer shows only one set of signals for all the protons of the resorcinol unit.[91] It apparently adopts a *cone* conformation with effective C_{4v} symmetry and an axial arrangement of the substituents R, which is in turn stabilized by intramolecular hydrogen bonds. There are no indications of the presence of a *cone* conformation with an equatorial arrangement of the groups R on the bridges, and even at lower temperatures no evidence for the formation of a conformation with C_{2v} symmetry (in which the octaesters occur[90]) as found for example for **22**. In the case of the *rcct* and *rctt* isomers there is an equilibrium between the "diamond" or "chair" conformation found for the octaesters and the *cone* conformation[89] in which one or two groups on the bridges are equatorial.

The resorcarene **20** with methylene bridges, derived from 2-hexylresorcinol, has a C_{4v} *cone* conformation at low temperature and undergoes a *cone* → *cone* inversion with $\Delta G^{\neq}$ = 12.0 kcal mol^{-1}, a value which is clearly lower than that observed for calix[4]arenes with *endo*-OH groups.[51] Although intraannular groups such as the OH groups can slow the ring inversion for steric reasons, the difference appears to be caused primarily by the weaker hydrogen bonds of the extraannular hydroxy groups (see also the spectroscopic data in Table 5).

4. Some Properties

Calixarenes generally have very high melting points (often above 300 °C, in some cases even above 400 °C) and a low solubility in all standard solvents.[1, 2, 92] (Their ready preparation by one-pot syntheses may be due in part to the fact that insoluble products precipitate out under the reaction conditions). The melting points can however be modified[93] and the solubility in organic solvents improved[92a, b] by the use of suitable derivatives (see Section 5). It is even possible to achieve solubility in water (up to 0.3 mol L^{-1}).[92c]

The physical behavior of calixarenes is mainly determined by the intramolecular hydrogen bonds between the phenolic OH groups. The strength of the latter can be established from IR and ^{1}H NMR spectra (Table 5). In general all calixarenes with *endo*-OH groups exhibit a considerable shift of the OH frequency to lower wavenumbers compared to the free phenols; this shift is much lower for compounds with *exo*-OH groups such as **12**. Here, as in the resorcarenes (**18**, **20**) only pairs of hydrogen-bond

[a] KBr pellet. [b] Two different OH groups. [c] [D$_6$]Acetone.

ed OH groups are possible[91] but not a completely closed ring. In the ^{1}H NMR spectra there is a corresponding shift of the OH signals to lower field. Both effects are in general parallel (see Table 5), in particular for compounds with *endo*-hydroxy groups.

When the *cone* conformation of bridged calixarenes of type **14** is deformed by shorter chains (this deformation has been characterized quantitatively by a series of X-ray crystal structures[39b, c, 70]) there is a continuous weakening of the intramolecular hydrogen bonds.[70] This has also been confirmed by photo-CIDNP (CIDNP = chemically induced dynamic nuclear polarization) studies.[94]

The acidity of the phenolic OH groups, which is for example important for all selective substitution reactions, is also determined by the system of intramolecular hydrogen bonds. The pK_{a1} of calix[4]arenes is considerably reduced in comparison with the pK_a values of corresponding phenols, as semiempirical calculations suggest.[84] However, the pK_{a2} value lies considerably higher.[97]

An example is provided by the values for the dissociation of the first two phenolic OH groups in calix[4]arenetetrasulfonate, which have recently been determined by two groups to be 3.34 and 11.5[98] and 3.26 and 11.8.[99] The reduction in pK_{a1} is lower for corresponding calix[6]- and calix[8]arenes[100] and is comparable with that of the pK_{a1} value for linear oligomers.[101] The dependence reported earlier of the pK_{a1} value of calix[4]arenes containing a *p*-nitrophenol unit on the *p*-substituent of the opposing phenol unit[102] was not confirmed in later studies.

Very little is known about the acidity of resorcarenes.[103] In the case of the *rccc* isomer the first four protons can be readily removed to give a symmetrical tetraanion (which is stabilized by four intramolecular O$^-$ ··· HO bridges),[103] while even methoxide in methanol cannot remove any further protons. However, the different conformation of the *rctt* isomer permits the formation of the corresponding octaanion.

5. Fundamental Reactions of Calixarenes

Chemical modification of calixarenes does not only permit the synthesis of new host molecules by the introduction of additional functional groups, it also allows control of the conformation of calixarenes and hindrance of conformational inversion. In addition, larger molecules based on calixarene units are becoming increasingly available (see Section 6). In this respect calixarenes are greatly superior to other macrocyclic molecules such as crown ethers or cyclodextrins.[5b]

5.1. Calixarenes of Type II

Calixarenes derived from phenol can undergo modification in two main ways: 1) by the introduction of residues (functional groups) at the phenolic hydroxy groups; 2) by (electrophilic) substitution in the *p*-position with respect to the phenolic hydroxy group (subsequent to elimination of the *tert*-butyl group originally present).

5.1.1. Complete O-Alkylation and O-Acylation

The reaction of all the OH groups with monofunctional reagents to give ether or ester derivatives can generally be carried out without any problems.[1, 86] In the case of calix[4]arenes this has an additional interesting aspect: since larger substituents (acetyl, propyl, or larger[104]) cannot pass through the macrocycle, it is possible to fix all the conformations discussed above and to isolate them as stable conformers. In the meantime, not only have a large number of O-alkyl and O-acyl derivatives been obtained in defined conformations, but in some cases all four conformers have been obtained in a pure form.[105]

As Table 6 demonstrates for one example, these conformations can be readily distinguished from their ^{1}H NMR spectra

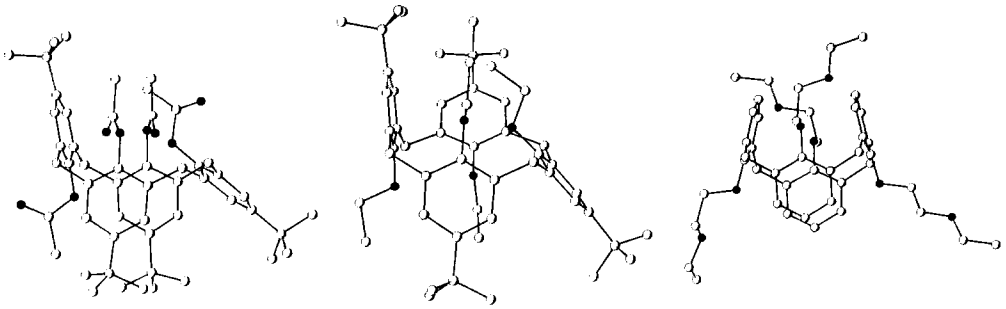
Table 6. Number and type of signals in the ^{1}H NMR spectra of tetraethers of *tert*-butylcalix[4]arene **26** ($n = 4$, Y = CH_2-R′ and O-CH_2-R′, R = $C(CH_3)_3$).

Conformation	ArH	O-CH_2-R′	Ar-CH_2-Ar	$C(CH_3)_3$
cone	1s	1s	2d	1s
partial cone	2s (2×2H) 2d (2×2H)	2s (2×2H) 2d (2×2H)	4d (4x2H)	3s (1:2:1)
1,2-*alternate*	2d (2×4H)	2d (2×4H)	1s (4H) 2d (2×2H)	1s
1,3-*alternate*	1s	1s	1s	1s

(and also determined in mixtures).[106] Furthermore, the conformations of such derivatives have often been confirmed by X-ray structural analysis. Figure 3 shows some examples.

It has often been possible to obtain tetraalkylated derivatives solely in the *cone* conformation. Apart from simple ethers with ethyleneglycol (**26a**)[108] or pyridylmethyl groups (**26b**),[109] the following are worthy of mention because of their importance as ionophores (see Section 8): ester (**27a**),[110] amide (**27b**),[111] and ketone derivatives (**27c**).[110a, 112] The latter can be readily obtained by reactions with reagents such as Br-CH_2-CO-OR, Cl-CH_2-CO-NR_2, and Cl-CH_2-CO-R, respectively. Sterically more demanding residues can also be introduced with retention of the *cone* conformation, as is shown by the synthesis of the phosphinate esters **26c**[113] and in particular the dendrimers **26e**.[114]

The formation of the *cone* conformation often appears to be favored by a template effect of the metal ions present (such as Na^+) (cf. the selectivity of ligands of this type). Thus the reac-



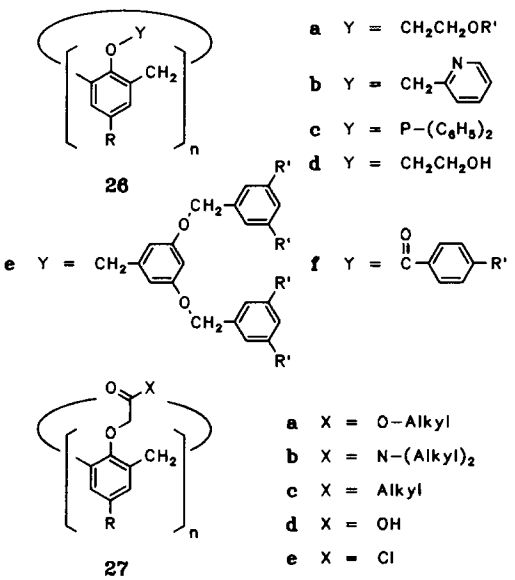


Fig. 3. Derivatives of calix[4]arenes with fixed conformations (oxygen atoms are black, hydrogen atoms not shown). Left: tetraacetate in the *partial cone* conformation [107a]; middle: tetraethyl ether in the 1,2-*alternate* conformation [107b]; right: tetraethoxyethyl ether in the 1,3-*alternate* conformation [107c].

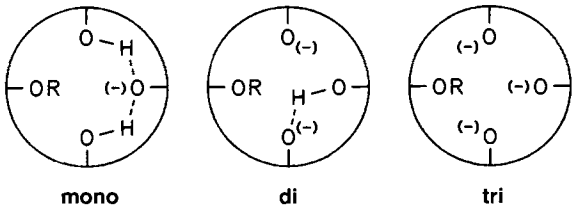
tion of ethyl bromoacetate with **1a** in acetone in the presence of Na_2CO_3 affords 100% of the *cone* isomer, while in the presence of Cs_2CO_3 the *partial cone* isomer is formed quantitatively. This effect is not so apparent in the case of the calix[4]arene which is unsubstituted in *p*-position. The same is true for **1a** when acetone is replaced by dimethylformamide (DMF) as solvent; *alternate* conformations have not been observed in this case.[105b] In contrast, ethers of type **26a** were obtained by alkylation with

the corresponding tosylates in DMF with Cs_2CO_3 as the base in the 1,3-*alternate* conformation (selectivity up to 100%, isolated yield up to 75%),[107c] while in the presence of NaH the *cone* conformation was formed.[115] Studies on the formation of the *p*-substituted tetrabenzoates **26f** showed a clear dependence of the resulting conformation on both the *p*-substituent in the benzoyl group to be introduced and the *p*-substituent present in the calixarene.[116] Even these few examples show that a general concept for the synthesis of a particular O-acyl or O-alkyl derivative in a certain conformation is not in sight at present because of the many factors involved and may perhaps never be achieved.

The complete reaction of all hydroxy groups to give derivatives of types **26** and **27** has also been described for calix[5]-,[117] calix[6]-,[1, 108, 110b, 118, 119] and calix[8]arenes.[1, 11, 110b, 119b, 120a] Different conformations should be obtainable, at least in the case of the calix[5]arenes, since it is probable that O-alkyl groups larger than the propyl group cannot pass through the macrocycle.[117b] However, defined derivatives of calix[5]arene have so far only been obtained in the *cone* conformation. For larger macrocycles (calix[6]arene and above) the complete fixation of a certain conformation by means of large substituents on the phenolic oxygen atoms appears less probable, since there will be an increasing tendency for the *p*-substituents to swing through the ring.[1, 121]

Substituents at the oxygen atoms can in turn be modified by further reactions. As examples we can mention hydrolysis,[117a, 122] transesterification,[122b] aminolysis,[123] and reduction[124] of esters of type **27a**. Many such esters[123] and amides **27b**[111e] have been obtained in this manner from the acid **27d** and the acid chloride **27e**, and also the alcohol **26d** has served as a precursor for further derivatives.[124a] Homologous alcohols with 3-hydroxypropoxy groups were obtained recently by hydroboration of allyl ethers.[124b]

5.1.2. *Selective Reactions at the Hydroxy Groups*



The regioselective reaction of single hydroxy groups in calixarenes is important for many purposes, in particular for the construction of larger molecules starting from several calixarene building units (see Section 6).[125] The possible regioisomers have been denoted in the case of calix[4]arenes by expressions such as *distal* or *proximal*; however, the numbering of the phenol units as used below (in analogy to the *alternate* conformations) is more readily applicable to higher oligomers.[126]

One of the first examples of selective functionalization to be described was that of the tribenzoate of the unsubstituted calix[4]arene.[127] (Other triesters were later obtained in acetonitrile by using 1-methylimidazole as the base[128]). The remaining OH group can undergo etherification; thus, monoethers are accessible after hydrolysis of the ester groups.[127, 129]

Direct monoalkylation has been carried out using an excess of the alkylating agent and K_2CO_3 (0.6 equiv in CH_3CN) or CsF (1.2 equiv in DMF) as a very weak base,[130] but also with NaH in toluene[105a, 131] or with $Ba(OH)_2$ in DMF.[105a] The controlled cleavage of 1,3-diethers[126] or tetraethers with either one or three equivalents of trimethylsilyl iodide offers another possible alternative.[132] Monoesters were also obtained in a similar manner from 1,3-diesters by reaction with imidazole.[128] The direct formation of triethers (in the *syn,syn* arrangment, see Section 5.1.3) was achieved by using $BaO/Ba(OH)_2$ in DMF.[105b, 117a, 133]

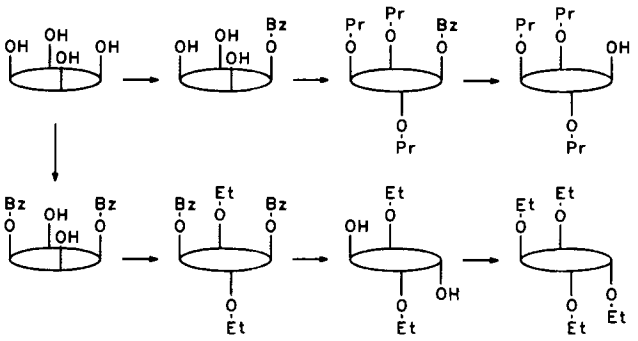
By far the best results in the selective O-alkylation (as in O-acylation[128, 134]) of calix[4]arenes were obtained by reaction of two equivalents of a relatively weak base (e.g. 1 mole K_2CO_3 per mole of calix[4]arene).[135] A variety of 1,3-diethers (includ-

ing the 2-pyridylmethyl ether,[109] see below) were thus obtained in yields (of the pure compound) which were often higher than those of the corresponding tetraethers. These results can also be readily understood on a theoretical basis,[125] since the most stable anion (stabilized by two intramolecular hydrogen bonds) of the monoether formed in the first step is obtained by deprotonation of the opposing hydroxy group (Scheme 6).

Scheme 6. Anions of a calix[4]arene monoether.

The formation of two isomeric (*syn,anti*) 1,3-dibenzoates, both in good yields, in the acylation with excess benzoyl chloride and NaH under very similar reaction conditions (THF, 0 °C, and toluene, reflux, respectively) is remarkable. [134b]

Dialkylation with a stoichiometric amount (in practice often 2.2 equivalents) of the alkylating agent in the presence of an excess of a strong base (e.g. NaH in DMF/THF) would on the other hand have to occur via the 2,4-dianion or via the trianion, from which the formation of the 1,2-diether should also be favored for statistical reasons. This has indeed been shown in a number of cases,[136] although the yields of 1,2-diethers (which are also sterically less favored than the 1,3-diethers) are in general lower.[136c]



An alternative route to 1,2-diethers is the selective cleavage of neighboring ether groups by $TiBr_4$, as shown for example in the case of the tetramethyl ether of **1a**.[137] The synthesis of the 1,2-bis(3,5-dinitrobenzoate) of *tert*-butylcalix[4]arene has been carried out starting from the corresponding 1,3-diester in the presence of imidazole.[128]

While the regioselective derivatization of calix[5]arenes by O-alkylation or O-acylation with monofunctional reagents has not yet been described, an increasing number of partial esters or ethers of (mostly *tert*-butyl-substituted) calix[6]arenes has been obtained recently. Some preparatively useful examples include 1,4-diethers[138a, b] as well as 1,2,4,5-tetraethers[138a, b] and -esters.[138a, 139] Mono-[138a] and 1,2-diethers[138c] as well as 1,2-di- and pentaesters[139] have also been prepared. It has recently been possible to obtain all the methyl ethers of *tert*-butylcalix[6]arene **1c** (in some cases in very good yields)[140] as well as ten of the twelve possible pyridylmethyl ethers.[138b]

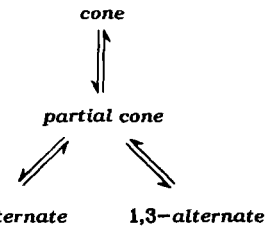
It is difficult (or at present not possible) to provide a rational explanation for the regioselective formation of certain O-alkyl or O-acyl products. Thus, for example the (unsubstituted) calix[6]arene affords the 1,2,3-trimethyl ether[141] under conditions which when applied to the *tert*-butylcalix[6]arene **1c** lead to the 1,3,5-trimethyl ether.[142] One of the products isolated from the phosphorylation of **1c** with $POCl(OEt)_2$ and $PSCl(OEt)_2$ was a 1,2,4-triester.[143]

Other more sophisticated selective functionalizations of the phenolic OH groups can however be expected in the near future, as exemplified by the 1,3,5,7-tetrabenzyl ether of calix[8]arene **1e** described recently.[144]

It is of course possible to obtain in a sequence of synthetic steps derivatives containing different O-acyl or O-alkyl residues;[118a, 135a, 136b, 142b, 145] in the case of calix[4]-arenes[105a, 107b, 145c] (and recently calix[6]arenes[138c]) different conformational isomers have also been described. The use of protecting groups for the preparation of particular conformers is demonstrated by the two examples[105a, 107b] shown in Scheme 7.

Scheme 7. Specific synthesis of calix[4]arene derivatives in a certain conformation using benzyl residues as protecting groups.

Subsequent reactions at the O-alkyl groups can also occur in a selective manner, as shown by the monohydrolysis of tetraethyl esters of type **27a** in nonpolar solvents.[146] Using the more reactive tetra-*tert*-butyl ester two opposing ester groups can be hydrolzed.[122c]



5.1.3. *Conformations of O-Alkyl Derivatives*

The residues present in partially O-alkylated (or O-acylated) products can also lie either on the same side (*syn*) or on opposite sides (*anti*) of the molecule. In contrast to the situation of the conformationally completely fixed tetra derivatives, it is *not appropriate* to use the terms *cone*, *partial cone*, etc. to describe such diastereomers (conformers) derived from calix[4]arenes, since free OH groups can still pass through the macrocycle, as is shown unequivocally by subsequent reactions in which derivatives with *different* conformations are obtained.[133c, 147] Thus, for example, a 1,3-diether in the *syn*-configuration can (at least in principle) assume a *cone*, *partial cone*, or 1,3-*alternate* conformation. Thus these terms should be used in such cases only for the characterization of *conformations*, while the relative orientation of the residues is described well by the terms *syn* and *anti*.[62]

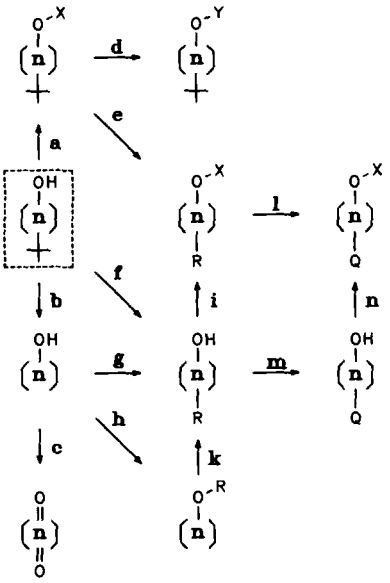
In practice *syn*-1,3-diethers exist in the *cone* conformation, which is characterised by the presence of *one* pair of doublets (AX system) for the methylene protons ($\Delta\delta \approx 0.5-0.6$). *Anti*-1,3-diethers, also show only *one* pair of doublets (AB system) for the methylene protons; however, the difference in the chemical shift is smaller ($\Delta\delta \approx 0.2$). To explain this, a conformation has been proposed in which the opposite phenol units are coplanar;[107b, 131b] this may, however, be equivalent to a rapid interconversion of the two equivalent 1,2-*alternate* conformations.[148] In the case of 1,2-diethers the *syn* isomers adopt the *cone* and the *anti* isomers the *partial cone* conformation, respec-

tively. This can readily be explained by the formation of a maximum number of OH–OH hydrogen bonds.[149]

Interesting, and in the main still unsolved, questions are posed by the methyl ethers of calix[4]arenes. The tetramethyl ethers are surprisingly nearly as flexible as compounds with four free OH groups. However, a mixture of several conformations generally exists in solution because of the lack of intramolecular hydrogen bonds (Scheme 8);[107b, 150] the composition of such a mixture is determined among other factors by the solvent[150] and by the substituents in the *p*-positions.[151] Temperature-dependent measurements do not only provide the energy differences between the various conformations;[151b] two-dimensional exhange NMR spectroscopy can be used in special cases to determine the rate constants for their interconversion.[152]

Scheme 8. Conformational interconversion for tetramethyl ethers of calix[4]arenes.

Although in the case of calix[4]arenes methoxy groups can also pass through the ring, mono- and dimethyl ethers are fixed in the *cone* conformation (with respect to the NMR timescale) up to high temperatures (125 °C).[150] No information is yet available on the energy barrier for the *cone* → *cone* interconversion, although it is apparent that this stabilization is caused by a combination of steric effects *and* intramolecular hydrogen bonds.



5.1.4. Substitution in p-Position

It is fortuitous that the calixarenes derived from *tert*-butylphenol are obtained particularly readily, since the *tert*-butyl group can easily be removed by $AlCl_3$-catalyzed transalkylation in the presence of a suitable acceptor such as toluene or phenol.[153] This reaction[154] plays a key role in calixarene chemistry, since a large variety of calixarenes with different substituents in the *p*-positions can be obtained by subsequent electrophilic substitution.

Virtually all the common substitutions which are possible for phenols (or phenol ethers) have been carried out on calixarenes or their alkyl ether derivatives: halogenation,[19, 155, 156] nitration,[157] sulfonation,[158] sulfochlorination,[159] chloromethylation,[160] aminomethylation,[161] acylation,[162] and coupling with diazonium salts.[163] Sulfonation[164] and nitration[165] products have also been obtained directly by *ipso*-substitution of the *tert*-butyl groups, and nitro compounds in addition via the sulfonic acids[158a] or the nitroso compounds.[157] Claisen rearrangements of allyl ethers[127, 153] and Fries rearrangements[166] have also been carried out.

The substituents thus introduced can undergo further reactions.[1, 86] Isomerization and/or ozonolysis of allyl groups,[153] haloform reactions of acetyl groups,[155a] aryl–aryl coupling by the Suzuki reaction,[167] reduction of nitro-,[115, 168] azo-,[79] or acyl groups,[162] or further substitution at chlorosulfone[159] and chloromethyl groups[151c, 160, 169] are just some important examples, in a by no means complete list, in which the "quinonemethide route" deserves special mention: aminomethylation with dimethylamine, quaternization ("complete methylation"), elimination of trimethylamine and addition of a nucleophile to the intermediately formed quinonemethide allows the introduction of very different residues.[170]

The number of possible derivatives can be imagined when one considers the combination of these reactions with suitable derivatizations at the phenolic OH groups (see Scheme 9).

Scheme 9. Summary of important chemical modifications which have been realized for calix[*n*]arenes of Type **II**: a, h, i, n: Formation of various ethers or esters, b: Transbutylation; c: Oxidation to quinones; d: Hydrolysis of ester groups, reduction of ester, amide, or nitrile groups; e: *ipso*-Nitration; f: Sulfonation; g: Electrophilic substitutions (halogenation, sulfonation, sulfochlorination, formylation, acylation, coupling with diazonium salts, chloromethylation, aminomethylation); k: Claisen rearrangement, Fries rearrangement; l: Reduction of nitro groups, aryl–aryl coupling, haloform oxidation, transformation of allyl groups; m: Nucleophilic substitution of quaternary ammonium groups.

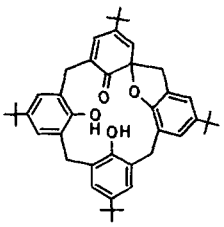
Again it is very desirable not to substitute *all* the *p*-positions but only certain positions, if possible selectively.[125] Although partial substitutions such as nitration,[115, 165a] formylation,[171] iodination,[156c] aminomethylation[170] of calix[4]arenes (or their tetraethers) have been described, each carefully directed selective functionalization begins with the OH groups. The selectivity that can be achieved here can then be transferred to the *p*-positions, since (as a rule) phenol units are more reactive than phenol ether or ester units.

The most important strategies described are the following, which can be combined to effect the synthesis of "more ambitious" structures:

- the selective de- or better transbutylation of partially O-alkylated or O-acylated calixarenes under carefully controlled reaction conditions, which has been successful in the case of calix[4]-[128, 135c] and calix[6]arene derivatives;[138a]
- the selective substitution of partially O-alkylated or O-acylated calixarenes. In the case of the calix[4]arenes examples of bromination,[135c] formylation,[135c] acylation,[172] nitration[135c, 168] and aminomethylation[135c] are known;
- the selective Claisen rearrangement, which has been described for mono-[127] and 1,3-diallyl ethers[135c] of calix[4]arenes.

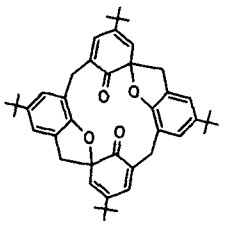
It can easily be predicted that these strategies will find further application in the future.

5.1.5. *Further Reactions*



An important modification of the calixarene skeleton is the oxidation of phenol units to *p*-quinones. The first examples of calixquinones were obtained from multistep syntheses;[79] however, the direct oxidation of phenol units or even of *tert*-butylphenol units is also possible, $Tl(OOCCF_3)_3$ being the most important reagent for this purpose.[173] It is also possible to oxidize phenol units in the presence of phenol ether[174] or phenol ester units.[173] Mono-, di-, and triquinone derivatives of calix[4]arene and diquinones of calix[6]arene[173] have been prepared in this manner and in some cases characterized by X-ray crystal structure analysis.[174a]

Apart from reduction to give hydroquinone units,[173] various addition reactions to the quinone system have been described;[175] these can in principle be used for the introduction of substituents at the *m*-position with respect to the *endo*-hydroxy groups.[175b]

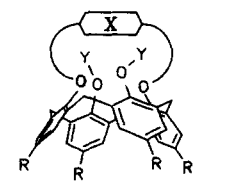


The complete oxidation of the methylene bridges to carboxyl groups and their subsequent reduction to hydroxy groups has also been reported;[176] the stereochemistry of the latter step is unclear.

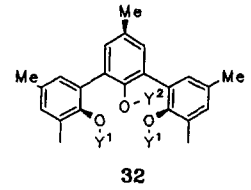
Many studies have dealt with the elimination of the phenolic OH groups[76, 120, 177] (with the goal of carrying out further substitution reactions at the free *endo* positions) or their exchange for NH_2[178] or SH groups[78, 177a]. While the complete reductive cleavage of all the phosphate groups using potassium in liquid ammonia was carried out successfully for calix[4]-, calix[6]-, and calix[8]arenes,[120] the reaction with liquid ammonia led to the introduction of only two amino groups.[178] However, in the case of the *tert*-butylcalix[4]arene **1a** the complete "replacement" of all OH groups by SH was possible.[78a] The decisive step in the synthesis of **24** was the Newman–Kwart rearrangement of the thiocarbamates.

Biali et al. have introduced an interesting strategy for the modification of the calixarene skeleton. Mild oxidation of **1a** with phenyltrimethylammonium tribromide leads to spirodienones such as **28** or **29**;[179a, b] trispirodienones[179c] are formed from **1c**. Starting from **28** it was possible to phosphorylate and subsequently eliminate the two (neighboring) OH groups[180] as well as to introduce *one endo*-amino group.[181]

28

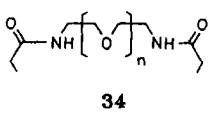


29



5.2. Resorcarenes

Exhaustive O-acylation and O-alkylation with monofunctional reagents is also no problem here. The corresponding octaesters have often been used for structural determinations or for isomer separation because of their better solubility.[43, 45, 89] Remarkable examples are provided by the introduction of eight ferrocene residues[48b] and the selective reaction of only one hydroxy group per resorcinol unit[182] (see Section 7.3).



Electrophilic substitutions in the 2-position of the resorcinol units are also possible. These include bromination,[183] coupling with diazonium salts,[184] and aminomethylation.[81b, 185] However, the most "spectacular" compounds, which were prepared from the cyclic tetramer of resorcinol, will be described in the next section.

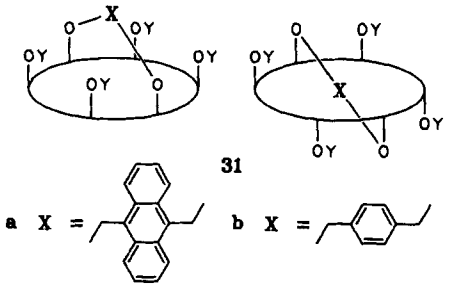
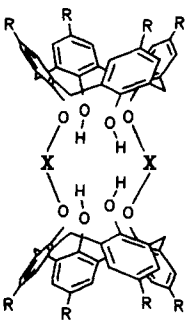
6. Macrobicyclic and Multimacrocyclic Compounds

The reactions between calixarenes and bifunctional reagents can lead, through bridging, to macrobicyclic molecules. In addition, more complex ("multimacrocyclic") structures such as double or triple calixarenes, cavitands, carcerands etc. have been prepared from calixarenes or resorcarenes.



6.1. Derivatives of Calixarenes of Type II

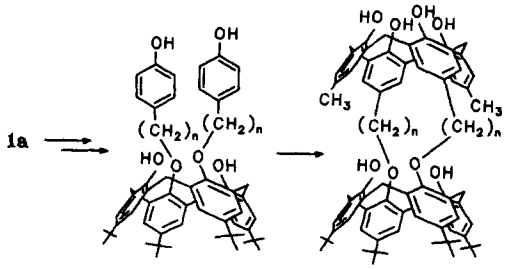
The first crown ethers **30** derived from tert-butylcalix[4]arene were prepared as early as 1983[186] and at the same time they provided the first examples of selective alkylation in the 1,3-position. While these crown ethers assume a *cone* conformation,[187] the subsequent alkylation of the remaining OH groups leads to derivatives which can be fixed in the *cone*, *partial cone*, or 1,3-*alternate* conformation.[188a] Di-O-alkylation in the 1,3-position with a monofunctional reagent, followed by cyclization with the corresponding ditosylate (Cs_2CO_3/CH_3CN) is an alternative route, which, because of the template effect of the Cs^+ ions, leads to compounds in the 1,3-*alternate* conformation.[189a] Analogous reactions were used to prepare bis-crown ether derivatives in the 1,3-*alternate* conformation[188] as well as larger molecules consisting of two calix[4]arene units linked by polyether chains.[190]



The accessibility of 1,2-dimethyl ethers also made possible the synthesis of mono- and bis-crown ethers of calix[4]arenes in which two neighboring phenol units are bridged.[137] While we were recently able to obtain 1,3-crown ethers in good

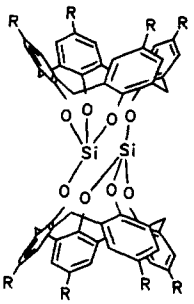
yield starting from *tert*-butylcalix[5]arene (including an example of a 1,2-crown),[191] crown ethers derived from larger calixarenes have not so far been described, although the first examples of 1,3- and 1,4-crowns of calix[6]arenes are known.[189b,c]

However, macrobicyclic derivatives of calix[6]arenes have been reported. The reactions of dicarboxylic acid dichlorides with 1,4-diethers of **1c** led to 2,5-bislactones.[138a,192] The bridging of opposite phenol units by reaction of **1c** with bishalomethylated arenes took place in the presence of $KOSiMe_3$ as the base. Exhaustive methylation of the remaining OH groups led to tetramethyl ethers which interestingly adopt different conformations.[192] While **31a** with its voluminous anthracene bridge apparently retains its conformation, the phenyl-bridged compound **31b** assumes a conformation in which this bridge is threaded through the macroring, thus motivating the authors to speak of a "self-anchored rotaxane".[192]



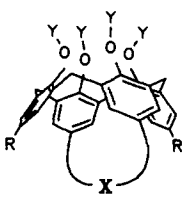
A structure which can be modified in a variety of ways and which has unique complex-forming properties (see Section 8.3.1) is generated by combining the rigid *m*-terphenyl skeleton with calix[4]arenes. In these calixspherands **32**,[193] which can be obtained from the free calix[4]arenes[193c] or from their 1,3-dimethyl ethers[193a,b] by reaction with bisbromomethylated *m*-terphenyls, the bridge again connects two opposite phenol units. In contrast, the intramolecular bridging reaction with phthalic acid dichloride involves neighboring phenol units,[194] so that the phthaloyl residue can in principle be used as a protecting group for neighboring OH groups.[195] Other bifunctional reagents, in particular those which do not tend to 1,3-bridging for steric reasons, have been used successfully for the synthesis of double (**33**) or even triple calixarenes.[196]

33



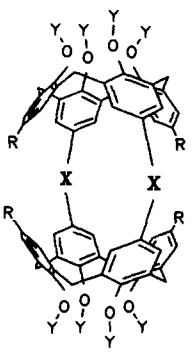
Starting from the readily available 1,3-diacid **27d** (in the form of its dichloride or dimethyl ester) and diamines or azacrowns, it was possible to obtain azacalix crown ethers **34**[123,197] or calixcryptands **35a**.[197] The calixcryptand **35b** was prepared in an analogous manner starting from the corresponding 1,3-diether.[198a] The Schiff bases **36**[199] and the ferrocene carbonamides **37**[198b] are also worthy of mention.

1,3-Diesters of 3,5-dinitrobenzoic acid lead after reduction of the nitro groups and subsequent double intramolecular bridging by amide bonds to "double-cavity calixarenes".[134] However, in this case the name promises more than the molecules in fact offer, because the tetralactam ring is collapsed and the host molecule is thus unable to take up a guest. The double calix[4]arenes **38** have been prepared starting from **1a**, the last step occurring in analogy to the synthesis of **14**. In contrast to **15** and **33**, the two calix[4]arene units (which exist in the *cone* conformation) in **38** are bridged in a head-to-tail manner.[200]



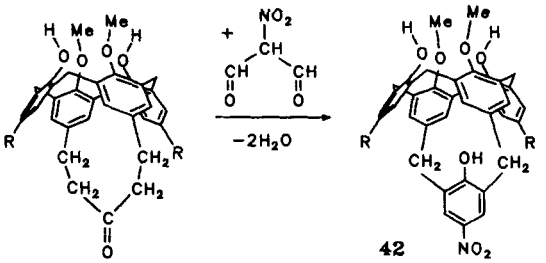
38

Derivatives in which the oxygen atoms of three neighboring phenol units are linked covalently by a single atom have also been prepared. The corresponding "multicyclic" phosphates can be obtained by heating "open-chain" diethyl phosphates with elimination of ethanol[201] or directly by reactions with phosphorus pentachloride.[202] Treatment of **1a** with silicon tetrachloride leads to the double calix[4]arene **39** bridged by two silicon atoms; in **39** the two cavities are oriented in opposite directions.[203] Similar structures containing aluminum[204a] or titanium[204b] are also known, and even the bridging of all four oxygen atoms of **1a** by a single atom (P, Mo, W)[205] has been described (see Section 9.2).

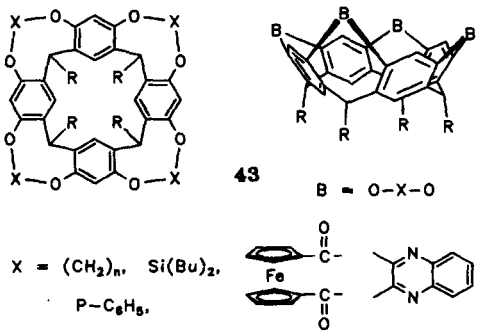


39

Starting from calix[4]arenes functionalized at opposing *p*-positions (at the "upper rim"), bridged calixarenes (**40**)[152,171,206] and double calixarenes (**41**)[156b,171,207] have been obtained in which the two cavities are oriented in opposing directions. Attempts to demethylate these "upper rim" calix crown ethers[152] (**40**, $X = CH_2\text{-}(O\text{-}CH_2\text{-}CH_2)_n\text{-}O\text{-}CH_2$, $Y = CH_3$), which resemble the bridged calix[4]arenes **14**, were not successful. However, the potential for the synthesis of molecules of the general type **40** and **41** is by no means exhausted.

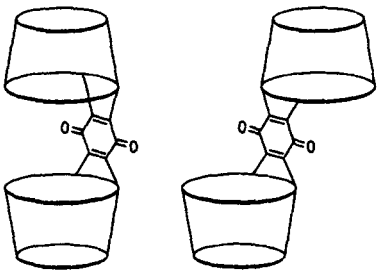


40



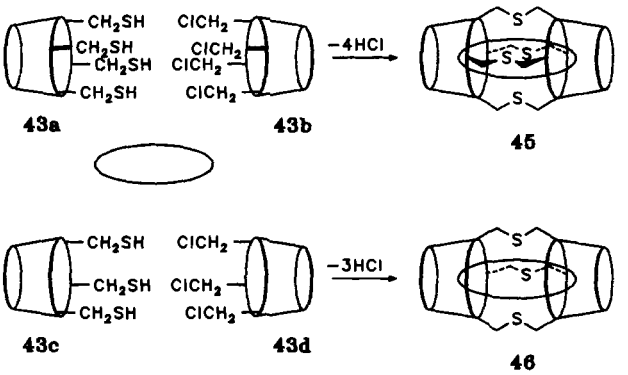
41

For example, one interesting aspect is bridging by the structural element CH_2-CH_2-CO-CH_2-CH_2, which can be converted by reaction with nitromalonaldehyde into a methylene-bridged *p*-nitrophenol unit, so that (formally) *two* new calix[4]arene systems are formed. Compounds of type **42** can thus be described as "bicyclocalix[4]arenes".[208]



6.2. Derivatives of Resorcarenes

By far the most ambitious three-dimensional structures have been prepared starting from calixarenes based on resorcinol, in particular by Cram et al. Although these compounds will not be discussed in detail here, the general principles are presented. Intramolecular linkage of the oxygen functions of neighboring resorcinol units in the all-*cis* isomer leads to the (more or less) rigid structures **43** with a permanent cavity ("enforced cavity"); these have been given the general name cavitands by Cram.[209] A great variety of examples with X = CH_2, $(CH_2)_2$, and $(CH_2)_3$ have been synthesized from reactions of resorcarenes with $BrCH_2Cl$ or the corresponding ditosylates and in many cases these have been characterized by X-ray structural analysis.[183] Cyclization has also been achieved by using $Si(Bu)_2$,[210] PC_6H_5,[211a,b] or P(O)OR.[211c] Molecules with deeper cavities are obtained if larger units are used for intramolecular bridging, for example, by reaction with ferrocene dicarboxylic acid dichloride[49c] or dichloroquinoxaline.[212]

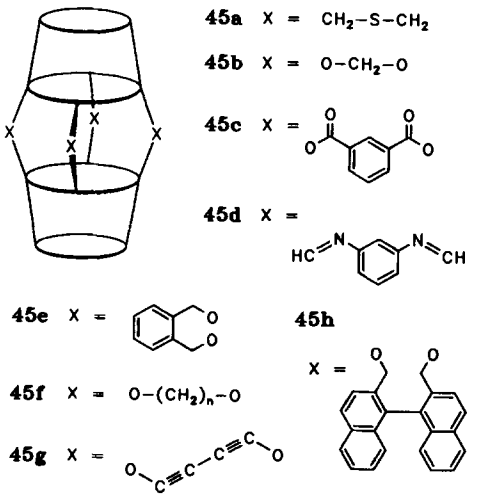


Apart from the completely bridged compounds, (nonspecific) incomplete reactions also afford singly, doubly, and triply bridged cavitands.[213a] The remaining six, four, or two hydroxy groups can then be used for further reactions, for example to introduce a different type of bridge (see Section 7.2). Two isomeric dimers **44a, b** ("ditopic cavitands") can be isolated if this additional bridging is carried out by using the tetrafunctional fluoranil; X-ray structural analysis has shown these to have the C and Z forms.[213a] The differing reactivity of the units with free hydroxy groups can also be used for further selective reactions (Claisen rearrangement,[213b] dehalogenation[213c]).

Cavitands of the type **43** can be functionalized in various ways in the 2-position of resorcinol, starting for example from 2-bromoresorcinol units, which can be obtained by bromination of the original calixarene prior to its conversion to the cavitand.[183] In this connection we should mention the remarkable quadruple sidechain bromination of cavitands of 2-methylresorcinol,[214] which proceeds in very good yields without any attack on the Ar-CHR-Ar structures. This is explained by the fact that the ring structure does not allow the formation of a planar benzyl radical.

Two of these functionalized cavitands **43a, b** can be connected through four bridges at the 2-positions in different ways,[215] as exemplified in Scheme 10.

Scheme 10. Synthesis of carcerands or hemicarcerands with the inclusion of a guest (prisoner) of suitable size (symbolized by the ellipse).



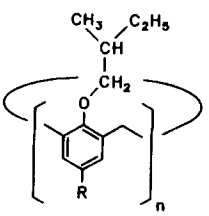
During this linkage reaction one (or even two) smaller molecules can be included in the new, completely closed cavity. Although these molecules are not held by covalent bonds, they can no longer escape from the cavity, since the openings available are too small. Cram has thus introduced the quite logical name "carcerand" for compounds of type **45** and "carceplex" for their inclusion complexes.

Several carcerands of this type (**45a, b**) have been described. They differ in the resorcarene **18** from which they are derived, and in particular in the structural elements which link two cavitands to form a carcerand. The presence of a molecule suitable for inclusion is necessary for the successful formation of a carcerand.[215d,e]

The linkage of two cavitands (**43c, d**) by only three bridges can also occur,[216] and this makes similar inclusions possible (Scheme 10). In compounds **46** one of the "doors" is large enough to permit the "imprisoned" molecule to "escape" under drastic conditions (heating for a longer period under high vacuum or in

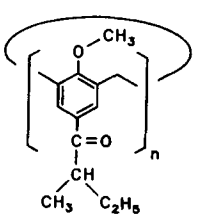
suitable solvents). Compound **46** has thus been given the name "hemicarcerand".

Hemicarcerands have a stable cavity which cannot collapse, even when it is empty. Their openings are however large enough (at least in principle) to permit smaller molecules to pass through them. This goal can also be achieved when two cavitands are linked by four bridges when, as in the examples **45c–h**, these bridges are large enough.[217]



Such an "empty" hemicarcerand is now prepared to take up any suitable molecule or atom which is offered. Thus hemicarceplexes with a large variety of included molecules which do not need to be present during the synthesis are available (see Section 9.6). Remarkable "prisoners" include noble gases, but also larger molecules such as cyclophanes have undergone inclusion.[217]

7. Chiral Calixarenes



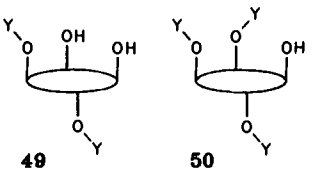
7.1. Derivatives with Chiral Substituents

Just like any other molecules calixarenes can be converted into chiral derivatives by the introduction of chiral substituents. In the case of calixarenes derived from phenols this can be done either at the phenolic OH groups or at the *p*-positions. Examples for this have been described mainly by Shinkai et al.[119]

The use of enantiomerically pure reagents leads directly to pure enantiomeric products (e.g. **47**, **48**), providing that the derivatization occurs without racemization. Thus, it is possible to obtain larger amounts of products, which is not yet the case in the examples to be discussed in Sections 7.2 and 7.3 below.

47

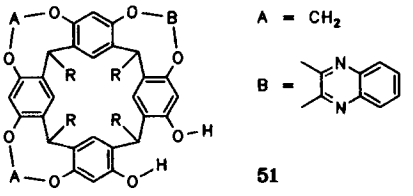
48



The chirality of compounds **47** and **48** is due solely to the chirality of the single units. However, calixarenes offer an additional possibility for the preparation of chiral host molecules because of their nonplanar molecular structure. Such inherently chiral calixarenes[218] have so far mainly been members of the calix[4]arene family.

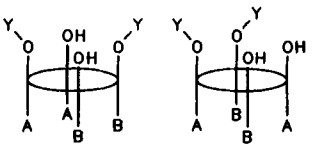
7.2. Asymmetric Calixarenes

The first attempts involved the synthesis of calix[4]arenes with three (in the sequence AABC)[30a] or four[29b] different *p*-substituted phenol units (**7**) or the introduction of a single *m*-substituted phenol unit.[32a, 175]



In order to obtain stable enantiomers the ring inversion, which in this case is equivalent to racemization, must be prevented, for example by the introduction of sufficiently large groups at the phenol oxygen atoms. Because of the asymmetry of such calixarenes it is necessary to achieve complete conversion of all the OH groups to a derivative in the *cone* conformation,[219a] and this can cause problems, which are probably also due to the asymmetry.[219] However, the tetrapropyl ether of a calix[4]arene containing *one* 3-methyl-4-isopropylphenol unit has been prepared in the *cone* conformation and separated into its enantiomers by chromatography using chiral stationary phases.[220]

The same asymmetric pattern can in principle be achieved by O-alkylation (or O-acylation) when different residues are bonded to the phenol oxygen atoms,[109, 131a] thus at the same time fixing the conformation. For this, at least two different groups are required for an all-*syn* arrangement of the O-alkyl groups. Additional possibilities arise when the O-alkyl groups are in an *anti*-arrangement; thus, for example, compounds of the type **49** or **50** are chiral. Such compounds[223] have been described mainly by Shinkai et al.[131a, 221] and Pappalardo et al.[109, 222]

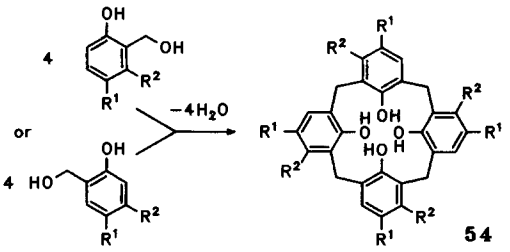


49 **50**

Chiral cavitands **51** have been obtained from resorcarenes using a similar principle by introducing two different bridges (A, B).[213a]

51

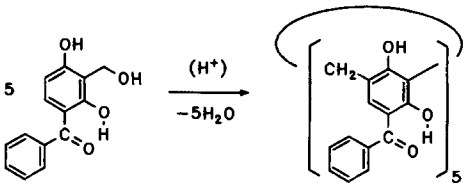
The 1,3-derivatives **52** of calix[4]arenes of the type AABB are readily prepared compounds with inherent chirality and are as usual obtained in very good yields.[224] Here the asymmetry is due to the fact that the plane of symmetry of the calixarene moiety differs from that of the oxygen substituent arrangement,[225] in



52 **53**

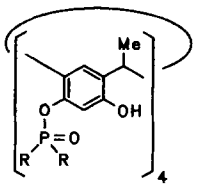
analogy, for example, to the atropisomers of biphenyls. Examples of 1,2-diether derivatives **53** of calix[4]arenes of the type ABAB can also be prepared;[226] this is however more difficult since 1,2-di-O-alkylation typically occurs less selectively than 1,3-di-O-alkylation.

Finally in this section we should mention the spirodienones **28**, which can be obtained from calix[4]arenes (and probably also from higher oligomers).[179] $Cr(CO)_3$ complexes of tetraethers of calix[4]arenes can also be asymmetrical.[227]



7.3. Dissymmetric Calixarenes

Dissymmetric calixarenes with an *n*-fold axis of symmetry are particularly attractive, not only from the aesthetic point of view. Calix[4]arenes **54** with C_4 symmetry have been obtained with yields in the cyclization step of up to 30%.[65, 228]



Because of the equivalence of their phenol units all the O-alkylation products (from mono- to tetraethers) are available in a defined manner. 1,3-Diether derivatives in particular (which have C_2 symmetry) have been prepared in good yields and separated into their enantiomers.[229]

The cyclocondensation of 2,4-dihydroxy-3-hydroxymethyl benzophenone leads surprisingly to the calix[5]arene **55** with C_5 symmetry, as has been shown unequivocally by NMR spectroscopy and mass spectrometry as well as by X-ray structural

analysis.[83] This is not only an unusual example of a molecule with inherent C_5 symmetry but also the first calix[5]arene derived from resorcinol in which in contrast to the resorcarenes *all* the resorcinol units are connected in the 2,6-position.[230]

56

C_4-symmetrical derivatives of the resorcarenes have recently been obtained by controlled esterification of only one OH group per resorcinol unit.[182] Compounds such as **56** could provide the starting point for many new attractive host molecules. The formation of the oxazine rings in the condensation of resorcarene with primary amines and formaldehyde occurs also regioselectively.[185b, c] In this case the C_4 symmetry was confirmed by an X-ray structural analysis.[185c]

While the calixarene-like macrocycles **3** with biphenyl units[22] are flexible (and thus achiral), their biphenyl units can be fixed in a particular conformation by etherification; this leads to chiral derivatives with atropisomeric units. Derivatives with overall C_2 symmetry have been obtained in excellent yields from the cyclic trimer **3a**,[231] while the isomer with D_3 symmetry is apparently less readily available.

8. Calixarenes as Host Molecules

One of the most important properties of calixarenes is without doubt their ability to include smaller molecules and ions reversibly. Although the parent compounds form inclusion compounds in the solid state with such different guests as arenes (benzene, anisole, pyridine, tetralin), acetone, chloroform, acetonitrile, methanol, and water[1, 2, 62] (see also Fig. 1), in solution their derivatives have become important as host molecules or ligands.

8.1. Complexation of Metal Ions: Calixarenes as Ionophores

8.1.1. Unmodified Calixarenes

Simple *tert*-butylcalixarenes are capable of (proton-coupled) transport of alkali metal ions (especially Cs^+) through an organic membrane (CH_2Cl_2/CCl_4); while the selectivity for Cs^+ was found to be highest for **1a**, the highest transport rate was found for **1e**.[10] The suggestion made by Izatt that Cs^+ ions could be complexed within the cavities of calixarene anions provided the best explanation so far for the high transport rate, which was observed under analogous conditions for the bridged calixarenes **14** when $n = 8$.[39] This is also supported by the structure of the Cs^+ salt[69] of **1a** (see Fig. 1c) and by the results of ^{131}Cs NMR measurements on the Cs complexes of **14**.[232]

Harrowfield et al. have described a number of other neutral complexes of Ca^{2+},[233] lanthanoides (La, Eu, Pr, Tm, Lu),[233, 234a–d] and actinoides(UO_2^{2+}, Th^{IV});[235] apart from **1a**, **1c**, and **1e** the bishomocalixarene **6** was also used as a ligand.[234c] Bimetallic complexes with **1e**[234a, b] are of interest because of their photophysical properties.[234d, e]

p-(Phenylazo)calixarenes bind silver and mercury ions selectively; this has been explained on the basis of metal ion induced azo-hydrazone tautomerism.[236] The tetramercaptocalixarene **24** in the 1,3-*alternate* conformation forms 1:2 complexes with mercury.[78b]

8.1.2. Neutral Ligands of the Podand Type

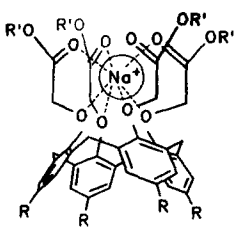
Complexation of Alkali Metal and Alkaline Earth Metal Ions

Derivatives with the structures **27a–c** have been studied in detail (extraction studies, complex formation constants in ho-

mogeneous solution, ion transport through liquid membranes),[110b, 111e, 117a, 122a] and several general rules can be formulated:

- Both esters and ketones prefer to complex alkali metal ions rather than alkaline earth metal ions.
- The ion selectivity depends on the ring size and in the case of calix[4]arenes also on the conformation.[105b]
- Tetraesters in the *cone* conformation are selective for Na^+ (e.g. $\beta(Na^+)/\beta(K^+) = 400$ in methanol[110b]), while the other conformations favor K^+.[105b]
- Pentaesters (*cone*) complex the larger cations preferably without making any particular distinction between K^+, Rb^+, and Cs^+.[117a]
- Hexaesters prefer Cs^+ (e.g. the hexaethyl ester of the calix[6]arene unsubstituted in the *p*-position shows a Cs^+/Na^+ selectivity of 230 in extraction experiments), while octaesters no longer exhibit any complexing abilities of note.[110b]
- "Fine tuning" of the selectivities is possible by varying the alkoxy groups.[135a]
- Tertiary amides bind alkali metal ions considerably more strongly than do the esters (lg β in MeOH is larger by almost 3), but at the cost of selectivity.[111c]
- In contrast to ester and ketone derivatives, amides are also stronger complexing agents for alkaline earth metal ions (high β values for Ca^{2+}, Sr^{2+}, and Ba^{2+} with respect to that for Mg^{2+}; the Ca^{2+}/Mg^{2+} selectivity of 7.8 (lg β in MeOH) is the largest observed for neutral ligands).[121]
- Derivatives with mixed functionalities[110b, 135d, 136b, 237] offer a further possibility for tailoring the complexing properties.

Structure of the Complexes



Complexes of **27a** ($n = 4$) with Na^+ or Li^+ in $CDCl_3$ are kinetically stable on the NMR timescale.[110a] Their ^1H NMR spectra are consistent with effective C_4 symmetry. This is also the case for the free ligands (see Table 7), although relaxation measurements show the latter to have a mobility greater than that of the complexes.[238] All known ligands of the type **27a–c** ($n = 4$) adopt a deformed *cone* conformation in the crystalline state in which two phenol units are almost parallel and the other two are "bent outwards".[2, 62b] The carbonyl oxygen atoms also point outwards.

Table 7. Comparison of the ^1H NMR spectra of **27a** and its kinetically stable Li^+ and Na^+ complexes in $CDCl_3$ (δ values, in parentheses the change in δ).

Proton	**27a**	+ LiSCN	+ NaSCN
Ar-H	6.75	7.04 (+0.29)	7.09 (+0.34)
O-CH_2-CO	4.78	4.81 (+0.03)	4.45 (−0.33)
Ar-CH_AH$_B$-Ar	4.83	4.61 (−0.22)	4.22 (−0.61)
Ar-CH$_A$-H_B-Ar	3.17	3.36 (+0.19)	3.37 (+0.20)
O-CH_2-CH_3	4.19	4.44 (+0.25)	4.35 (+0.16)
O-CH_2-CH_3	1.27	1.38 (+0.11)	1.39 (+0.12)
C(CH_3)$_3$	1.05	1.12 (+0.07)	1.11 (+0.06)

At present the only crystal structure known is that of the K^+ complex of the tetraamide,[111d] which shows "ideal" C_{4v}-symmetry.[239] The K^+ ion is embedded in a "sandwich-like" manner between the planes of the phenol and carbonyl oxygen atoms, which are slightly twisted about the common fourfold axis. It is assumed on the basis of NMR measurements that all analogous complexes have a similar type of structure in solution.

The fourfold symmetry, which follows from the spectrum of the free ligand in solution, thus apparently represents the time average of two (identical) conformations with twofold symmetry which are in equilibrium via a fourfold transition state. The complexation of a cation (see Scheme 11) causes the carbonyl groups to twist inwards and "forces" the ligand in the complex into a "true" fourfold symmetry.[219b, 240, 241]

Scheme 11. Na^+ complex of the tetraester derivative **27a**.

In the case of tetraester derivatives of the calix[4]arenes **54**, twofold symmetry is also observed in solution at low temperatures and the complex is kinetically (and probably thermodynamically) less stable.[65] This is in agreement with the considerable decrease in the complex formation constants (by more than five orders of magnitude for Na^+) for the tetraester derivatives of bridged calix[4]arenes (**14**) when the length of the bridge is reduced from eight to five carbon atoms.[40] The deformation thus caused can no longer be accomodated in the complex.

Little is known about the structure (and in some cases even about the composition) of corresponding derivatives of larger calixarenes. The hexaamide **27b** ($n = 6$) apparently forms a 1:2 complex with Na^+ which probably exists in a *cone*-like conformation.[118a] In contrast, guanidinium ions form 1:1 complexes, the corresponding trimethoxytriamide being clearly more selective. Hexaester or hexaamide derivatives of this type generally exist in solution as mixtures of conformers, while in the crystalline state a 1,2,3-*syn*-4,5,6-*anti*-conformation is often found.[2, 62b]

Other Cations

Tetraamides such as **27b** ($n = 4$) also form complexes with lanthanide ions,[242] which in contrast to the free ligands are often soluble in polar solvents (water, methanol).[243] The Tb^{III} complex exhibits luminescence in aqueous solution with a high quantum yield and long lifetime.[242] The luminescence properties can be further enhanced when one of the amide groups is replaced by a "sensitizer" group (e.g. phenacyl, 4-phenylphenacyl).[244]

Ester derivatives of type **27a** ($n = 5$) can also complex silver ions.[117a] The complexation of transition metals (heavy metals) is certainly favored by the incorporation of "softer" donor atoms such as nitrogen (as the amine),[198a, 245] sulfur,[198a, 246] or phosphorus.[247] Systematic, and in particular comparable, studies on the complexation of metal ions are scarce, so that general conclusions cannot yet be drawn. The examples in Table 8 indicate the possibilities available.[124] Simple ethers of the

Table 8. O-Alkyl derivatives of *tert*-butylcalix[4]arene in the *cone* conformation as an ionophore in CHEMFETs [124].

Detectable ion	O-Alkyl group
Ag^+	$Y^1 = Y^3 = OCH_2CH_2SCH_3$; $Y^2 = Y^4 = OH$
Cu^{2+}	$Y^1 - Y^4 = OCH_2CH_2SC(S)N(C_2H_5)_2$
Cd^{2+}	$Y^1 - Y^4 = OCH_2CH_2OCH_2C(S)N(CH_3)_2$
Pb^{2+}	$Y^1 - Y^4 = OCH_2C(S)N(CH_3)_2$

calix[4]arene can also complex silver ions; however, the arenes function as π-electron bases. NMR studies and X-ray crystal structure analyses of ethers in the *cone* and *partial cone* conformation show that the Ag^+ ion is bound in a sandwich-like manner between two opposite phenyl units.[248]

8.1.3. Calix Crowns, Calix Cryptands

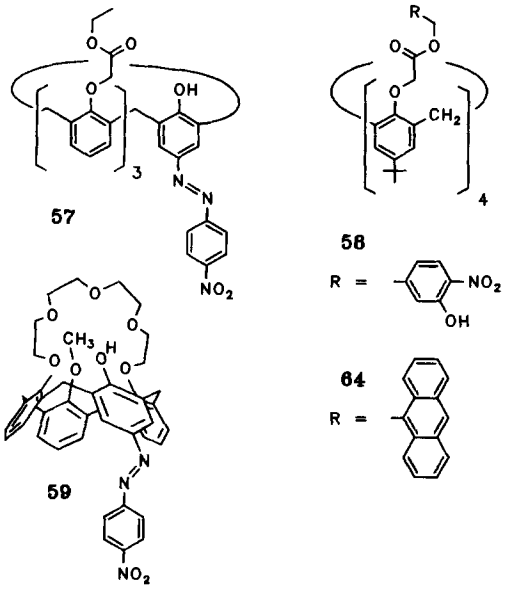
Among the alkali metal ions K^+ is complexed selectively by crown ethers of the type **30** ($n = 3$), which can be used as carriers in liquid membranes.[249a, b] It is interesting that the free dimethyl ether apparently exists in the *cone* conformation, while the K^+ complex adopts a (flattened) *partial cone* conformation.[193b] Derivatives in the *cone*, *partial cone*, and 1,3-*alternate* conformations can be obtained when the methoxy groups are replaced by ethoxy groups; these are sufficiently stable for the necessary studies.[249c] Here, the *partial cone* conformation has shown the highest K^+/Na^+ selectivity (1.2×10^4) so far observed for a synthetic ionophore.[188]

Cs^+-selective ligands are obtained if the crown ether ring is enlarged ($n = 4$).[250a] The most active in this case are derivatives (Y = *n*Pr, *i*Pr, *n*-octyl) which are fixed in the 1,3-*alternate* conformation.[189a] The Cs^+/Na^+ selectivities of 3×10^4 and greater found for extraction (*o*-nitrophenyl hexyl ether) from acid solutions (1 M HNO_3) offer promising prospects for the enrichment of ^{137}Cs from radioactive waste. This high selectivity is due to interactions between the "soft" Cs^+ ion and the π electrons,[250b, c] which were confirmed by the X-ray structure analysis of a Cs^+ picrate complex.[189a] 1,3-Crown ethers derived from calix[5]arene also show Cs^+ selectivity,[251] while no particular complexing properties have been described for the 1,2-crowns based on calix[4]arene.

The calixspherands **32** form alkali metal ion complexes of unusual kinetic stability.[193, 252] The half-lives for the decomplexation of Na^+ and K^+ in $CDCl_3$ (saturated with D_2O), are 3.7 and 2.2 years (!), respectively, when $Y = Y^1 = Y^2 = CH_3$. In the crystalline state and also in solution the free ligand is present in the *cone* conformation[193c, 252a] (an earlier report[193b] suggested otherwise), while in the complex it adopts a flattened *partial cone* conformation. The complexed ion is thus extremely effectively shielded against attack by (for example) water molecules, so that its removal from the complex by stepwise solvation is hindered.

The substitution described above gives a half-life of only 2.8 h for the particularly interesting Rb^+ ion. The results of force field calculations[253] indicate that the larger cation causes a more pronounced bending of the *m*-terphenyl bridge and thus a decreased shielding. The increase in the kinetic stability with increasing size of the substituent Y^2 on the central ring of the *m*-terphenyl unit is in agreement with this explanation.[193c] The half-life for decomplexation increases to 139 h when $Y^2 = Et$, and to 180 days when $Y^2 = i$Pr, while the thermodynamic stability of the complexes remains the same. The half-lives for the exchange of Rb^+ for Na^+/K^+ in polar solvents such as acetone or DMSO[252b] are sufficiently large to enable practical applications in the area of medical diagnostics (the Rb/Kr method).[254a] Even for Ag^+ ions the kinetic stabilities achieved are considerable;[254b] these can certainly be increased by partial replacement of the donor oxygen atoms by sulfur.

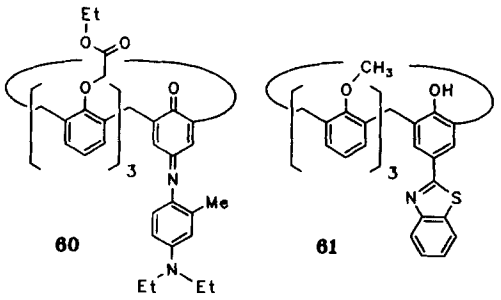
8.1.4. Ligands with Additional Ionizable Groups



The introduction of additional ionizable groups makes it possible in principle to obtain neutral complexes with metal ions, which should for example make the transport of cations through liquid membranes independent of the anion. Under suitable conditions calixarene carboxylic acids of the type **27d** bind alkali metal ions, and in particular alkaline earth metal ions, much more strongly than do the corresponding esters, ketones, or amides,[122c] high Ca^{2+}/Mg^{2+} selectivities again being observed. Like similar siderophores, derivatives with hydroxamic acid residues show a great affinity for Fe^{3+} ions.[255a] If the number of carboxy groups in compounds of type **27** are matched with the charge of the cation, ligands are obtained which form neutral complexes. Very recent examples include Ca^{2+}-selective ligands[255b] and receptors for lanthanoides (Eu^{3+}, Tb^{3+}),[255c] which in addition to amide functions contain two and three $-OCH_2COOH$ groups, respectively. The combination of such ionizable groups with, for example, the structure of the calix crowns should open up further possibilities.

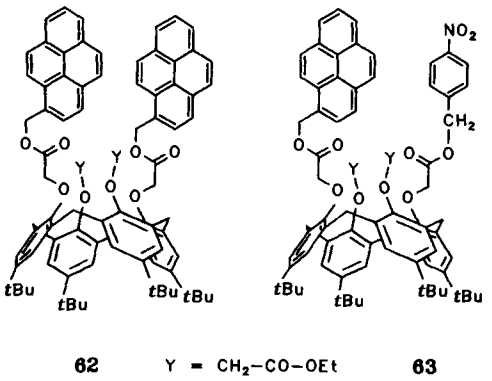
In contrast to many (in practice competing) heavy metal ions with an octahedral coordination sphere, uranyl ions (UO_2^{2+}) prefer to form complexes with hexagonal (or pentagonal) planar coordination; suitable derivatives of calix[6]arene (or calix[5]arene) readily make this possible. Shinkai et al. in particular have studied calix[5]- and calix[6]arenes with sulfonate[256a, d] or phosphonate groups[256e] in the *p*-position and/or O-alkyl groups such as $-CH_2COOH$[256a, b, f] or $-CH_2C(O)NHOH$[256c] as uranophiles in extraction and transport experiments.[256b] Under suitable conditions complex formation constants of up to $K_{uranyl} = 10^{18}-10^{19}$ (the values for the analogous calix[4]arenes are 15–16 powers of ten lower) and selectivities of $K_{uranyl}/K_{Me} = 10^{12}-10^{17}$ have been observed. The low rate of complexation and decomplexation, which is orders of magnitude lower than for the corresponding linear oligomers, seems to be a problem.[256d] The presence of only three carboxyl groups with C_3 symmetry affords selectivity advantages with respect to hexacarboxylic acids (**27d**).[256f] Molecular dynamics simulations on the complexation of UO_2^{2+} by calix[6]arenes were described recently.[256g]

8.1.5. Chromoionophores

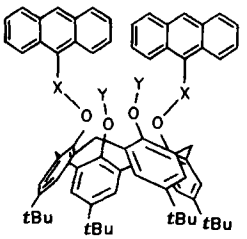


For sensor applications the generation of an optical signal as a direct result of the complexation of a metal ion is desirable. In recent years a series of calix[4]arene derivatives has been synthesized which exhibit a change in their absorption (UV/Vis) or fluoresecence spectra in the presence of metal ions and which thus have potential for applications in optical sensors.[257] The examples discussed below also show the wide range of possible variations in the calixarene skeleton.

The triester **57** (Li^+)[258a], the tetraester **58** (Li^+ better than Na^+),[258b, c] and the crown ether **59** (K^+)[129] exhibit considerable changes (bathochromic shifts) in their absorption spectra when the metal ions given in parentheses are added; these are due to the dissociation of the azophenol or nitrophenol units in the metal complex. While in the case of **57** and **58** the phenolate oxygen atom acts directly as a donor, the complexation of **58** probably occurs in the conventional manner (with phenol and



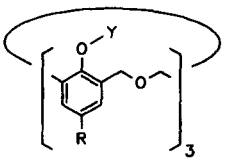
carbonyl oxygen atoms as the donors). The proximity of the positive charge of the metal cation will however favor the deprotonation of the nitrophenol in the presence of a suitable amine.



Large bathochromic shifts in the longer wavelength range are observed in the case of indophenol derivatives;[259] these result from the interaction between the metal ion and the carbonyl oxygen of the chromophoric system. Compound **60** shows Na^+-selectivity,[259a] while a corresponding derivative with two opposing indophenol units is Ca^{2+}-selective.[259b] The trimethyl ether **61**[260] is constructed on the same principle used in **57**: it contains a benzothiazole-substituted phenol unit, the fluorescence spectrum of which shows Li^+-selective changes.

The tetraesters **62** and **63**,[261] in which two pyrene residues or a pyrene and a *p*-nitrobenzyl residue, respectively, are attached to opposite phenol units, provide an impressive demonstration of the conformational change discussed in Section 8.1.2 which occurs on complexation of Na^+ ions in derivatives of type **27**. In the free ligands these two groups can come into contact, while they are spatially separated in the Na^+ complex. Thus **62** shows a strong (intramolecular) excimer emission for the pyrene residues which is reduced by Na^+ ions in favor of the monomer emission.[261a] In **63**, however, the fluorescence of the pyrene residue is quenched by the nitrobenzyl group.[261b] The complexation of Na^+ ions again separates the two groups and thus prevents the fluorescence quenching.[262]

The anthryl group can also act as a fluorophore, and the tetraesters **64**[263] undergo changes in their fluorescence spectra in the presence of Li^+, Na^+, and K^+ ions. The intramolecular photodimerization of anthryl residues has been made use of in the derivatives **65**,[264] the observed effects depending on the nature of the binding to the calixarene. In the case of **65a** the photodimer complexes Na^+ ions better than does the starting material,[264a] and the thermal back reaction is slowed down considerably by Na^+ ions; with **65b**, however, the extractability of the Na^+ ions is decreased considerably by the dimerization.[264b]



65a, X = CH_2CH_2O, Y = $CH_2CH_2OC_2H_5$

65b, X = $CH_2C(O)OCH_2CH_2O$, Y = $CH_2CH_2CH_3$

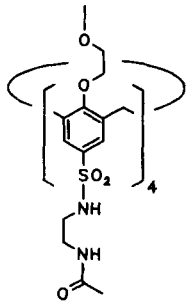
The following observation is also of interest in connection with light-switchable molecular systems.[264c] Ditopic receptors for metal ions are obtained when two molecules of type **27d** are joined by the ester residues.[265] ^1H NMR studies show that a metal ion can interchange in an intramolecular manner between the two binding sites. Similar ditopic receptors can be obtained when the linkage occurs by two bridges[265c] and certainly can also be equipped with chromophoric groups. An (intramolecular) exchange could then also be followed optically.

8.2. Complexation of Organic Cations

Water-soluble calixarene derivatives such as the *p*-sulfonic acids complex ammonium ions;[266] this is mainly due to the electrostatic interaction with the calixarene anion.[267] Depending on the pH value (and the variations in the charge distribution in the host induced thereby) the inclusion can occur in different orientations.[267b] The tetraanions of resorcarenes are also good receptors for quaternary ammonium ions such as choline, association constants of up to 10^5 L mol^{-1} being observed.[103] Cor-

Y = Alkyl

Y = CH_2–CO–OR



66

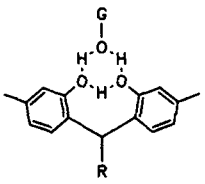
responding complexes have been detected in vacuum using a mass spectrometer.[81]

Neutral ligands such as the alkyl ethers (**26**, Y = *n*Pr) can function as π-bases and complex tetraalkylammonium ions in organic solvents.[268a] The triester and triether **66** of the trioxacalix[3]arene in the *cone* conformation exhibit high affinity for ammonium ions in extraction experiments because of their threefold symmetry.[268c, d]

8.3. Complexation of Anions

In comparison with the large variety of ligands which have been described for metal cations the development of selective host molecules for anions is still in its infancy. This is also true for receptors based on calixarenes. Thus calix[4]arenes with two opposite cobaltocene groups which in solution form 1:1 and 1:2 complexes unspecifically with mono- and dianions have only recently been synthesized.[269a] Selectivity for $H_2PO_4^-$ with respect to HSO_4^- and Cl^- (electrochemical detection by cyclovoltammetry in acetone) has been reported for the ferrocenamide-bridged calix[4]arene **37**.[189b, 269b] The sulfonamide **67** binds anions by hydrogen bonds; a remarkable selectivity (10^2) was found in $CDCl_3$ for HSO_4^- (with an association constant of 10^5 L mol^{-1}) with respect for example to Cl^- or NO_3^-.[159a] Calix[4]arenes with urea residues bound by spacers to the "lower rim" bind halide ions ($Cl^- > Br^- > I^-$, K_{ass} up to 7×10^3 L mol^{-1} in $CDCl_3$).[270] Consideration of the structures described in Section 8.1 indicates that the development of receptors which can bind cations *and* anions selectively at the same time can only be a question of time. Such ligands would be of considerable importance for transport across liquid membranes (see Addendum).

67



The selective inclusion of halide ions in the solid state by metal complexes of phosphonites derived from resorcarenes is mentioned for the sake of completeness.[211b]

8.4. Complexation of Neutral Molecules

The development of host molecules for neutral guests, a possibility which was indicated by the first X-ray structural analyses of calixarenes, is basically still in its infancy. Unspecific complexation of aromatic hydrocarbons (caused by hydrophobic interactions) has for example been described for various water-soluble calixarenes; a certain selectivity is derived from the ring size.[161] Measurements of association constants for a genuine molecular inclusion are made difficult by the fact that it is necessary to work below the critical micelle concentration, and it is in fact often the case that a suitable guest (e.g. a dye) is chosen according to the host available.[271]

The inclusion of organic guest molecules has also been observed for cavitands derived from resorcarenes.[212b] These compounds can in principle be used for the removal of organic impurities from water.[272]

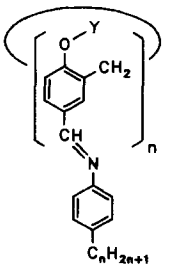
Aoyama et al. have carried out detailed studies on the use of resorcarenes **18** (in particular with R = $C_{11}H_{23}$) as host molecules. In nonpolar solvents such as chloroform they bind a large number of guest molecules which contain hydroxy groups.[273]. The predominant interaction occurs through hydrogen bonds (Scheme 12),[274] which involve two neighboring OH groups of the host and one OH group of the guest.

Scheme 12. Interaction with the hydroxy groups of a guest G in resorcarenes.

Guests such as diols,[273a, b] sugars,[273b, c, d] or dicarboxylic acids[273e] are bound through (at least) two contacts of this type. In the case of simple alcohols CH-π interactions (which cannot be excluded in other cases) are also involved as a second contact.[273f] Considerable selectivities have been observed in spite of the relatively simple structure of the host. Thus dicarboxylic acids can be differentiated according to their length[273e] and diols with respect to the stereochemical arrangement of the hydroxy groups.[273a] In contrast to glucose, fructose can be solubilized in CCl_4 by complexation[273d] and the formation of glycosides from ribose occurs with high stereoselectivity.[273i] In the formation of complexes with glycosides there is an additional strong cooperative effect due to hydrogen bonds between the associated guest molecules.[273g, h] Water-soluble calixarenes (R = $CH_2CH_2SO_3H$) derived from resorcinol (**18**),[275] from pyrogallol (**19a**),[276a] and from 2-methylresorcinol (**19b**)[276b] can bind molecules such as hydrophobic sugars and nucleosides[275] as well as amino acids[276a] in solution, the host functioning as a π base. A resorcarene derivative obtained by aminomethylation with proline can serve as a chiral NMR shift reagent.[276c]

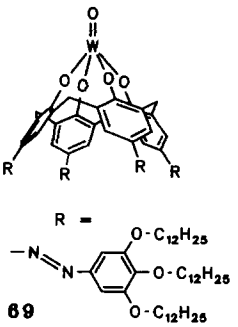
9. Supramolecular Structures

Self-assembly to give supramolecular structures: catch-phrases such as these (in some cases already overused) characterize recent developments which go beyond the narrow area of host–guest chemistry. In what follows we shall discuss (without making any claim to completeness) various relevant results in the calixarene area which reflect present trends and possible future developments.



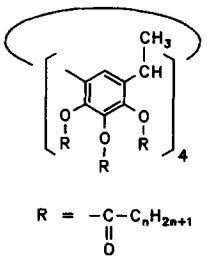
9.1. The Crystalline State

A variety of remarkable supramolecular arrangements have been described for calixarenes in the crystalline state. These are in some cases determined by weak forces,[277] interactions between methyl groups and π systems often playing a decisive role.[187] As well as the inclusion of *one* guest molecule in a single molecular cavity,[278a] it is also possible for *two* molecules of, for example, *tert*-butylcalix[4]arene to encapsulate one single



guest molecule (anisole).[279] The double[278b] or triple inclusion[234c] of guests has also been observed. Self-complexation can lead to chainlike molecular arrangements.[71c, 195] In the case of alkali metal salts of calix[4]arene sulfonates J. L. Atwood et al. have described layer-type structures, which they describe as "organic clay".[280] In the case of transition metals "second sphere" and with Eu^{3+} even "third sphere" coordination by calixarenes has been described.[281]

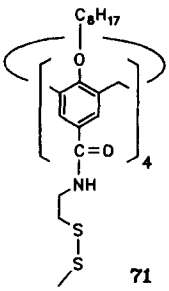
9.2. Liquid Crystalline Systems



The calix[*n*]arenes **68** (Y = CH_3) can form liquid crystalline phases as is typical for azomethines of this type.[282a] Columnar mesophases are however obtained when Y = *n*Pr and $n = 4$, since the calixarene is now fixed in the *cone* conformation,[282b] so that the molecules have a "rigid" bowl-shaped mesogeneous center. Columnar mesophases are also observed for **69**, the center here being even more rigid because of the quadruple binding of a tungsten atom.[283] Similar examples (**70**) were described earlier starting from all-*cis* resorcarenes,[50, 284] in which the axial arrangement of the methyl groups at the bridges leads to the conformational fixation of the center.

68

69

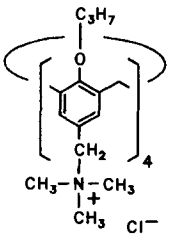


70

It should be mentioned in this connection that because of its permanent dipole moment the *cone* tetrapropyl ether of tetranitrocalix[4]arene can undergo orientation in thin polymethylmethacrylate (PMMA) films when strong electrical fields are applied;[285a] it was possible to increase the concentration of the "NLO-phore" to 100%(!) (NLO = nonlinear optic).[285b]

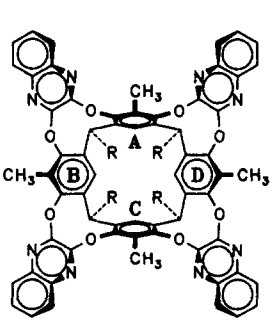
9.3. Mono- and Multilayers

Suitably substituted calixarenes can also be spread on aqueous subphases; depending on the derivative, the hydrophilic end can lie on the "upper rim" or the "lower rim".[108a, 165b, 286, 287] Monolayers of this type can be stabilized by cross-linking reactions.[286b] Mono- and multilayers have also been transferred to suitable carriers using the Langmuir–Blodgett technique.[165b, 286c, d] Thioether derivatives of cavitands form monolayers spontaneously on gold surfaces.[288, 317b] Such results may have considerable potential in sensor techniques or nonlinear optics. The affinity of various sugars for monolayers of **18** (R = $C_{11}H_{23}$) (and correspondingly modified electrodes) has already been demonstrated.[289]



71

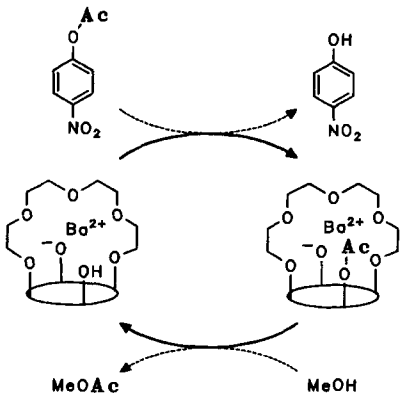
It is possible by transferring monolayers of the calix[6]arene **71** to polymeric carrier materials (poly[1-(trimethylsilyl)-1-propyne]) to obtain membranes whose permeability for gases can be regulated by their "molecular pore size".[286c–e] The permeability for SF_6 was already too small to be measured after only two layers had been transferred, whereas smaller molecules like nitrogen and helium still diffused through the membrane. The "perm selectivity" P(He)/P(N_2) was found to be 21 ± 4.



9.4. Aggregation in Solution

Long-chain *p*-acylcalixarenes, for example, *p*-dodecanoylcalix[8]arenes, and their linear analogues, form stable gels in a variety of organic solvents (including some alcohols).[290] Comparisons with the corresponding methyl ethers and *p*-alkylcalixarenes show that a three-dimensional network is built up, probably through hydrogen bonds between the hydroxy and carbonyl groups. Calix[4]arene ethers which bear a self-complementary α-pyridone residue at two opposite *p*-positions prefer to form linear aggregates linked by hydrogen bonds which can be "denatured" by urea derivatives.[291] The influence of the conformation is shown by the aggregation of the (moderately) water-soluble tetraammonium salt **72**; while the isomer with the *cone* conformation forms micelles, that with the 1,3-*alternate* conformation does not.[292]

72



Compounds such as **73** with "rectangular surfaces" ("velcrands") form defined dimers ("velcraplexes") in solution and in the crystal by the "lock and key principle".[293] The 2-methyl groups of two opposing resorcinol units (A, C) are oriented upwards, the other two (B, D) outwards. The methyl groups A and C then act as "pegs" and fit into the "holes" formed by B and D. Both homo- and heterodimers are found in chloroform with association constants of up to 10^5 L mol^{-1}.[293c]

73

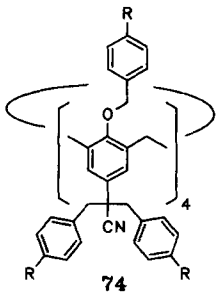
9.5. Calixarenes as Transacylase Models

Calixarenes and calixarene derivatives can be used as catalysts, for example for solvolysis reactions,[294] or as phase transfer catalysts.[108b, 118b, 295] A particularly interesting system which has been characterized in detail is the Ba^{2+} complex of the crown ether **30** ($n = 3$, R = *t*Bu).[296] It exhibits typical features of an enzyme catalysis, such as "burst kinetics" and steady state behavior for an intermediate product. Under certain conditions the methanolysis of *p*-nitrophenyl acetate is accelerated by a factor of 10; since this effect is not caused by either Ba^{2+} ions or the crown ether when used separately it appears justified to speak of a "supramolecular catalyst" (Scheme 13). The monoacetate of **30** was isolated and identified as an intermediate in the reaction; its alkaline methanolysis is accelerated by a factor of more than a million by Ba^{2+} and Sr^{2+} ions.[297] The catalytic cycle has a turnover number of 5.5×10^{-3} min^{-1} (i.e. eight cycles per day); while this is of course not comparable with those typical for enzymes, the model system is unique in type.

Scheme 13. The Ba^{2+} complex of calix[4]-crown-5 as a transacylase model.

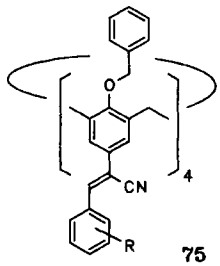
While similar catalytic effects can be observed for crown ethers of *tert*-butylcalix[5]arene, crown ethers derived from bridged calixarenes and from C_4-calixarenes are inactive,[298] probably because they exist in a more rigid conformation with the hydroxy groups oriented inwards.

9.6. Reactions within the "Interior" of Molecules



Completely new perspectives have been opened up by the inclusion of smaller molecules in carcerands and hemicarcerands, a process characterized by Cram as "constrictive bonding". It was possible using such a hemicarcerand as a "molecular reaction vessel" to produce the highly reactive cyclobutadiene from α-pyrone as the "prisoner" (in this instance the word guest is not really appropriate!). Cyclobutadiene normally reacts immediately, for example to yield cyclooctatetraene by dimerization. However, the perfect isolation of each single molecule prevents such intermolecular reactions: at normal temperatures cyclobutadiene is stable in the interior of the hemicarcerand. The controlled reaction with reactants which are small enough to pass through the "gate" of the hemicarcerand is however possible. Thus for example oxygen gives maleindialdehyde[299] by a synthetic route which, while certainly not cheap, is definitely unique. According to the authors the interior of carcerands or hemicarcerands must be considered as a "new state of matter".

9.7. Conclusions

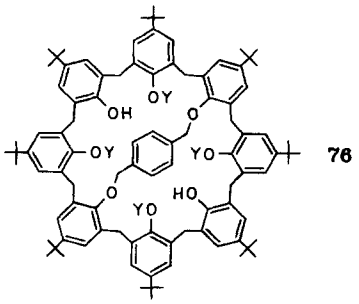


The few examples discussed here demonstrate that the title chosen for this report is certainly not an exaggeration. Many research groups are striving to synthesize even larger molecular systems with controlled functionalities. The calixarene structure, which behaves as a "molecular chameleon"[300] can be used in many ways as a building block. A final example which helps to make this clear is the molecule with a permanent cavity of about 1.5 to 2.0 nm in diameter[301], consisting of two subunits of types **I** and **II**, which are bridged by a total of eight relatively rigid bridges.

10. Addendum[302]

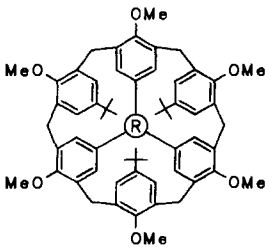
From the multitude of new derivatives of calix[4]arenes products derived from p-cyanomethylcalix[4]arene should be mentioned which can be converted in good yield to the dodecabenzyl derivative (**74** in the *cone* or 1,3-*alternate* conformation)[303] or by an aldol condensation with benzaldehydes to **75**. In these cases the cyano functionalities are still available, so that com-

74

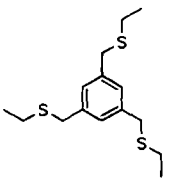


75

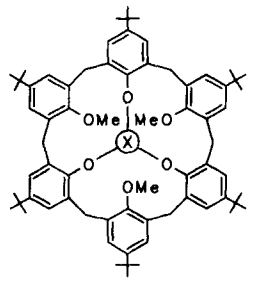
pounds such as **74** could serve as starting materials for novel dendrimers. The possibilities for incorporation of phosphorus are also apparently unlimited;[304] compounds containing phosphorus with coordination numbers from 3 to 6 have been described.[304a, b] Of particular interest are sandwich-like organometallic compounds which are formed in good yields by metalation of up to four of the "phenolic outer surfaces" by (for example) cyclopentadienyl derivatives of rhodium or iridium.[305] These compounds are stable, have been characterized by X-ray crystallography, and because of the presence of "positive" phenol building blocks they are suited for the inclusion of anions.



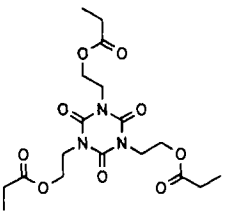
Further progress has been made in the selective derivatization (O-alkylation and acylation) of calix[6]arenes.[306] The effects of the dominant factors, such as relative acidity of the OH groups, conformation of the intermediates, size and reactivity of the reagent, are apparently slowly becoming much clearer. As in the case of calix[4]arenes the substitution pattern obtained can also be transferred to the *p*-positions, for example by selective trans-

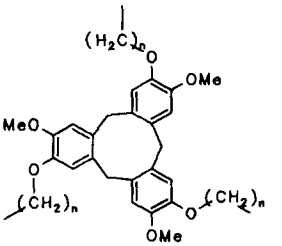


butylation (see below) or by *ipso*-nitration.[306b] In addition to numerous ethers, the first examples of "double" calix[6]arenes have also been obtained.[306c]

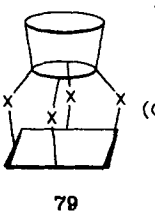


1,3,5,7-Tetra-O-alkyl derviatives of calix[8]arenes have also been obtained in yields of up to 50%.[307a] These have been converted by means of difunctional reagents to the first 1,5-O-bridged calix[8]arenes **76**.[307b] The isolation of the 1,2,4-tri- and 1,2,3,4-tetramethyl ethers of *t*-butylcalix[8]arene **1e** in yields of 68 and 21%, respectively, demonstrates that other substitution patterns are also possible.[307a]

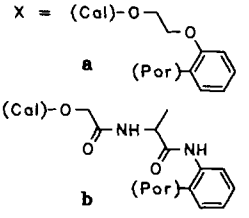




76



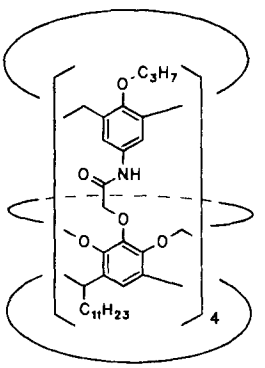
77, R = 



78a, X = 

78b, X = 

The combination of calix[6]arenes with building blocks that have threefold symmetry[308, 309] to afford larger host molecules such as **77** and **78** is remarkable: the coupling can take place either at the "upper rim"[308a] or the "lower rim".[308b, 309] In each case the starting material was the 1,3,5-trimethyl ether of **1c**. Initial derivatization of the hydroxyl groups or the *p*-positions was followed by reaction with trifunctional reagents[308] or in the case of the inherently chiral C_3-symmetrical cryptocalix[6]arenes **78b**[309] by the formation of the cyclotriveratrylene system in analogy to cryptophanes.[4]

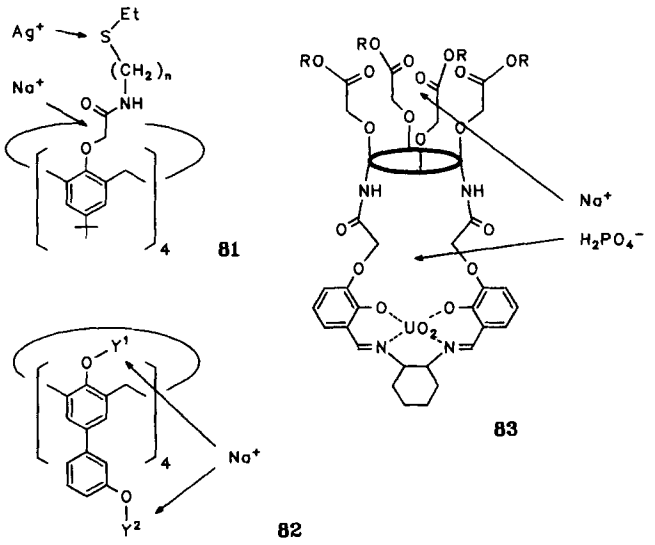


79

Compounds in which the porphyrin system is linked to one (**79**)[310] or two[311] calix[4]arene units to form larger structures have also been prepared for the first time in preparatively satisfactory yields. In this case it is possible to start from calix[4]arene derivatives with benzaldehyde side arms (on the upper or lower rim) and to build up the porphyrin system by condensation with pyrrole.[310a, 311] In the case of **79a** the calixarene even acts as a template.[311] The linkage of a correspondingly functionalized porphyrin with a calixarene derivative represents a second synthetic route;[310b] **79b** is chiral because of the alanine residues present. Further exciting developments in these directions can be expected.

Larger molecules with up to three calix[4]arene units have also been constructed for the first time from derivatives which exist in the 1,3-*alternate* conformation.[312a] Although the spacers so far used in the linkages (bisphenol A) are still too long (and thus too flexible) for the term "nanotubes" to be really valid, this goal now appears attainable in the short term. It has been shown for suitable derivatives in the 1,3-*alternate* conformation[312b] that Ag^+ ions can probably be transported through such "tubes". Double calix[4]arenes in which two units are linked by Cu^{II} complexes[313] or hydrogen bonds[314] are also of interest. It is remarkable that only the formation of dimers, and not of larger associates, is reported.

Cram et al. have synthesized new hemicarcerands of type **45** which contain other bridges.[315] Using the corresponding carceplexes it is possible to carry out either reactions of the included molecule (e.g. oxidation of divalent phenols to quinones without the observation of side reactions[315b]) or reactions at the bridges without loss of the included molecule.[315a] Photochemical reactions of included molecules are also possible.[316]



80

The carcerands **80** prepared by Reinhoudt et al. are particularly remarkable; these consist of a cavitand based on resorcarene and a calixarene.[317a] In contrast to compounds **45** they have *no* plane of symmetry orthogonal to the fourfold axis of the molecules and thus have a permanent dipole moment in the direction of this axis. Included molecules can thus take up two orientations, as has been shown in the case of dimethylacetamide and N-methylpyrrolidone. However, these rotate rapidly about the molecular axis, so that the carceplex as such has effective C_4 symmetry. The authors consider that they have discovered a new type of stereoisomerism, which they refer to as *carceroisomerism*. Carceplexes of this type could conceivably be used for information storage on a "molecular basis". Since resorcarenes containing long-chain thioether residues at the bridges can form

monolayers on gold surfaces,[288, 317b] such systems are in principle thus "manageable".

A large number of new chromo-[318] and fluorogenic[319] calixarene derivatives has been prepared. Of particular interest are: pyrene derivatives (cf. **62**, **63**) of type **66**[319a] for ammonium ions, guanidinium-sensitive pyrene derivatives of **1c**[319c] and chromogenic calix[6]arenes containing an indoaniline unit (cf. **60**), which are sensitive to uranyl ions.[318c] The capabilities of the basic calix[4]arene skeleton are particularly clear in the case of the ditopic receptors **81**–**83**. Compound **81** combines hard and soft donor groups on one side of the molecule,[320] while **82** exhibits "cooperation" in the bonding of metal ions by the ether amide ligand functions Y^1 and Y^2 on the both sides of the molecule.[321] The calix[4]arene-salen hybrid **83** is a bifunctional receptor for NaH_2PO_4.[322]

$Y^1 = Y^2 = CH_2-CO-N(Et)_2$

The multifarious possibilities available to calixarenes are demonstrated further by the use of specifically modified derivatives as phase transfer catalysts,[323] as pseudo-stationary phases in capillary electrophoresis[324] and as host components in sensors[325] (e.g. for organic molecules), though space does not permit a detailed discussion. Redox-active hosts such as calixarenes with *p*-quinone units may however provide new possibilities.[326]

Special mention should be made of the separation and purification of C_{60} with the help of calixarenes.[327] In contrast to C_{70}, C_{60} forms a relatively insoluble 1:1 complex with *tert*-butylcalix[8]arene in toluene; this can be purified by recrystallization and split into its components with $CHCl_3$, which can then readily be separated. The denser C_{60} sinks to the bottom of the vessel and can in this way be obtained in larger quantities with a degree of purity >99.5%.[327a] Enrichment of C_{70} is possible by complexation with *tert*-butylcalix[6]arene. Thus the authors suggest that the readily available calixarenes afford an inexpensive approach to the expensive fullerenes. The supramolecular interaction between fullerenes and calixarenes or similar host molecules[327d] also appears to be of fundamental interest.

Our own work in this area has been supported by the Deutsche Forschungsgemeinschaft and the European Community, and we thank both organizations for this support. I also wish to thank those many colleagues who have helped in the preparation of this manuscript both by critical discussion and constructive suggestions and by providing me with results, manuscripts, and figures. My thanks are due in particular to Dr. I. Thondorf for the figures based on X-ray structural analyses and to Dr. C. Grüttner and Dipl.-Chem. O. Mogck for their careful corrections.

[41] a) V. Böhmer, H. Goldmann, M. Tabatabai, unpublished results. b) Here we should also mention similar double calix[4]arenes with one or four bridges: V. Böhmer, H. Goldmann, W. Vogt, J. Vicens, Z. Asfari, *Tetrahedron Lett.* **1989**, *30*, 1391–1394.

[42] This defines the orientation of the group R with respect to one of the CHR bridges. If the macrocyclic system is viewed as being planar, these groups are either on the same side (c) or on the opposite side (t) to the group taken as a reference (r). However, this classification is not always used. Gutsche uses the *cis/trans* notation to denote the relative orientation of two neighboring bridges (cf. [1]). Thus he describes the *rtct* isomer as the *trans,trans,trans,trans* isomer. Further confusion is caused by the fact that these configurational isomers can (at least in principle) adopt different conformations, and that these two stereochemical aspects are not always clearly distinguished.

[75] Since the aromatic systems (including the atoms bonded to them) can be considered to be planar even as a very good approximation, a calix[*n*]arene can in principle be described by $(n-1)$ pairs of such torsional angles. However, *n* pairs are given for the sake of clarity. The *cone* conformation (and any *cone*-like conformation) is characterized by a continual change of sign (+ −) within these pairs. The other conformations of calix[4]arenes are described as follows: *partial cone* + −, + −, + +, − ; 1,2-*alternate* + −, + −, + +, −, and 1,3-*alternate* + +, − , + +, −. The conformations of calix[6]arenes (Fig. 2) have torsional angles with the following sign sequences: left) + −, + −, − +, + −, + −, − + ; right) + −, + −, + , − +, − +, −. Compare: F. Ugozzoli, G. D. Andreetti, *J. Incl. Phenom. Mol. Recogn.* **1992**, *13*, 337–348.

[90] In these octaesters, which are derivatives of isomers with different configurations, the conformation with an axial arrangement of the groups at the carbon atoms of the bridges seems to be general (but see ref. [45c]). The *rccc* isomer has a flattened *cone* conformation with C_{2v} symmetry, often described as the boat conformation. The interconversion $C_{2v} \rightarrow C_{2v}$ occurs via a transition state with C_{4v} symmetry. The *rcct* isomer has a chair conformation with C_{2h} symmetry, which can be the time average of two *partial cone* or two 1,2-*alternate* conformations. The *rcci* isomer takes up a 1,2-*alternate* conformation with C_s symmetry, which has also been described as the diamond conformation (see ref. [45a]).

[91] The two signals, each for four OH protons, which are observed in $CDCl_3$ but not in [D_6]acetone or [D_6]dimethyl sulfoxide, are assigned to different OH groups in systems of cyclic hydrogen bonds, see ref. [274].

[92] Solubilities in benzonitrile (and several other solvents) have recently been reported: a) A. F. Danil de Namor, M. T. G. Pardo, D. A. P. Tanaka, F. S. S. Velarde, J. D. C. Garcia, M. C. Cabaleiro, J. M. A. Al-Rawi *J. Chem. Soc. Faraday Trans.* **1993**, *89*, 2727–2736; b) A. F. Danil de Namor, *Pure Appl. Chem.* **1993**, *65*, 193–202; c) M. H. B. Grote Gansey, W. Verboom, D. N. [218] Comprehensive review: V. Böhmer, D. Kraft, M. Tabatabai, *J. Incl. Phenom. Mol. Recogn.*, in press.

[219] a) Otherwise a complex mixture of isomeric or similar derivatives would be formed. Thus for example four different mono- or trialkyl derivatives (with a *syn* arrangement) or four different tetraalkyl derivatives in the *cone* conformation are possible; b) L. Zetta, A. Wolff, W. Vogt, K.-L. Platt, V. Böhmer, *Tetrahedron* **1991**, *47*, 1911–1924.

[220] a) S. Shinkai, T. Arimura, H. Kawabata, H. Murakami, K. Araki, K. Iwamoto, T. Matsuda, *J. Chem. Soc. Chem. Commun.* **1990**, 1734–1736; b) S. Shinkai, T. Arimura, H. Kawabata, H. Murakami, K. Iwamoto, *J. Chem. Soc. Perkin Trans. 1* **1991**, 2429–2434.

[221] K. Iwamoto, H. Shimizu, K. Araki, S. Shinkai, *J. Am. Chem. Soc.* **1993**, *115*, 3997–4006.

[222] a) S. Pappalardo, S. Caccamese, L. Giunta, *Tetrahedron Lett.* **1991**, *32*, 7747–7750; b) G. Ferguson, J. F. Gallagher, L. Giunta, P. Neri, S. Pappalardo, M. Parisi, *J. Org. Chem.* **1994**, *59*, 42–53.

[223] Unfortunately a recent systematic classification (cf. ref. [221]) of all possibilities contains some mistakes and inconsistencies. The number of different O-alkylation products (in brackets the number of the chiral compounds) is as follows: 34 (17) tetra-, 13 (9) tri-, 8 (3) dialkyl ethers. Compare: V. Böhmer, D. Kraft, W. Vogt, *Supramol. Chem.* **1994**, *3*, 229–301.

[224] V. Böhmer, A. Wolff, W. Vogt, *J. Chem. Soc. Chem. Commun.* **1990**, 968–970.

[225] Mono- and tri-O-alkyl derivatives of calix[4]arenes of the type AABB have also no plane of symmetry, and analogous considerations apply to macrocycles such as **2** or **5** with a "non-quadratic" arrangement of the phenolic oxygen atoms; see ref. [23b].

[226] F. Marschollek, V. Böhmer, W. Vogt, unpublished results.

[227] a) H. Iki, T. Kikuchi, S. Shinkai, *J. Chem. Soc. Perkin Trans. 1* **1992**, 669–671; b) H. Iki, T. Kikuchi, S. Shinkai, *ibid.* **1993**, 205–210; c) for the conformation see H. Iki, T. Kikuchi, H. Tsuzuki, S. Shinkai, *Chem. Lett.* **1993**, 1735-1738; d) $Cr(CO)_3$ complexes can also be used for selective functionalization: T. Kikuchi, H. Iki, H. Tsuzuki, S. Shinkai, *Supramol. Chem.* **1993**, *1*, 103–106.

[239] Since this highly aesthetic structure is one of the most often reproduced representations of calixarenes we shall not include it here.

[240] The synergistic effect of acetonitrile on the complexation of alkali metal ions can also be understood on the basis that its inclusion in the hydrophobic cavity favors fourfold symmetry. a) A. F. Danil de Namor, N. Apaza de Sueros, M. A. McKervey, G. Barrett, F. Arnaud-Neu, M.-J. Schwing-Weill, *J. Chem. Soc. Chem. Commun.* **1991**, 1546–1548; b) A. F. Danil de Namor, M. C. Cabaleiro, B. M. Vuano, M. Salomon, O. I. Pieroni, D. A. P. Tanaka, C. Y. Ng, M. A. L. Tanco, N. M. Rodriguez, J. D. C. Garcia, A. R. Casal, *Pure Appl. Chem.* **1994**, *66*, 435–440; c) compare also the crystal structure of the calix[4]arene tetracarbonate: M. A. McKervey, E. M. Seward, G. Ferguson, B. L. Ruhl, *J. Org. Chem.* **1986**, *51*, 3581–3584.

[241] a) The conformational change of the O-alkyl groups can also be used in order to align them for an interaction with a further guest: H. Murakami, S. Shinkai, *J. Chem. Soc. Chem. Commun.* **1993**, 1533–1535; b) results of molecular dynamics calculations suggest, however, that this conformation of the complex can also not be regarded as "rigid": P. Guilbaud, A. Varnek, G. Wipff, *J. Am. Chem. Soc.* **1993**, *115*, 8298–8312.

[242] a) N. Sabbatini, M. Guardigli, A. Mecati, V. Balzani, R. Ungaro, E. Ghidini, A. Casnati, A. Pochini, *J. Chem. Soc. Chem. Commun.* **1990**, 878–879; b) Tb^{III} complexes of calixarene sulfonates also exhibit luminescence in aqueous solution: N. Sato, I. Yoshida, S. Shinkai, *Chem. Lett.* **1993**, 1261–1264.

[243] In contrast, Eu^{III} and Tb^{III} complexes of calix[4]arene ethers with pyridine N-oxide groups decompose in water: S. Pappalardo, F. Bottino, L. Giunta, M. Pietraszkiewicz, J. Karpiuk, *J. Incl. Phenom. Mol. Recogn.* **1991**, *10*, 387–392.

[244] N. Sato, S. Shinkai, *J. Chem. Soc. Perkin Trans. 2* **1993**, 621–624.

[245] T. Nagasaki, S. Shinkai, *Bull. Chem. Soc. Jpn.* **1992**, *65*, 471–475.

[246] See for example: K. M. O'Connor, G. Svehla, S. J. Harris, M. A. McKervey, *Anal. Proc.* **1993**, *30*, 137–139.

[247] See for example: D. Matt, C. Loeber, J. Vicens, Z. Asfari, *J. Chem. Soc. Chem. Commun.* **1993**, 604–606.

[248] A. Ikeda, H. Tsuzuki, S. Shinkai, *J. Chem. Soc. Perkin Trans. 2* **1994**, 2073–2080; cf. also ref. [250b].

[249] a) W. F. Nijenhuis, E. G. Buitenhuis, F. de Jong, E. J. R. Sudhölter, D. N. Reinhoudt, *J. Am. Chem. Soc.* **1991**, *113*, 7963–7968; b) with regard to the simultaneous transport of anions see: H. C. Visser, D. M. Rudkevich, W. Verboom, F. de Jong, D. N. Reinhoudt, *ibid*, **1994**, *116*, 11554–11555; c) in sensors (ion selective electrodes (ISE), CHEMFET) the slow isomerization leads to a continuous decrease in the selectivity: Z. Brzozka, B. Lammerink, D. N. Reinhoudt, E. Ghidini, R. Ungaro, *J. Chem. Soc. Perkin Trans. 2* **1993**, 1037–1040.

[250] a) In contrast, reduction of the size of the ring ($n = 2$) leads to the selectivity for Na^+, see ref. [325c]; b) similar observations have been made for tetra-O-alkyl derivatives in the 1,3-*alternate* conformation: A. Ikeda, S. Shinkai, *Tetrahedron Lett.* **1992**, 7385–7388 and *J. Am. Chem. Soc.* **1994**, *116*, 3102–3110; c) K^+ complexes in *1,3-alternate*-conformation: P. D. Beer, M. G. B. Drew, P. A. Gale, P. B. Leeson, M. I. Ogden, *J. Chem. Soc. Dalton Trans.* **1994**, 3479–3485.

Carbon–Hydrogen Bonds of DNA Sugar Units as Targets for Chemical Nucleases and Drugs**

Geneviève Pratviel, Jean Bernadou,* and Bernard Meunier*

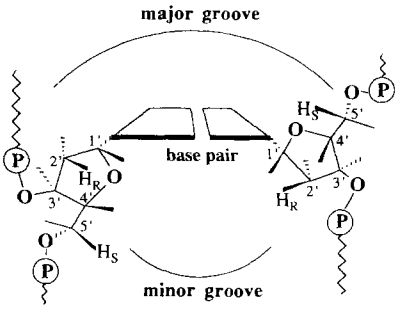
This review article focuses on the molecular aspects of DNA cleavage by synthetic chemical nucleases (transition metal complexes endowed with redox properties and DNA affinity) and natural drugs (cytotoxic agents such as bleomycins or enediynes). Unlike deoxyribonucleases, which catalyze the nucleophilic attack of water on the phosphorus atom of a particular phosphodiester entity, these nonhydrolytic DNA-cleavers are able to oxidize the sugar units, generally by hydrogen atom abstraction. Examples of oxidative attack on each of the five different C–H bonds of deoxyribose are known, depending on the nature, structure, type of activation, or mode of DNA interaction of the DNA-cleaver. Further evolution at the site of the initial lesion leads to the release of bases, oxidized deoxyribose units, or oxidized sugar fragments appended to the base or the terminal phosphate. In most cases the loss of a part (at least) of a nucleoside, with the concomitant loss of one base information, primarily induces the cleavage of the DNA strand. For both types of DNA cleavage reagents studied within the two last decades, the modes of activation and DNA binding are presented, as well as the details on the mechanism of deoxyribose oxidative degration. Because of the need for highly efficient and highly specific reagents, the development of new artificial and selective DNA cleavers, supported by an improved knowledge of these different mechanisms of DNA cleavage, is to-day a challenging area in the rational design of antitumoral or antiviral agents, as well as in the field of molecular biology.

Keywords: bleomycin · DNA cleavage · enediynes · transition metal complexes

1. Introduction

A large body of evidence has accumulated over the past three decades on the role of oxidative damage to biological macromolecules in ageing phenomena, chronic inflammation, ischemia, cancer, autoimmune diseases, transcription activation and, recently, in the induction of HIV expression.[1–2] Defenses against oxidative stress are organized in living organisms with nonenzymatic systems like vitamines [α-tocopherol (vitamin E), ascorbic acid (vitamin C), or β-carotene (vitamin A)], or with enzymes like superoxide dismutases, glutathione, peroxidase, and catalase.[2].

Within the two last decades, much data has been published on chemical and biochemical aspects of the structural damage generated by oxidative stress on cellular constituents (DNA, proteins, lipids, and carbohydrates). Aerobic life can be considered as a well-organized system against injury from oxidation by elimination of oxidants and reparation of damage to macromolecules. Repair of DNA is performed by DNA repair enzymes by several routes: nucleotide or base-excision repair, mismatch repair, and error-prone repair.[3] Oxidative damage to DNA can be initiated by ionizing radiation,[4] photooxidation (UV or visible light with or without photosentitizers),[5] hydroperoxides activated by traces of adventitious transition metals salts,[6] hydroxyl radicals,[7] or various other oxidizing agents (for a recent review article on the oxidative degradation of DNA, see ref. [8]). In this latter category, we find drugs like bleomycin, cytotoxic agents with an enediyne motif, and chemical nucleases mainly based on redox-active transition metal complexes (for recent review articles, see ref. [9]). DNA damage can be produced by oxidation of nucleobases or sugar units. More than 20 modified purines and pyrimidines resulting from oxidative damage have been identified.[10] This base damage threatens genomic integrity and is the origin of lethal effects or mutations in DNA. On the other hand, damage to deoxyribose leads to the loss of one base information and/or a break on a DNA strand, which might correspond to a lethal lesion, especially when an oxidation process produces a double-strand break (DSB), that is, two close single-strand breaks (SSBs) on opposite strands.



We will see in the present review that many highly cytotoxic drugs or chemical nucleases are able to generate double-strand breaks by oxidation of sugars on both strands of B-DNA (for a textbook on DNA structures, see ref. [11]). More precisely, all these sugar degradation processes are initiated by H abstrac-

tions, since the aliphatic nature of deoxyribose does not favor oxidation by electron abstraction. The C–H bonds of deoxyriboses have a well-defined arrangement, and their orientations with respect to drugs or chemical nuclease are also controlled by DNA itself by DNA–drug interactions. In addition, the homolysis of a C–H bond depends also on the substituents on the carbon: less energy is required to remove a H atom from a tertiary carbon than from a secondary carbon atom. But more important is the relative orientation of the drug to the sugar C–H bonds. For drugs interacting within the minor groove of B-DNA, two tertiary C–H bonds are easily accessible: C4′–H and C1′–H. The third tertiary C–H bond (C3′–H) is only accessible from the major groove. C2′ and C5′ are secondary carbon atoms. In both cases, one C–H bond is accessible from the minor groove the (*pro-R*) H atom at C2′ and the (*pro-S*) H atom at C5′; for assignments of prochiral hydrogen atoms at C5′ and C2′ see ref. [12]) and the other from the major groove. In Scheme 1 the different arrangement of deoxyribose C–H bonds with respect to the minor groove is depicted. It is essential for the rational drug design of antitumoral, antiviral agents, or other pharmaceuticals based on DNA cleavers to understand the way of these DNA sugar carbon–hydrogen bonds are activated at the molecular level.

Before the molecular aspects of deoxyribose C–H bond activation are analyzed (Section 3), the different modes of activation and DNA binding of chemical nucleases and drugs involved in this deoxyribose oxidative damage will be described (Section 2).

Scheme 1. Among seven C–H bonds of deoxyribose that are possible targets for oxidative activation, four point into the minor groove (indicated by wedge-shaped bonds), and three into the major groove (H_R and H_S refer to the absolute configuration (*pro-R* or *pro-S*) of hydrogen atoms at C2′ and C5′).

2. Chemical Nucleases and Drugs Able To Cleave DNA by Oxidation of a Sugar Unit

This section will be devoted to a survey of the nonhydrolytic chemical nucleases and drugs able to cleave the DNA phosphodiester backbone by sugar oxidation. These DNA cleavers differ completely from deoxyribonucleases that accomplish DNA scission by catalyzing the nucleophilic attack of a water molecule on the phosphorus atom of a particular phosphodiester bond.[13] In the past 15 years, several redox-active coordination complexes have been synthesized, and naturally occurring nucleolytic agents have been discovered that are able to cleave the phosphodiester backbone of nucleic acids under physiological conditions

Geneviève Pratviel was born in Toulouse (France) in 1959. She attended the University Paul Sabatier and received her degree in Biochemistry in 1983 and her PhD in Pharmacology in 1986 under the supervision of Bernard Meunier. After spending post-doctorate fellowship in the group of Prof. A. Sartorelli at Yale University she came back to the group of Bernard Meunier as a CNRS researcher in 1988 at the Laboratoire de Chimie de Coordination du CNRS. Her research interests are the mechanism of DNA cleavage applied to the development of biologically active compounds and genetic tools.

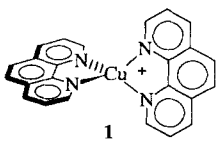
J. Bernadou

B. Meunier

Jean Bernadou was born in Villefranche-de-Rouergue (France) in 1947, studied Chemistry, Pharmacy (doctorate in Pharmaceutical Sciences in 1975) and Medicine (doctorate in 1985) at the University Paul Sabatier of Toulouse, where he was appointed Professor of Medicinal Chemistry in 1987. His collaboration with the group of Bernard Meunier started in 1980 with his research interests in the mechanisms of action of antitumor drugs. He is currently working on biological applications of metalloporphyrins, in particular on the topic discussed in the present review article.



Bernard Meunier was born in Poitiers (France) in 1947 and obtained a first doctorate degree with Robert Corriu at the University of Montpellier in 1972. He joined Hugh Felkin at the Institut de Chimie des Substances Naturelles du CNRS of Natural Chemistry at Gif-sur-Yvette and obtained a second doctorate in 1977. After one year as post-doc at Oxford University with K. Prout, he moved to the Laboratoire de Chimie de Coordination du CNRS, where he is presently research director. His current research interests focus on metalloporphyrin-catalyzed oxidations, ligninase models, oxidations of pollutants, DNA cleavage by cationic manganese porphyrins, and anti-HIV molecules based on metalloporphyrin derivatives.

by oxidative attack on deoxyribose moieties. These synthetic nucleolytic agents are complexes of transition metals, $Cu(oP)_2$, Fe–EDTA,[*] or metalloporphyrins that perform DNA strand scission after activation 1) by reducing agents in the presence of molecular oxygen or hydrogen peroxide, or 2) by oxygen atom donors such as iodosylbenzene, magnesium monoperphthalate, or potassium monopersulfate. In some cases these DNA breaks are mediated by photoactivatable complexes (bipyridyl or phenanthroline complexes of rhodium, ruthenium, or cobalt). The most sophisticated nucleolytic agents are natural products isolated from strains of *Streptomyces* (bleomycin, neocarzinostatin), *Micromonospora echinospora* (calicheamicin), or *Actinomadura verrucospora* (esperamicin). All these chemical nucleases and drugs can be distinguished from other DNA-modifying compounds used in nucleic acid chemistry[14] by their preferential deoxyribose-directed reactivity. We have also included recent information on irradiation of 5-halouracil-containing DNAs and on photocleavage of DNA by rhodium complexes in order to illustrate the possibility of oxidative attacks on positions 2′ and 3′ of deoxyribose units. We propose an almost complete description of the different ways of activating five of the seven C–H bonds of deoxyribose: C1′–H, one (*pro-R*) hydrogen atom at C2′, C3′–H, C4′–H, and one (*pro-S*) hydrogen atom at C5′ (Scheme 1). Schemes 14 to 18 each summarize one of these five possibilities, and detail the subsequent potential reaction pathways. These schemes also display reaction products that have been isolated or chemically characterized and that can be used as reporters to identify at molecular level the attack sites on deoxyriboses by DNA cleavers. (For an excellent early review of the different routes for DNA cleavage, see ref. [9b].)

2.1. Bis(1,10-phenanthroline)copper, $Cu(oP)_2$

2.1.1. Mechanism of Potentiation

$Cu(oP)_2$ (**1**, Scheme 2) was the first chemical nuclease demonstrated to have an efficient nucleolytic activity on double-stranded DNA.[15,16] There are two essential coreactants, the Cu^I complex **1** and hydrogen peroxide.[15,17] Despite the frequent use of **1** as a cleaving agent, the exact nature of the reactive species involved in this DNA cleavage is still unknown. A popular view is that the hydrophobic cationic complex **1** binds to DNA and forms an intermediate that reacts with H_2O_2 to generate a hydroxyl radical ($HO^{\bullet}$). However, according to reports on the detailed chemistry of the cleavage reaction, freely diffusible hydroxyl radicals are not responsible for the strand scission.[17,18] Williams et al.[19] concluded that the DNA damaging species can diffuse over a limited range from the binding site of **1**, which suggests that it is also unlikely to be an oxo–copper complex. Whether this reactive species is a hydroxyl radical coordinated to a cupric ion (called crypto-OH[18]) is still an open question. The damage to DNA bases by activated **1** is typical of processes induced by hydroxyl radicals,[20] which suggests that at least a minor reaction pathway involves free hydroxyl radicals.

1

Scheme 2. Structure of bis(1,10-phenanthroline) copper **1**.

The one-electron reduction of the starting complex $Cu^{II}(oP)_2$ can be accomplished by adding exogeneous reducing agents (ascorbate,[21] thiols like mercaptopropionic acid,[17,21–23] 2-mercaptoethanol,[21] NADH[24]) or by using superoxide generators (xanthine/xanthine oxidase,[17] cobalt-60 γ-radiolysis). One-electron reductants such as the superoxide anion and thiol accomplish directly the reduction of the Cu^{II} complex, but two-electron reductants such as NADH are involved in a multistep reaction in which superoxide plays a central role.[24] H_2O_2 can be either added exogeneously, or generated in situ by spontaneous dismutation of the superoxide anion produced during oxidation of the Cu^I complex by molecular oxygen, by cobalt-60 γ-radiolysis of water, or from xanthine/xanthine oxidase.[17] In the presence of hydrogen peroxide, the DNA cleavage proceeds as rapidly under anaerobic conditions as under aerobic conditions.[17] In the absence of added hydrogen peroxide, oxygen is required, but its exclusive role is as a precursor for hydrogen peroxide in the oxidation of thiol catalyzed by $Cu(oP)_2$.[17]

As demonstrated by kinetic studies, the nuclease activity of $Cu(oP)_2$ proceeds by an ordered mechanism: the freely diffusing $Cu^{II}(oP)_2$ is first reduced to the Cu^I complex [Eq. (1) and (2)], which binds reversibly to DNA [Eq. (3)]. This noncovalently bound Cu^I complex is then oxidized by hydrogen peroxide to generate the reactive species responsible for DNA strand scission[25] [Eq. (4)]. The Cu^{II} complex also binds to DNA but the direct reduction of $Cu^{II}(oP)_2$–DNA by $O_2^{\bullet-}$ is very slow and can be neglected.[26]

$$2Cu^{II}(oP)_2 + 2RS^- \longrightarrow \underset{\mathbf{1}}{2Cu^{I}(oP)_2} + RSSR \quad (1)$$

$$Cu^{II}(oP)_2 + O_2^{\bullet-} \longrightarrow \underset{\mathbf{1}}{Cu^{I}(oP)_2} + O_2 \quad (2)$$

$$Cu^{I}(oP)_2 + DNA \longrightarrow Cu^{I}(oP)_2\text{-}DNA \quad (3)$$

$$Cu^{I}(oP)_2\text{-}DNA + H_2O_2 \longrightarrow [(oP)_2Cu^{III}\text{-}OH]DNA + OH^- \quad (4)$$

2.1.2. Interaction with Nucleic Acids

The pattern of DNA digestion in the presence of $Cu^I(oP)_2$ (**1**) is consistent with its binding in the minor groove of a right-handed double helix. The reactivity of **1** in the minor groove of DNA[27] is confirmed by "footprinting" studies on netropsin- and EcoRI-dodecamer complexes that are oxidatively degraded by $Cu^I(oP)_2$ (netropsin binds within the minor groove, and Eco RI within the major groove[15b,28]). The reaction mechanism involving the H atoms at C1′ and C4′ of the deoxyriboses (which are located within the minor groove) as the main targets of the oxidative attack are also in accord with this position for the cleaver.[15b] Initial observation of the inhibition of cleavage by intercalators implied that the cleavage reaction proceeded through an intercalative complex.[17] The nucleolytic activity $Cu^I(oP)_2$ is sequence-dependent but not nucleotide specific.[15c,29] The unsubstituted aromatic phenanthroline ligands of $Cu(oP)_2$ preclude hydrogen bonding interactions with bases as crucial factors for specificity.[15c] The only observed specificity is related to a predominant preference for binding at 5′-TAT triplets in the minor groove, which were cleaved most

[*] IUPAC nomenclature has not been used in this review.

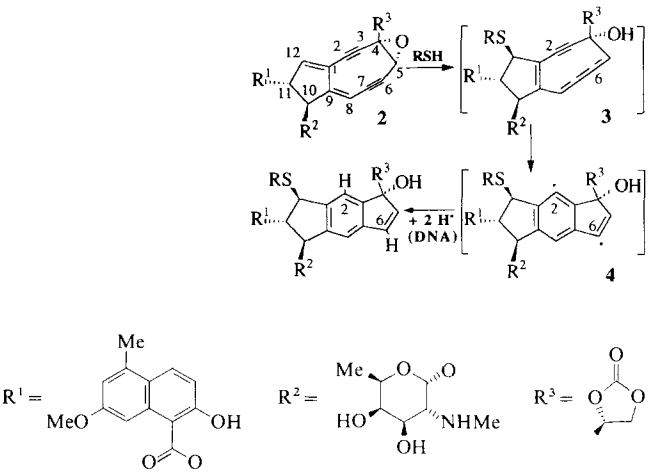
strongly at the deoxyadenosine sugar ring. The related sequences TGT, TAAT, TAGpyr and CAGT were moderately preferred, while CAT and TAC triplets, and polypurine and polypyrimidine sequences were cleaved less often.[30, 31] The preference of Cu(*o*P)$_2$ for TAT may be related, in part, to sequence-dependent variations of the B conformation of DNA.[31] Stacking interactions are favored with a propeller-twisted base-pair. Changes in roll and twist angles open the minor groove of DNA at the TA step and facilitate penetration of the helix by an *o*P ring in either a partial intercalation or groove binding mode. Cu(*o*P)$_2$ is precluded by its tetrahedral geometry from full intercalation, but a model in which one phenanthroline ligand partially intercalates at a TA step is plausible.[32] Since Cu(*o*P)$_2$ attacks DNA from a binding site within the minor groove, the geometry of this structural domain must govern the cleavage specificity by the complex. Mutational changes can generate additional sites detectable by the complex, whereas DNase I, for example, did not detect substantial changes accompanying these base substitutions.[15b, 33] Single-stranded DNA is a poor substrate.[17, 22, 33a] Double-strand scission of DNA by Cu(*o*P)$_2$ is accomplished by two successive single-strand nicks. DSBs have been observed with a semisynthetic nuclease prepared by chemically linking Cu(*o*P)$_2$ to *E. coli* trp repressor.[34]

RNA is also a substrate for the nuclease activity of **1**. The copper complex shows a preference for single-stranded loops relative to double-stranded A structures present in RNA, but the detailed mechanism of cleavage is still unknown.[35]

The Cu(*o*P)$_2$/H_2O_2 system cleaves A, B, and Z forms of DNA at different rates: the B structure is the most easily cleaved; the A structure, formed by RNA–DNA hybrids, is cleaved on both strands at roughly one third the rate for B-DNA under comparable conditions; in contrast, the left-handed Z structure, with its deep narrow minor groove, is completely resistant to Cu(*o*P)$_2$ degradation.[15b, 22]

The nuclease activity of **1** can be aimed at specific DNA sequences by attachment of one *o*P ligand to the 5′ end of complementary oligodeoxynucleotides (ODNs). Although the *o*P–ODN does not permit attack at a unique site on the DNA like restriction enzymes, targeting of the nuclease activity by hybridization provides a method for analyzing single-stranded DNA[23, 36, 37] and RNA.[38] It is also possible to design an *o*P–ODN that can recognize and cleave specific sequences selectively on double-stranded DNA by the formation of a triple-helix.[37, 39] Sequence-targeted cleavage of nucleic acids by conjugates of phenanthroline complexes and oligo-α-deoxynucleotides, which are resistant to nucleases, could be used to regulate gene expression in vivo.[40]

The nucleolytic activity of **1** has also been directed at specific sites of attack with DNA-binding proteins as carriers, in order to study the interactions of DNA-binding proteins with DNA restriction fragments or to isolate long DNA fragments for sequencing, cloning, or chromosomal mapping.[34, 41] This strategy has been applied to the design of *tat*-based chemical nucleases useful for site-specific cleavage of HIV TAR RNA.[42] Sequence-specific scission of DNA by RNA-bound **1** has recently been described.[43] Conjugates prepared by tethering 1,10-phenanthroline to a dye binding in the minor groove like Hoechst 33258 have been used to increase the reactivity or to modify the selectivity.[44]

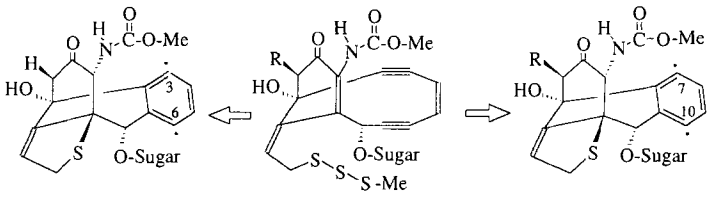


Extensive cleavage of DNA has been achieved with a chiral system related to **1** in which copper(II) is bound to one chelation site of a multifunctional ligand (4′,7′-phenanthrolino[5′,6′:5,6]pyrazine) while the second site is occupied by $Ru^{II}(bpy)_2$. Cleavage is almost exclusively limited to the *Λ* isomer of this chiral bimetallic complex.[45]

Mechanisms of DNA cleavage by **1** will be discussed in detail in Sections 3.1.1 and 3.4.1.

2.2. Enediyne Anticancer Antibiotics

2.2.1. Mechanism of Potentiation



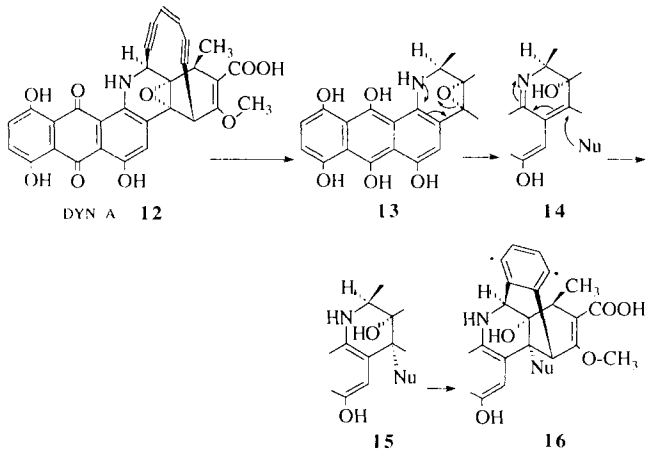
Naturally occurring enediyne anticancer antibiotics are prodrugs metabolized into active biradicals that can abstract hydrogen atoms from the sugar phosphate backbone of DNA in the presence of thiols.[9g] Among enediyne antibiotics, neocarzinostatin (NCS) has been extensively studied by Goldberg et al., and its mechanism of DNA cleavage is the best documented.[9d] Neocarzinostatin cleaves DNA through a nonprotein chromophore, NCS-chrom (**2**, Scheme 3). The nucleophilic addition

Scheme 3. Formation of a biradical **4** from **2** in the presence of a thiol, and abstraction of two hydrogen atoms from deoxyriboses of DNA.

of a thiol (or hydride) on the C12 position of **2** (→ **3**) gives rise to the rearrangement (cycloaromatization) to an indacene biradical (**4**) with C2 and C6 as radial centers. This biradical is able to abstract one or two hydrogen atoms from the DNA backbone, leading to SSBs or DSBs, respectively. The thiol necessary for the activation of **2** must have strong reducing properties, a good affinity for DNA, or a high nucleophilicity to ensure optimal activation.[46]

The other natural products presented in Schemes 4 and 5, calicheamicin γ_1^I (**5**, CAL; a total synthesis was recently described[47]), esperamicins **7**–**10** (ESP A, C, D, E), and dynemicin **12** (DYN), possess an enediyne unit as part of an overall structure that also contains a DNA-binding moiety (a glycosylated aminosugar or an intercalating structure) and a triggering

Scheme 4. Structures of CAL, ESP A, C, D, E, and their biradical species (for numbering rules see refs. [9f, 57].



device (a methyltrisulfide group for CAL and ESP or a quinone for DYN). Reduction of these natural products with thiols initiates aromatization (Bergman type cycloaromatization,[48] see Schemes 3–5) of the enediyne moiety to a biradical species that is responsible for the DNA damaging properties[9g, 49] and the cytotoxicity of these drugs. In the case of activated CAL or ESP, the reducing thiol does not form a covalent adduct with the dye and gives rise to the 1,4-phenylene biradicals **6** and **11**.

DNA breaks mediated by enediyne compounds require oxygen, but neither reduced forms of dioxygen (such as the superoxide anion, hydrogen peroxide, or the free hydroxyl radical) nor transition metals are involved in the DNA damage (**2**,[50] **5**[51]). In the presence of DNA, sulfhydryls, and O_2, the enediyne compounds undergo a single oxidation–reduction cycle, which results in DNA cleavage and leaves an inactive form of the drug, devoid of further redox properties. The first step of the reaction, the generation of the biradical that abstracts H· from DNA, does not require O_2. In the next step with **2**, DNA cleavage is associated with the uptake of one equivalent of O_2 per mole of drug (DNA radical reacting with O_2) and is followed by the uptake of at least one equivalent of reducing agent. Under anaerobic conditions, misonidazole can replace dioxygen in the cleavage step (the DNA radical is quenched by misonidazole) and one equivalent of thiol is consumed per mole of **2**.[52] For other enediyne molecules the stoichiometry of O_2 and reductants has not been studied.

For **2** the C6 radical of the activated form **4** of the dye (Scheme 3) performs the predominant H abstraction (C5′ chemistry) from DNA.[53] The remaining C2 radical of the drug either reacts across the minor groove with the opposite strand of DNA in the case of suitable special DNA sequences (C1′, C4′, or C5′ chemistry) or degenerates and leaves the DNA at the level of a single-strand break. Selective quenching of the radical at C2 results in the conversion of **4** to a monofunctional reacting species[54] and is due to H· donation mainly from solvent or from the bound thiol. This could account for the predominance of SSBs (80%).

In the case of CAL (**5**, see Scheme 4), DDBs form 95% of DNA damage.[55] Both hydrogen atoms incorporated at the C3 and C6 positions of CAL biradical **6** originate solely from DNA.[12a, 56] For the esperamicin family **7**–**10** (see Scheme 4), the two radical centers on the reactive species **11** are C7 and C10.[9g, 57]

Dynemicin A (**12**, Scheme 5) can, for example, be activated through the reduction of the quinone unit to the compound **13**; opening of the adjacent epoxide provides **14** and attack by a nucleophile gives **15**. Then, in the absence of geometrical con-

Scheme 5. One proposition for the formation of the biradical **16** from DYN A (**12**) by bioreduction (Nu = nucleophile).

straints imposed by the epoxide ring, this activated intermediate undergoes a facile cycloaromatization to the biradical **16**, which causes the classical DNA H abstraction of this series of compounds.[9g, 58] So far, no detailed study of H abstraction from DNA by **12** has been reported.

Photochemical (for **2**, ESP **7**–**10**,[59] and **12**[60]), radiolytical (**2**),[61] or thermal activation (ESP[62]) are also possible and lead to DNA cleavage.

2.2.2. *Interaction with Nucleic Acids*

2.2.2.1. NCS-Chrom

Strong interaction of NCS-chrom (**2**) with DNA (affinity constant approximately $5 \times 10^6\ M^{-1}$), and proper positioning of the activated form of the drug provide clues to its DNA cleaving efficiency. NCS-chrom binds to DNA through intercalation of its naphthoate moiety and through external interaction of its protonated aminosugar residue with phosphate groups. The biradical part of the activated form is positioned in the minor groove of DNA,[63] and the intercalated part of the drug increases the distance between two base pairs within the interaction site. This detail is important when the site of the DSBs are compared with those for other enediyne drugs. Double-strand breaks of **2** are two base pairs (bp's) apart in the minor groove, compared to a 3 bp shift for other enediyne drugs. SSBs occur mostly at T residues (T ≫ A ≫ C > G) and show base specificity rather than sequence specificity.[9d] Double-strand breaks are sequence specific: 5′-AGC or 5′-AGT are the main DSB sites. They also involve different mechanisms on each strand: H5′ abstraction by the C6 radical of **2** occurs on one strand, and for some particular sequences, the C2 radical is properly located for the second H abstraction on the opposite strand, where it mediates mainly either C1′ or C4′ chemistry. All SSBs are due to C5′ chemistry, and for the DSBs studied so far, at least one strand is cleaved after H5′ abstraction.

Depending on the thiol used in DNA cleavage experiments with **2**, the amount and the nature of cleavage products are modified.[46, 64] The thiol is involved in the nucleophilic activation of the chromophore through a covalent bond, so it may

change the interaction of the activated drug with the minor groove of DNA and modify the C4′ to C5′ chemistry ratio, as well as the total amount of C4′ chemistry observed at some residues.[64] The nature of the thiol is also important for the DSB/SSB ratio.[46] One striking example is the generation of direct double-strand breaks by glutathione (GSH). GSH was shown to force the drug deeper into the minor groove of DNA at 5′-AGC/3′-TCG sequences, which increased drug activity at the C1′ sugar carbon.[46, 65]

The positioning of **2** in the minor groove of DNA is also dependant on the local microstructure at the interacting site. The introduction of mismatches in double-strand cleavage sites, or the replacement of guanine by inosine (without an NH_2 group pointing into the minor groove), changes the access of the biradical form of the drug to the C1′, C4′, or C5′ sugar carbons of DNA.[66]

Mechanisms of cleavage for **2** will be discussed in Section 3.1.2., 3.4.2.1 and 3.5.1.1 (C1′, C4′, and C5′ chemistries, respectively).

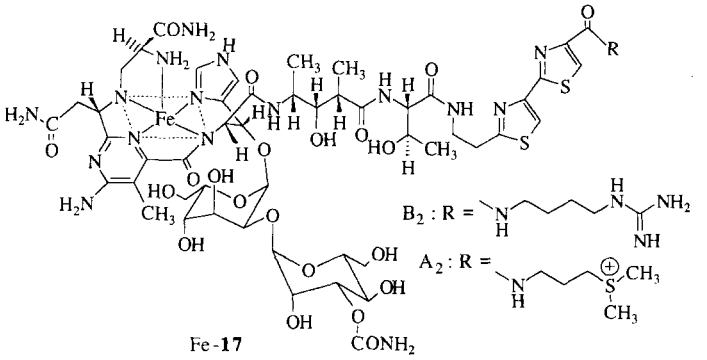
2.2.2.2. *Other Enediynes*

The other enediyne molecules mediate single- and a substantial number of double-strand breaks, because of the unique fit of the drugs in DNA. The generation of a phenylene biradical results in staggered double-strand cleavage sites through synchronous homolytic H abstractions from deoxyribose sites on opposing strands. This series of compounds also attacks DNA in the minor groove.

Calicheamicin γ_1^I: CAL **5** causes double-strand DNA lesions (more than 95%) in a plasmid or in a model of the cleavage site.[55] Each strand is cleaved by different mechanism. The preferred attack sites are the 5′ penultimate pyrimidine C of a 5′-TCCT sequence and the nucleotide N, three nucleotides toward the 3′ side of the paired G in the complementary sequence 3′-*N*NA*G*GA.[51].

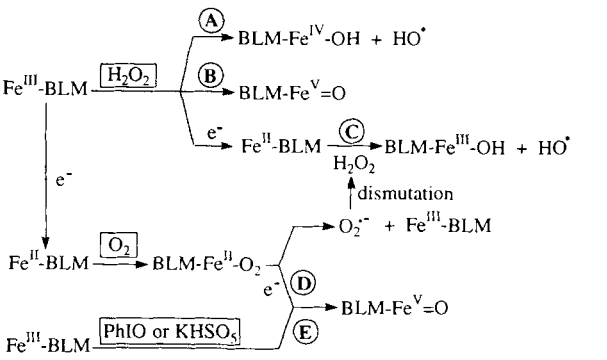
In 1992 other sites of cleavage were reported: 5′-C*T*CT, 5′-ACCT, 5′-T*T*TT.[67a] CAL requires double-stranded helical DNA at the 5′ site of a 5′-TCCT sequence in order to anchor efficiently. This drug binds to the minor groove of B-DNA by orienting its oligosaccharide side chain toward the 3′ end of a 5′-TCCT sequence. For a review of CAL-DNA interactions, see ref. [9f]. The interaction of the drug with its recognition sequence is very sensitive to changes, and truncated or modified drugs show altered cleaving and recognition properties.[67] Variations of DNA sequence within the preferential binding site also affect the cleavage.[67b] There seems to be a real synergism of the two parts of the intact drug (carbohydrate domain and aglycone core) for the sequence-selective, double-strand cleaving efficiency of calicheamicin. CAL mediates C5′ chemistry on the T*C*CT strand (Section 3.5.1.2) and C4′ chemistry on the complementary strand (Section 3.4.2.2). Some C1′ chemistry may be involved in double-strand lesions,[55] but in the absence of any precise data will not be discussed further.

Esperamicins: Esperamicins **7**–**10** (Scheme 4) exhibit base selectivity (T > C > A > G), but less sequence selectivity than calicheamicin, in spite of their structural similarities. ESP A (**7**) is the only member of the ESP family to mediate SSBs. ESP C, D, and E (**8**–**10**) lack the fucosyl anthranilate moiety, and afford a substantial number of DSBs.[68] So, the presence of two side chains in ESP A might explain the production of SSBs, whereas a suitable single arm might confer the ability to generate DSBs (ESP C, D, and E). In the ESP family, the trisaccharide tail seems to be very important for the cleaving efficiency, since ESP D (**9**) or E (**10**), with one or two sugars missing) were considerably less efficient DNA cleavers while showing the same sequence selectivity.[57, 68a, 69]



The binding of ESP to DNA is not as strict as for CAL (**5**) or for NCS-chrom (**2**). ESP may bind in the minor groove in two opposite orientations.[57] A 3′-staggered asymmetric cleavage pattern on the same sequences was reported for the double-strand cleaver ESP C **8** as well as for the single-strand cleaver ESP A **7**.[57, 68a] ESP A only mediates SSBs by targeting C5′ carbons on one or the other strand of the target DNA sequence, while ESP C, D, or E mediate DSBs with different mechanisms on each strand (two possible orientations of the drug in its target site). The authors propose that each radical position (C7 and C10) of the activated drug **11** has its own mechanism of deoxyribose-H abstraction: the radical at C7 would abstract a H4′ atom and that at C10 a H5′ atom. Because the activated entity **11** can bind in two orientations to DNA, a radical center can attack either the one or the other strand and so promote the corresponding chemistry on either strand. SSBs generated by ESP A can be explained by the loss of reactivity of the C7 radical center, probably due to congestion from the nearby fucosyl anthranilate group, and to the ability of the remaining C10 radical for H5′ abstraction. The mechanism of DNA cleavage for ESP involves both C4′ and C5′ chemistry (see Sections 3.4.2.3 and 3.5.1.3, respectively).

Dynemicins: Intercalation and minor groove binding have been proposed for the interaction of this type of drug with DNA.[58b] DYN A (**12**) causes single- and double-strand breaks, but is not base-specific. Dynemicins preferentially attack the base adjacent to the 3′ side of purine bases (5′-G*C*, 5′-G*T*, 5′-A*T*, and 5′-A*G*). They mediate strand breaks, three bp's apart (in the 3′ direction) in the two DNA strands.[70]



General remarks on enediyne drugs: The bifunctional nature of the enediyne biradicals make them potential double-strand cleavers. The degeneration of the biradical species to an entity with one active radical center may be due to altered positioning of the activated drug, or to steric hindrance or quenching of one of the radical centers by the fucosyl anthranilate moiety (for the ESP family) or by the thiol unit (for **2**). The optimal efficiency of enediyne drugs may thus not always be achieved, because of these surrounding tails.[55, 57] The radical center that is not influenced by a surrounding side chain will ordinarily mediate C5′ chemistry; the other one will react with the C4′ position of deoxyribose,[9d, 55, 57] and in some cases with C1′[66, 71] or C5′.[64]

2.3. Bleomycins

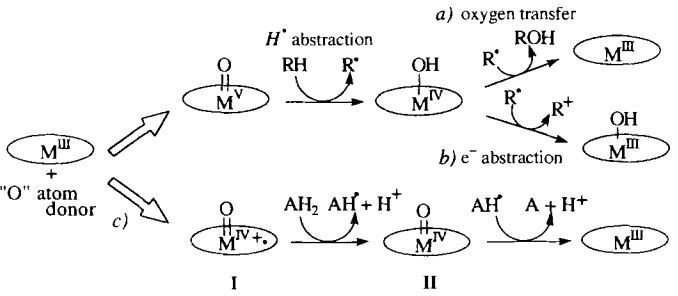
The bleomycins **17** (BLM, Scheme 6) are a family of glycopeptide-derived antibiotics, discovered by Umezawa and coworkers in 1966,[72] that have been used clinically against non-Hodgkin lymphomas, squamous cell carcinomas, and testicular tumors.[73] Their cytotoxic activity against mammalian cells is

Scheme 6. Structure of bleomycins A_2 and B_2 and proposed structure for their chelation of an iron atom.

Scheme 7. Potential pathways for activation of Fe–BLM complexes in the presence of O_2, H_2O_2, or oxygen atom donors (PhIO, $KHSO_5$).

generally assumed to correlate with their ability to bind to and cleave DNA.[74] More recently RNA has been reported as a possible target for BLM-mediated cleavage (see Section 3.4.3 for further details). Three domains can be distinguished in the structure of BLMs:[9a–b] the bithiazole and the positively charged chain contribute to specific binding to DNA; the pyrimidine, β-aminoalanine, and imidazole moieties are involved in dioxygen activation by chelating iron; finally, the gulose and carbamoylated mannose residues are perhaps responsible for the selective accumulation of BLM in some cancer cells, and might also participate in iron coordination and oxygen activation.[75] A large variety of analogues of BLM were snythesized to provide new insights into chemical or biochemical aspects of BLM activity. It has been possible, for example, to establish the coordination structures of metallobleomycins with more certainty,[76] to improve the dioxygen activating capability[77] or the DNA cleaving activity,[78] to carry out asymmetric epoxidation,[79] to modify the sequence specificity,[80] to better define the structural elements primarily responsible for controlling sequence-specific DNA cleavage,[81] and to develop chiral bleomycin models that discriminate according to chirality on cleaving DNA.[82]

2.3.1. *Mechanism of Potentiation*



BLM-induced DNA breaks are mediated by several redox-active metals (iron, cobalt, copper) which are strongly chelated by nitrogen atoms of the peptide moiety of BLM and which react with molecular oxygen.[9a–b, 83] Oxygen activation by Fe^{II}–BLM requires an additional electron. This can be provided by disproportionation of two Fe^{II}–BLM molecules, by reductants such as ascorbic acid[84] or alkyl thiols,[84a, 84c] or by electrochemical reduction.[85] A key step in DNA lesions is the homolysis of the C4′–H bond of deoxyribose rings[86] by the "activated" bleomycin.[84a, 87] The exact nature of this activated BLM is still a matter of debate. All the hypotheses concerning the H4′-abstraction step can be classified in two categories (Scheme 7): a Fenton route (HO• as reactive species, routes Ⓐ and Ⓒ[84a]) or a P-450-like route (with BLM–Fe^{V}=O as hydroxylating agent, routes Ⓑ, Ⓓ, Ⓔ, first suggested by Burger et al.[87b]). Evidence to support a particular pathway can be obtained from the different ways of generating "activated BLM", from spectroscopic characteristics of intermediates, and from observed chemical reactivity.

Activated bleomycin can be generated by three different oxygen sources: molecular oxygen and electrons, hydrogen peroxide or alkyl hydroperoxides, and single oxygen atom donors. The usual methods for Fe–BLM activation (either Fe^{III}–BLM/O_2/$2e^-$ or Fe^{III}–BLM/H_2O_2) produce active species that behave similarly toward DNA.[88] Neither route distinguishes between the Fenton or the P-450 mechanism, since both are compatible with pathways Ⓒ and Ⓓ or Ⓐ and Ⓑ of Scheme 7. The formation of oxo–iron species has been well established for cytochrome P-450 itself with single oxygen atom donors like $NaIO_4$, H_2O_2, ROOH, or iodosylbenzene,[89] and for synthetic metalloporphyrins with peracids, iodosylbenzene, or NaOCl.[90] The association of iodosylbenzene with Fe^{III}–BLM strongly supports the formation of BLM–Fe^{V}=O[91] (route Ⓔ, Scheme 7); however, in this case possible Lewis acid catalysis which does not necessarily imply a FeV=O intermediate has been discussed.[92] Moreover, iodosylbenzene is not a benign oxygen surrogate in reactions with BLM, especially for the long incubation times generally used, and results should be viewed with caution.[93] With potassium monopersulfate ($KHSO_5$), a water-soluble oxygen atom donor at physiological pH (Scheme 7, route Ⓔ), activated Fe–BLM can give single- and double-strand breaks on DNA[94] or transfer oxygen to olefins.[95] When Fe^{III}–BLM is activated by particular alkylhydroperoxides that were shown to undergo homolytic scission of the O–O bond route Ⓐ in Scheme 7,[96a] the activated species is not capable of DNA cleavage.[96b] These data support the assignment of "activated BLM" to a high-valent bleomycin oxo–iron complex (the formation of such oxo–iron species from an alkylhydroperoxide requires a heterolytic splitting of the peroxidic O–O bond). The inefficiency of radical scavengers[97] in these reactions suggests that the active cleavage pathway goes predominantly through an oxo–iron route.

Consideration of the transformations of small molecules with activated Fe–BLM[9a, b] provides additional support for the existence of a BLM–Fe^{V}=O species. Also, the absence of similarities between the DNA cleavage pattern produced by Fe–MPE, a well-known producer of hydroxyl radicals and that produced by Fe–BLM (see Sections 3.4.2 and 3.4.4) indicates that Fe–MPE and Fe–BLM do not share a major common oxidative pathway for DNA cleavage, and that the free hydroxyl-

radical can be excluded as a major reactant for Fe–BLM-induced cleavage.[98a]

The nondiffusible activated BLM species, two redox equivalents above the nonactivated Fe^{III}–BLM, is formulated as BLM–Fe^{V}=O, and is capable of H abstraction from deoxyribose to give a carbon-centered radical. The resulting BLM complex, BLM–Fe^{IV}–OH, is still a strong oxidant (one redox state above that of the initial Fe^{III}–BLM) and may react with the generated carbon-centered radical to produce a hydroxylated derivative by a typical P-450 model route (oxygen-rebound mechanism[89a]) (Scheme 8, route a). But, as was recently

Scheme 8. Three possible oxidative pathways for BLM or Porph complexes (M = Fe or Mn): a) P-450 route; b) diverted P-450 route; c) peroxidase route. **I** is equivalent to the so-called "compound I"; **II** is equivalent to "compound II".

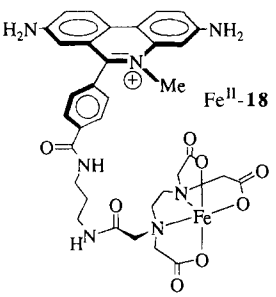
demonstrated on DNA,[99] the incorporated oxygen atom comes from the solvent. Thus this result points to an alternative possibility: activated BLM in the second step of the reaction can behave like a peroxidase (see classical mechanism in Scheme 8, route c), mediating an electron abstraction rather than transfer of an OH entity (diverted P-450 route, see Scheme 8, route b). Then, a water molecule can react with the generated carbocation and give the hydroxylated derivative.

Finally, little damage is detected on bases when DNA is incubated with Fe–BLM under conditions where DNA breaks are detected.[100] In 1993 it was reported that DNA can be cleaved by Ni^{III}–BLM if potassium monopersulfate is the oxidant.[101]

2.3.2. *Interaction with Nucleic Acids*

The association constant of Fe–BLM with duplex DNA is on the order of $10^5\ M^{-1}$.[102] BLM-mediated DNA cleavage is characterized by its sequence selectivity: most strand breaks occur at 5′-G-pyr sequences. In BLM, a small difference in the terminal amine chain and the absence of the gulose-mannose sugar moiety have a negligible effect on the sequence specificity of DNA cutting. Binding is mediated in part through electrostatic interactions, and probably also by intercalation or partial intercalation of the bithiazole moiety. Metallo–BLM probably binds in the minor groove of the B-DNA helix, where it covers 2 or 3 bp's on DNA. The 2-amino group of the guanine base adjacent to the 5′ side of the cleaved pyrimidine base is one key element of specific 5′-GC or GT recognition by the metallobleomycins; the bithiazole group probably plays an important role as an anchor on B-DNA.[103] Structurally altered DNA such as methylated DNA[104] or platinated DNA oligomers[105] may be relevant to changes in specificity or reactivity.

BLM produces double-strand breaks in DNA with a frequency far in excess of that expected from coincidence of single-strand breaks. The cleavage site on one strand is a pyrimidine in a 5′-G-pyr sequence, but in the complementary strand, the cleavage occurs at a site where single-strand cleavage is not common.[106] Both breaks result from specific attack on C4′.[107]



Attempts to modify the specificity of BLM have been undertaken by coupling BLM to oligonucleotides. The conjugates efficiently cleave the DNA at the GT sequence near the oligonucleotide binding site.[108]

Some studies have concluded that the cleavage of RNA is unlikely to be important for therapeutic action of BLM–Fe,[109] but other findings suggested the opposite.[81, 110] In spite of recent reports that RNA was not cleaved by BLM,[111] the three major classes of RNA have been shown to be degraded by BLM–Fe.[110, 112] RNA cleavage appears to be much more selective than DNA cleavage. While 5′-G-pyr-3′ sequences are also represented to a large extent among observed RNA cleavage sites, the cleavage seems to occur predominantly in single-stranded regions and at the junctions between single- and double-stranded regions. This suggests recognition of RNA tertiary structures, rather than recognition of specific sequences.

BLM has so far only been involved in C4′ deoxyribose oxidation (see Section 3.4.3 for details).

2.4. Fe–EDTA and Fe–MPE

Methidiumpropyl-EDTA (**18**, MPE, Scheme 9) is an early example of DNA-binding molecules able to target the redox activity of a metal ion like iron and to generate DNA breaks. It contains the DNA intercalator methidium, covalently bound by a short hydrocarbon tether to the metal chelator EDTA.[113, 114]

Fe^{II}-**18**

Scheme 9. Structure of the iron(II) complex of methidiumpropyl EDTA (**18**).

2.4.1. *Mechanism of Potentiation*

Both MPE and EDTA in the presence of iron(II) and molecular oxygen are able to break the backbone of DNA, probably by H abstraction from deoxyribose.[113, 115, 116] Fe–MPE cleaves plasmid DNA at a concentration two orders of magnitude lower (10^{-6} M) than Fe–EDTA (10^{-4} M). Addition of reducing agents such as dithiothreitol, sodium ascorbate, or NADH, which regenerate Fe^{II} from Fe^{III}, enables DNA cleavage at concentrations comparable to those used with bleomycin (10^{-8} M).[113]

Presumably in this mechanism, Fe^{II} reacts with O_2 to give Fe^{III} and $O_2^{\bullet-}$ [Eq. (5)]. The superoxide anion in protic media rapidly disproportionates to produce H_2O_2 [Eq. (6)]. Fe^{II} and H_2O_2 can then produce hydroxyl radicals by the known Fenton-type

$$Fe^{II}\text{–MPE} + O_2 \longrightarrow Fe^{III}\text{–MPE} + O_2^{\bullet-} \quad (5)$$

$$2O_2^{\bullet-} + 2H^+ \longrightarrow H_2O_2 + O_2 \quad (6)$$

chemistry [Eq. (7)].[113] When sodium ascorbate is used as reducing agent in the presence of dioxygen, a catalytic cycle is created, requiring lower concentrations of iron for DNA cleavage [Eqs. (5)–(8)].[115, 117]

$$Fe^{II}\text{-MPE} + H_2O_2 \longrightarrow Fe^{III}\text{-MPE} + HO^{\bullet} + OH^- \quad (7)$$

$$Fe^{III}\text{-MPE} + \text{reductant} \longrightarrow Fe^{II}\text{-MPE} \quad (8)$$

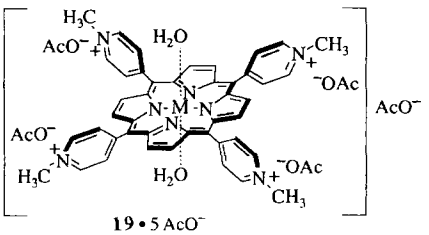
Superoxide dismutase, which depletes the system of free superoxide, and catalase, which disproportionates hydrogen peroxide into water and oxygen, are both able to inhibit the DNA cleavage mediated by Fe–MPE. This ability indicates the importance of free hydrogen peroxide as key intermediate in strand scission. Furthermore, in the absence of dioxygen no strand scission can be observed.[98, 113, 115] Because the concentration of the hydroxyl radical species decreases with distance from its point of formation, the decrease in the level of cleavage with distance from the position of the EDTA group is also consistent with a mechanism involving HO·.[118]

Fe^{III}–MPE was also examined for DNA-cleaving ability. Its direct oxidation with iodosylbenzene enhances cleavage of plasmid DNA. Whether this involves a perferryl species MPE–Fe^{V}=O or a coordinated hydroxyl species is still a matter of discussion.[9b, 98, 113]

2.4.2. *Interaction with Nucleic Acids*

Fe–EDTA is a negatively charged complex which does not associate electrostatically with DNA, so hydroxyl radicals cleave DNA with almost no sequence dependence.[98, 119, 120] This system is a useful reagent for footprints of proteins[117, 120, 121] or of small molecules (distamycin and actinomycin[122]), and can also provide information about DNA structures (unusual conformations adopted by the adenine tracts in DNA,[123] four-arm Holliday structures,[124] and bent DNA[116]).

Fe–MPE cleaves DNA in a relatively poor sequence-specific manner, which is not unexpected since the methidium unit is an intercalator of low overall base specificity. The only specificity known for this system is a slight preference for GC rich regions. Sequence specificity is significantly lower than that of DNase I, and the wide use of this reagent has proved to be very useful for many applications: for instance, the determination of the location, size, and relative importance of the binding sites of small molecules on native DNA[120, 125] or proteins on restriction fragments,[121, 126] and study of RNA[127] and chromatin[128] structures. For a discussion on the relative advantages of Fe–EDTA and Fe–MPE in footprinting experiments, see ref. [129]. The DNA-binding affinities of Ni^{II} and Mg^{II} complexes of MPE are similar to that of ethidium bromide (about $10^5\ M^{-1}$). The affinities of Fe^{II}–MPE or Fe^{III}–MPE cannot be determined, due to their efficiency as DNA cleavers. The binding site is probably a 2-bp site.[98]



The attachment of Fe–EDTA to sequence-specific DNA binding molecules such as antibiotics, polypeptides, oligonucleotides, or proteins provide new classes of "DNA affinity cleaving molecules" and is the basis for the design and construction of artificial restriction endonucleases with defined target sequences and binding-site sizes.[98, 130] Accordingly, hybrid molecules have been synthesized by associating EDTA with distamycin,[9i, 98, 131] a chiral derivative of netropsin,[130, 132] oligopeptides,[119, 133] or oligonucleotides, in order to cleave single-stranded DNA (or RNA) under mild conditions[118, 134] or double-stranded DNA (by triple helix formation).[135]

The chemistry of Fe–EDTA complexes with DNA will be detailed in Section 3.4.4.

2.5. Cationic Metalloporphyrins

2.5.1. *Mechanism of Potentiation*

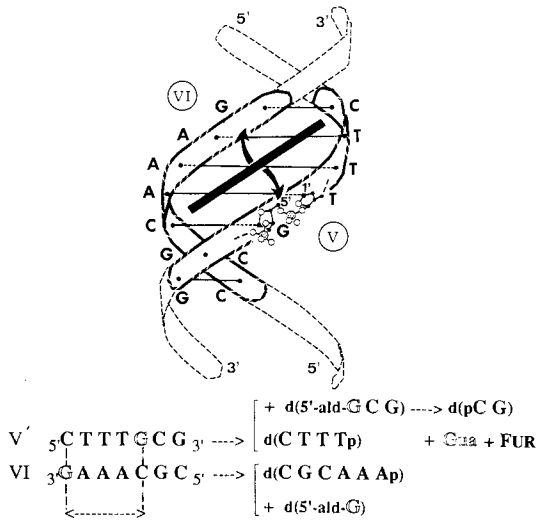
Synthetic metalloporphyrins are able to mimic oxygenation and oxidation reactions mediated by heme enzymes.[90a] Beside this mode of reactivity, iron or manganese porphyrins with peripheral positive charges, for example, Fe– or Mn–*meso*-tetra(4-*N*-methylpyridiniumyl)porphyrins **19** (Fe–TMPyP, Mn–TMPyP, Scheme 10; for crystallographic data on Mn–TMPyP see ref. [136]), exhibit strong interaction with DNA

19 • 5 AcO^-

Scheme 10. Structure of M–TMPyP pentaacetate (M = Fe^{III} or Mn^{III}) [136].

that brings a powerful oxidizing species into the vicinity of the target. The active oxidative species in the case of DNA cleavage is probably the same as that involved in catalytic oxygenation and oxidation reactions described for metalloporphyrins in general, namely, an oxoporphyrinato complex with the metal in a high oxidation state and able to hydroxylate a C–H bond or to epoxidize an olefin.[90a] This active species is generated in the presence of oxygen atom donor compounds like iodosylbenzene,[137] hydrogen peroxide,[138a] potassium monopersulfate,[138a–b, 138d] or magnesium monoperphthalate.[138c] Another way to generate oxo-metalloporphyrins is to use molecular oxygen associated with an electron source, as does cytochrome P-450.[89a, 137, 139] The most efficient method of oxidative cleavage of DNA is the oxidation of cationic Mn–porphyrins by $KHSO_5$.[138, 140] Data on DNA cleavage by Mn^{III}–TMPyP/$KHSO_5$ suggest that diffusible radical species are not involved in the reaction, because the breaks are well-defined and H_2O_2 is at least three orders of magnitude less efficient in generating the active species leading to cleavage.[138a] The high-valent TMPyP–Mn^{V}=O is a monoreacting DNA cleaver (unlike bireactive biradicals of enediyne drugs).[138a] Catalytic activity can be observed only if it is protected from self-oxidation (leading to the chromophore bleaching) by strong interaction with its target. For example when the DNA/Mn–porphyrin ratio was high (75 μM bp/5 nM Mn-porphyrin), up to five SSBs per Mn–TMPyP molecule were observed.[138a] A proposed activation/reaction cycle is presented in Scheme 8. The high-valent

TMPyP–Mn^{V}=O species that cleaves DNA is too reactive to be characterized. As discussed in Section 2.3.1 for high-valent BLM–Fe^{V}=O, neither P-450 (route a in Scheme 8) nor "diverted P-450" (route b) reactivity has been established for this compound. Whether the activated intermediate TMPyP–M^{IV}–OH oxygenates the DNA substrate directly by the rebound of the "HO equivalent" (route a) or by an electron transfer (route b) is still unknown. Studies of the source of O atom incorporated in DNA sugars would help answer this question (see Section 2.3.1).[99]



Electrochemically activated Mn^{III}–TMPyP and Fe^{III}–TMPyP have been used for DNA cleavage in the presence of O_2.[141] The mechanism of activation and cleavage in this case is potentially relevant to reports on chemical activation. Photochemically activated porphyrins are also able to cleave DNA,[142] probably by singlet oxygen production.

2.5.2. *Interaction with Nucleic Acids*

Mn–TMPyP belongs to a class of cationic metalloporphyrins that do not intercalate between DNA base-pairs but instead bind in the minor groove of AT-rich regions of DNA.[140, 141, 143] The Mn–porphyrin framework is devoid of any H-bonding donor/acceptor capacity and intercalation is precluded by the presence of an axial ligand on manganese.[136] Thus the ability of Mn–TMPyP to select AT-rich regions of DNA is apparently electrostatic or steric in origin. It has been proposed that this cationic metalloporphyrin is attracted by the high negative potential at the surface of the minor groove[144] of A · T-rich sequences. A close contact with the minor groove is necessary to improve the binding interaction and the cleaving efficiency of the metalloporphyrin, as deduced from studies on variations in total charge and in charge distribution at the macrocycle periphery.[143a–c, 145] At high ionic strength, the reagent is unable to bind or cleave DNA.[138a, 146]

Considering the size of Mn–TMPyP, it could span over five to six base-pairs in the minor groove of B-DNA, but the preferred cleaving site consists of three consecutive AT base-pairs creating a suitable "box" for highly selective DNA cleavage.[137, 138d, e, 143a, d] At this site Mn–TMPyP strictly mediates C5′ oxidation on nucleosides on both 3′ sides of the AT box:[147] one single-strand break on each strand leads to double-strand cleavage with a four base-pair shift to the 3′ end of the opposite DNA strand (Scheme 11). So far, there is no definite proof that such a cleavage pattern results from two SSBs by the same metalloporphyrin activated twice in the minor groove, or that it is effected by two different activated metalloporphyrins. On large DNA substrates, SSBs prevail[138a] and on oligonucleotides substrates (with one or two "AT boxes") DSBs are easily obtained.[147] Besides cleavage at $(A \cdot T)_3$ cleaving sites, some secondary reaction sequences are also noted, in which any one of the A · T pairs is replaced by a G · C base-pair.[143a] This secondary reactivity is particularly noticeable under drastic cleaving conditions[147] and is one order of magnitude less than that for $(A \cdot T)_3$ sites.

Mn–TMPyP is also able to degrade G · C-rich sequences with a reactivity two orders of magnitude weaker than the degradation of $(A \cdot T)_3$ sites. The mechanism of DNA lesions in these regions of DNA is not fully understood and may involve

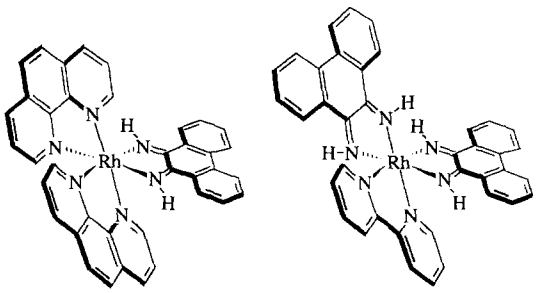
Scheme 11. On using the Mn–TMPyP/$KHSO_5$ system the scission on the two strands of duplex V/VI shows a 4 bp shift (dashed double-headed arrow, bottom left) in direction of the 3′-ends. This is shown by analysis [147] of the cleavage products (bottom right).

sugar oxidation (C5′ or C1′) and/or base oxidations. Affinity constants of up to $10^7\ M^{-1}$ have been published for Mn–TMPyP at the $(A \cdot T)_3$ binding site.[138e] Other values ($10^5\ M^{-1}$ for A · T sequences and $10^3\ M^{-1}$ for G · C sequences) have also been reported.[148]

Hybrid molecules based on a metallotris(methylpyridinioyl)porphyrin moiety attached to oligonucleotides have been prepared, and were shown to selectively cleave a single-stranded 35-mer DNA corresponding to the initiation codon region of the *tat* gene of HIV-1.[149]

The mechanisms of DNA cleavage by Mn–TMPyP through C1′ and/or C5′ oxidation are described in Sections 3.1.3 and 3.5.2, respectively.

2.6. Photoactivated DNA Cleaving Agents: The Case of Phenanthrenequinonediiminerhodium(III) Complexes



A number of studies have focused on the use of metal complexes or drugs to design spectroscopic DNA probes or photoactivated DNA cleaving agents.[150a–d] Photoactivation promotes strand cleavage only for some of these molecules.[150e] As well as metalloporphyrins or enediynes (Sections 2.5.1 and 2.2), a range of simple inorganic octahedral molecules are also capable of inducing single-strand scissions by photoexcitation of different absorption bands. This cleavage is induced by metal complexes known to bind to DNA principally in two noncovalent modes: 1) a groove-binding mode stabilized by hydrophobic interactions of the ligands with the major or the minor groove of DNA[150e, 151] and 2) intercalation.[152] For some of these photoactivatable complexes, the exact mode of DNA binding is still a matter of debate.[153] Rhodium,[154] ruthenium,[155] and cobalt[156] complexes have been used as cleaving agents for probing nucleic acid conformation and for the recognition of specific sites on a DNA strand.

Recently, a precise mechanism involving oxidative attack on the C3′–H bond of deoxyribose has been deduced for phenan-

threnequinonediiminerhodium(III) complexes and will be discussed in detail in this review.

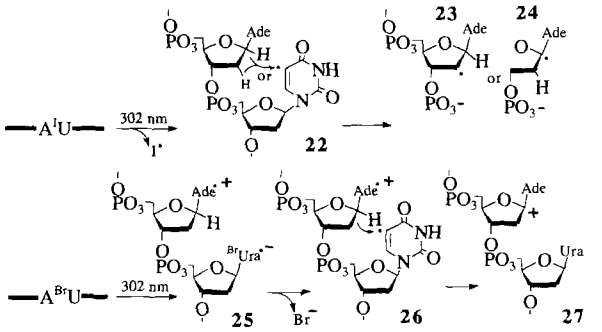
2.6.1. *Mechanism of Potentiation*

The production of sharp and well-defined gel bands after the cleavage of restriction fragments or oligonucleotides suggest that DNA strand scission by photoactivated rhodium complexes is not mediated by a diffusible oxidant. The cleavage appears to involve a species that is generated precisely at the binding site and induces strand scission of DNA at that site. Irradiation of the rhodium complex at the wavelength of the ligand-to-metal charge transfer band (LMCT) leads to an excited state with a lifetime in the μs range. The active radical species from **20** and **21** (Scheme 12) that cleave DNA is likely to be the radical cation of the phi ligand that is intimately bound to DNA and is formed by the LMCT band irradiation. The position of the phi radical cation in the site enables a fast H abstraction from the deoxyribose ring, initiating the cleaving reaction.[157]

$Rh^{III}(phen)_2phi$ **20** $Rh^{III}(phi)_2bpy$ **21**

Scheme 12. Structures of the (9,10-phenanthrenequinonediimine)rhodium(III) complexes **20** and **21**.

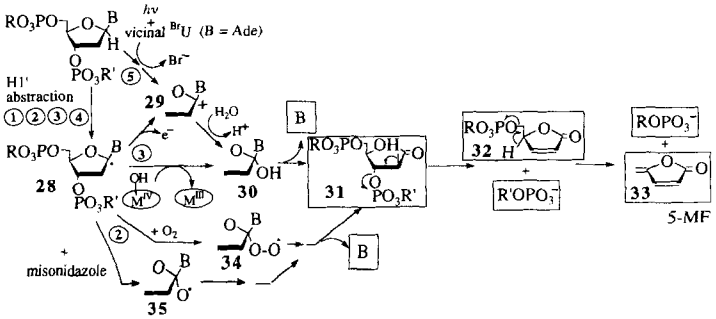
2.6.2. *Interaction with Nucleic Acids*



Upon photoactivation, the diphenanthroline complex **20** cleaves double-stranded DNA at 5′-pyrimidine–purine steps and in particular at the consensus sequence 5′-pyrimidine–purine, while **21**, despite containing ancillary imines for potential hydrogen bonding, cleaves DNA efficiently but in a generally sequence-neutral fashion. The asymmetry in the cleavage pattern to the 5′ side on each strand suggests that the rigid complex attacks B-DNA from the major groove of the helix. Given the propensity of the phi ligand for intercalation, **20** should contain the phenanthroline ligands in ancillary, nonintercalative positions along the groove, while for **21** one phi and one bpy should occupy the ancillary sites.[154a] NMR studies have recently provided direct structural evidence for specific intercalation of the octahedral chiral complex *Δ*-**20**, and indicate a preferential partial intercalation of the phi ligand whereas the phenanthroline ligands bind in ancillary positions.[158] Intercalation through the major groove is consistent with results of mechanistic studies on DNA cleavage by rhodium complexes, which demonstrate that H3′ abstraction is the initial step (see Scheme 16 and Section 3.3). Photocleavage experiments indicated enantioselective targeting of the 5′-CG step by *Δ*-**20**.

3. Hydrogen Abstraction from Different Positions of Deoxyribose, Leading to DNA Cleavage[159]

Each deoxyribose unit of DNA contains seven C–H bonds as possible targets for oxidative activation; four of them are located in the minor groove and three in the major groove (see Scheme 1). For all the chemical nucleases and drugs presented (in Section 2) a common initial step consists of one H abstraction, leaving the relevant carbon on the sugar as a radical species. We present here the manner in which this initial lesion leads to DNA cleavage under the different experimental conditions used in accord with the experimental evidence for the proposed mechanisms.



3.1. H1′ Abstraction: Cu(*o*P)$_2$, NCS-Chrom, Mn-TMPyP, and Halouracil-Containing Nucleotides

H1′ abstraction has been described for oxidative attack on DNA by Cu(*o*P)$_2$ (**1**), NCS-chrom (**2**), and Mn–TMPyP (**19**, M = Mn), producing a C1′-centered radical **28** (see Scheme 14). Photoreaction of 5-halouracil-containing oligonucleotides gives rise to C1′- or C2′-centered radicals (**23** or **24** in Scheme 13,

Scheme 13. Proposed reaction mechanisms for oxidative attack at C1′–H and C2′–H bonds in the case of halouracil-containing oligonucleotides [159].

respectively) via **22** or, alternatively, via **25** and **26** to the 1′ cation **27** (Scheme 13; see also **29** in Scheme 14). Usually, the next key steps of the DNA cleavage reaction (Scheme 14) are 1) the release of base associated with the formation of the oxidized abasic derivative **31**, 2) the first *β*-elimination inducing the

Scheme 14. Proposed reaction mechanisms when the initial site of attack by the oxidizing agent is at C1′ of the deoxyribose [159]. (①: **1**, ②: **2**, ③: **19**, ④: vicinal ^{I}U, ⑤: vicinal ^{Br}U)

strand break that leaves a 5′-phosphate end and a metastable α,β-unsaturated lactone (**32**) at the 3′ end, 3) the second and fast β-elimination allowing the recovery of the 3′-phosphorylated-ending DNA fragments and 5-methylene furanone (**33**) as the main sugar residue. Depending on the nature of the DNA cleaving agent, different aspects of this general cleavage pathway are more pronounced than others. C1′ chemistry for Fe^{II}–EDTA, Fe^{II}–MPE, and related compounds is considered to account for some experimental results; this point is briefly presented in Section 3.4.4.

3.1.1. $Cu(oP)_2$

Analysis of the products of DNA cleavage by $Cu(oP)_2$ (**1**) and hydrogen peroxide showed that phosphomonoesters are present at both the 5′ and 3′ termini (3′-phosphomonoester termini are the potent inhibitors of *E. coli* DNA polymerase activity, which provided the first evidence for the DNA scission reaction[15a, 15d]) and that bases are also released; the cleavage was proposed to occur by initial oxidation of the deoxyribose to a resonance-stabilized furan derivative.[29a] Later, under conditions where no reductant was used as coreactant, 5-methylene-2-furanone (**33**) was identified.[160] A possible reaction pathway that could accommodate the formation of these products from C1′ radical **28** is summarized in Scheme 14. The putative intermediate **32** at the 3′ terminus was observed by polyacrylamide gel electrophoresis (PAGE) during the cleavage reaction of a synthetic dodecamer and a restriction fragment containing the lactose control region.[28] No other information exists about intermediate steps except that the cleaving activity does not require the presence of molecular oxygen.[17]

The C1′ oxidation pathway accounts for 80–90% of the scission events induced by **1** (10–20% are related to cleavage chemistry at C4′, see Section 3.4.1).[15b] The relative importance of the two pathways, suggestive of a different rate of attack at two locations, depends on the DNA sequence,[28] as demonstrated by determination of the ratio of 3′-phosphoglycolate (attack at C4′) to 3′-phosphate (attack at C1′).

3.1.2. NCS-Chrom

C1′ chemistry occurs particularly at the *C* residue of double-strand lesion sites such as 5′-AG*C*/3′-TCG sequences,[9d, 71, 161] where it represents the major pathway of attack (72%), although some minor chemistry at C4′ or C5′ was also noted.[66a, 71] It is always accompanied by a strand break on the complementary 3′-*T*CG strand, where C5′ of the T residue is attacked. So, double-strand cleavage consists of a two-nucleotide 3′-stagger of the cleaved residues that represents the classic 3′-shift mediated by the NCS-chrom activated biradical **4** derived from **2** (see also Section 3.4.2). One important feature of this cleavage is the strong preference for glutathione (over neutral thiols, ME or DTT) in the C1′ chemistry induced by **2** (see Section 2.2.2.1).

Since the nucleolytic activity of **2** is dependent on the presence of molecular oxygen, a peroxy radical (**34**, Scheme 14) is probably involved initially with subsequent conversion into the oxidized intermediate **31** with concomitant release of base. Such oligonucleotides (**31**), observed on polyacrylamide gels,[161] migrated slightly faster than the full-length DNA and were transformed to the corresponding phosphate-ending fragments upon alkali treatment. DNA fragments carrying the α,β-unsaturated lactone **32** at their 3′ end (one β-elimination from **31**) were also seen on polyacrylamide gels of 5′-[^{32}P]-labeled oligonucleotides;[66a, 71] they migrated ahead of the corresponding 3′-phosphate-ending fragments. After enzymatic digestion of intermediate **31**, 2-deoxyribonolactone generated by the release of cytosine was isolated and characterized.[162] But 5-MF (**33**), the expected end-product of this reaction chain, was never observed because of the presence of reducing cofactors. When $NaBH_4$ was used as an activator for **2**, alkali-dependent breakage at the C residue was not prevented, which indicated that $NaBH_4$ is not able to reduce the oxidized intermediate **31**.[161] In addition, by careful examination of 5′-[^{32}P]-labeled DNA fragments through PAGE analyses, new bands could be observed with smaller mobility than that of the corresponding phosphate bands. These bands, which are converted into the 3′-phosphate-ending bands by piperidine treatment, were attributed to the adduct (Michael addition) between thiol and the 3′-terminal, α,β-unsaturated lactone **32**.[66b, 163] The mobility of this thiol adduct varies with the structure of the thiol.[66b] Such bands were also observed in the case of C4′ chemistry of **2** (see Section 3.4.2).

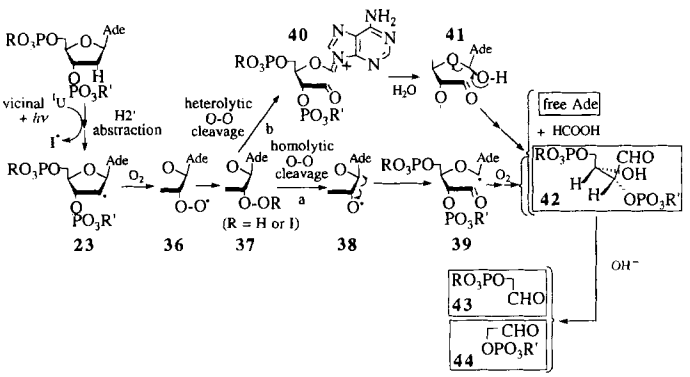
Under anaerobic conditions misonidazole can replace dioxygen for the production of the alkali-labile lesion at the C residue.[161] The mechanism is not fully understood: the question whether an oxy radical (**35**) or a peroxy radical (**34**) is involved as intermediate is still open (see Section 3.4.2).

Direct evidence for H1′ abstraction was also provided by experiments where H1′ was replaced by deuterium. Values of $k_H/k_D \approx 4$ for the deuterium isotope effect were determined from studies of alkali-induced cleavage of oxidized abasic derivatives (**31**).[71] Deuterium abstraction studies of the reacted chromophore (monitored by ^{1}H NMR spectroscopy) also indicate that the C2 of **2** is involved in the attack at the C residue of a 5′-AG*C* sequence.[54a]

3.1.3. Mn–TMPyP

The following stable reaction products were identified from several DNA and oligonucleotides cleavage reactions with Mn–TMPyP/$KHSO_5$: 5′- and 3′-phosphorylated termini, free bases, and 5-methylene furanone **33**.[164] The mechanism proposed to explain the formation of the product 5-methylene furanone is hydroxylation of C1′ as indicated in Scheme 14. The cleavage does not require the presence of molecular oxygen (M. Pitié et al., unpublished results). Two hypotheses (Schemes 8 and 14) may explain the evolution after the initial lesion: 1) the radical centered at C1′ (**28**) might be reoxidized by the Mn^{IV}(OH)-porphyrin by one-electron abstraction, giving the carbocation **29** that reacts with water and produces the 1′-hydroxylated derivative **30** ("diverted P-450 route" in Scheme 8, route b) or 2) the radical is directly hydroxylated by the Mn^{IV}(OH)porphyrin (cytochrome P-450 chemistry, see route a in Scheme 8 and Section 2.5.1). So far, neither the oxidized oligonucleotides **31** containing the abasic site nor oligonucleotides **32** bearing the α,β-unsaturated lactone have been observed except indirectly through their ultimate reaction product **33**.

With Mn–TMPyP/$KHSO_5$ as cleaving reagent, C1′ is the main oxidation target for single-stranded or GC-rich double-stranded DNA, but only a minor target for AT-rich sequences containing DNA (C5′ becomes then the main target, see Section 3.5.2).[164b]



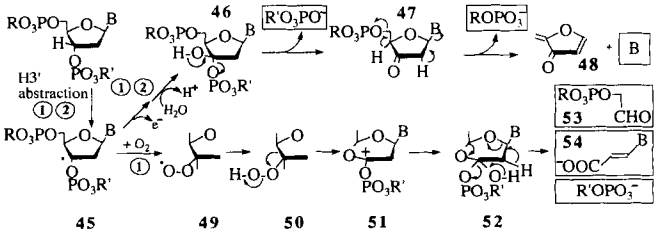
3.1.4. Halouracil-Containing Oligonucleotides

In an attractive hypothesis, formation of the 1′ cation **27** could occur in the UV-photoreaction of small oligonucleotides containing the 5′-A^{Br}U sequence (see Scheme 13). After an intramolecular electron transfer from adenine at the 5′ side to the adjacent ^{Br}U, the resulting ^{Br}U anion radical **25** would release a Br^- anion to produce a uracilyl radical **26**, which could then abstract the adjacent C1′ hydrogen atom of the deoxyadenosine radical cation to give rise to the 1′ cation **27**. Addition of another water molecule, loss of a proton, and release of the base (Scheme 14) would give the deoxyribonolactone derivative **31** (oxidized abasic site) which has been detected by HPLC and transformed to the corresponding phosphate-ending fragments upon treatment with hot NaOH. Without treatment with alkali and after enzymatic digestion of the oligonucleotide **31**, 2-deoxyribonolactone (with concomitant release of Ade) was isolated and characterized by spectroscopic and chemical methods.[165] The expected product 5-MF (**33**) coming from reaction of the oxidized abasic site of **31** was not observed, probably because of its instability under the experimental conditions (hot alkali treatment).

Photoreaction of 5-iodouracil-containing oligonucleotides[166] proceeds by an entirely different mechanism, which postulates competition between C1′ and C2′ oxidation products of the sugar residue at the 5′ side adjacent to the iodouracil residue. The sequence of events is indicated in Schemes 13 and 15. Photoreaction of ^{I}U proceeds by homolytic cleavage of the C5-I bond of uracil; the resulting uracilyl-5-yl radical (**22**, see Scheme 13) competitively abstracts the C2′ (→ **23**) or C1′ (→ **24**) hydrogen atoms of the deoxyribose at the 5′ side of ^{I}U. The C1′ and C2′ oxidation products **31** and **42** were observed (Schemes 14 and 15, respectively).

3.2. H2′ Abstraction: Iodouracil-Containing Nucleotides

While the chemistry of DNA damage resulting from H abstraction at C1′, C3′, C4′, and C5′ of the DNA deoxyribose is well documented, the DNA lesion resulting from H abstraction at C2′ has been scarcely studied. Characterization of erythrose-containing sites arising from H· abstraction at C2′ was only reported as one of the major types of damage induced by γ-radiolysis of DNA.[167] Very recently another example of deoxyribose C2′ oxidation in DNA was described during photoreaction of various 5-iodouracil containing oligonucleotides,[166] C2′ oxidation products were isolated directly for the first time. The proposed mechanism (Scheme 15) involves the peroxy radical **36**, which could be converted by homolytic cleavage of the O–O bond (via **37**, pathway a) into the oxy radical species **38**. β-Scission leads to **39**. The formation of the oxy radical from peroxy radical in double-stranded lesions of DNA by fragmentation of an O_4 bridge across the minor groove has been invoked

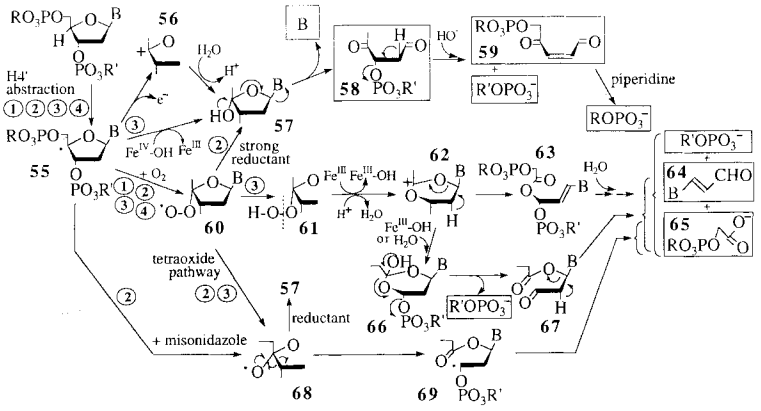


Scheme 15. Proposed reaction mechanisms when initial site of attack by the oxidizing agent is at C2′ of the deoxyribose [159].

for enediyne compounds (Sections 3.4.2, 3.5.1). But in the present case, combination of two C2′ peroxy radicals of A residues of 5′-A^{I}U/3′-A^{I}U does not seem sterically possible. Further reaction of **39** with molecular oxygen produces **42**, accompanied by the release of adenine. Alternatively, heterolytic cleavage of the O–O bond, perhaps favored by the formation of an R′OOI (pathway b), would also produce **42** via intermediates **40** and **41**. Under alkaline conditions the unstable compound **42** is cleaved and gives rise to fragments containing phosphoglycolaldehyde termini (**43** and **44**) by a retroaldol reaction. Compounds **42**, **43**, and **44** have been characterized, but the exact route of their formation remains to be elucidated.

3.3. H3′ Abstraction: Rhodium Complexes 20 and 21

Extensive studies have focused on DNA photocleavage by several photoactivated DNA cleaving agents. Among them, the phenanthrene-quinonediimine complexes of rhodium(III) (**20** and **21**) have received particular attention in terms of molecular mechanisms of DNA cleavage (Scheme 16).[154a, 157] While the complexes have similar photochemical properties, overall binding modes, and affinities, their cleavage patterns indicate different recognition characteristics (see Section 2.6.1.2), which may be understood based on the different molecular shapes of these two complexes. The shape of these compounds also governs the chemistry of strand scission. Because both complexes yield oligomers containing 3′- and 5′-phosphate termini and nucleic acid bases as primary products the sugar units seem to be reaction sites.[154a] For **21** these oligomeric products account for approximatively 70% of the reaction, but, in addition, base-



Scheme 16. Proposed reaction mechanisms when initial site of attack by the oxidizing agents (①: **21**, ②: **20**) is at C3′ of the deoxyribose [159].

substituted propenoic acids (**54**, so-called base propenoic acids) and oligomers **53** with a 3′-phosphoglycolaldehyde terminus are obtained (the remaining 30% of reaction).[157] The products obtained are consistent with photoreaction of rhodium complexes intercalated in the major groove of DNA, where the bound complex has a direct access to H3′. So the first step proposed is H3′ abstraction. This fact has been confirmed by using specifically tritiated DNA.[157] In an oxygen-independent pathway, C3′ radical **45** is converted into the 3′-hydroxylated compound **46**, probably by one electron abstraction by the rhodium complex (the excited state of this complex might be sufficiently oxidizing) and subsequent attack of a water molecule on the 3′ carbocation. Elimination of the 5′-phosphorylated end provides **47** (with ketone end group), which gives rise, by two successive β-eliminations, to the 3′-phosphorylated end, free base, and 2-methylene-3-furanone (**48**). In an oxygen-dependent pathway, the 3′ radical **45** gives, successively, peroxy radical (**49**) and a hydroperoxide derivative (**50**), which provides in several steps **51** and **52** (Criegee type rearrangement), the compound with 5′-phosphorylated terminus, a phosphoglycolaldehyde (**53**) and a base propenoic acid (**54**). So far, the search for any metastable intermediates, as have been seen for other carbon targets of deoxyribose, was unsuccessful.

C3′ chemistry might be invoked in DNA cleavage by Fe^{II}–EDTA and some related compounds to explain some experimental results; this point will be briefly presented in Section 3.4.4.

3.4. H4′ Abstraction: Cu(*o*P)$_2$, Enediynes, BLM, and Fe–EDTA/MPE

H4′ abstraction has been proposed as the common first step of the oxidative attack at C4′ by NCS-chrom (**2**), CAL (**5**), BLM (**17**), Cu(*o*P)$_2$ (**1**), and Fe–MPE (Fe–MPE) (Scheme 17). The resulting radical intermediate **55** can either be hydroxylated at C4′ (**57**) to yield, after cleavage, a 5′-phosphorylated terminus and a 3′-terminus bearing the sugar residue (**59**) or add an oxygen molecule to form a peroxy radical (**60**), which by different pathways can give rise to base propenal **64**, 3′-phosphoglycolate **65**, and compounds with 5′-phosphorylated termini. Partitioning between these two main pathways depends on the O_2 concentration and the nature of the cleaving DNA molecules and their activating cofactors.

Scheme 17. Proposed reaction mechanisms when initial site of attack by the oxidizing agent (①: **1**, ②: enediynes, ③: M-**17**, ④: Fe-**18**) is at C4′ of the deoxyribose. Final product **64** has never been observed for cleavages by **1** and Fe-**18** and could not be characterized for cleavages with enediynes [159]. The C4′-hydroxylated **58** is represented in its open-chain form.

3.4.1. Cu(*o*P)$_2$

Electrophoretic analyses of the scission of 5′- and 3′-[^{32}P]-labeled oligomers and large DNA fragments give important insights into the chemistry of the DNA strand scission by Cu(*o*P)$_2$ (**1**). The 3′- and 5′-phosphomonoesters are the main termini generated by this complex and are generated by C1′ oxidation chemistry (see Section 3.1.1 and Scheme 14). In addition, the 3′-phosphoglycolate products **65** are indicative of C4′ oxidative chemistry (Scheme 17).[15b, 28] Whereas ^{60}Co irradiation (another way for H1′ or H4′ abstraction) generates equivalent amounts of 3′-phosphomonoesters and 3′-phosphoglycolates,[28, 168] the amount of 3′-phosphoglycolate produced in cleavage mediated by **1** is substantially less than that of the 3′-phosphomonoester; C4′ chemistry is thus only a minor oxidation pathway. So far, no base propenal **64** or other fragments from sugars with three or five carbon atoms could be isolated, so the exact pathway from the C4′ radical **55** to the phosphoglycolate **65** is still unknown, and the mechanism remains to be proven (see also Sections 3.4.2 and 3.4.4).

3.4.2. Enediynes

3.4.2.1. NCS-Chrom

H4′ abstraction from deoxyriboses was mainly detected at T residues of 5′-G*T* steps on synthetic oligonucleotides.[64, 169, 170] Further studies revealed that this minor mechanism of DNA oxidation predominantly occurs in staggered double-strand lesions at the *T* residue of 5′-AG*T*/3′-TCA sequences.[46b, 171] But NCS-chrom (**2**) may shuttle between H4′ and H5′ abstraction at the same *T* residue, depending on the thiol,[64, 170] deuteriation,[64, 170] or the sequence of DNA.[66b] On the opposite strand at 5′-AGT/3′-*T*CA sites, the cleavage of *T* is due mainly to H5′ abstraction, but a shift to 4′ chemistry[66b] cannot be excluded.

The products from C4′ chemistry of **2** (Scheme 17) are the 4′-hydroxylated abasic derivative **58** (alkali-labile site) and the 3′-phosphoglycolate **65** (direct DNA break); both are derived from the common 4′-carbon-centered radical **55**. Unlike BLM complexes (see Section 3.4.3)[64] the base propenals **64**[9d, 66b] or malonaldehyde-like compounds containing C1′ and C2′ of deoxyribose[172] have been mentioned but have not yet been clearly described. Moreover, the fate of radical **55** does not depend on O_2 concentration (O_2 is involved in the production of both types of lesions) but is dependent on the nature of the **2**-activating thiol and on the type of lesion (SSB versus DSB). More phosphoglycolates occur at double-strand lesions sites.[46, 66b] Acidic or negatively charged thiols (that have low affinity for DNA, such as GSH and MPA) afford the greatest extent of phosphoglycolate production, but thiols with high reducing efficiency or ability to donate H· (which depends on the stability of the generated sulfanyl(thiyl) radical) did not induce 3′-phosphoglyco-

late production. So, the partitioning between the two routes involves a reduction-sensitive DNA intermediate. When this intermediate is reduced, the 4′-hydroxylated abasic **58** is formed; otherwise phosphoglycolates **65** are produced. The intermediate could be the peroxy radical **60** or the oxy radical **68**.

If the reduction-sensitive intermediate is the C4′-peroxy radical **60**, an easy reduction to the hydroperoxide **61** (by the reductant itself or by intramolecular H· donation[64]) would give the phosphoglycolate precursor (Criegee-type rearrangement) usually proposed.[57, 173] But, in the presence of a strongly reducing thiol, this peroxy radical intermediate may be preferentially converted into the 4′-hydroxylated precursor **57** of the 4′-hydroxylated abasic derivative **58**.

A second hypothesis, favored by Goldberg and co-workers, is that the reduction-sensitive intermediate is the C4′-oxy radical **68**. If this radical is reduced to the C4′-hydroxylated compound **57**, it gives rise to the 4′-hydroxylated abasic **58**. If not, it should rearrange to the phosphoglycolate[46b] by the classical β-scission of the oxygen radical mechanism (via **69**).[174] The same mechanism is also invoked in Sections 3.2 and 3.5.1.1 to explain experimental findings. Three features make the oxy radical the better candidate for phosphoglycolate production: 1) the predominance of phosphoglycolates at DSB sites could be explained by the formation and subsequent Russel fragmentation of a putative O_4 bridge across the minor groove [Eq. (9)];[46, 64, 174, 175] 2) in the case of cleavage by **2** of DNA,

$$2\,ROO^{\cdot} \longrightarrow ROOOOR \longrightarrow 2\,RO^{\cdot} + O_2 \qquad (9)$$

a Criegee-type rearrangement of the peroxide does not seem feasible (absence of metal, nonacidic conditions),[9d, 176] 3) when misonidazole replaces dioxygen to trap the carbon-centered radical **55**, the oxy radical **68** is formed directly, and the percentage of phosphoglycolate **65** increases.[46b, 64, 66]

Experimental evidence for C4′ oxidation on DNA cleavage by **2** is provided by the following experimental evidence: 1) HPLC monitoring of the oligonucleotide **58**, that has the full length but the 4′-hydroxylated abasic site.[169] The structure of this alkali-labile lesion was established by characterization of the pyridazine derivative that is formed by hydrazine treatment, and by comparison of the HPLC retention time of such oligonucleotides after their reduction to diols (two diastereoisomers) with that of a synthetic (*R*) isomer standard.[169] 2) PAGE analysis of 5′-[^{32}P]-labeled oligonucleotides ending with 3′-phosphate, 3′-phosphoglycolates (**65**), and intermediate **59**.[170] This latter intermediate is not usually observed directly on polyacrylamide gels because of its sensitivity to electrophoresis conditions.[170] If the loading buffer pH is above 8 a second β-elimination can occur (especially during the heat denaturation step before sample loading), transforming the band of **59** into the corresponding 3′-phosphate band. A nonambiguous quantification of 4′-alkali-labile oligonucleotides **58** can thus be done only after adding hydrazine to convert the **58** into a stable 3′-(3-pyridazinylmethyl)phosphate that will migrate slower than the corresponding Maxam–Gilbert sequencing marker[46b, 64] (see ref. [177] for details on this method). On the other hand, 3′-[^{32}P]-labeled substrates typically afford fragments ending with 5′-phosphate groups only after treatment with alkali.[46b] 3) Deuterium labeling at the 4′ position of deoxyriboses.[64, 170] The ratio of the kinetic isotope effect k_H/k_D was 4 for the glycolate formation and 3.7 for pyridazine formation (pathway via the 4′-hydroxylated abasic site).[64] When the kinetic isotope effect was analyzed at T sites of various G*T* steps, k_H/k_D ranged from 2.5 to 5.5.[170] 4) Gel chromatography. A minor band, slowly moving on polyacrylamide gels, was attributed to an adduct between the thiol used for the activation of **2** and the 3′-terminal unsaturated sugar **59** (Michael addition).[66b, 163]

3.4.2.2. CAL

H4′ abstraction from DNA sugars by CAL (**5**) was observed as part of a double-strand lesion at the frequent symmetric cleavage site 5′-GAT*C*CT/3′-*C*TAGGA. The oxidized bonds are the C5′–H bond of the *C* residue on the TCCT strand and the C4′–H bond of the *C* residue on the other strand.[12a, 55, 67b] The DNA cleavage products of the 5′-[^{32}P]-labeled AGGA strand consist of 3′-phosphoglycolates **65** (Scheme 17) and 4′-hydroxylated abasic derivatives **58**, which as pyridazine derivatives were resolved by PAGE analysis. No evidence for the production of base propenal has been reported. Interestingly, the formation of phosphoglycolate on one strand is always associated with C5′ chemistry on the complementary strand, supporting the involment of an O_4 bridge for glycolate production (Russel fragmentation, see Section 3.4.2.1).[46b, 55] Deuterium experiments followed by ^{1}H NMR spectroscopy showed that[12a] the deuterium atom on C4′ of the C residue in 3′-*C*TAGGA strand was transfered to the C3 position of the reduced CAL biradical **6** (see Scheme 4).

3.4.2.3. ESP

H4′ abstraction only occurs in double-strand lesions mediated by cleavers of the ESP family **8**–**10**. Phosphoglycolate **65**, the 4′-hydroxylated abasic derivative **59**, and the 3′-phosphate end have been identified on sequencing gels from 5′-[^{32}P]-labeled fragments of DNA.[57] In view of the structural similarity between ESP C (**8**) and CAL (**5**), the C7-centered radical of the activated drug **11** is assumed to abstract the H4′ atom (see Scheme 4). As was mentioned for C5′ chemistry (Section 3.5.1.3), no isotope effect was observed in this C4′ chemistry.[57]

3.4.3. Bleomycin

Two sets of products of DNA strand breaks by metallobleomycins (for example, **17**) have been identified, both of which involve oxidative destruction of the deoxyribose moiety. These products are now known in great detail: one set of products includes base propenals (**64**),[86, 178] 3′-phosphoglycolates (**65**),[179] and 5′-phosphate termini; the second set consists of free bases[180] and the evolution product from an alkali-labile lesion (4′-hydroxylated abasic derivative **58**).[177a] The proposed mechanistic pathway is outlined as ③ in Scheme 17.

As demonstrated by tritium and deuterium isotopic effects on H4′ abstraction,[9b, 181] the formation of both bases and base propenals is probably the consequence of a rate-determining C4′–H bond cleavage as the first step, followed by an oxygen-dependent partitioning of the intermediate **55**. The release of base requires no additional O_2 and is accompanied by the pro-

duction of an oxidatively damaged sugar **58**, which results in strand scission only in the presence of alkali (pH 12). The formation of base propenals **64** requires additional O_2 to that required to form "activated BLM", and is accompanied by spontaneous DNA strand scission and 3′-phosphoglycolate termini production. The magnitude of the 4′ isotope effect is not sensitive to changes in the partition ratio of the two proposed DNA cleavage pathways, but is sensitive ($k_H/k_D = 2-7$) to structural and electronic changes in the metal–BLM complex, underscoring the importance of favorable parameters in the orientation of the transition state.[182]

Results of cleavage of DNA deuteriated at other positions of the deoxyribose ring afford no isotope effect, suggesting high regiospecificity for the BLM-mediated C–H bond cleavage.[182]

Proposed mechanism for production of base propenals **64** *and 3′-terminal phosphoglycolate* **65**: Under aerobic conditions the 4′-radical **55** rapidly combines with O_2 to form a 4′-peroxy radical **60** at what is probably a diffusion-controlled rate.[183a] The fate of peroxy radical has been extensively studied.[9b, 183] It can undergo a wide variety of reactions including formation of O_4-containing compounds [Eq. (9)], H abstraction from reductants such as a thiol [Eq. (10)], and chain termination due to reduction by to low-valent transition metal ions [Eq. (11)].

$$ROO^{\cdot} + RSH \longrightarrow ROOH + RS^{\cdot} \quad (10)$$

$$ROO^{\cdot} + M^{II} \longrightarrow ROO^{-} + M^{III} \quad (11)$$

Thus the peroxy radical gives rise principally to the 4′-hydroperoxide **61**, and in some cases to the 4′-oxy radical **68**. The further conversion of 4′-hydroperoxide **61** has been proposed to occur by acid-catalyzed heterolytic cleavage of the peroxide O–O bond in a Criegee-type rearrangement. Instead of proton-catalysis, the Fe^{III}–BLM intermediate could act as a Lewis acid catalyst. A molecule of water or the putative iron-bound hydroxide could trap the carbocation intermediate **62** to give **66** and ultimately the dicarbonyl derivative **67** as a precursor to **64** and **65**.

Because of the stereospecific removal of the 2′-(*pro-R*) proton of deoxyribose and the fact that its release is kinetically more favorable than the release of base propenal from DNA,[178] an alternative pathway has been proposed: removal of the 2′-(*pro-R*) proton from the carbocation **62** and concomitant *anti*-elimination at O4′ would generate intermediate **63**. Further reaction yields propenal **64**, phosphoglycolate derivative **65**, and 5′-phosphate termini. This mechanism was confirmed by ^{18}O incorporation into the carbonyl group of **65** (in experiments carried out with $^{18}O_2$) and into the aldehyde group of **64** (in experiments carried out with $H_2{}^{18}O$).[173]

Proposed mechanism for release of nucleobases: The C4′ radical **55** may undergo a radical rebound mechanism analogous to that proposed by Groves and co-workers[89a] for P-450 systems (see also Scheme 8, pathway a) to produce the C4′-OH intermediate **57**. Alternatively, the radical **55** could be oxidized by BLM–Fe^{IV}–OH (electron transfer, see also Scheme 8 pathway b, and Section 2.3.1) to produce a C4′ carbenium ion **56**, which could then add water to give the C4′–OH intermediate **57**. This intermediate can collapse to produce free base and C4′-hydroxylated abasic **58**, represented here in its open form. In the presence of alkali, **58** could undergo a strand scission to afford 5′-phosphate termini and 3′ ends bearing an unsaturated oxidized sugar residue (**59**). A few years ago, oligonucleotides carrying this residue were observed in PAGE analyses of products from the BLM-mediated cleavage of a 5′-[^{32}P] DNA fragment.[170] Intermediate **59** was identified after 1) stabilization by $NaBH_4$ reduction, purification, and hydrolyses with P_1 nuclease and alkaline phosphatase to produce a mixture of *erythro*- and *threo*-2-deoxypentitols,[9b, 184] 2) reaction with NaOH to give a transient 2,4-dihydroxycyclopentenone,[177a, 185] and 3) treatment with aqueous alkylamines (for example, piperidine) to release 3′-phosphate termini.[177a] Reaction with hydrazine also allows quantitative detection of C4′-hydroxylated abasic **58** by transformation to 3′-(3-pyridazinylmethyl) phosphate termini.[177]

Attempts to define the source of oxygen in the oxygen carbohydrate moiety **58** (either molecular oxygen or water in the rebound or the electron transfer mechanisms) have been undertaken with ^{18}O labeled dioxygen or water.[9b, 99] The oxygen atom introduced in C4′ was derived almost exclusively from water, thus supporting the C4′-carbenium route.

The cleavage patterns observed during DNA strand scission mediated by photoactivated Co^{III}–BLM are dependent on the irradiation frequency but independent of O_2, and are very similar to those observed for Fe–BLM. They suggest that 3′-phosphoglycolate-modified ends,[186] free bases, and alkali-labile sites resulting in 3′-phosphate-modified ends [187] are produced. All the data are consistent with C4′ oxidation of deoxyribose, but the mechanism leading to the observed products has yet to be established unequivocally.

For the chemistry of RNA cleavage,[110–112] it has been suggested that Fe–BLM-mediated RNA degradation follows an oxidative pathway. Experimental data indicate release of bases concomitantly with RNA cleavage. In PAGE analysis, end-labeled RNAs give cleavage bands believed to have 3′-phosphoglycolate and 5′-phosphate termini. Due to the sensitivity of RNA to alkaline conditions (alkali-labile lesions cannot be detected easily) and to the difference in the sugar moiety of RNA and DNA (the postulated 2-hydroxylated base propenals are probably unstable if formed, and would hydrolyse fast to liberate bases), a molecular mechanism for RNA cleavage of the same type as for DNA cleavage has yet to be conclusively proven.

The question arises whether additional "minor" chemistry can occur in the degradation of DNA by BLM. H1′ abstraction analogous to that of H4′ has been postulated for DNA[188] and also for the DNA strand of an RNA–DNA heteroduplex.[189] While reasonable (in such a heteroduplex the opening of the minor groove leads to an enhanced accessibility of activated BLM to H1′ in addition to H4′), no evidence has been obtained for DNA degradation by a C1′ pathway.[190] Recently, modified self-complementary octadeoxyribonucleotides containing one ribo- or one arabino nucleoside at a position susceptible to oxidative degradation by Fe^{II}–BLM were found to afford products resulting from C1′ chemistry.[191]

It has also been demonstrated that activated BLM can induce damage to bases in a side reaction. The modified bases (such as 8-hydroxyguanine which was present in amounts about one-hundredth that of base propenal[85]) are identical with those

generated when hydroxyl radicals react with DNA. This finding suggests involvement of HO• in this reaction, probably through a partial decomposition of the oxo iron complex responsible for the main route of oxidative damage to C4′ of DNA.[100]

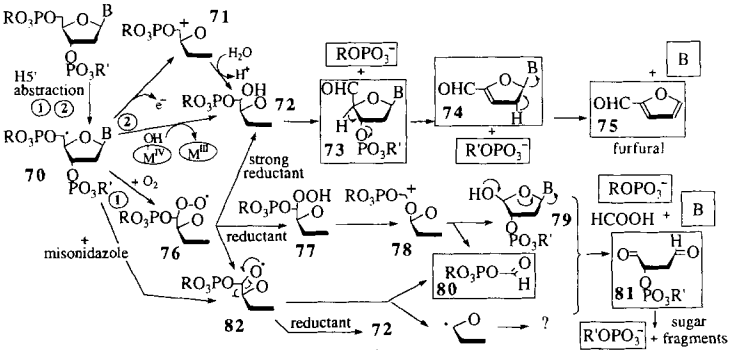
3.4.4. *Fe–EDTA, Fe–MPE, and Related Compounds*

The molecular mechanism of DNA cleavage by Fe–EDTA and derivatives in the presence of molecular oxygen or hydrogen peroxide has only been studied in detail for Fe–MPE. Little information on the mechanism of cleavage by Fe–EDTA itself is available;[98] generally it is assumed to be similar to that of Fe–MPE. Some particular aspects of the cleavage reaction have been described for hybrid molecules where Fe–EDTA is attached to sequence-specific DNA-binding molecules.

Although the mechanism of the DNA strand scission by Fe–MPE is still not understood in detail, some features have emerged.[98a] The products released from calf thymus DNA are the four nucleotide bases in a Ade + Thy/Gua + Cyt ratio in agreement with known DNA composition, which is consistent with the low specificity of Fe–MPE cleavage. Base release and strand scission are stoichiometric. The DNA termini at the cleavage sites are 5′-phosphates and roughly equal proportions of 3′-phosphates and 3′-phosphoglycolates. Few base propenals were detected: since β-mercaptoethanol (and probably also DTT) reacts with base propenals,[98a] these nucleoside residues would probably not be observed under these conditions even if they were formed.

All results are consistent with an oxidative degradation of deoxyribose rings of the DNA backbone, most likely by the hydroxyl radical which can abstract a hydrogen atom to initiate the DNA cleavage. C4′ chemistry as predominant route, C1′ chemistry in the minor groove, and C3′ chemistry in the major groove could account for the product distribution.

The main position of attack could be the 4′-hydrogen atom of the deoxyribose in the case of Fe–MPE, but this has not been clearly demonstrated for Fe–EDTA. H4′ abstraction as first step of the cleavage reaction may explain the release of nucleobases and the formation of 5′-phosphate and 3′-phosphoglycolate termini (**65**) by an O_2-dependent pathway (see Scheme 17). The absence of base propenals **64** (or unsuccessful efforts to characterize them) is reminiscent of observed results with Cu(*o*P)$_2$ (**1**) and enediynes, where, in the minor C4′ pathway of oxidative cleavage, the nature of monomeric species accompanying C3′–C4′ cleavage remains to be established (see Sections 3.4.1 and 3.4.2).



Chemistry at C1′ must be considered as a possible explanation for the presence of significant amounts of 3′-phosphate termini (see Scheme 14). However, due to the presence of reductants, 5-methylene-2-furanone (**33**), has not been characterized, so this proposed mechanism remains unconfirmed.[9b, 98a] Both the reactions outlined above should occur in the minor groove.

Chemistry occurring in the major groove has been also postulated.[9b] H3′ abstraction (see Scheme 1) produces the radical **45** (Scheme 16). Further reaction of this species in the absence of oxygen should give rise to free bases, 2-methylene-3-furanone (**48**), and 3′-phosphate and 5′-phosphate termini. In the presence of oxygen the production of 5′-phosphate termini, 3′-phosphoglycolaldehydes **53** (which would be oxidized to glycolic acid), and base propenoic acids **54** (which would not be expected to react with thiobarbituric acid, the usual reagent for base propenal characterization) may account for some results reported by Hertzberg and Dervan.[98a] This is not, however, likely to occur in the case of derivatives in which Fe–EDTA is attached to distamycin,[9i, 113, 131a] oligopeptides,[119, 131a, 133a] or proteins,[192] where, on the basis of PAGE analyses, the oxidative attack clearly occurs within the minor groove. On the other hand, when Fe–EDTA is attached to oligonucleotides[135] or some proteins,[193] the cleavage patterns support an oxidative attack from within the major groove, and so, in these cases, a mechanism involving H3′ abstraction has to be taken into consideration. In a similar manner the oxidative H5′(*pro-R*) abstraction (H5′ points towards the entrance of the major groove) has to be considered as another possible target (see Scheme 18).

An alternative mode to the direct HO•-mediated hydrogen abstraction from deoxyribose may involve an initial attack on the base moiety. This either gives a radical base species able to abstract a hydrogen atom from deoxyribose or creates an abasic site leading to strand break. This alternative pathway is based on the idea that base destruction accompanies the strand scission event.[9b]

3.5. H5′ Abstraction: Enediynes and Cationic Manganese Porphyrins

Until now, oxidative chemistry at C5′ of deoxyribose has been demonstrated only for enediynes and Mn–TMPyP. These compounds initiate the oxidation of the deoxyribose by H5′ abstraction, giving a C5′-centered radical **70** (Scheme 18).

Scheme 18. Proposed reaction mechanisms when initial site of attack by the oxidizing agent (①: enediynes **2**, **5**, **7**–**10**; ②: **19**) is at C5′ of the deoxyribose [159].

3.5.1. *Enediynes*

3.5.1.1. *NCS-Chrom*

C5′ chemistry represents the major mode of DNA cleavage by NCS-chrom (**2**): it causes all single-strand breaks and the cleavage of at least one strand for double-strand lesions.

Eighty percent of SSB lesions consist of breaks in which a 5′-aldehyde (**73**, Scheme 18) is facing a 3′-phosphate terminus, whereas in 20% one deoxyribose moiety is lost, and release of base accompanies 3′-phosphate and 5′-phosphate termini formation.

The C5′ radical **70** created by activated **2** combines with O_2 (as demonstrated by $^{18}O_2$ incorporation)[194] to give the 5′-peroxy radical **76**. The reduction of this radical by a excess of thiol (or other strong reductant) could result in the recovery of the 5′-hydroxy species **72** as proposed in the literature; alternatively **72** may come from **82**. Spontaneous cleavage of **72** affords fragment **73** with a 5′-aldehyde end. Nucleosides bearing the 5′-aldehyde group have been observed after enzymatic hydrolysis by HPLC.[195] When 3′-[^{32}P]-labeled fragments of DNA were analyzed on polyacrylamide gels, abnormal mobility of 5′-aldehydes **73** was also noted.[196] Aldehydes move about as fast as the markers produced by chemical treatment in the Maxam–Gilbert procedure, which have a 5′-phosphate end and two more nucleotides. Because of the presence of reducing agents, neither intermediate **74** nor end product **75** (Scheme 18) was observed. Some bands on polyacrylamide gels corresponded to fragments with a 5′-COOH end; their production was probably attributable to the presence of traces of metal.[9e, 196]

Some C5′ chemistry (10–20%) gives rise to gaps in a DNA strand with concomitant loss of a base. The fragments end with 5′-phosphate and 3′-phosphate.[196] To explain these lesions the following two mechanisms have been proposed: 1) The peroxy radical **76** is reduced to the hydroperoxide **77**. A Criegee-type rearrangement giving successively **78**, **79**, and **80**, could then account for the observed products **80** and **81**. This mechanism does not seem likely, because of the absence of any acid or metal catalysis.[9d, 64, 173] 2) The peroxy radical **76** is transformed to the oxy radical **82**, followed by a β-fragmentation with cleavage of the C4′–C5′ bond to generate an unstable 3′-formylphosphate-ending fragment **80**, which hydrolyzes into formic acid and a compound with 3′-phosphate terminus. In the case of double strand lesions the O_4 bridge may account for the formation of the oxy radical **82** [Eq. (9)].[46b] When misonidazole replaces O_2, these gaps constitute almost the only form of DNA lesions.[52, 197] In an ^{18}O-transfer experiment the carbonyl oxygen of the activated formyl moiety (trapped as formyl–Tris adduct) was derived from the nitro group oxygen of misonidazole.[198] The spontaneous transfer of formyl residues from **80** to nucleophiles (Tris or hydroxylamine)[197, 198] and a derivative of **81** stabilized by reduction with $NaBH_4$[199] were evident.

Because C5′ is located at the periphery of the DNA double strand, reduction of the sensitive intermediates **76** or **82** to the C5′-hydroxylated compound **72** may be readily achieved, which explains the predominance of 5′-aldehyde **73** and the lack of dependence on the reducing power of the thiol.

Small isotopes effects were observed in abstraction of deuterium from the 5′ position of T residues from a duplex oligonucleotide containing a TGTTTGA sequence ($k_H/k_D = 1.6$),[64] a 5′-AGC/3′-TCA sequence (1.25), or a restriction fragment of pBR322 plasmid (1.0–1.6 at T of 5′-GT steps; other T residues showed a variable sensitivity to 5′ deuteriation).[170] H5′ of deoxyribose is incorporated at the C6 radical of the activated NCS-chrom biradical **4** (see Scheme 3).[53]
