CAL **5** mediates DSBs at preferred interaction sites: the H5′(*pro-S*) abstraction that occurs on the second nucleotide residue of the four-base-pair sequences 5′-TCCT or 5′-TTTT[51, 67a] involves the C6 radical of the activated CAL (**6**, see Scheme 4).[12a, 56] In PAGE analysis of cleavage products of the TCCT strand, the 5′-[^{32}P]-labeled fragments exhibited mobilities identical to the corresponding Maxam and Gilbert sequencing markers, thus suggesting the presence of 3′-phosphate ends.[51, 67b] Two major 3′-labeled fragments were resolved, one ending in a 5′-aldehyde (**73**, Scheme 18), and one ending in a 5′-carboxylic acid (dependent on metal traces, as described for NCS-chrom).[51]

3.5.1.3. ESP

Only C5′ chemistry is involved in SSBs mediated by ESP A (**7**), and this chemistry also occurs in DSBs for ESP C (**8**).[57] In the latter case, the activated drug mediates H5′ and H4′ abstraction on both strands of DNA. At some residues only 5′ chemistry is observed, at other ones both types of chemistry can take place. PAGE analysis of the cleavage of DNA substrates labeled with ^{32}P at the 5′ or 3′ ends showed 3′-phosphate termini and 5′-aldehyde-ended fragments **73**. The 5′-aldehyde terminus was characterized by its usual reduction to 5′-alcohol by NBH_4 treatment or by its conversion into a 5′-phosphate end upon piperidine treatment (this catalyzes two successive β-eliminations on **73** with the loss of deoxyribose moiety).

Sequence-specific isotope effect ratios for the cleavage of DNA were found to be very low (not significantly different from 1). In addition, contrary to what was observed for NCS-chrom, deuteration at either C5′ or C4′ had no effect on the relative partitioning of oxidative attack.[57] H5′ abstraction is due to the C10 radical of the activated biradical drug **11** (see Scheme 4).[57]

3.5.2. *Cationic Manganese Porphyrins*

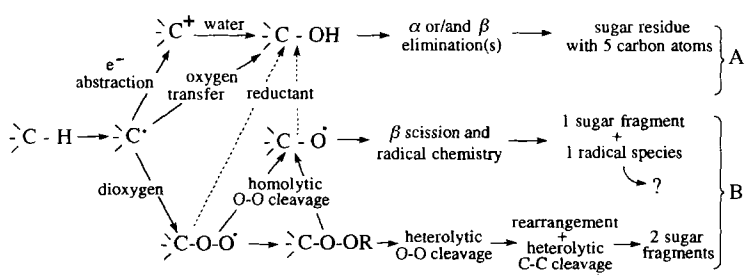
Besides oxidative attack at C1′–H, (see Section 3.1.3), oxidative activation of C5′–H[147] constitutes the principal mechanism of activated Mn–TMPyP for cleavage of A · T-rich sequences of double-stranded DNA[137, 138d] (② in Scheme 18). In HPLC analysis of the products released in solution after a heating step, free bases, oxidized nucleosides (**74**),[200] and furfural (**75**) were observed and characterized.[164] Cleavage fragments from small oligonucleotides were analyzed by HPLC separation techniques or PAGE analyses,[137, 138e, 146, 147, 201] and their transformation by chemical and/or enzymatic treatment allowed their identification: 3′-phosphate-ending fragments were subjected to alkaline phosphatase to obtain the corresponding oligonucleotides with 3′-OH endings; 5′-CHO-ending fragments were either heated (inducing two successive β-eliminations, see below), oxidized by I_2 in an alkaline medium (5′-COOH end), or reduced by $NaBH_4$ (5′-CH_2OH end). Depending on the extent of cleavage and on the sequence at the 3′ side of $(A \cdot T)_3$ site, 5′-COOH-ending fragments could be observed immediately after cleavage of 3′-[^{32}P]-labeled oligonucleotides.[201, 202]

The proposed mechanism is indicated in Scheme 18. The activated cationic metalloporphyrin initiates the oxidation of the deoxyribose by H5′ abstraction to give a C5′ radical (**70**). Even in the absence of oxygen (the same cleaving reactivity was observed in absence or in presence of O_2: M. Pitié et al., unpublished data), **70** can be hydroxylated directly by

TMPyP–Mn^{IV}–OH, or in two steps by one-electron transfer followed by reaction of water with the carbocation **71**, to give the 5′-OH derivative **72**. Spontaneous cleavage follows, with formation of a 3′-phosphate end and 5′-aldehyde **73** (direct break of the DNA backbone). A first β-elimination then produces a second break on the DNA backbone with release of a 5′-phosphate end and the α,β-unsaturated aldehyde **74**. Finally a second β-elimination gives rise to free base and furfural (**75**) as sugar degradation product. The 5′-COOH ending fragments sometimes observed[201, 202] are probably due to a second oxidation by the recycled activated Mn–TMPyP at the same site.

The intermediate **74** was completely characterized by reduction with $NaBH_4$ (selective reduction of the aldehyde at C5′ to the alcohol without affecting the double bond) followed by hydrogenation with palladium on charcoal, to give 2′,3′-dideoxyribonucleosides having the natural β or the nonnatural α configuration at C4′.[200] The use of ^{31}P NMR spectroscopy has confirmed the formation of two 3′- and 5′-phosphate monoester ends in roughly equal proportions, which supports the mechanism described above.[164d]

It should be noted that selective C5′ chemistry can take place on both 3′ sides of the $(AT)_3$ double-strand cleavage site of the Mn–TMPyP/$KHSO_5$ system. This leads to direct strand breaks with a four base-pair, 3′-stagger of the cleaved residues,[147] which confirms that oxidative attack of the activated metalloporphyrin occurs from the minor groove of DNA (see Scheme 11).



3.6. Concluding Remarks on Section 3

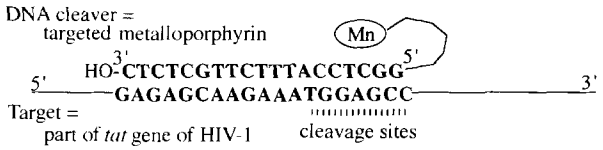
The oxidative attack on DNA by chemical nucleases and drugs described in the present section starts with the formation of a carbon-centered radical on positions 1′, 2′, 3′, 4′, or 5′ of deoxyribose (Scheme 19). This initial step corresponds formally to a one-electron oxidation ($H^{\cdot} = H^+ + e^-$). However, some DNA cleavers are capable of two-electron oxidations, and only in this case is direct hydroxylation of a carbon radical at the sugar possible, either by oxygen or electron transfer (Scheme 8, routes a and b). Further reaction of the unstable hydroxylated derivative could, without cleavage of any C–C bond, give rise to a sugar residue with five C atoms characteristic of each initial oxidative lesion (top of Scheme 19): 5-methylene-2-furanone (**33**, attack at C1′), 3-methylene-2-furanone (**48**, C3′), the C4′-hydroxylated abasic derivative (**58**, C4′), furfural (**75**, C5′).

If the rate of oxygen or electron transfer is too slow (as in the case of BLM), or if the DNA cleaver is only capable of one-electron oxidation (as in the case of enediynes and photoactivated halouracil oligonucleotides), the carbon radical reacts with molecular oxygen (for recent papers on the kinetics of oxygen rebound in hydroxylation reactions, see ref. [203]). The resulting unstable peroxy radical may be reduced to a hydroperoxide (R = H) by reductants [see Eqs. (10) and (11)] or by intramolecular H donation.[64] A heterolytic cleavage of the peroxide O–O bond may induce a rearrangement and the subsequent heterolytic cleavage of one adjacent C–C bond of the sugar (a Criegee-type rearrangement, for example). Two sugar fragments are usually (or might be) observed. Depending on the initially attacked carbon site and on which adjacent C–C bond is cleaved, two sets of two sugar fragments can be generated: one-carbon plus four-carbon fragments (C2′ chemistry: formic acid + **42**; C5′ chemistry: **80** + **81**) or two-carbon plus three-carbon fragments (C3′ chemistry: **53** + **54**; C4′ chemistry: **65** + **64**). Alternatively, for example when two peroxy radicals combine (O_4 route), a homolytic cleavage of the peroxide O–O bond giving an oxy radical may lead to a homolytic cleavage of the same adjacent C–C bond. The β-scission of the oxy radical would afford two kinds of fragments: one is the same as produced in the preceeding pathway: **42** (C2′), **54** (C3′), **65** (C4′), and **80** (C5′); the other one is a radical species whose fate is unknown and whose products have not yet been described.

In addition, the oxy and peroxy radicals can be considered reduction-sensitive intermediates, and their possible reduction can afford a hydroxylated sugar by competitive pathway.

All these reaction pathways are well illustrated and detailed in Schemes 17 and 18 for C4′ and C5′ chemistry. In Scheme 15, C2′ hydroxylation (that would lead to the ribo or arabino derivative) is not shown, since neither two-electron oxidation by halouracil derivatives nor reduction of a reduction-sensitive intermediate can be performed under the experimental conditions used. In addition no chemical agents able to hydroxylate C2′ directly have so far been reported. In Scheme 16, in the absence of O_2 the hydroxylated product **46** must be formed after a one-electron oxidation of the intermediate **45** (probably by the excited state of the rhodium complex); however, the exact nature of the species able to abstract H3′ is still unknown. Hydroxylation of C1′ can easily account for the observed products in Scheme 14. No other products of DNA degradation except oxidized abasic sites have been described, probably because the glycosidic bond is cleaved in preference to a sugar C–C bond.

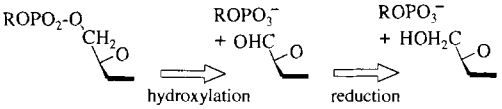
Scheme 19. Two-electron (A) or one-electron (B) oxidation of deoxyribose mediated by drugs can lead to three main pathways for sugar evolution (R = H, OOR′).



4. Concluding Remarks

Apart from nuclease enzymes, no naturally occurring, low molecular weight compounds have been discovered that can efficiently mediate hydrolysis of the phosphodiester bonds of the DNA backbone. The DNA-cleavage route selected by nature for cytotoxic drugs (bleomycin, enediyne) is a sugar oxidation and not a hydrolysis of phosphodiesters. So it is not surprising that synthetic transition metal complexes exhibiting redox properties and DNA affinity have been

developed as "chemical nucleases" (a misnomer—what about "chemical DNA sugar oxidases"?). Deoxyribose is a key target for DNA cleavers, and current knowledge of the different modes of oxidation of deoxyribose units leading to DNA breaks has been reviewed in the present article. Development of these artificial and selective DNA cleavers is a challenging area in the rational design of antitumoral and antiviral agents as well as in the field of molecular biology. The need for highly efficient (quantitative cleavage of the target must be reached) and highly specific (sequence specificity on large DNA fragments) cleaving reagents is obvious, and considerable progress has already been made. Improvements in several directions are still required:



1) Cleaving efficiency: Discovery of truly double-strand and catalytic DNA cleavers (and also highly efficient RNA cleavers) is required in order to create new cytotoxic agents and tools for gene engineering. In the field of cancer chemotherapy, enediynes represent an example where an understanding of the chemistry and modes of action can help the design of highly efficient in vitro drugs, such as the synthetic dynemicins analogues described by Nicolaou and Smith.[9h] But the question whether in vitro efficiencies transferable to in vivo conditions still remains.

2) Specificity: A specific molecular site of attack without dispersion of lesions is also highly challenging, especially if genomic double-stranded DNA is the ultimate target. This property is not necessary in some cases: absence of selectivity allows use of some chemical nucleases as footprinting reagents for DNA or RNA, and they have some advantages over the DNase method. Sequence selectivity has been drastically increased by the covalent binding of DNA-cleaving moieties to oligonucleotides or to DNA-binding small molecules, peptides, or proteins. In particular, the attachment of an efficient DNA cleaver to a deoxyoligonucleotide should lead to a family of synthetic restriction enzymes with tailored specificity that might be useful in the analysis of complex genomes or could enhance the ability of an antisense deoxyoligonucleotides to block the expression of targeted gene. As an example of these last potential medical applications, we recently reported that the attachment of the cleaver motif {tris(methylpyridiniumyl)porphyrinato}-manganese(III), which is endowed with cytotoxic properties,[204] to a selected 19-mer vector allows selective recognition and cleavage of a 35-mer single-stranded DNA containing the initiation codon of the *tat* gene of HIV-1 (Scheme 20).[149]

Scheme 20. Selective cleavage by a tailored manganese porphyrin of a 35-mer single-stranded DNA containing the initiation codon of the *tat* gene of HIV-1 [149].

3) Selection of oxidizing agents able to leave DNA fragments ending with suitable termini for further enzymatic workup: Even though the cleavage of any selected DNA sequence is now possible, no efficient chemical models of a restriction enzyme that can hydrolyze a selected phosphodiester bond are yet available. However, in an alternative pathway, hydroxylation of C3′ or C5′ of deoxyribose immediately followed by reduction of the resulting 3′-ketone or 5′-aldehyde may enable this hydrolysis step to be mimicked (oxidation step + reduction step = "pseudo-hydrolysis"). This was recently demonstrated by using the Mn–TMPyP/$KHSO_5$ system and its specific hydroxylating activity at the C5′ position of deoxyribose [Eq. (12)]. The fragments may be coupled again by chemical methods, so this system might provide an alternative to the restriction endonuclease/ligase systems.[202]

(12)

Finally, even after a decade of fruitful research on chemical nucleases, the field is still open for discoveries of new efficient cleavers of RNA and double-stranded DNA in order to produce new selective cytotoxic agents and/or tools for genetic engineering.

5. Addendum

After submission of the original manuscript several articles have appeared in the literature. These papers are briefly mentioned below together with the appropriate sections where they should be inserted.

Section 2.1: Cleavage of megabase DNA substrates was performed with a DNA-binding protein modified by Cu(*o*P).[205] The structure of the *Escherichia coli* Fis–DNA complex was probed by a protein modified with a copper–phenanthroline cleaver.[206]

Section 2.2: The role of biradical species in DNA cleavage by neocarzinostatin chromophore (**2**) has been discussed recently.[207] Moreover, there is a critical role of the iodine substituent of the calicheamicin oligosaccharide and the guanine C2-NH_2 group within the minor groove of the target DNA.[208]

Section 2.3: The stability of the oxygenated form of Fe^{II}–BLM has been investigated.[209] A recent study by electrospray mass spectrometry of activated bleomycin suggested that the iron peroxide BLM–Fe^{III}–OOH is the active species.[210] The same iron peroxide was also proposed for bleomycin models.[211] A hybrid molecule containing bleomycin and the DNA-binding domain of Hin recombinase was used as DNA cleaver.[212] Both strands of a DNA–RNA heteroduplex were cleaved by Fe–BLM.[213]

Section 2.4: Fe–MPE and Fe–EDTA were used for mapping RNA regions in eukaryotic ribosomes. RNA fragments were analyzed by primer extension with reverse transcriptase using oligodeoxynucleotide primers.[214] The tertiary structure of $tRNA^{Phe}$ has been investigated by RNA–EDTA–Fe^{II} autocleavage.[215]

Section 2.5: The transfer in water of an oxygen atom from the high-valent TMPyP–Mn^{V}=O species to a water-soluble olefin was investigated. A "redox tautomerism" involving an axial water molecule was proposed to explain the incorporation of the oxygen atoms from water and from the peroxide in a 50:50 ratio.[216] The interaction of cationic porphyrin derivatives with calf thymus DNA was studied by linear dichroism and fluorescence energy transfer.[217]

Section 2.6: Binding of *Δ*- and *Λ*-$[Ru(phen)_3]^{2+}$ with a self-complementary decamer was investigated by NMR spec-

troscopy.[218] Enantioselective recognition of DNA by $Rh^{III}(phen)_2(phi)$ (**20**) was found to be controlled by the opening in the major groove that results from changes caused by propellerlike twisting of a base pair.[219]

Appendix: Important Abbreviations Used in the Text

A:	2′-deoxyadenosine
Ade:	adenine
bpy:	bipyridine
BLM:	bleomycin
bp:	base-pair
C:	2′-deoxycytidine
CAL:	calicheamicin
Cyt:	cytosine
DSB:	double-strand break
DTT:	dithiothreitol
DYN:	dynemicin
EDTA:	ethylenediaminetetraacetate
ESP:	esperamicin
G:	2′-deoxyguanosine
Gua:	guanine
GSH:	glutathione
ME:	mercaptoethanol
5-MF:	5-methylene-2-furanone
MPA:	3-mercaptoproprionic acid
MPE:	methidiumpropyl EDTA
N:	nucleotide
NADH:	nicotinamide adenine dinucleotide, reduced form
NCS:	neocarzinostatin
NCS-chrom:	neocarzinostatin chromophore
ODN:	oligodeoxynucleotide (The deoxyribo prefix was omitted in this review, since it focuses on DNA.)
*o*P:	*ortho*-phenanthroline = 1,10-phenanthroline (The classical abbreviation used is phen (see J. Reedijk, *Comprehensive Coordination Chemistry, Vol. 2* (Ed.: G. Wilkinson, Pergamon, **1987**, pp. 73–98); however we decided to keep the formulation $Cu(oP)_2$ for the bis(1,10-phenanthroline)copper complex popularized by D. Sigman in oxidative DNA cleavage research.)
PAGE:	polyacrylamide gel electrophoresis
phi:	phenanthrenequinonediimine
phen:	1,10-phenanthroline
Porph:	a porphyrinato ligand
pu:	purine
Py:	pyridine
pyr:	pyrimidine
TMPyP:	*meso*-tetrakis(*N*-methylpyridinio-4-yl)porphyrinato
SSB:	single-strand break
T:	thymidine
TAR:	trans-activation responsive region
tat:	trans-activator of transcription
Thy:	thymine
Tris:	tris(hydroxymethyl)aminomethane
Ura:	uracil

The authors are deeply indebted to the many co-workers and collaborators whose names are listed in the references. We are also grateful to the Centre National de la Recherche Scientifique (CNRS), the Association pour la Recherche contre le Cancer (ARC, Villejuif), the Agence Nationale de Recherches sur le Sida (ANRS, Paris), the Région Midi-Pyrénées and Genset (Paris) for financial support. We thank Lisa Rosenberg (University of British Columbia) for her assistance in preparing the manuscript.

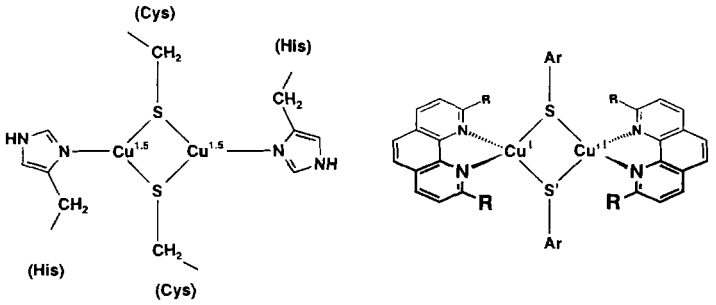
The Dinuclear Cu_A Center in Cytochrome *c* Oxidase and N_2O Reductase—A Metal–Metal Bond in Biology?

Helmut Bertagnolli* and Wolfgang Kaim*

Neighboring metal centers that cooperate functionally in proteins are bridged predominantly by O, N, or S donor ligands.[1] In special cases (such as in, for example, deoxyhemocyanin, an oxygen transport protein of molluscs and arthropods that can bind O_2 side-on), the metal centers (here Cu^I) can be held without additional bridging at a "nonbonding" distance of $d > 3.5$ Å by the protein framework.[2] Recently a *direct* metal–metal bond in biology was postulated for the first time for the dinuclear Cu_A center in a water-soluble protein domain of the cytochrome *c* oxidase of *Bacillus subtilis*;[3] this proposal was based on the results of new EXAFS measurements (EXAFS = extended X-ray absorption fine structure) and their interpretation in comparison with results from a model compound.

deoxyhemocyanin



Although cytochrome *c* oxidase (COX) is one of the most important enzymes because of its role as terminal site for O_2-respiration,[4] there have been misconceptions concerning the metal content until very recently, as a glance at the latest editions of biochemistry textbooks shows.[5] They still assume the presence of two heme–iron centers (heme *a* and heme a_3) and only two copper ions (Cu_A and Cu_B). The heme a_3/Cu_B associate is presumed to be the catalytic center for O_2 binding and reduction that can be blocked by cyanide ions, whereas the isolated heme *a* and Cu_A centers have electron-transfer functions at relatively high potentials. The Cu_A center is characterized by absorption of light of long wavelengths (about 830 nm), small EPR hyperfine splitting, and unusually low *g* factor components, and has long been thought of as a mononuclear ion coordinated to two cysteine and two histidine residues.[1b, 5a, 6] In 1987, after a careful elemental analysis of the membrane protein COX (M_r 204 kDa), which comprises 13 very different subunits, Steffens, Bielwald, and Buse proposed that the enzyme indeed contained two heme groups, but a total of *three* copper ions.[7]

In the meantime a copper center detected in N_2O reductase (from the denitrifying bacterium *Pseudomonas stutzeri*) and characterized by Zumft et al. was found to have features that did not fit into the classical division of biological copper centers (types 1, 2, or 3).[1] However, it closely resembled the Cu_A center of cytochrome *c* oxidase.[8] Detailed EPR studies of the oxidized form by Kroneck et al.[9a] suggested a dinuclear, mixed-valent Cu^I/Cu^{II} system, in which *one* unpaired electron interacted with *two equivalent copper centers*. In such an electronically coupled dinuclear system, the oxidation states of both metal centers would be 1.5. Comparative EPR studies on N_2O reductase and cytochrome *c* oxidase at different microwave frequencies,[9b] taking into account the three different isotope combinations $^{63}Cu/^{63}Cu$, $^{63}Cu/^{65}Cu$, and $^{65}Cu/^{65}Cu$,[10] gave such a good agreement that there is no doubt about the existence of a dinuclear structure of the Cu_A center and the spin delocalization. In addition to the numerous mixed-valent Fe^{II}/Fe^{III} clusters in proteins[1, 11a] and the Mn^{III}/Mn^{IV} dimers with their characteristic EPR spectra in water oxidase and several other enzymes,[11b] the oxidized Cu_A centers are apparently another example of a biological, essentially mixed-valent, multinuclear arrangement.

Last year two concrete proposals were published for the detailed coordination of the two copper ions of Cu_A, based on unambiguously conserved amino acid residues (two Cys, two His, one Met). Lappalainen and Saraste suggested an arrangement in which the two metal ions are bridged by two cysteinate S centers (Scheme 1, left).[12] Low molecular weight models for this proposal exist in the form of neutral Cu^I/Cu^I dinuclear complexes (Scheme 1, right),[13] which have strongly differing geometries for the central CuSCu'S' four-membered ring, depending on the substitution in the 2,9 positions of the 1,10-phenanthroline ligands. Both structurally characterized Cu^I_2 model complexes (Scheme 1, right) are, however, only irreversibly oxidized.[13b]

An alternative structure (Scheme 2, left) for the Cu_A center of COX was put forward by Blackburn et al.,[3] based on EXAFS data for water-soluble Cu_A containing domains expressed from *Bacillus subtilis* and for a tricationic, sulfur-free Cu^I/Cu^{II} com-

plex (Scheme 2, right). A distance of about 2.5 Å attributed to the Cu–Cu vector was interpreted as an indication of a first direct metal–metal bond in a biological system; the two histidine and cysteinate groups were assumed to be nonbridging ligands, and in addition, weak coordination to a methionine residue and a nonidentified group X was postulated.[3]

Scheme 2.

When such important conclusions are involved one question must be posed: Can EXAFS measurements[3] really provide unambiguous identification of a copper–copper bond in COX? The answer must be—and the authors concede this in several places in the text—no! Although these EXAFS measurements have the great advantage that a crystallographically characterized complex (Scheme 2, right) with a linear N-Cu-Cu-N arrangement and a Cu–Cu distance of 2.415 Å could be used as a model, two different EXAFS techniques were unfortunately applied. The model complex was studied in the solid phase where its transmission was measured; the COX domain, on the other hand, was examined in 20% glycerol solution, and the fluorescence radiation of a frozen solution was recorded. This means that the authors neglected to ensure that the concentration of copper ion absorbers in the two systems was as similar as possible. Still more important, however, is the application of two different principles of measurement. The type of background is different for measurements in transmission and fluorescence, and its determination is by no means trivial. Consequently, the extent to which the two measurements are comparable is limited.

The interpretation of EXAFS spectra is done by simulation. Such simulations require either a good model substance or theoretical back-scattering amplitudes and phases. The authors used the theoretical values of the program EXCURV 88 and are convinced that the multiple scattering in the simulation of the EXAFS spectrum of the model complex and COX can be neglected, although these effects can be substantial for a linear arrangement of atoms, which is the case in the model complex. The EXAFS spectrum of the model system was simulated with nine parameters. In the COX system the number is even higher since, in addition, the coordination number of at least two shells is varied and a fifth coordination shell is fitted. In the light of this number of parameters it must be asked, as indeed for almost all simulations of EXAFS spectra, whether a fit just as good can be achieved with other parameter values. The authors are very well aware of these problems and simulate the EXAFS spectra of the model system and COX domain with a set of parameters in which a Cu–S bond is assumed instead of a Cu–Cu bond. The fit index, a measure of the goodness of fit, changes by only 3% through this procedure.

Is that sufficient to postulate a Cu–Cu bond? No! And this is ultimately recognized by the authors, for they write "...the fit also converges to approximately the same value of the fit index." Then they continue "However, chemical considerations argue forcibly against the Cu–S interpretation. The Debye–Waller term ... is close to zero". However, merely a small value for the Debye–Waller factor is far from a definite indication of the existence of a metal–metal bond.

Let us gloss over the interpretation of the EXAFS measurements for the moment. Even if the copper–copper distance was indeed about 2.5 Å, doubt would remain about the presence of "true metal–metal bonding".[3] Surprisingly small copper–copper distances have been observed both in bridged Cu^{II}–Cu^{II} complexes (2.65 Å in dimeric copper(II) acetate with strong antiparallel spin–spin coupling) and multinuclear Cu^{I} compounds, yet it has not been found necessary to postulate a metal–metal bond, even for systems with d(Cu–Cu) = 2.35 Å.[14] In the mixed-valent model complex of Scheme 2, a model that is only of moderate value with respect to the electronic structure,[3] the crystallographically determined Cu–Cu distance of about 2.4 Å is comparable in size, and here too, the geometry is dictated by the ligands. The Cu–Cu distance in the doubly thiolato-bridged Cu^{I}_2 complex of Scheme 1 (R = H) is also just 2.61 Å, so neither the existence of a "biological metal–metal bond" nor the actual bridged or nonbridged structure of the dinuclear Cu_A center can be deduced from the available data. Nevertheless, as hypotheses, the structures in Schemes 2 and 3 provide an ideal field for modeling the composition, spectroscopy, and function of the Cu_A centers in proteins.

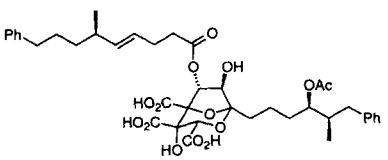
Total Syntheses of Zaragozic Acid

Ulrich Koert*

Who is nowadays not aware of the negative effects on health of high cholesterol levels in blood? Atherosclerosis, hypertension, and myocardiac infarction can be the consequences of this metabolic disturbance (Scheme 1).[1] On the one hand the



Scheme 1. Cholesterol in the human body: endogeneous build up, exogeneous introduction, and pathological consequences.

diet influences the cholesterol level exogenously, on the other hand the body builds up cholesterol endogenously. The biosynthetic pathway of cholesterol begins with a branching of the citric acid cycle. Starting from 3-hydroxy-3-methylglutaryl-(HMG)-CoA, farnesyldiphosphate is formed via mevalonate. The coupling of two molecules of farnesyldiphosphate yields squalene, which is then converted into cholesterol.

If this endogenous production of cholesterol could be reduced, it would be of significant therapeutic use. With the discovery of the mevinic acids almost 15 years ago, an enzyme inhibitor for an enzyme participating in cholesterol biosynthesis, namely HMG-CoA reductase, was found for the first time. Today lovastatin, simvastatin, and pravastatin are standard components of the battery of pharmaceuticals.

Now a group of recently discovered natural products that inhibit another enzyme, squalene synthase, has become the focal point of attention: the zaragozic acids. In 1992 researchers at Merck, Sharp and Dohme,[2] and Glaxo[3] independently reported the discovery of a new family of natural products with squalene synthase inhibiting properties. The Merck group gave the new compounds the name zaragozic acids after the Spanish city of Zaragoza in which they had been found for the first time in fungal cultures. The Glaxo researchers named the new compounds squalestatins after their squalene synthase inhibiting effect.

Zaragozic Acid C 1

Zaragozic Acid A 2
(Squalestatin S1)

Representative compounds of this new group of natural products are zaragozic acid C (**1**) and zaragozic acid A (**2**) (= squalestatin S1). All zaragozic acids share a common 2,8-dioxabicyclo[3.2.1]octane skeleton (Fig. 1a), which is extremely polar as a result of three carboxyl groups in positions 3, 4, and 5 as well as three hydroxyl groups at C4, C6, and C7. An alkyl side chain (CH_2-C1-SK) is found at C1 and a fatty acid side chain at C6-O (C6-O-SK-CO). The spatial arrangement of the three COOH groups and the OH group at C4 is remarkable. This arrangement of functionalities corresponds to that of a citric acid molecule (Fig. 1b) in a frozen conformation. Thus, the binding site of squalene synthase for zaragozic acids could be one for citric acid.

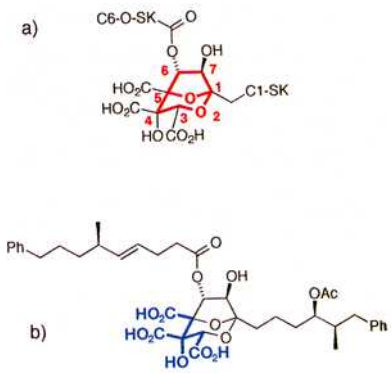

Fig. 1. a) Structure of the zaragozic acids with the 2,8-dioxabicyclo[3.2.1]octane skeleton (red); b) conformationally frozen citric acid partial structure (blue) in zaragozic acid C.

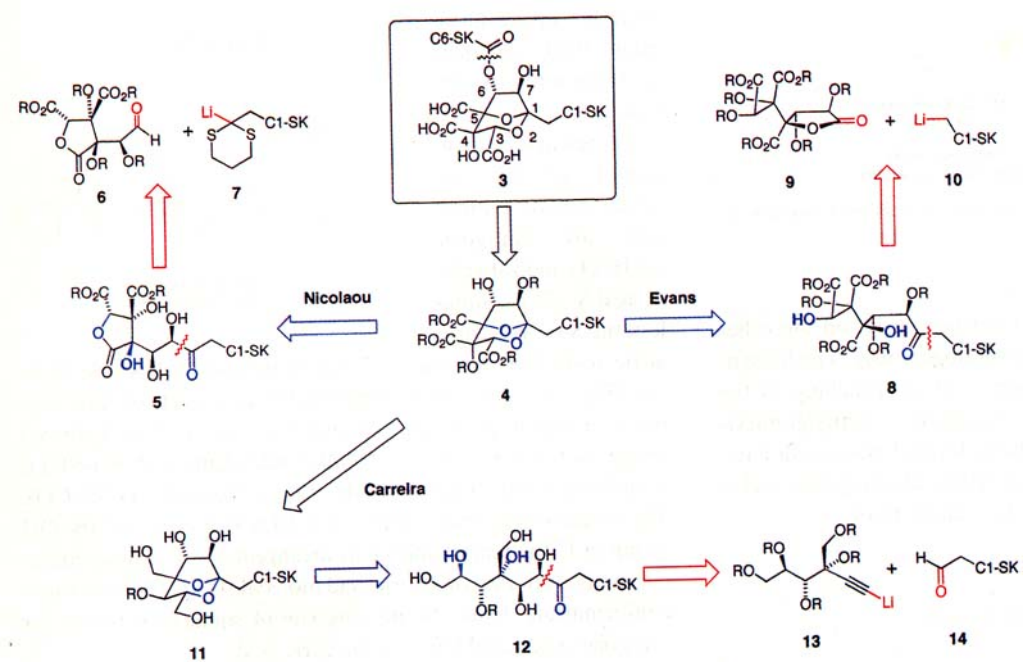
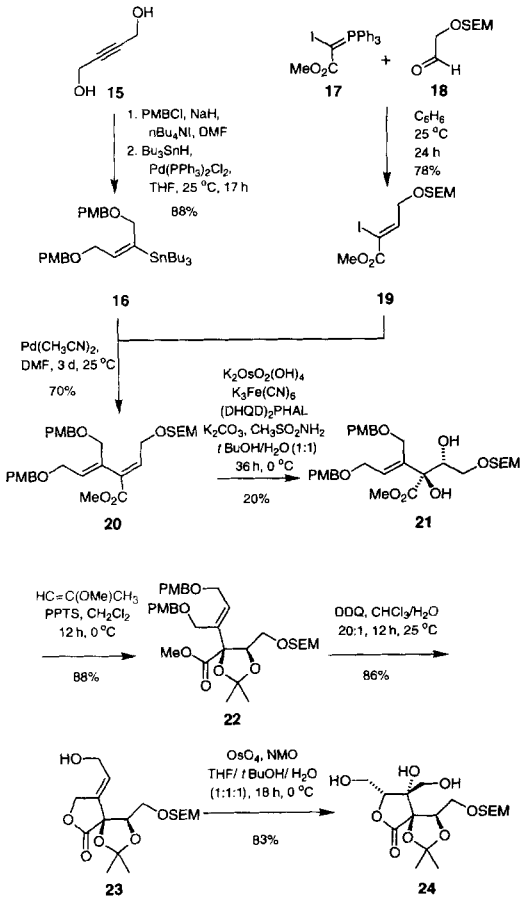
The biological activity of zaragozic acids and the complexity of their structures have attracted the attention of numerous synthetic chemists within a very short space of time.[4] At the end of 1994, three total syntheses were published: one by Carreira et al. (zaragozic acid C),[5] one by Nicolaou et al. (zaragozic acid A),[6] and one by Evans et al., which was carried out in collaboration with researchers at Merck, Sharp and Dohme (zaragozic acid C).[7] These three syntheses are compared in this highlight.



Scheme 2 shows the three retrosyntheses of zaragozic acids **3**. All three research groups introduce the acyl side chain at C6-O as the last step. Thus, the alcohol **4** is obtained as the precursor of the complete molecular skeleton **3**.

Apart from that, the synthetic pathways differ. Nicolaou derives the dioxabicyclo[3.2.1]octane skeleton from the ketone **5**, which can be split into the two building blocks **6** and **7** by cleavage of the C1–C7 bond. The synthetic strategy of Evans regards the ketone **8** as the precursor of the dioxabicyclo[3.2.1]octane **4**. The retrosynthetic cut between C1 and the adjacent C atom of the C1 side chain yields the building blocks **9** and **10**. These two syntheses have the common feature that the dioxabicyclo[3.2.1]octane is constructed inclusive of the carboxyl functions. A different route was followed by Carreira. In this the three carboxyl groups are introduced after the completion of the dioxabicyclo[3.2.1]octane. Thus, compound **4** is traced back to the tetraol **11**, which should be accessible from the acyclic precursor **12**. The cleavage of the C1–C7 bond leads to the building blocks **13** and **14**. Compared with the strategies of Nicolaou and Evans, Carreira thus has the chance to rapidly assemble the dioxabicyclo[3.2.1]octane. However, as it turned out the construction of the three carboxyl functions requires a considerable number of steps at the end of the synthesis. In all three syntheses, the dioxabicyclo[3.2.1]octane skeleton is obtained by acetal formation of a 4,6-dihydroxyketone by using standard procedures. The efficiency with which the acyclic precursors **5**, **8**, and **12** with their five stereogenic centers can be assembled will be important in the assessment of the syntheses.

The synthesis of zaragozic acid A[5] by Nicolaou is summarized in Schemes 3–7. Four of the five stereogenic centers are constructed by two stereoselective Sharpless dihydroxylations (Scheme 3). In the first, the diene **20**, which is synthesized in a few steps from the simple building blocks **15**–**18**, is converted enantioselectively to give the diol **21** (20% yield, 78% *ee*); in the second the olefin **23** is diastereoselectively dihydroxylated, and the product undergoes spontaneous lactonization to give **24** (83% yield, as a single diastereomer after crystallization).



In the subsequent 12 steps (Scheme 4) the two primary alcohol functions in **24** are oxidized to carboxyl functions and protected as benzyl esters. After trimethylsilyl(TMS)-protection of the OH group at C4 Nicolaou then obtains the aldehyde **30**. Addition of the lithium compound prepared from the dithiane **31** to the C1 side chain (Scheme 5) of **30** delivers, with the formation of the alcohol **32**, the missing fifth stereogenic center. This addition is however unselective: two epimeric alcohols are formed (total yield 75% in a 1:1 ratio) and must be separated by chromatography. Removal of the thioacetal function in **33** leads to the hemiacetal **34**.

Under carefully worked out acidic conditions the lactone hemiacetal **34** rearranges into the dioxabicyclo[3.2.1]octane **35** (Scheme 6). By changing the alcohol protecting group and exchanging the methyl ester for a benzyl ester the diol **38a** is

react. The selectivity of 3:2 in favor of the desired C6-OH group established by Nicolaou is rather low. Starting from **39** protecting group manipulations (5 steps, Scheme 7) gave the target compound zaragozic acid A (**2**).

The synthesis of zaragozic acid C (**1**) by Carreira[6] is given in Schemes 8–10. This synthesis starts from D-erythronic γ-lactone (**42**), a compound from the chiral pool.[8] An impressive feature of the synthesis is the conversion of the amide **43** into the alcohol **44** (Scheme 8): The reaction of ethoxyvinyllithium with the dimethylamide **43** can be stopped at the ketone intermediate. The subsequent reaction of the carbonyl function with the organomagnesium compound prepared from TMS–C≡CH proceeds stereoselectively (20:1). The vinyl ether group in **44** is a latent ester function: the ozonolysis of **44** in ethanol affords the ethyl ester **45**. Subsequently the terminal acetylene **47** is obtained via **46** by a standard sequence. The C1 side chain is attached through the coupling of **47** with the aldehyde **48** to give the ketone **49**. The two stereogenic centers still missing are produced by Sharpless dihydroxylation of the olefin **50** obtained after the oxidation and removal of the silyl protecting groups. Without a chiral ligand stereoselectivity cannot be achieved in this bishydroxylation step. With a chiral ligand, the diol is formed in a reagent-controlled reaction in the ratio 64:36 in

Scheme 9. Total synthesis of zaragozic acid C (**1**) by Carreira, part 2. Piv = pivaloyl, DMSO = dimethyl sulfoxide, DIBAH = diisobutylaluminum hydride.

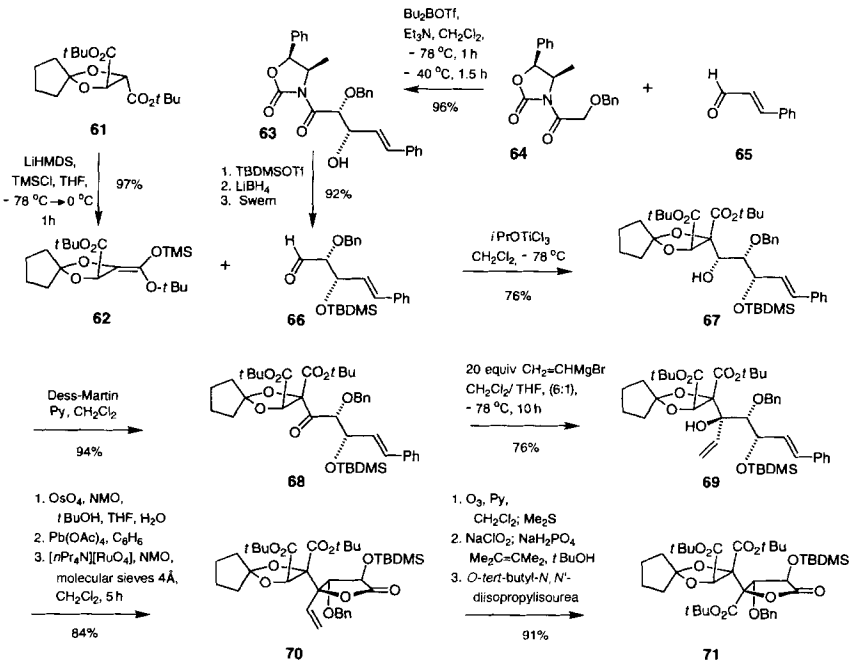
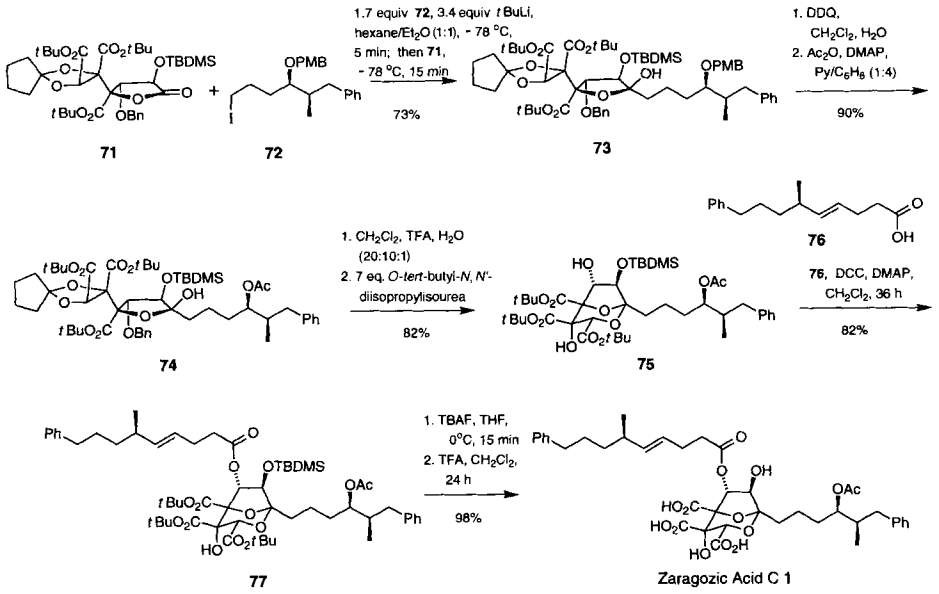
Scheme 10. Total synthesis of zaragozic acid C (1) by Carreira, part 3. TFA = trifluoroacetic acid.



favor of the desired stereoisomer. In the subsequent synthetic step, the diol is cyclized under acidic conditions to give the dioxabicyclo[3.2.1]octane acetal (**51**).

To construct the missing quaternary center C4 Carreira transforms the compound **51** into the ketone **53** (Scheme 9). The addition of lithiated TMS–C≡CH to the carbonyl function of **53** to give the alcohol **54** is achieved with a stereoselectivity of 86:14. At this stage the pivaloyl protecting groups are replaced by acetyl protecting groups and the triple bond is reduced to a double bond to give compound **56**.



Carreira now oxidizes the two primary alcohol groups sequentially to give the carboxyl functions (**56** → **57** → **58**, Scheme 10). The third carboxyl function is formed by ozonolysis and subsequent oxidation of the aldehyde (**58** → **59**). This is followed by a remarkably selective hydrolysis of the triacetate **59** to give the monoacetate **60** in 92% yield(!). With regard to his final step, the introduction of the acyl side chain at C6-O, Carreira faces the same problem as Nicolaou: how can the C6-OH group be esterified selectively in the presence of the free C7-OH group? Carreira is unable to provide a satisfactory solution to the selectivity problem. From the reaction of the diol **60** with the acid chloride **61** he obtains the regioisomeric esters in the ratio 3:1 in favor of the undesired isomer. The desired isomer can be isolated by chromatography and after acidic hydrolysis of the *tert*-butyl esters the target compound zaragozic acid C (**1**) is obtained.

The total synthesis of zaragozic acid C (**1**) by Evans[7] is shown in Schemes 11 and 12. Evans identified a tartaric acid unit in the C3-C4 partial structure of zaragozic acid. Accordingly, his synthesis commences from a tartaric acid derivative (Scheme 11). The enantiomerically pure acetal **61** is readily accessible from di-*tert*-butyl D-tartrate. This is transformed into the silylketene acetal **62**, which reacts in a Lewis acid catalyzed aldol addition with the aldehyde **66** to give the adduct **67**. The aldehyde **66** was prepared stereoselectively with the oxazolidinone method developed by Evans (**64** + **65** → **63** → **66**). The Dess–Martin oxidation of **67** yields the ketone **68**. Addition of vinylmagnesium bromide to the keto-carbonyl function in **68** leads to the stereocontrolled construction of the quaternary center C5 with the formation of **69**. The stereochemical course of this addition can be explained with a chelate-controlled transition state controlled by the adjacent benzyl ether. Next, Evans transforms the styryl group in **69** oxidatively into a carboxyl function and closes the butyric lactone ring to give **70**. By the sequence **70** → **71** the vinyl group is transformed into the missing third carboxyl function of the zaragozic acid skeleton.

In the further course of the synthesis (Scheme 12) Evans attaches the side chain to C1 by the reaction of the organolithium compound accessible from the iodide **72** with the lactone **71** under the formation of **73**. The replacement of the *para*-methoxybenzyl(PMB) protecting group with an acetyl group yields the hemiacetal **74**. Subsequently, the hemiacetal **74** is converted under acidic conditions into the dioxabicyclo[3.2.1]octane **75**. With wise foresight the C7-OH group has been protected since

Scheme 11. Total synthesis of zaragozic acid C 1 by Evans, part 1. HMDS = 1,1,1,3,3,3-hexamethyldisilazanide.

Scheme 12. Total synthesis of zaragozic acid C (**1**) by Evans, part 2. DCC = dicyclohexylcarbodiimide, TFA = trifluoroacetic acid.

the beginning of the synthesis as a silyl ether with the result that the problem of selectivity between C6-OH and C7-OH does not arise in the following acylation step. The acyl side chain can thus be attached to C6-O without any problems: the reaction of the alcohol **75** with the carboxylic acid **76** affords the desired ester **77** in 82% yield. The deprotection of **77** to give the target compound zaragozic acid C (**1**) is almost quantitative.

A discussion of the preparation of the C1 side chains and the C6-O carboxylic acid, which was also effected by the three research groups by different methods, is not within the scope of this highlight. The interested reader should refer to the information in the original literature.[4d, 4e, 5–7]

All three total syntheses of zaragozic acid are examples of modern, efficient syntheses of natural products. The comparison of the number of steps and the overall yields of different synthetic routes always difficult and of only limited value. The longest linear sequence as a measure for the number of steps for the presented syntheses is 33 (Nicolaou), 36 (Carreira), and 21 steps (Evans). The overall yields are calculated to be 1 (Nicolaou), 1 (Carreira), and 15% (Evans). Noteworthy in the synthesis by Evans is the highly selective formation of each new stereogenic center. The stereo- and regioselectivities of some of the steps in the syntheses by Nicolaou and Carreira will surely be improved. The two research groups of Carreira and Nicolaou have been the first cross the finish line in the race for the total synthesis of zaragozic acids.

Dedicated to Professor F. Albert Cotton on the occasion of his 65th birthday

One of the most important aspects for the future of chemical research is the examination of the experimental conditions under which it is possible to construct arrangements of higher complexity from simple building blocks, if possible, with tailor-made structural and functionality features. The aim of such experiments is not only to improve the understanding of the extreme complexity of natural processes, but also to synthesize molecular materials with desired properties. In this context, reactions in which the organization of weakly interacting species in an isolated system are influenced "from outside" are of interest, too. These problems are current topics in the field of supramolecular chemistry.[1-3]

The treatment of vanadium pentoxide with *tert*-butylamine, triethylamine (both as deprotonating agents), and hydrazine hydrate as reducing agent in the presence of sodium azide and phenylphosphonic acid produces the unusual host–guest compound **1** in a mixture (2.5:1) of water and *N*,*N*-dimethylformamide (DMF).

$(Et_3NH)_3(tBuNH_3)_2Na_2[(H_2O)_2, N_3^- \subset V_{14}O_{22}(OH)_4(PhPO_3)_8]\cdot 6H_2O\cdot 2DMF$

1

The compound has a closed, nanodimensional cavity and two external, open truncated cones or, in other words, ion channels formed by phenyl rings (Fig. 1a). The fundamental significance of the truncated cones is that the exchange of their contents enables a systematic study of the resulting influence on the organization of the guests in the cavity. Compound **1** was characterized by a single-crystal X-ray structure analysis,[4] bond valence sum calculations,[5] magnetochemical measurements, IR, Raman, and UV/Vis/NIR spectroscopy, elemental analysis, and manganometric titration of the V^{IV} centers.[4] Only the neutral molecules and anions occupying the central cavity of **1** are considered as included guests, and not those located in the truncated cones and coronands, that is, those on the outside wall of the host. (The nucleophilic [16]crown-8 type coronand is built from four $PhPO_2$ units and four vanadium atoms.[6, 7]) In the central cavity ten electron density maxima are found within the horizontal plane of symmetry, forming an approximate ellipse. Two H_2O molecules and an N_3^- ion lie disordered in these ten positions (Fig. 1a). The disordering is a consequence of the size of the cavity and the resulting weak interactions of the guests with the host (cf. the interpretation of the IR spectrum). In each truncated cone a Na^+ ion coordinated to two H_2O and one DMF molecules is located in such a way that the distorted octahedral coordination sphere of the Na^+ ion is completed by two O atoms of the coronand and the H_2O molecule in the center of the coronand (Fig. 2).

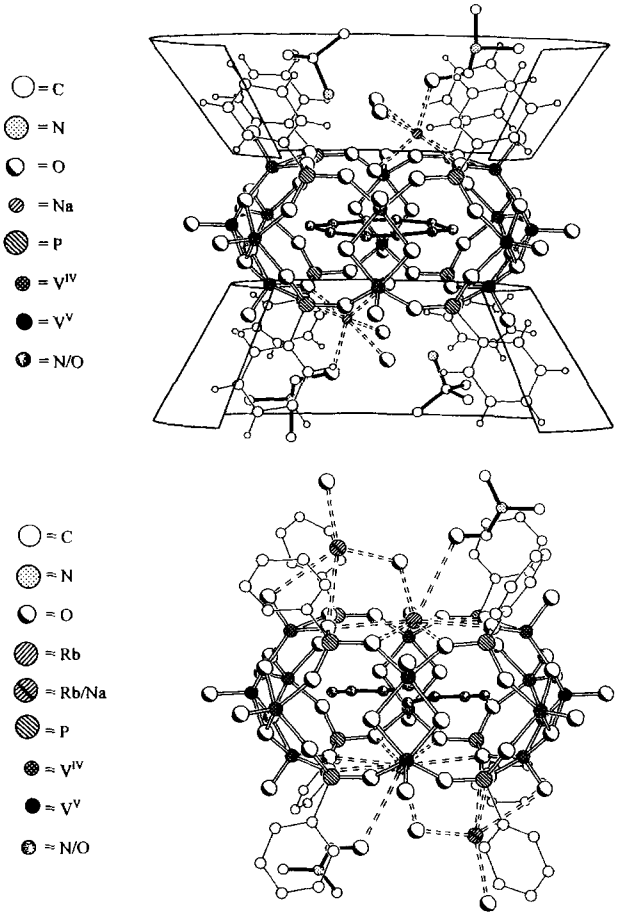

Fig. 1. a) Structure of the anion in crystals of **1** with two Na^+ and two $tBuNH_3^+$ ions, as well as six H_2O and two DMF molecules in the truncated cones (indicated schematically as cones from which a window has been cut out). b) Structure of the anion of **2** with one Na^+ and three Rb^+ ions as well as four H_2O and two DMF molecules in the truncated cones. The view in both cases is approximately along an idealized C_2 axis. Characteristic distances [pm]: **1**: Na-O(H_2O) 227.9–298.5, Na-O(DMF) 232.5, N($tBuNH_3$)-O(H_2O) 282.0, 285.9; **2**: Rb-O (coronand) 307.8–374.0, Rb-O(H_2O) 292.2, Rb-O(DMF) 357.5, Rb/Na-O(H_2O) 271.3, 287.8.

Treatment of **1** with about a thirteenfold excess of RbBr (the diameter of Rb^+ corresponds approximately to that of the coronand) in a 1:1.3 mixture of H_2O and DMF yields compound **2** (Fig. 1b). This shows that the exchange of the guests in the truncated cones of **1** has led to a reorganization and migration

$Et_3NH(tBuNH_3)_2(0.5\,Rb, 0.5\,Na)_2Rb_2[(H_2O)_2, N_3^- \subset V_{14}O_{22}(OH)_4(PhPO_3)_8]\cdot 10\,H_2O\cdot 2DMF$ **2**

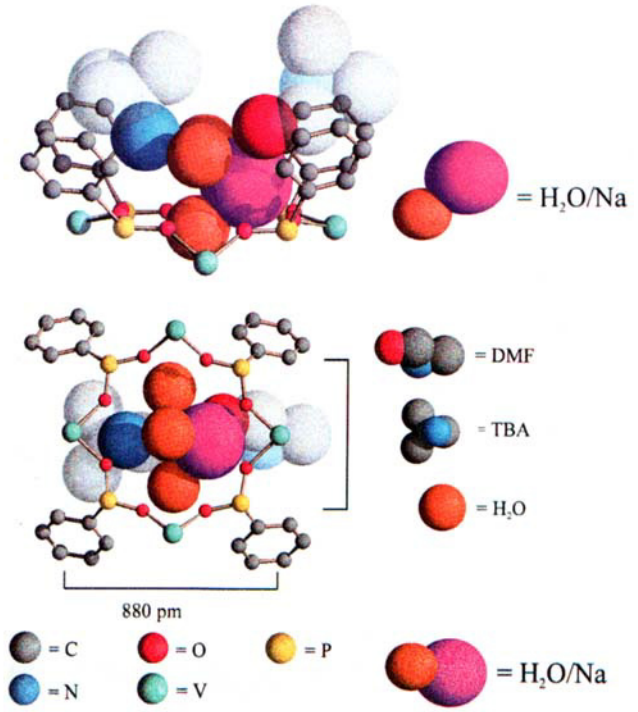

Fig. 2. Illustration of the arrangement of the particles in a truncated cone of **1**, in which the exchangeable particles that control the organization in the cavity (H_2O/Na^+; in **2** replaced by Rb^+) are emphasized. The view at the top is approximately parallel to the coronand plane, while that at the bottom is perpendicular to it, looking from the center of the cavity in the direction of the coronand.

of the particles in the cavity. In the horizontal plane of symmetry are now eight electron density maxima, which can be divided into two almost L-shaped groups (reproducible in several independent measurements with different single crystals! Fig. 1b).

A Rb^+ ion can now be found in the center of the coronand of **2**, as expected, instead of the H_2O molecule in **1**; this cation has an optimal "fit" because of its size. It is linked to a second Rb^+ ion by a bridging H_2O molecule. This ion takes the position of the tBuNH$_3^+$ ion of **1** (the position is occupied to about 50% by a Na^+ ion). The approximate square-pyramidal environment for the second Rb^+ ion is completed by two μ_2-O atoms of the coronand, a terminal O atom of the $\{V_5O_9\}^{3+}$ unit, and another H_2O molecule. The site of the DMF molecule remains almost the same as in **1**.

An important aspect is that the exchange of the content of the truncated cones and in particular of the H_2O molecule in the center of the coronand of **1** by a Rb^+ ion in **2** leads to a significant reorganization and migration of the particles in the central cavity that can be easily understood. During the reaction a H_2O molecule moves from its position in **1** to the bridging position between two V centers in **2**. Furthermore, the N_3^- ion "sets itself up" between the electrophilic centers (a V^V atom of the $\{V_5O_9\}^{3+}$ unit and a Rb^+ ion in the center of the coronand) (Fig. 1b).

The only weak interaction of the N_3^- ion with the host and its presence in the cavity is distinctly evident from the half width of the characteristic ν_{as}(NNN) band of compounds **1** and **2** at 2043 and 2044 cm^{-1}, respectively, which is only about a tenth of that in the corresponding alkali metal salts. In this context we must point out the possibility of using such compounds as ion cages, for example for spectroscopic studies.[8]

Compound **1**, whose anionic host part is soluble in organic solvents without decomposition, is apparently a suitable starting compound for further studies, because the contents of the truncated cone, and in particular the Na^+ ion that is slightly too small for the coronand, can easily be exchanged. The ambivalent cage system has an extremely high formation tendency, and on account of its size and the presence of a nucleophilic and an electrophilic component it can accommodate very different guests like NH_4^+, K^+, Rb^+, H_2O, MeCN, MeOH, Cl^-, Br^-, N_3^-, and even fragments of ion lattices.[6, 9] In our opinion these features enable further fundamental investigations into the influence of different "external fields" on the type of organization of diverse particles in the cavity of **1**, that is, the attempt to assess the extent of their control from the truncated cone. Controlled interactions of the type described here may be regarded as models for processes in ion channels in both the biological and the inanimate world. They might, however, also be relevant for the understanding of interactions between hydrophilic regions of proteins, their active metal cluster sites or their ligands, and substrates. Since, for instance, the N_3^- ion is a substrate of nitrogenase and some H_2O molecules fill the space between the homocitrate ligand of the FeMo cluster and the protein,[10] the relevance to this topical field is apparent. Of fundamental, general interest is certainly the fact that here the study of intermolecular interactions that are important, for instance, for molecular epigenesis is possible within smaller aggregates in a quasi-closed system.

Experimental Procedure

1: A mixture of V_2O_5 (1.10 g, 6.1 mmol), tBuNH$_2$ (1 mL), Et_3N (1 mL), H_2O (50 mL), and DMF (20 mL) was vigorously stirred in a 100 mL wide-necked Erlenmeyer flask at 60 °C until a grey-green solution formed. After addition of NaN_3 (1.00 g, 15.4 mmol), $PhPO_3H_2$ (2.00 g, 12.7 mmol), and N_2H_5OH (0.18 mL, 3.8 mmol), the volume of the then dark green solution was reduced to 50 mL under stirring at 60 °C, filtered, and cooled to room temperature. The resulting green crystals (which weathered slowly out of the mother liquor, but were soluble without decomposition in DMF and MeCN) were filtered off after 2–3 days (yield: 79% based on V).

2: A solution of **1** (520 mg, 162 μmol) and RbBr (340 mg, 2055 μmol) in a mixture of H_2O (4.5 mL) and DMF (6 mL) was heated at 80 °C with stirring for 10 min, filtered, cooled to room temperature, and allowed to stand in a closed vessel under an inert atmosphere to crystallize. The green crystals, which slowly weathered out of the mother liquor but were soluble without decomposition in DMF and MeCN, were filtered off after 3–4 days (yield: 53% based on V).

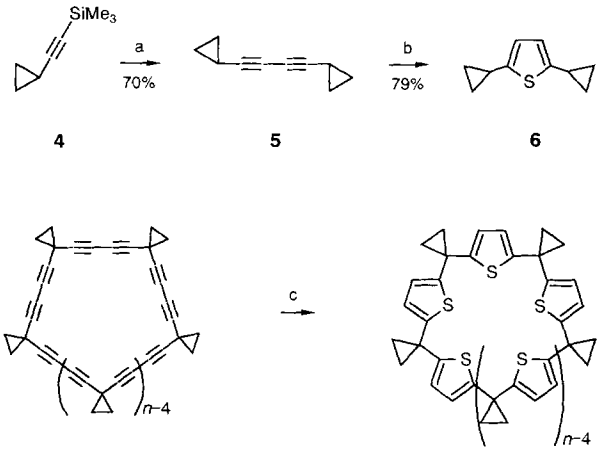
The Reactivity of 1,3-Butadiyne Moieties in the "Exploding" [*n*]Rotanes—A Crown of Thiophenes**

Sergei Kozhushkov, Thomas Haumann, Roland Boese, Burkhardt Knieriem, Stefan Scheib, Peter Bäuerle, and Armin de Meijere*



Dedicated to Professor Martin Klessinger on the occasion of his 60th birthday

In recent years, a variety of cyclic, macrocyclic, and oligocyclic polyacetylenes have been prepared.[1–5] On top of having interesting structural and physical properties, such compounds should show a rich chemistry due to the high reactivity of their acetylene moieties towards electrophiles, nucleophiles, and metal compounds.[4–6] In particular, molecules with 1,3-diyne units[7] should tend to give interesting new structures upon reaction with various reagents. Under this aspect the recently reported macrocyclic dehydrooligomers of 1,1-diethynylcyclopropane with spirocyclopropane rings between each two 1,3-diyne units such as **1**–**3**[8,9] are intriguing, as any clean transformation of all their diyne units would lead to novel cyclic structures with alternating spirocyclopropane and various other groups. In view of the known heterocyclization of 1,3-diynes to thiophenes,[10] we have probed the "exploding" [*n*]rotanes **1**–**3** for such transformations.

1, n = 5
2, n = 6
3, n = 8

To find the best suitable reaction conditions for substrates containing cyclopropane rings, the thiocyclization of dicyclopropyldiacetylene (**5**),[3] which was readily prepared from (trimethylsilylethynyl)cyclopropane (**4**)[11] by direct treatment with CuCl and $Cu(OAc)_2$[12] (Scheme 1), was tested. The best result was achieved with $Na_2S \cdot 9H_2O$ under strongly basic conditions (KOH/DMSO);[13] 2,5-dicyclopropylthiophene (**6**) was obtained from this reaction in 79% yield.[14]

1, n = 5
2, n = 6
3, n = 8

7, n = 5 (22%)
8, n = 6 (59%)
9, n = 8 (58%)

Scheme 1. a: 12 equiv CuCl, 16 equiv $Cu(OAc)_2$, 20 °C, 12 h. b: 2.2 equiv $Na_2S \cdot 9H_2O$, 2 equiv KOH, DMSO, 55 °C, 3 h. c: same as b, but 1 h.

Under the same conditions, the exploding [*n*]rotanes **1**–**3** react within 1 h to produce the corresponding macrocycles **7**–**9** with alternating thiophene and spirocyclopropane rings in surprisingly good yields (up to 59% for n = 6, Scheme 1). The relatively low yield of the [5.5]-macrocycle **7**[15] is caused by its instability, which led to partial decomposition upon attempted purification by column chromatography and recrystallization. The [6.6]-macrocycle **8** is significantly more stable and can be obtained in pure form by recrystallization from chloroform, but the [8.8]-macrocycle **9** is less stable again. At room temperature, **7** polymerizes rapidly in the solid state as well as in solution. Nevertheless, all three macrocycles **7**–**9** have been unequivocally identified and fully characterized by their mass spectra (EI ionization), in which the molecular ions appear as the parent peaks (100% relative intensity), and diagnostically simple ^{1}H and ^{13}C NMR spectra (Table 1). The exact molecular masses of compounds **7**–**9** have been determined as 610.0951, 732.1141, and 976.1522 g mol^{-1} by high-resolution mass spectrometry,[16] confirming their molecular formulas as $C_{35}H_{30}S_5$ for the cyclic dehydropentamer **7**, $C_{42}H_{36}S_6$ for the cyclic dehydrohexamer **8**, and $C_{56}H_{48}S_8$ for the cyclic dehydrooctamer **9** of 2-cyclopropylthiophene.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Projekt Me 405/15-3) and the Fonds der Chemischen Industrie. We thank the companies BASF, Bayer, Degussa, Hoechst, and Hüls AG for generous gifts of chemicals.

Table 1. Physical and spectroscopic data of compounds **6**–**9**. NMR spectra: 250 MHz (^{1}H, $\delta(CHCl_3) = 7.26$), 62.9 MHz (^{13}C, additional DEPT, $\delta(CDCl_3) = 77.0$).

6: Colorless oil. ^{1}H NMR: $\delta = 0.65-0.85$ (m, 4H), 0.85–1.05 (m, 4H), 2.0–2.12 (m, 2H), 6.60 (s, 2H). ^{13}C NMR: $\delta = 9.12$ (CH_2), 10.99, 122.10 (CH), 145.0 (C) [14]

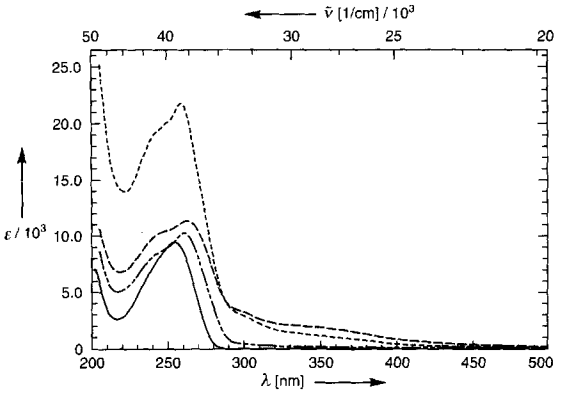
7: Yellow unstable powder. ^{1}H NMR: $\delta = 1.30$ (s, CH_2), 6.56 (s, CH). ^{13}C NMR: $\delta = 18.90$ (CH_2), 122.18 (CH), 21.58, 149.12 (C)

8: Colorless crystals, m.p. 248–250 °C (decomp.). ^{1}H NMR: $\delta = 1.33$ (s, CH_2), 6.57 (s, CH). ^{13}C NMR: $\delta = 19.88$ (CH_2), 123.84 (CH), 21.96, 148.22 (C)

9: White powder, decomp. > 100 °C. ^{1}H NMR: $\delta = 1.34$ (s, CH_2), 6.59 (s, CH). ^{13}C NMR: $\delta = 20.10$ (CH_2), 123.94 (CH), 21.98, 148.15 (C)

The ^{1}H NMR signals for compounds **7**–**9** show a weak downfield shift with increasing ring size, as was observed for **1**–**3**,[9] but in the ^{13}C NMR spectra only the signals of the methylene, methine, and cyclopropyl quaternary carbons are shifted downfield, whereas those of the thiophene quaternary carbons are shifted upfield with increasing ring size (Table 1).

The UV spectra of the macrocycles **7**–**9** in comparison to that for the basic chromophore 2,5-dicyclopropylthiophene (**6**) show a distinct bathochromic shift of the intense main absorption in the region 220–280 nm ($\varepsilon = 10200-21600$) and a distinct splitting into two bands (Fig. 1).[17]



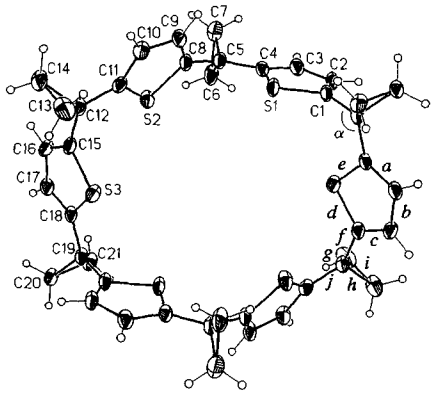


Fig. 1. UV spectra of 2,5-dicyclopropylthiophene (**6**) (—) and the "crowns of thiophenes" **7** (– – –), **8** (------) and **9** (– · – · –) in *t*-butyl methyl ether.

While attempts to grow good quality crystals of compounds **7** and **9** failed, [24](2,5)-cyclopropylthiophenocrown-6 (**8**) crystallized on slow concentration of a dilute solution in ethanol/dichloromethane in the form of needles, for which an X-ray structure analysis has been successfully performed. The macrocycle of **8** adopts a chairlike conformation (Fig. 2) with a center of inversion (overall S_6 symmetry). The two cyclopropyl groups on each thiophene unit are alternately almost bisected or perpendicular[18] to the planes of the adjacent thiophene groups (mean torsional angles S1-C4-C5-C8, S2-C11-C12-C15, and S3-C18-C19-C1′ = 8.6° and S1-C1-C19′-C18′, S2-C8-C5-C4, and S3-C15-C12-C11 = 98.8°). Accordingly, each cyclopropane ring has a close to optimal orientation for conjugation only with one of its neighboring thiophene moieties.

This unusual conformation with three sulfur atoms above and three below the equatorial plane probably results as an energetic compromise between the mutual repulsion of the sulfur atoms and a maximum conjugation between the cyclopropane and thiophene fragments. The diagonal interatomic distances between the sulfur atoms are far from being equal (S1–S3 = 6.523(2), S1–S1′ = 7.399(3), S1–S2′ = 6.090(2), S2–S3′ = 6.611(2), S2–S2′ = 7.406(3), S3–S3′ = 7.704(3) Å), and the whole assembly of

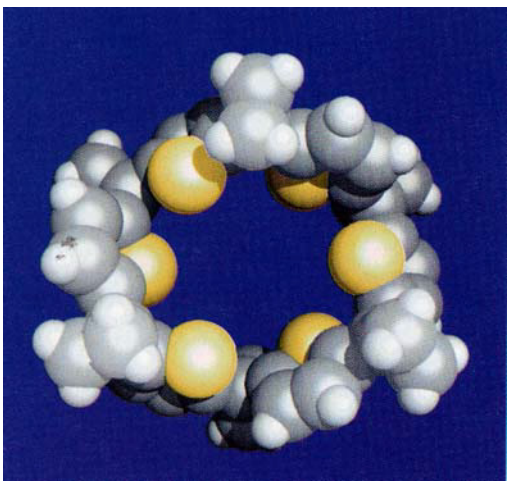

Fig. 2. Top: Crystal structure of [24](2,5)-cyclopropylthiophenocrown-6 $C_{42}H_{36}S_6$ (**8**) [19]. The numbering of atoms does not follow that recommended by IUPAC. Bond lengths [Å] and angles [°] (averaged over S_6 symmetry): $a = 1.353(4)$, $b = 1.405(3)$, $c = 1.365(5)$, $d = 1.719(2)$, $e = 1.723(4)$, $f = 1.489(4)$, $g = 1.515(3)$, $h = 1.509(9)$, $i = 1.486(6)$, $j = 1.488(6)$, $\alpha = 116.2(6)$. Bottom: The colored picture shows the three sulfur atoms each above and below the equatorial plane of the macrocycle **8**.

six sulfur atoms in one molecule corresponds to a large chair with a mean torsional angle of 56.0° and interatomic distances of S1–S2 = 4.208(2), S2–S3 = 3.659(2), S3–S1′ = 3.792(2) Å, two of which are a little smaller than the sum of van der Waals radii (3.90 Å[20]) of two sulfur atoms. In the cyclopropane rings the proximal bonds are longer than the distal ones (Fig. 2), which expresses an electron-withdrawing action of the thiophene moieties according to established theory.[21] The differences in the bond lengths ($\Delta = 0.029$ and 0.023 Å), however, are smaller than those in the exploding [6]rotane **2** ($\Delta = 0.055$ Å[8, 9]), but larger than those in vinylcyclopropane ($\Delta = 0.015$ Å[22]). It is probably the steric interaction of two neighboring sulfur atoms that causes the exocyclic angle on the spirocyclopropane rings ($\alpha = 116.2°$) to be a little larger than that in compound **2** ($\alpha = 115.5°$[8, 9]). The six thiophene units are undistorted with approximate local C_{2v} symmetry and bond lengths very close to those in thiophene[23a] and 2,5-disubstituted thiophenes.[23b]

In order to better understand the conformation of macrocycle **8**, its geometry was optimized both by molecular mechanics (MM2 + π-SCF[24]) and semiempirical calculations (AM1 and PM3[25]). These predict a conformation resembling a crown of thorns with three sulfur atoms pointing up and three down; in this conformation all the cyclopropane and neighboring thiophene rings are oriented perpendicular[18] with respect to each other.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0782 $ 10.00+.25/0

The crystal structure is not a minimum energy conformation according to these calculations, but a second minimum, slightly higher in energy than that for the crown, is found for a chair conformation close to that observed in the crystal. Apparently, the potential energy surface for conformational changes of this macrocycle is rather flat, and crystal lattice forces can easily change the adopted structure in the solid state. These macrocycles **7**–**9** all suffer from transannular strain, which may be the predominant reason for the observed instability of compound **7**.

The electrochemical behavior of the cyclopropyl-substituted thiophene model compound **6** and the [6.6]-macrocycle **8** were determined by cyclic voltammetry in methylene chloride with added tetrabutylammonium hexafluorophosphate. As expected for monomeric thiophenes, both oxidation potentials are irreversible indicating a quick follow-up reaction of the radical cations created. The peak potential found for 2,5-dicyclopropylthiophene (**6**) ($E_{pa} = 0.95$ V vs Fc/Fc^+) is distinctly lower than that of the cyclic compound **8** with $E_{pa} = 1.39$ V vs Fc/Fc^+.[26] These findings are in accord with the chairlike structure of **8** in which only one of the two cyclopropyl substituents on each thiophene moiety has the correct orientation for conjugative interaction. This decreased conjugation leads to an increased oxidation potential for **8**. The electrochemical measurements were hampered by the unusual fact that the oxidation of both compounds led to an immediate formation of an insulating film on the working electrode. Obviously, the first formed heterocyclic cation radicals undergo subsequent rearrangement (e. g. with ring opening of the cyclopropyl moieties) leading to highly reactive intermediates.[27]

The facile and high-yielding reaction of the exploding [*n*]rotanes with sodium sulfide to give structurally intriguing compounds suggests that other macrocyclic oligodiacetylenes should be capable of undergoing analogous transformations. Work along these lines is in progress.

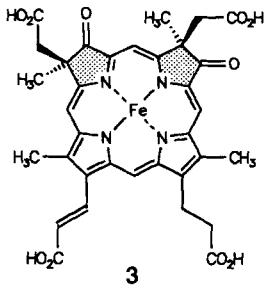
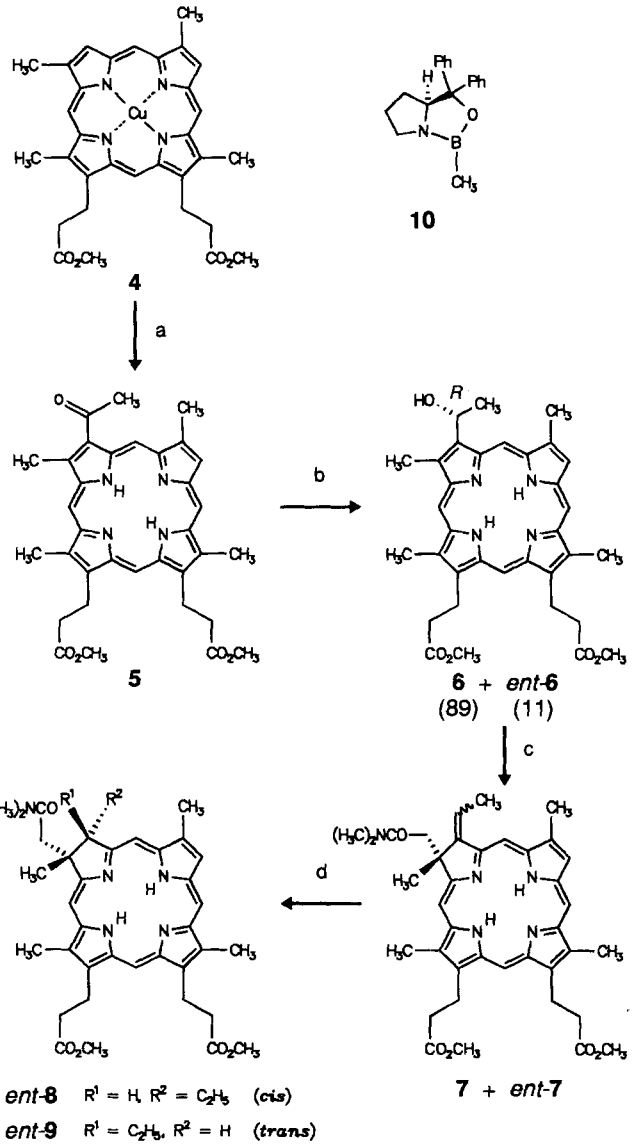
A Simple, Chirogenic, Enantioselective Synthesis of Chlorins and Isobacteriochlorins**

Dirk Kusch, Elke Töllner, Anngret Lincke, and Franz-Peter Montforts*



Factor I (**1**), sirohydrochlorin (**2a**), siroheme (**2b**), and heme d_1 (**3**) are naturally occurring porphyrinoids with the basic chlorin or isobacteriochlorin framework. Partially reduced derivatives of the metal-free macrocycles **1** and **2a** are important intermediates in the biosynthesis of vitamin B_{12};[1] the iron-containing isobacteriochlorins **2b** and **3** play a central role as cofactors for sulfite- or nitrite-reducing enzymes in bacteria and plants.[2]

1



2a M = 2H
2b M = Fe

3

All but two syntheses of chlorins known to date[2] produce racemic mixtures; the exceptions are the syntheses of enantiomerically pure chlorophyll a, which was obtained by resolution of a racemate at the end of the synthesis,[2, 3] and factor I (**1**), which was synthesized from an optically active synthetic building block.[2, 4] Subsequent to the synthesis of the pure enantiomer sirohydrochlorin **2a**, [2, 5a] Battersby et al. were also able to synthesize the enantiomerically pure ligand of heme d_1 (**3**) in a total synthesis encompassing approximately 35 steps,[5b] and to establish the absolute configuration of **3**, since a glutamic acid derivative with a known configuration was used as a synthetic element. We recently determined the relative configuration of **3**.[2, 6] Here we describe a simple procedure for the synthesis of optically active chlorins and isobacteriochlorins with geminal dialkyl substituents, by chirogenic, enantioselective reduction and subsequent Claisen rearrangement with transfer of chirality.

The acylporphyrins **5** and **11**[7] form the starting point for our investigation. They have already been synthesized from the copper(II) complex **4** (Schemes 1 and 2). Under conditions which were carefully optimized with respect to concentrations of starting material and reagent, solvent, and temperature, and with rigorous exclusion of water, the prochiral ketones **5** and **11** can be reduced to give in high yield the alcohol **6** and hematoporphyrin dimethyl ester **12a** with borane dimethyl sulfide and the methyloxazaborolidine **10** as homochiral catalyst. The enantiomeric excess for **6** was 78%, determined by HPLC and ^{1}H NMR spectroscopy. The hematoporphyrin dimethyl ester **12a** was formed with an enantiomeric excess of 92%. The *R*

CH_2N_2, ether, MeOH, room temperature, 1 h (11.8% **14**/*ent*-**14** relative to **12a** + *ent*-**12a** in the reduction mixture); d) $Pd(OAc)_2$, THF/H_2O (4/1), $HSi(OEt)_3$, room temperature, 20 min (66.5% **15a–d** + *ent*-**15a–ent-15d**; e) 1. *p*-TsOH, MeOH, reflux, 50 h; 2. $Ni(acac)_2$, $CHCl_3$, MeOH, reflux, 8 h (59.9% **16a** + isomers; 36.8% **16a**/*ent*-**16a**). – All new compounds were characterized by elemental analysis, UV/Vis and ^1H NMR spectroscopy, and mass spectrometry. The scaled data agree with the corresponding data in the racemic series.

configuration of the stereogenic centers in **6** and **12a** can be concluded from the determination of the absolute configuration of **9** and **14**, which agrees with the transition state model for this type of reduction suggested by Corey.[8d]

The higher enantiomeric excess of **12a**, compared to the simple reduction of **5** to **6**, is only surprising at first glance. A closer observation shows that the fractions x of the resulting enantiomers **12a** and *ent*-**12a**, as well as those of the diastereomers **12b** and *ent*-**12b**, correspond in the product mixture to the terms of the binomial equation (a) [equations (b)–(d)], where W_{Si} and W_{Re} are the probabilities for attack from

$$W_{Si}^2 + 2\,W_{Si}W_{Re} + W_{Re}^2 = 1 \quad \text{(a)}$$

$$x(\mathbf{12a}) = W_{Si}^2 \quad \text{(b)}$$

$$x(\mathbf{12b}) + x(\textit{ent}\text{-}\mathbf{12b}) = 2\,W_{Si}W_{Re} \quad \text{(c)}$$

$$x(\textit{ent}\text{-}\mathbf{12a}) = W_{Re}^2 \quad \text{(d)}$$

the enantiotopic sides of the two keto groups.[11] Thus, it follows that the enantiomeric excess is significantly higher after two reductions than after the first reduction, since here the less probable (and undesirable) attack on the *Re* side mostly leads to formation of the unconvertable diastereomer, easily separable from the mixture, and the formation of *ent*-**12a** (W_{Re}^2) from it is secondary.[12] Analysis by HPLC of the hematoporphyrin ester in an achiral phase gives a diastereomer ratio of (**12a** + *ent*-**12a**)/(**12b** + *ent*-**12b**) of 2.53:1, from which an enantiomeric excess **12**/*ent*-**12** of 92% and a *Si*-selectivity (W_{Si}) of 83% can be calculated using equations (a)–(d). The fractions of the four stereoisomers were determined by HPLC of the corresponding dibenzoate in a homochiral phase (Fig. 1). Although the peaks for *ent*-**12a** and for one of the diastereomers **12b** and *ent*-**12b** coincide, an enantiomer excess of 88% and thus a *Si*-selectivity of 80% could be determined, since the signal for **12a** is completely separated. The selectivity thus corresponds to that determined for the reduction of **5**.

In the further course of the synthesis, the mixture of **6** and *ent*-**6**, as well as that of all the stereoisomers of **12**, underwent an amidoacetal Claisen rearrangement, in which the chirality of the hydroxy-substituted centers of the starting materials was completely transferred to the dialkylated centers of the products.[13, 15] The enantiomerically enriched chlorin **7** (**7**:*ent*-**7** = 89:11) is formed from **6**/*ent*-**6**, and the enantiomerically enriched isobacteriochlorin **13** (**13**:*ent*-**13** = 96:4) from **12a**/*ent*-**12a** (**12a**:*ent*-**12a** = 96:4). The undesired product of the rearrangement diastereomeric to **13**, formed from **12b**/*ent*-**12b**, is easily separated at this stage by flash chromatography. Thus the much more difficult separation of the hematoporphyrin ester stereoisomers can be avoided.

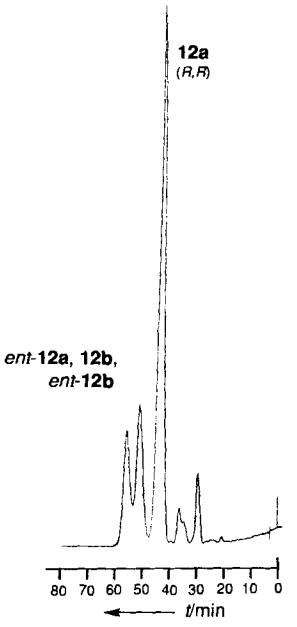

Fig. 1. Chromatogram from the HPLC of the dibenzoates of **12a**, *ent*-**12a**, **12b**, and *ent*-**12b** on a homochiral phase [Nucleosil Chiral 2, *n*-heptane/dioxane (77/23)].

Hydrogenation of the exocyclic double bonds in **7** and **13** is best performed with the method described by Tour.[16] Here the *cis* diastereomers **8** (from **7**) and **15a–d** of which the *cis,cis,cis* isomer **15b** dominates (from **13**) are kinetically preferred. The fraction of the thermodynamically more stable *trans* diastereomers **9** and **15a** formed as secondary products can be increased by subsequent acid-catalyzed equilibration. The enantiomerically enriched **9** was isolated by preparative HPLC (Table 1). The enantiomerically enriched *trans,trans,trans* isomer **15a** could be separated from its stereoisomers, which were only present in small amounts, by formation of **16** by complexation with nickel(II) (Table 1). The *trans*-ethylchlorin **9** can be clearly differentiated from *cis* isomer **8** by mass spectrometry or ^{1}H NMR spectroscopy. The absolute configuration of **9** is obtained by comparison of its CD spectrum with that for the octamethyl ester of Factor I, whose configuration is known. According to the mirrored courses of the CD curves (Fig. 2) for enantiomerically enriched **9** and for the octamethyl ester of Factor I,[18] **9** has the (*2R,3R*) configuration.[19]

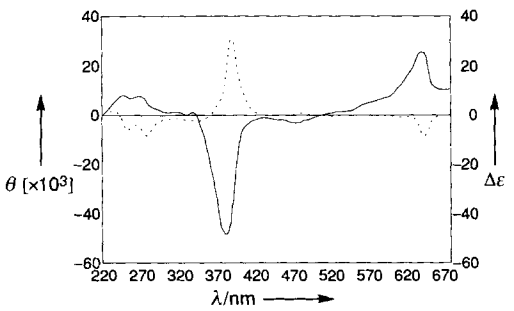

Fig. 2. CD spectra of the octamethyl ester of Factor I (·····) [18] and *trans*-chlorin **9** (**9**:*ent*-**9** = 89:11) (——) in MeOH. The $\Delta\varepsilon$ scale applies to the CD curve for the octamethyl ester of Factor I, and the θ scale for that from **9**.

The relative configuration of (isobacteriochlorinato)nickel(II) (**16**) follows from the typical fragmentation pattern of the mass spectrum,[17] whereas the absolute configuration is fixed by the enantioselective reduction, subsequent course of the synthesis, and comparison of its CD spectrum with that of the (sirohydrochlorinato octamethyl ester)nickel(II), whose configuration is known.[19]

Oxidative cleavage of the exocyclic double bond in **13**/*ent*-**13** (**13**:*ent*-**13** = 96:4) with simultaneous hydrolysis of the amide groups produces enantiomerically enriched dioxoisobacteriochlorin (**14**, Table 1). Compound **14** is an intermediate in all the previous syntheses[5, 6] of the metal-free ligand of heme d_1 (**3**) and, according to the comparison of the CD spectra, proves to be enantiomeric to the corresponding intermediate given in ref. [5b].

Table 1. Selected physical data for **9**, **14**, and **16**.

9: CD (MeOH, **9**:*ent*-**9** = 89:11): $\theta(\lambda)$ = +8020 (250 nm), +7700 (270), −48070 (383), −2950 (480), +25700 (640).

14: CD (MeOH, **14**:*ent*-**14** = 96:4): $\theta(\lambda)$ = −7750 (237 nm), −7600 (249), +7290 (288), +9150 (347), +9150 (366), −15550 (417), +3130 (440), −5810 (568), −2680 (642).

16: CD ($CHCl_3$, **16**:*ent*-**16** = 96:4): $\theta(\lambda)$ = −1610 (259 nm), +2980 (297), −7320 (374), +990 (405), +620 (415), +1240 (436), −370 (491), +4220 (554), +11540 (592); ^{1}H NMR (360 MHz, $CDCl_3$): δ = 3.76 (dd, $^3J_1$ = 9.2 Hz, $^3J_2$ = 3.9 Hz, 1H; 3-H), 3.83 (dd, $^3J_1$ = 8.9 Hz, $^3J_2$ = 5.3 Hz, 1H; 8-H), 6.48 (s, 1H; 5-H), 7.20 (s, 1H; 20-H), 7.42 (s, 1H; 10-H), 8.37 (s, 1H; 15-H); UV/Vis ($CHCl_3$): $\lambda_{max}(\varepsilon)$ = 594 (30700), 548 (7050), 524 (4550), 389 (32700), 280 nm (8300); MS (70 eV): *m/z* (%): 824 (28) [M^+ for ^{58}Ni], 737 (100) [$M^+ - C_4H_9NO$], 650 (50) [$M^+ - 2C_4H_9NO$].

The dependence of the catalytic functions and the redox properties of the isobacteriochlorins presented here and their metal complexes on their absolute and relative configurations is of interest for the understanding of many processes catalyzed in nature by hydroporphinoid compounds.[1d, 2] It should be mentioned that one of the hematoporphyrin stereoisomers **12b** and *ent*-**12b** is identical to porphyrin c, which was isolated from cytochrome c of various species.[20] Elsewhere we will give a full report of the first stereochemical assignment of porphyrin c to one of the synthesized hematoporphyrin stereoisomers, which is of importance for research into evolution.

[9] The enantiomeric excess of **6** was determined by HPLC, after conversion into the benzoate (benzoic acid anhydride, 4-dimethylaminopyridine, CH_2Cl_2, room temperature, 90 min) and chromatography on Nucleosil Chiral 2 (Macherey-Nagel) with *n*-heptane/dioxane 85/15 (1 mL min^{-1}) as solvent. t_R(benzoate of **6**) = 142 min, t_R(benzoate of *ent*-**6**) = 161 min.

[10] Lanthanoid shift experiments with tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato]praseodymium(III) in $CDCl_3$ produced splitting of all signals in ^{1}H NMR spectra of **6**. The especially strong splitting of the signals of protons of pyrrole-fixed methyl groups and of some methine protons enabled the determination of the enantiomeric excess.

[11] The equations (b)–(d) are based on two assumptions: 1) that the reductions are independent of one another, which is valid because of the relatively large separation of the keto groups; and 2) that the selectivity is the same for both keto groups.

[12] The most prominent example of increased enantiomeric excess by multiple enantioselective chirogenic reactions is the perhydroxylation of squalene: G. A. Crispino, P. T. Ho, K. B. Sharpless, *Science* **1993**, *259*, 64-66.

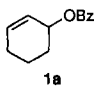
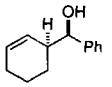
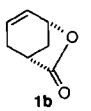
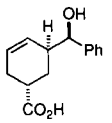
Highly Stereoselective Allylation of Benzaldehyde: Generation of a Stereochemically Defined Allylzinc Species from a π-Allylpalladium Intermediate and Diethylzinc**

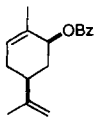
Yoshinao Tamaru,* Akihiro Tanaka, Kengo Yasui, Sachio Goto, and Shuji Tanaka

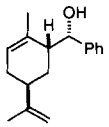


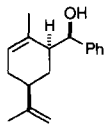


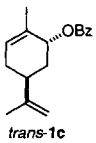


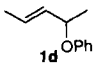


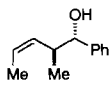


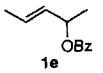


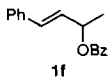


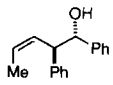


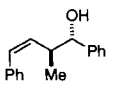


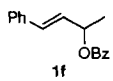


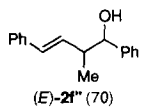


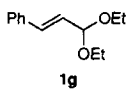


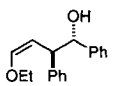


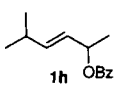


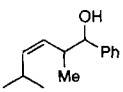


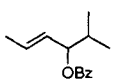












Generation of stereochemically defined organometallic reagents is important for efficient, stereoselective synthesis. Here we describe the stereoselective addition of 2-cyclohexenylzinc species, generated by the Pd^0-catalyzed reaction of 2-cyclohexenyl esters and diethylzinc, to benzaldehyde. We also report the analogous reaction of structurally fluxional acyclic 1,3-disubstituted allylzinc species generated in a similar way.

Recently we reported that diethylzinc can be used to promote the Pd^0-catalyzed allylation of carbonyl compounds (aldehydes, ketones, esters, lactones, acid anhydrides) with allylic substrates (allyl benzoates, acetates, phenyl ethers).[1] At that time, we proposed a reaction mechanism that involves the hitherto undefined equilibrium between a π-allylpalladium intermediate and diethylzinc, and diethylpalladium and an allylzinc species (umpolung of π-allylpalladium).

To obtain further information about the mechanistic details and also to test the synthetic scope of the umpolung technique, we examined the allylation of benzaldehyde with 2-cyclohexenyl substrates **1a–c** (Table 1, entries 1–4). The reactions proceeded smoothly under the conditions previously reported (**1** (1.2 mmol), benzaldehyde (1 mmol), diethylzinc (2.4 mmol), and tetrakis(triphenylphosphane)palladium (0.05 mmol) in THF (5 mL) at room temperature under nitrogen)[1] and provided homoallyl alcohols **2a–c** in good yields.

In sharp contrast to the moderate stereoselectivity for the allylation with 1- or 3-monosubstituted allylating agents (*syn*:*anti* ≈ 2:3),[1] all the reactions with 2-cyclohexenyl substrates provided the *syn* addition products exclusively. Furthermore, the reaction was stereoselective with respect to the configuration of allylic stereocenters. The reaction of **1b**[2] provided the inversion product *trans-syn*-**2b** as a single stereoisomer in quantitative yield (entry 2). A pair of stereoisomers *cis*- and *trans*-**1c**[3] showed similar selectivity: *cis*-**1c** furnished a mixture of an inversion (*trans-syn*-**2c**) and a retention product (*cis-syn*-**2c**) in a ratio of 87:13 (entry 3), and *trans*-**1c** afforded analogous products in a ratio of 82:18 (entry 4).

Table 1. Palladium(0)-catalyzed regio- and stereoselective allylation of benzaldehyde by umpolung of π-allylpalladium [a].

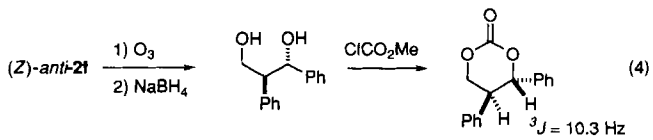
[**] Support from the Japanese Ministry of Education, Science and Culture is gratefully acknowledged. We thank Y. Ohhama for his splendid assistance with the NMR experiments.

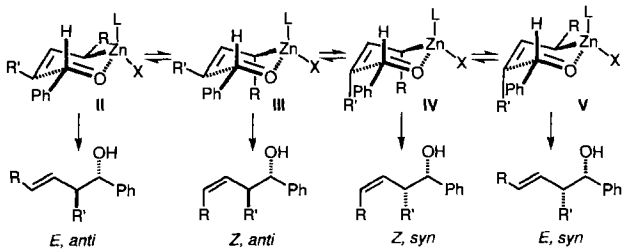
The structures of products **2a–c** were determined unequivocally by NOE experiments[4] with the derivatives obtained through stereochemically well-defined transformations [Eqs. (1)–(3)].

Esterification of *trans-syn*-**2b**, followed by isomerization with LDA (4 equiv at −78 °C for 1 h in THF) provided a mixture of *trans*- and *cis*-**3** (43:57); only the *cis* isomer underwent lactonization (cat. toluenesulfonic acid in 1,2-dimethoxyethane at reflux for 8 h) to provide the bicyclic lactone **4** in 71% yield [Eq. (2)]. Iodoetherification[5] of the mixture of *cis-syn*- and *trans-syn*-**2c** (72:16, entry 4) provided bicyclic ethers *endo*- and *exo*-**5** (85:15, 80% yield based on *cis-syn*-**2c**); *trans-syn*-**2c** was recovered intact (80%).

A mechanistic rationale for the *syn*-selective addition with inversion of configuration at the allylic stereocenter is shown for *trans*-**1c** in Scheme 1. It is assumed that the cyclohexenylzinc species *cis*-**7** is formed selectively from *trans*-**1c** with inversion of the allylic stereocenter;[6] conversion of *trans*-**1c** into the π-allylpalladium complex *cis*-**6**[7] proceeds with inversion and subsequent transformation into *cis*-**7** with retention. The resulting *cis*-**7** is configurationally rather stable under the reaction conditions and adds to benzaldehyde via a six-membered chairlike transition state structure **I**.[8]



Scheme 1. Mechanistic rationale for inversion of configuration at the allylic center and *syn*-selective addition.

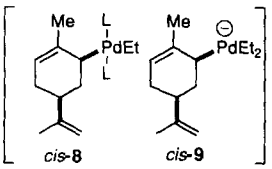


Stimulated by the excellent *syn* selectivity of the addition of cyclohexenylzinc, we examined acyclic 1,3-disubstituted allylic substrates and found that they also displayed pronounced selectivity, providing the *anti* products with (*Z*) configuration either exclusively (entries 5–7, 9) or selectively (entries 10, 11).[10] Despite the rather vigorous reaction conditions (room temperature, 1–3 d), the exclusive formation of (*Z*) isomers suggests that these reactions are controlled kinetically. Indeed, when the product mixture obtained from the reaction of **1f** was heated at 65 °C for a long period of time, (*Z*)-*anti*-**2f** disappeared completely and a diastereomeric mixture of (*E*)-**2f''** formed (3:2, entry 8).

Allylating agents with unsymmetrically substituted allyl groups showed interesting regioselectivity.[11] Allylic termini bearing phenyl groups are generally more reactive than the others (entries 7, 9). Whereas the reaction of **1g** and benzaldehyde yielded 1-ethoxy-3-phenylpropene **2g**, in the analogous reaction with 1,1-diethoxy-2-propene (4.8 equiv Et_2Zn, room temperature, 26 h) addition proceeded exclusively at the allylic terminus bearing the ethoxy groups[12] to furnish 3-ethoxy-4-hydroxy-4-phenyl-1-butene in 75% yield. When the steric bulk of the substituents in positions 1 and 3 differs substantially, the allylic terminus with the smaller substituent reacts preferentially (entries 10, 11).

The (*Z*) configuration of the products was determined from the coupling constants between the olefinic protons ($^3J = 10$–11 Hz). The *anti* configuration was deduced from the ^3J coupling constants of the *trans* protons of the cyclic carbonate derived from (*Z*)-*anti*-**2f** by ozonolysis, reductive workup, and esterification [Eq. (4)].[13]

Four plausible transition state structures are shown in Scheme 2. Structures **II** and **V** seem to be unfavorable because of the *gauche* interactions between the equatorial substituent R and both the ligand L and the counterion X[14] associated with the Zn^{2+} ion. Of the transition state structures with R in axial position, **III** is favored over **IV**, in which R and R′ have a 1,3-diaxial relationship.[16] Thus, addition may proceed selectively through **III** to give the (*Z*)-*anti* products. The preference of Ph as R′ might be due to resonance stabilization; the preference of Me over *i*Pr as R′ may be explained by the the smaller steric hindrance towards carbonyl carbon atom.



Scheme 2. Transition state structures for the addition of a π-allylzinc complex to benzaldehyde and the resulting products.

The advantages of the palladium-catalyzed allylation described here are the excellent stereoselectivity (*syn* addition with inversion of the allylic stereocenter for 2-cyclohexenyl substrates and (*Z*)-*anti* addition for acyclic 1,3-disubstituted allylic substrates) and the applicability to a range of allylic substrates[17] readily prepared from allylic alcohols and α,β-unsaturated aldehydes, as well as the ease with which the reaction can be performed.

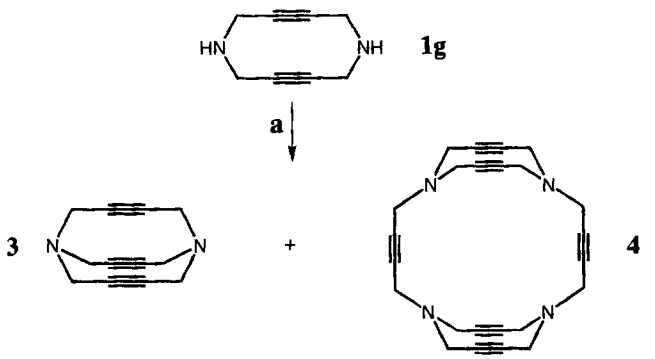
Novel "π-Boat" Cage Compounds as Potential Cryptands**

Rolf Gleiter,* Kirstin Hövermann, Joachim Ritter, and Bernhard Nuber

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

Since the discovery of the complexation properties of crown ethers, these species and their polycyclic congeners, the cryptands, have been studied in detail.[1] Because of their functional and geometrical properties azacryptands serve as excellent hosts for metal cations, organic cations, neutral organic molecules, and anions.[2]

Aliphatic and aromatic moieties have been used as bridging units. The aromatic units can serve as complexing functions for neutral organic molecules especially if π-π interactions between host and guest are possible. Thus numerous cryptands containing various π systems have been investigated.[3, 4] Nevertheless, there are only a few cryptands in which alkyne units combined with heteroatoms were used as building blocks.[5, 6] Our recent synthesis of *N,N'*-dialkyl-1,6-diazacyclodeca-3,8-diynes **1a–g**[7, 8] led to the idea of using the diazacyclodecadiynediyl unit **2** as a building block for new cryptands (Fig. 1). Each unit contains a pair of strongly interacting parallel triple bonds as a π system and two amine functions as linking elements.



1a-g **2**

Fig. 1. **a**, R = Me; **b**, R = Et; **c**, R = *i*Pr; **d**, R = *t*Bu; **e**, R = *p*-tolyl; **f**, R = Ac; **g**, R = H.

Recent X-ray structure investigations[7, 8] have shown that **1a–g** can be considered as an elongated piperazine; however, they show more conformational flexibility than piperazine, since the triple bond units diminish the Pitzer strength between the methylene groups. As a result the boat conformation of **1a–g** is nearly as stable as the chair conformation, as indicated by dynamic NMR investigations and semiempirical calculations.[8, 9] This opens possibilities to use this unit for the construction of novel cagelike molecules by intra- and intermolecular bridging. We favored the 2-butyne-1,4-diyl unit as a linking bridge for geometrical and steric reasons. In fact we obtained the bicyclic triyne **3** by reacting **1g** with 1,4-dibromo-2-butyne as the main product in nearly 10% yield (Scheme 1). The bicyclic triyne **3** is the first example of a topological prismane-like preorganization of triple bonds. Compound **3** is stable in solution and at temperatures below −40 °C in the solid state (white crystals). In contrast, the dihydrochloride **3** · 2 HCl is stable at

Scheme 1. a) 1,4-Dibromo-2-butyne, K_2CO_3, THF, 66 °C, high dilution, **3**: 10%, **4**: 6%.

room temperature. The macrocyclic cage compound **4** was isolated as a side product.

This result encouraged us to study the reaction of **1g** with several α,α′-dihaloxylenes. However, to date these experiments have not led to bicyclic products; 1,4-bis(bromomethyl)benzene gave the "trimer" **5** and with the 1,3 isomer, the "dimer" **6** and "trimer" **7** were obtained. 2,6-Bis(bromo)methylpyridine afforded the "dimer" **8** (Scheme 2).

The most relevant NMR spectroscopic and mass spectrometric data of the new cage compounds are listed in Table 1. The structure of the bicyclic triyne **3** can be proved by NMR spectroscopic data since due to its D_{3h} symmetry it shows only one signal in the ^{1}H NMR spectrum and two signals in the ^{13}C NMR spectrum. To distinguish between possible dimeric and trimeric structures of **4**–**8** additional FAB$^+$ spectrometric data were necessary.

The X-ray structure investigations[10] on single crystals of the *meta*-cyclophane **6** show that the diyne ring moieties adopt a boat conformation[11, 12] (Fig. 2). The nitrogen lone pairs are

oriented equatorial outside, forcing the benzylic methylene groups into an axial inside position. The preference for axial oriented substituents in diazacyclodecadiynes has been shown in all known cases **1a**–**g**[13]. From the NMR spectroscopic data an equilibrium between an "outside" (**6a**) and an "inside" isomer (**6b**) cannot be excluded.[12, 13] This isomerization process could take place by nitrogen inversion and rotation of the benzylic methylene groups (Scheme 3).

Scheme 2. Reaction conditions: K_2CO_3, THF, reflux, high dilution; a) 1,4-bis(bromomethyl)benzene, **5**: 20%; b) 1,3-bis(bromomethyl)benzene, **6**: 27%, **7**: 15%; c) 2,6-bis(bromomethyl)pyridine, **8**: 25%.

Unlike in the *meta*-cyclophanes **6** and **8**, the diazacyclodecadiyne units in **4** show a fast ring inversion process at room temperature on the NMR time scale, indicated by two sharp ^{1}H NMR singlets in the ratio 2:1. The ^{1}H NMR signals of the NCH_2 groups of **6** and **8** are split into an AA′BB′ pattern owing to the inequivalency of the axial and equatorial hydrogen atoms of the cyclodecadiyne boat. The decreased rigidity of the "trimer" **5** is reflected by a broad signal for the NCH_2 groups in the ^{1}H NMR spectrum at room temperature. This signal is split into a sharp AA′BB′ pattern at 253 K (in $CDCl_3$, T_c = 295 K, $\Delta G^{\neq}$ = 14 kcal mol^{-1} (Table 1).

^{1}H NMR (300 MHz, $CDCl_3$) investigations reveal the complexation of one water molecule in **8** as evidenced by H/D exchange experiments [**8** · H_2O: δ = 3.57 (s, H_2O)]. Preliminary complexation experiments of **8** with Cu^+ ions revealed strong shifts and splitting of the aromatic and the benzylic hydrogen atoms in the ^{1}H NMR spec-

Coordination of CO to the Alkaline Earth Metallocene $[(Me_5C_5)_2Ca]$**

Peter Selg, Hans H. Brintzinger,*
Richard A. Andersen,* and István T. Horváth*

Dedicated to Professor Richard R. Schmidt on the occasion of his 60th birthday

Compared to the countless transition metal carbonyl complexes, in which CO acts as a π acceptor for d electrons on the metal center, CO coordination to main group compounds has been observed in a few instances only. A gas-phase species HCO^+ has been found to have its ν(CO) absorption at 2184 cm^{-1}.[1] Diborane reacts with CO to give a volatile complex $[H_3B\text{-}CO]$ with $\nu(CO) = 2165$ cm^{-1}.[2] Microwave spectroscopy yields a dipole moment of 1.8 D for this molecule,[3] consistent with the charge distribution $[H_3B^-\text{-}C{\equiv}O^+]$.[4] Me_3Al was found to form a complex $[Me_3Al\text{-}CO]$ with $\nu(CO) = 2185$ cm^{-1} in a CO matrix at 15–35 K.[5] The increase of ν(CO) above that of free CO (2143 cm^{-1})[6] in all of these complexes indicates that CO is acting solely as a σ-donor ligand here. In $[Me_2Si\text{-}CO]$ and $[(Me_5C_5)_2Si\text{-}CO]$,[7, 8] on the other hand, ν(CO) is decreased to 1962 and 2065 cm^{-1}, respectively, consistent with a π-donor action of these divalent silicon species. Apart from low-temperature matrix studies,[9] CO coordination to alkaline earth compounds has not been reported so far. Here, we describe evidence

for the formation of the first carbonyl complex of an organo alkaline earth molecular compound, $[(Me_5C_5)_2Ca\text{-}CO]$.

When a solution of $[(Me_5C_5)_2Ca]$[11] in toluene is exposed to CO pressures of 2.5–70 bar in an elevated-pressure IR cell,[12] a new ν(CO) absorption appears at 2158 cm^{-1}. The appearance of this band, as well as its loss in intensity upon release of CO pressure, is practically instantaneous; repeated measurements at any given pressure show that these changes are reversible. Figure 1 shows the IR spectrum as a function of CO pressure at 10 °C. It is apparent that the change in absorbance at 2158 cm^{-1}, $\Delta E(2158)$, is a suitable measure for the extent of complex formation. A linear Hildebrand–Benesi plot[13] of $\Delta E(2158)^{-1}$ against

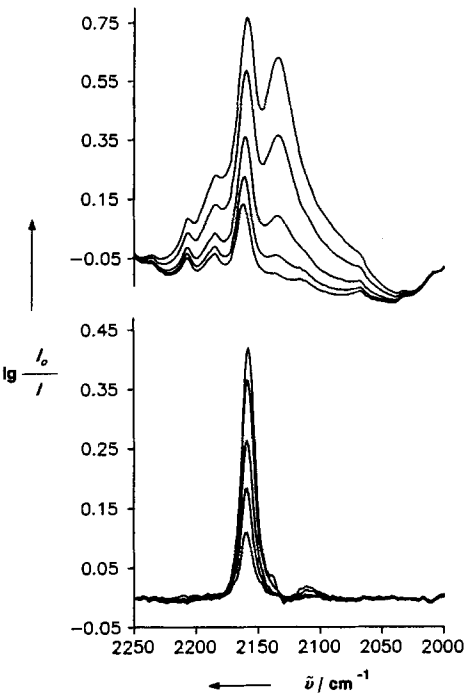

Fig. 1. IR spectra of a 4×10^{-2} M solution of $[(Me_5C_5)_2Ca]$ in toluene at 10 °C at CO pressures of 5, 10, 20, 40, and 60 bar; top: Base-line corrected spectra; bottom: Spectra corrected for the absorption of solvent and free CO in solution.

$p(CO)^{-1}$ indicates a stoichiometry $[(Me_5C_5)_2Ca\text{-}CO]$[14] and an equilibrium constant $K = 0.036$ bar^{-1} for the reaction between solvated decamethyl calcocene and gaseous CO [Eq. (a)]. Since

$$[(Me_5C_5)_2Ca](tol) + CO(gas) \rightleftharpoons [(Me_5C_5)_2Ca\text{-}CO](tol) \quad (a)$$

the concentration of dissolved CO is proportional to CO pressure, $c(CO) = p(CO) \times 7.1 \times 10^{-3}$ M bar^{-1}, throughout the temperature and pressure range considered here,[12] a value of $K = 5.1$ M^{-1} is obtained for the corresponding reaction involving dissolved CO [Eq. (b)]. IR spectroscopic measurements in the

$$[(Me_5C_5)_2Ca](tol) + CO(tol) \rightleftharpoons [(Me_5C_5)_2Ca\text{-}CO](tol) \quad (b)$$

temperature range of −27 to + 32 °C give values for the equilibrium constants as summarized in Table 1;[16] from these, thermodynamic values of $\Delta H_a^\circ = -25 \pm 5$ kJ mol^{-1} and $\Delta S_a^\circ = -110 \pm 10$ J $mol^{-1}K^{-1}$ are obtained for complex formation according to Equation (a), while values of $\Delta H_b^\circ = -25 \pm 5$ kJ mol^{-1} and $\Delta S_b^\circ = -70 \pm 10$ J $mol^{-1}K^{-1}$ are obtained for Equation (b).

Table 1. Temperature dependence of equilibrium constants K for reaction (a) and K for reaction (b) in toluene, as determined by IR spectroscopy (with e.s.d.).

T/°C	+32	+10	+3	−9	−18	−27
K/kbar^{-1}	15(3)	36(8)	51(3)	71(3)	115(14)	127(11)
K/M^{-1}	2.1	5.1	7.2	10.0	16.1	17.9

These data are confirmed by a ^{13}C NMR study at elevated CO pressures.[17] Solutions of $[(Me_5C_5)_2Ca]$ in $[D_8]$toluene under CO pressures up to 80 bar give only one ^{13}C NMR signal each for their C_5-ring, CH_3, and CO carbon atoms in the temperature range between + 30 and −70 °C,[18] indicating that the exchange of CO is rapid on the NMR time scale. The chemical shifts of these signals change with increasing CO pressure as indicated in Table 2. As changes in chemical shifts, $\Delta\delta$, are a

Table 2. ^{13}C NMR data for $[(Me_5C_5)_2Ca] + CO \rightleftharpoons [(Me_5C_5)_2Ca\text{-}CO]$ in $[D_8]$toluene at $T = 31.5$ °C [a].

p(CO)/bar	$\delta(CH_3)$	$\delta(C_5)$	δ(CO)
0	10.39	113.94	184.7 [b]
15	10.53	113.75	183.36
30	10.61	113.62	183.59
50	10.67	113.55	183.80
80	10.72	113.48	183.96
$[(C_5Me_5)_2Ca\text{-}CO]$	10.90(1) [b]	113.19(4) [b]	180.4 [b]

[a] Measured with a JEOL JMN GX 400 spectrometer operated at 96.4 MHz. chemical shifts relative to $\delta(C_6D_5CD_3) = 20.4$. [b] Obtained by least- square analysis from the values observed at p(CO) = 15–80 bar.

linear function of the mole fractions of free and complexed species, the equilibrium constant K, as well as the limiting values of $\Delta\delta$ for complete complex formation, can be obtained by a least-squares analysis of the essentially linear plots of $\Delta\delta^{-1}$ against $p(CO)^{-1}$. A value of $K = 0.024$ bar^{-1} at 31.5 °C, obtained in this manner, is in agreement with that derived from the IR data discussed above. A chemical shift of $\delta = 180.4$, determined for CO in $[(Me_5C_5)_2Ca\text{-}CO]$, places this CO resonance at higher fields than that of free CO in toluene solution ($\delta = 184.7$). $[(Me_5C_5)_2Ca\text{-}CO]$ differs in this regard from transition metal carbonyl complexes with partly filled *n*d subshells; in these, the CO ligands have their ^{13}C NMR signals at substantially lower fields than the signal of free CO.[19, 20]

With regard to both the ^{13}C chemical shift of its CO ligand to higher fields and the shift of ν(CO) to higher frequencies, compared to the respective values of free CO, $[(Me_5C_5)_2Ca\text{-}CO]$ resembles a number of recently reported noble metal CO complexes, mostly with *n*d^{10} electron configuration.[15] Our results show that d electrons are not essential for exothermic CO coordination. $[(Me_5C_5)_2Ca]$ appears to make up for its lack of d electrons by an unusual Lewis acidity, which is probably related to its bent structure.[21, 22] Metal–ligand bond formation can thus presumably occur with expenditures of reorganization energy much smaller than those required to bend typical transition metal sandwich compounds.[22, 23] In accord with this notion, no carbonyl complex formation is observed, up to CO pressures of 50 bar, in solutions of $[(Me_5C_5)_2Mg]$ in toluene, for which a strictly linear geometry has been established.[11] Preliminary experiments with the bent alkaline earth metallocene $[(Me_5C_5)_2Sr]$ [22, 24] indicate the formation of a carbonyl complex with $\nu(CO) = 2159$ cm^{-1}, similar to that observed for $[(Me_5C_5)_2Ca\text{-}CO]$.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0792 $ 10.00+.25/0

This is the first example of CO binding to a molecular alkaline earth metal compound. Previously described $[(Me_5C_5)_2Ca]$ complexes, such as $[(Me_5C_5)_2Ca(PEt_3)]$,[25] $[(Me_5C_5)_2Ca(Me-C\equiv C-Me)]$,[26] $[(Me_5C_5)_2Ca(Me_3Si-C\equiv C-C\equiv C-SiMe_3)]$,[27] and $[(Me_5C_5)_2Ca(CN\text{-}2,6\text{-}xylyl)_2]$ [25] show that one or two ligands can be coordinated at the Ca center. In the case of the carbonyl complex reported here, only one CO ligand appears to be taken up in the pressure range studied. The binding of CO to the Ca center is weaker than that of the diethyl ether ligand in $[(Me_5C_5)_2Ca(OEt_2)]$, as OEt_2 is not displaced by CO at pressures up to 120 bar. This observation and the similarity of ν(CO) frequencies in $[H_3B\text{-}CO]$ and $[(Me_5C_5)_2Ca\text{-}CO]$ are consistent with the view that CO acts solely as a σ-donor ligand towards $[(Me_5C_5)_2Ca]$ and that dipolar interactions are important for the Ca–CO bond.

Benzopyranoisoxazolidines as Chiral Auxiliaries for Asymmetric Synthesis**

Atsushi Abiko, Osamu Moriya, Sandra A. Filla, and Satoru Masamune*

Highly stereoselective α-alkylation of carboxylic acid derivatives (RCH_2COX) can be performed with many known chiral auxiliaries such as oxazolidinone,[1] sultam heterocycles,[2] and others.[3] Here we report new chiral isoxazolidine auxiliaries (**1a** and **1b**), which not only effect equally high asymmetric induction but also offer the following distinct advantages: 1) acylation of the auxiliaries is achieved with an acid chloride and triethylamine, 2) alkylation with β-branched electrophiles can be performed by using their triflates, and 3) alkylated products can be converted directly into the corresponding alcohols, aldehydes, and ketones in one step with recovery of the auxiliary (see Scheme 1).[4]

Scheme 1. a) CH_3CH_2COCl, Et_3N/CH_2Cl_2. b) R^1X, KHMDS/THF. c) $LiBH_4$-EtOH/Et_2O or $LiAlH_4$/THF for **4**; DIBAL-H/THF for **5**; CH_3MgBr/THF for **6**.

Syntheses of **1a** and **1b** are very simple and readily applicable to a large-scale preparation (about 1 mol). The isoxazolidine skeleton was constructed by an intramolecular [3 + 2] cycloaddition involving a nitrone.[5] Thus, heating a mixture of *o*-allyl-

9	(−)-**2b**	$C_6H_{11}CH_2OTf$ (C)	90	98:2	81–82	64	−21.0 (1.7)	

[a] Measured at 20 °C in $CHCl_3$ as solvent except for entries 1 and 2 (benzene) and entries 5 and 6 (CH_2Cl_2). The concentration c is indicated in parenthesis. All of the major products **3** provided the corresponding (*S*)-alcohol **4** with >98 %*ee*.

oxybenzaldehyde (either **7a** or **7b**) and oxime **8**, in the presence of a catalytic amount of Bu_2SnO in toluene at reflux for 6 h in a Dean–Stark apparatus gave rise to the adduct **9**, which was subjected to acid hydrolysis (2 N HCl/EtOH = 1:1) at room temperature overnight to provide (±)-**1** [either (±)-**1a** in 80% yield or (±)-**1b** in 90% yield] (Scheme 2, Table 3). The use of Bu_2SnO

Scheme 2. a) **7a** or **7b** (0.17 mol), **8** (0.17 mol), Bu_2SnO (0.01 mol), reflux/toluene (200 mL). b) 2 N HCl/EtOH.

as a catalyst was essential for the cyclization. The resolution of both (±)-**1a** and (±)-**1b** was achieved with remarkable ease and efficiency.[6] Each enantiomer of the two racemates was obtained in about 80% yield and with >98% *ee*, and the absolute configurations of (+)-**1a** and (−)-**1b** were established by means of X-ray analysis of their derivatives.[7] Isoxazolidines are easily acylated with an acyl chloride in the presence of triethylamine, and the preparation of acyl derivatives of **1a** and **1b**, for example **2a,b** (Table 3), presented no problem.

Of the many bases examined for the deprotonation of (−)-**2**, potassium disilazide (KHMDS) was found to be the most satisfactory. The monoalkylated products were obtained in excellent yields under the following conditions: For most of the alkylations listed in Table 1, a cold solution of KHMDS (1.2 equiv, 0.2 M) in THF was transferred by cannula to a solution of (−)-**2** (1.0 equiv, 0.2–0.5 M) and an alkylating reagent (Table 1) in THF at −78 °C, and the resulting reaction mixture was stirred for 3 h at −78 °C (procedure A). In some cases, the procedure was slightly modified to enhance the yield of alkylated product; procedure B used the preformed enolate of **2**, and procedure C 3 equiv of hexamethylphosphoric triamide (HMPA) as an additive in ether. Sufficient care must be taken to keep the temperature low, because the enolate decomposed to some extent at higher temperature.[8] (The enolate of **2a** is less stable than that of **2b**.) The reaction mixture was worked up in the usual manner, and the diastereomeric ratio was determined by HPLC and/or ^1H NMR. It should be emphasized that **2** is not only alkylated with reactive electrophiles such as benzyl bromide, allyl bromide, and *n*-pentyl iodide, but also with cyclohexylmethyl triflate. This reaction with cyclohexylmethyl triflate serves as a model for an important transformation often encountered in natural product synthesis and usually cannot be achieved with conventional (oxazolidinone) auxiliaries.[9] Diastereomerically pure **3** could be isolated by crystallization and/or chromatography, the latter taking advantage of a large R_f difference between the diastereomers.

Efficient conversion of **3** into the corresponding alcohols **4**, aldehydes **5**, and ketones **6** with the concomitant recovery of **1a** or **1b** is a process just as important as diastereoselective alkylation. Treatment of **3** (1 equiv) with $LiBH_4$ (3 equiv) and ethanol (3 equiv), or with an excess of $LiAlH_4$, provided the alcohols **4**,[10] which were compared with the known enantiopure compounds to establish the absolute configuration of **4** (Table 1). It should be noted that separation of the alcohol **4** from the auxiliary **1** was effected by simple acid–base extraction. Conversion of **3** into **5** and **6** also proceeded smoothly with diisobutylaluminum hydride (DIBAL-H, 1.1 equiv) in THF (0 °C, 3 h) and Grignard reagents (3.0 equiv) in THF (−20 to 0 °C, 4–5 h), respectively (Table 2), without any loss of optical purity.

The utility of these chiral isoxazolidines is best illustrated by the successful transformations of **10** to **11a** and **11b**,[11] and of **12** to **14**, **15**, and **16** through **13**[12] (Scheme 3), which

[5] Oppolzer et al. described a synthesis of (±)-**1a** (W. Oppolzer, K. Keller, *Tetrahedron Lett.* **1970**, 1117), which has been much improved in the present study. See also B. S. Orlek, P. G. Sammes, D. J. Walker, *J. Chem. Soc. Chem. Commun.* **1993**, 1412.
[6] A solution of (±)-**1a** (15 g) and (+)-10-camphorsulfonic acid (23 g) in acetone (200 mL) provided, upon six recrystallizations, (+)-salt, $[\alpha]_D^{20} = +61.5$ ($c = 1.10$ in MeOH) and (−)-salt, $[\alpha]_D^{20} = -13.6$ ($c = 1.15$ in MeOH) in 80% and 70% yields, respectively. It should be noted that the salts of (+)-**1a** and (−)-**1a** crystallized alternately from the same solution! From these salts, (+)-**1a**, $[\alpha]_D^{20} = +62.4$ (c = 1.11 in $CHCl_3$), m.p. 95–96 °C and (−)-**1a**, $[\alpha]_D^{20} = -62.4$ ($c = 1.11$ in $CHCl_3$) were recovered quantitatively. For the resolution of **1b**, (±)-**1b** was allowed to react with L-dibenzoyltartaric anhydride to give a diastereomeric mixture of amides, from which the (+)-amide was separated by crystallization from ethyl acetate and hexane. Simple alkaline hydrolysis afforded (−)-**1b**, m.p. 85–86 °C, $[\alpha]_D^{20} = -11.1$ ($c = 1.14$ in $CHCl_3$) in 80% overall yield. Optically pure (+)-**1b**, m.p. 85–86 °C, $[\alpha]_D^{20} = +11.1$ ($c = 1.33$ in $CHCl_3$) was obtained in 80% yield from the (+)-**1b**-rich mother liquor after removing (±)-**1b**, m.p. 120 °C, (20%) which first crystallized out from ether.
[7] The (+)-salt of **1a** with (+)-10-camphorsulfonic acid and an aldol adduct of (+)-**2b** were used for X-ray crystallographic analysis. The absolute configuration of the diol derived from the aldol is known. Detailed information will be published in a full paper.

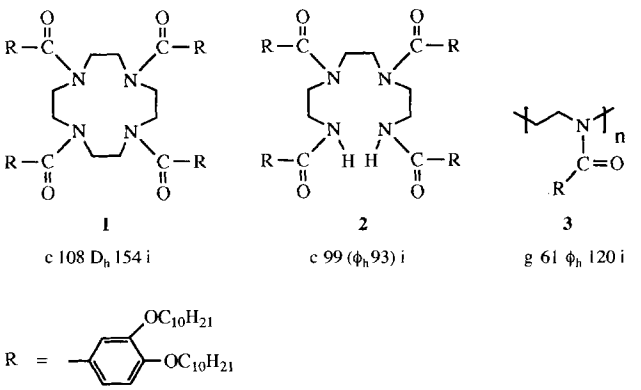
Formation of a Hexagonal Columnar Mesophase by N-Acylated Poly(ethylenimine)**

Hartmut Fischer, Surya S. Ghosh, Paul A. Heiney, Nicholas C. Maliszewskyj, Thomas Plesnivy, Helmut Ringsdorf,* and Markus Seitz



The macroscopic properties of self-organizing systems are strongly governed by the molecular structure of their constituent units. Nevertheless, in many cases the same supramolecular structures can be constructed with a wide variety of building blocks. In particular, hexagonal columnar mesophases (ϕ_h) are formed by various molecular structures.[1] The constituent unit of the liquid-crystalline phase may consist of relatively rigid macromolecules with flexible side chains, for example poly(dialkylsilane) or substituted poly(glutamate)s.[2–5] In addition, disk-shaped molecules exhibit predominantly this type of columnar arrangement (discotic hexagonal columnar mesophases, D_h).[6] Macrocyclic oligoamines (azacrowns) can also act as such central cores, provided that the conformational dynamics of the macrocycle is reduced by N-acylation with aromatic acids[7–11] or by complexation with transition metal ions.[12,13] In general, the

stability of the columnar mesophase formed by these molecules decreases with increasing ring size and thus increasing flexibility. Recently even open chain N-acylated oligoamines of comparable structure were found to exhibit liquid-crystalline phases.[14]

In this paper the scope of these systems containing N-acylated ethylenimine as the basic—in principal nonmesogenic—structural unit will be extended to a linear polymer, which will be compared to a macrocyclic and an open chain analogue (Fig. 1).

1 c 108 D_h 154 i

2 c 99 (ϕ_h 93) i

3 g 61 ϕ_h 120 i

Fig. 1. Structure and phase behavior of **1**, **2**, and **3**. The transition temperatures are given in °C (c: crystalline; D_h: discotic hexagonal columnar; i: isotropic; g: glassy; φ_h: hexagonal columnar; phase transition temperatures from the first cooling and second heating curves of the DSC measurements, scan rate 10 K min^{-1}).

For the macrocycle **1** the hexagonal columnar structure of the mesophase, which is still a matter of controversy for the cyclic, low molecular weight compounds,[14–17] is unambiguously demonstrated by the hexagonal X-ray diffraction pattern (Fig. 2).[18]

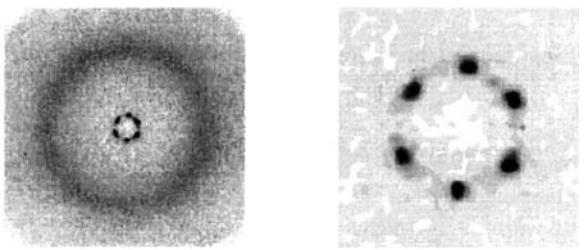

Fig. 2. X-ray picture (flat-plate camera) of a magnetically aligned monodomain of macrocycle **1** at 150 °C (cf. [18]). The low-angle region is shown magnified in the right picture.

In the oligoamide **2**, the open-chain analogue of **1**, the intrinsic discoid structure is lost. Nevertheless, a monotropic mesophase of presumably hexagonal columnar structure can be found as indicated by polarization microscopy and differential scanning calorimetry (DSC). This mesophase formation can, in principle, be explained by intramolecular hydrogen bonds between the terminal amide units which provide a disklike molecular conformation in the open-chain compound **2**, too.[14] The higher conformational flexibility of this system relative to that of macrocycle **1** is reflected by the monotropic nature of the mesophase.

The formation of hexagonal columnar mesophases by N-acylated oligoamines is therefore not restricted to macrocyclic, and thus intrinsic discoid, structures. In longer open-chain polymeric amides a discoid conformation by intramolecular hydrogen bonding is no longer favorable. Therefore, the N-acylated linear poly(ethylenimine) **3** was not expected to exhibit mesomorphic properties.

Nevertheless, an enantiotropic liquid-crystalline phase was detected for the polymer **3**. Slow cooling from the isotropic phase into the mesophase gave a texture characteristic for hexagonal mesophases with homeotropic regions. This texture is remarkably similar to those of the low molecular weight compounds **1** and **2**. In addition, preliminary studies on contact preparations show miscibility of **2** and **3** over the whole concentration range within the LC state, which indicates that both compounds have the same mesophase structure.

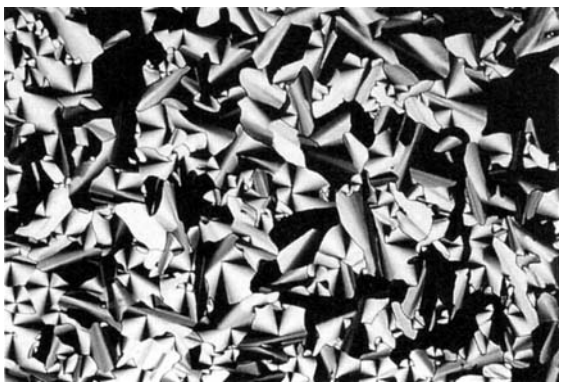

Fig. 3. Texture of the N-acylated linear poly(ethylenimine) **3** under the polarizing microscope at 116 °C, obtained after cooling from the isotropic phase to the given temperature (cooling rate: 0.2 K min^{-1}).

In accord with results from polarizing microscopy, the DSC heating trace (Fig. 4) shows a peak at 120 °C corresponding to the transition from a liquid-crystalline to an isotropic phase ($\Delta H_{\phi_h \rightarrow i}$ = 1.2 kJ mol^{-1} per repeating unit). In addition, one glass transition is found at 61 °C and another transition at about 80 °C.[19]

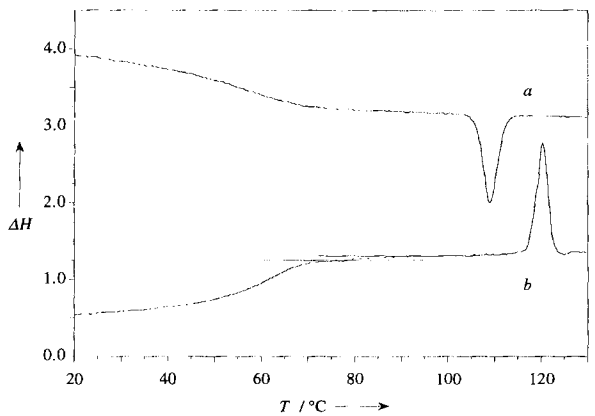

Fig. 4. DSC thermogram of the N-acylated poly(ethylenimine) **3**; a) first cooling b) second heating trace; scan rate: 10 K min^{-1}. As a guide for the eye, the second transition at about 80 °C is emphasized by two straight lines [19].

The X-ray diffraction pattern of the polymer **3** at 85 °C (Fig. 5) shows three reflections in the small-angle region with lattice spacings in the ratio of $1:1/\sqrt{3}:1/2$ characteristic of a hexagonal columnar arrangement. The hexagonal lattice parameter was determined to be 35.6 Å. In comparison, for the macrocyclic compound **1** the intercolumnar distance at 120 °C is 33.2 Å.

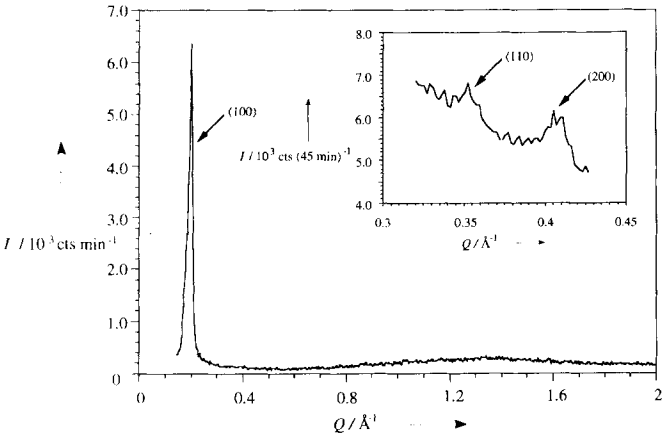

Fig. 5. X-ray diffraction pattern of **3** obtained at 85 °C after cooling from the isotropic state. Units are $Q = 4\pi\sin\theta/\lambda = 2\pi/d$. Inset shows scattering near the (110) and (200) peaks.

All investigated systems—macrocycle **1** and open-chain oligomer **2**, as well as the linear polymer **3**—exhibit the same supramolecular structure in the mesophase (Fig. 6). Whereas in the azacrown derivative **1** the discoid geometry is given by the

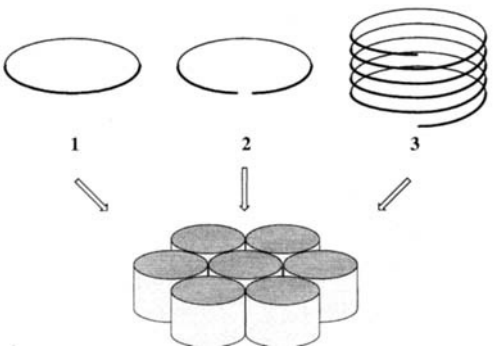

Fig. 6. Formation of hexagonal columnar phases by macrocyclic **1**, open-chain oligomeric **2**, and polymeric ethylenimine derivatives **3**. As a chiral center is lacking, both left- and right-handed helices are formed by the polymer.

molecular structure, in the open-chain oligoamide **2** this geometry can perhaps be achieved by means of hydrogen bonding. Conclusions about the molecular arrangement of the polymer **3** are speculative. However, based on the same mesophase behavior of the compounds under discussion, a possible molecular structure of the polymer could consist of a helical polymeric main chain (Fig. 6) radially surrounded by the side chains. This view is supported by the larger intercolumnar distance of the polymer **3** relative to that of the azacrown derivative **1**; for an extended polymer chain a smaller distance was expected.

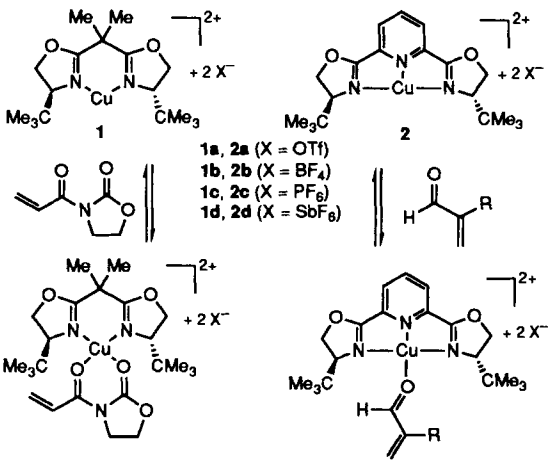
Although the structure of **3** is not necessarily perfectly helical, the system may resemble that of poly-L-glutamates with long alkyl chain substituents, for which hexagonal columnar mesophases have indeed been observed.[20] However, whereas in the synthetic polypeptide the unsubstituted polymeric chain is helical, in the substituted poly(ethylenimine) **3** the formation of a helical structure of the main chain may be solely induced by the steric requirements of the 3,4-bisdecyloxybenzoyl substituents.[21] This side group has thus an important structural influence on the polymeric main chain, since the hexagonal columnar structure is in striking contrast to the lamellar structures that have been observed in linear poly(ethylenimines) acylated with benzoyl derivatives.[22, 23]

Finally, as the constituent unit is identical in the polymeric and the low molecular weight compounds, the described systems bridge the gap between classical discotic mesophases (that is, hexagonal columnar mesophases formed by disk-shaped molecules) and thermotropic liquid-crystalline columnar phases formed by linear polymers.

Experimental Procedure

The synthesis of the compound **1** (**2**) was performed by acylation of the commercially available 1,4,7,10-tetraazacyclododecane (triethylenetetramine tetrahydrochloride) with 3,4-bisdecyloxybenzoyl chloride according to known procedures [8, 9].

Synthesis of **3**: 3,4-bisdecanoxybenzoyl chloride (4.52 g, 10 mmol), linear poly(ethylenimine) (0.4 g, 9.3 mmol; prepared according to described procedures [24, 25]; degree of polymerization estimated to about 22) and *N*,*N*-dimethylaminopyridine (1.3 g, 11 mmol, DMAP) were stirred for 3 days at 70 °C in 150 mL of absolute *N*,*N*-dimethylformamide (DMF) under an argon atmosphere. The white precipitate was separated and dried for two days under high vacuum to remove the solvent. The crude product was suspended in dichloromethane and washed three times with water. After drying with anhydrous sodium sulfate the solution was concentrated, and the polymer precipitated in cold acetone. This procedure was repeated (purity of the product checked by TLC), and the polymer finally recrystallized from acetone to yield 1.4 g of a white powder. (Additional product was obtained by concentration of the filtrate of the reaction mixture. However, the product obtained in this way was rather impure and had to be extensively purified.)



According to elemental analysis and ^{1}H NMR spectroscopy, the polymer is almost quantitatively acylated (>95%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.85 (t, 6H; $CH_3(CH_2)_9O$), 1.1–1.4, 1.5–1.9 (br., 32H; $CH_3(CH_2)_8CH_2O$), 3.3–3.6 (br., 4H; CH_2-N-CH_2), 3.8–4.0 (br., 4H; $CH_3(CH_2)_8CH_2O$), 6.6–6.8 (br., 4H; aromatic ring protons). Elemental analysis: calcd for $(C_{29}H_{49}NO_3)_n$ (corresponds to 100% substitution; M(repeat unit) = 459.72): C 75.77, H 10.74, N 3.05; found: C 75.40, H 10.63, N 2.94. GPC ($CHCl_3$; polystyrene standard): M_n = 10500 (calculated for P_n = 22: M_n = 10114).

[18] Azacrown **1** has a high tendency to align on glass surfaces. In addition, a magnetic field of about 0.8 T has been applied perpendicular to the glass capillary. Goniometer scans confirm the hexagonal structure of the mesophase by the observance of (100) and (110) reflections, the corresponding distances of which are in the ratio of $1:1/\sqrt{3}$. However, the (110) reflection is weak and can only be observed by prolonged measuring times.
[19] Based on preliminary dielectric spectroscopy measurements the glass transition at 61 °C corresponds to mobility of the side groups. More extensive DSC studies on tempered samples showed that the second glass transition may arise from the melting of crystalline regions.

Scheme 1. Chiral Lewis acids derived from square-planar Cu^{II} complexes and their associated coordination complexes with complementary one- and two-point binding dienophiles.

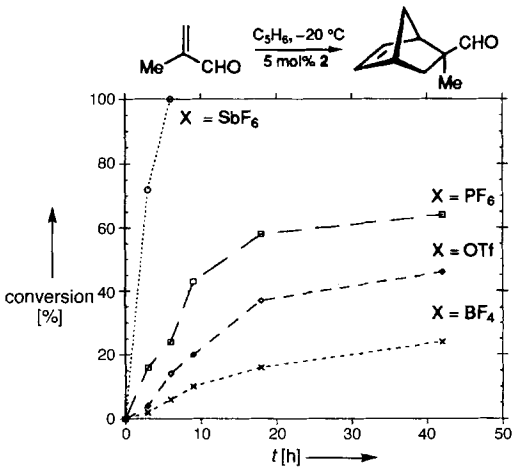
C_2-Symmetric Cationic Copper(II) Complexes as Chiral Lewis Acids: Counterion Effects in the Enantioselective Diels–Alder Reaction**

David A. Evans,* Jerry A. Murry, Peter von Matt, Roger D. Norcross, and Scott J. Miller

We have recently documented the utility of chiral bis(oxazoline)copper(II) complexes **1** (oxazoline = dihydrooxazole) in the catalysis of asymmetric group transfer reactions such as cyclopropanation[1, 2] and aziridination.[3, 4] In addition, we have demonstrated that the C_2-symmetric bis(oxazoline)copper(II) triflate complex **1a** (triflate = trifluoromethanesulfonate = OTf) is also capable of functioning as an effective chiral Lewis acid in the Diels–Alder reaction with two-point binding *N*-acylimide dienophiles.[5] In an effort to broaden the utility of Lewis acidic chiral Cu^{II} complexes, we have prepared Cu^{II} complexes with tridentate bis(oxazolinyl)pyridine[6] (pybox) ligands, [Cu^{II}(pybox)X_2] (**2**) and probed their reactivity as chiral Lewis acids (Scheme 1). In conjunction with this investigation, we have uncovered dramatic counterion effects that strongly influence the reactivity of these Lewis acids. In this communication, we document the scope of these catalysts in enantioselective Diels–Alder reactions with unsaturated aldehyde and imide-derived dienophiles.

We began with an investigation of [Cu^{II}(pybox)] complexes which we anticipated would possess a preferred square-planar coordination geometry with a single accessible coordination site for carbonyl-derived dienophiles such as α,β-unsaturated aldehydes. Indeed, we have found that [Cu^{II}(pybox)] complexes **2** serve as effective chiral Lewis acids with aldehyde-derived dienophiles. For example, the cycloaddition of methacrolein with cyclopentadiene catalyzed by (pybox)Cu(OTf)$_2$ (**2a**) (5 mol%, CH_2Cl_2, −20 °C) afforded the desired cycloadducts with good *exo:endo* selectivity (96:4) and enantioselectivity (*exo* adduct: 85% ee).[7] However, extended reaction times (120 h) were required for complete conversion.

In an effort to increase catalyst reactivity, the cationic complexes **2b**–**2d** were prepared[6] and evaluated. As illustrated in Figure 1, a large counterion effect was observed in these reactions. For example, the cycloaddition of methacrolein with cyclopentadiene that required 120 hours for complete conversion with catalyst **2a** (X = OTf) was complete in 8 hours with catalyst **2d** (X = SbF_6). This comparison reveals that the counterion structure dramatically affects catalyst efficiency and that the "noncoordinating" counterions SbF_6^-, PF_6^-, and BF_4^-, strongly differ in degree of interaction with the Lewis acidic Cu^{II} center.[8]



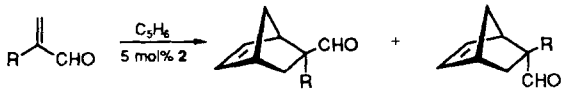


Fig. 1. Plot of the conversion [%] as a function of the reaction time [h] for the Diels–Alder reaction of methacrolein with cyclopentadiene catalyzed by **2** at −20 °C.

From the results of the preceding study, the cationic (pybox)Cu(SbF_6)$_2$ complex (**2d**) was determined to be the catalyst of choice, and its optimized performance in the Diels–Alder reactions of cyclopentadiene with representative aldehyde dienophiles is given in Table 1. The *tert*-butyl ligand **2** was originally chosen in analogy with the acrylimide results and provides enantioselectivities comparable to those reported in the literature.[9] Importantly, we have also found that the (*S*)-benzyl-pybox ligand, derived from L-phenylalanine, provides comparable

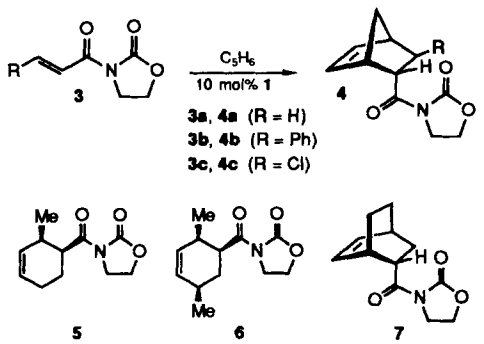
Table 1. Enantioselective Diels–Alder reactions of α-substituted acroleins with cyclopentadiene catalyzed by Cu^{II} complexes **2a** and **2d** [a].



R	Catalyst	T[°C]	t[h]	*exo:endo*	*ee*[%]
H	**2d**	−20	18	6:94	85
Br	**2a**	−40	60	97:3	87
Br	**2d**	−78	12	98:2	96
Me	**2a**	−20	120	96:4	85
Me	**2d**	−40	8	97:3	92

[a] Reactions were performed in 4 mL CH_2Cl_2 with 2.0 mmol dienophile, 2.4 mmol cyclopentadiene, and 5 mol% catalyst. The *exo:endo* ratios determined by GLC. The enantiomeric excesses were determined by GLC after conversion of products to the (*R*,*R*)-pentanediol acetals (see ref. [10]).

enantioselectivities. For example, the Diels–Alder reaction of α-bromoacrolein with cyclopentadiene in the presence of the benzyl-pybox ligand provides the adduct in 95% enantiomeric excess. This readily available ligand is an attractive alternative to the more expensive *tert*-butylglycine derived variant.

The correlation of catalyst reactivity with the coordinating ability of the counterion for the [(pybox)Cu(X)$_2$] catalysts **2** led us to reinvestigate the bis(oxazoline)copper(II) catalyzed Diels–Alder reactions of acrylimides **3**. The bis(oxazoline)copper triflate complex **1a** was originally chosen with the expectation that the imide dienophile would successively displace both of the electronegative triflate ligands from the metal center in conjunction with the bidentate ligation of dienophile and Lewis acid.[5]

To the extent that the triflate counterion impairs the two-point dienophile binding motif, other coordination geometries could lead to diminished enantioselection. Accordingly, complexes **1b–d** were prepared and evaluated as catalysts in the Diels–Alder reaction of acrylimide **3a** (R = H) with cyclopentadiene (Table 2). As in the preceding study, catalysts **1a–1d** exhibited significantly different levels of activity in the Diels–Alder reaction. Again, the SbF_6-derived complex **1d** was found to be the catalyst of choice. For example, the rate of the Diels–Alder reaction of **3a** with cyclopentadiene catalyzed by **1d** (X = SbF_6) was approximately 20 times faster (−78 °C, 99% *ee*) than the rate of the analogous reaction promoted by the less efficient triflate complex **1a**. The cationic bis(oxazoline) complex **1d** was then probed for generality with a selection of cyclic and acyclic dienes.

Inspection of Table 2 reveals that the Diels–Alder reactions of these substrates are significantly improved with the more reactive cationic catalyst. The cycloadditions of the less reactive

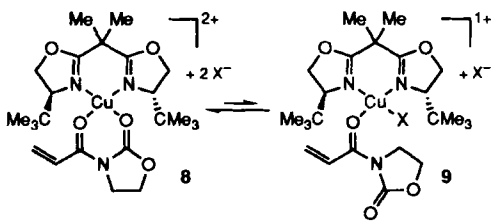


Table 2. Enantioselective Diels–Alder reactions of imide-derived dienophiles **3a–c** with dienes catalyzed by **1a** (X = OTf) and **1d** (X = SbF_6) at 25 °C [a].

Dienophile	R	Diene	Catalyst	t[h]	Yield [%] [b]	*endo:exo* [c]	*endo ee* [%] [d]	Product

[a] All reactions were carried out in CH_2Cl_2 (0.3 M in substrate) at 25 °C with 10 mol% catalyst. [b] Values refer to isolated yields. [c] Determined by ^1H NMR spectroscopy and/or GLC or HPLC. [d] Determined by chiral HPLC or GLC. [e] This reaction was performed on 11.0 g (62.4 mmol) of **3c** to give 14.5 g of **4c** (96% yield, 95% ee). [f] Ratio of **5** to all other isomers.

β-substituted dienophiles **3b** (R = Ph) and **3c** (R = Cl) with cyclopentadiene proceed with excellent selectivities (95–96% *ee*) at room temperature. In particular, the performance of the latter dienophile, a potentially useful acetylene surrogate, was significantly enhanced with the cationic catalyst. Complex **1d** (X = SbF_6) is also an excellent catalyst for less reactive dienes. For example, the two acyclic dienes and cyclohexadiene underwent catalyzed cycloadditions with the imide **3a** to afford the derived cycloadducts in good yields and enantioselectivities in the 93–94% range at room temperature.

In all instances, the cationic Cu^{II} complex **1d** (X = SbF_6) affords higher levels of asymmetric induction than the analogous triflate complex **1a**. The sense of asymmetric induction is fully consistent with the intervention of a square-planar catalyst-substrate complex **8**,[5] featuring the chelated dienophile in the s-*cis* conformation. We speculate that the moderately lower enantioselection exhibited by the triflate-based catalyst might be due to the intervention of a competing cycloaddition from a less highly organized one-point catalyst–dienophile complex such as **9**.

In summary, this study provides a rational basis for the design of Lewis acids based on the coordinating capacity of cationic Cu^{II} complexes which possess sufficient Lewis acidity to catalyze a range of synthetically useful Diels–Alder reactions. In particular, documentation of the importance of counterion structure in the use of cationic metal centers as Lewis acids has been made for the first time. Investigations on the scope of these complexes as chiral Lewis acids are ongoing.

Experimental Procedure

Diels–Alder reaction of methacrolein with cyclopentadiene catalyzed by **2d**: To a dry flask in an inert atmosphere dry box was added $CuBr_2$ (22 mg, 0.10 mmol), $AgSbF_6$ (69 mg, 0.20 mmol) and *tert*-butyl[pyridine-bis(oxazoline)] **2** (33 mg, 0.10 mmol). The flask was fitted with a serum cap, removed from the dry box and charged with 4 mL CH_2Cl_2. The resulting heterogenous mixture was allowed to stir for 6 h and then filtered through a plug of cotton to give a clear blue-green solution. This solution was then cooled to −40 °C and cyclopentadiene (2.4 mmol, 158 mg, 164 mL) was added followed by methacrolein (140 mg, 166 mL, 2.0 mmol). The reaction was monitored by taking a 100 μL aliquot and filtering through a small plug of silica gel eluting with 2 mL of diethyl ether. The solvent was removed in vacuo and the resulting oil dissolved in $CDCl_3$ and analyzed by ^1H NMR spectroscopy. The reaction mixture was monitored until the conversion was ≥95%. The crude reaction mixture was filtered through a plug of silica gel eluting with diethyl ether. The resulting solution was concentrated to give (1*R*,2*S*, 4*R*)-2-methylbicyclo-[2.2.1]hept-5-ene-2-carboxaldehyde as a clear colorless oil. $[\alpha]_D = +21.4$ ($c = 2.3$, EtOH); $R_f = 0.5$ (40% hexane/CH_2Cl_2); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 9.69$ (s, 1H, CHO), 6.29 (dd, $J = 5.6$, 3.0 Hz, 1H, C(6)-H), 6.11 (dd, $J = 5.6$, 3.0 Hz, 1H C(5)-H), 2.89 (br s, 1H, C(1)-H), 2.82 (br s, 1H, C(4)-H), 2.25 (dd, $J = 11.9$, 3.8 Hz, 1H, C(3)HXH$_Y$), 1.39 (m, 2H, C(7)H$_2$), 1.01 (s, 3H, Me), 0.76 (d, $J = 11.9$ Hz, 1H, C(3)H$_X$HY); ^{13}C NMR (101 MHz, $CDCl_3$): $\delta = 205.8$, 139.5, 133.1, 53.9, 48.5, 47.6, 43.2, 34.6, 20.0; IR (neat): $\tilde{\nu} = 2973$, 2870, 2705, 1720, 1448, 1333, 1119 cm^{-1}; Exact mass calcd for $C_9H_{12}O$ 136.0893; found 136.0888 (EI). At this point the *exo*:*endo* product ratio was ascertained by GLC: DB-1701, 110 °C, 5 psi, t_r(*exo*) = 5.40, t_r(*endo*) = 6.01. This aliquot was then derivatized and used for determination of the enantioselectivity of the reaction. The cycloaddition product (14 mg, 0.10 mmol) was diluted with CH_2Cl_2 (0.5 mL) and (−)-(2*R*,4*R*)-pentanediol (20 mg, 0.20 mmol) and a few crystals of *p*-TsOH were added. After stirring for 6 h at room temperature, tlc analysis indicated that acetalization was complete. The reaction mixture was eluted through a short plug of silica with ether and analysed by capillary GLC. In this way the enantiomeric excess of the *exo* cycloaddition product was determined. Using the enantiomer of the diol, (+)-(2*S*,4*S*)-pentanediol, gave the same numeric value for the *exo* enantiomeric excess (within ±2% ee) indicating that there was negligible kinetic resolution during the acetalization reaction. Purification by flash chromatography gave the pure (2(1*R*,2*S*, 4*R*),9*R*,11*R*)-4,6-dimethyl-2-(2-methylbicyclo[2.2.1]hept-5-ene-2-yl)-1,3-dioxane. R_f 0.42 (20% EtOAc/hexanes); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 6.13$–6.07 (m, 2H, C(5)-H, C(6)-H), 4.69 (s, 1H, C(8)-H), 4.32–4.28 (m, 1H, C(9)-H) 3.91–3.84 (m, 1H, C(11)-H) 2.73 (br s, 1H, C(1)-H), 2.65 (br s, 1H, C(4)-H), 1.76–1.55 (m, 3H, C(7)-CH$_2$, C(3)-H$_X$H$_Y$), 1.36 (d, $J = 7.0$ Hz, 3H, C(9)-CH$_3$), 1.28-1.33 (m, 2H, C(10)-CH$_2$), 1.20 (d, $J = 6.2$ Hz, 3H, C(11)-CH$_3$), 0.86 (s, 3H, C(2)-CH$_3$), 0.74 (dd, $J = 2.7$, 12.0 Hz, 1H, C(3)-H$_X$H$_Y$); ^{13}C NMR (101 MHz, $CDCl_3$): $\delta = 137.2$, 135.7, 99.5, 67.9, 67.7, 47.9, 47.4, 45.5, 37.2, 36.9, 21.9, 18.8, 17.3; IR (neat): $\tilde{\nu} = 3058$, 2969, 1449, 1375, 1334, 1240, 1136, 1058, 1004 cm^{-1}; Exact mass calcd for $C_{14}H_{22}O_2$ 222.1625; found 222.1620 (EI); GLC, DB-1701, 110 °C, 5 psi, t_r(minor product) = 29.89, t_r (major product) = 30.63 min.

Diels–Alder reaction of β-chloroimide **3c** with cyclopentadiene. A solution of catalyst **1d** (X = SbF_6) was prepared by mixing $CuCl_2$ (766 mg, 5.7 mmol), *tert*-butyl-bis(oxazoline) **1** (1.89 g, 6.3 mmol), and $AgSbF_6$ (3.92 g, 11.4 mmol) in CH_2Cl_2 (57 mL), stirring for 8 h at ambient temperature and filtering through celite. Imide **3c** (10.96 g, 62.4 mmol) was then added as a solution in CH_2Cl_2 (60 mL) by cannula (5 mL rinse of CH_2Cl_2). Immediately thereafter, cyclopentadiene (62 mL, 744 mmol) was added by syringe. The resulting solution was stirred at room temperature for 24 h. The reaction mixture was directly applied to a short column of silica gel (6 × 6 cm) and eluted with approximately 1 L of 1:1 ethyl acetate/hexane. Concentration afforded the unpurified product **4c** which was analyzed. ^1H NMR analysis indicated that the reaction had proceeded to >98% conversion. The unpurified reaction mixture was analyzed directly by chiral GLC, which showed the *endo*/*exo* ratio to be 87:13 (*endo* isomer 96% ee, chiraldex G-TA column; oven temperature = 150 °C, flow rate = 20 psi; t_r(*endo* major enantiomer) = 47.40, t_r (*endo* minor enantiomer) = 57.62, t_r(*exo* enantiomer 1) = 50.27, t_r(*exo* enantiomer 2) = 51.85). The product mixture was then purified by chromatography (8 × 32 cm silica gel, 30% ethyl acetate/hexane) to afford 14.45 g (59.8 mmol, 96%) of **4c** as a white solid. Recrystallization from ethyl acetate/hexane yielded enantiomerically pure **4c**: $[\alpha]_D = -113$ ($c = 1.10$, CH_2Cl_2); IR (CH_2Cl_2): $\tilde{\nu}$ 3000, 1781, 1699, 1480, 1387 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 6.23$ (dd, 1H, $J = 5.6$, 3.3 Hz, C*H*=CH), 5.90 (dd, 1H, $J = 5.6$, 2.7 Hz, CH=C*H*), 4.41 (t, 2H, $J = 7.8$ Hz, OCH$_2$), 4.24 (m, 1H, -CH-), 4.13 (m, 1H, -CH-), 4.05–3.87 (m, 2H, -NCH$_2$), 3.39 (br d, 1H, $J = 1.4$ Hz, bridgehead H), 3.06 (br s, 1H, bridgehead H), 2.10 (br d, 1H, $J = 9.1$ Hz, one of -CH$_2$-), 1.72 (dd, 1H, $J = 9.0$, 1.7 Hz, one of -CH$_2$-); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 172.0$, 153.2, 136.2, 134.4, 62.1, 58.8, 54.8, 52.4, 48.1, 46.9, 42.8; exact mass calcd for $C_{11}H_{12}N_1O_3Cl_1$ requires *m/z* 241.0506; found *m/z* 241.0494 (EI).

Aminocyclopentadienes, Aminoferrocenes, and Aminocobaltocenes**

Herbert Plenio* and Dirk Burth

More than forty years after the discovery of ferrocene, examples of aminocyclopentadienes and aminoferrocenes are still scarce.[1] Even what is probably the best synthesis (four steps starting from ferrocene) of the parent compound aminoferrocene $FcNH_2$ to date affords only small amounts;[2] alternate synthetic routes are equally demanding.[3] Several *N*,*N*-dialkylaminoferrocenes can, according to a paper by Boche et al., be prepared from *O*-tosylated *N*, *N*-dialkylhydroxylamines in good yields;[4] however, the number of hydroxyl derivatives[5] is limited and, in addition, the handling of these compounds poses certain risks,[6] which severely limits the possible applications of this reaction.

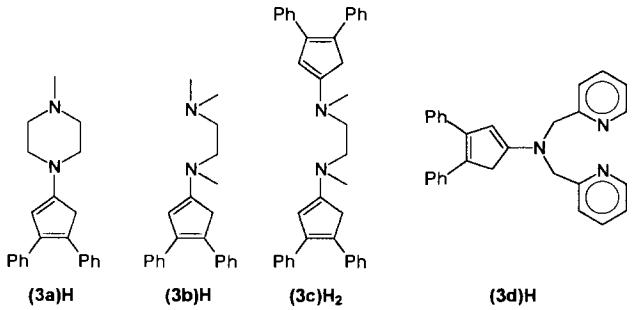
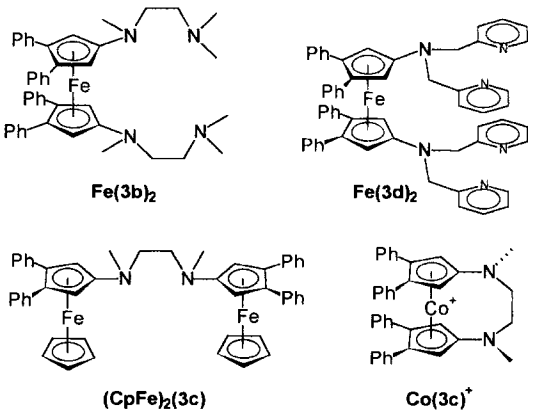
[**] This work was supported by the Graduiertenkolleg "Ungepaarte Elektronen in Chemie und Biologie" and the Fonds der Chemischen Industrie. We wish to thank Prof. Dr. H. Vahrenkamp for his support as well as A. Warneke and T. Ludwig for their experimental assistance.

In the context of our own research in the area of redox-switchable ferrocene crown ethers,[7] we became interested in developing an efficient synthesis for aminocyclopentadienes, aminoferrocenes, and aminocobaltocenes.



The reaction of ketones with secondary amines leads to enamines by the elimination of water.[8] Using cyclopentenones[9] as starting materials this reaction seemed ideally suited[7] for the preparation of *N,N*-dialkylaminocyclopentadienes, which could then be further reacted to yield the desired substituted ferrocenes and cobaltocenes.

Thus 3,4-diphenylcyclopent-2-enone (**1**)[10] and 2-indanone (**2**) were treated with secondary amines such as *N*-methylpiperazine (**a**), trimethylethylenediamine (**b**), *N,N'*-dimethylethylenediamine (**c**), and bis(2-picolyl)amine (**d**) (Scheme 1). In case of **1**, *N,N*-dialkylaminocyclopentadienes (**3a**)**H**, (**3b**)**H**, (**3c**)$\mathbf{H_2}$, and



Scheme 1. Synthesis of *N,N*-dialkylaminocyclopentadienes **3** and -indenes **4**.

(**3d**)**H**, respectively, were afforded as pale yellow solids (Scheme 2) in yields ranging from 45–70%. The analogous indenes (**4a**)**H**, (**4b**)**H**, (**4c**)$\mathbf{H_2}$, and (**4d**)**H** were obtained in yields of >80%.[11] As a general observation, reactions involving 2-indanones (**2**) proceed at a faster rate and under milder conditions than the analogous reactions with 3,4-diphenylcyclopent-2-enone (**1**). An important characteristic of the secondary amines HNR_2 employed in this study is the presence of donor units in the R group. This allows the formation of σ donor metal complexes with the amine nitrogen as binding site.[12]

Scheme 2. A selection of the new *N,N*-dialkylaminocyclopentadienes **3** (the corresponding 2-(*N,N*-dialkylamino)indenes **4** are not shown).

The derivatives (**3a**)**H**, (**3b**)**H**, and (**3c**)$\mathbf{H_2}$, as well as (**4a**)**H**, (**4b**)**H**, and (**4c**)$\mathbf{H_2}$ (not shown) are readily deprotonated with *n*BuLi to give the corresponding lithium compounds, which were found to be stable in a moisture- and oxygen-free atmosphere. The *N,N*-dialkylaminoferrocenes **Fe**(**3a**)$_2$, **Fe**(**3b**)$_2$, and **Fe**(**3c**) were obtained in 30–50% yield by treating the lithium salts of **3** with $FeCl_2$. The corresponding cobaltocenes **Co**(**3a**)$_2$, **Co**(**3b**)$_2$, and **Co**(**3c**) can be synthesized in yields of 40–60% in an analogous fashion by reacting the lithium salts of **3** with $CoBr_2 \cdot 3THF$ (the products were isolated as their cobaltocinium salts following oxidation) (Scheme 3). The lithium salts of **4** react in the same way. The derivative (**3d**)**H** decomposed rapidly upon attempted deprotonation; however, the *N,N*-dialkylaminoferrocene **Fe**(**3d**)$_2$ could be prepared by treating (**3d**)**H** with $Fe(NiPr_2)_2$ which had been generated in situ. (**CpFe**)$_2$(**3c**) is readily accessible by irradiating a mixture of **Li**$_2$(**3c**) and $[CpFeL]^+[PF_6]^-$ with UV light (L = *p*-xylene).

Scheme 3. A selection of the new aminoferrocenes and aminocobaltocenes.

Oxidation of these new aminoferrocenes and aminocobaltocenes ($E_{1/2}$ **Fe**(**3c**) −0.01 V, **Fe**(**3d**)$_2$ 0.00 V, **Co**(**4b**)$_2$ −1.15 V, **Co**(**4c**) −1.08 V) occurs at significantly more negative potential than reported for ferrocene ($E_{1/2}$ = + 0.40 V in CH_3CN vs. Ag/AgCl) and cobaltocene ($E_{1/2}$ = − 0.94 V in CH_3CN vs. Ag/AgCl). As a result of the weakly electron-withdrawing nature of the aryl groups both the aminoferrocenes and aminocobaltocenes are less sensitive to oxidation than 1,1'-bis(dimethylamino)ferrocene ($E_{1/2}$ = − 0.23 V in CH_3CN vs. SCE) and 1,1'-bis(dimethylamino)cobaltocene ($E_{1/2}$ = −1.35 V in CH_3CN vs. SCE).[4, 13]

According to X-ray diffraction analyses[14] the structures of the aminoferrocenes **Fe**(**3a**)$_2$[15] and **Fe**(**3d**)$_2$[16] are very similar, despite the fact that the substituents at the amino groups vary considerably. Figure 1 depicts the structure of **Fe**(**3a**)$_2$ in the crystal as viewed along the axis centroid-Fe1-centroid. This projection shows that the six substituents of the ferrocene are arranged in such a manner that no unfavorable steric interactions result. The stacked phenyl rings are almost coplanar (12.4°); the distance between the two nitrogen atoms N1 and

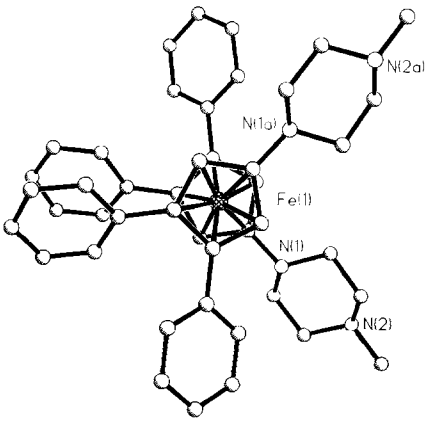


Fig. 1. Structure of **Fe**(**3a**)$_2$ in the crystal as viewed along the axis centroid-Fe1-centroid. For clarity, the hydrogen atoms have been omitted.

N1a is only 508.9 pm and thus they are already well preorganized for the chelating complexation of a metal ion. The substituents of the ferrocene are arranged in a similar way in the solid state for $\mathbf{Fe(3d)_2}$ (Fig. 2). The distance N1–N2 is also rather small (503.8 pm), and the planes of two stacked phenyl rings are only slightly tilted (24.1°). The bond lengths and angles in $\mathbf{Fe(3a)_2}$ and $\mathbf{Fe(3d)_2}$ are unremarkable.

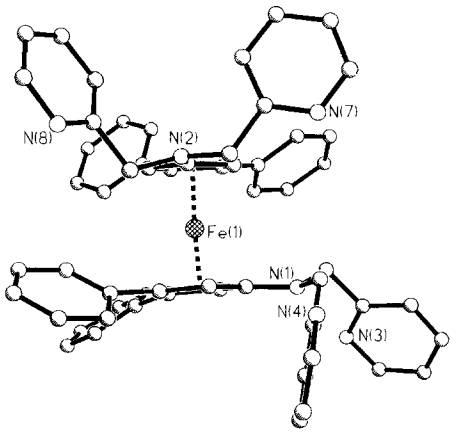

Fig. 2. Structure of $\mathbf{Fe(3d)_2}$ in the crystal as viewed along the plane of the cyclopentadienyl rings. For clarity, the hydrogen atoms have been omitted.

The nitrogen atoms contained in the side chains of the aminoferrocenes can be used for the formation of σ donor complexes. For instance, the isolation of a stable complex between two $LiClO_4$ and $\mathbf{Fe(3b)_2}$ demonstrates the relationship of the latter to TMEDA (tetramethylethylenediamine).

In summary, the reaction of 3,4-dimethylcyclopent-2-enone (**1**) and 2-indanone (**2**) with secondary amines provides a convenient entry to an almost unlimited number of *N,N*-dialkylaminocyclopentadienes **3** and -indenes **4**, respectively. Further reaction of compounds **3** and **4** has been shown to afford the corresponding aminoferrocenes and aminocobaltocenes. We are currently investigating the reactions of **3** and **4** with other metal salts and the complexation behavior of the donor atoms in the side chain.

Experimental Procedure

The following compounds were synthesized and fully characterized: *N,N*-dialkylaminocyclopentadienes, **(3a)H**, **(3b)H**, **(3c)H**, and **(3d)H**; 2-(*N,N*-dialkylamino)-indenes, **(4a)H**, **(4b)H**, **(4c)H**, and **(4d)H**; ferrocenes, $\mathbf{Fe(3a)_2}$, $\mathbf{Fe(3b)_2}$, **Fe(3c)**, $\mathbf{(CpFe)_2(3c)}$, $\mathbf{Fe(3d)_2}$; cobaltocenes, $\mathbf{Co(3a)_2}$, $\mathbf{Co(3b)_2}$, **Co(3c)**, $\mathbf{Co(4a)_2}$, $\mathbf{Co(4b)_2}$, **Co(4c)**, and $\mathbf{Co(4d)_2}$. Only a representative selection of experimental procedures and NMR data is given here.

(3d)H: A mixture of **1** (5.85 g, 25 mmol), bis(2-picolyl)amine (**d**) (5.0 g, 25 mmol), and *p*-toluenesulfonic acid (0.05 g) in benzene (100 mL) was heated to reflux for 48 h under N_2 in a water separator. After the solvent had been removed by vacuum destillation, the residue was recrystallized from toluene/hexane to afford **(3d)H** as a yellow powder. Yield: 6.0 g (58%). ^{1}H NMR ($CDCl_3$): δ = 3.64 (s, 2H, CpH), 4.66 (s, 4H, CH_2-Py), 5.26 (s, 1H, CpH), 6.97–7.34 (m, 14H, ArH + PyH), 7.63 (dt, J = 1.8, 7.7 Hz, 2H, PyH), 8.55 (d, J = 4.34 Hz, 2H, PyH).

$\mathbf{(3c)H_2}$: ^{1}H NMR ($CDCl_3$): δ = 2.92 (s, 6H, CH_3), 3.43 (s, 4H), 3.54 (s, 4H), 5.19 (s, 2H, CpH), 7.0–7.40 (m, 20H, ArH). ^{13}C NMR ($CDCl_3$): δ = 38.70, 42.66, 50.34, 102.20, 123.30, 124.52, 126.78, 126.84, 128.02, 128.31, 128.37, 137.64, 138.51, 143.58, 155.93.

(4b)H: Trimethylethylenediamine (**b**) (155 mg, 1.52 mmol) was added to a solution of **2** (200 mg, 1.52 mmol) in methanol (5 mL) and heated to reflux for 2 h. After the methanol had been removed by vacuum destillation, the product **(4b)H** was obtained as a brown oil. ^{1}H NMR ($CDCl_3$): δ = 2.25 (s, 6H, CH_3), 2.44 (t, J = 7.6 Hz, 2H, NCH_2), 2.86 (s, 3H, CH_3), 3.28 (t, J = 7.6 Hz, 2H, NCH_2), 3.36 (s, 2H, NC-CH_2), 5.29 (s, 1H, NC=CH), 6.77–7.18 (m, 4H, ArH). ^{13}C NMR ($CDCl_3$): δ = 36.75, 37.58, 45.21, 50.56, 55.77, 95.80, 116.02, 119.04, 122.02, 126.06, 136.00, 147.46, 156.29.

$\mathbf{Fe(3d)_2}$: **(3d)H** (414 mg, 1 mmol) was added to a solution of $FeCl_2$ (63.5 mg, 0.5 mmol) and $LiN(i\text{-}C_3H_7)_2$ (107 mg, 1 mmol) in THF (15 mL) at −78 °C. The reaction mixture was allowed to slowly warm to room temperature. After 2 h the solvent was removed by vacuum destillation and the residue was purified by chromatography using cyclohexane/ ethyl acetate/ Et_2NH (5:5:1) as eluant. Further purification was accomplished by recrystallization from toluene/hexane to give $\mathbf{Fe(3d)_2}$ as a deep red powder; yield: 154 mg (35%). ^{1}H NMR ($CDCl_3$): δ = 4.19 (s, 4H, CpH), 4.23 (s, 8H, CH_2-Py), 7.11 (ddd, J = 1.4, 4.8, 7.4 Hz, 4H, PyH), 6.59–6.79 (m, 20H, PyH + ArH), 7.17–7.23 (m, 8H, PyH + ArH), 8.10 (ddd, J = 0.9, 1.8, 4.8 Hz, 4H, PyH). ^{13}C NMR (C_6D_6): δ = 59.06, 60.81, 82.03, 116.61, 121.73, 122.40, 125.88, 127.90, 130.20, 135.92, 139.17, 149.51, 159.95. $C_{58}H_{48}FeN_6$ (884.9), calcd. (found): C 78.72 (78.25), H 5.47 (5.50), N 9.50 (9.78).

Fe(3c): ^{1}H NMR (C_6D_6): δ = 2.60 (s, 6H, CH_3), 2.95 (s, 4H, CH_2), 4.60 (s, 4H, FcH), 6.92–7.03 (m, 12H, ArH), 7.34–7.39 (m, 8H, ArH). ^{13}C NMR (C_6D_6): δ = 38.49, 48.86, 57.68, 82.99, 111.42, 125.96, 127.78, 129.71, 138.78.

$\mathbf{(CpFe)_2(3c)}$: ^{1}H NMR (C_6D_6): δ = 2.47 (s, 6H, CH_3), 3.01 (s, 4H, CH_2), 4.10 (s, 10H, C_5H_5), 7.06–7.10 (m, 12H, ArH), 7.50–7.55 (m, 8H, ArH). ^{13}C NMR ([D_6]acetone): δ = 39.84, 52.96, 57.50, 71.28, 81.85, 115.7, 126.57, 128.35, 130.40, 140.11. $C_{48}H_{22}Fe_2N_2$ (760.58), calcd. (found): C 75.80 (76.12), H 5.83 (5.58), N 3.68 (3.92).

$\mathbf{Co(4b)_2^+[CF_3SO_3]^-}$: ^{1}H NMR ($CD_3CN$): δ = 2.33 (s, 12H, CH_3), 2.49 (t, J = 6 Hz, 4H, NCH_2), 2.97 (s, 6H, CH_3), 3.31 (br, 4H, NCH_2), 5.72 (s, 4H, CpH), 7.08–7.12 (m, 4H, ArH), 7.28–7.33 (m, 4H, ArH). $C_{29}H_{38}CoF_3N_4O_3S \cdot CH_3OH$ (670.68), calcd. (found): C 53.73 (53.53), H 6.31 (6.21), N 8.35 (8.10).

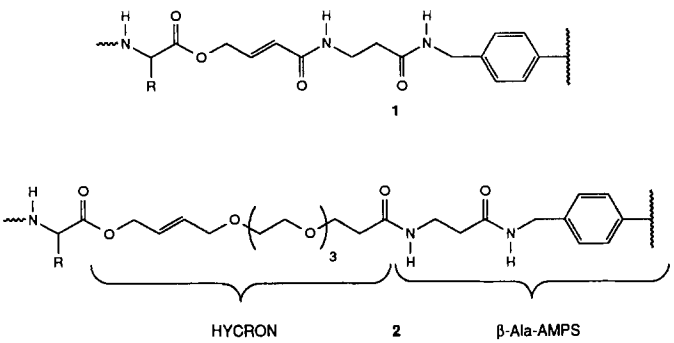
GOOF = 1.09, residual electron density = +0.50, −0.40 e Å^{-3} [15b].

A Novel Allylic Anchor for Solid-Phase Synthesis—Synthesis of Protected and Unprotected O-Glycosylated Mucin-Type Glycopeptides**

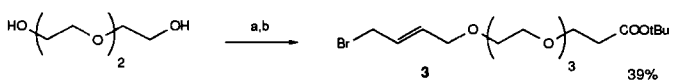


Oliver Seitz and Horst Kunz*

Dedicated to Professor Hans Jeschkeit on the occasion of his 65th birthday

Solid-phase synthesis provides rapid access to biologically relevant peptides.[1] The anchor group used between the target peptide and the polymeric support plays a very significant role. For glycopeptides as well as phosphopeptides or peptides containing acid- and base-sensitive protecting groups, which are to be employed in fragment condensations, the anchor group has to meet specific requirements. The same applies to the area of combinatorial chemistry for the preparation of peptide[2] and structure libraries.[3]

Anchoring through allyl esters[4] not only allows peptide derivatives to be detached without affecting acid- and base-labile structural elements, but also provides orthogonal stability relative to the temporary protecting groups commonly used in solid-phase peptide synthesis.[5] Thus, the *tert*-butyloxycarbonyl (Boc) group and the fluorenylmethoxycarbonyl (Fmoc) group can be used as N-terminal protecting groups. The cleavage of the allyl ester can be achieved by a palladium(0)-catalyzed transfer of the allyl group to a scavenger nucleophile like morpholine or *N*-methylaniline, which traps the allyl moiety irreversibly.[6] As a result, stabilized, long-lived cations are not generated as is the case with the frequently employed acid-labile anchors based on alkoxybenzyl, benzhydryl, or trityl esters.[7] This also avoids alkylation of nucleophilic structural elements[8] of the peptide and does not endanger acid-labile structural elements.

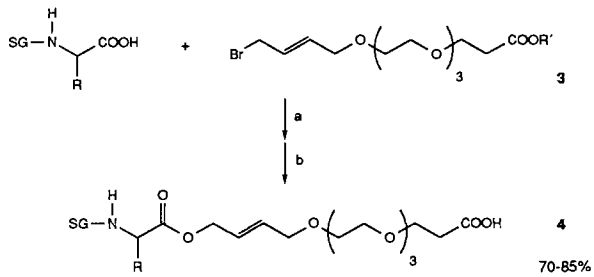


Derivatives of hydroxycrotonic acid were initially used to functionalize the polymeric support, aminomethylpolystyrene (AMPS), with allylic anchor groups.[5a] Insertion of a standard amino acid, for instance β-alanine, between the anchor and the polymer creates a spacer effect and allows the determination of the peptide loading independent of the degree of dryness.[9] Complex glycopeptides have been synthesized successfully according to this principle (β-HYCRAM **1**, Scheme 1).[10]

Scheme 1. Segments of peptide-loaded β-Ala-aminomethylpolystyrene (β-Ala-AMPS) with allylic anchor groups: β-HYCRAM **1** and novel anchor group HYCRON in **2**.

While the glycopeptides could be detached from the resin in high yields when the Boc strategy was used, reduced yields were observed when the Fmoc group was used as the temporary amino protection group. β-HYCRAM-bound glycine was used as a low molecular weight model. Upon exposure to morpholine/DMF (1:1) for 3 d, 12% of the allyl ester was aminolyzed.[11] As in many solid-phase syntheses, however, losses can occur at the dipeptide stage (formation of diketopiperazine) and, due to steric hindrance, during the cleavage process itself. Therefore a new anchor of the allyl ester type should incorporate a flexible, polar spacer in order to reduce steric hindrance and associations with the polystyrene matrix.[4] The achievements in solid-phase synthesis with graft copolymers made of polyethyleneglycol and polystyrene demonstrate the beneficial properties of polar spacers.[12] Moreover, the α,β-unsaturated carbonyl structure should be replaced to increase the stability against nucleophilic attack.

Structure **2** contains an allylic anchor (HYCRON) that meets the requirements outlined above. The precursor **3** of the allyl anchor, which allows the linkage to both the starting amino acid and the polymeric support, is synthesized by a sodium glycolate catalyzed Michael addition of triethgleneglycol to *tert*-butyl acrylate (Scheme 2) and subsequent reaction of the Michael adduct with 1,4-dibromo-2-butene under phase-transfer conditions.



Scheme 2. a) H$_2$C=CH-COO*t*Bu, THF, sodium glycolate (1 mol%); b) BrCH$_2$-CH=CH-CH$_2$Br, NaOH, Bu$_4$NHSO$_4$, H$_2$O, CH$_2$Cl$_2$.

To load the polymer with the starting amino acid, the amino acid–anchor adduct **4** is prepared. Adduct **4** is obtained by reaction of the protected amino acid with allyl bromide **3** under phase-transfer conditions and subsequent cleavage of the carboxyl protecting group R′ (Scheme 3). The nucleophilic esterification avoids racemization of the starting amino acid, for example, the anchored threonine **5**.

The applicability of the new anchor (HYCRON) was tested in the solid-phase synthesis of the O-glycosylated tetrapeptide **6**. Peptide **6** is a partial structure of peptide T, a threonine-rich segment of the HIV-envelope protein gp 120.[13]

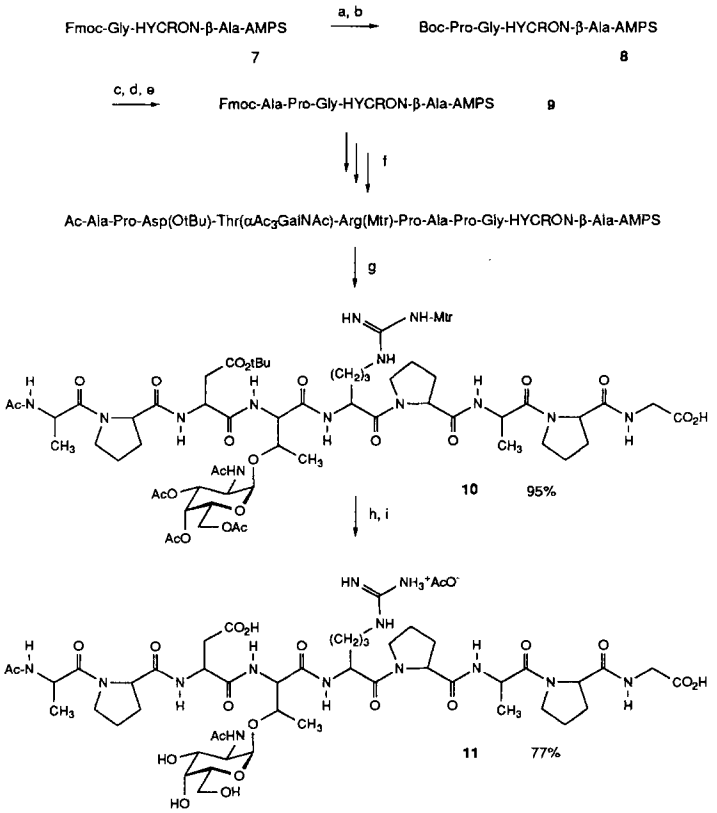
Griesinger and Dr. R. Wechselberger, Universität Frankfurt/Main, for their help with multidimensional high-field NMR experiments.

Scheme 3. a) $NaHCO_3$, Bu_4NBr, H_2O, CH_2Cl_2; b) R' = *t*Bu: CF_3COOH; R' = CH_2COPh: Zn/AcOH.



For the synthesis of **6**, aminomethylpolystyrene carrying β-alanine was loaded with the threonine anchor adduct **5** (Scheme 4). This as well as the following coupling reactions were accomplished with a three- to fourfold excess of diisopropylcarbodiimide (DIC)[14] and hydroxybenzotriazole (HOBt).[15] Any unchanged amino groups were capped after each coupling with

Scheme 4. a) DIC/HOBt, CH_2Cl_2; b) Fmoc detachment: DMF/morpholine (1:1); coupling: DIC/HOBt, CH_2Cl_2; capping: Ac_2O/pyridine (1:3); c) [$(PPh_3)_4Pd$], MeNHPh, DMF/DMSO (1:1) (see text).

The glycosylation pattern of the mucins and the balance of these phenomena appear to be closely related. It has been shown that T_N antigen structures (Ser/Thr(αGalNAc)) in breast tissue are tumor-associated, whereas T antigen structures (Ser/Thr(α-3-(βGal)-GalNAc)) are even tumor-specific.[19]

The Fmoc group of the glycine-loaded polymer **7** (Scheme 5), which was prepared from the adduct of the amino acid and the

Scheme 5. a) DMF/morpholine (1:1); b) Boc-Pro, DIC/HOBt; c) CH_2Cl_2/CF_3COOH (1:1); d) iPr_2NEt/CH_2Cl_2 (1:10); e) Fmoc-Ala, DIC/HOBt; f) see text; g) [$(PPh_3)_4Pd$], morpholine, DMF/DMSO (1:1); h) CF_3COOH/MeSEt/MeOPh (40:1:1); i) NaOMe/MeOH (pH = 8.5). Mtr = 4-methoxy-2,3,6-trimethylbenzenesulfonyl.

acetic anhydride/pyridine. The cleavage of the Fmoc group was achieved by exposure to DMF/morpholine (1:1) for 50 min. The carbohydrate building block was introduced as a preformed glycosyl amino acid (Fmoc-Thr(αAc_3GalNAc)). Detachment of the O-glycosylated tetrapeptide **6** was accomplished by a palladium(0)-catalyzed allyl transfer to *N*-methylaniline (96% yield).[16] The scavenger nucleophile *N*-methylaniline is not basic enough to cleave the Fmoc group. After twofold chromatography, the protected *O*-glycotetrapeptide **6** was obtained in a total yield of 77%[17] and was characterized by reversed-phase high-performance liquid chromatography (RP-HPLC), high-field NMR spectroscopy, and FAB-MS.

Glyconanapeptide **11** was prepared in another solid-phase synthesis using HYCRON-anchoring. Peptide **11** represents a partial sequence of the repeating unit of the MUC-1 mucin. Mucins are highly O-glycosylated proteins that are expressed in membranes of various epithelial cell types.[18] One phenomenon observed during tumor genesis is that the mucin-mediated adhesion and anti-adhesion processes are no longer under control.

anchor (**4**, SG = Fmoc, R = H), was detached with morpholine/DMF. The next amino acid to be coupled was *N-tert*-butyloxycarbonyl proline. The subsequent acidolysis of the Boc group from **8** prevents diketopiperazine formation during the cleavage of the protecting group. Subsequent couplings were performed exclusively with Fmoc-protected amino acids. All acylation reactions were performed in DMF. *O*-Glycosylthreonine and the following aspartic acid building block were coupled with *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium tetrafluoroborate (TBTU)[20] and *N*-methylmorpholine. The other amino acids were activated with DIC and HOBt. In the case of the N-terminal amino acids proline and alanine, the coupling reactions were each repeated once. The terminal alanine was acetylated after Fmoc cleavage. The palladium(0)-catalyzed detachment of the polymer-bound glyconanapeptide was accomplished with the scavenger nucleophile morpholine in a yield of 93%.[16] After chromatography on silica gel, the glycopeptide **10** was isolated in a total yield of 95%.[21] Purity (>95% by HPLC) and structure of **10** were established by RP-HPLC, high-field NMR spectroscopy, and FAB-MS.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0804 $ 10.00+.25/0

To obtain the unprotected glycopeptide, the acid-labile protecting groups of **10** were cleaved with trifluoroacetic acid in the presence of ethyl methyl sulfide and anisole as cation scavengers.[22] The *O*-acetyl groups were removed by a sodium methoxide catalyzed transesterification in methanol.[7a] The *O*-glycopeptide **11** was purified by gel permeation chromatography on Sephadex G-15 and characterized by RP-HPLC, high-field NMR spectroscopy, and FAB-MS.[23]

These results show that allylic anchoring of the C-terminal amino acid to the HYCRON anchor provides the basis for an efficient solid-phase peptide synthesis. Without changing the allylic anchor, both Fmoc and Boc groups can be used as temporary protecting groups during the synthesis. Furthermore, both acid- and base-labile structural elements are maintained in the palladium(0)-catalyzed cleavage reaction, for example *tert*-butyl ester and *tert*-butyl ether groups, the Fmoc group, and the O-glycosidic bond in the synthesized glycopeptides **6** and **10**. With this method, glycopeptides can be obtained in high yields and in high purity directly after deblocking.

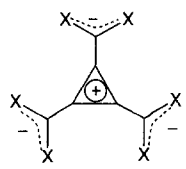
Hexakis(trimethylsilylethynyl)[3]radialene: A Carbon-Rich Chromophore with Unusual Electronic Properties**

Tim Lange, Volker Gramlich, Walter Amrein, François Diederich,* Maurice Gross, Corinne Boudon, and Jean-Paul Gisselbrecht



In our program targeting the construction of novel all-carbon molecules and polymeric networks,[1] we became interested in the synthesis of hexaethynyl[3]radialene (**1a**, $C_{18}H_6$), which had been independently identified both by Hopf and Maas[2] and by one of us[1a] as a suitable molecular precursor for a regular two-dimensional all-carbon network. A variety of [3]radialenes have been prepared, and their electronic and redox properties are strongly dependent on the nature of the substituents at the double bonds.[2] Derivatives with alkyl substituents generally are colorless and difficult to reduce, whereas those with electron-accepting groups, for example hexacyano[3]radialene (**2**) and hexakis(methoxycarbonyl)[3]radialene (**3**),[3] are colored and reducible to the corresponding radical anions and subsequently to the dianions. Radialene **2** is yellow and very unstable; it is readily reduced in two consecutive reversible one-electron steps to the stable dianion $\mathbf{2}^{2-}$ (see Table 1).[3] Radical anion $\mathbf{2}^{\bullet-}$

1a R = H

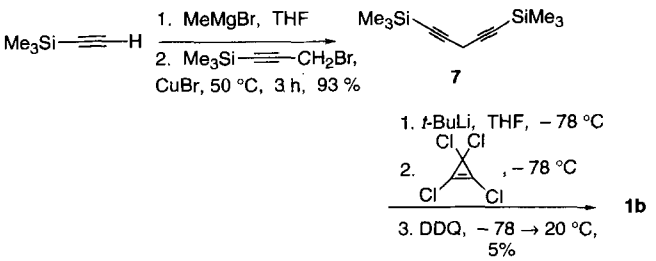
acts as acceptor component in a variety of donor–acceptor complexes with both organic and organometallic donors, which had been prepared as potential organic ferromagnets.[4] In contrast, the yellow radialene **3** is a stable compound which can be reduced to the dianion $\mathbf{3}^{2-}$ via a short-lived radical anion $\mathbf{3}^{\bullet -}$.[3] MO calculations, ^{13}C NMR spectra, and X-ray structural data[4b] suggest that resonance structure **4** featuring an aromatic cyclopropenium cation and negative charges delocalized over the electron-withdrawing groups contributes significantly to the ground states of $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$.



Hexaethynyl[3]radialene (**1a**) is isoelectronic and isosteric with the hexacyano derivative **2**, and it therefore was of interest to compare the structural and electronic properties of the two compounds. Since previous studies had shown that $(R_3Si\text{-}C{\equiv}C)_2C{=}$ fragments were electron accepting[5] and that dialkynylmethyl anions $(R_3Si\text{-}C{\equiv}C)_2CR'^-$ had significant stability,[6] we expected **1** to show the characteristic properties of an electron-accepting radialene. Additional incentive for the synthesis of **1** was provided by the computational prediction of its structure in high-level calculations by Schaefer and co-workers.[7] Here we describe the synthesis of hexakis(trimethylsilylethynyl)[3]radialene (**1b**) and report its low-temperature X-ray crystal structure and its unusual electronic and redox properties.

Initial attempts to prepare **1b** or the triisopropylsilyl-protected analogue **1c** from **5a**, **b** by the carbenoid cyclooligomerization method of Iyoda et al.[8] yielded the persilylethynylated butatrienes **6a**, **b** but no trace of radialene (Scheme 1).[5] Attempts to add carbenes or carbenoids, including those formed

Scheme 1. Unsuccessful attempts to prepare [3]radialene **1b**.

from **5a**, **b**, to the central double bond in **6a**, **b** also failed. The preparation of **1b** eventually succeeded starting from 1,5-bis(trimethylsilyl)-penta-1,4-diyne (**7**)[9] following, with modifications, the route employed by Fukunaga in the synthesis of **2** and **3** (Scheme 2).[3a] Addition of tetrachlorocyclopropene at –78 °C to the carbanion obtained by deprotonation of **6** with *t*BuLi, followed by oxidation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) of the presumably formed dianion $\mathbf{1b}^{2-}$

Scheme 2. Synthesis of [3]radialene **1b**.

yielded [3]radialene **1b** as a dark-red solid which melts under decomposition at 183 °C. DDQ was chosen as the oxidizing agent since it is sufficiently soluble in THF at the low temperatures required for the oxidation of $\mathbf{1b}^{2-}$ to **1b**. The new radialene is stable under laboratory conditions and dissolves in all common aprotic solvents. The low yield of 5% must be ascribed to side reactions, due in part to the instability of the intermediate dianion $\mathbf{1b}^{2-}$ and to decomposition of **1b** during chromatographic purification. The $i\text{Pr}_3\text{Si}$ derivative **1c** cannot be prepared by the same route, presumably because of the severe steric overcrowding of the six bulky $i\text{Pr}_3\text{Si}$ groups in the radialene product. Attempts to deprotect **1b** under mildest conditions with borax in solvents ranging from MeOH to THF and mixtures thereof converted **1b** to a new product as indicated by thin-layer chromatography; however, these solutions so far have been too unstable to allow spectral identification of this product as **1a**.

Radialene **1b** was characterized by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry. The spectrum obtained in the positive-ion mode with 2,5-dihydroxybenzoic acid (DHB) as matrix showed the molecular ion at m/z 654.4 as base peak in a highly resolved molecular ion cluster with an isotopic pattern in perfect agreement with that calculated (Fig. 1). Besides a complete absence of fragmentation,

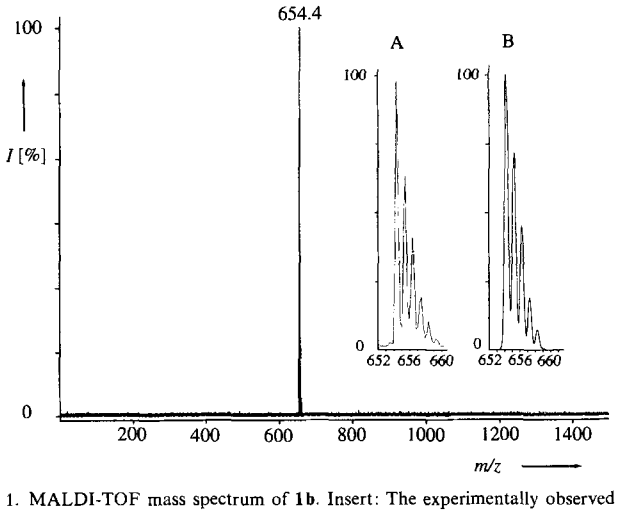


Fig. 1. MALDI-TOF mass spectrum of **1b**. Insert: The experimentally observed molecular ion cluster (A) is in excellent agreement with the calculated isotope pattern (B).

the reflectron spectrum also featured an unusually complete suppression of any matrix interference.[10] In contrast, electron impact mass spectrometry (70 eV) only gave a molecular ion with a relative intensity less than 0.05% besides a multitude of fragments due to extensive decay processes of the Me_3Si groups. This underscores once more the importance of LD-TOF mass spectrometry for the characterization of carbon-rich materials.[11]

In the IR spectrum (KBr) of **1b**, the C≡C stretches are observed at 2132 cm^{-1}, and the strong absorption at 1512 cm^{-1} is assigned to the double bonds. The ^1H NMR spectrum (500 MHz, $CDCl_3$) contains one singlet at $\delta = 0.23$, and the ^{13}C NMR spectrum (125.7 MHz, $CDCl_3$) displays the expected five peaks at $\delta = -0.2$, 92.5, 105.4, 106.0, and 126.7.

Radialene **1b** is highly colored; solutions in hexane are, quite unexpectedly, intensely purple-red and crystals are deep red. The electronic absorption spectrum in hexane (Fig. 2) extends to an end absorption around $\lambda = 620$ nm with the strong longest

wavelength band at $\lambda_{max} = 567$ nm ($\varepsilon = 41\,000$). These optical properties contrast those of yellow **2** and **3**, and rather resemble those of the highly colored tris(fluoren-9-ylidene)cyclopropane (**8**)[8b] and tris(9-anthron-10-ylidene)cyclopropane **9**,[12] π-acceptor radialenes (Table 1) with much larger π-electron chromophores.[13]

8 **9**

Unambiguous structural proof for **1b** was obtained by low-temperature (143 K) X-ray analysis of red platelets grown by slowly evaporating a solution of CH_3CN and CH_2Cl_2 (Fig. 3).[14] The carbon chromophore is nearly planar with a maximum deviation of 0.046 Å out of the best plane. The ideal D_{3h} symmetry of **1b** is reduced in the crystal presumably because of crystal packing effects. Significant distortions are seen owing to the steric compression between pairs of $Me_3Si-C\equiv C$ groups attached to neighboring exocyclic double bonds. The angles at the acetylenic C atoms deviate from linearity; the strongest angle reduction is observed for the bond angle C(44)-C(45)-Si(46) (165.9(2)°). In addition, the three ≡C−C−C≡ angles are reduced to an average value of 114.3°. Crystal packing effects rather than the steric compression of the Me_3Si groups seem to determine the extent (between 0.04 and 0.44 Å) to which the six Si atoms are turned out of the best plane of the carbon chromophore.

The C−C bond lengths in the three-membered ring adopt values between 1.420(5) and 1.431(3) Å, which is in the range of the endocyclic bonds observed in the parent [3]radialene and its hexamethyl derivative.[15] At values between 1.350(4) and 1.358(3) Å, the exocyclic C−C bonds adopt values typical for C=C bonds; Schaefer and co-workers had calculated by DZP SCF ab initio methods a value of 1.338 Å for **1a**.

The redox properties of **1b** were examined by stationary voltammetry on a platinum rotating disk electrode (RDE) and by cyclic voltammetry (CV) in either THF or CH_2Cl_2 containing Bu_4NPF_6 as supporting electrolyte. The radialene was readily reduced in two reversible one-electron charge transfers; the

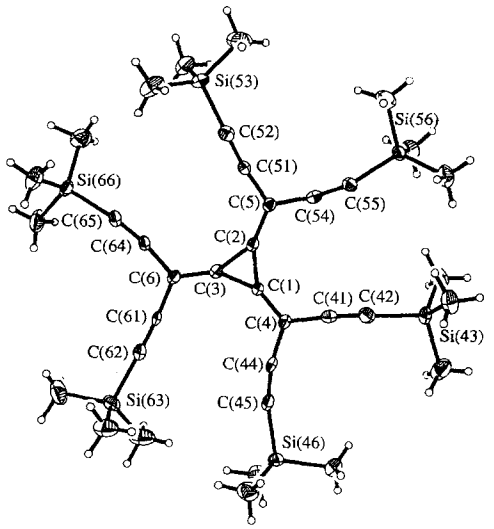

Fig. 3. Molecular structure of **1b** in the crystal. Selected bond lengths [Å] and bond angles [°]: C(1)-C(2) 1.429(4), C(1)-C(3) 1.420(5), C(1)-C(4) 1.355(4), C(2)-C(3) 1.431(3), C(2)-C(5) 1.358(3), C(3)-C(6) 1.350(4), C(4)-C(41) 1.429(4), C(4)-C(44) 1.436(3), C(5)-C(51) 1.431(4), C(5)-C(54) 1.430(4), C(6)-C(61) 1.439(4), C(6)-C(64) 1.428(4), all C≡C bonds are between 1.204(4) and 1.211(5); C(1)-C(2)-C(3) 59.5(2), C(1)-C(2)-C(5) 150.1(3), C(1)-C(3)-C(2) 60.2(2), C(1)-C(3)-C(6) 149.4(2), C(2)-C(1)-C(3) 60.3(2), C(2)-C(3)-C(6) 150.4(3), C(2)-C(1)-C(4) 148.2(3), C(3)-C(1)-C(4) 151.5(2), C(3)-C(2)-C(5) 150.4(3), C(41)-C(4)-C(44) 113.3(2), C(51)-C(5)-C(54) 114.4(2), C(61)-C(6)-C(64) 115.5(2), C(4)-C(44)-C(45) 169.6(3), C(44)-C(45)-Si(46) 165.9(2), C(5)-C(54)-C(55) 171.3(3), C(54)-C(55)-Si(56) 165.7(2), C(6)-C(64)-C(65) 172.0(3), C(64)-C(65)-Si(66) 169.8(2), all other C−C≡C and C≡C−Si angles between 171.3(3) and 177.8(2).

reductions occurred at −0.40 and −0.95 V, respectively, in THF (Fig. 4) and at −0.52 and −1.09 V in CH_2Cl_2 (vs. Ag/AgCl, see Table 1). The slopes of the waves obtained on the platinum RDE were close to the 58 mV expected for a one-electron

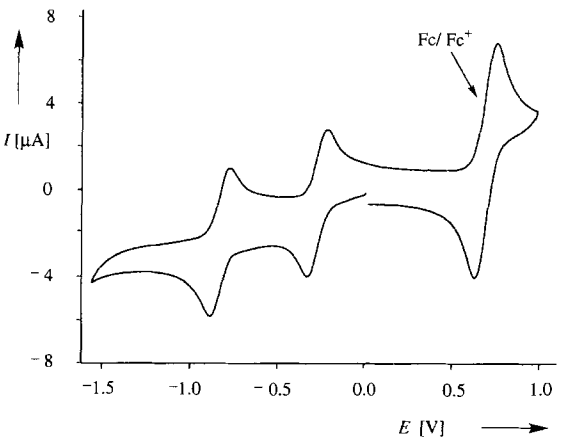

Fig. 4. Cyclic voltammogram of **1b** in THF (0.1 M Bu_4NPF_6) recorded with a Pt electrode at a sweep rate of 0.1 Vs^{-1}; Ag/AgCl reference electrode.

Nernstian charge transfer. In cyclic voltammetry the two reductions had the characteristics of a reversible one-electron charge transfer for scan rates ≥ 0.1 Vs^{-1}, whereas for lower sweep rates the second charge transfer became slightly "irreversible", characteristic of a subsequent chemical step associated with the second charge transfer under the experimental conditions.[16]

Thin-layer spectroelectrochemical measurements were carried out on an optically transparent thin-layer electrode. The conversion of **1b** to $\mathbf{1b}^{\bullet -}$ in THF showed well-defined isosbestic points at $\lambda = 306$, 345, 432, and 608 nm (Fig. 5). The radical

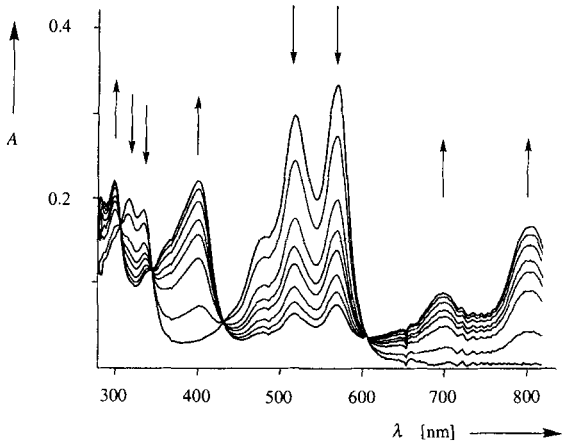

Fig. 5. Time-resolved UV/Vis spectra for the reduction of **1b** in THF (0.1 M Bu_4NPF_6) on an optically transparent thin-layer electrode; first reduction step at a controlled potential of −1.2 V vs. ferrocene.

anion $\mathbf{1b}^{\bullet -}$ could be quantitatively oxidized back to the neutral radialene only for short electrolysis times (less than 120 s); for longer reduction times, only a 90% recovery of **1b** was possible.

Further reduction of $\mathbf{1b}^{\bullet -}$ resulted in a decrease of the bands at around 700–800 nm, and the generated species were no longer oxidizable back to $\mathbf{1b}^{\bullet -}$ nor to the initial neutral species **1b**, probably as a result of chemical reactions of the strongly basic dianion. Large-scale electrolysis in CH_2Cl_2 in a classical three-electrode cell showed for the first reduction step a color change from purple-red to violet and for the second reduction step a color change from violet to light green.

Table 1. Redox potentials of electron-accepting [3]radialenes.

Radialene	$E^{1/2}_{red}$ (I)	$E^{1/2}_{red}$ (II)	Solvent	Reference electrode	Ref.
1b	−0.40	−0.95	THF	Ag/AgCl [a]	–
	−0.52	−1.09	CH_2Cl_2	Ag/AgCl [a]	–
2	+1.13	+0.34	CH_3CN	SCE	[3a]
3	+0.16	−0.07	CH_3CN	SCE	[3a]
8	−0.27	−0.75	DMF	Ag/AgCl	[8b]
9	+0.02	−0.28	CH_3CN	SCE	[12b]

[a] The redox potentials of **1b** were measured against ferrocene as internal standard as −0.96 and −1.51 V (in THF) and −0.94 and −1.51 V (in CH_2Cl_2). Ferrocene was oxidized in THF at +0.56 V and in CH_2Cl_2 at +0.42 V vs. Ag/AgCl.

With its six electron-withdrawing alkyne substituents at the double bonds, radialene **1b** exhibits redox properties similar to those of other derivatives with electron-accepting substituents and can be reduced stepwise and, under CV conditions, reversibly to the radical anion $\mathbf{1b}^{\bullet -}$ and subsequently to dianion $\mathbf{1b}^{2-}$. The cyclopropenium resonance structure **4** should contribute less to the stabilization of the ground state in $\mathbf{1b}^{2-}$ than in $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$, since C≡C bonds stabilize negative charges in α position less effectively than cyano and methoxycarbonyl groups. The different stabilization of negative charges by the six substituents in the radical anion and dianion explains why **1b** is reduced at much more negative potentials than **2** and **3** (Table 1). No good explanation is currently available for the unexpectedly strong bathochromic shift of the electronic absorption spectrum of purple-red-colored **1b** compared to the spectra of yellow-colored **2** and **3**; further clarification of the electronic properties of **1b** and its reduced forms awaits high-level computational studies.

Experimental Procedure

To a solution of **7** (0.8 g, 3.84 mmol) in dry THF (25 mL) at −78 °C was added dropwise under Ar 1.7 M *t*BuLi (2.2 mL, 3.84 mmol) in pentane. The mixture was stirred for 1 h at −78 °C, then tetrachlorocyclopropene (114 mg, 0.64 mmol) in THF (1 mL) was added dropwise, and the red solution was stirred a further 10 min. At −78 °C, DDQ (0.22 g, 0.96 mmol) in THF (2 mL) was added, and the solution was allowed to warm to 20 °C. Pentane was added, and the organic phase was washed with 0.5 N HCl (1 ×) and saturated aqueous NH_4Cl (2 ×), dried ($MgSO_4$), and concentrated to dryness. The reaction mixture was dry-loaded on a plug of SiO_2, the plug eluted with hexane, and the filtrate, after concentration, chromatographed (80 g SiO_2, hexane/CH_2Cl_2 8:1) to afford **1b** (21 mg, 5%) as a red solid; m.p. 183 °C (decomp). IR (KBr): ν [cm^{-1}] = 2958 s, 2896 m, 2132 m, 1512 s, 1405 w, 1248 s, 1089 w, 851 s, 757 s, 699 m, 661 w, 628 m; ^1H NMR (500 MHz, $CDCl_3$): δ = 0.23 (s); ^{13}C NMR (125.7 MHz, $CDCl_3$): δ = 126.7, 106.0, 105.4, 92.5, −0.2; UV/Vis (hexane): λ_{max} (ε) = 567 (41 000), 516 (36 100), 479 (sh, 18 400), 333 (23 200), 314 (24 400), 298 (sh, 16 400), 230 (22 600), 221 (21 500); MALDI-TOF-MS: *m/z* 654 (M^+).

[10] The complete suppression of matrix interference suggests that the ionization of **1b** in the DHB matrix must proceed by a pure charge transfer (CT) process at a laser fluence well below the normal threshold of proton transfer in MALDI. This is consistent with recent results from Ledingham and co-workers. (C. T. J. Scott, C. Kosmidis, W. J. Jia, K. W. D. Ledingham, R. P. Singhal, *Rap. Commun. Mass Spectrom.* **1994**, *8*, 829–832), who report extensive subthreshold photoactivity of DHB. Alternatively, CT ionization of **1b** can be viewed as a matrix-assisted resonance two-photon ionization process, because the radialene absorbs strongly at the laser wavelength of 337 nm (3.67 eV).

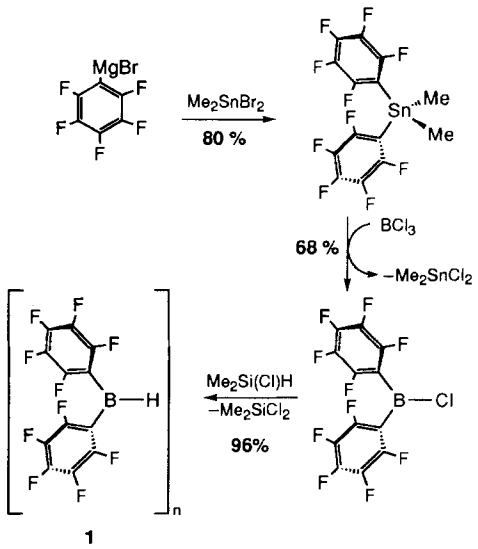
[16] Although the solvents were dried, traces of moisture in the electrochemical cells cannot be excluded. Therefore, the chemical step mentioned could be the protonation of the dianion $\mathbf{1b}^{2-}$.



Bis(pentafluorophenyl)borane: Synthesis, Properties, and Hydroboration Chemistry of a Highly Electrophilic Borane Reagent**

Daniel J. Parks, Rupert E. von H. Spence, and Warren E. Piers*

Hydroboration is one of the most widely used reactions in organic synthesis.[1] A wide variety of borane reagents have been reported such that a library of reagents exists tailored to many different chemical situations. We were interested in the electrophilic and potentially very reactive borane $HB(C_6F_5)_2$ for possible applications in generation of soluble Ziegler–Natta-type olefin polymerization catalysts. These studies revealed this borane to be an exceptionally active hydroboration reagent. In this communication we describe its synthesis, characterization, and a preliminary survey of its activity towards alkenes and alkynes.

Bis(pentafluorophenyl)borane (**1**) was prepared from the known chloroborane $(C_6F_5)_2BCl$[2] in the absence of Lewis bases by reaction with hydride sources such as $[Cp_2Zr(Cl)H]_n$, Bu_3SnH, and $Me_2Si(Cl)H$ (Scheme 1). Traditional metathetical methods for transformations of this type[3] were not advisable because they necessitated the use of donor solvents which were difficult to remove completely (if at all) owing to the high Lewis acidity[4] of **1**.[5] The most convenient hydride transfer agent proved to be $Me_2Si(Cl)H$ since it also served as solvent for the reaction and the by-product Me_2SiCl_2 was easily removed; **1** was observed to precipitate over the course of one hour and was isolated in high yield by filtration. The overall yield of **1** from bromopentafluorobenzene was 52%.

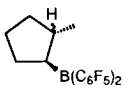
Borane **1** is a white, microcrystalline, oxygen- and moisture-sensitive solid which was found to be to stable (i.e. it retained 100% of its activity) for at least three months when stored under an inert atmosphere at room temperature. Spectroscopic evidence indicated that the solid material is dimeric in structure. The infrared spectrum of the solid showed a strong band at 1550 cm^{-1} characteristic[6] of the ν_{asym} in-phase mode for a B-(μ-H)$_2$-B unit, and no bands corresponding to stretching vibrations of terminal B–H bonds were evident.[7] Solution NMR data were, however, consistent with the presence of monomeric

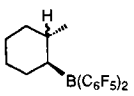
1

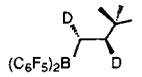
Scheme 1. Synthesis of $(C_6F_5)_2BH$ (**1**). In the last step the reagent $Me_2Si(Cl)H$ also serves as the solvent.

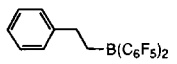
$(C_6F_5)_2BH$. Most convincingly, the ^{11}B NMR spectrum revealed the presence of a minor species ($\approx 10\%$) with a signal at $\delta = 60.1$ ppm in addition to a major species giving rise to a signal at $\delta = 18.0$. The downfield resonance appears in the region associated with monomeric dialkylboranes,[8] while the signal due to the major species is more typical of a dimeric borane.[9] Thus, although borane **1** is a dimer in the solid state, dissociation into a monomeric borane is facile in aromatic solvents.

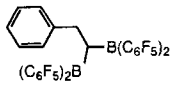
Bis(pentafluorophenyl)borane is a highly active hydroboration reagent towards a range of simple alkenes and alkynes (Table 1). Addition of the olefin or alkyne to a suspension of the borane in benzene led to the rapid dissolution of the solid, and the reaction was complete *within two minutes*.[10] Even sterically demanding olefins (Table 1, entry 1) were hydroborated very rapidly, and the rates of hydroboration of methylcyclohexene and methylcyclopentene were almost identical.[11, 12] These observations are in contrast with those seen in reactions employing the common hydroboration reagent 9-borabicyclo[3.3.1]nonane (9-BBN) which, under identical conditions, required several hours to go to completion with these substrates. The only substrates that do not react rapidly with **1** are those having a $B(C_6F_5)_2$ functionality attached, in other words those formed upon monohydroboration of alkynes (entries 6–8). Not only are these alkenes more sterically encumbered, the electron-withdrawing effect of the $B(C_6F_5)_2$ substituent likely deactivates the double bond towards subsequent hydroboration. By comparison, hydroborations of alkynes with 9-BBN generally proceed more rapidly for the second hydroboration, often precluding isolation of the singly hydroborated product unless excess substrate is employed.[13]

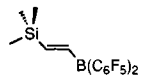


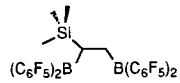


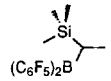












Entries 2–4 in Table 1 demonstrate that **1** hydroborates the substrates by the commonly accepted *cis* addition mechanism.[14] Regioselectivity was found to be excellent for substrates for which multiple products were possible. For example, styrene was hydroborated to give the isomer shown with >98% selectivity (as shown by ^1H NMR spectroscopy and oxidation to 2-phenylethanol, vide infra). In some instances (entries 1–3) facile isomerization by means of a retrohydroboration–rehydroboration sequence was observed over the course of a few hours at room temperature. This behavior is typical for substrates with thexyl substituents,[15] but for other substrates elevated temperatures are usually required to induce these rearrangements.[16] Fortu-

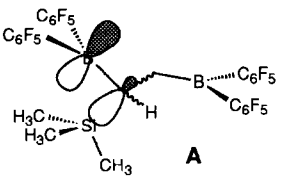
[a] 100% yield by ^{1}H NMR (see ref. [10]). [b] Regioselectivity >98%. [c] [D_1]-**1** was used. [d] Small amounts (≈4%) of the other regioisomer were also detected. [e] The second hydroboration initially produced a mixture of regioisomers which converted quantitatively into the thermodynamic product shown (see text). [f] A thermodynamic mixture of isomers was observed (85:15); the major isomer is shown (see text).



nately, the difference in the rates of initial hydroboration and rearrangement in these systems allows for good control in obtaining either the kinetic or thermodynamic products.

Selective monohydroboration of terminal alkynes was effected by reaction of substrates with a single equivalent of **1** (entries 7, 8). Although slower, double hydroboration occurred upon addition of a second equivalent of the borane. In the reaction of **1** with phenylacetylene, the product was the 1,1 isomer in accord with the normal selectivity observed with other borane reagents.[10] In contrast, the thermodynamic product for trimethylsilylacetylene was the 1,2 isomer. Initially, a mixture of the two possible products of double hydroboration was observed (ratio of 1,1:1,2 = 2.5:1, Scheme 2), which converted to the 1,2 regioisomer quantitatively. A similar phenomenon was observed for trimethyl(vinyl)silane (entry 9). The kinetic product in this reaction was that with the expected selectivity, 1-trimethylsilyl-2-bis(pentafluorophenyl)borylethane. Upon heating to 100 °C this compound isomerized to a mixture (ratio = 85:15) of the two possible regioisomers; the primary isomer was that with

Scheme 2. Hydroboration of trimethylsilylacetylene using 1.

boron attached to the α-carbon atom (see structural formula in Table 1). In the products arising from reaction of silylated substrates with BH_3 boron has been observed to occupy the α-position for electronic reasons, when steric repulsions between the Me_3Si group and boron substituents are at a minimum. Similarly, hydroboration of substrates with the general formula $RC{\equiv}CSiMe_3$ is selective: in the products boron is attached to the carbon atom α to silicon in the monohydroborated product.[17] These observations suggest that there is a thermodynamic preference for silicon to occupy a position β to a boron center in analogy to the well-known "β-silicon effect"[18] in the stabilization of carbocations. Instead of stabilizing a carbocation-like transition state structure, the boron migrates to form a more stable ground state structure **A**.

The generality of this phenomenon and its possible applications are being explored further.

Oxidation of the hydroborated products $RB(C_6F_5)_2$ could not be effected cleanly with aqueous methods or with *meta*-chloroperbenzoic acid (MCPBA) owing to the proteolytic instability of the $B(C_6F_5)_2$ group (loss of HC_6F_5). We have found that anhydrous Me_3NO[19] is a mild and efficient reagent for oxidizing alkylboranes to provide alcohols in good yields. For example 3,3-dimethyl-1-butanol was isolated in 58% yield (unoptimized) from the hydroboration of *tert*-butylethylene. We are exploring other methods for functionalizing these boranes. We are also interested in the properties of the boranes, particularly the dihydroborated products shown in entries 7 and 8, which should be excellent chelating Lewis acid activators for a variety of organic reactions and Ziegler–Natta olefin polymerization systems.[20]

Experimental Procedure

1: Into an evacuated flask containing $(C_6F_5)_2BCl$ (7.00 g, 18.4 mmol) at −78 °C was condensed $Me_2Si(Cl)H$ (10.2 g, 108 mmol). The flask was warmed to room temperature, upon which the chloroborane dissolved and a new white precipitate formed. The reaction mixture was stirred for 1 h and then filtered to give 6.14 g (17.7 mmol, 96%) of the borane as a white crystalline powder. ^{1}H NMR (C_6D_6): δ = 4.2 (br, full width at half maximum ≈25 Hz); ^{11}B NMR (C_6D_6, 25 °C): major component δ = 18.0; minor component δ = 60.1; ^{19}F{^{1}H} NMR (C_6D_6, 10 mM, 25 °C): major component (90%) δ = −134.8 (2F), −148.0 (1F), −160.7 (2F); minor component (10%) δ = −130.5 (2F), −143.4 (1F), −161.7 (2F); IR (Nujol, NaCl): ν = 1652 s, 1550 m (B-H), 1521 m, 1406 w, 1395 w, 1315 s, 1307 w, 1149 s, 1111 s, 1050 w, 1018 m, 975 s, 949 m, 937 w, 767 m, 661 m, 634 w, 624 w; MS (CI$^-$, 70 eV): *m/z* = 346 (M^+); anal. calcd for $C_{12}F_{10}BH$: C 41.67, H 0.29; found: C 41.87, H 0.33.

Deuteriobis(pentafluorophenyl)borane [D_1]-**1**: To a solution of $(C_6F_5)_2BCl$ (1.45 g, 3.8 mmol) in hexane (6 mL) was added a solution of tributyltin deuteride (1.11 g, 3.8 mmol) in hexane (2 mL) over 5 min. This led to the immediate precipitation of a white solid. After 1 h the reaction mixture was filtered; the solid was washed with

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0810 $ 10.00+.25/0

a little cold hexane to give [D_1]-**1** (1.07 g, 3.1 mmol, 81%). $^2H\{^1H\}$ NMR (C_6H_6): $\delta = 4.2$ (br, full width at half maximum = 6 Hz).

General hydroboration procedure: To a suspension of $HB(C_6F_5)_2$ (0.1 mmol) in dry benzene (0.6 mL) under an argon atmosphere was added the dried alkene or alkyne substrate (1 equiv) by syringe. The mixture was sonicated for 30–60 s and then shaken. The reaction progress was monitored by ^1H NMR spectroscopy.

New Process for the Sulfonation of Phosphane Ligands for Catalysts**

Wolfgang A. Herrmann,* Guido P. Albanese, Rainer B. Manetsberger, Peter Lappe, and Helmut Bahrmann

Two-phase procedures have opened a new perspective for organometallic homogeneous catalysis as exemplified in hydroformylation.[1] Sulfonated phosphane ligands have proved themselves in the Ruhrchemie/Rhône–Poulenc process[1, 2] and suggest that a large potential may be anticipated for other C–C coupling reactions, too.[3] Fuming sulfuric acid (oleum), often the only effective sulfonating agent for arylphosphanes is not always satisfactory as a reagent for synthesis:[3d] parallel to the sulfonation of the aryl groups it also causes the formation of undesirable phosphane oxides, which, according to our present understanding, are useless for catalytic purposes and, in addition, are laborious to separate.[4]

These side reactions can be suppressed with low concentrations of SO_3 and short reaction times, but then mixtures of products with different degrees of sulfonation are formed. Phosphanes with a low degree of sulfonation, on the other hand, lead to an increased loss of the catalytically active (noble metal) complexes through extraction into the organic phase because of their poor water-solubility.[1a] Both disadvantages—phosphane formation and low, nonuniform degree of sulfonation—frequently militate against the industrial use of sulfonated phosphanes. In the following we show how these problems can be avoided.

Treating the standard ligand triphenylphosphane (TPP) according to the previous standard procedure at 20 °C with 30% oleum (30 wt% SO_3) under laboratory conditions yields, after 24 hours, a mixture of sulfonated products containing 12.4 mol% of phosphane oxides (Fig. 1a; ^{31}P NMR: $\delta = 36.45$), which must be separated from the sulfonated derivatives by a multistage extraction.[4]

We have now discovered that the addition of orthoboric acid to the sulfonation charges lessens the phosphane oxidation or suppresses it completely. The boric acid is initially dissolved in

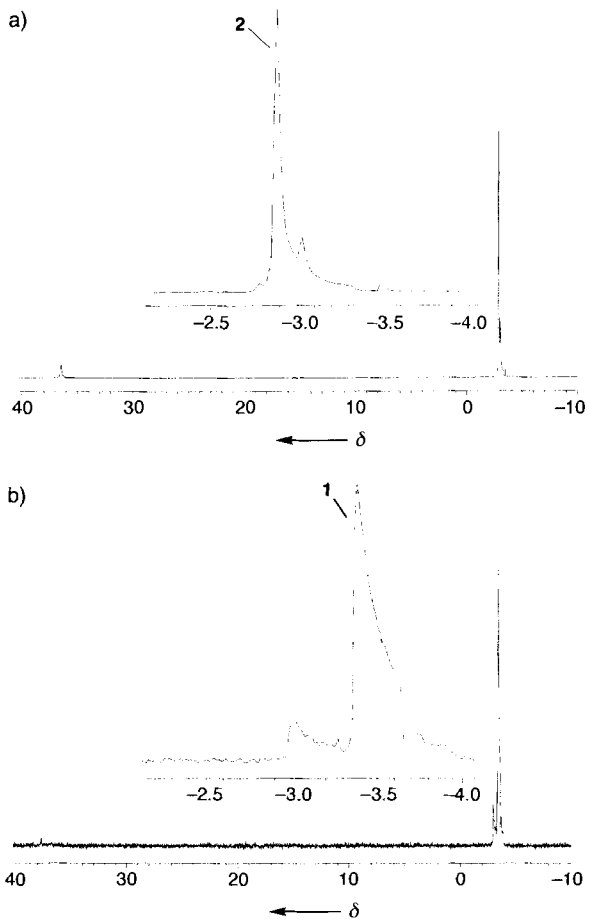

Fig. 1. a) ^{31}P NMR spectrum of triply sulfonated triphenylphosphane **2** (TPPTS; $\delta = 2.88$, 53.8 mol%), prepared according to the conventional procedures of ref. [4], crude hydrolysis mixture with 33.8 mol% of **1**. b) ^{31}P NMR spectrum of doubly sulfonated triphenylphosphane **1** (TPPDS), prepared with $H_2SO_4/B(OH)_3$/oleum; see text. The spectrum shows a very small amount of phosphane oxide ($\delta = 37.68$).

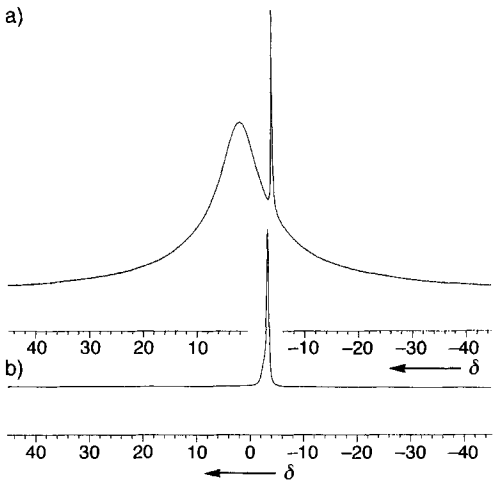
96% sulfuric acid. The water that forms in the process [Eq. (a)] is then quantitatively "titrated" by oleum to H_2SO_4 [Eq. (b)],

$$B(OH)_3 + 5H_2SO_4 \rightleftharpoons [H_3SO_4]^+ + [B(OSO_3H)_4]^- + 3H_2O \quad (a)$$

$$3H_2O + 3SO_3 \rightleftharpoons 3H_2SO_4 \quad (b)$$

which removes the sulfur trioxide and simultaneously generates a superacidic medium [Eq. (a)],[5a] which apparently shows no significant oxidizing power. According to Gillespie et al., the Hammett acidity H_0 of the system $H_2SO_4/B(OH)_3/SO_3$ at low SO_3 concentrations increases substantially faster than that of the H_2SO_4/SO_3 system at the same SO_3 concentration. In the ^{11}B NMR spectrum apart from the signal of a three-coordinate boron species ($h_{1/2}$ = 425 Hz, $\delta = -0.11$), a signal of a highly symmetrical four-coordinate species ($h_{1/2}$ = 61 Hz, $\delta = -3.21$) is observed on addition of $B(OH)_3$ to 96% H_2SO_4. This resonance is likely to correspond to the borate $[B(OSO_3H)_4]^-$, an assignment supported by the values for the comparable systems $B(OSO_2CF_3)_3$ and $[B(OSO_2CF_3)_4]^-$, which have signal widths at half height of 198 and 53 Hz, respectively (CH_2Cl_2; ^{11}B NMR: $\delta = -1.11$ and -3.53, respectively).[6] As shown by ^{11}B NMR spectroscopy (Fig. 2), the equilibrium (a) is shifted completely to the right when the water produced by the reaction is removed by oleum [Eq. (b)]. These reactions may be followed easily through the electric conductivity of the solutions.[5b]



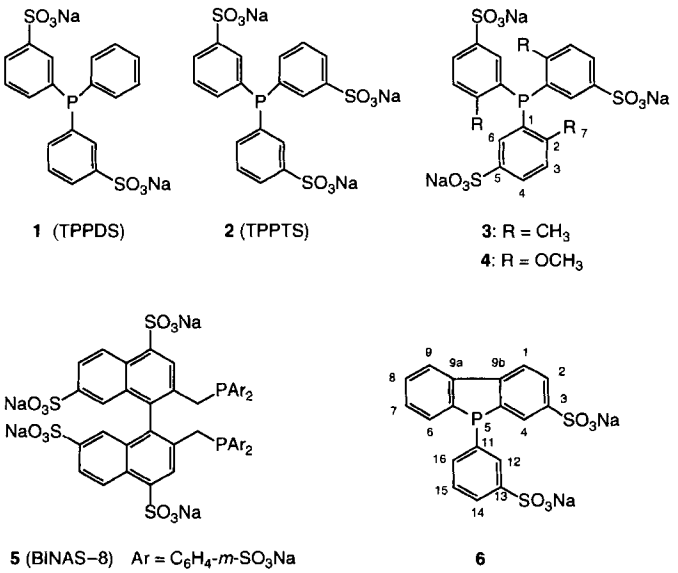


Fig. 2. a) ^{11}B NMR spectrum of boric acid in concentrated sulfuric acid. b) ^{11}B NMR spectrum of a) after addition of oleum; see text.

The boric acid effect stems from cooperation of two favorable circumstances: 1) The phosphanes to be sulfonated are quantitatively quaternized [Eq. (c)], which provides stability against oxidation. 2) Sulfonating species that are far weaker in oxidizing power than SO_3 are formed, for example $[H_3SO_4]^+$.

$$PR_3 + [H_3SO_4]^+ \longrightarrow [HPR_3]^+ + H_2SO_4 \quad (c)$$

The new process is advantageous for the following reasons:

1) For the first time a controlled sulfonation is possible: For example, we obtain selectively the disulfonated derivative TPPDS (**1**, Fig. 1b; ^{31}P NMR: $\delta = -3.38$) from TPP if the temperature of the sulfonation is 58 °C, whereas it is otherwise only accessible in a mixture. This conversion is virtually quantitative after three days. Interestingly even at 120 °C no further sulfonation to the triply sulfonated TPPTS (**2**) takes place, although noticeable phosphane oxidation occurs. TPPTS forms readily, however, if **1** is sulfonated with an excess of 30 wt% SO_3 at room temperature for three days. TPPTS already has industrial application.[1-3, 7]

2) The common ligands in homogeneous catalysis can now be exhaustively sulfonated without side products. Thus, within three days at 95 °C, tris(2-methylphenyl)phosphane affords the triply sulfonated phosphane **3**, a new ligand that enables comparative kinetic studies because of its *ortho* substitution. The deactivated tris(2-methoxyphenyl)phosphane can be converted into the new triply *meta*-sulfonated phosphane **4** with $H_2SO_4/B(OH)_3/SO_3$ [Eq. (a) and (b)] at room temperature within four days.

3) Highly sulfonated and therefore sufficiently water-soluble phosphanes can often be prepared only by this procedure. Thus with 1,1'-binaphthalene-2,2'-diylbis(methylene)bis(diphenylphosphane) (NAPHOS) only a mixture of four- to eightfold sulfonated species is achieved by conventional sulfonation with oleum (65% SO_3) (Fig. 3a), whereas now the product BINAS-8 (**5**, n = 8) can be prepared selectively without phosphane oxidation for the first time (Fig. 3b; ^{31}P NMR: $\delta = -10.44$).[8] However, an excess of SO_3 is required in this case. The

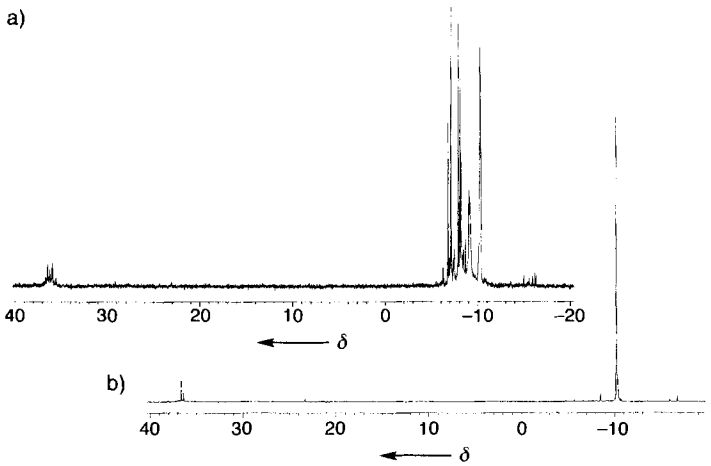

Fig. 3. a) Sulfonation of NAPHOS with oleum (65% SO_3). The actual SO_3 concentration is only 40% as a result of dilution with 96% H_2SO_4 (used to predissolve NAPHOS). The ^{31}P NMR spectrum shows the formation of phosphane oxides (δ = 35–37) and a mixture of many different sulfonated derivatives ($\delta = -6$ to 11). b) Sulfonation of NAPHOS with $H_2SO_4/B(OH)_3$/oleum (with the same SO_3 concentration as in a)); see text. The ^{31}P NMR spectrum confirms the uniformity of the product BINAS-8 (**5**). The amount of phosphane oxides (δ = 36–37) is about 3 mol%.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0812 $ 10.00+.25/0

catalyst formed by this ligand with rhodium(I) is the most efficient to date for propene hydroformylation with respect to activity, productivity, and *n*/*iso* selectivity.[9]

4) A sulfonation of the phospholes, in particular, failed previously because of the pronounced sensitivity to oxidation of this class of compounds. Now from 5-phenyl-5*H*-dibenzophosphole at 145° the selectively sulfonated product **6** can be obtained after 15 h in almost 90% yield as the first known water-soluble phosphole.[8] Phospholes are very promising ligands, inter alia for the hydroformylation of higher (and also functionalized) olefins.[10]

5) The excess boric acid is virtually completely removed in the hydrolytic product workup.

Studies into the kinetics of the sulfonation of triphenylphosphane point to different sulfonation species in the H_2SO_4/$B(OH)_3$/SO_3 system: Under identical conditions, in particular the same SO_3 concentration, highly sulfonated derivatives are formed more quickly than with the conventional H_2SO_4/SO_3 system. Probably the active electrophilic species in addition to SO_3 is essentially $[H_3SO_4]^+$,[11] which according to Equation (a) is present in higher concentrations.

In the light of the rapid development of two-phase catalysis, in particular with water as catalyst medium, the process described here for the direct sulfonation should represent an important breakthrough in catalyst development mainly as a consequence of its efficiency.

Experimental Procedure

Disodium *P*-phenyl-3,3′-phosphanediylbis(benzenesulfonate) **1**: Orthoboric acid (4.80 g, 77.8 mmol) was dissolved in concentrated sulfuric acid (96%, 20 mL). Oleum (20 mL, 65 wt% SO_3) was added dropwise so that in the sulfonation mixture a SO_3 concentration of about 0.9 wt% resulted. This excess SO_3 was removed under high vacuum at 60 °C within 45 min. Then triphenylphosphane (3.00 g, 11.4 mmol) was added (boric acid/phosphane = 6.8/1). The mixture was stirred until all solids were completely dissolved, heated to 58 °C for 4 days, and after cooling hydrolyzed with 50 mL degassed water. The extraction was performed with triisooctylamine (16 mL) in toluene (49 mL). The organic phase was washed with H_2O (3 × 20 mL) to remove the boric acid completely. After reextraction with NaOH (7.5 M) to pH = 11.8, the aqueous phase was neutralized with 3 M H_2SO_4, evaporated to dryness under vacuum, and the solid residue extracted with CH_3OH (40 mL). After removal of the solvent from the extract, **1** was recovered as a white glassy solid. Yield 4.69 g (94%), correct elemental analysis for C, H, Na, P, S, O.

Trisodium 3,3′,3″-phosphanetriyltris(4-methylbenzenesulfonate) **3**: Orthoboric acid (0.40 g, 6.6 mmol) was dissolved in concentrated sulfuric acid (96%, 3.75 mL), after which tris(2-methylphenyl)phosphane (0.50 g, 1.4 mmol) was dissolved in the mixture. Oleum (6.75 mL, 65 wt% SO_3) was added dropwise to the N_2-saturated solution, which had been cooled to 0 °C. After stirring for 3 days at 25 °C, the mixture was hydrolyzed on ice and extracted with triisooctylamine (2 mL) in toluene (20 mL) and worked up further as for **1** [12]. Yield 95%, correct elemental analysis for C, H, Na, P, S, O.

Trisodium 3,3′,3″-phosphanetriyltris(4-methoxybenzenesulfonate) **4** was prepared analogously to **3**.

Disodium 5-(3-sulfonatophenyl)-5*H*-dibenzophosphole-3-sulfonate **6**: Orthoboric acid (2.40 g, 38.4 mmol) was dissolved in concentrated sulfuric acid (96%, 8 mL). Oleum (10 mL, 65 wt% SO_3) was added dropwise so that in the sulfonation mixture a SO_3 concentration of about 5.6 wt% resulted. This excess SO_3 was removed under high vacuum at 60 °C within 45 min. Finally 5-phenyl-5*H*-dibenzophosphole (500 mg, 1.9 mmol) was added (boric acid/phosphane = 20/1), and the mixture was stirred until all solids had dissolved. The charge was heated for 15 h at 145 °C and after cooling hydrolyzed with degassed water (20 mL). The extraction was achieved with triisooctylamine (4 mL) in toluene (30 mL). The further workup of the product was as for **1** [12]. Yield: 852 mg (89%).

First Determination of the Ionization Potential of Americium and Curium**

Rüdiger Deissenberger, Stefan Köhler, Friedhelm Ames, Klaus Eberhardt, Nicole Erdmann, Heike Funk, Günter Herrmann, Heinz-Jürgen Kluge, Martin Nunnemann, Gerd Passler, Joachim Riegel, Franz Scheerer, Norbert Trautmann,* and Franz-Josef Urban

Investigations of chemical and physical properties of very heavy elements have, among other goals, the aim of determining whether the regularities of the Periodic Table of Elements are maintained up through the heaviest elements or whether they are disturbed by relativistic effects, that is, by changes of the electronic structure due to the relativistic mass increase of inner electrons. The first ionization potential of neutral atoms is one of the properties which sensitively depends on these relativistic effects.

Plutonium is the heaviest element whose first ionization potential has been determined experimentally. For the elements located at the beginning of the actinide series, ionization potentials have been measured by techniques such as surface ionization, electron impact, and laser spectroscopy.[1-6] Their ionization potentials have also been derived from thermochemical data by means of the Born–Haber cycle,[7] by calculations,[8] and by extrapolation from the spectral properties of the atoms.[9, 10] The most accurate ionization potentials have been obtained from the convergence of long series of highly excited Rydberg states;[4, 6] however, this required a large amount of data.

For elements beyond plutonium, ionization potentials have been derived only by extrapolation[10] based on the systematics of excited electron states. The reasons why experimental data cease in this region are illustrated by a precision measurement of the ionization potential of plutonium by using Rydberg series, which was published recently,[6] although performed some time ago: To produce an atomic beam of sufficient density, up to 2 g of radioactive plutonium-239 had to be used.

We present a method requiring much less material, only about 10^{12} atoms (≈ 0.4 ng). This method opens the possibility for determining ionization potentials of the heavier actinide elements. Because of their strong radioactivity, these elements can be conveniently handled only in very small quantities or are available only in extremely limited amounts. We have used this new approach to determine the ionization potential of the elements americium and curium for the first time. In order to test the method and its precision, the ionization potentials of thorium, neptunium, and plutonium were also measured, for which precise values are known. As an additional test, the ionization potential of americium was also determined by convergence of Rydberg series.

The new method is based on a technique developed for the determination of ultratrace quantities of actinide nuclides by resonance ionization mass spectrometry.[11] Americium may serve as an example, with the excitation scheme used shown in Figure 1. An atomic beam of the element is excited in two steps by intersection of two laser beams exactly tuned to the resonance energies (wavelengths $\lambda_1 = 640.52$ nm and $\lambda_2 = 654.42$ nm). A third laser beam ($\lambda_3 \approx 578$ nm) then scans the region of the ionization threshold by further excitation after the second resonance excitation step. The threshold appears as a sudden increase of the photoion count rate recorded with a channel plate detector after time-of-flight mass analysis. In the interaction zone of the atomic beam and the laser beams, an electric field is applied whose strength is varied from measurement to measurement. With increasing field strength E, the ionization threshold W_{th} is shifted to lower values, as Figure 2a,b shows for field strengths of

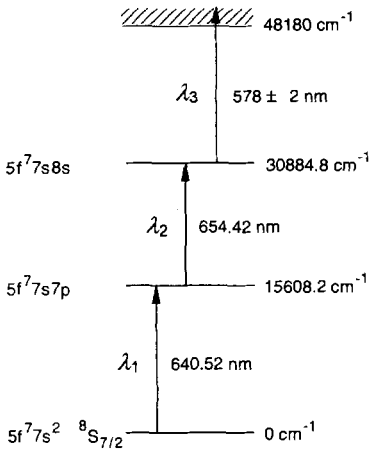

Fig. 1. Excitation scheme for americium as used in the determination of the first ionization potential by resonance ionization mass spectrometry. The two lower excitation steps λ_1 and λ_2 are kept in resonance, whereas the upper step λ_3 is tuned over the ionization threshold.

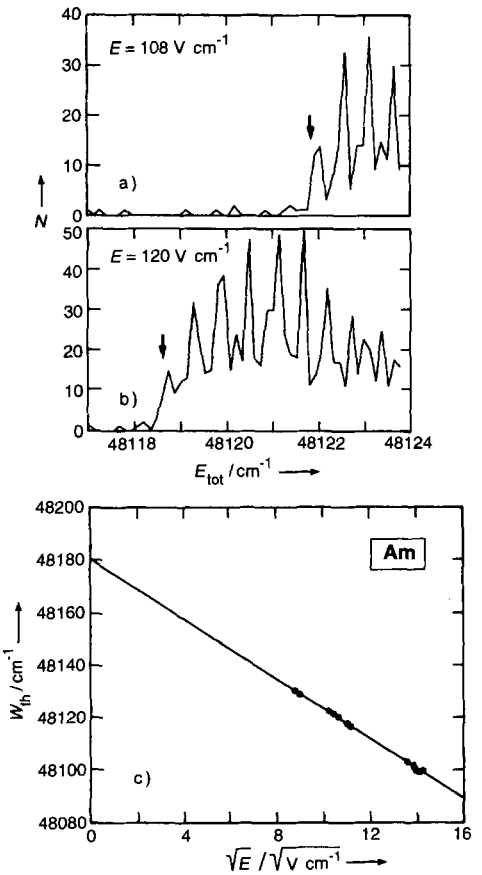

Fig. 2. Ionization threshold (arrows) of americium when applying an electric field of a) $E = 108$ Vcm^{-1} and b) $E = 120$ Vcm^{-1} to the zone of interaction between atomic beam and laser beams. Recorded is the number of ions N as function of the tuned wavelength λ_3 of the third laser; N is plotted versus the total photon energy E_{tot} of the three laser beams. In c) the resulting ionization thresholds W_{th} are plotted versus the square root of the field strength E. A straight line is obtained, as is expected according to Equation (a). Extrapolation to $E = 0$ gives the first ionization potential I_{Am} of americium.

108 Vcm^{-1} and 120 Vcm^{-1}. The arrows mark the respective ionization thresholds. The peak structure seen beyond the thresholds is due to the Stark effect.

The quantities W_{th} and E are related to the first ionization potential I of the neutral atom as given in Equation (a).[12]

$$W_{th} = I - const\sqrt{E} \quad (a)$$

Figure 2c shows this for americium. By extrapolation to $E = 0$, the ionization potential $I_{Am} = 48180(3)\ cm^{-1} = 5.9736(3)$ eV is obtained. In the literature, only an extrapolated value $I_{Am} = 5.993(10)$ eV is reported,[10] deduced from the systematics of $5f^7 7s^2$ and $5f^7 7s8s$ states in the lighter actinide elements. Our additional determination by the convergence of three Rydberg series[14] gives $I_{Am} = 5.9739(2)$ eV, thus confirming the result obtained by resonance ionization mass spectrometry in electric fields. All these data were measured with 10^{12} atoms of americium-243; with a 7370 year half-life, it is the longest-lived americium isotope. Typical in such an experiment are count rates of a few Hertz and counting times of 10 to 30 minutes per field strength setting.

In Table 1 the ionization potentials measured by us are given and are compared with the most accurate values previously reported. The agreement is excellent. From this, we conclude that there is also high reliability for those ionization potentials that have been determined for the first time.

Table 1. First ionization potential I of actinide elements, determined by photoionization in an electric field (PIE), by convergence of Rydberg series (RSC), by life-time measurements of Rydberg and autoionizing states (LTM) as well as values extrapolated from level systematics (Ext).

Element	This work		Literature		
	I [eV]	method	I [eV]	method	ref.

Curium	5.9914(2)	PIE	6.021(25)	Ext	[10]

Experimental Procedure[11]

The elements were electrochemically deposited as hydroxides on thin metal foils and covered with a layer of a reducing metal, for example, on rhenium foils with coating layers of rhenium or lead-doped platinum [16] or on tantalum with titanium coating. Thorium was used directly as a thin metal foil. By heating such filaments in the time-of-flight mass spectrometer, atomic beams were produced.

Laser beams with wavelengths from 520 to 850 nm (260 to 425 nm by frequency doubling) and bandwidths of several Gigahertz ($\approx$1 GHz with an intracavity etalon) were obtained from dye lasers pumped by two pulsed copper vapor lasers (repetition rate 6.5 kHz, power 30 W, pulse length 30 ns, wavelengths 510.6 and 578.2 nm with an intensity ratio of 2:1). The wavelengths were determined by a wavelength meter, occasionally also from absorption bands of molecular iodine. The laser beams were coupled into the apparatus either by quartz fibers or by prisms. The ions produced by intersection with the atomic beam were accelerated to an energy of 2.9 keV. After a drift length of 2.0 m the ions were detected with a channel plate detector.

Thorium was excited and ionized in three steps ($\lambda_1 = 580.42$ nm, $\lambda_2 = 622.90$ nm, $\lambda_3 \approx 568$ nm), neptunium in two steps [17] ($\lambda_1 = 311.82$ nm, $\lambda_2 \approx 544$ nm), plutonium in three steps ($\lambda_1 = 649.07$ nm, $\lambda_2 = 629.75$ nm, $\lambda_3 \approx 579$ nm), and curium in three steps ($\lambda_1 = 655.64$ nm, $\lambda_2 = 640.74$ nm, $\lambda_3 \approx 573$ nm).

[12] Equation (a) results as follows. According to the saddle point model [13], the excitation energy $W_{(r)}$ of an atom with a highly excited electron is given, relative to its electronic ground state, by 1) its Coulomb-energy in the nuclear field with an effective nuclear charge Z_{eff}, 2) by its potential energy in the applied external field of strength E, and 3) by the first ionization potential I. In the one-dimensional approximation [Eq. (b)]:

$$W_{(r)} = -\frac{Z_{eff}\, e^2}{4\pi\, \varepsilon_0\, r} - e\,E\,r + I \quad (b)$$

where r is the distance of the excited electron from the nucleus, e the electron charge, and ε_0 the dielectric constant of vacuum. For the ionization threshold W_{th}, which is the maximum value of $W_{(r)}$, Equation (c) results.

$$W_{th} = I - 2\sqrt{\frac{Z_{eff}\, e^3}{4\pi\, \varepsilon_0}}\sqrt{E} = I - const\sqrt{E} \quad (c)$$

[13] B. H. Bransden, C. J. Joachain, *Physics of Atoms and Molecules*, Longman, London, **1984**, p. 227.
[14] The energies of the levels E_n of Rydberg states of the principal quantum number n can be fitted [15] by Equation (d), to obtain the first ionization potential I. Here, R_{El} is the Rydberg constant of the respective element, and a, b are constants resulting from the fit. In our measurements of Rydberg series of americium, these states were populated by tuning the third laser. For ionization of the Rydberg states, an electric field of 100 Vcm^{-1} was applied 10 μs after the laser pulse.

$$E_n = I - \frac{R_{El}}{\{n - [a + b(I - E_n)]\}^2} \quad (d)$$

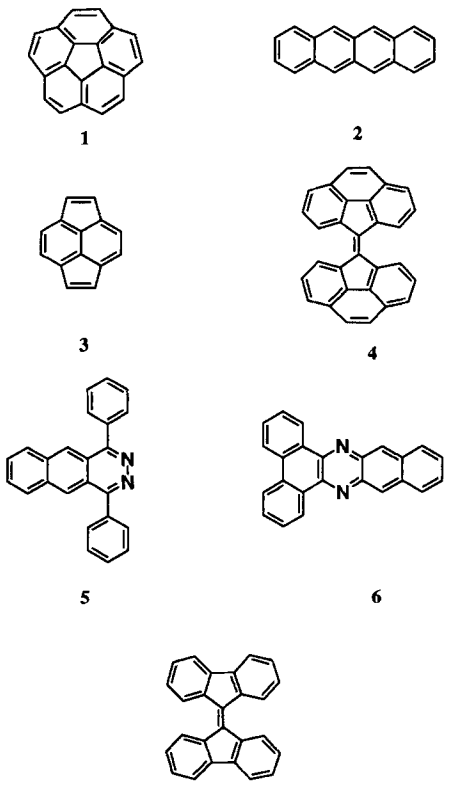
Self-Diffusion of Charged Polycyclic Systems and Their Parent Compounds: A PGSE NMR Study**

Yoram Cohen* and Ari Ayalon

Polycyclic anions with conjugated π electron systems have been investigated extensively in the last decades as test cases for Hückel theory.[1] These systems have also been used to study ion-pairing phenomena.[2] Although aggregation of organometallic compounds was predicted by theory and detected by experiment,[3] polycyclic dianions with π-conjugation in which the charge is thought to be delocalized over a relatively large organic skeleton have been treated in most studies as isolated species. Streitwieser has shown that lithium salts of conjugated hydrocarbon dianions may exist as "ion triplets" in which the lithium cations are located on opposite faces of the dianion.[4] It is therefore important to gain better insight into the actual species that prevail in the solution after metal reduction of polycyclic systems.

Diffusion measurements with the pulsed gradient spin echo (PGSE) NMR technique[5] has been used extensively to study chemical and biological systems.[6-8] Recently, the PGSE NMR technique was used to study aggregation of nucleotides[9a] and complexation of macrocycles[9b] as well as hydration of macromolecules.[10] Nevertheless, to the best of our knowledge, such measurements have never been performed on charged polycyclic systems.



Here we report the self-diffusion coefficients of several polycyclic anions and their parent compounds as obtained by the PGSE NMR technique. Interestingly, the self-diffusion coefficients of the dianions were smaller than the self-diffusion coefficients of the parent compounds in all cases. Surprisingly, in some systems the decrease in the self-diffusion coefficient upon charging is much more pronounced than for other systems, thus suggesting that some of these species may exist preferentially as dimeric sandwich aggregates.

The self-diffusion coefficients were measured by the PGSE NMR technique (Fig. 1),[5] according to which the ratio between the echo intensity (at $t = \tau$) in the absence and in the presence of rectangular pulsed gradients G, ($A_{\tau,0}$ and $A_{\tau,G}$ respectively) is given by Equation (1)[5] where G is the gradient strength of the pulsed gradients [G cm^{-1}], γ the gyromagnetic

$$\ln(A_{\tau,G}/A_{\tau,0}) = -\gamma^2 G^2 \delta^2 (\Delta - \delta/3) D \quad (1)$$

ratio [rad s^{-1}], δ the length of the diffusion gradients [s], Δ the time separation between the edge of the first gradient and the second pulsed gradients [s], and D the self-diffusion coefficient of the observed spins [cm^2 s^{-1}].

The diffusion coefficients of the tetraanion of corannulene (**1**) and the dianions of tetracene (**2**), pyracylene (**3**), bi-(4*H*-cyclopenta[*def*]phenanthren-4-ylidene) (**4**), 1,4-diphenylbenzo[*h*]phthalazine (**5**), tribenzo[*aci*]phenazine (**6**) (Scheme 1), and their parent compounds were determined in [D$_8$]THF by the PGSE NMR technique in the presence of benzene and dichloromethane as internal and external standard, respectively.[11]

Scheme 1.

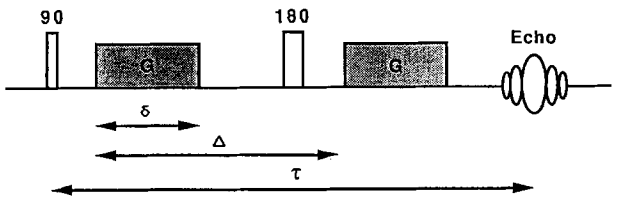


Fig. 1. The Stejskal–Tanner pulse sequence [5].

The data (see Fig. 2 and Table 1) show clearly that the self-diffusion coefficients of the ions are smaller than those of their neutral parent polycycles. From the data of Table 1 it is clear that the investigated systems can be divided into two groups on the basis of the relative changes in the diffusion coefficients upon reduction. In the first group (systems **1** to **3**) the self-diffusion coefficient of the ion is nearly half that of the parent compound. In the second group (systems **4**–**6**) there is only a 20–30% decrease in the self-diffusion coefficient upon formation of the anion. We found that $\mathbf{2}^{2-}/2\,Li^+$, $\mathbf{2}^{2-}/2\,Na^+$, and $\mathbf{2}^{2-}/2\,K^+$ have similar diffusion coefficients. Changing the concentration of $\mathbf{2}^{2-}/2\,Li^+$ by a factor of 10 had only little effect on the self-diffusion coefficient of the dianion after correcting for the changes in the viscosity of the solutions. The fact that no significant changes have been observed in the diffusion coefficient of

the benzene, which served as an internal standard proves that the observed changes in the diffusion coefficients are not due to change in the sample viscosity following the reduction.

The decrease in the self-diffusion coefficient upon reduction may arise from several factors, including ion-pair formation, aggregation of the ions, or increased solvation of the ions by the THF molecules. It appears that, at least in the case of the reduction of **2** to $\mathbf{2}^{2-}$, the nature of the alkali metal cation has only a relatively small effect on the diffusion coefficient of the dianions formed. This can be concluded from the similar diffusion coefficients of $\mathbf{2}^{2-}$/2Li^{2+}, $\mathbf{2}^{2-}$/2Na$^+$, and $\mathbf{2}^{2-}$/2K$^+$ (see Table 1).

[a] After correcting for viscosity changes. [b] Very broad signal for benzene, undetectable in the spin echo.

A plausible explanation for the above observations is that the reduction of **1**, **2**, and **3** (first group) affords charged systems in which, in addition to the decrease in the diffusion coefficient caused by increased solvation of the anions and association of the cations, an additional decrease in the diffusion coefficient is caused by a self-aggregation process. The corannulene tetraanion ($\mathbf{1}^{4-}$/4Li$^+$),[12a] which has been prepared recently, was subjected to an extensive study that demonstrated that $\mathbf{1}^{4-}$/4Li$^+$ forms a stable dimer with sandwich structure in THF solution.[12b] The similarity in the changes in the diffusion coefficients observed upon reduction of **1**, **2**, and **3** suggests that **2** and **3** may also form dimeric sandwich aggregates in which the alkali cations connect the two hydrocarbon dianion moieties.[13] In the reduction of systems **4**–**6** the main factors responsible for the decrease in the diffusion coefficients upon reduction seem to be solvation and ion-pair formation. In principle, the dimeric aggregates should be more stable in charged systems that have a rigid skeleton that can deviates only slightly from planarity. Interestingly, systems **1**–**3** are all such systems. System **4** is the only carbocyclic system we tested in which there is merely a 20–30% decrease in the self-diffusion coefficient following dianion formation. Dianion $\mathbf{4}^{2-}$, which was shown to be closely related to bifluoren-9-ylidene dianion ($\mathbf{7}^{2-}$)[14], probably adopts a nonplanar conformation similar to that of $\mathbf{7}^{2-}$, for which solution and crystal structures show a marked deviation from planarity.[15] This deviation from planarity in $\mathbf{4}^{2-}$ will cause severe steric interactions that will tend to reduce the stability of the dimeric sandwich aggregates. The ion $\mathbf{6}^{2-}$ might be an exception, as it is not clear whether this dianion can adopt a nonplanar structure. However, it has been pointed out that this dianion can be described as a superposition of virtually an "uncharged phenanthrene" molecule and a "benzo[*g*]quinoxaline dianion" moiety, which may suggest that these two π subunits are not coplanar.[1d, 16]

In principle several methods such as colligative methods, NMR relaxation time measurements, or even NMR chemical shifts may provide information about the aggregation state of a chemical species. However, since the polycyclic charged systems investigated here are prepared via radical anions, measurements of relaxation time will provide no insight into the actual species prevailing in solution. Arguments based on chemical shifts are difficult to apply to charged systems, since their chemical shifts are also affected by the ion-pairing equilibrium. Doubly and multiply charged polycycles are extremely reactive intermediates and are also more difficult to study by colligative methods.

In conclusion, we measured the changes in the self-diffusion coefficients of several polycyclic systems after their reduction by metal. There is a marked decrease in the self-diffusion coefficients upon reduction. The systems investigated may be divided to two groups: systems **1**–**3**, in which the diffusion coefficient of the charged system is nearly half that of the neutral parent compound and systems **4**–**6** in which the diffusion coefficient is decreased by only 20–30% upon reduction. In systems **4**–**6** the reduced self-diffusion coefficient of the charged system is attributed to ion-pair formation and more importantly to the excessive solvation of the dianions by the THF molecules. Dianions $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$ show a more pronounced decrease in the diffusion coefficient, resembling the one observed for $\mathbf{1}^{4-}$/4Li$^+$, which is known to exist as a sandwiched dimer. This similarity suggests that dianions $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$ may also exist, at least

partially, as dimeric sandwich aggregates. Dimerization of charged polycycles may be more important than previously thought.

[11] Measurements were carried out on sealed extended 5 mm NMR tubes containing a solution of the polycyclic compound in [D_8]THF, a small amount of benzene as internal reference, and a capillary of methylene chloride as an external reference. After the diffusion coefficients of the neutral sample had been determined, the tube was inverted to allow contact between the solution and the metal (lithium or sodium wire, or potassium minor) which reduced the polycyclic system. All ions gave their known ^{1}H NMR spectrum. All diffusion measurements were performed on a Bruker 500 MHz ARX NMR spectrometer equipped with a Z-gradient unit in an inverse probe for 5 mm NMR tubes. The pulsed gradients used were in the range from 0 to 41.57 cm^{-1}. The total echo time was typically 124 ms while δ and Δ were 2 ms and 62 ms, respectively. All diffusion coefficients are averages of at least 3 experiments, only data having a correlation coefficient (R^2) of more than 0.998 were included.

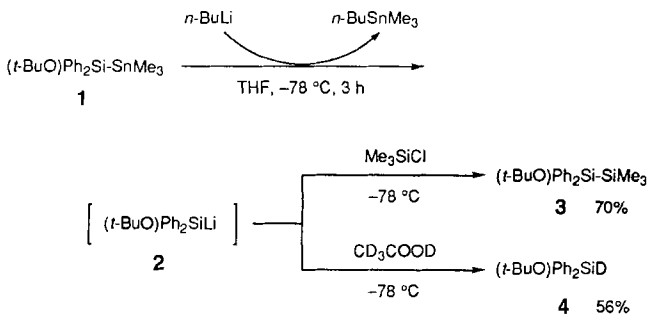
The Chemistry of Silylenoids: Preparation and Reactivity of (Alkoxysilyl)lithium Compounds**

Kohei Tamao* and Atsushi Kawachi

Over the past few decades a considerable number of studies have been made on carbenoids,[1] namely α-heteroatom-substituted organometallic compounds with nucleophilic and electrophilic properties. In contrast to this, the silicon analogues, namely the silylenoids,[2] have been much less extensively studied. To date only one theoretical study has been performed on SiH_2LiF.[3] The result of this study suggests that the Si–F bond is weakened when lithium is attached to the silicon atom, resulting in the appearance of a positive charge on silicon. Some experimental reports have postulated silylenoids $R_2Si(X)M$ as intermediates in the reduction of dihalosilanes R_2SiX_2 with alkali metals M, especially in polysilane synthesis.[4] The reactivities of silylenoids, however, have never been investigated. Such a study may thus shed new light on the mechanism of polysilane synthesis.

We now report the first experimental aspects of silylenoid chemistry (Scheme 1) in (alkoxysilyl)lithium compounds.[5] The



Scheme 1. Nucleophilic and electrophilic nature of silylenoids.

previously reported (aminosilyl)lithium compounds were stable functionalized silyl anions[6] and did not exhibit silylenoid character.[7] In view of the thermodynamic stability and kinetic lability of their substituents, (alkoxysilyl)lithium compounds[8] are expected to behave as silylenoids. Our particular interest has focused on the electrophilic nature of the (alkoxysilyl)lithium compounds as the most diagnostic indication of the silylenoid character, in agreement with the theoretical prediction. The results described herein may be regarded as the silicon version of the chemistry of lithium (alkoxy)carbenoids reported by Wittig et al. in 1957.[1g]

A tin–lithium exchange reaction[6, 9] at low temperature is the key step for the preparation of [(*tert*-butoxy)diphenylsilyl]lithium (**2**) (Scheme 2).[10] The (*tert*-butoxysilyl)stannane[11] **1** was allowed to react with two equivalents of *n*BuLi in THF at −78 °C for 3 h to give **2** as a yellow solution; **2** was trapped with Me_3SiCl to give the corresponding disilane **3** in 70% yield and with [D_4]acetic acid to give the deuterated silane **4** in 56% yield. Compound **2** was stable at −78 °C for at least 6 h (as the trapped product **3**, 66% yield) but it underwent self-condensation almost completely at 0 °C within 2 h (see Scheme 3). This finding markedly contrasts the high stability of the (aminosilyl)lithium compounds, which are stable at 0 °C for several days.[6]

[**] We thank Prof. Y. Ito, Kyoto University, for useful discussions and support of this work. We are also grateful to Prof. P. von R. Schleyer (Erlangen) for fruitful discussion. A. K. thanks the Japan Society for the Promotion of Science (Fellowship for Japanese Junior Scientists). Thanks are also due to the Shin-etsu Chemical Co. and the Nitto Kasei Co. for gifts of chlorophenylsilanes and dichlorodimethylstannane, respectively.

Scheme 2. Preparation of **2**.

The ^{29}Si NMR chemical shift of **2** was observed at $\delta = 11.3$ (-80 °C, THF). This is a large downfield shift compared to the corresponding chlorosilane (tBuO)Ph_2SiCl ($\delta = -23.3$ ($\Delta\delta = +34.6$) and exhibits a remarkable contrast to the upfield shift of ordinary triorganosilyllithium compounds compared to chlorosilanes, for example $\delta(Ph_2MeSiLi) = -20.5$ and $\delta(Ph_2MeSiCl) = 10.0$ ($\Delta\delta = -30.5$).[12] It is noteworthy that the large downfield shifts for **2** is reminiscent of the well-known ^{13}C NMR behavior of carbenoids.[1d, e, h]

The ambiphilic reactivity of **2** was confirmed by the reactions summarized in Scheme 3. At 0 °C, **2** underwent bimolecular self-condensation smoothly, by nucleophilic substitution of the *tert*-butoxy group by another molecule of silyllithium, to give the

Scheme 3. Reactions of **2**. 12-C-4 = [12]crown-4.

disilanyl **5**, which afforded **6** in 56% yield after trapping with Me_3SiCl. In this self-condensation one molecule of **2** behaves as a nucleophile and the other as an electrophile. The generation of **5** was confirmed by the ^{29}Si NMR spectrum at 0 °C, which showed signals at $\delta = -43.7$ (Li–Si) and -2.3 (O–Si).[13]

The nucleophilic butylation of **2** with excess nBuLi (5 equiv based on **1**) in the presence of TMEDA (7 equiv based on **1**) afforded butyldiphenylsilyllithium (**7**). Upon trapping with Me_3SiCl, **7** gave the corresponding disilane **8**, in addition to the self-condensation product **6**.[14] The ratio **8**/**6** was 89/11 (62% total yield).[15] In the presence of TMEDA but in the absence of nBuLi, **2** undergoes self-condensation mainly at 0 °C for 2 h to form **6** in 51% yield, together with a small amount of **3** (7%), indicative of the preservation of the ambiphilic character of **2**.

The ambiphilic reactivity of **2** disappears completely by addition of a crown ether which is expected to form a "solvent-separated ion pair" **9**[1f] (Scheme 3). Thus, in the presence of two equivalents of [12]crown-4,[16] **9** was stable even at 0 °C for 2 h, giving the trapped product **3** in 63% yield, and underwent neither self-condensation nor butylation.[17]

The ambiphilic reactivity of **2** could, in analogy with carbenoid chemistry,[1] be accounted for by contribution from two limiting electronic structures, that is, a nucleophilic silylenoid structure **2a** and an electrophilic silylenoid structure **2b**[3] (Scheme 3). In **2b**, the electropositive lithium atom bound to silicon ionizes and activates the silicon–oxygen bond,[18] so that the silicon center becomes more susceptible to the nucleophilic attack than that in the ordinary neutral alkoxysilanes. The low-field ^{29}Si NMR signal for **2** supports the contribution of the electrophilic structure **2b**.

Some control experiments offered supporting evidence for the activation of the silicon–oxygen bond in **2**. A counter model, (tBuO)Ph_2SiMe, containing a neutral methyl group instead of a cationic lithium atom,[19] was hardly butylated with nBuLi (5 equiv) to form nBuPh$_2$SiMe (4% yield at 0 °C after 10 min in THF in the presence of TMEDA (5 equiv)). Under the same conditions, **2** was butylated to give **8** in 24% yield, together with 9% of **6**. Furthermore, (tBuO)Ph_2SiMe hardly reacted with **2** (1 equiv) or with $PhMe_2SiLi$ (10 equiv) at 0 °C for 2 h and gave essentially no silylated product (tBuO)$Ph_2SiSiMePh_2$ or $PhMe_2SiSiMePh_2$, whereas under these conditions **2** underwent self-condensation exclusively. The tBuO–Si bond in **2** is thus much more reactive than that in the model compound towards the nucleophiles.

No free silylene[2] appears to be generated under the present conditions, since in the presence of various trapping agents such as diethylmethylsilane, diphenylacetylene, and 2,3-dimethylbutadiene, no silylene-trapped products were obtained.[8, 20]

Two further points deserve comment. First, the ambiphilicity of the silylenoid allows the successive introduction of a nucleophile and of an electrophile to a silylene moiety.[21] The important point to be noted is that a nucleophile is introduced first with ease because of the high electrophilicity of silylenoid. This contrasts sharply with the conventional transformations involving simple silyl anions in which only an electrophile is introduced. This new reaction pattern may thus suggest potential synthetic utility of silylenoids.

Second, the reactivity of the silylenoid may be of use in terms of the elucidation of the mechanism of silicon chain elongation reactions in polysilane synthesis by reductive coupling of dihalosilanes R_2SiX_2 with alkali metals M.[4, 22] Our results thus strongly suggest a possibility for the direct conversion of the initially formed silylenoid species $R_2Si(X)M$ into a β-halodisilanyl metal species XR_2SiSiR_2M by self-condensation: This step has not previously been proposed for the mechanism of polysilane synthesis.[4, 22, 23]

Further studies are directed toward the development of various silylenoid species such as (halogenosilyl)lithium compounds, as well as the elucidation of the mechanism of polysilane synthesis.[24]

Experimental Procedure

2: To a solution of **1** (312 mg, 0.74 mmol) in THF (3.0 mL) was added dropwise over 1 min a hexane solution of nBuLi (0.91 mL, 1.5 mmol, 1.64 M) at -78 °C. The solution was stirred for 3 h to give a yellow solution of **2**.

3: To a solution of **2** in THF [prepared from **1** (0.74 mmol) and nBuLi (1.5 mmol) in THF (3.0 mL)] was added chlorotrimethylsilane (0.21 mL, 1.6 mmol) at -78 °C.

After stirring for 30 min, the solution was allowed to warm to room temperature. The solution was analyzed directly by GLC and the yield of **3** was estimated (70%) by using *n*-docosane as internal standard. A pure sample of **3** was obtained as a colorless oil by preparative GLC. ^{1}H NMR (200 MHz, C_6D_6, $\delta(C_6D_6) = 7.20$): $\delta = 0.28$ (s, 9H), 1.26 (s, 9H), 7.24–7.28 (m, 6H), 7.76–7.81 (m, 4H); ^{13}C NMR (50 MHz, C_6D_6): $\delta \approx -1.21$, 32.3, 73.3, 128.3, 129.5, 135.3, 139.2; MS (70 eV): m/z(%): 328 (1) [M^+], 313 (1) [$M^+ - Me$], 255 (7) [$M^+ - SiMe_3$], 199 (100); elemental analysis for $C_{19}H_{28}Si_2$: calcd: C 69.45; H 8.59; found: C 69.55; H 8.59.

6: A solution of **2** [prepared from **1** (0.800 mmol) with *n*BuLi (1.6 mmol) in THF (2.0 mL)] was allowed to warm to 0 °C and stirred for 2 h, followed by addition of chlorotrimethylsilane (0.22 mL, 1.76 mmol). The solution was stirred at 0 °C for 2 h and then allowed to warm to room temperature. A 5% aqueous solution of NH_4Cl (5 mL) was poured into the mixture. The mixture was extracted with Et_2O (3 × 10 mL). The combined organic layers were washed with H_2O (10 mL) and brine (10 mL), and dried over $MgSO_4$. The solution was concentrated to yield crude **6**. The yield of **6** was estimated by ^{1}H NMR spectroscopy (56%); mesitylene was used as internal standard. Pure **6** was obtained as a colorless oil by column chromatography on silica gel (hexane/CH_2Cl_2 = 10/1, $R_f = 0.46$). ^{1}H NMR (200 MHz, C_6D_6, $\delta(C_6D_6) = 7.20$): $\delta \approx 0.24$ (s, 9H), 1.28 (2, 9H), 7.14–7.20 (m, 12H), 7.76–7.83 (m, 8H); ^{13}C NMR (50 MHz, C_6D_6): $\delta = -0.51$, 32.24, 75.39, 128.00, 128.12, 128.77, 129.78, 135.90, 136.97, 138.54; MS (70 eV): m/z(%): 510 (1) [M^+], 453 (37) [$M^+ - t$Bu], 437 (1) [$M^+ - SiMe_3$], 255 (8), 240 (9), 199 (100); elemental analysis for $C_{31}H_{38}Si_3$: calcd: C 72.88; H 7.50; found: C 72.63; H 7.48.

[2] In analogy with the conventions applied for carbenoids, we will use the term "silylenoid" for a compound in which a metal atom and a leaving group are bound to the same silicon atom. The term "silylenoid character or nature" on the other hand will be used in more mechanistic sense for a species that reacts electrophilically.

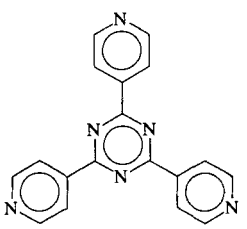
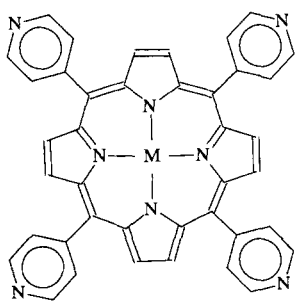
[23] Our proposal is based on the reasonable assumption that the silylenoid character of lithium(alkoxy)silylenoids can be applied to the reactivity of metal(halo)silylenoids.

[24] The sila-Wittig rearrangement of (alkoxysilyl)lithium compounds, that is the organic group migration from oxygen to silicon, analogous to the Wittig rearrangement, has also been observed and will be reported in due course.



2,4,6-Tri(4-pyridyl)-1,3,5-triazine as a 3-Connecting Building Block for Infinite Nets**

Stuart R. Batten, Bernard F. Hoskins, and Richard Robson*



The results presented here form part of a study of the infinite two- (2D) and three-dimensional (3D) coordination networks derived from a family of 4-pyridyl-containing building blocks such as **1**,[1, 2] **2** (hereafter tpt), and **3**[3] amongst others.[4] This

sort of investigation may lay the foundations for much more rational crystal engineering than is presently possible, allowing the future design and construction of solids with tailor-made properties (e.g. catalytic or electronic). Fujita et al. have recently made the very significant observation[5] that a cadmium-containing 2D square grid network derived from **1** that we originally reported[2] has catalytic properties, whilst PtS-related networks obtained, by design, from **3** generate very large channels with obvious implications for catalysis.[3]

We describe below the first crystallographically characterized 3D framework involving tpt (**2**), the trigonal member of the family. Some transition metal derivatives of this ligand have been previously isolated,[6] and molecular species in which three Zn centers are bonded to a single tpt ligand have been described.[7]

Infinite frameworks based on the simpler trigonal building block $C(CN)_3^-$ have been previously reported.[8, 9] This ligand with several divalent hexacoordinating metal ions affords derivatives of composition $[M\{C(CN)_3\}_2]$ containing two identical and independent but interpenetrating 3D (6,3)-connected nets with the same topology as the rutile prototype.[2, 9]

Mixtures of tpt-**2** in 1,1,2,2-tetrachloroethane and mercuric perchlorate in methanol produce brilliant, highly solvated crystals of composition **4** whose structure has been determined by

$[Hg(tpt)_2](ClO_4)_2 \cdot 6C_2H_2Cl_4$ **4**

single-crystal X-ray diffraction. A view of the Hg ions and tpt components of the cubic unit cell is shown in Figure 1. All metal centers are equivalent as are all tpt units, all ClO_4^- ions, and all $C_2H_2Cl_4$ molecules. The Hg centers and the tpt units form an infinite (6,3)-connected 3D network which we estimate to account for only approximately half the volume of the crystals; the spacious intraframework regions are occupied by well-ordered $C_2H_2Cl_4$ molecules and ClO_4^- ions.

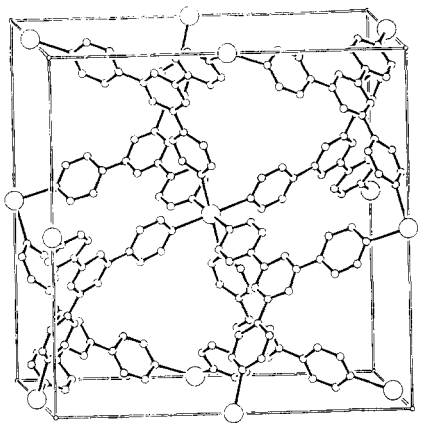

Fig. 1. The cubic unit cell of **4** showing only the Hg ions and tpt components. Large circles represent Hg atoms and small circles either C or N atoms. For clarity the C_5N and C_3N_3 rings are represented so as to obscure any structural features directly behind them. The Hg centers have an N_6 environment only slightly distorted from regular octahedral (Hg–N, 2.443(8) Å, N–Hg–N, 88.8(4)° and 91.2(4)°) provided by six tpt molecules each of which is coordinated to three metal centers at the corners of an equilateral triangle (Hg···Hg edge, 13.760(2) Å).

The three-dimensional disposition of these intraframework species is most simply represented in terms of the contents of a unit cell octant, as in Figure 2, all of which are equivalent. Each octant has a metal center at alternate corners, three of them being connected together by a tpt unit which is distorted from

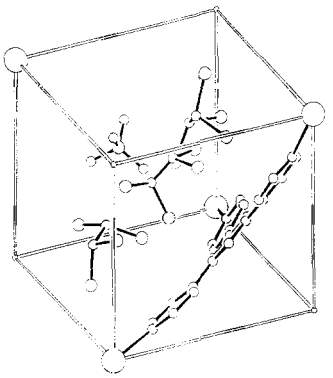

Fig. 2. An octant of the unit cell. Large circles represent Hg atoms, intermediate circles Cl atoms, and small circles either C, N, or O atoms. The angle between the planes of the triazine and pyridine rings is 9.5°. Three equivalent $C_2H_2Cl_4$ molecules are found within each octant arranged around the threefold axis. Within each $C_2H_2Cl_4$ molecule the torsional angle H-C-C-H is 60.5°.

internal coplanarity to become slightly domed; the displacement of the center of the triazine unit from the midpoint of the associated triangle of Hg centers is 0.86 Å. The fourth metal ion in the octant lies on a threefold axis perpendicular to the average tpt plane. Each octant contains one ClO_4^- ion with one of its Cl–O bonds coincident with the threefold axis and the oxygen pointing towards the tpt unit.

The large intraframework spaces are best described, in the absence of discernible linear channels, as consisting entirely of cavities between face-to-face tpt units of the type shown in Figure 3, each one merging into twelve others with which it shares large connecting "windows". The extensive solvation ($6C_2H_2Cl_4$ per Hg) reflects the spaciousness of these interconnected cavities.

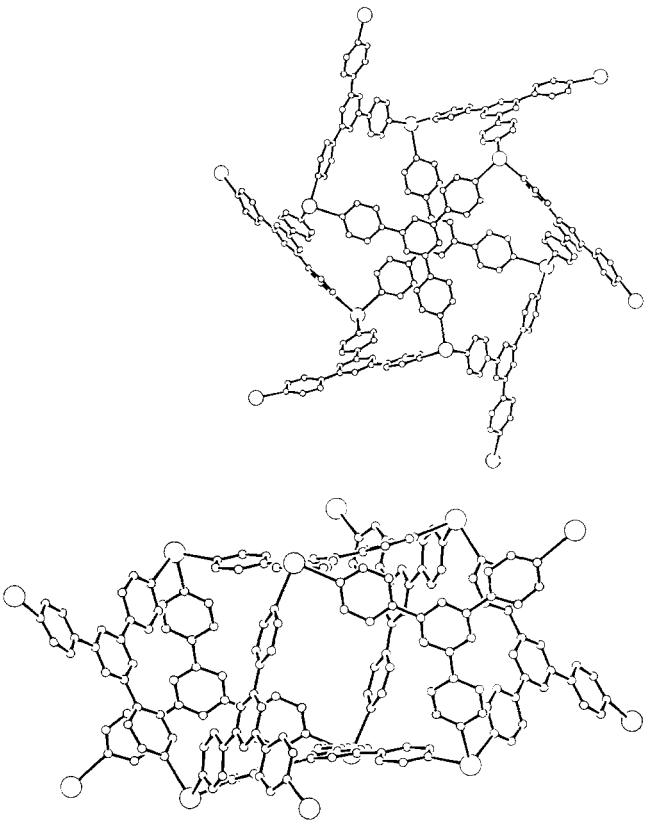

Fig. 3. A cavity formed between face-to-face tpt units. Top: Viewed slightly displaced from the threefold axis; bottom: viewed approximately edge-on to the face-to-face tpt units. For clarity C_5N and C_3N_3 rings are represented so as to obscure any structural features directly behind them. The separation between the triazines of the two face-to-face tpt units is 9.5 Å.

The high degree of solvent and anion ordering in the structure of **4** is in marked contrast to the pronounced, liquidlike disorder which has been an outstanding feature of the highly solvated infinite framework solids constructed from other large molecular building blocks.[3, 10] However, the intraframework spaces in **4** admittedly represent a significantly smaller fraction of the crystal volume than in the others.

To the best of our knowledge the (6,3)-connected net of **4** has not been described before but, by sheer coincidence, an identical topology had been seen in our laboratory in crystals of $Cd(CN)_2 \cdot 2/3\,Et_3N$ only a short time before the present example was discovered.[11]

Well-characterized hexapyridinate complexes are rare, undoubtedly because of steric interference involving pyridine α-hydrogen atoms. (Of course, octahedral tris-2,2′-bipyridine (bpy) complexes in which this steric clash does not arise are stable and common.) To the best of our knowledge only three examples of crystallographically characterized metal hexapyridinates have been reported. In $[Fe(py)_6][Fe_4(CO)_{13}]$ (py = pyridine) the Fe–N bonds are distinctly elongated (2.25–2.29 Å) and the cation has a high-spin electronic configuration in contrast to the low-spin $[Fe(bpy)_3]^{2+}$.[12] $[Ru(py)_6](BF_4)_2$ with slightly shorter coordinate bonds (2.10–2.14 Å) is spin-paired.[13] The third example is $[Hg(py)_6](CF_3SO_3)_2$ in which the Hg–N distances of 2.42–2.48 Å are very similar to those in **4** (2.443(8) Å).[14]

The net underlying the structure of **4** can be related to the cubic pyrites net by the following imaginary transformation. The trigonal centers in a face-to-face pair (see pair in Fig. 3) are first deformed to become more pyramidal such that their separation decreases. The two approching centers are then bonded together, their connectivities increasing from three to four, to form a new net with the same topology as pyrites.

The (6,3)-connected topology adopted by the $[Hg(tpt)_2]^{2+}$ framework is to be contrasted with the rutile-related connectivity adopted by many divalent derivatives of the trigonal building block $C(CN)_3^-$.[2, 9] An essential feature of the rutile net is the presence of "four-membered" circuits (two octahedral centers and two trigonal centers). If the $[Hg(tpt)_2]^{2+}$ framework were to adopt the rutile connectivity, the analogous "four-membered" rings involving two octahedral metal centers and two planar tpt units, which would have to be coplanar or close to it, would lead to pronounced clashing between α-hydrogens of separate tpt units. Tpt, if it remains planar or close to it, would therefore seem innately unsuited to form a rutile-like net.

We estimate that for a given octahedral-to-trigonal distance, the (6,3) net of **4** is approximately 10% more dense than the rutile net, which is somewhat surprising since the shortest circuits in **4** are "six-membered" (three octahedral and three trigonal centers) in contrast to the "four-membered" shortest circuits in the rutile net. It is interesting to speculate why the net in **4** appears not to be adopted by AX_2 solids. We are presently exploring other three-dimensional nets formed by tpt, several of which generate large intraframework cavities and channels.

Experimental Procedure

Mixing $Hg(ClO_4)_2 \cdot 3H_2O$ (14 mg, 0.031 mmol) in methanol (10 mL) and tpt (25 mg, 0.080 mmol) in $C_2H_2Cl_4$ (10 mL) initially gave a small amount of very fine, cloudy white precipitate. After three days, however, large colorless crystals of $[Hg(tpt)_2](ClO_4)_2(C_2H_2Cl_4)_6$ grew (45 mg, 70%). The crystals were sensitive to loss of solvent.

Elemental analysis for $Hg(tpt)_2(ClO_4)_2 \cdot$ ca. $5C_2H_2Cl_4$: calcd: C 29.6, H 1.8, N 9.0, Cl 41.8; found: C 29.2, H 1.5, N 9.2, Cl 41.0. A crystal was sealed in a Lindemann glass capillary for crystallographic analysis. Crystal data of **4**: $M = 2031.25$, cubic, space group $Pa\bar{3}$ (no. 205), $a = 19.460(3)$ Å, $V = 7369(2)$ Å^3, $Z = 4$, crystal dimensions $0.29 \times 0.23 \times 0.14$ mm, $\rho_{calcd} = 1.830$, $\rho_{(meas.)} = 1.85(1)$ g cm^{-3}, $F(000) = 3976$, 5382 reflections measured, 3580 unique reflections, $2\theta_{max} = 60°$. Intensity data were measured at 295(1) K with $Mo_{K\alpha}$ radiation (graphite monochromator) using an Enraf-Nonius CAD-4MachS diffractometer and employing the $\omega/2\theta$ scan method; corrections for Lorentz, polarization, and absorption effects were applied ($\mu(Mo_{K\alpha}) = 30.1$ cm^{-1}, min./max. transmission = 0.5505/0.6878). The structure was solved using direct methods (SHELXS-86). A full-matrix least-squares refinement (SHELX-76) was then employed with anisotropic thermal parameters applied to all non-hydrogen atoms; pyridine hydrogens were assigned to calculated positions and refined with a common isotropic thermal parameter; no tetrachloroethane hydrogens were observed or included in the refinement; however their positions were calculated to allow the torsional H-C-C-H angle to be calculated. At convergence $R = 0.0442$ and $R_w = 0.0395$ for the 1149 observed reflections [$I \geq 3\sigma(I)$] with 146 parameters; max. residual electron density = 0.91 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Reaction of a Vanadium(III) Amide with H_2: Isolation and Characterization of a Polynuclear Mixed-Valence Polyhydrido–Nitrido Complex**

Pietro Berno and Sandro Gambarotta*

The hydrogenolysis of a M–C bond by molecular hydrogen to form a metal hydride and a hydrocarbon is a key transformation in the organometallic chemistry of transition metals[1] and a fundamental step in both catalysis[2] and metal-promoted organic synthesis.[3] In contrast, only very little is known about the reaction of H_2 with M–X bonds (X = heteroatom)[4] in spite of the great possibilities that can be envisioned for catalysis. This challenging new aspect of molecular catalysis is now the target of active research, though almost exclusively with the late transition metals. Since early transition metals have been successfully used for promoting a very large number of organic transformations (insertion,[5] reductive coupling,[6] hydroamination,[7]

[**] This work was supported by the Natural Science and Engineering Research Council of Canada.

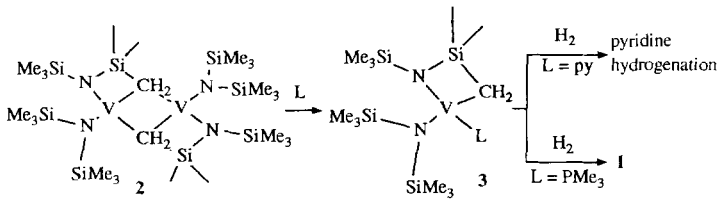
cyclization,[8] hydrosilation reactions,[9] etc.), cleavage of bonds between early transition metals and heteroatoms such as phosphorus, nitrogen, sulfur, or oxygen by molecular hydrogen would certainly open new and interesting perspectives.

Complexes with low-valent vanadium centers are particularly appealing, because vanadium is an important component of some metalloenzymes and proteins[10] and is involved in some promising transformations such as the catalytic hydrogenation of N_2.[11] Even more interesting is the fact that this reaction is promoted by in-situ-generated V^{II} hydroxide or V^{II} catecholate in conjunction with protic cocatalysts. These observations, together with the discovery that anionic, organic supporting ligands containing amide groups are able to transfer H_2 from the alkylamide to a substrate, and form metallacyclobutane rings and olefinic functions in the process,[12] prompted us to study the reactivity of the V–N bond of a novel series of V^{III} amides towards H_2.

In this paper we describe the hydrogenolysis of an amide-stabilized vanadacyclobutane to form an unprecedented mixed-valent complex **1** from trihydridodivanadium and nitrido divanadium complex fragments.

$[\{(Me_3P)_3V\}_2(\mu\text{-}H)_3]^+[\{[(Me_3Si)_2N]_2V\}_2(\mu\text{-}N)_2]^-$ **1**

The reaction of the dinuclear complex **2**[13] with either pyridine or PMe_3 cleaved the dinuclear structure to form the corresponding monomers **3a**[14] or **3b**. Although the cleavage of the



$[\{[(Me_3Si)_2N]V[CH_2(SiMe_2)N(SiMe_3)]\}_2]$ **2**

$[\{(Me_3Si)_2N\}V\{CH_2(SiMe_2)_2N(SiMe_3)\}(L)]$

3a: L = pyridine

3b: L = PMe_3

dinuclear structure did not affect the stability of the four-membered metallacyclobutane moiety, it has profound repercussions on its reactivity.[15] While the reaction of **1** with H_2 gave only intractable materials, the reaction of **3a** with H_2 (60 atm) in an autoclave at room temperature gave the expected hydrogenolysis of the V–C bond and, in addition, the stereoselective hydrogenation of the pyridine ring.[14] The same reaction carried out under identical reaction conditions with the PMe_3 complex yielded the novel complex **1** in moderate but reproducible yield (45%) (Scheme 1). The complex was isolated as deep-brown, very air-sensitive crystals from hexane. The formula had to be inferred from microanalytical data, since the ^1H NMR spectrum could not be interpreted because of the paramagnetism (μ_{eff} = 3.27 μ_B per formula unit). The presence of three hydrides in the complex was also supported by the formation of three equivalents of H_2 during a degradation experiment with seven equivalents of HCl in a closed vessel connected to a Toepler pump; the resulting gaseous mixture was analyzed by gas chromatography. The presence of the two nitrido moieties in the anionic units was indicated by the formation of NH_3 during the

Scheme 1.

hydrolysis. The absence of IR absorptions in the region 4000–2900 cm^{-1} ruled out the possibility that the nitrido ligands might actually be NH or NH_2 groups.

The molecular structure of **1** was elucidated by an X-ray crystal structure analysis (Fig. 1).[16] The molecule is composed of two separate $[\{(Me_3P)_3V\}_2(\mu\text{-}H)_3]^+$ and $[\{[Me_3Si)_2N]_2V\}_2(\mu\text{-}N)_2]^-$ fragments. The first unit is dinuclear with the two octahedrally coordinated vanadium atoms bridged by three hydrides [V3–H116 = 1.77(7) Å, V3–H64 = 1.88(2) Å, V3–H148 = 1.79(2) Å, V4–H64 = 1.87 Å, V4–H116 = 1.90(2) Å, V4–H148 = 1.78(2) Å] and arranged in the same face-sharing bioctahedral structure previously observed for the $[\{(thf)_3V\}_2(\mu\text{-}Cl)_3]^+$ cation.[17] The V–V distance [V3–V4 = 2.399(1) Å] suggests direct metal–metal interaction (either partial V–V bond or magnetic exchange). The second unit is also dinuclear

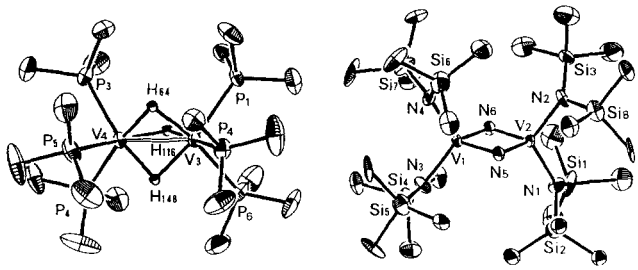


Fig. 1. Structure of **1** in the crystal (ORTEP diagram). The cation is depicted on the left, the anion on the right. Selected bond lengths [Å] and angles [°]: V1-V2 2.583(1), V1-N5 1.769(5), V1-N6 1.776(4), V2-N5 1.771(4), V2-N6 1.776(4), N5···N6 2.420(3), V2-N1 1.965(5), V2-N2 1.958(5), N1-V2-N2 114.1(2); N1-V2-N5 112.6(2), N1-V2-N6 112.5(2), V2-N1-Si1 118.5(3), V2-N1-Si2 121.2(3), V3-V4 2.399(1), V3-P1 2.514(2), V3-P4 2.505(2), V3-P6 2.498(2), V3-H64 1.88(2), V3-H116 1.77(7), V3-H148 1.79(2); P1-V3-P4 96.68(6), P1-V3-P6 96.48(7), P4-V3-P6 98.13(7), P1-V3-H116 87.0(2), P4-V3-H116 170.0(2), P6-V3-H116 91.0(2).

and is formed by two vanadium atoms linked together through a shared edge of their distorted coordination tetrahedra. The V–N distance, which is considerably shorter than usual for a bridging nitrogen atom is consistent with the presence of some V–N multiple-bond character.[18] The V_2N_2 core is planar with a rather short V···V distance [V1···V2 = 2.583(1) Å] and with structural parameters very similar to those of the recently reported $[\{Cp^*V(N)Cl\}_2]$ ($Cp^* = \eta^5\text{-}C_5Me_5$).[19] The long N···N distance [N···N = 2.420(3) Å] rules out the possibility that this unit might actually be a mixed-valence vanadium complex with a dinitrogen ligand bound side-on.[20] The cationic unit provides a rare example of a polyhydridovanadium structure.[21]

The oxidation states of the four vanadium atoms could not be conclusively assigned on the basis of the magnetic susceptibility measurements. Furthermore, attempts to isolate new species by both cation and anion exchange were unsuccessful yielding only extremely intractable air-sensitive oils. However, the structural similarity of the hydrido moiety with that of $[\{(thf)_3V\}_2(\mu\text{-}Cl)_3]^+$,[17] and of the recently crystallographically characterized $[\{(Me_3P)_3V\}_2(\mu\text{-}Cl)_3]^+Cl^-$,[22] makes very plausible the proposal that the unit $[\{(Me_3P)_3V\}_2(\mu\text{-}H)_3]$ contains vanadium in the divalent state and is cationic. The fairly high magnetic moment indicates that this unit is probably paramagnetic, in spite of the short V–V distance. The hydride moiety is undoubtedly formed by the hydrogenolysis of both the $V\text{–}CH_2$ and $V\text{–}N(SiMe_3)_2$ bonds since large amounts of $(Me_3Si)_2NH$ were identified in the GC-MS of the reaction mixture. The fact that no traces of methane or silanes (Me_3SiH, Me_2SiH_2, SiH_4) were detected in the reaction mixture discourages the idea that the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0823 $ 10.00+.25/0

two bridging nitrides arise from the hydrogenolysis of the N–Si bond. This result suggests that these groups are formed by reduction of dinitrogen, either present in the autoclave or during the workup of the reaction mixture. In agreement with these observations, reactions carried out on exclusion of N_2 yielded only intractable and pyrophoric oils.

The transformation of four molecules of **2** (containing V^{III}) into one molecule of **3** (containing two V^{II}, one V^{IV} and one V^{V}) implies a disproportionation with concomitant loss of one electron. The remaining five electrons necessary for the six-electron reduction of dinitrogen are provided by the oxidation of two and a half molecules of H_2. This also produces five of the eight hydrogen atoms necessary to protonate the four CH_2 moieties and the four NR_2 groups during the formation of four molecules of free amine. The remaining three protons are provided by three additional molecules of H_2 which simultaneously generate the three hydrides necessary for the cationic moiety of **3**. The overall stoichiometry is therefore as formulated in Equation (a).

$$4\,\mathbf{3b} + 5.5\,H_2 + N_2 \longrightarrow \mathbf{1} + 4\,(Me_3Si)_2NH \qquad (a)$$

Further work to clarify the reaction mechanism is presently in progress.

Experimental Procedure

PMe_3 (14.2 mmol) was added to a purple-blue solution of **1** (3.5 g, 4.74 mmol). The resulting burgundy red solution was transferred to an autoclave, pressurized with H_2 (60 atm), and allowed to stand at room temperature for 36 h. After venting, the autoclave was opened, and the clear brown solution was transferred to a Schlenck tube. After 2 days of stirring unter N_2 a brown crystalline solid started to separate. When the toluene was removed under vacuum and replaced by hexane, dark brown crystals of **1** precipitated immediately (1.5 g, 45%). Crystals suitable for X-ray diffraction were grown at room temperature in concentrated toluene solution. Elemental analysis: calcd (found) for $C_{42}H_{129}N_6Si_8P_6V_4 \cdot 1/2$ toluene: C 39.37 (39.31), H 9.77 (9.69), N 6.12 (6.09). IR (Nujol, KBr): $\tilde{\nu}$ [cm^{-1}] = 1421 (sh), 1030 (m), 1282 (m), 1241 (vs), 1173 (w), 1081 (w), 1019 (w), 951 (vs), 848 (vs), 786 (s), 754 (m), 724 (m), 700 (sh), 665 (s), 627 (m), 559 (vw). μ_{eff} = 2.73 μ_B per formula unit.

[16] Crystal data of **1**: $C_{42}H_{129}N_6Si_8P_6V_4 \cdot 1/2$ toluene, M_r = 1378.88, triclinic, $P\bar{1}$, a = 18.033(3), b = 19.693 (2), c = 12.464(3) Å, α = 102.75(1), β = 106.58(1), γ = 80.82(1)°, V = 4115(3) Å^3, Z = 2, ρ_{calcd} = 1.113 g cm^{-1}, μ = 6.84 cm^{-1}, $F(000)$ = 1484, R = 0.066 (R_w = 0.085) for 675 parameters and 9097 unique reflections. Non-hydrogen atom position were refined anisotropically. All the hydrogen atom positions were located and refined in the case of the bridging hydrides. Half a molecule of toluene was found in the lattice and was disordered over two positions. Some of the carbon atoms of the trimethylsilyl groups were also disordered over four positions. The disorder was modeled by splitting the occupancies of the carbon atoms over the two positions. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Synthesis and Structure of the First Transition Metal Borylene Complexes

Holger Braunschweig* and Trixie Wagner

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

Transition metal compounds with terminal[1] or bridging[2–4] carbene, nitrene, or oxo ligands are known; however, the analogous borylene complexes have not yet been described. With $[\mu\text{-BX}\{(\eta^5\text{-}C_5H_4R)Mn(CO)_2\}_2]$ **1**, **2**, we were able to synthesize [Eq. (a)], and in the case of **1a**, structurally characterize the first dinuclear complexes with a bridging borylene ligand.

1a R = H, X = NMe_2
1b R = Me, X = NMe_2
2 R = Me, X = *t*Bu

All three compounds can be isolated in the form of red crystals and are characterized by their high stability. For example, in the solid state they can be handled in air for long periods and melt without decomposition between 100 °C and 110 °C. The constitution in solution is derived from the NMR spectra. Despite the BN π-bonding component that is expected for products **1a** and **1b**, the ^{11}B NMR signal at $\delta = 103$ indicates little shielding. In the case of compound **2**, in which the *t*Bu group prevents π saturation of the boron atom, there is an extremely low-field shifted ^{11}B NMR signal at $\delta = 170$. The ^1H and ^{13}C NMR spectra prove that both C_5H_4R groups and the nitrogen-bound methyl groups in **1a**, **b** are equivalent. This, along with the nonequivalence of the four ring protons in C_5H_4Me (**1b**, **2**), supports the presence of a C_2-symmetrical molecule whose C_2 axis passes through the B–X bond.

The results of the X-ray structure analysis[5] of **1a** show that the molecule has approximate C_2 symmetry (Fig. 1) also in the crystalline state. The two manganese atoms and the boron atom form an isosceles triangle, in which the distance between the boron atom and each manganese atom is 203(1) pm and the distance between the two manganese atoms is 279.0(2) pm. The nitrogen atom bound to boron is trigonal-planar coordinated. The plane formed by C_2N (passing through the nitrogen atom) is only slightly rotated (8(3)°) with respect to the Mn_2B plane. The length of the boron–nitrogen bond is 139(1) pm and lies in the expected region for a boron–nitrogen double bond. The molecular structure is essentially analogous to that of the known methylene- and vinylidene-bridged complexes $[\mu\text{-}CH_2\{(\eta^5\text{-}C_5H_4Me)Mn(CO)_2\}_2]$[6] and $[\mu\text{-}CCH_2\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2]$,[7] respectively. These can be considered as dimetallacyclopropane derivatives. The agreement of the structural data and the CO stretching frequency supports the description of compounds **1** and **2** as dimetallaboriranes.

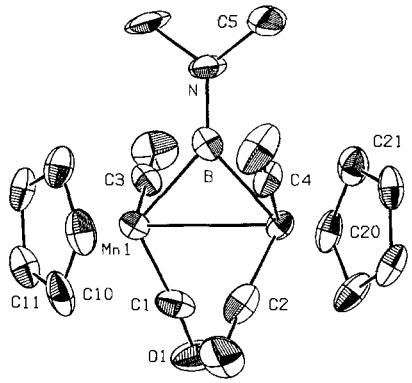

Fig. 1. Crystal structure of **1a**. Selected bond lengths [Å] and angles [°]: B-Mn1 2.03(1), B-Mn2 2.03(1), Mn1-Mn2 2.790(2), B-N 1.39(1), Mn1-Lp1 1.783(1), Mn2-Lp2 1.782(1); Mn1-B-Mn2 86.8(4), Mn1-Mn2-B 46.6(3), Mn2-Mn1-B 46.6(3); Lp1 is the point crossed by the plumbline from Mn1 through the plane formed by the atoms C10 to C14.

The formation of compounds **1a**, **b** and **2** is evidently the result of a complex reaction. In order to gain some insight into the course of the reaction, it was monitored by ^1H, ^{11}B, and ^{29}Si NMR spectroscopy. In addition to the borylene complexes, the only other boron-containing compound which is stoichiometrically formed is the corresponding diborane(6) derivative $(XBH_2)_2$ (X = NMe_2, *t*Bu). The boranes can be isolated from the reaction mixture by condensation in vacuum and unambiguously characterized by their ^1H and ^{11}B NMR spectra. The analogous reaction in [D$_6$]benzene yields the same product. Therefore, the solvent can be eliminated as the source of the boron-bound hydrogen atom in the diborane(6). The cleavage of the boron–boron bond in the starting diborane(4) decisively contributes to the formation of the borylene complex. This is demonstrated by the unsuccessful reaction of $K[(\eta^5\text{-}C_5H_4R)Mn(SiMePh_2)(CO)_2]$ with the boranes $XBCl_2$ [X = NMe_2, *t*Bu]. In addition to the above-mentioned diborane(6), the only characterizable side-product is a small amount of $[(\eta^5\text{-}C_5H_4R)Mn(CO)_3]$. The ^1H and ^{29}Si NMR spectra of the reaction solution as well as the THF-soluble reaction residue show that no soluble silicon-containing compound is formed during the reaction. Investigations of all the reaction components by gas chromatography and mass spectrometry provide no evidence of other products. The Ph_2MeSi group remains in the insoluble residue, in which silicon can be qualitatively analyzed by suitable methods. A chlorosilane elimination, as known for the reaction of $K[(\eta^5\text{-}C_5H_4Me)Mn(SiMePh_2)(CO)_2]$ with numerous chloride compounds,[8] does not take place; however, the Ph_2MeSi group is decisive for the occurrence of the reaction as is shown by the unsuccessful reaction of the diborane(4) with $K[(\eta^5\text{-}C_5H_4Me)Mn(H)(CO)_2]$.

Experimental Procedure

1a: A suspension of $K[(\eta^5\text{-}C_5H_5)Mn(SiMePh_2)(CO)_2]$ [9] (1.34 g, 3.3 mmol) in benzene (15 mL) was treated at room temperature with $B_2(NMe_2)_2Cl_2$ (0.18 g, 1.2 mmol) [10]. After stirring for 24 h all volatile components were removed in high vacuum (25 °C/0.001 Torr), and the residue was taken up in hexane (20 mL). After filtration, 0.62 g (46%) [μ-(dimethylamino)boryl-bis{dicarbonyl)η^5-cyclopentadienyl)manganese}(*Mn–Mn*)] **1a** was obtained at −40 °C as red crystals. NMR spectra in [D$_6$]benzene at 25 °C; ^1H NMR (500 MHz, TMS): $\delta = 2.85$ (s, 6H, NMe_2), 4.20 (s, 10H, $2C_5H_5$); ^{11}B NMR (160 MHz, $Et_2O \cdot BF_3$): $\delta = 103.0$; ^{13}C NMR (126 MHz, TMS): $\delta = 44.24$ (NMe_2), 84.85 (C_5H_5); IR (KBr): $\tilde{\nu} = 1960$ (m), 1917 (s), 1883 (s) cm^{-1} (C=O); correct elemental analysis.

1b: As described for **1a**, $K[(\eta^5\text{-}C_5H_4Me)Mn(SiMePh_2)(CO)_2]$ (2.00 g, 4.8 mmol) in benzene (20 mL) was treated with $B_2(NMe_2)_2Cl_2$ (0.36 g, 2.4 mmol) and 0.41 g (40%) red, crystalline **1b** was obtained. NMR spectra (same conditions as for **1a**): ^1H NMR: $\delta = 1.86$ (s, 6H, $2MeC_5H_4$), 2.93 (s, 6H, NMe_2), 3.99, 4.05, 4.10, 4.22 (4s

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0707-0825 $ 10.00+.25/0

br., 8H, $2MeC_5H_4$); ^{11}B NMR: $\delta = 102.8$; ^{13}C NMR: $\delta = 13.48$ (MeC_5H_4), 44.53 (NMe_2), 82.10, 84.18, 85.83, 87.56 (MeC_5H_4), 101.05 (MeC_5H_4); IR (KBr): $\tilde{\nu} = 1956$ (m), 1916 (s), 1883 (s) cm^{-1} (C=O); correct elemental analysis.

2: As described for **1a**, $K[(\eta^5\text{-}C_5H_4Me)Mn(SiMePh_2)(CO)_2]$ (2.44 g, 5.8 mmol) in benzene (20 mL) was treated with $B_2tBu_2Cl_2$ [11] (0.60 g, 2.9 mmol) and 0.42 g (32%) red, crystalline **2** was obtained. NMR spectra (same conditions as for **1a**); ^1H NMR: $\delta = 1.38$ (s, 9H, *t*Bu), 1.85 (s, 6H, $2MeC_5H_4$), 4.03, 4.10, 4.25, 4.30 (4s br., 8H, $2MeC_5H_4$); ^{11}B NMR: $\delta = 170.0$; ^{13}C NMR: $\delta = 13.31$ (MeC_5H_4), 31.97 (*t*Bu), 81.44, 83.01, 84.86, 89.98 (MeC_5H_4), 103.37 (MeC_5H_4); IR (KBr): $\tilde{\nu} = 1951$ (m), 1922 (s), 1878 (s) cm^{-1} (C=O); correct elemental analysis.

Corrigenda

The original title of the communication by G. Pampaloni et al., *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1188, was shortened by the editorial office; it should read: $[Zr_3Cp_2(O_2CNiPr_2)_6(\mu_3\text{-}O)(\mu_2\text{-}CCO)]$, the First Crystallographically Established Ketenylidene Complex Obtained by a Metal-Assisted Deoxygenation of Carbon Monoxide; A Model for CO Reductive Cleavage on Metal Surfaces.

In the review article "Organometallic Compounds for Nonlinear Optics—The Search for En-light-enment!" by N. J. Long (*Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 21–38) the β values for two compounds should be replaced by more recently published values. While the review was in press an article appeared in *SPIE*, Vol. 2143, pp. 14–19, in which the values quoted in the review from ref. [55] were corrected by the original authors. The β values of the complex ions $[(CN)_5Ru(\mu\text{-}CN)Ru(NH_3)_5]^-$ and $[(C_5H_5)Ru(PPh_3)(\mu\text{-}CN)Ru(NH_3)_5]^{3+}$ originally reported were found to be too large by a factor of six.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995

For the practical application of molecules in nonlinear optics the reader can turn to Zyss and Chemla: *Nonlinear Optical Properties of Molecules and Crystals*, to Prasad and Williams: *Introduction to Nonlinear Optical Effects in Molecules and Polymers*, or to the many review articles on the subject—but read Wagnière's book first. Similarly, the *Introduction to Nonlinear Laser Spectroscopy* by Levinson and Kano would be a good port of call for the molecular spectroscopist.

Linear and Nonlinear Optical Properties of Molecules is competitively priced and should find its way onto the bookshelf of everyone working in molecular nonlinear optics or molecular spectroscopy in condensed phases. It is perhaps not the first book to turn to for a student entering the field, but will be invaluable when the time comes to construct a systematic framework for rationalizing and understanding the optical effects observable in molecular systems. The appendices contain a wealth of useful formulas and relationships and will be of use even to experienced practitioners in the field.

Modern Medicinal Chemistry. (Ellis Horwood Series in Pharmaceutical Technology.) By *J. B. Taylor* and *P. D. Kennewell*. Ellis Horwood, New York, 1993. 290 pp., paperback $ 42.50.—ISBN 0-13-590399-8

Developments in medicinal chemistry have proceeded very rapidly in recent years as a result of the enormous advances in organic chemistry, biochemistry, molecular biology, physiology, and computer technology. It is doubtless for this reason that the authors of the book *Introductory Medicinal Chemistry*, which appeared 13 years ago, have now produced an updated version.

The present book contains five chapters: 1. Introduction; 2. The Pharmaceutical Phase; 3. The Pharmacokinetic Phase; 4. The Pharmacodynamic Phase; 5. Drug Discovery Processes. Chapter 1 contains a brief outline of the historical development of medicinal chemistry, illustrated by some examples of pharmacologically active agents. The authors discuss industrial and commercial aspects of the development of pharmaceutical products, and the relationship between the pharmaceutical industry and the legislators. Chapter 2 describes in detail the various forms in which pharmaceutical preparations are administered and the different types of applications. Chapter 3 then deals with the processes whereby active substances are absorbed and distributed, and their clearance, biotransformation, and metabolization, including the physicochemical and biochemical principles involved. The simple diagrams that are provided here as an aid to readers unfamiliar with anatomical terms are especially useful. Chapter 4 begins with an introduction to cell and membrane structure, then discusses receptor theories and kinetic and thermodynamic aspects of the interaction between ligands and receptors. Throughout the discussions much space is devoted to the relevant enzymes and their different types of inhibitors. Examples of particular enzyme inhibitors and the mechanisms whereby they function are briefly described. In Chapter 5 the authors describe the process of drug discovery, the basic principles of drug design, and some representative methods. Lastly they discuss the process of optimization starting from lead structures.

The book is mainly intended for undergraduate students of chemistry and pharmacology. On the whole it is well written and illustrated, and contains a good presentation of the general principles of pharmacology. However, there are some weaknesses. For example, not enough emphasis is given to the role of organic chemistry. The representation of chemical structures is not clear and consistent, and stereochemical details are often ignored or shown wrongly [e.g., compare the formulas of vitamin C (p. 13), tetramisol (p. 18), and L-dopa (p. 19)]. The definition of a non-competitive antagonist on page 126 is incorrect. The development of ligands for membrane receptors is scarcely mentioned. The description of the development of enzyme inhibitors is difficult to understand without previous specialist knowledge. Instead of the large number of examples given here, with the inevitable consequence that the principles involved are treated only superficially, it would have been better to discuss fewer examples in greater detail.

Model Reactions for Photosynthesis—Photoinduced Charge and Energy Transfer between Covalently Linked Porphyrin and Quinone Units

Harry Kurreck* and Martina Huber

Dedicated to Professor Fabian Gerson

Photosynthesis is one of the fascinating fields of current interdisciplinary research. It seems miraculous that nature, in the process of evolution, has managed to bring about the process of photosynthesis. The first step involves a charge separation at the reaction centers, which proceeds with 100% quantum yield from the photoexcited singlet state of the bacteriochlorophyll donor, despite the fact that the wasteful deactivation of the electron into the ground state should be highly favored. Biomimetic model compounds (that is, those which resemble the pigments nature has developed) have been constructed from porphyrins and quinones. These model systems have allowed the study of the factors contributing to the highly efficient charge separation. This report focuses on recent developments in the study of electron transfer in porphyrinoquinones. Some of the results of these investigations may not be not fully understood and are often the subject of controversial discussions.

Keywords: electron transfer · energy transfer · photosynthesis · porphyrins · quinones

1. Introduction

Life has been present on earth for over three billion years. In the process of evolution the development of photosynthesizing organisms (bacteria) represented an enormous step.[1, 2] A billion years later the development of plant photosynthesis with the two photosystems I and II provided the means by which a large part of the biosphere was created and maintained. Fundamental to photosynthesis is the reduction of CO_2 with the "weak", but abundant, reducing agent water, with concomitant formation of oxygen. However, even now, important new insights can be obtained by the study of photosynthetic bacteria that contain only one photosystem and therefore cannot split water, but require H_2S or inorganic acids as reducing agents.

From a chemical point of view life can be described as the ongoing interplay between animals and plants in terms of the Krebs and Calvin cycles, the most important cycles in the biosphere. The overall energy balance of these processes, which are driven by the literally life-giving sun, is endergonic.

The conversion of light energy into chemical energy, which has been optimized in the process of evolution, is a subject of interest not only in the area of basic research. The development of efficient, artificial photosynthetic systems for the conversion and storage of solar energy also requires a fundamental understanding of the processes that take place in natural photosynthesis. Such knowledge is also needed in herbicide research.[3]

A large number of coupled redox systems are involved in photosynthesis, in which the relationship between the various redox potentials plays a vital role. In order to understand the significance of sunlight to photosynthesis in this context, one must bear in mind that the ground and excited states of molecules can have drastically different redox potentials. In photosynthesis, the primary donor must first be photochemically promoted to an electronically excited state, which has appropriate electron-transfer (ET) characteristics. Porphyrins and their derivatives (chlorophyll, bacteriochlorophyll) with large π-electron systems are particularly well suited for this task, firstly because their molar extinction coefficient[*] is high, and secondly, because they absorb light over a wide spectral range. When one also takes into consideration other photosynthetically significant pigments (antenna systems), about 50% of the range of wavelengths of the radiation incident on the earth can be used photosynthetically. From a chemical point of view it is also important that the frequency range between UV and IR radiation is utilized, thus avoiding the possibility of photochemical bond cleavage by UV light on the one hand, and taking into account that IR radiation lacks the energy required to be photochemically significant.

In the photosynthetic reaction centers (RCs) the choice and arrangement of the participating pigments ensures a "down-

hill" ET. After excitation (by light) of the donor (the "special pair"—a dimer of bacteriochlorophyll (BChl) molecules, see Fig. 1), an electron is transferred stepwise via the intermediate bacteriopheophytin acceptor (BPh) to the primary and secondary quinone acceptors. In the first charge-separation step the electron is rapidly (in about 3 ps) transferred a large distance (17 Å) from the singlet photoexcited state of the special pair to the pheophytin. The role of the additional BChl molecule (the "extra-bacteriochlorophyll") in this transfer (that is, whether there is a short-lived intermediate state ($BChl_2^{+}BChl^{\bullet -}$), or whether the BChl contributes as a superexchange mediator[4]) is currently the subject of controversial discussions.[5] The results of a recent study favor the former interpretation, namely that the extra-bacteriochlorophyll in fact serves as an intermediate in the ET, that is, as a transient radical anion.[6] Investigation of the RCs of *Rhodobacter sphaeroides* with polarized light using sub-picosecond absorption spectroscopy revealed the existence of the extra-bacteriochlorophyll anion with a half-life of 0.9 ps. This species exhibited a marked dichroism. The stepwise ET via extra-bacteriochlorophyll appears therefore to be confirmed.

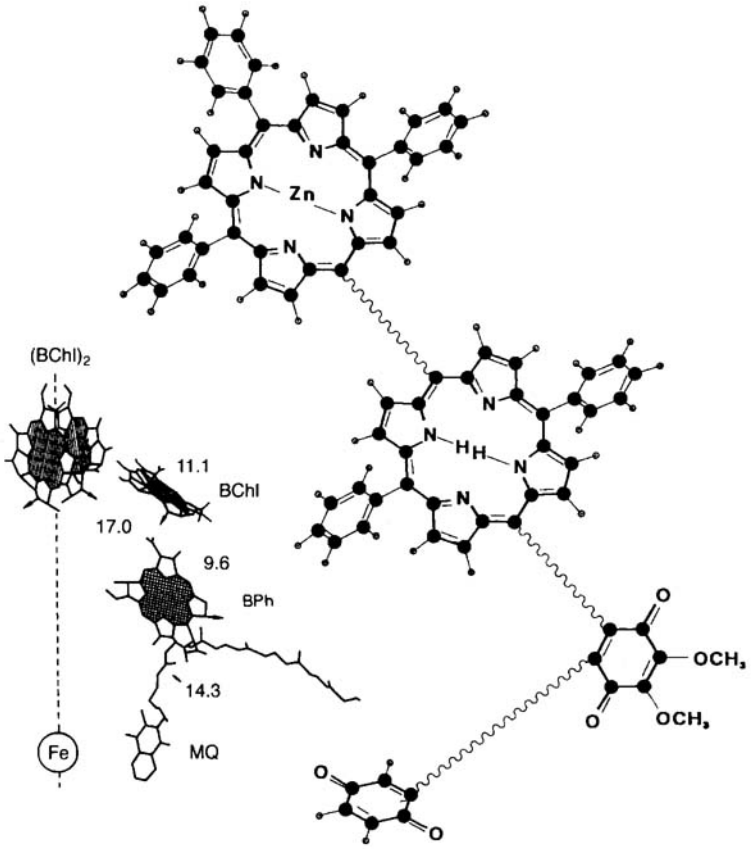

Fig. 1. Idealized model tetrad, consisting of a Zn-containing porphyrin and a free-base porphyrin, a ubiquinone(0) derivative, and a quinone. The redox potentials of the individual redox-active components provide a "downhill" cascade for the ET. On the left the arrangement of the pigments in a natural reaction center (only the photosynthetically active L or A branch of *Rhodopseudomonas viridis*) is depicted for comparison (cf. [8]); $(BChl)_2$: bacteriochlorophyll dimer ("special pair"); BChl: extra-bacteriochlorophyll; BPh: bacteriopheophytin; MQ: menaquinone. The numbers give the center-to-center distance of the pigments in Å.

Quinones appear to be predestined to be electron acceptors in nature for a variety of reasons: a) they possess suitable redox potentials, b) they can be converted stepwise into stable reduction products (hydroquinones) via the semiquinones, c) they can form hydrogen bonds, and undergo protonation/deprotonation reactions with ease, and finally, d) they are relatively small mobile molecules that can shuttle redox equivalents to the quinone pool.

Current research into the primary reactions of photosynthesis can be divided into two areas: on the one hand, the cultivation, isolation and, where possible, crystallization of natural plant or bacterial photosynthetic systems (for example, the reaction centers), and on the other, the development (that is, synthesis) of biomimetic model compounds. Model compounds have the advantage that specific properties of the complex ET reactions can be tuned by designing and preparing suitable organic molecules consisting of donor(s), bridge(s), and accep-

Harry Kurreck, born in 1932 in Halle/Saale, obtained his doctorate at the Freie Universität (FU) Berlin. He completed his habilitation in 1970 on the subject of triplet ground states and excited states in the cyclopentadienyl system. Since 1970 he has been Professor at the Institut für Organische Chemie der FU Berlin. His priority research topic is EPR/ENDOR studies on paramagnetic organic and bioorganic systems. In recent years he has concentrated in particular on the synthesis of model compounds for photosynthesis with the aim of making a contribution to the understanding of the primary step in photosynthesis by applying stationary and time-resolved optical spectroscopy and magnetic resonance methods.

H. Kurreck

M. Huber

Martina Huber, born in 1961 in Heidelberg, studied chemistry in Berlin, completing her doctorate there in 1989 with a thesis on electron transfer in biomimetic model compounds. During the two years of her subsequent postdoctorate period with Professor G. Feher (University of California San Diego, USA) she studied the electronic structure of primary electron donors of photosynthesizing bacteria. In addition she was involved in the X-ray structure analysis of modified reaction centers. Since 1991 she has worked on her habilitation at the FU Berlin on a thesis on magnetic resonance spectroscopy of single-crystal reaction centers of photosynthesizing bacteria.

tor(s). The synthesis of such model compounds should stimulate new insights into the ET mechanism, the final goal being the synthesis of compounds in which a rapid and highly efficient forward reaction (charge separation) can take place, which, combined with a slow back reaction, results in a long-lived, charge-separated state.

Our report focuses on model compounds that closely resemble the natural pigments of the reaction centers. Covalently linked porphyrin dimers and oligomers model the special pair of the reaction center and the light-collecting function of the antennae. Porphyrins and quinones have likewise proved to be particularly attractive in the study of ET phenomena. Figure 1 compares an idealized model compound, a "tetrad",[10] with the arrangement of pigments in a bacterial reaction center, as deduced from X-ray crystal structure analysis.[7-9]

Static and time-resolved optical and magnetic resonance spectroscopic methods have been applied to the identification and characterization of these systems. For the study of ET processes, time-resolved spectroscopy is indispensable. Since there are already several pertinent reviews on this subject,[11-14] we will focus on the current problems and trends in this area of research, using selected examples. For a better understanding of the ET process, a general outline of the ET theory will be presented in a phenomenological form, with particular emphasis on the Marcus theory,[15-22] the significance of which was underlined by the award of the Nobel Prize to R. A. Marcus in 1992.[23]

2. Theory of Electron Transfer

The following is a short synopsis of the theoretical basis of the rate of ET processes, insofar as it is necessary for the understanding of the experimental observations (for the presentation of fundamental theory and advanced methods of approximation, see refs. [19, 24-28]). Firstly, the case of diabatic[29] ET, characterized by a weak electronic coupling between donor and acceptor, will be discussed to introduce the relevant parameters, and secondly, the limits of the diabatic approximation and the formulation of adiabatic ET will be considered.

For diabatic ET, Fermi's golden rule applies, which describes the probability of radiationless transitions [Eq. (a)].[30] V_{DA} is

$$k_{ET} = \frac{2\pi}{\hbar} V_{DA}^2 F_{FC} \qquad (a)$$

the electronic matrix element, F_{FC} the Franck–Condon factor (more precisely, the squared overlap integral of the vibrational wave functions weighted by the Boltzmann distribution).

Franck–Condon Factor F_{FC}

Marcus provided an expression on the basis of a classical approximation, which according to modern quantum mechanical interpretation, can be identified with one part of the Franck–Condon term.[15-18] In the Marcus approximation the electronic states of the system consisting of donor and acceptor are represented by parabolic functions both before (D–A) and after (D^+–A^-) the ET (Fig. 2, D–A corresponds to ^{S*}P-S-Q, D^+–A^- to $P^{\bullet+}$-S-$Q^{\bullet-}$).[31] The position of the two parabolas relative to each other is completely described by two parameters: the standard free energy of reaction ΔG^0,[*] and the reorganization energy λ. Since allowed transitions between the electronic states can only occur where the parabolas cross, the free energy of activation $\Delta G^{\ddagger}$ can be calculated from ΔG^0 and λ (see Fig. 2). From this, the expression (b) for ET rates, given by

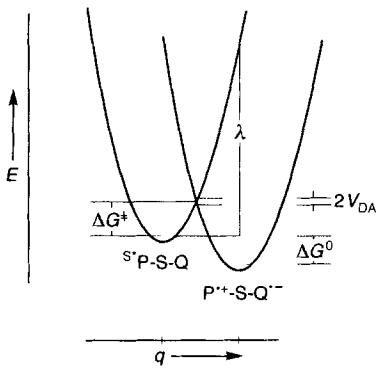

Fig. 2. Representation of the energy hypersurfaces for ET reactions in the context of the Marcus approximation. The potential energy of ^{S*}P-S-Q (porphyrin P in the singlet excited state, quinone Q in the ground state) and $P^{\bullet+}$-S-$Q^{\bullet-}$ (state after ET from P to Q) is shown as a function of the nuclear coordinate q. ΔG^0 is the standard free energy of reaction, $\Delta G^{\ddagger}$ is the free energy of activation, which can be calculated from ΔG^0 and λ (the reorganization energy). V_{DA}: electronic matrix element; V_{DA} is related to the splitting of the energy hypersurfaces in the transition region. For large values of V_{DA} the energy levels are split in such a way that the limiting case of adiabatic ET can be reached (modified from J. Schlüpmann, *Dissertation*, Freie Universität Berlin, **1992**).

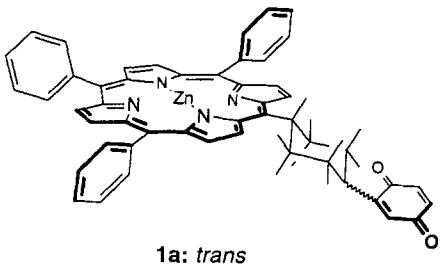
$$k_{ET} = \kappa\, e^{-\frac{(\Delta G^0 + \lambda)^2}{4\lambda k_B T}} \qquad (b)$$

Marcus, is obtained. k_B is the Boltzmann constant, T the absolute temperature and κ a proportionality constant. The exponential dependence of the rate k_{ET} on $\Delta G^{\ddagger}$ corresponds to the approach of Eyring; the interpretation of κ will be considered in greater detail below [see Eq. (c)].

For exergonic reactions, that is, those where $\Delta G^0 < 0$, the ET rate increases with increasing exergonicity, reaches a maximum at $-\Delta G^0 = \lambda$, and decreases again for very negative ΔG^0 ("energy gap law"; this is the inverted region). It took approximately twenty years to verify this prediction of Marcus by experiment[32] (see also ref. [22]). Subsequently, the inverted region was also detected in ET studies of porphyrin–quinone model compounds.[33, 34]

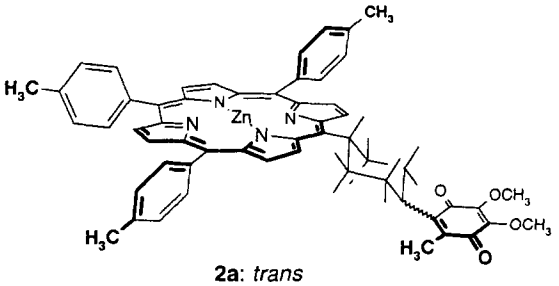
Interestingly, the quantum mechanical derivation of the rates of ET reactions leads to an expression [Eq. (c)] that is very similar to that derived from Marcus Theory,[35] (see, for example, ref. [36]). Thus, κ in Equation (b) can be interpreted as a combination of the prefactor of the Franck–Condon factor [penultimate term in (c)] and V_{DA}, the electronic matrix element.

$$k_{ET} = \frac{2\pi}{\hbar} V_{DA}^2 \frac{1}{\sqrt{4\pi\lambda k_B T}} e^{-\frac{(\Delta G^0 + \lambda)^2}{4\lambda k_B T}} \qquad (c)$$



[*] The term Gibbs energy has been suggested for G.

Electronic Matrix Element V_{DA}



The electronic matrix element describes the probability of electronic transition between the energy hypersurfaces of reactant and product (Fig. 2). A commonly used approximation is Equation (d),[37, 38] where S_{DA} is the overlap integral of the elec-

$$V_{DA} = KS_{DA} \quad \text{(d)}$$

tronic wave functions (in general, molecular orbitals) and K is a proportionality factor whose magnitude depends on the system investigated. To a first approximation S_{DA} is calculated as the overlap integral between the molecular orbital occupied by the electron to be transferred and the molecular orbital of the acceptor into which it is transferred. Such an approach was used for a porphyrin–quinone model compound (**1a**).[39, 40] The exponential decay of the wave function with increasing internuclear distance leads to an exponential decrease in rate with increasing distance between D and A. V_{DA}, however, also depends on the relative orientation of D and A.[39, 41] Compounds like **1a, b** with a cyclohexanediyl bridge and diffferent acceptors, as in **2a, b**, were studied thoroughly by spectroscopic methods (see Section 4).

1a: *trans*
1b: *cis*

2a: *trans*
2b: *cis*

The "medium" between D and A can similarly contribute to the magnitude of V_{DA}. Of particular significance for model compounds are the bridge and possibly also solvent molecules. In bacterial reaction centers, for example, aromatic amino acid residues of the protein and the monomeric bacteriochlorophyll (BChl, Fig. 1) that lies between the primary electron donor $(BChl)_2$ and BPh, have been discussed as possible mediators in the ET process (cf. Section 1). One possible way in which the medium can participate in the ET process is provided by the superexchange mechanism. According to this mechanism, the MOs of the medium participate in the ET, thus facilitating it, although the state in which the electron (or the hole) is situated on the bridge is not considered an intermediate state (in the sense of a kinetic intermediate). Quantum mechanically, this participation can be described by an equation of the form (e),

$$V_{DA} = V^0_{DA} + (V_{DS}V_{SA})/\Delta E_{DS} \quad \text{(e)}$$

which can be derived from perturbation theory.[28] In this equation V^0_{DA} is the electronic matrix element corresponding to the direct interaction of D and A and V_{DS} and V_{SA} are the matrix elements of the interaction of the donor (D) or the acceptor (A) with the bridge orbitals (S). ΔE_{DS} is the difference in energy between the orbitals of D and S which take part in the ET. The influence of the bridge orbitals on V_{DA} thus depends not only on their electronic interaction (that is, in particular on whether their orientation to the relevant orbitals on D and A is favorable) but also whether they lie energetically close to the orbital on D. Also, the possibility of hole transfer must be considered as well as electron transfer. In other words both the LUMO and the HOMO of the bridge must be taken into account. Several quantum mechanical methods have been employed for the calculation of V_{DA} in this mechanism.[42, 43] In Section 4.1 an example of a possible superexchange mechanism in a model compound will be discussed.[44]

Diabatic and Adiabatic Electron Transfer

The use of Equation (a) assumes that the electronic matrix element is small (weak electronic interaction, corresponding, for example, to a large distance between D and A, a condition often fulfilled in biologically relevant ET processes) or that the probability of electronic transition is small compared to the rate of motion of the nuclei. This condition is not fulfilled in a couple of cases. 1) For strong electronic interactions the splitting of the energy levels is so large that each time the system reaches the transition region, ET takes place. Consequently, the reaction rate should be independent of V_{DA} and Equation (a) cannot be valid. 2) If the motion along a reaction coordinate (for example, a nuclear motion that is required for the ET, or solvent relaxation) is slow in comparison with the motion of the electron, it can control the rate of the whole process. For more detailed discussion of this area see, for example ref. [21] and particularly ref. [45].

To classify ET reactions, an adiabaticity parameter g has been defined [Equation (f)],[46, 47] where ω_C is the vibrational frequency characteristic of the slowest nuclear motion.[48] For $g \ll 1$, the reaction is considered to be diabatic, and when $g \gg 1$, the reaction is adiabatic. For adiabatic ET the rate constant is given by Equation (g) as quoted by Heitele.[21] The only new

$$g = 2\pi V^2_{DA}/\omega_C \hbar \lambda \quad \text{(f)}$$

$$k_{ET} = \frac{1}{\tau_L}\sqrt{\frac{\lambda}{16\pi k_B T}}\, e^{-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda k_B T}} \quad \text{(g)}$$

parameter introduced here is τ_L, which is given by the equation $\tau_L = 1/\omega_C$.[48] As expected, the rate is independent of V_{DA}. Recently, however, Bixon and Jortner have discussed why this approximation may not hold for reactions in the inverted region and for $\Delta G^\ddagger = 0$.[49]

An example in which a transition from diabatic to adiabatic has been postulated is the reduction in rate of ET reactions of porphyrin–quinone model compounds in alcoholic solution, upon lowering the temperature (see Section 4.3).[50, 51] In this case the occurrence of the porphyrin triplet state and the observation of triplet products from the ET reaction at low temperatures has been interpreted as being due to a reduction in the ET rate from the singlet state, the dominant route of the reaction at room temperature. A slowing down of the reorientation of solvent molecules at or near the glass point of the alcohol, causing a transition from diabatic ET to adiabatic ET, has been postulated as the mechanism of the rate reduction. The relevant rate constant for this process, ω_C in Equation (f), is the longitudinal dielectric relaxation time τ_L of the solvent at a given temperature. As has been thoroughly discussed in [21], this relaxation time can be correlated with the Debye relaxation time of the solvent (τ_D), a parameter which is more easily determined experimentally (see, however, ref. [45]).

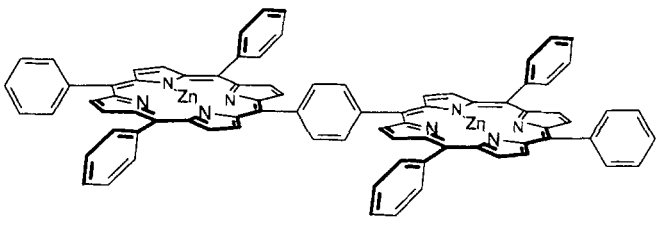
To illustrate the theoretically, and also practically, important interplay of the various parameters, their effect on k_{ET} will be discussed below.

Temperature Dependence of Rate of ET

The exponential term in Equations (b), (c), and (g) indicates that the temperature dependence of the rates should follow, to a first approximation, the Arrhenius equation. However, discrepancies can arise through, for example, a temperature dependence of the activation entropy ($\Delta S^{\neq}$). A special situation occurs for the case where $-\Delta G^0 = \lambda$, in which case $\Delta G^{\neq} = 0$ (Fig. 2), and the rate of ET is, according to the exponential term, independent of temperature. The proportionality of k_{ET} to $1/\sqrt{T}$, derived from the preexponential factor in Equation (c), would lead to a slight rate increase at lower temperatures.[52] For ET reactions in which $\Delta G^{\neq} \neq 0$, the $1/\sqrt{T}$ rate dependence should be less important than the exponential temperature dependence.

Besides these temperature dependencies, which are explicitly expressed in the equations, other implicit factors must be considered, in which the temperature influences one or other of the factors present in Equations (c) and (g). For example, a temperature-related change in the standard free enthalpy of reaction ΔG^0 can be caused by a change in the *static* dielectric constant of the solvent if the solvation of the charge-separated state changes as the temperature is varied. Temperature-dependent conformational changes in the D–A compound can also modulate V_{DA} and thereby k_{ET}. Naturally, the transition from diabatic to adiabatic ET described above is another consequence of change in temperature, which, in this case, has such a drastic influence that the ET rate has to be determined by a different set of molecular and/or local properties in different temperature ranges (cf. (c) and (g)). Further effects of temperature on solvent relaxation are discussed in refs. [45] and [53]. The possibilities mentioned here are expected to have widely varying effects depending on the model compound and the experimental conditions. A quantitative analysis of the temperature dependence, therefore, requires a consideration of all the possible factors involved.

Dependence of the Rate of ET on Distance

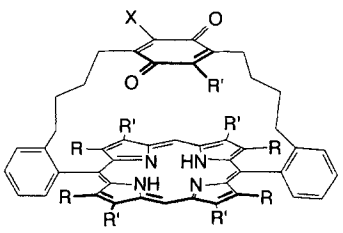


By far the largest influence of the donor–acceptor distance on k_{ET} comes from the exponential distance dependence of V_{DA}. Additionally, the donor–acceptor distance affects λ and ΔG^0.[54] A change in the distance dependence in this context is also expected from the superexchange mechanism, as discussed before.

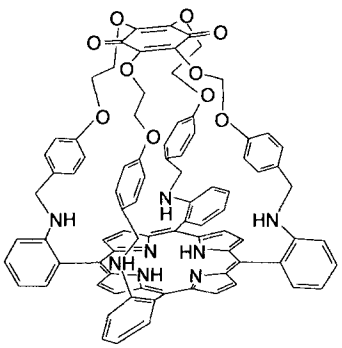
Influence of the Solvent

The different means by which the solvent can influence k_{ET} have already been reported in detail.[21, 45, 53] One example that has already been treated here is the influence of the dielectric relaxation time (τ_L) on k_{ET}. The static dielectric constant of the solvent influences ΔG^0, particularly with respect to the solvation of the charge separated state $D^+ - A^-$. Finally, the high frequency dielectric constant (expressed by the refractive index n) affects the reorganization energy (more exactly, the external reorganization energy λ_0).[23]

3. Model Compounds, Syntheses, and Structures



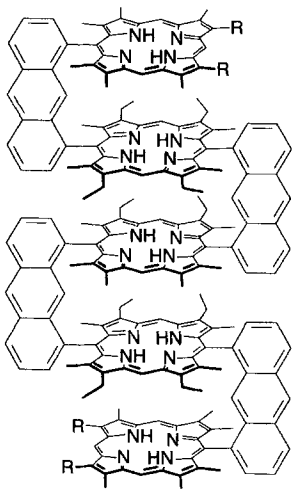
The design and synthesis of the porphyrin, and in particular the porphyrin–quinone system, is one of the more difficult tasks of synthetic organic chemistry. The preparation of model compounds of the type porphyrin–bridge–quinone (P-S-Q), can be carried out by the building block principle—for example, the retrosynthetic strategies P-S-Q⇒S-Q⇒Q or P-S-Q⇒P-S⇒S. Of these two possibilities, the first has been preferred by most workers. One can distinguish between targeted syntheses, where the alkylated porphyrins are generally constructed from dipyrromethanes and *a,c*-biladiene derivatives,[55, 56] and "one-pot" reactions in which, for symmetrically substituted, *meso*-arylated porphyrins, the appropriate aldehyde is treated with pyrrole; for the synthesis of unsymmetrical porphyrin derivatives (such as the "hybrid porphyrins"[57]) different aldehydes are treated with pyrrole. The very nature of the latter variant leads to a multitude of products that can be very difficult to separate. This results in yields as low as a few percent. Porphyrin dimers such as **3** can be synthesized from bisaldehydes; if the



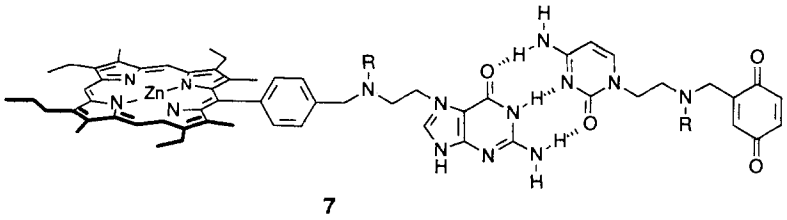
3

aldehyde contains the quinone component, or its (protected) precursor, P-S-Qs (or their precursors) can be formed.[58, 59] Particularly troublesome are those syntheses in which the molecule needs to display the characteristics that are especially desired for an investigation of the ET process—a rigid structure with defined geometry (in particular distance between, and rela-

tive orientation of donor and acceptor). Such properties are almost always achieved by the introduction of severe steric hindrance. Good examples of this type are the porphyrin–cyclophanes[60–63] such as **4** (with various substituents and substituent patterns)[64, 65] and **5**,[66, 67] in which the structural parameters can be varied in a specific manner by the use of different bridges. Recently reports have appeared on the synthesis of vertically stacked porphyrin–quinone–quinone and porphyrin–porphyrin–quinone cyclophanes. Such rigid molecules are suitable for the study of sequential electron transfers.[68]



4



5

To simulate the stepwise ET pertinent to natural photosynthesis, model systems have been constructed that contain three or more covalently linked redox-active components.[11–14, 69] Vertically stacked porphyrins—structurally related to the porphyrinophanes mentioned above—such as **6** (R = $(CH_2)_5CH_3$) have also been synthesized, in which the porphyrin components are bonded in a *syn-peri* configuration by anthracene bridges.[70]

6

New, promising routes to the generation of well-defined model structures have recently been tested. Such methods had already been proposed, in particular by Rebek et al.,[71, 72] in connection with enantioselective complexation and for the modeling of synthetic receptors, and are based on the principle of molecular recognition. In this concept, covalent bond formation is replaced by noncovalent interactions such as, for example, H bonding.[73–75] Thus, an example of this approach would be first of all to link nucleobases, such as guanine and cytosine, covalently with porphyrins. Self-organization, as a consequence of Watson–Crick base pairing, allows the formation of defined porphyrin dimers or P-S-Qs. This principle was employed to prepare **7**, which contains stable hydrogen bonds analogous to the binding between complementary nucleic acid strands as in DNA and RNA. A related approach is the preparation of porphyrin dimers by self-organization of porphyrins with oppositely charged, peripheral substituents. These dimers are held together by electrostatic forces.[76, 77] Similarly, the use of crown ethers linked to quinone acceptors aims at the defined modification of model compounds without the use of covalent bonds.[78] The acceptor strength can be varied by complexation of the crown with different counterions. To investigate the influence of the extra-bacteriochlorophyll (cf. Fig. 1) on the ET between the special pair and the bacteriopheophytin, a rotaxane was synthesized that contained a crown-ether-like phenanthroline macrocycle sandwiched between two porphyrin units, each of which contained a different metal.[79]

7

Despite the impressive successes of preparative chemistry in synthesizing model compounds comprising multiple donors and acceptors, there still remains the challenging task of modifying the (seemingly more easily synthesized) diads in a specific way. The spectroscopic results obtained for diads can generally be more easily and clearly interpreted than those of triads, tetrads etc. Diad systems are, therefore, particularly well suited for the extension of our knowledge of the mechanism of the ET reactions.

4. Spectroscopic Investigations

An electron can be excited from the HOMO of the (porphyrin) donor into an antibonding MO by absorption of light of the appropriate frequency. The fate of the excited electron (until its eventual return to the ground state) is determined by the competition between internal conversion (IC), fluorescence, and spin–orbit-induced intersystem crossing (ISC). Furthermore, the charge- and energy-transfer processes of the specific chromophore and the properties of the quinone acceptor also have a role to play (cf. Fig. 3).[80] The relative contribution of each individual mode of decay is determined by the relative rates of each process. Spectroscopic methods enable the participating donors and acceptors to be studied in their ground and excited states, along with their spin states, spin dynamics, and the lifetimes of the transients. Extensively treated in the literature are optical methods such as fluorescence spectroscopy, transient absorption spectroscopy, resonance Raman spectroscopy, and magnetic resonance spectroscopy such as EPR spectroscopy and its extension to electron nuclear double resonance (ENDOR) and electron nuclear nuclear triple resonance (TRIPLE) spectroscopy. Pulsed EPR methods such as, for example, Fourier-transform (FT) and electron spin echo envelope modulation (ESEEM) are of increasing interest.[81] A review of the successfully applied new methods has appeared.[82]

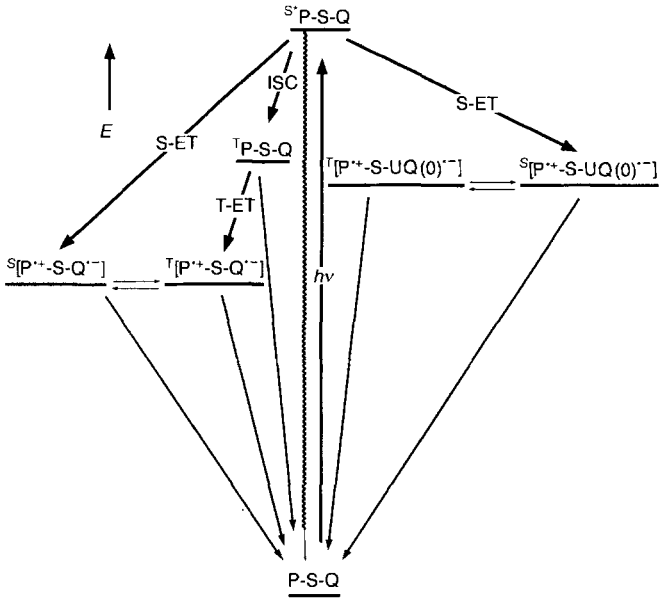


Fig. 3. Energy level diagram and reaction scheme for the photoexcitation of the *cyclohexanediyne-linked porphyrinquinones* **1** (P-S-Q) and **2** (P-S-UQ(0)) (that is, with a ubiquinone derivative as acceptor—the zero indicates that the oligoisoprenyl side chain is completely missing). The following symbols are used: ^{S*}P-S-Q and ^{S*}P-S-UQ(0) indicate the first singlet excited states of the porphyrin donor, ^{T}P-S-Q the triplet state of the porphyrin donor; singlet and triplet states of the charge-separated diradicals are labeled analogously. S-ET, T-ET symbolize singlet or triplet electron transfer, ISC selective spin–orbit intersystem crossing (the triplet ET path on the right hand side is not drawn). The wavy line represents the fluorescence decay of the singlet excited state. For estimates of the relative energy states, see [50, 51, 123]. P-S-UQ(0) and ^{S*}P-S-UQ(0) are not shown but assumed to be isoenergetic with the corresponding P-S-Q states.

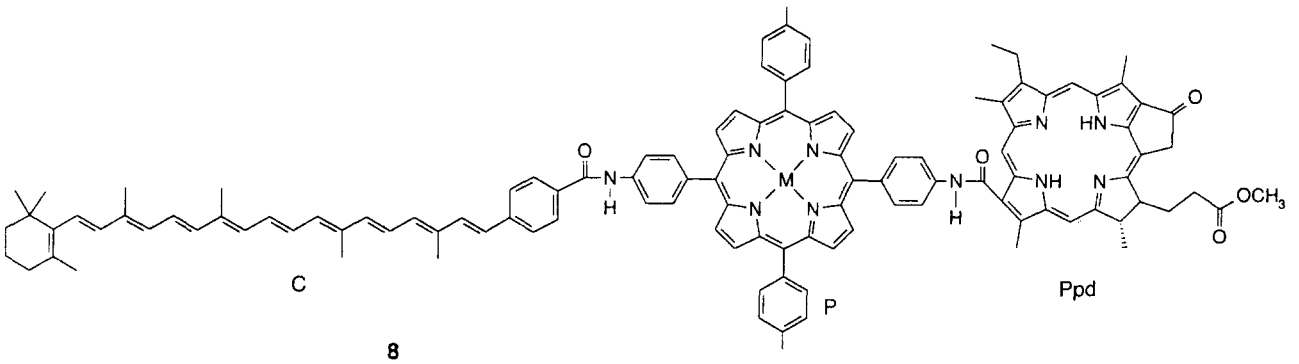
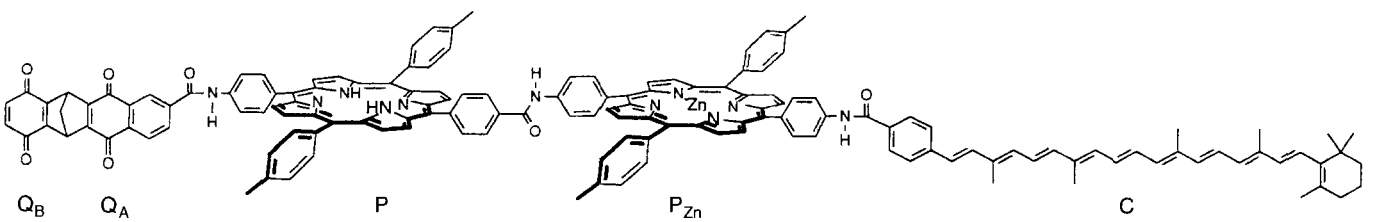


4.1 Optical Spectroscopy

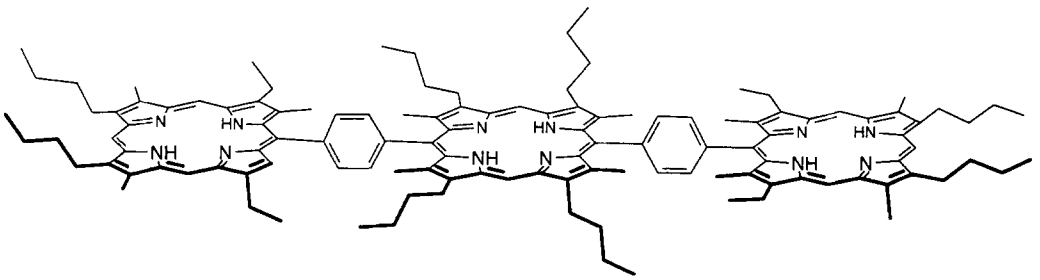
As biologically active and extremely photoactive macrocycles with extended π-electron systems, the porphyrins display intense absorption bands in the visible and UV spectrum. For example, the Soret band has a molar extinction of about 100000. The four-orbital model, developed by Gouterman, has been extremely useful in the understanding of the optical properties of porphyrins .[83] Porphyrins and metalloporphyrins have relatively long-lived excited states, which makes them ideal precursors for subsequent reactions—for example ET. Additionally, porphyrins display a very effective ISC, which renders them capable of reactions arising from the triplet state.[84] It has been mentioned that the pigments relevant to photosynthesis are the partially hydrogenated porphyrins. These pigments, the chlorins and bacteriochlorins, are green rather than red, which is typical of the porphyrins. The origin of this difference in color is a destabilization of the π-electrons in the chlorins that raises the energy of the HOMO, but leaves the energy of one of the LUMOs practically unaltered.[85–87]



The potential of optical methods will now be demonstrated for the example of covalently linked porphyrins and later for porphyrins covalently bound to quinones (P-S-Qs).[88] Investigations into the possible participation of the bridge in the ET processes, for example within the framework of the superexchange mechanism (cf. Sections 1 and 2) will be discussed. This question is of interest in connection with the primary ET step in bacterial reaction centers, which involves the extra-bacteriochlorophyll (see Section 2). A possible function of the extra-bacteriochlorophyll in the other (inactive) pigment branch in the photosynthetic reaction centers is triplet energy transfer. The triad **8** has been chosen as representative example. Finally, the multistep energy and electron transfer of the complex pentad **9**, built up from a carotenoid (C), two porphyrins (P and P_{Zn}), and two quinones (Q_A and Q_B), will be described.

Covalently Linked Porphyrins

In photosynthetic organisms, light energy is first absorbed by a network of pigments—amongst others, (bacterio)chlorophylls in the light-collecting or antenna complexes. The light energy is then passed on further in rapid and vectorial energy transfer processes to the reaction center, where it initiates the



8

9

electron-transfer processes discussed in Section 2. In order to study the energy-transfer processes, porphyrins have been covalently linked in various ways, for instance as in the synthesis of complex systems such as **6**.[70] Sessler et al. have recently performed optical investigations on the porphyrin trimer **10**.[89] The absorption spectrum of **10** reveals that the absorption

10

bands in the visible range are broader than those of the corresponding monomer. This points to an excitonic interaction between the porphyrin units. The fluorescence quantum yield and lifetime of the excited singlet state are clearly reduced relative to those of the monomer. The radiationless quenching process responsible for this reduction cannot be explained by an increased ISC rate to the triplet state (which would also result in fluorescence quenching, see Fig. 3); rather it is attributed to an increase in the rate of IC. The lifetime of the triplet state is also substantially reduced. Obviously, the excitonic coupling favors the radiationless deactivation processes that couple the ground and excited states. In addition, through the coupling of **10** with quinone acceptors, the interplay of energy transfer within the trimer and electron transfer to the quinone could be studied.[89] The photophysical properties of sandwich-type porphyrin dimers, coupled through a lanthanide ion, were studied by very fast (on the femtosecond time scale) spectroscopy.[90] In these systems rapid radiationless deactivation processes were also observed. Of further interest is the observed wavelength-dependent variation in kinetics, which can be related to vibrational relaxation in the ps range.

Porphyrinquinones

When photoexcited into the S_1 state, porphyrin becomes a strong reducing agent, which has, for example, the ability to reduce quinones (compounds **1** and **2**) to semiquinones (cf. the energy level diagram in Figure 3). The effect of this ET can be observed with the naked eye, since solutions of these compounds do not visibly fluoresce at room temperature in contrast to solutions of tetraphenylporphyrinatozinc (ZnTPP) or the hydroquinoid forms of **1** and **2**. The fluorescence quenching results from intramolecular singlet-ET from the porphyrin to the quinone, which causes fast decay of the S_1 excited state of the former. This effectively reduces the lifetime of S_1.[40, 91]

The rate constant for the charge separation can be determined by picosecond fluorescence spectroscopy. The fluorescence decay can be measured by time-resolved single-photon counting[92] or with a synchroscan-streak-camera.[40, 93] In the case of **1**, the fluorescence decays monoexponentially over several lifetimes. The fluorescence decay curves for the metal-free P-S-Qs **1a** and **2a**, as well as those for their hydroquinoid derivatives, are shown in Figure 4. The difference between compounds with a hydroquinoid and a quinoid fragment can be clearly seen. Additionally, the more rapid decay of the excited state of **1a** relative to that of **2a** is recognizable. This difference is due to the smaller driving force of **2a** (that is, the less negative ΔG^0; ΔG^0 is related to the free energy of activation $\Delta G^{\neq}$, see Section 2)—cf. Figure 3. The more strongly negative reduction potential (by about 200–300 mV; measured by cyclic voltammetry[94]) makes the substituted quinones in **2a,b** poorer oxidants than the unsubstituted analogs **1a,b**. The incorporation of zinc into the porphyrin derivatives causes a drastic reduction in the lifetime of the singlet state of the porphyrin, which is partially brought about by an increase in the ET rate. This acceleration is to be expected, since the ET reaction is more strongly exergonic than for metal-free P-S-Q, and the reaction should lie in the "normal region", according to the nomenclature of Marcus.[40]

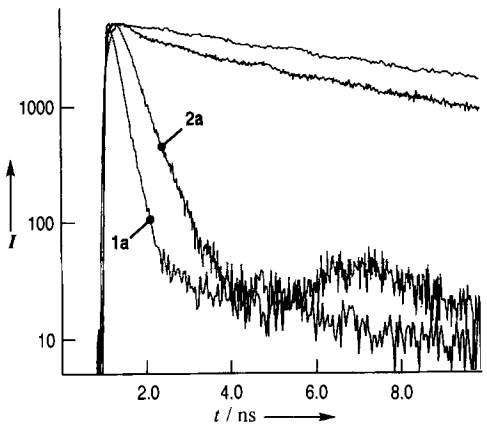


Fig. 4. Logarithmic representation of the fluorescence decay curve for the Zn-free P-S-Qs **1a** and **2a** (lower curves) and their hydroquinoid forms in CH_2Cl_2 at 295 K (upper trace: hydroquinone of **1a**). The more rapid fluorescence decay of **1a** is obvious. Simulations yield lifetimes for the excited states of 225 ps for **1a** and 360 ps for **2a** (ordinate: fluorescence intensity I in arbitrary units; abscissa: time t after the laser pulse) [91].

In a systematic study of a P-S-Q diad system, which strikingly illustrates the value of model studies, the dependence of the ET rates on the exergonicity ΔG^0 of charge separation and recombination was studied. This was achieved by variation of the solvent and the substituents (and thus the redox potential) of the quinone in such a way as to probe the normal and the inverted region of the Marcus curve (see Section 2).[95] According to this study, the rates of ET for charge separation and for charge recombination behave very differently with respect to variation in temperature or solvent polarity. In the systems investigated, the forward reaction should take place in the normal region of

the Marcus curve, whereas the back reaction (charge recombination) should lie in the inverted region. As expected, the value of k_{ET} for charge recombination becomes smaller with increasing exergonicity. Nevertheless, the temperature dependence of the rates in this range does not correspond to that predicted by Marcus theory. The temperature dependence of recombination in the range investigated (295 K to 193 K) is, in fact, distinctly less pronounced than that for charge separation, which lies in the normal region. It was thus suggested that charge separation and charge recombination have different mechanisms. The previously mentioned results of Bixon and Jortner (Section 2) are possibly of interest in this context.[49]

Staab et al. have studied the fluorescence behavior of porphyrinquinone–cyclophanes of the type **4**. They described the dependence of k_{ET} on the reduction potential of the acceptor components—varied by changes in substitution—and the solvent polarity.[96] If the quinone component contains methyl substituents, no fluorescence quenching is observed in apolar solvents, and therefore no ET. Obviously, the ET to the high-energy, charge-separated state is too slow relative to the lifetime of the excited singlet state of the porphyrin chromophore under normal fluorescence decay conditions, and thus is not competitive. On the other hand, in polar solvents, the charge-separated state is stabilized, and ET competes with normal fluorescence. Quinones with chloro substituents are stronger electron acceptors, and in these model compounds the increased driving force ΔG^0 for the ET is reflected by an effective fluorescence quenching.

The investigations of ET reactions from a donor to an acceptor connected to it by a bridge stimulate the question whether the unpaired electron is transferred through space or through the bonds of the bridge. In particular, the contribution of the molecules lying between the donor and the acceptor can be of great significance in the case of weak electronic coupling. The π-electron systems of the donor and acceptor need not be conjugated through the bridge; even aliphatic bridges can, for example, contribute to k_{ET} by the superexchange mechanism (see Section 2). Wasielewski et al. have studied the influence of the energy of the bridge orbitals. They compared the compounds **11a** and **12a** (unsubstituted bridges) with **11b** and **12b** (electron-donating methoxy substituents on the bridges) by means of absorption, fluorescence, and transients absorption spectroscopy.[44] Relevant configurations for a possible contribution of the bridge in forward and back ET reactions can be represented as in Scheme 1.

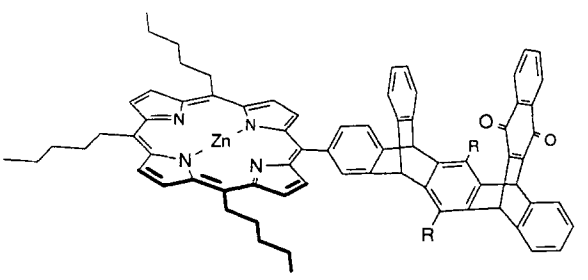
Forward reaction:

$$P\text{-}S\text{-}Q \longrightarrow P^{\bullet+}\text{-}S^{\bullet-}\text{-}Q \longrightarrow P^{\bullet+}\text{-}S\text{-}Q^{\bullet-}$$

Reverse reaction:

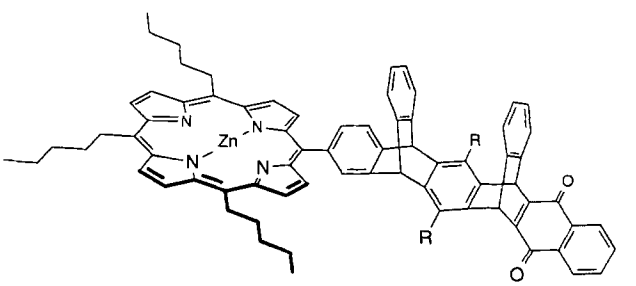
$$P^{\bullet+}\text{-}S\text{-}Q^{\bullet-} \longrightarrow P^{\bullet+}\text{-}S^{\bullet-}\text{-}Q \longrightarrow P\text{-}S\text{-}Q$$

or



$$P^{\bullet+}\text{-}S\text{-}Q^{\bullet-} \longrightarrow P\text{-}S^{\bullet-}\text{-}Q^{\bullet-} \longrightarrow P\text{-}S\text{-}Q$$

Scheme 1.



In the forward reaction the superexchange can contribute by means of the participation of the LUMOs of the bridge. Since the reduction potential of the bridge is not substantially altered by the methoxy substituents, it is to be expected that **11a/12a** and **11b/12b** should display similar rates of ET even if superexchange was relevant. Of the two configurations which are possible for the reverse reaction, a contribution to the superexchange by the second possibility would be favored on energy grounds. The oxidation potential of the bridge is altered by the substituents in such a way that the contribution to superexchange should be larger for **11b/12b** than for **11a/12a**. The experiment did indeed show that the forward reaction is hardly affected by the substituents, whereas the reverse reaction is markedly influenced. The rate of recombination from the charge-separated state is a factor of 3 to 4 larger for **11b/12b** than for **11a/12a**. The influence exerted by the substituents indicates that the bridge takes part in the ET reaction.[97]

A contribution from superexchange to the ET rate is also discussed in an investigation of free-base porphyrin/Zn-porphyrin/quinone triads with transient absorption spectroscopy in the femtosecond range; in these compounds the quinone is directly covalently linked to a porphyrin in the *meso* position.[98] From a comparison of the kinetics, it was concluded that the participation of the (central) Zn-porphyrin in the ET process along the lines of the superexchange mechanism was very likely. Furthermore, the role of vibronic relaxation was discussed, which could also cause similar time-dependent shifts on the picosecond and subpicosecond time scale.

Johnson et al.[99] and Wasielewski et al.[100] have investigated a covalently linked triad, constructed from a chlorophyll donor connected to a quinone acceptor through a porphyrin bridge; the distance between porphyrin and quinone is larger than in the previously described compounds[98] in which the redox-active components are directly coupled. Comparison of the optical properties of the monometalated with the doubly metalated and the free-base derivatives led to the conclusion that, upon charge separation, a charge-transfer state between the porphyrin and quinone can be assumed to exist, in which the porphyrin bridge is oxidized and the quinone reduced. Finally, the system relaxes into a charge-separated state, in which the chlorophyll is

11a, R = H
11b, R = OCH_3

12a, R = H
12b, R = OCH_3

oxidized and the quinone reduced. At 77 K, the recombination to the ground state is so slow that lifetimes of the order of milliseconds were observed for the charge-separated state. A superexchange mechanism in which the porphyrin LUMO takes part appeared to be incompatible with the kinetic data. In this respect the behavior of the model compound differs from the superexchange mechanism postulated for the first charge-transfer step in bacterial photosynthesis.[101]

A potential function of the extra-bacteriochlorophyll on the inactive pigment branch has been addressed in a different type of model compound. In the primary reactions of photosynthesis, light-induced charge separation results from singlet-ET. Triplet states occur only as by-products, for instance, as a result of too intense light irradiation through reverse-ET from the charge-separated transient. Possible triplet states of chlorophyll are dangerous, since they function as effective singlet oxygen generators; in nature they are, therefore, quenched by carotenoids. However, in bacterial reaction centers the carotene lies a considerable distance away from the bacteriochlorophyll dimer (the special pair). The possibility has therefore been mooted that the extra-bacteriochlorophyll in the inactive pigment branch, which lies between the dimer and the carotene, could serve as a triplet relay to the carotene where the triplet state is quenched. Gust et al. have recently investigated the triad **8**, consisting of a carotenoid (C), a porphyrin (P), and a pyropheophorbid (Ppd), by time-resolved optical spectroscopy and obtained the following results:[102] The Ppd excited singlet state is accesible either by direct excitation or by energy transfer from the neighboring excited porphyrin. The excited state of Ppd can undergo intersystem crossing to the triplet state. In oxygen-free solution this triplet state decays by triplet energy transfer to the carotene via the triplet state of the porphyrin (Scheme 2).

$$\text{C-P-Ppd} \xrightarrow{h\nu} \text{C-P-}^1\text{Ppd} \xrightarrow{\text{ISC}} \text{C-P-}^3\text{Ppd} \longrightarrow \text{C-}^3\text{P-Ppd} \longrightarrow {}^3\text{C-P-Ppd}$$

Scheme 2.

If oxygen is present in the solution, this quenching process competes effectively with the formation of singlet oxygen; consequently, the carotene actually does perform a protective function, at least to some extent. If the triad contains a zinc porphyrin instead of the free base, the triplet energy transfer is very ineffective, since the energy of the triplet state of porphyrinatozinc is too high. In this system no protection against photogenerated singlet oxygen is observed from the porphyrin triplet relay. The triplet relay ceases to be effective at lower temperatures, because the first energy transfer step is endergonic. Such behavior is also observed in natural systems.

The pentad **9** exemplifies the energy transfer and ET processes of photoexcited states (Fig. 5).[11, 103] The studies on **9** include stationary and time-resolved fluorescence methods (single-photon counting) as well as transients absorption spectroscopy. Both porphyrins can be photoexcited to their first excited singlet state S_1 by laser with light at 590 nm . Since the Zn-containing porphyrin fragment does not display strong fluorescence, one can assume that $^1P_{Zn}$ transfers the energy to the free base P with formation of ^1P (step 1, Fig. 5). ^1P can be directly generated by

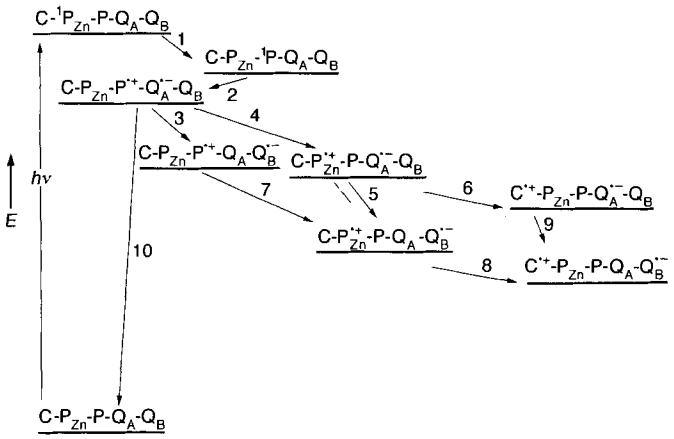


Fig. 5. Energy level diagram for the pentad **9** (C-P_{Zn}-P-Q_A-Q_B). The figure shows the various energy-transfer and electron-transfer steps and the transients involved; see text as well [11, 103].

excitation at 650 nm. Emission from ^1P is known to be substantially weaker than in the corresponding monomer. Obviously, therefore, fluorescence quenching by ET to the neighboring quinone Q_A is taking place (step 2, Fig. 5). The charge-separated states $P^{\bullet+}$, $Q_B^{\bullet-}$ or $P_{Zn}^{\bullet+}$, $Q_A^{\bullet-}$ are produced by the competing ET steps 3 and 4. After further branching ET steps, the charge-separated state $C^{\bullet+}$-P_{Zn}-P-Q_A-$Q_B^{\bullet-}$ is formed. This state has a relatively long lifetime of about 200 μs, brought about by the stepwise separation of charge and the concomitant increase in the distance between positive and negative charge. It can be detected by transient absorption spectroscopy on the nanosecond time scale. It has also been stated that the lifetime of the final charge-separated state of the corresponding completely metal-free pentad is even longer, namely 340 μs. However, the quantum yield is, in this case, lower than in the former pentad because of competing back reactions.

4.2. (Stationary) EPR and ENDOR Investigations

It has already been shown that the electronic interaction between donor and acceptor and thus their electronic wave functions are of significance for the understanding of the properties of ET. Also, since a (porphyrin) radical cation and a (semiquinone) radical anion are formed upon transfer of an electron, the exact determination of the spin density distribution in the corresponding radical fragments is of interest. Furthermore, since the spin density distribution is related to the structure (relative spatial configuration, twist angles), additional information about the preferred conformation of the P-S-Qs can be obtained. Because the large π-electron system provides many magnetic nuclei that contribute to the hyperfine structure, the higher resolution of ENDOR spectroscopy relative to EPR can be exploited to particular advantage.[104–106] When there are several radical species in solution or when there are different conformers present, ENDOR-induced EPR (EIE) spectroscopy is the technique of choice to record the spectra of individual components of the mixture.[105, 106] In Figure 6 the separation of the spectra of two species is presented for the semiquinone anion of **2b** (EIE spectra I and II). It should be noted that the

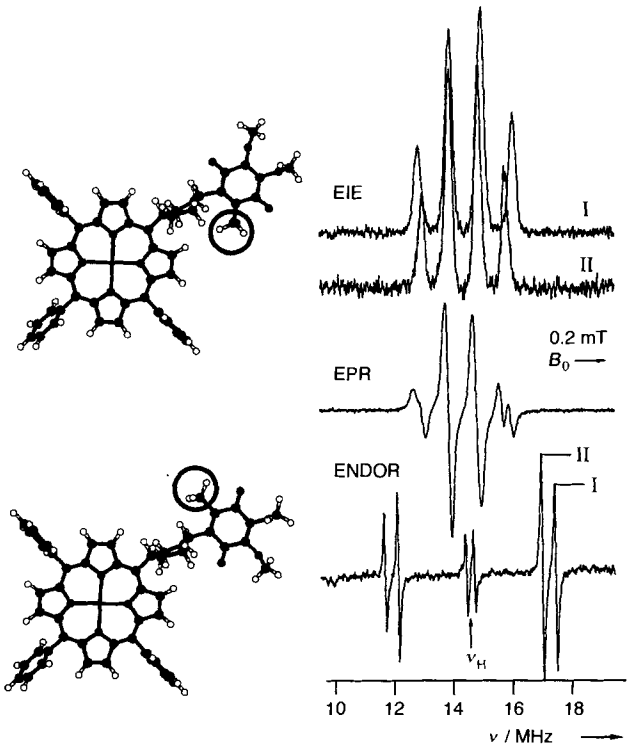

Fig. 6. EPR (290 K), ENDOR (290 K), and EIE spectra (270 K) of the chemically generated semiquinone radical anion of **2b**. The energetically favored conformations (derived from Alchemy III and MNDO calculations) are depicted. (The circles highlight the different positions of the CH_3 groups adjacent to the bridge). It can be seen that the spectra, in particular the EIE spectra, indicate two species with different *g*-factors. The Roman numerals in the ENDOR spectrum characterize the field positioning used in measuring the spectra I and II, respectively (in the Alchemy formulas the *p*-CH_3 groups on the phenyl rings of the porphyrin are omitted) [59, 91].

orientation of the quinone components relative to the cyclohexanediyl bridge in these confomers differs by 180°.[59, 91]

As already mentioned, the special pair in bacterial reaction centers consists of a bacteriochlorophyll dimer. In the radical cation, the unpaired electron is delocalized over both bacteriochlorophyll units. EPR and particularly ENDOR investigations have revealed that the ^1H and ^{14}N hyperfine coupling constants are smaller than those of the corresponding monomers.[107–110] It should be reasonable to model the special pair by using covalently bound porphyrin dimers. Many examples of such compounds have already been prepared (see Section 4.1).[111–113] EPR and ENDOR studies of radical derivatives of the porphyrin dimer **3** and modified compounds with *meta*-phenylene or diphenylmethano bridges have been carried out. A comparison of the hyperfine coupling constants with those of the monomeric analog, the ZnTPP radical cation,[114, 115] indicates that the unpaired electron in the former compounds is almost completely delocalized over both porphyrins, whereas in the compound with the methano bridge, the electron is localized on only one porphyrin unit. The CH_2 group behaves as an isolator between the two π-electron systems. Thus, only the first two compounds with delocalization of the unpaired electron over both porphyrin units exhibit a sufficiently large π–π overlap to cause delocalization and thus to mimic the electron distribution in the special pair in the bacterial reaction center.

4.3. Time-Resolved EPR Investigations in Isotropic Liquids

For the detection and investigation of paramagnetic, transient species, time-resolved EPR spectroscopy, be it the continuous wave (cw) or Fourier Transform method, is the technique of choice. Compared to optical spectroscopic methods like time-resolved fluorescence spectroscopy and absorption spectroscopy, EPR methods have the disadvantages of poorer time-resolution and more complicated data analysis (for example, the signal intensity in optical methods is directly proportional to the number of molecules in the observed state); nevertheless, short-lived intermediates can be more accurately—and often unambiguously—identified through their magnetic properties. In ET processes paramagnetic species can be generated not only by spin selective ISC, but also through the radical-pair mechanism. Shortly after their formation, the population of their spin systems created in this manner deviates from the thermal Boltzmann distribution. Fast spectroscopic techniques reveal ESP (electron spin polarization) effects, which are reflected by enhanced absorption or emission signals in the EPR spectra.[116] The polarization pattern of the EPR spectra often contains detailed information about the spin dynamics of the system under consideration. Time-resolved EPR investigations into the transient paramagnetic states of the reaction centers of bacteria and also of plants (photosystem I) have played an important role in the understanding of light-driven primary processes in photosynthesis.[117–121]

The processes induced by light excitation of the porphyrin chromophore (sketched in Figure 3) as exemplified by two selected model compounds, the cyclohexylene-connected P-S-Qs **1** and **2**, will now be described. After light excitation of the singlet ground state S_0 of the porphyrin to the first excited singlet state S_1 (any higher singlet states will deactivate to S_1 in less than 12 ps), deactivation to the ground state can occur by IC, fluorescence, or via the triplet state T_1, which is populated by ISC (^{T}P-S-Q, Fig. 3). In the presence of a quinone acceptor, another decay channel is opened through which singlet ET from S_1 or triplet ET from the ISC-derived triplet state T_1 of the porphyrin fragment can take place. The corresponding transient diradical ^{S,T}[P$^{\cdot+}$-S-Q$^{\cdot-}$] is formed, either in the triplet or singlet state. In principle, these two spin states can coherently mix in the sense of a radical-pair mechanism, or interconvert by ISC. The deactivation to the ground state by ET takes place from diradicals with singlet character.

In isotropic liquid solutions at room temperature **1** and **2** display rapid ET (in the picosecond range) from the optically excited S_1 state of the porphyrin to the quinone[40, 91] (see also the discussion of optical measurements of ET in **1** and **2** in Section 4.1). However, at lower temperatures in alcohols, (for example, ethanol, 150 K) EPR signals appear (Fig. 7); they can be attributed to a superposition of the signals of the triplet states of the porphyrin (^{T}P-S-Q) and of the radical pair (^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$]). The detection of ^{T}P-S-Q implies that the singlet ET (S-ET in Fig. 3), which dominates at room temperature, must be slowed down enough that the ISC to the porphyrin triplet state can successfully compete. The decrease in k_{ET} on cooling is explained by the transition from the diabatic ET to the solvent-controlled adiabatic ET (see Section 2).[50, 51, 122, 123] An estimation of k_{ET} from the relaxation time τ_L of ethanol in the

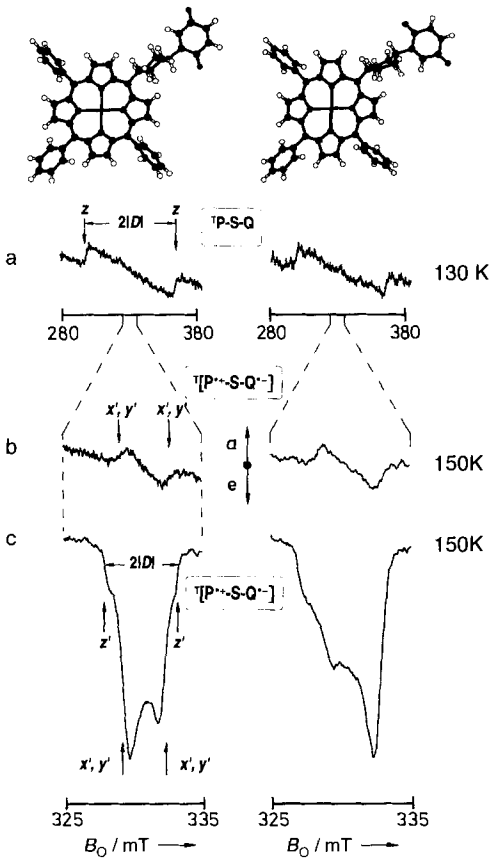

Fig. 7. Spin-polarized transient EPR spectra of P-S-Qs **1a** (left) and **1b** (right) after pulsed laser excitation of the porphyrin segment (10 ns, 584 nm, 8 mJ, pulse frequency 20 Hz). a) Spectra of ^{T}P-S-Q: delay time for **1a** 0.2 μs (polarization pattern (aaa eee), direct detection), for **1b** 0.4 μs (integration time 0.5 μs); b) early spectrum of ^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$], delay time 0.5 μs, integration time 0.5 μs, (aa ee); late spectrum of ^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$], delay time: 5 μs, integration time 0.5 μs. For interpretation see text. The structures were obtained from MNDO calculations and Alchemy III. Zero field splitting parameter D: a) 32.6 (**1a**), 32.8 (**1b**); b,c) 2.65 (**1a**), 3.75 mT (**1b**) [50, 91].

temperature range employed agrees roughly with the rate of ET obtained from experiment. In view of the problems connected with a quantitative analysis of the influence of solvent on the rate of ET,[21] this level of agreement can be considered to be satisfactory.[124] (However, it must be explicitly pointed out that according to newer theoretical and experimental investigations, fundamentally more complex relationships for solvent mobility and their influence on ET rates must be taken into account; see, for example, ref. [45, 53].)

The results of the time-resolved EPR investigations have already been thoroughly described.[50, 122] The essential results are summarized below. About 0.3 ps after the laser pulse, both compounds **1a** and **1b** display EPR spectra that extend over about 60 mT and consist essentially of three groups of signals, whose signal rise times are different (Fig. 7).[50, 91] While the intensity of the outer groups of signals decreases with time, the inner group becomes more intense. The polarization pattern of the outer groups is (aa ee) at low field (a = absorption, e = emission), whereas that of the middle group changes with time from (aa ee) to complete emission (ee ee). The outer signals in Figure 7a coincide well with those expected from a porphyrin in the triplet state; they represent the typical z turning points of an EPR powder pattern (xyz molecular coordinate system; principal axis z, perpendicular to the porphyrin plane). More exactly, they are the accidentally coincident z and y components, while the x components, which are superimposed at the center of the spectrum, cancel out because of their opposite phase; cf. also ref. [50].

The central group of signals, detectable after a delay of 0.5 μs, can be similarly assigned to a triplet species (expanded scale, Fig. 7b), namely the diradical ^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$]. The zero field splitting parameters D of 3.75 mT and 2.65 mT yield electron separations of 8.8 Å and 10.7 Å for the *cis* and *trans* compounds, respectively, according to the point–dipole model.[125] The point–dipole model is applicable in this case, since the distance between the unpaired electrons in the diradical is large relative to the extent of the π-electron systems of the porphyrin and quinone. Figure 7 shows the preferred conformations of the P-S-Qs **1a** and **1b**, as derived from the molecular modeling program Alchemy III. The separation of the two unpaired electrons in the diradical, obtained from the zero field splitting should correspond to the center-to-center distance of porphyrin and quinone, assuming that the spin densities are localized at the respective centers of gravity. As expected, one finds a smaller separation for *cis*-^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$] (righthand structure in Fig. 7) than for the *trans* compound.

Apart from the detection of the triplet state and the direct identification of the transient triplet species, the aforementioned polarization patterns are of particular interest, since they give information about the spin dynamics of the ET (Fig. 8). For the

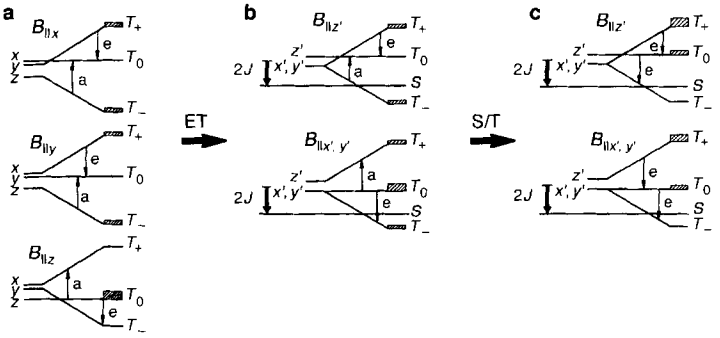

Fig. 8. Zeeman energy levels and excess spin populations for the three canonical orientations (B_0 field in each case parallel to one of the three major axes x, y, z of the zero field splitting tensor) of the triplet states ^{T}P-S-Q ($D>0$, $E\neq0$) and ^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$], (principal axes: x', y', z'; $D<0$, $E=0$). a) High field population of ^{T}P-S-Q as a result of spin selective ISC [126, 127]; b) initial population of the radical pair ^{T}[P$^{\cdot+}$-S-Q$^{\cdot-}$], J: exchange interactions; c) later population, arising from different recombination rates into the ground state P-S-Q (see text) [50].

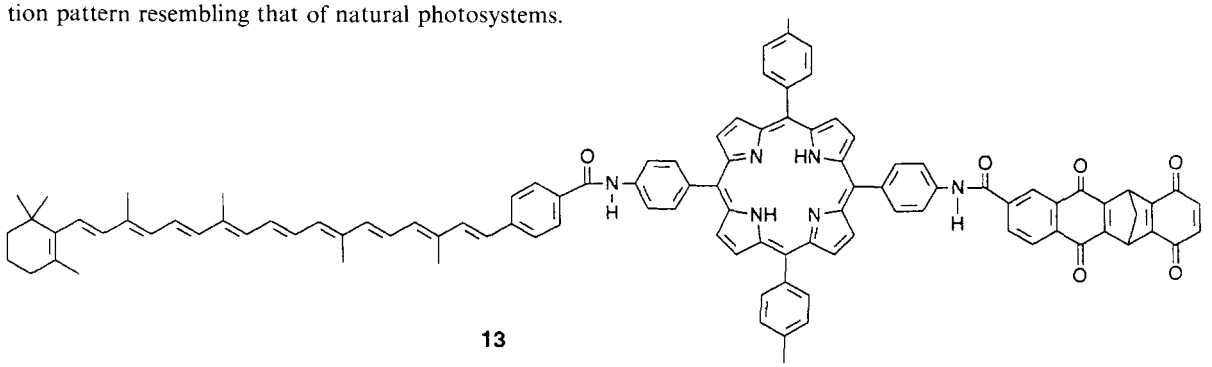
Zn-containing P-S-Q **1**, the polarization pattern (aa ee) (actually (aaa eee)) of the signal assigned to the triplet state of the porphyrin corresponds to that reported in the literature for ZnTPP.[126, 127] The polarization is due to an anisotropic ISC, in which the T_z level is exclusively populated. In the high field approximation, T_0 for $B\|x$ and $B\|y$ are then "empty" with respect to the radiative part, whereas this level for $B\|z$ is overpopulated.

The polarization pattern assigned to the diradical, which appears after a delay of about 1 μs (aa ee), can be explained when the following assumptions are made: 1) The spin polarization of the porphyrin is carried over to the diradical during the ET.



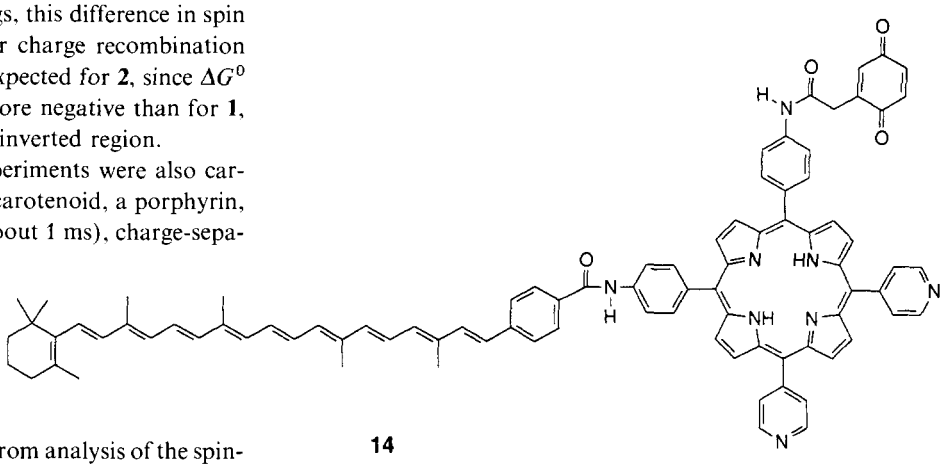
2) The z' principal axis is rotated by about 90° to the z axis and connects the centers of the porphyrin and quinone, with the result that T_0 for $B \| z'$ is empty and that for $B \| x'y'$ is overpopulated. 3) D of the diradical has the opposite sign to that of the triplet porphyrin.[128]

The development, over time, of the polarization pattern of the radical pairs' EPR spectra, which after a few microseconds change from (aa ee) to purely emissive spectra, can be explained by S/T mixing. The admixture of singlet character to T_0 and T_- levels causes a greater rate of depopulation from these levels by recombination into the ground state; thus the spectra turn completely into emission. The behavior is particularly complex, because, simultaneously with the decay of ET-induced polarization (due to spin–lattice relaxation), a new electron spin polarization is developed by S/T mixing. This temporal change of signal phase for both P-S-Qs can be seen clearly in Figure 7b and c. In both compounds the low-field z' and $x'y'$ transitions change from absorption to emission.[50]

The spin dynamics in the P-S-Qs are sensitive to structural variations in the molecular systems, as discussed in the following example: Compound **2** (already discussed in terms of its optical properties), in which the only difference to **1** is the replacement of the quinone fragment by ubiquinone, displays a completely different EPR polarization pattern to **1** for the corresponding charge-separated state $^{T}[P^{\bullet+}\text{-S-UQ}(0)^{\bullet-}]$. Instead of the early polarization pattern (aa ee), the pattern of **2** is, surprisingly, (ee aa).[129] Amongst other things, this difference in spin dynamics can be caused by the slower charge recombination from $^{S}[P^{\bullet+}\text{-S-UQ}(0)^{\bullet-}]$. This is to be expected for **2**, since ΔG^0 for charge recombination should be more negative than for **1**, and therefore should lie further in the inverted region.

Time-resolved FT- and cw-EPR experiments were also carried out on tetrad **13**, built up from a carotenoid, a porphyrin, and two quinones.[130] A long-lived (about 1 ms), charge-separated state in which the charges were localized on the ends of the tetrad (that is, on the carotenoid and on the terminal quinone) was photochemically generated. The transient radical species could, therefore, be very accurately characterized. It was assumed from analysis of the spin-polarized EPR spectra that the singlet ET probably occurred from the excited singlet state of the porphyrin.

Time-resolved EPR spectra could also be obtained from the already mentioned chlorophyll-porphyrin-quinone triads,[98] for which the lifetime of the charge-separated state is of the order of milliseconds. These spectra displayed a spin polarization pattern resembling that of natural photosystems.



13

4.4. EPR Investigations in Anisotropic Liquids

The primary processes in natural photosynthetic reaction centers take place in membrane-bound protein complexes. The protein may have an influence on the unidirectionality of the ET, due to the spatial fixation of the redox-active pigments, and may contribute to the high efficiency of the charge separation. The central event of photosynthesis can be described as a light-driven cyclic flow of electrons, whose net effect is the generation of a proton gradient over the membrane[8, 9, 131] (see also the "chemiosmotic hypothesis"[132]). Any modeling of photosynthetic processes with the P-S-Qs in isotropic media, as discussed so far, thus lacks important contributions. It would, therefore, be challenging to model the photosynthetic membrane on, for example, micelles, vesicles, lipid membranes, or liquid crystals. Even though it is quite unlikely that the topological parameters of photosynthesis could be exactly mimicked by using such media, valuable information might still be obtained about the behavior of redox-active components in anisotropic surroundings.

Moore et al. have synthesized the amphiphilic triad **14** with the hydrophilic pyridinoporphyrin and the hydrophobic carotenoid fragments and studied it in various media including liposomes (phosphatidylcholine), that is, in closed, liquid-filled vesicles. They showed by measurement of the fluorescence

14

quenching with ascorbic acid/cytochrome c that the triad actually spanned the membrane of the liposome.[133] The carotenoid radical cation, formed through light-induced charge separation, oxidized cytochrome c (II) to cytochrome c (III), which then brought about oxidation of the ascorbic acid.

Liquid Crystalline Solutions

When liquid crystals are host media, they allow the individual anisotropic hyperfine components of paramagnetic derivatives of the P-S-Q guest molecules to be studied by EPR spectroscopy. Thus, quinones were chemically reduced to semiquinones, and the degree of ordering and the orientation of the guest molecules could be determined by static EPR or ENDOR spectroscopy from the anisotropic hyperfine shifts in nematic or smectic phases.[134]

The triplet state of ZnTPP, obtained photochemically by ISC in a liquid-crystalline matrix, has been investigated by means of time-resolved EPR spectroscopy.[126, 135, 136] As a result of the nematic ordering of the host molecules in an external magnetic field, the guest molecules also adopted a preferred orientation. In the nematic phase the preferred orientation of the porphyrin molecule aligns the line joining two opposite pyrrole nitrogen atoms parallel to the field axis. If the solution is frozen, the reorientation of the nematic molecules is hindered, which allows the angular dependence of the triplet spectrum to be studied by turning the sample tube in the magnetic field. By incorporation of mesogenic substituents in the porphyrin system, a different orientation can be forced upon the molecules, since the mesogenic substituents dictate the favored orientation.[137]

Recently the light-induced, intramolecular ET of the P-S-Qs **1a** and **1b** was studied in liquid crystals with time-resolved EPR spectroscopy.[138] Transient, paramagnetic species could be detected in the nematic phase over a wide range of temperatures (210–320 K). In isotropic (ethanol) solution this range is limited to 30 K (130–160 K). Whereas the EPR spectra of the charge-separated state in isotropic solution display an (aa ee) polarization pattern (Fig. 7[50]), in liquid-crystalline solution an (ee aa) pattern is observed. The definitive interpretation of these results is currently under intense debate. It has been postulated, for example, that the very bulky porphyrin donor is oriented in exactly the same way as ZnTPP, and therefore dictates the orientation of the P-S-Q. Accordingly, the dipolar axis of the diradical is tilted away from the field axis, since the bridge is bonded to the porphyrin framework in the *meso* position. This geometry could significantly influence the polarization pattern. The marked temperature dependence of the polarization is explained by competing triplet and singlet ET processes.

Micelles and Inverse Micelles

Micellar aggregates have proved their worth in modeling the photochemical ET processes in photosynthetic membranes.[139, 140] Thus, for example, mixtures of porphyrins or chlorophylls and quinones have been irradiated, and the interaction of the resulting ions with the interface of charged micelles has been studied with optical spectroscopy[141] and magnetic resonance methods.[142–145] The behavior of these mixtures was compared with that of the corresponding mixtures in isotropic solutions.[146] The semiquinone radical anion is destabilized by Coulombic interaction with the negatively charged micelles and expelled from the micelle. Remarkably, in micelles with a positively charged head group, an accelerated back-ET to the ground state was observed.[144] This is presumably due to the Coulombic attraction between the head group and the negative semiquinone radical anion.

Recently the first tentative experiments on light-induced ET of P-S-Qs in inverse micelles[147] were reported.[148, 149] Upon irradiation of a solution of **1a** in inverse micelles of cetyltrimethylammonium bromide (CTAB) (pH about 7) with light of high intensity, signals from radical species were observed in cw-EPR experiments (see below). The radicals observed here must have a distinctly longer lifetime than the signals described in Section 4.3, which were detected with time-resolved EPR spectroscopy.[150] Also missing is the characteristic dipole–dipole interaction described in Section 4.3. The following observations were made: Shortly after irradiation, the EPR spectrum of the doublet semiquinone fragment was obtained (Fig. 9a), which could be identified by comparison

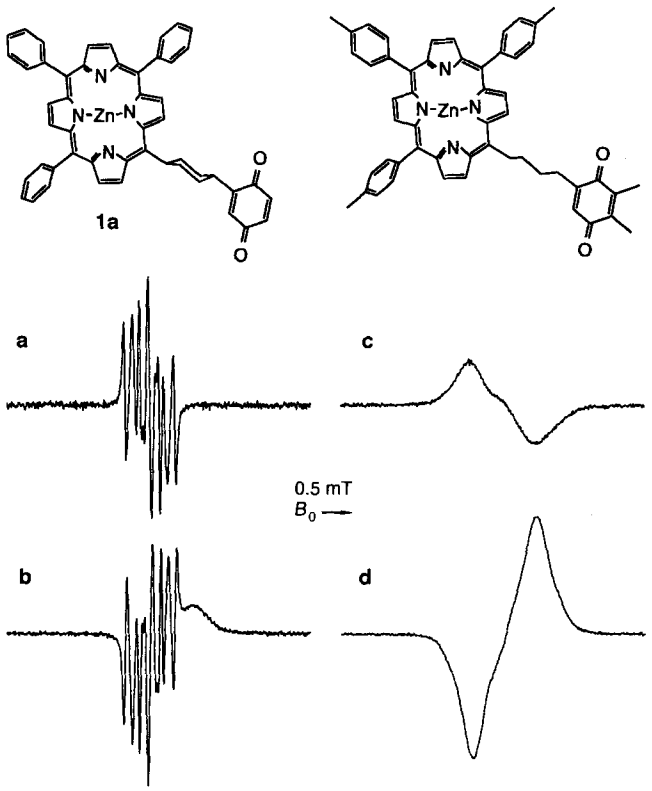


Fig. 9. EPR spectra of radicals produced by illumination in situ (in the resonator) in inverse micelles as solvent from the P-S-Q depicted (structures calculated by Alchemy III). Starting concentration 5×10^{-4} M; light source: 1000 W Hg-Xe lamp (Oriel), 395 nm cut-off filter. a) **1a**. b) Hydroquinone form of **1a** in inverse CTAB micelles. c) EPR dark spectrum of the P-S-Q (shown on the right) in inverse TX-100 micelles after irradiation and switching off the light. d) Emission EPR spectrum observed during irradiation [152].

with the spectrum of the identical chemically produced radical. The EPR signals disappear on extinguishing the light, and reappear on renewed exposure.[151] This result suggests that spin-polarized radical ions are formed in a rapid cyclic ET process. Upon extended irradiation these EPR signals become emission signals. Interestingly, if the hydroquinone derivative of **1a** is used instead of the quinone **1a** itself under otherwise equivalent reaction conditions, the EPR spectrum is entirely an emission spectrum immediately after the irradiation is started (Fig. 9b).[152] In addition, a second emission signal is observed, which can be assigned to the porphyrin radical. The spectral features therefore represent a superposition of both species.

Whereas the light-induced process in the P-S-Q system undoubtedly begins with an ET from porphyrin to quinone (the porphyrin hydroquinone derivative is formed to some extent in a photochemical side reaction), other processes must be considered in the hydroquinone system, since the hydroquinone cannot function as an electron acceptor. An ET from the hydroquinone to the porphyrin unit, with formation of the porphyrin radical anion, is conceivable.

It is remarkable that upon irradiation of the P-S-Q depicted in Figure 9 (right) in neutral inverse TX-100 micelles, a radical is formed that is also stable in the dark (Fig. 9c); its EPR spectrum appears, of course, in absorption.[153] Irradiation causes the phase of these absorption signals to turn into emission (Fig. 9d), which also brings about an increase in signal intensity (probably by spin polarization). Apparently, shortly after the photochemically induced ET, pronounced ESP processes take place creating the spin-polarized products that have sufficiently long lifetimes to be detected by cw-EPR spectroscopy. One can speculate whether, besides the triplet and radical-pair mechanisms, the recently developed radical-triplet-pair mechanism[154, 155] plays a role in this case. As a result of this mechanism, emission EPR spectra of doublet radicals appear, whose spin polarization is caused by interaction with triplet states (see also ref. [156]).

In this context, an extremely interesting experiment must be mentioned in which the quinone of a bacterial reaction center was pre-reduced to the Q_A semiquinone anion radical, which gave an EPR doublet signal in the dark.[157, 158] After photoexcitation of the bacteriochlorophyll dimer, ET proceeds only to the bacteriopheophytin. Because of the longer lifetime of this charge-separated state, an effective radical pair interaction between the radical cation of the bacteriochlorophyll dimer and the bacteriopheophytin radical anion takes place. The spin polarization caused by this process is transferred to the semiquinone doublet radical, whose signal is completely converted into emission. The differences in the interactions relevant to the spin-polarized states in the reaction center (spatially fixed redox components) and in (micellar) solution have already been discussed.[118, 119]

This report should be wound up with a curious experiment concerning ET between porphyrin and quinone: If one grinds up a mixture of crystals of a donor (ZnTPP) and an acceptor (substituted quinones) in an agate mortar, one observes an intense EPR powder spectrum typical of a triplet ground state (Fig. 10), which is assumed by the authors to be generated from a mechanochemically induced electron transfer leading to the formation of the stable diradical ZnTPP radical cation/semiquinone radical anion.[159, 160] The triplet state was unambiguously identified by EPR high field/low temperature polarization experiments (2 mm, F-band; 4.2 K) and also by the detection of the $\Delta m_s = 2$ ("half field") transition (see Fig. 10).

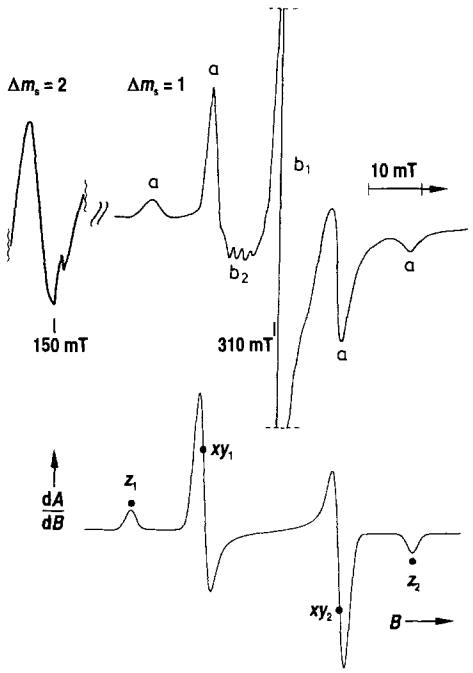

Fig. 10. Solid state EPR triplet spectrum (top, X band, 3 cm) of the diradical produced mechanochemically from a mixture of ZnTPP and 3,5-di-*tert*-butyl-*o*-quinone (see text). The signals a represent the ($\Delta m_s = 1$) *z* and *xy* components of the triplet molecule's spectrum, whereas the signals b belong to doublet radical impurities; the (split) signal at 150 mT corresponds to the $\Delta m_s = 2$ "half-field transition" [159]. For comparison, the first derivative of the $\Delta m_s = 1$ high-field part of an idealized EPR triplet spectrum is shown (bottom).

5. Summary and Outlook

The optical and magnetic properties of the photoexcited states of covalently linked porphyrins and porphyrinquinones can be modified substantially by tailor-made structural variations. These biomimetic model systems are suitable for experimental verification of ET theories and for the study of the photophysical processes that take place in the primary reactions of photosynthesis. However, the limitation remains that, for example, the spin dynamics observed in the ET processes of these artificial porphyrinquinone cascades[98, 119, 161] very rarely reproduce the polarization patterns found in natural systems successfully.[118] The synthesis of tailor-made P-S-Qs for the study of current problems and questions, including that of noncovalently bound redox-active systems and anisotropic media (micelles, vesicle membranes) is a challenge for the preparative chemist. Future work will, fundamentally, be coupled to the studies of natural photosynthesis; here, model compounds can make valuable contributions. In future work, the following questions will have to be addressed:

- what is the source of the unidirectionality (why is only one branch of the reaction center photosynthetically active?)[162]
- does the superexchange mechanism contribute significantly to ET or are other mechanisms more important
- how do the complex redox and protonation/deprotonation steps take place in both quinone acceptors
- what is the role of the amino acid residues of the protein in which the pigments are embedded (do they determine the unidirectionality?)

and finally

- what is the role of the very specific incorporation of the protein in the membrane in the early photosynthetic processes.

It certainly cannot be expected that the artificial photosynthetic devices presented in this article will address all the features of the native energy and ET processes. Nevertheless, despite the

preparative difficulties associated with the porphyrinquinones, their structural, chemical, and physical similarities to the natural pigments make them very attractive models. On the other hand, a great deal of information about fundamental questions of charge and energy transfer has also been obtained from less complex (nonbiomimetic) models.

Finally, if the concept is correct that the extra-bacteriochlorophyll plays a crucial role—be it as mediator or as a kinetic intermediate—in the efficiency of light-induced charge separation, the construction of the ultimate biomimetic model compound that exactly mimics the primary step of photosynthesis remains conceptually and preparatively a difficult challenge to meet.[163]

Our thanks are due to the co-workers named in the references and also to the many members of the group not mentioned, who have been involved in the difficult syntheses of the model compounds. We would also like to thank our friends and colleagues from the Department of Physics (the Möbius group) for constant, patient discussion of the results of our collaborative research. In particular we should mention Prof. Dr. K. Möbius, Dr. M. Plato, Dr. F. Lendzian, and Dr. J. Schlüpmann. M. H. thanks Prof. G. Feher for the very informative and fruitful postdoctoral work in his group and Prof. J. Fajer for fascinating discussions during his stay in Berlin. This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft (normal funding and SFB project 337 "Energy and Charge Transfer in Molecular Aggregates").

Addendum

The model compound mentioned in Section 3, in which a crown ether linked with a quinone acts as acceptor and which has a flexible butanediyl bridge to the porphyrin[78] was recently studied in the nematic phase of a liquid crystal by means of time-resolved EPR spectroscopy.[164] After a short period of irradiation with laser light, the transient diradical in the triplet state, formed by ET, proved to have an extended structure; from the changes in the EPR spectra after longer irradiation, a (photoinduced) refolding of the quinone over the porphyrin plane was deduced. In isotropic, moderately polar solvents, such a refolding can also be detected by NMR spectroscopy in the ground state of the analogous Zn complex.[78]

As could have been predicted, the fascinating, redox-active fullerenes have also joined the family of model compounds. "Buckyballs" have been covalently linked to porphyrins[165] and quinones.[166] These systems are very attractive for investigations with time-resolved spectroscopy.

[4] The superexchange mechanism was developed during the discussion on whether the ET takes place through the bonds of the bridge ("through bond") or through space. According to this mechanism, the ET from donor to acceptor proceeds without a multistep process in which the electron is transferred initially to the bridge. The mixing of orbitals from the bridge increases the electronic interaction through "virtual" states; see text for further explanation. Cf., for example, V. Balzani, F. Scandola, *Supermolecular Photochemistry*, Ellis Horwood, New York, **1991**, p. 94.

[31] Actually, the parabolas represent sections through the multidimensional energy hypersurfaces of the reactants and the products. These sections are to be understood as trajectories along the nuclear coordinates relevant for the reaction. The representation of the potentials as parabolas is analogous to the description of vibrations according to the model of a harmonic oscillator where both electronic states are described with the same (averaged) force constant. One advantage of this description is that the theoretically predicted rate of ET depends on only a few parameters, which can be determined independently by experiments. Thus the theory is experimentally verifiable.

[34] It is amazing that for all solvents used in ref. [33], the same reorganization energy was found (the ET rates measured in the different solvents are plotted in one diagram, in which the rate constants of the model compounds are represented as a function of $-\Delta G^0$), even though the magnitude of λ, which determines the position of the curve maximum, should, in fact, depend strongly on the dielectric constant of the medium (see, for example, the cited publications of Marcus and refs. [21, 95]).
[35] The semiclassical approximation is given, which holds for the limiting case of high temperature in which the vibrational states can be treated as a continuum. On the basis of this formulation, the parallels to Marcus theory are most easily visualized.

[48] In the formulation of Rips and Jortner [47], τ_L is used instead of ω_C ($\tau_L = 1/\omega_C$). Otherwise, the adiabaticity parameter differs by a factor of 2, which, for the purposes of the qualitative discussion presented here, is irrelevant.

[52] At low temperatures, quantum mechanical tunneling processes and the quantization of the vibrational states will, nevertheless, be of increasing importance. The approximation given above for k_{ET} [Eq. (c)] must then be abandoned in favor of an explicit calculation of the Franck–Condon term.

[80] This is a typical representation of the state diagram in which the energy levels of the individual states are determined from both optical data (absorption spectrum) and electrochemical data (redox potentials). If the optically determined energy separation S_0–S_1 is identified with the sum of the oxidation and reduction potentials, a common zero point is obtained.

[87] Herein lies the answer to the centuries old question—more poetical than scientific—as posed by John Donne, a poet, or Sir Walter Raleigh: *Why is blood red and grass green?* The answer is an anticlimax, because there is no poetry in it: The HOMO in chlorin lies at higher energy.
[88] Details of the instrumentation and the experimental conditions are not discussed in this review; they are available in the cited literature.

[97] It should be mentioned that, as regards effective charge separation with acceleration of the back-reaction, the substitution of the bridge yielded the wrong effect. The desired lengthening of the lifetime of the charge-separated state should be able to be achieved by incorporating electron acceptors in the bridge since a retardation of the back-reaction is required.

[128] The zero field splitting D in the triplet state of the porphyrin is positive [127], whereas that for the diradical is negative. In the latter case, the dipole–dipole interaction of the unpaired electrons can be calculated classically, because the distance between the electrons is sufficiently large.

[150] The minimum lifetime of a light-induced, paramagnetic state must be of the order of several milliseconds in order to have a sufficiently large stationary lifetime, and thus a stationary radical concentration, for a cw-EPR experiment. For the spin-polarized radicals observed here, the signal intensity for a given radical concentration can be larger; this increase in sensitivity enables paramagnetic states of shorter lifetimes to be detected. In any case, the time constant of the apparatus (which is set by the detection system's electronics) fixes the lower limit for the lifetime at about 200 μs; cf. A. R. McIntosh, J. R. Bolton, *J. Magn. Reson.* **1978**, *32*, 167. In time-resolved cw-EPR the time-resolution is of the order of 100 ns.
[151] As is to be expected for a porphyrin system, the EPR signals disappear on prolonged irradiation, because irreversible, photoinduced decomposition takes place, or are part of the processes leading to radical products. The photostability of the P-S-Qs ranges between a few minutes and a few hours and depends on the nature of the bridge between porphyrin and quinone.
[152] C. W. M. Kay, H. Kurreck, S. N. Batchelor, P. Tian, J. Schlüpmann, K. Möbius, unpublished.
[153] On irradiation of mixtures of ZnTPP and halogenated quinones in dipalmitoylphosphatidinylcholine vesicles, EPR spectra were obtained that had a similar structure to the spectrum shown in Figure 9c. These EPR spectra were interpreted as a superposition of the spectrum of the ZnTPP cation and that of the semiquinone anion: M.-P. Lanot, L. Kevan, *J. Phys. Chem.* **1989**, *93*, 5280.

Anticoagulatory Substances of Bloodsucking Animals: From Hirudin to Hirudin Mimetics

Johannes Dodt*

Bloodsucking animals contain substances in their saliva that specifically interfere with the blood clotting system. These substances are mainly low molecular weight proteins with a molecular mass of between 4 and 50 kDa. Some have become accessible in large quantities with the help of genetic engineering, and as a result their structures and structure–activity relationships have been studied and clinically tested. In the light of what is known about the mode of action of these natural products at the molecular level, new compounds with possible therapeutic effect can be derived. In the last ten years this approach has been tested with the proteinase inhibitor hirudin, obtained from medicinal leeches, and with the thrombin/hirudin complex. The serine protease thrombin plays a central role in the complex pathway of the blood clotting process and its pathophysiological effect finally results in thrombosis. The selectivity of the formation of complexes from hirudin and thrombin lies in the bivalent interaction of the inhibitor with the active site of the enzyme as well as with a substrate recognition site outside of the active site, the so-called fibrin(ogen) binding site (FBS). The knowledge of this mode of action enabled the synthesis of bifunctional thrombin inhibitors based on hirudin peptides. Hirudin and hirudin mimetics in vivo have been shown to be highly potent anticoagulants for the treatment of arterial and venous thrombosis.

Keywords: blood clotting · hirudin · pharmaceuticals · thrombin

1. Antithrombotic and Fibrinolytic Substances of Bloodsucking Parasites

The use of leeches as a remedy was recommended as early as the Sanscrit writings in India. Leech therapies were first described by the physician Nicandros of Colophon (200–130 B.C.) in Asia minor, but the real founder of this healing method was Themison of Laodicea in the first century B.C..[1] Ancyllus mentioned the bdellotomy or leech cut in 140 A.D., as a method to increase the withdrawal of blood. At the beginning of the nineteenth century leeching was widespread in Europe. In particular, the napoleonic army surgeon Broissais and his pupil Bouillaud regarded almost every illness as being due to excess irritation. Thus, leeches were not only employed for the withdrawal of blood, thereby, providing general relief for the patient, but also to cure widely differing illnesses such as the accumulation of blood, inflammations, infectious diseases, glandular function disturbances, and mental illnesses.[1, 2] The anticoagulatory effect of the salivary gland secretions of the leech Hirudo medicinalis (genus Hirudinidae) was first described by Haycraft in 1884.[3] In 1957 Markwardt managed to isolate a pure protein with inhibitory effect against thrombin,[4] which was named hirudin. Alongside this inhibitor a series of low molecular weight proteins have been isolated from bloodsucking parasites in past years, which specifically interfere in the reactions of blood clotting. As a result of their potential therapeutic use this field of anticoagulants is still being intensively researched today.

This article will initially provide a review of the reactions involved in blood clotting and subsequently present the mode of action of antithrombotic and fibrinolytic substances of bloodsucking parasites, as well as discuss the advantages and disadvantages of the underlying therapeutic concepts. The thrombin-specific inhibitor hirudin is a worthwhile example for investigating structure–activity relationships, not only because of its potential pharmaceutical use as an antithrombotic, but also because of its novel reaction mechanism.[5] The mode of action of hirudin was determined by X-ray crystallography of thrombin/r-hirudin complexes and from protein chemical and enzyme kinetic studies with recombinant hirudin (r-hirudin) and mutants of hirudin. These results gave impetus to the synthesis of low molecular weight peptide-based thrombin inhibitors. The development of these hirudin derivatives to obtain new anticoagulants will be shown with examples and their possible therapeutic application discussed.

1.1. The Physiology of Blood Clotting

Blood clotting (coagulation) must protect the vascular system of the body from life-threatening loss of blood when the vascu-

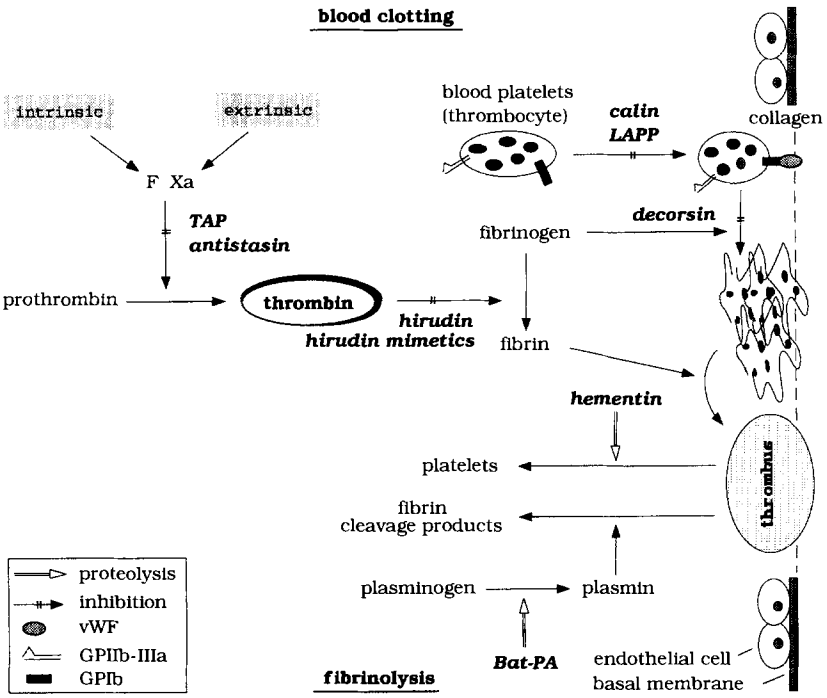
lar system is damaged. On the one hand mechanisms are present which concentrate and limit this coagulation process to the site of injury.[6-8] On the other hand, the fibrinolytic system takes care of the degradation of blood clots (thrombuses) and ensures that they do not lead to life-threatening occurrences such as lung embolism, stroke, and or cardiac infarction.[9]

Blood clotting is a complex system consisting of a) cellular and humoral components of the flowing blood, b) components of the vessel wall, and c) vasomotoric reactions, which interfere in the dynamic of blood flow. The cellular components are thrombocytes (blood platelets) and leucocytes, and the humoral components comprise clotting and fibrinolytic factors. Disturbances in the interplay of components can lead to complications, in which the equilibrium can be shifted either to favor bleeding or thrombosis.

Thrombocytes circulate passively through blood vessels, which are lined with a layer of endothelial cells (Fig. 1). As a primary response to a blood vessel injury the thrombocytes adhere to the site of injury, change their shape, secrete their granular contents, and aggregate. The status of blood platelet activation is modulated through a series of stimulating and inhibiting mediators.[10, 11] The blood platelets have specific receptors on their plasma membrane that pick up these stimuli and translate them into a physiological response.[12] During adhesion the thrombocytes bind through surface receptors to proteins of the extracellular matrix, which are exposed on damage of the endothelial cell layer.[13] This leads to activation of the blood platelets, amplification of the signal produced, and to the completion of platelet occlusion. The signal is enhanced either through the release of already formed components in the granular contents or by the synthesis of new substances. The granular contents, which enhance the signal, are serotonin and adenosinediphosphate (ADP) and the von Willebrand factor (vWF), fibrinogen and thrombospondin. The vWF supports adhesion of platelets to the subendothelial through the membrane glycoproteins Ib (GPIb) and, thus, effects their activation. A change in the conformation of the glycoprotein IIb-IIIa (GPIIb-IIIa; a member of the integrin family) as a consequence of this activation is an important prerequisite for the aggregation, in which the blood platelets bridge together directly across the fibrinogen molecules of the plasma.



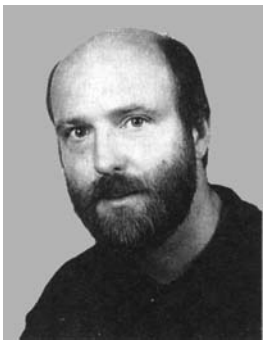


Fig. 1. Schematic representation of clotting and fibrinolysis processes with particular attention to the points of attack by the proteins of bloodsucking parasites; modified from ref. [140].

At the same time as the conglomeration of the platelets, the soluble components of the blood clotting pathway are activated, which leads to the formation of a fibrin net with trapping of platelets and other plasma cells at the site of injury. Blood clotting appears to be a succession of zymogen activations (substrate activations), in which the activated form of one factor catalyzes the activation of the next factor. A central feature of the blood clotting cascade is the formation of complexes between proteases and regulatory proteins (cofactors) and their substrates (zymogens) on membrane surfaces, for example on the surfaces of platelets.[6-8, 14] The course of the activation processes on the membrane surface restricts the

Johannes Dodt, born in 1954 in Recklinghausen, studied chemistry at the Universities of Münster and Munich. In 1985 he was awarded his doctorate under the supervision of Prof. Dr. H. Fritz for work which was undertaken at the Department of Clinical Chemistry and Clinical Biochemistry in the Surgical Clinic and Outpatient Clinic of the Ludwig-Maximilians-Universität in Munich. After a period of postdoctoral study under Prof. Dr. H. G. Gassen at the Institute for Biochemistry at the Technische Hochschule Darmstadt, from 1988 he was employed as a researcher and in 1993 he became a lecturer (Privatdozent) at the same institute. In 1994 he worked at Georgetown University in Washington D. C. The emphasis of his research work is in the area of proteases and protease inhibitors.

formation of thrombin at the site of injury. The series of events are, depending on the stimulus, formally divided into the reactions of the intrinsic or extrinsic pathways, which via a common pathway lead to the activation of the blood clotting factor α-thrombin. The key event for the initiation of blood clotting is the exposure of thromboplastin (a component of the extrinsic pathway), which is the cofactor for the factor VIIa-mediated activation of factor IX and factor X.[15-17] In the common pathway prothrombin is activated to thrombin by the prothrombinase complex (factor Xa, factor Va, phospholipids, Ca^{2+} ions) on the surface of activated blood platelets.[14]

Thrombin plays a central role in blood clotting and exerts an enzymatic as well as a hormone-like function, which either enhances or minimizes the blood clotting process.[18, 19] Fibrin results from the cleavage of fibrinogen by thrombin,[20] which polymerizes and forms the basis of the blood clot (thrombus). Factor XIIIa, which covalently meshes fibrin molecules together, is activated by thrombin[21] just like the cofactor proteins V[22] and VIII[23] in a positive feed-back reaction. In addition, thrombin is able to activate factor XI (intrinsic pathway) in the presence of negatively charged phospholipids (activated blood platelets).[24] Thrombin is the strongest stimulator of platelet aggregation, which is triggered by thrombin-mediated cleavage of the thrombin receptor.[25, 26] However, thrombin is also involved in the regulation of antithrombotic mechanisms. During binding to the endothelial cell receptor thrombomodulin the proteolytic activity is altered and thrombin becomes a potent activator of protein C.[27, 28] This protease inactivates the cofactor proteins Va and VIIIa, through which thrombin formation is halted. The interaction of thrombin with endothelial cells leads to the increased release of the tissue plasminogen activator (tPA), which induces fibrinolysis, or liberates, for example, prostaglandin I_2 (PGI_2) or nitrogen monoxide (NO), which exerts an influence on platelet aggregation.[29] The enzymatic activity of thrombin is regulated by endogenous inhibitors. α_2-Macroglobulin[30] as well as the serpins AT III[31] and heparin cofactor II[32] belong to this group of inhibitors.

In the fibrinolytic system the inactive zymogen plasminogen is converted into plasmin by plasminogen activators. The activated protease dissolves the blood clots, and the fibrin is degraded into soluble fibrin products. In this process the plasminogen activator and plasminogen bind together to the fibrin surface in order to ensure an optimal activation of plasminogen and the necessary contact with the fibrin substrate.[9] The fibrin surface also protects plasmin against inactivation by α_2-antiplasmin,[33] whilst the plasmin transported through the bloodstream is quickly inhibited by this inhibitor. Excessive reactions of plasmin in the blood leads to the consumption of the α_2-antiplasmin and degradation of the clotting factors V and VIII as well as of fibrinogen which results in a tendency towards bleeding.[34]

1.2. Leech Components: A Specific Intervention in the Blood Clotting Cascade

The adhesion and aggregation reactions of blood platelets are important targets for the development of effective antithrombotic substances.[35, 36] The active components of the leech intervene in different reaction steps in which blood platelets participate. The leech antiplatelet protein (LAPP) of the leech *Haementeria officinalis* (Table 1) inhibits the adhesion of platelets to collagen as well as the collagen-mediated aggregation.[37, 38] On the other hand, the protein calin of the leech *Hirudo medicinalis* inhibits, the adhesion of blood platelets to subendothelial structures,[39] whilst moubatin from the tick *Ornithodoros moubata* specifically inhibits the collagen-mediated aggregation reaction.[40, 41] The significant role of the glycoprotein GPIIb-IIIa for the aggregation reaction is apparent in patients with the Glanzmann syndrome.[42] As a consequence of a congenital defect or a deficiency of functioning GPIIb-IIIa, the platelets do not bind fibrinogen and do not aggregate. As this reaction is the common pathway of the platelet reaction for all stimuli, antagonists of GPIIb-IIIa can be seen as promising antithrombotic substances.[44] Decorsin obtained from the Mexican leech *Macrobdella decora* inhibits the platelet reaction since it is an antagonist of GPIIb-IIIa.[45] The antagonistic effect of this protein is mediated by the Arg-Gly-Asp (RGD-) sequence motif, as is also known for disintegrins from snake venoms.[46] The RGD sequence was originally discovered as the adhesion motif of fibronectin[47] and is also present in fibrinogen, vWF, and vitronectin circulating in the plasma. Therapeutic application in the treatment of unstable angina, acute cardiac

[a] No information.

infarction, stroke, and as a supportive measure in thrombolytic therapy could be achieved with the above mentioned substances, which interfere in the platelet reactions.[44,48] As regards to the therapeutic use of such proteins and peptides, the question, however, remains open as to how the early stages of the platelet reaction, which are not inhibited by GPIIa–IIIA antagonists, affect the clotting.

The aim of the therapeutic application of plasminogen activators is the recanalization of thrombosed vessels, for example after cardiac infarction. A problem of this therapy with plasminogen activators available today (tissue plasminogen activator, single-chain plasminogen activator of the urokinase type, streptokinase, antistreplase) is in the simultaneous systemic activation of the fibrinolytic system, which results in a consumption of α_2-antiplasmin and the undesired plasmin reactions. Although the activity of tPA is fibrin-dependent, in this case it is not only the necessary therapeutic dosage, but also the additional stimulation of tPA activity through fibrin cleavage products which is responsible for these effects.[49] The vampire bat *Desmodus rotundus* possesses a plasminogen activator (Bat-PA) (see Table 1), which in vitro exhibits activity selectively in the presence of fibrin.[50,51] Therefore it is to be expected that the up to 600-fold fibrin selectivity of Bat-PA as compared to human tPA is advantageous for its pharmacological properties in thrombolytic therapies.[52] The advantage of the higher fibrin selectivity could, however, be reduced by the nonhuman origin of this proteinase and the associated danger of immune reactions. In a thrombosis model, experimentally occluded femoral arteries in rabbits were quickly recanalized by Bat-PA without triggering systemic effects such as fibrinogenolysis or plasminogen deficiency.[53] Bat-PA could, therefore, enhance the safety and effectiveness of a thrombolytic therapy, since the negative side effects of the thrombolytic therapies used up until now in the animal model were not observed. These results should at present, however, not be overestimated, since the fibrin selectivity attained in animal experiments with tPA was not confirmed in humans.[54] Moreover, the high fibrin selectivity of bat-PA in no way signifies a guarantee for a reduced risk of bleeding, since the converse is conceivable, that is the selectivity aimed exclusively at clots might dissolve the necessary hemostatic occlusion. Fundamentally, there is the danger in the application of plasminogen activators that thrombus-bound thrombin is released, which can lead to renewed clotting and especially the activation of platelets through cleavage of the thrombin receptor.[25,26] Accompanying antithrombotic measures certainly have a positive effect on the thrombolysis.[55]

Depending on the origin of a clot, platelet-rich or erythrocyte-rich clots can form. The hementin enzyme,[56] present in the leech *Haementeria ghilianii* (see Table 1) in the Amazon region, effects a specific and effective dissolution of platelet-rich thrombuses.[57] As tPA is relatively ineffective against platelet-rich clots in therapeutic doses,[58] hementin could as a result of its property, complement the thrombolytic therapeutic agents employed today.

The formation of thrombin in the blood clotting cascade causes the formation of all clots. A series of leeches and ticks have highly potent inhibitors (see Table 1) to control this key enzyme (hirudin, hemadin, rhodniin) or the thrombin activator factor Xa (antistasin, tick anticoagulant peptide (TAP)). These inhibitors have already proved themselves in vivo in a series of arterial as well as venous thrombosis models.[59–62] After a detailed presentation of the thrombin/hirudin complex formation and the development of hirudin mimetics the pharmacological aspects of these inhibitors will be discussed (see Section 4).

2. Thrombin/Hirudin Complexes: Hirudin, the Basic Structure of a New Class of Serine Protease Inhibitors

Based on the primary structure of hirudin,[63–65] consisting of 65 amino acid residues, the hirudin molecule can be divided into two regions: an N-terminal domain held together by three disulfide bridges and a C-terminal region, which shows a high content of acidic amino acid residues (Fig. 2A). An additional

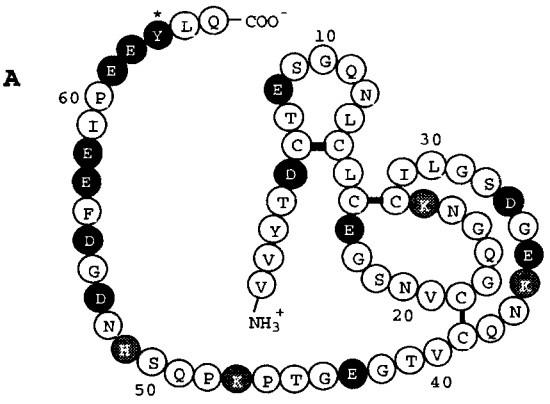

Fig. 2. Primary structures of hirudin-type thrombin inhibitors from leeches. A) Complete covalent structrure of hirudin[65]; *: the amino acid residue Tyr63 in naturally occurring hirudin is posttranslationally esterified with a sulfate. B) Comparison of the sequences of the isoforms 1–5 of hirudin from *Hirudo medicinalis*(1,2) [64,67]; *Hirudinaria manillensis*(3,4) [71,72]; *Haemadipsa sylvestris* (5) [73] (y: tyrosine sulfate ester; t: O-glycosylation of threonine). Hemadin (5) shows little sequence identity to the other inhibitors. It can, however, on the grounds of common structural characteristics be classed with the hirudin-type inhibitors [73].

acidic residue is produced by posttranslational modification of the tyrosine residue at position 63 into a sulfate ester *y*.[63,66,67] Up until now more than 20 primary structures of different forms of hirudin have been elucidated,[64,67–70] which partly differ only by few residues and show a minimal identity of 65% (Fig. 2B). In the *Hirudinidae* family, hirudin-type inhibitors, also from the leech *Hirudinaria* manillensis, were isolated and cloned.[71,72] The thrombin inhibitor hemadin from *Hemadipsa sylvestris* (family *Haemadipsidae*) is up until now the smallest naturally occurring thrombin inhibitor with 57 amino acid residues. It has, indeed, very little sequence identity to hirudin

(Fig. 2B), but based on common structural features, can be classed as the same type of inhibitor.[73]

The elucidation of the primary structure of hirudin forms made possible the cloning of a cDNA of hirudin[74] as well as the chemical synthesis of the corresponding genes.[75, 76] Production of the protein by genetic engineering methods facilitated structural investigations of the inhibitor in solution, the structural elucidation of the complex formed between thrombin and hirudin by X-ray structural analysis of protein crystals, and kinetic studies of the thrombin/hirudin complex formation using mutants of hirudin. In the following, hirudin mutants are designated as XnY-hirudin, where the amino acid residue X (single letter nomenclature) is replaced by the amino acid residue Y at position n.

2.1. The Three-Dimensional Structure of the Thrombin/r-Hirudin Complex

Based on its homology to trypsin and chymotrypsin, thrombin belongs to the class of the trypsin-like serine proteases. Like trypsin, thrombin has a specificity for basic amino acid residues in the P1 position of substrates. It is capable of cleaving a series of small peptide substrates but shows a marked specificity over macromolecular substrates. The structural basis for its substrate specificity was apparent from the three-dimensional structure of thrombin in the complex with the inhibitor D-Phe-Pro-Arg-chloromethyl ketone (PPACK-thrombin) (Fig. 3).[77] The active site with its catalytically active amino acid residues proceeded (see Figs. 3 and 4) from west to east with the binding of substrates from the N to the C terminus. Towards the "east rim", the active site forms a groove, the fibrin(ogen) binding site (FBS). The catalytic triad Ser195-His57-Asp102 does not differ from the other trypsin-like serine proteases; however, insertions as regards to trypsin lead to a deepening and narrowing of the structure of the active site. This is limited towards the "north rim" by the (Tyr-Pro-Pro-Trp)-loop and towards the "south

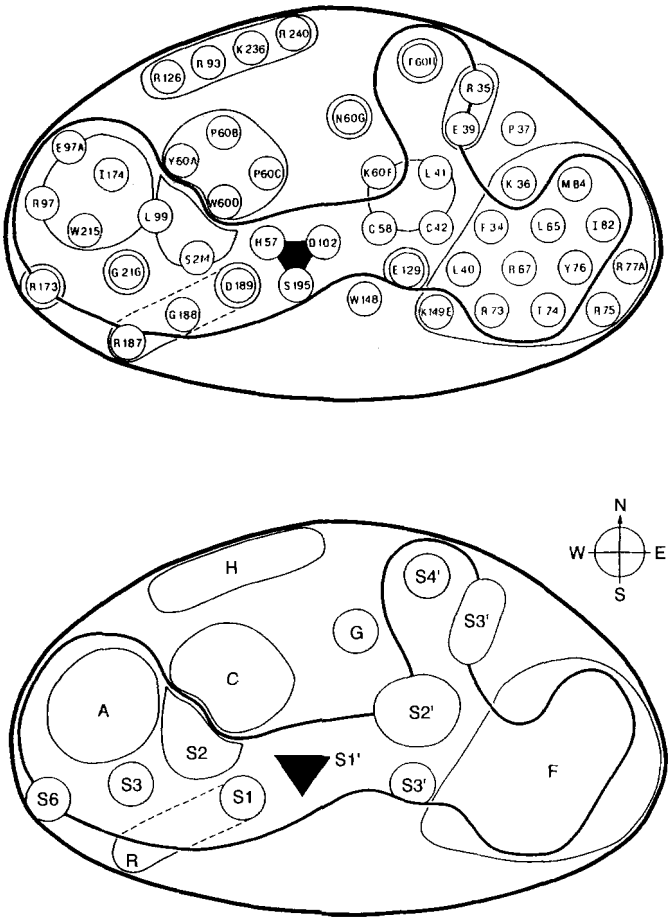

Fig. 4. Schematic representation of binding sites on the thrombin surface, from ref.[106]. Top: Representation of amino acid residues that are involved in the formation of the binding site; bottom: division of the surface into functional areas. ▼ = active site; S1–S6 = N-terminal specificity pockets to the cleavage site; A = aryl binding site; F = fibrin(ogen) binding site; H = assumed heparin binding site; G = glycosylation; S1′–S4′ = assumed C-terminal specificity pockets to the cleavage site; C = chemotactically acting region; R = Arg-Gly-Asp sequence. The compass defines the orientation relative to the active site.

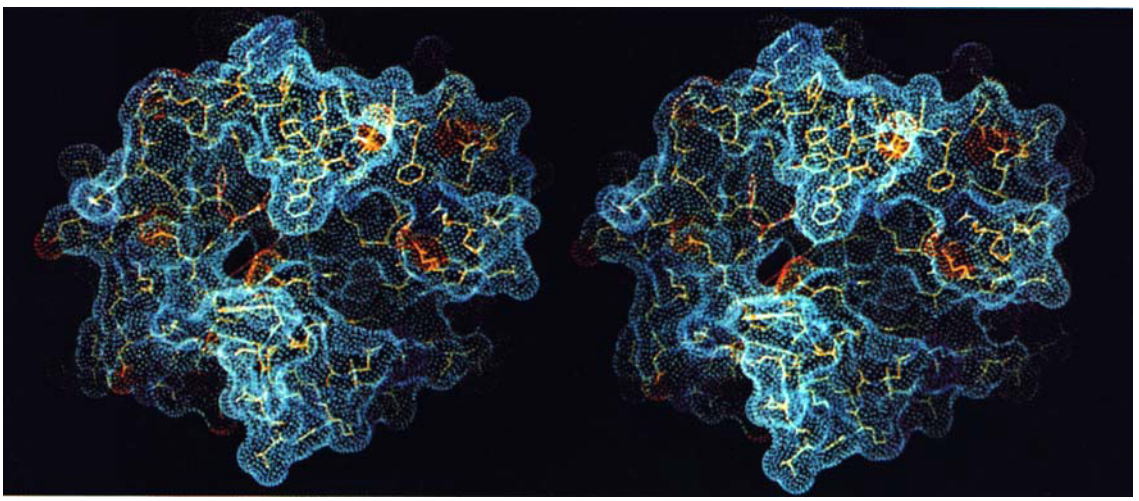

Fig. 3. View into the active site of human thrombin; stereorepresentation from ref.[77]. The molecular surface, represented by points (dot surface), corresponds to the portion of van der Waals radii of surface atoms, which is able to come into contact with solvent molecules (Connolly surface) [141]. The dark blue, orange-red, or light blue surfaces represent basic, acidic, or other amino acid residues, respectively. The peptide-based irreversible inhibitor D-Phe-Pro-Arg-chloromethylketone (orange-red) is bound in the active site. The side chain of the arginine residue of this inhibitor penetrates the specificity pocket S1. The recognition of macromolecular substrates occurs in the fibrin(ogen) binding sites, a groove running along the thrombin surface, which extends along the active site from west to east.

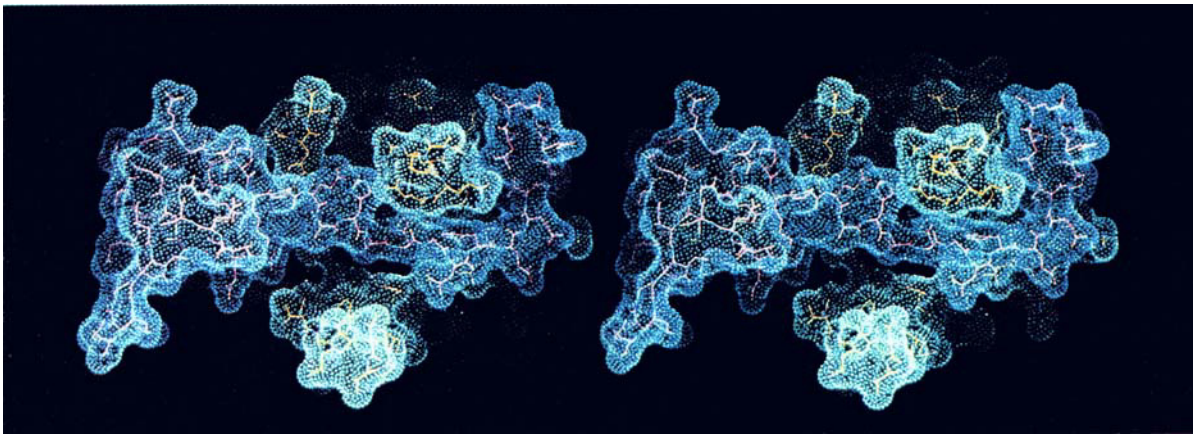

Fig. 5. Stereorepresentation of the structure of the thrombin/r-hirudin complex. A section of the thrombin structure is green, the hirudin structure is shown blue. The N-terminal region of the inhibitor (h-Tyr3 to h-Lys47) folds into a globular domain (left), whilst the C-terminus of the hirudin proceeds into a stretched out form along the FBS of thrombin and ends in a short 3_{10} helix. The orientation of thrombin corresponds to that shown in Figs. 3 and 4.

rim" by the Trp148-loop (Glu146 to Gly149D,[*] also called γ-loop) (Fig. 4). These additional structural elements determine in part the specificity of thrombin through steric exclusion of protein substrates. It was apparent from molecular modeling studies that "canonical protease inhibitors" would collide especially with the rigid (Trp-Pro-Pro-Trp)-loop, giving rise to a weak interaction with thrombin.[78] The primary specificity pocket S1 has an aspartic acid residue (t-Asp189),[**] which forms salt bridges with positively charged side chains of basic P1 residues. The hydrophobic S2 pocket is suitable for accommodating nonpolar residues of intermediate size (Pro, Ile, Ala, Val) and forms another hydrophobic pocket (aryl binding pocket A), which can interact especially with aromatic residues (Fig. 4). In the cleavage of macromolecular substrates such as fibrinogen, interactions with the active site of thrombin are not sufficient; in addition the recognition of the FBS is required.[79–81] These binding sites are formed from an accumulation of positively charged amino acid residues from the peptide chains t-Phe34 to t-Leu41 and t-Lys70 to t-Glu80 (Fig. 4).

In the complexes between serine proteases and inhibitors, which react with each other according to a "canonical pattern", an antiparallel β-sheet forms between the amino acid residues of a peptide loop situated on the surface of the inhibitor (reactive site loop) and the active site of the enzyme. The tertiary structure of this peptide loop is conserved in a family of inhibitors (e.g. Kazal, Kunitz, etc.). The conformation of the "reactive site loop" is practically identical in the free and in the bound form, and it is assumed that stabilization of the conformation by interactions with the core region of the inhibitor leads to stable enzyme/inhibitor complexes.[82] The "reactive site loop" is coordinated like a substrate by the target enzyme. It contains a hydrolyzable peptide bond (P1–P1′), whose P1 amino acid side chain determines the primary specificity of an inhibitor for a protease,[83] since the side chain of the P1 amino acid residue in this case binds in the specificity pocket (S1) of the target protease.[82]

The structure of the thrombin/r-hirudin complex in the crystal shows that from its mode of action, hirudin, in contrast to the canonical inhibitors, is a bivalent inhibitor.[84, 85] Hirudin is in contact with the active site at one end and with the FBS of thrombin at the other end (Fig. 5). In the complex the disulfide-bridged N-terminal domain (residues 1–48) lies above the active site of the thrombin molecule and, thus, prevents substrates gaining access to the active site. The C-terminal chain of the r-hirudin, which is completely disordered in solution,[86,87] adopts a stretched conformation and lies in the long groove on the thrombin surface which forms the FBS.

The N terminus of the inhibitor has essentially the same structure in the complex as in solution (determined by NMR studies).[86, 87] The N-terminal residues h-Ile1[***] to h-Thr4 penetrate the active site of thrombin (Fig. 6), in which the residues from h-Ile1 to h-Tyr3 form a parallel β-sheet with the thrombin residues t-Ser214 to t-Gly219. The free α-amino group of the N terminus of r-hirudin forms hydrogen bonds with the hydroxyl oxygen atom of the t-S195 residue participating in the catalysis and further with the carbonyl oxygen atom of the t-Ser214 residue. The side chain of h-Ile occupies the hydrophobic S2 pocket and the phenyl ring of h-Tyr3 residue fits into the aryl binding site (Fig. 6). Remarkably, the specificity pocket S1 remains unoccupied. Although h-Thr2 is situated at the entrance to this pocket, the side chain is too small to penetrate this pocket significantly. Intramolecular hydrogen bonds between the ε-amino group of the h-Lys47 residue and h-Thr4 or h-Asp5 could restrict the degrees of freedom of the five N-terminal residues. The N-terminal tripeptide is orientated in its position in the complex by a salt bridge between h-Asp5 and t-Arg221-A. A large proportion of the N-terminal domain does not interact with α-thrombin. Of the 48 N-terminal residues 15 are directly involved in 103 interactions of less than 4 Å; 41 of these intermolecular contacts[78] are attributed to the N-terminal tripeptide of the hirudin.

[*] The nomenclature of the amino acid residues is given according to ref.[77]. The numbering refers to the topologically equivalent residues of chymotrypsin. With insertions as regards to chymotrypsin one starts with the corresponding position (e.g. Thr149), assigning this number to the corresponding residue (here Gly) and add A, B, C, and so on (according to the position within the inserted amino acid residues, here D).

[**] The prefix t- denotes the amino acid residues of thrombin.

[***] The prefix h- denotes amino acid residues of hirudin.

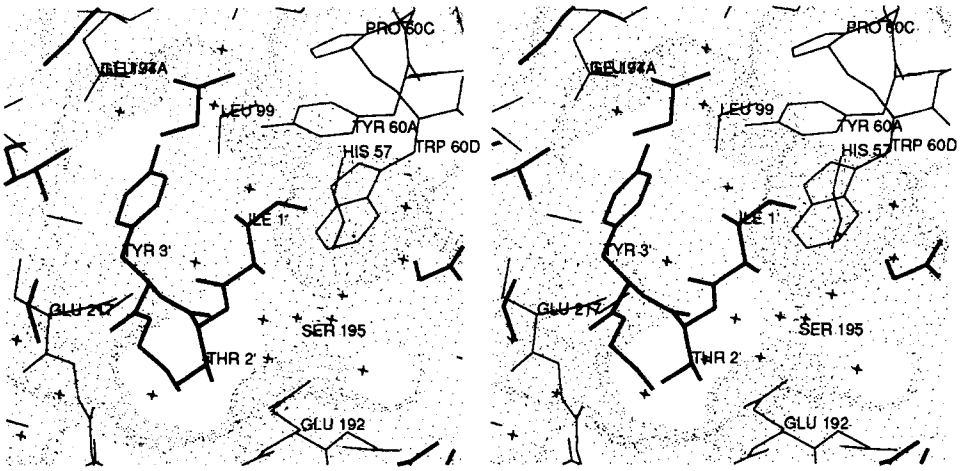

Fig. 6. The hirudin region h-Ile1–h-Thr4 (thick lines; nomenclature of the hirudin residue see Fig. 4) surrounded by amino acid residues of thrombin (thin lines), which are shown with the Connolly surface (see Fig. 3) and water molecules (crosses). The white area around h-Thr2 marks the entrance to the S1 pocket, which in the thrombin/r-hirudin complex is not occupied by an amino acid side chain of the inhibitor. The amino acid residue h-Ile1 occupies the hydrophobic S2 pocket of thrombin, its α-amino group is in hydrogen bonding distance to t-His57 Nε and t-Ser195 Oγ. Stereorepresentation from ref.[82]

The C-terminal region of the r-hirudin present in a stretched conformation (3.7 nm) with the positions 48–65 occupies the FBS (Figs. 5 and 7). A knick in the peptide chain at h-Asp55 causes a division into two regions of 1.8 nm and 1.9 nm in length. The C-terminal peptide chain begins with a polyproline-II helix of h-Pro46 to h-Pro48 followed by the residues h-Glu49 to h-His51, which form salt bridges and hydrogen bonds with thrombin. The following three residues cannot be described in more detail due to the difficulty in interpreting the electron density map. In this peptide segment there are 33 intermolecular contacts of less than 4 Å with thrombin. The conformation of the residues h-Asp55 to h-Pro60 is likewise stretched (1.5 nm long). The C terminus ends with a 3_{10} helix, which is formed from the amino acid residues h-Glu61 to h-Leu64. The contacts with the enzyme stem partly from ionic interactions between the acidic (h-Asp55, h-Glu57, h-Glu58, h-Gln65) and the basic residues of the FBS, and partly from nonionic interactions (h-Phe56, h-Ile59, h-Pro60, h-Tyr63, h-leu640). Of the 11 amino acid residues of the C terminus, eight residues form 81 contacts of less than 4 Å with thrombin.

The structure of the thrombin/r-hirudin complex is assigned to a completely novel bivalent type of inhibitor. Hence, it was also of biochemical interest to investigate more closely the complex formation.

2.2. The Formation of the Thrombin/Hirudin Complex

Studies to determine the role of individual amino acid residues or of structural areas of the molecule for the complex formation were partly carried out prior to X-ray structural analysis with r-hirudin mutants and hirudin fragments, chemically or enzymatically modified forms of thrombin, peptide antibodies against parts of the thrombin and chemical modifications of the amino acid residues of enzyme/inhibitor complexes. The studies provided a schematic picture of the formation of thrombin/hirudin complexes. In the following, studies shall be discussed in the context of the structure of the complex that are a prerequisite for an understanding of the formation mechanism.

Natural hirudin reacts quickly with α-thrombin ($k_{on} = 4 \times 10^8\ M^{-1}s^{-1}$) with the formation of 1:1 equimolar complexes ($K_i = 2.7 \times 10^{-14}$ M).[88] Hirudin can be regarded as a thrombin-specific inhibitor, even if recently the inhibition of the clotting enzyme factor Xa was determined to have an inhibition constant K_i of approximately 3×10^{-3} M.[89]

Studies of the kinetics of the thrombin/hirudin complex formation show that hirudin is a competitive inhibitor.[88] This is in agreement with the crystal structure of the complex, which excludes a simultaneous binding of the substrate and the three N-terminal residues of hirudin (see Fig. 5).[84] Since the apparent association rate constant, k_{on}, is dependent on the ionic strength and not, however, on the substrate concentration, a mechanism with at least two reaction steps was postulated.[88, 90] The elucidation of the reaction steps was achieved by stopped-flow measurements with r-hirudin.[91] The first and rate-determing step involves the binding of the C terminus of hirudin to thrombin. A rate constant of $2.9 \times 10^8\ M^{-1}s^{-1}$ was determined for this bimolecular step. After a change in conformation the N terminus reacts with the active site in the third step. For the

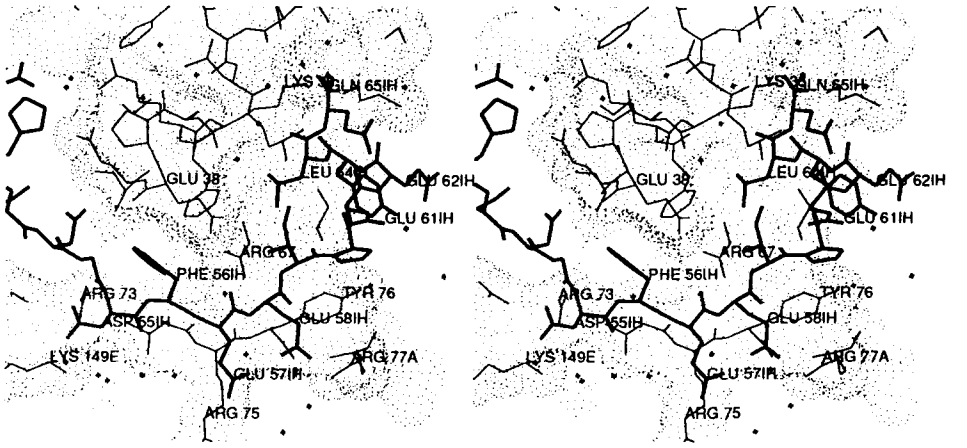

Fig. 7. Fibrin(ogen) binding sites of thrombin (thin lines) and C-terminal region of hirudin (thick lines) in the thrombin/r-hirudin complex, stereorepresentation from ref.[82]. The structure of thrombin is shown together with the Connolly surface.

decomposition of the complex the dissociation of the N terminus is rate-determining.

The free energy of binding of the reaction between r-hirudin and α-thrombin ($\Delta G_B = -75$ kJ mol^{-1}) virutally consists of the sum of the free energy of binding of the N terminal ($\Delta G_B = -42$ kJ mol^{-1}) and C terminal ($\Delta G_B = -32.6$ kJ mol^{-1}) hirudin fragments hirudin(1–51) and hirudin(52–65).[79, 81] That is, the binding of one fragment does not exert a large cooperative effect on the binding of the other fragment.[79, 81] However, C-terminal peptides modulate the amidolytic activity of the thrombin against tripeptidyl substrates.[79–81, 92] The peptides, depending on length and substrate, act as hyperbolic inhibitors or activators, that is catalytically active ternary enzyme/substrate/peptide complexes are formed. In the presence of the C-terminal peptide hirudin(52–65), the Michaelis constant for the tripeptidyl substrate is two to fourfold lower, and interaction with the N-terminal fragment is favorable by 2–3 kJ mol^{-1}.[79] The binding of C-terminal hirudin peptides leads to conformational changes in the γ-loop of thrombin, just as does the binding of "active site"-directed inhibitors.[93] The communication between the FBS and the active site by conformational changes in the γ-loop has, however, yet to be proven.[93] In the cleavage of fibrinogen, the C-terminal peptides behave as competitive inhibitors, which points to a mutually exclusive interaction with the FBS.[80, 81] N-terminal fragments of hirudin behave, as would be expected, as competitive inhibitors of fibrinogen cleavage and of tripeptidyl substrates.[79, 81]

Studies with shortened forms of hirudin already indicated the significance of an intact N terminus for the complex formation.[94] The contribution of the N terminal three amino acid residues for the complex formation were investigated by site-directed mutagenesis.[95–97] The two N-terminal positions, which in all forms of natural hirudin have branched hydrophobic amino acid residues, tolerate the exchange of amino acid residues to varying degrees. A comparison of the free energies of binding of the natural hirudins with those of the corresponding double mutants indicated that there was no cooperative effect in the binding of both the residues,[97] which would have been expected in the case of an interaction among the residues, or if the reaction mechanism had altered. Substituting the two N-terminal valine residues with glycine causes the free energy of binding to be lowered by 20.6 kJ mol^{-1} and may be considered to represent the maximal contribution to the complex formation (Table 2). Remarkably, the V2R mutant, which as a result of the lowering of the dissociation rate constant, has a K_i value one order of magnitude lower than that of r-hirudin. Based on molecular modeling studies one can assume that the arginine residue penetrates the specificity pocket and forms a salt bridge with t-Asp189.[97] One should, on the grounds of homology, postulate this interaction for the naturally occurring thrombin inhibitors from *Hirudinaria manillensis* and *Haemadipsa sylvestris* [73] (Fig. 2B). The h-Tyr3 residue forms a contact with the aryl binding pocket, which is formed from the t-Tyr60-A, t-Ile174, t-Trp60-D, and t-Leu99 residues. Furthermore, an interaction is observed with the aromatic system of t-Trp215, which is arranged perpendicular to the h-Tyr3 residue. The free energy of binding of the Y3A mutant, reduced by 12.6 kJ mol^{-2} (Table 2), underlines the significance of this aromatic residue,

[a] The change in the free energy of binding for complexes between thrombin and hirudin (designated here as the free energy of binding ΔG_B) was calculated according to the Equation $\Delta G_B = RT\ln K_i$. We have defined the change of in the free energy of binding for a particular mutant ($\Delta\Delta G_B$) relative to the free energy of binding for r-hirudin. The difference in the free energy of binding for a double mutant at positions x and y can be correlated by the Equation $\Delta\Delta G_{B(x,y)} = \Delta\Delta G_{B(x)} + \Delta\Delta G_{B(y)} + \Delta\Delta G_I$ with those of the corresponding single mutants [142]. $\Delta\Delta G_I$ is a measure of the extent of cooperation between the two sites and can be either positive or negative. [b] The values for r-hirudin from ref.[96] are given in parentheses.

which is conserved in almost every known form of hirudin up until now. Y3W- and Y3F-hirudin even show an improved affinity for thrombin (Table 2).[96]

The role of acidic amino acid residues of the C terminus of hirudin was elucidated by enzyme kinetic studies with hirudin mutants. Recombinant hirudins lack a sulfate ester at the h-Tyr63 position, which is manifest in a tenfold reduction of the equilibrium dissociation constants (see Table 2).[88, 98] Enzymatic phosphorylation[99] or sulfation[100] of h-Tyr63 restores the inhibitory properties. The negative charges of the h-Glu57, h-Glu58, h-Glu61, and h-Glu62 residues were substituted in turn with glutamine residues by site-directed mutagenesis. The contribution of the ionic and nonionic interactions to the free energy of binding was determined from the dependence of the equilibrium dissociation constants of the ionic strength for each of the mutants. The nonionic contribution is practically identical for every mutant (62.2–64.1 kJ mol^{-1}), whereas the ionic contribution decreases linearly with the decrease in the number of charges (29.6–8.9 kJ mol^{-1}). At zero ionic strength the ionic contribution constitutes approximately a third of the free energy of binding and approximately a fifth under physiological conditions.[101] The association rate constants for conditions, under which only nonionic interactions should result in a contribution, is expressed by the value $k_{on\infty}$. This value is virtually constant for all of the hirudin mutants and, thus, suggests that through the mutations no great changes in the tertiary structure of the inhibitor, which influence the interaction with thrombin, should have occurred (Table 3).[101] The contribution of the ionic interactions to the total free energy of binding is presumably, however, of secondary importance. Kinetic studies with mutants of hirudin, whose acidic amino acid residues between positions 55 to 65 were substituted, verify the dependence of the rate constant, k_{on}, on the number of charges in the molecule, which is expected for ionic interactions (Table 4).[90, 102] The decrease in the free energy of binding for each negatively charged group lies between 2.3 and 5.9 kJ mol^{-1}. Mutations at position 61 and 62 result in additive effects and do not indicate any interaction between these two residues. However, mutations at positions 57

[a] The free energy of binding (ΔG_B) is calculated from the sum of the free energy of binding for nonionic ($\Delta G_{B(nio)}$) and ionic ($\Delta G_{B(io)}$) interactions. Equilibrium dissociation constants of the inhibitors were determined at ionic strengths (I) between 0.05 and 0.65. For an evaluation of the data see ref.[101]. [b] In the case of ionic interactions the rate constants of association (k_{on}) are also dependent on ionic strength. For an evaluation of the data see ref.[101].

and 58 yield a nonadditive effect, which can be accounted for by a change in the reaction mechanism or by large conformational changes of approximately 0.7 Å, which are necessary for the formation of the ion pair between h-Glu57 and t-Arg77A.[102] These results appear initially not to be in agreement with the X-ray structure, from which only intermolecular interactions between h-Asp55, h-Glu57, and h-Glu58 are apparent.[78, 84, 85, 103] Calculations of electrostatic field strengths clarify, however, that the C terminus of the hirudin and the FBS of the thrombin forms complementary electrostatic fields, whose interaction contributes to the binding energy without necessarily having to form direct ionic contacts.[82, 104] In this case the negatively charged amino acid residues of the C terminus could exert a kind of docking function, through which the number of collisions that do not lead to the product are reduced and the almost diffusion-controlled rate of complex formation is facilitated.[101] Despite the dominant function of the acidic residues of the C terminus for the thrombin/hirudin complex formation, the lowering of the free energy of binding by (in total) approximately 10 kJ mol^{-1}, when mutating h-Phe56, h-Pro60, and h-Tyr63 to alanine (see Table 4), shows clearly the contribution of nonpolar interactions of the C terminus to the total free energy of binding.[105]

Based on the described and until now unique pathway of the complex formation between an inhibitor and a serine protease, and the fact that hirudin shows neither a sequence nor a topological homology to the other inhibitors of the serine proteases, this inhibitor is to be regarded as having the basic structure for a new family of serine protease inhibitors.[65]

3. The Development of Hirudin Mimetics

Since the three-dimensional structures of α-thrombin and of complexes of α-thrombin and inhibitors are available, and the enzyme plays the central role in the clotting process, this proteinase is a suitable candidate for the development of antithrombotic active substances. Inhibitors of thrombin can be divided into peptide-based and nonpeptide-based compounds as well as those which are directed against the active site and/or the fibrin(ogen) binding sites.[106] Investigations on C-terminal peptides of hirudin that react with FBS have led to the synthesis of potent antithrombotic peptides and prompted the development of bivalent peptides, which react with both the active site and the FBS.

3.1. C-Terminal Peptides of Hirudin

The participation of the C-terminal amino acid residues of hirudin in the thrombin/hirudin interaction could already be deduced from the complete loss of the inhibitory activity (under the conditions of measurement) in the proteolytic decomposition of up to 22 of the C-terminal amino acid residues.[66, 94] The synthetic peptide N^{α}-acetylhirudin(46–65) (**3**; Table 5), 21 amino acids in length, is capable of inhibiting the cleavage of fibrinogen in a clotting test, without blocking the active site.[107]

Table 5. Inhibition of human thrombin by hirudin and C-terminal hirudin peptides.

[a] IC_{50} values give the concentrations of inhibitor which double the clotting time. [b] Values for bovine α-thrombin.

This peptide was shortened to a length of eleven amino acid residues (hirudin(55–65) **5a**) or twelve amino acid residues (hirudin(53–64) **6**), whilst retaining the anticoagulatory activity (Table 5).[108–110] In the case of peptide **5a** the aromatic amino acid residue Phe56 is particularly important for the activity,[108] although this amino acid residue in hirudin only contributes 1.9 kJ mol^{-1} to the free energy of binding.[105] Sulfation of the tyrosine residue of **6** (the sulfated peptide is designated as hirugen **7**) enhances the anticoagulatory effect by a factor of 12.[110] With the aid of hirugen the interaction of the tyrosine sulfate ester with thrombin was elucidated for the first time.[111] The oxygen atoms of the sulfate group surprisingly do not form an ion pair with the charged groups, but either form a hydrogen bond directly to the t-Tyr76 or t-Ile81 residue or indirectly

through water molecules. Otherwise, the structure of the hirugen is almost identical to that of the hirudin(53–64) (**6**) in the thrombin/r-hirudin complex.

Conformational restriction of peptides through cyclization can, on the grounds of entropy, lead to the increase of its biological activity and to protection from proteolytic cleavage. Structure–activity studies on the peptide **5a** did not indicate any critical role of the amino acid residues Asp55, Glu58, Glu61, Glu62, Tyr63, Leu64, and Gln65 for the activity of this peptide.[108] The residues 58 and 61 were, based on molecular modeling studies, selected for the cyclization with formation of a lactam ring.[112] The amino acid residue Glu61 was replaced by either lysine or ornithine, and the residue 58 was replaced by glutamic acid or aspartic acid. This approach enabled the investigation of the ring-size dependence (16- to 18-membered lactam rings) of the antithrombotic activity of cyclized peptides. Amongst these peptides the *cyclo*-(Glu58, Lys61)-[hirudin(55–65)] with an 18-membered lactam ring is the most active. These results confirmed calculations, according to which the 18-membered ring preferentially adopts one conformation, which is similar to that in the bound state.[112] The biological activity of this peptide is, however, only higher by a factor of 2–4 than that of the corresponding linear peptide. One possible explanation might be found in the observation that C-terminal peptides already adopt an ordered structure in solution, which is similar to that in the bound state.[113] The stability of the cyclized peptides to proteolytic decomposition by plasma proteases as well as by pepsin, trypsin, and chymotrypsin is considerably enhanced. This protection is also partly manifest in the exocyclic peptide bonds of the inhibitors.[112]

3.2. Bivalent Thrombin Inhibitors Based on Hirudin Peptides

The C-terminal hirudin peptides indeed, possess structural elements for the specific recognition of thrombin; however, they cannot interact with the active site. Inhibitors, which utilize additional binding sites outside of or in conjunction with the active site, should have enhanced specificity and activity. Therefore the aim was to synthesize potent bivalent thrombin inhibitors by coupling peptides, which show a) a thrombin-specific recognition sequence and b) an inhibition of the active site of thrombin.

The similarity of the hirudin sequence Thr(45)-Pro-Lys-Pro(48) to the thrombin cleavage site Thr(154)-Pro-Arg-Ser(157) in the prothrombin molecule,[63] and the occurrence of the sequence D-Phe-Pro-Arg-X in thrombin inhibitors, which interact with the active site (X represents a non-cleavable bond), prompted the idea to substitute the amino acid residues Thr45 with D-Phe and Lys45 with Arg in the peptide **3**.[92] The residues 55–65 should facilitate the first interaction of this inhibitor with the FBS and support the intramolecular reaction with the active site. The two separate binding sites are separated by four amino acid residues in the substituted peptide. Whilst N^{α}-acetylhirudin(55–65) (**5b**) and D-Phe-Pro-Arg-Pro show IC_{50} values of 3.5 (see Table 5) and 250 μM, respectively, in the clotting test with bovine α-thrombin, coupling of the two binding sites across a spacer (peptide **8**, Table 6) effects a lowering of the IC_{50} values to 70 nM (4.1 nM for the human enzyme).[92] The free energy of binding of the two inhibitors behaves additively in the coupling as has already been described for the hirudin amino and carboxy terminal fragments (see Section 2.2). Peptide **8** is a competitive inhibitor of thrombin-mediated cleavage of tripeptidyl substrates with K_i values of 31 nM and 2.8 nM for bovine and human α-thrombin, respectively (Table 6).[92] Peptides of the general formula D-Phe-Pro-Arg-Pro-$(Gly)_n$-[hirudin(53–64)] (hirulog **9**) exhibit a comparable inhibitory activity with K_i values in the nM region.[114] The inhibitory effect is dependent on the number of glycine residues n (n = 2, 4, 6, 8). Hirulog compounds with n = 4–8 glycine units have K_i values of 2.3–3 nM, whilst a shorter spacer (n = 2) effects an increase in the K_i value of up to 64 nM. The specificity of hirulog-1 (n = 4) for thrombin was confirmed by studies on the inhibition of the enzyme factor Xa, plasmin, and trypsin; their amidolytic activity is scarcely influenced by hirolog-1, even with a 1000-fold molar excess. The X-ray structure analysis of the thrombin/hirulog-1 complex[111] showed that the interactions of individual functional regions of the bivalent inhibitor corrrespond to those of the individual components in the complex.

Table 6. Inhibition of human thrombin by peptides, which mimic the reaction mechanism of hirudin. The bivalent peptides deactivate the enzyme by interactions of the N-terminal amino acid residues (shown in three letter code) with the active site and blocking the FBS by the acidic C-terminal amino acid residues (the positions on the hirudin are given). These regions are coupled together by a suitable spacer (the amino acid residues are given in single letter code).

[a], [b] see Table 5.

Although the P1′ amino acid residue constitutes an imino amino acid, peptides **8** and **9** are slowly hydrolyzed by thrombin.[92, 115] The reversal of the configuration at the proline residue 48, indeed, leads to proteolytic resistance of the Arg–D-Pro peptide bond; however, the K_i value (46 nM) and the IC_{50} value (45 nM) are enhanced.[92] Consequently, inhibitors with a noncleavable Arg–X bond were, thus, developed. Peptide **10** (see Table 6) was synthesized based on peptide **8**;[116] formally in this compound the peptide link of the Arg–X bond was replaced with a noncleavable ketomethylene functionality. The P1′ residue is isosteric with a glycine residue. Peptide **10** is a competitive thrombin inhibitor as regards to the cleavage of tripeptidyl substrates with a K_i value of 370 pM (see Table 6).

A similar procedure was selected in the preparation of hirulog-3 (**11**) starting from **9**: here a β-homoarginine residue, in which the peptide bond is displaced by a methylene group, was incorporated.[117] The three-dimensional structure of the thrombin/hirulog-3 complex [118] shows that the interactions of the D-Phe-Pro-(β-homoArg) portion of the hirulog-3 ressembled those of the D-Phe-Pro-Arg sequence of the PPACK

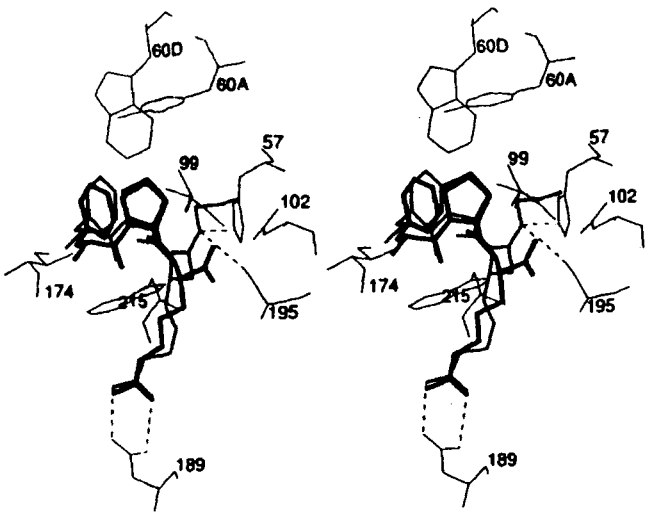

Fig. 8. Comparison of the interactions at the active site of thrombin (thin lines) between D-Phe-Pro-(β-homoArg)-Gly sequence in the thrombin/hirolog-3-complex (medium thickness) and the D-Phe-Pro-Arg sequence in the PPACK-thrombin and the thrombin/hirulog-1 complex (thick lines); stereorepresentation from ref.[118]. Hydrogen bonds are represented as dashed lines. The numbering of the amino acid residues of thrombin is given in accordance with [*] on page 872.

thrombin structure (Fig. 8). The guanidinyl group of the β-homoarginine residue forms a hydrogen bond-mediated ion pair with the t-Asp189 residue of the S1 pocket of thrombin comparable with that of the corresponding arginine residue. The methylene group of the β-homoarginine residue effects a displacement of the peptide chain by approximately one C–C bond length and thereby protects the peptide bond from nucleophilic attack by the t-Ser195 residue. The C terminii of hirulog-3 (**11**) and of r-hirudin are practically identical in structure in terms of their complexes with thrombin, whereas there is a mean structural deviation of 6 Å for the linker sequence (Fig. 9). The chain of the pentaglycine linker sequence of hirulog-3 is in much closer contact with thrombin than the corresponding r-hirudin unit. The S1′–S4′ binding sites of thrombin were identified for the first time from this structure: The P1′ amino acid side chain is restricted to small residues. The replacement of the P1′ amino acid Gly in hirulog-3 by the much larger Val residue reduces the free energy of binding by 8.6 kJ mol^{-1}, and supports this finding.[117] Alanine, serine, and threonine residues could presumably interact better than glycine, and small hydrophobic residues such as valine, leucine, and isoleucine could fill the S2′ pocket very well. The S3′ and S4′ pockets cannot be clearly described. Protein substrates of thrombin have either an arginine residue, or an amino acid with an amide functionality in the side chain or with a small side chain (e.g. Ser, Ala, Gly) at the P3′ position. However, the question still remains open whether natural substrates of thrombin are similarly in very close contact with thrombin in the P1′–P2′ region as the pentaglycine linker sequence of **11**. Since the P1′–P4′ residues in hirulog-3 are all glycine residues which can only undergo very weak interactions with thrombin, again from the thrombin/hirulog-3 structure new aspects for optimizing the antithrombotic activity of bivalent peptide inhibitors came to light.

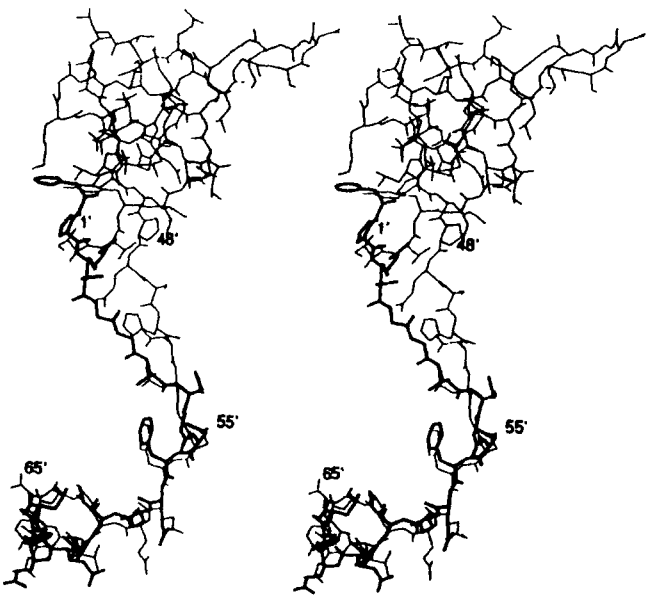

Fig. 9. Comparison of the structures of r-hirudin [84] (thin lines) and hirulog-3 [118] (thick lines) in their complexes with thrombin (stereorepresentation). Only the structures of the inhibitors are shown.

In this section the development of selective bivalent thrombin inhibitors based on hirudin has been described. In vitro hirudin and the thrombin-specific bivalent hirudin analogues of the compound types **9** to **12** possess similar anticoagulatory properties (see Table 6). Since these peptides, like hirudin, inhibit the activity of the protease thrombin and are presumably less antigenic than hirudin, they have aroused great interest in the last two to three years due to their clinical relevance and have led to the development and investigation of pharmacological properties of hirudin mimetics.[61]

4. Pharmacological Properties of Direct-Acting Thrombin Inhibitors

Experimentally produced thrombuses are prevented with hirudin (natural and recombinant) and hirudin analogues. This is applicable in vivo for venous thrombuses as well as for arterial occlusions.[60, 61, 119] What are the differences that make hirudin and hirudin mimetics (i.e. direct-acting thrombin inhibitors) particularly advantageous anticoagulants compared to heparin, which is currently the most important class of compound in the area of anticoagulants?

As has already been described in detail in this review hirudin and hiruidin mimetics react directly with thrombin. In contrast to this the effect of heparin is to interact with the plasma proteinase inhibitor antithrombin III (AT III). Heparin acts here as a cofactor and merely accelerates the complex formation of AT III with the clotting factors IXa, Xa, XIa (a = activated factor) or thrombin by several orders of magnitude.[120–123] Direct-acting inhibitors have the following advantages. 1) As the use of anticoagulants principally interferes in the clotting process, there is also the risk of bleeding. In studies on humans and animals an increase in the bleeding time was not observed in therapeutic applications of hirudin and hirudin mimetics;[59–61] in addition the direct-acting thrombin inhibitors have no effect on the blood platelets. During the application of

heparin, on the other hand, bleeding and a reduction in the number of thrombocytes presented the most important and most common complications.[124, 125] 2) Heparin is a heterogeneous preparation of glucosaminoglycans (a review is given in ref. [126]). As a result of its indirect mode of action heparin activity is coupled to the availability of the plasma protease inhibitors AT III or heparin cofactor II. Hirudin and hirudin mimetics, on the other hand, directly inhibit thrombin activity. They can, thus, be employed as effective anticoagulants even with a deficiency of AT III (e.g. disseminated intravascular coagulation) and their application does not lead to the consumption of endogenous inhibitors. 3) During the formation of a clot, a part of the α-thrombin binds to the fibrin and is trapped by the clot.[127] This thrombin is not accessible to heparin/AT III complexes and after being released from the clot has further proteolytic activity against low molecular weight and macromolecular substrates (e.g. fibrinogen).[128, 129] The direct-acting thrombin inhibitors hirudin and hirulog, however, inactivate the thrombin bound up by the clot.[127, 129, 130] 4) Neutralization of heparin by platelet factor 4, histidin-rich glycoprotein, or vitronectin as a result of an increased plasma level, or increased concentration at the site of the clotting process, could explain the limited effect of heparin.[131] The effect of direct-acting thrombin inhibitors is, on the other hand, not influenced by these proteins.

Although hirudin and r-hirudin are foreign proteins for humans and animals, they are tolerated well and do not lead to any detectable antibody formation.[132] Hirudins have a high bioavailability with simple pharmacokinetics. After a bolus injection the distribution phase lasts between 10 to 15 minutes, and a half-life of 0.5 to 1.5 hours was determined for the elimination.[60, 119, 133] Hirudins are distributed in the extracellular space and are excreted by the kidneys. 75–95% of the inhibitor is found in the urine in an unchanged and non-metabolized form.[134] Hirudins lead to a dose-dependent prolongation of the clotting parameters with intravenous as well as subcutaneous application.[59, 60, 119] The pharmacokinetic properties of hirulog-1[61] are similar. Hirulog-1 likewise effects a dose-dependent prolongation of the clotting parameters after intravenous or subcutaneous application and is eliminated by the kidneys after a half-life of approximately 0.6 hours. Hirulog is tolerated well and no antihirulog antibody formation is observed.[61]

The employment of direct-acting thrombin inhibitors is intended for the following clinical situations which have been proven in studies with animals: 1) prophylaxis and postoperative treatment of venous thrombosis and diffuse microthrombosis; 2) prevention of arterial thrombosis especially in heart surgery; 3) protection from reocclusion in fibrinolysis therapy and angioplasty; 4) protection from thrombotic occlusions in microsurgery; 5) avoidance of proliferation of smooth muscle cells of damaged vessel walls (restenosis prophylaxis) and 6) thrombosis prophylaxis during hemodialysis and other extracorporeal blood circulation (e.g. heart–lung machines).

Problems in connection with the clinical use of hirudin and hirudin mimetics can be seen in the choice of tests for monitoring the status of clotting and the availability of a hirudin antagonist. It must be determined whether measurement of the activated partial thromboplastin time (APPT), the activated clotting time (ACT), the thrombin time (TT), or thrombin inhibition in a chromogenic test give a correlation to the hirudin concentration or to the clotting status. These methods must be validated for this purpose. As antagonists of thrombin inhibitors, prothrombin complexes, monoclonal antibodies, factor VIIa, or VIIIa will be discussed, whose application remains to be assessed against the fast normalization of the clotting parameters when the inhibitor dose is stopped. To emphasize the possible advantages of the clinical application of direct-acting thrombin inhibitors, the results of some thrombosis models are presented.

Successful coronary thrombolysis depends on a fast recovery and maintenance of the blood flow in the region affected by the infarct. In tPA-induced thrombolysis in an experiment with rats the influence of thrombin inhibitors on the time until lysis of the clot and on the number of reocclusions during infusion of the inhibitor was determined.[135] Clot formation was caused by stenosis in the distal aorta after removal of the endothelial. After inducing thrombolysis with r-tPA (1 $mg\,kg^{-1}$ as a bolus injection) followed by r-tPA infusion (1 $mg\,kg^{-1}h^{-1}$ for 30 minutes) isotonic sodium chloride solution or a solution of the inhibitor (heparin, r-hirudin, or hirulog-1) were administered to the animals, in concentrations which led to a three- to fourfold enhancement of the activated partial thromboplastin time (APTT). Whereas the direct inhibitors significantly reduced the time for the lysis, heparin has no effect on the number of reocclusions during the time of observation. In the case of r-hirudin and hirulog no reocclusions occurred. It is assumed that the superior effect of direct-acting thrombin inhibitors stems from the inhibition of clot-bound thrombin, whilst in the case of heparin the thrombin released from the clots causes both the activation of blood platelets and the plasma clotting systems. In a thrombolysis model with streptokinase in dogs the influence of heparin and r-hirudin on reperfusion and reocclusion and remaining clot material was examined.[136] Whilst no recanalization was observed in the control animals, r-hirudin and heparin dose-dependently support the action of streptokinase. In the administration of r-hirudin or heparin in concentrations, which lead to a twofold prolongation of the APTT, r-hirudin shows, in contrast to heparin, a significantly higher occurrence of reperfusion (in eight out of eight animals (100%) in contrast to one out of eight animals (12%)), a shorter time up to reperfusion (33 min as opposed to 59 min), a longer lasting effect of reperfusion (106 to 10 min), and less remaining clot material. These studies were undertaken under conditions which only slightly influenced the clotting time, but did not influence the bleeding time.[136] However, the clinical relevance of these findings will only become apparent after the application of direct-acting thrombin inhibitors in humans.

The increase in the size of thrombuses in patients with venous thrombosis is as a result of the adhesion of fibrin onto already existing clots. The expansion of clots is supported by circulating and clot-bound thrombin. The development of such thrombuses can be completely inhibited by r-hirudin.[137] In a study on rabbits it was shown that r-hirudin not only effectively inhibited the enlargement of thrombuses, but this effect lasted for nine hours after infusion of r-hirudin, whilst the clotting parameters (APTT, TT) reach normal levels already 1.5 hours after infusion of the inhibitor.[138] In addition, experiments carried out in vitro

can only be interpreted by the fact that the far reaching and long lasting effect through plasma elimination again stems from the inhibition of clot-bound thrombin.

Clinical studies support the finding obtained from the animal experiments that direct-acting thrombin inhibitors have a better antithrombotic effect than heparin.[48] Advantageous application and dosage in humans and careful analysis of the data is to be determined in future studies.

5. Summary and Outlook

In the present review highly specific substances of bloodsucking parasites have been described, which specifically interfere in the complex clotting and fibrinolytic processes. The selective thrombin inhibitor hirudin from the leech *Hirudo medicinalis* belongs to this group of natural products. The structural data and structure–activity relationships of the thrombin/hirudin complex formation have been summarized, which has allowed the design and synthesis of novel hirudin derivatives.

These substances of bloodsucking parasites can also help to deepen our knowledge about the significance of individual reaction steps in blood clotting and fibrinolysis for hemostasis and thrombosis. Thus, for example, by employing hirudin or hirulog-1 for deep arterial injuries the thrombin dependency of arterial thrombotic occlusions was documented.[61] The employment of hirudin and of the specific factor Xa-inhibitor r-TAP in a thrombolysis model with r-tPA revealed that both clot-bound thrombin and active prothrombinase complexes contribute to the thrombogenicity of platelet-rich clots.[62]

The knowledge of the mode of action of the specific components of bloodsucking animals can, moreover, be useful when making specific changes to endogenous proteins. The thrombin-specific inhibitor rhodniin from the bug *Rhodnius prolixus* (see Table 1), based on its primary structure, belongs to the class of canonical proteinase inhibitors.[139] If this hypothesis should be confirmed, the results from structure–activity relationships of this leech protein could possibly be used for implementing specific changes to endogenous canonical inhibitors.

The successes outlined in the description of the hirudin mechanism, the resulting development of hirudin mimetics, and the obvious therapeutic advantages of direct-acting thrombin inhibitors should encourage us to intensify research in the area of natural products from bloodsucking parasites. A possible application of this research lies in the discovery of new proteins and the elucidation of unexpected mechanisms. Such molecules could serve as new lead structures and, as in the case of hirudin and hirudin mimetics, stimulate the specific development of better and safer anticoagulants.

I am very grateful to Priv.-Doz. Dr. W. Bode (Max-Planck Institut für Biochemie, Martinsried) for the preparation of the color illustrations.

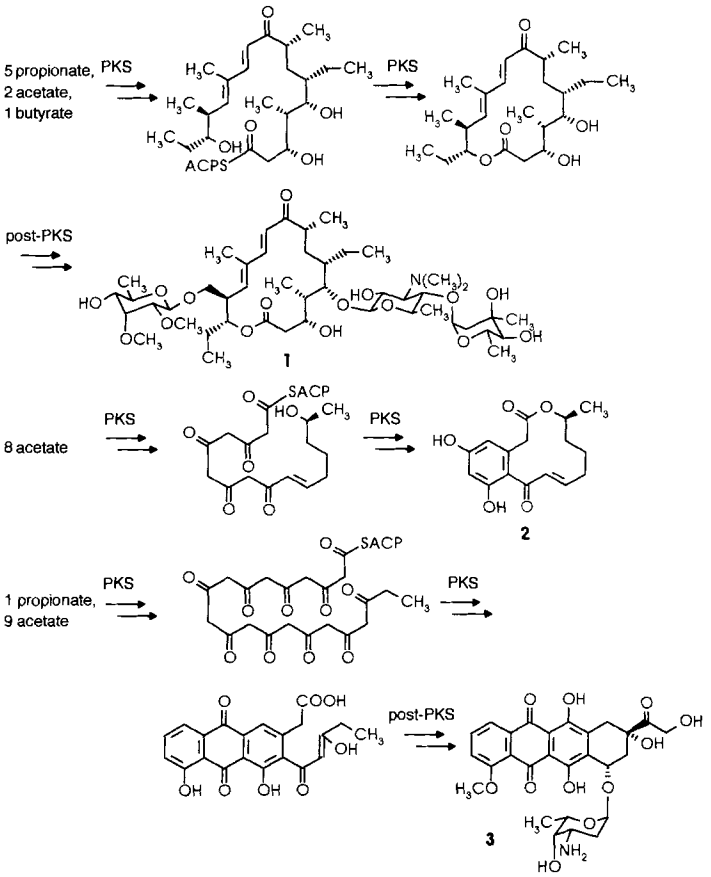
Combinatorial Biosynthesis—An Approach in the Near Future?

Jürgen Rohr*



The search for new drugs requires the testing of tens of thousands of samples, whether pure compounds or natural products containing crude extracts, before a novel, promising lead structure is identified. As the chances of empirical screening assays and drug development procedures based on the natural product pool decline, it will be increasingly difficult to provide the existing screening assays with sufficient material. In this era of gene technology, an alternative strategy to the currently much discussed combinatorial chemistry approach for the generation of compound libraries[1] may be combining biosynthetic genes or changing them. Arbitrary or selective mutation may yield a whole palette of novel molecules and their variants, or specially tailored potential drugs. Recent developments in the polyketide area provide an optimistic outlook for restructuring and recombining building blocks and building principles of natural products.

The polyketide biosynthetic pathway is of the utmost relevance to combinatorial biosynthetic approaches, as this pathway, which is utilized by vastly different living organisms such as microorganisms, fungi, and plants, is naturally diverse. It also produces important pharmaceuticals, for example antibiotics, cytostatics, and immunosuppressants.[2] In this context, years of extensive biosynthetic investigations on the polyketide pathway, on the molecular biological level in particular, are beginning to bear fruit. An application of the knowledge gained, namely the targeted combination of polyketide synthase genes, succeeded recently, and an extension of this strategy is in sight. Simultaneously, further general information on polyketide biosynthesis was gained.

Polyketides are constructed by multifunctional enzymes, the polyketide synthases (PKSs), from short carboxylic acid units (primarily acetate, propionate, butyrate) which are activated as coemzyme A thioesters and by carboxylation (e.g., as malonyl CoA and methylmalonyl CoA) for the decarboxylative (Claisen) polycondensations. The β-oxo ester intermediates can be reduced during this assembly process (or afterwards, see below), further dehydrated, and hydrogenated, as in the related fatty acid biosynthesis.[2d]

Variation possibilities that finally result in the immense repertoire of polyketides arise from the degree of reduction of the β-keto function during the assembly process (→ carbonyl, hydroxymethylene, olefin, or methylene group), the stereochemical information introduced thereby (R/S alcohols, E/Z alkenes), and the type of building blocks used (acetate, propionate, butyrate, amino acid starter units etc.) and the number used (→ type of side chains, chain length). In addition, the folding of the growing polyketide chain, which may be stabilized by subsequent intramolecular ring-closing reactions (aldol condensations, Diels–Alder reactions etc.) results in various molecular frameworks. Finally a myriad of "post-polyketide" modifications (oxidations, reductions, alkylations, acylations, glycosylation reactions, introduction of further heteroatoms, etc.) may convert the biosynthesized molecular frameworks into highly specific bioactive drugs (Scheme 1).

Genetic studies have defined two classes of polyketide synthases—"modular", complex PKSs (type I) and those that

Scheme 1. Three typical examples of the variety of polyketide biosyntheses. Assembly of the primary polyketide through polyketide synthase (PKS), cyclizations (mainly also by PKS), and subsequent functionalizations (post-PKS) to give the macrolide antibiotic tylosin (**1**) [5a], the phytotoxin dehydrocurvularin (**2**) [5b], and the cytostatic adriamycin (**3**) [5c].

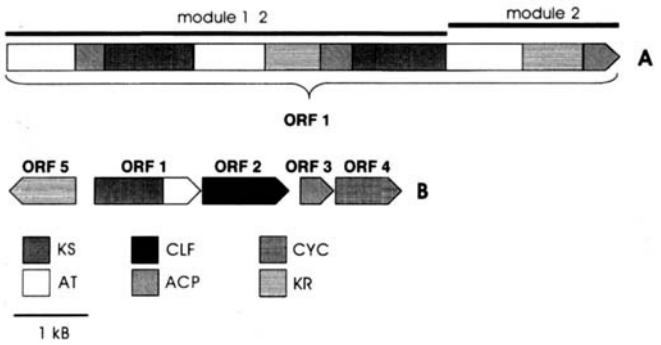
synthesize polycyclic aromatic polyketides (type II),[2b, 3] although it is likely that the transition between these two types is rather blurred.[4] Typical products of type I PKS are macrolides (e.g. tylosin (**1**),[5a] dehydrocurvularin (**2**)[5b]) and polyethers; type II PKS produce mostly aromatic polycycles such as anthracyclines[5c] (e.g., adriamycin (**3**)), tetracyclines, and angucyclines[5d] assembled from several, usually six-membered rings. Type II PKSs are assemblies of multifunctional proteins, which is reflected in their genetic pendant (Fig. 1, **B**). The first open



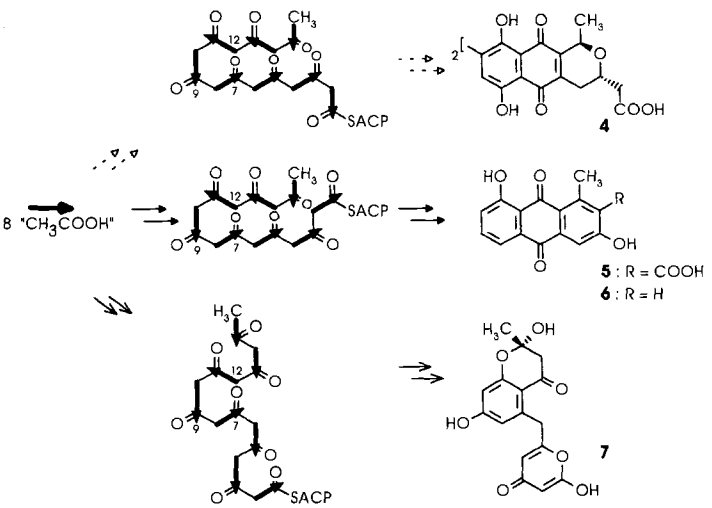


Fig. 1. Genetic analysis of polyketide synthases. **A:** Part of a type I PKS from the erythromycin biosynthesis [11a]; **B:** type II PKS from the actinorhodin biosynthesis [3,6a]. KS = ketosynthase, AT = acyltransferase, CLF = chain length determining factor, ACP = acyl carrier protein, CYC = cyclase, KR = ketoreductase.

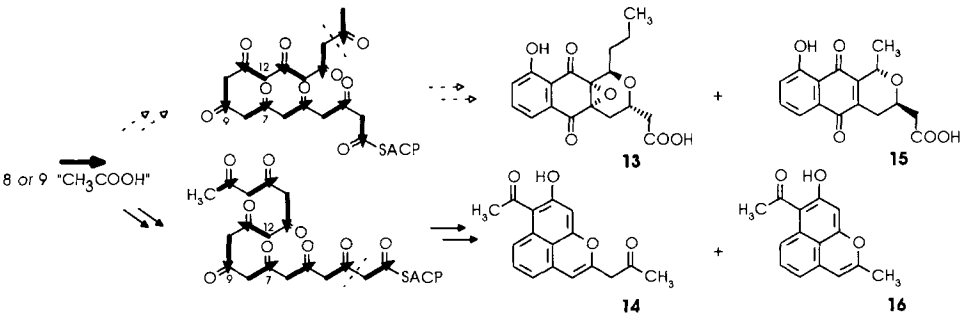
reading frame (ORF1) codes for the β-ketosynthase/acyltransferase subunit (KS/AT), which catalyzes Claisen condensations, among other reactions. The second reading frame (ORF2) codes for a yet unidentified subfunctionality, which is currently thought inter alia to control the length of the growing polyketide chain (chain length determining factor, CLF). ORF3 codes for the acyl carrier protein (ACP), which binds the growing polyketide chain, while ORF4 encodes a cyclase and ORF5 a ketoreductase, which is not always present. These principles were defined through intensive genetic studies on streptomycetes, mainly on *S. coelicolor* and *S. glaucescens*, which produce actinorhodin (**4**) and tetracenomycin C (**8**), respectively.[3, 6]

That an intercombination of similar polyketide synthase genes can generate so-called hybrid antibiotics was shown by Hopwood et al. ten years ago. In sensational experiments they succeeded in (arbitrarily) mixing genes for the biosynthesis of actinorhodin with those for granaticin and for medermycin.[6d, e] After these initial successes, in which, however, only marginal changes in the biosynthetic products could be achieved (other configurations, an additional OH group), the excitement surrounding hybrid organisms and hybrid antibiotics died down.



At the end of 1993 Khosla et al. described a host–vector system that allowed the specific exchange of polyketide synthase genes for the first time.[7] The system was originally designed for the modification of the more thoroughly investigated type II polyketide synthases, but it turned out to be suitable for type I PKSs as well.[8] The systematic exchange of type II PKS subunits on the genetic level not only further defined their functions, but also indicated the possible degrees of combinatorial freedom and thus opened up routes to completely novel molecules. In Khosla's *Streptomyces* host–vector system, a PKS gene acceptor–donor system, the specially designed organism (*Streptomyces coelicolor* CH999) that serves as a gene acceptor was constructed from the wild-type organism, the actinorhodin-producer *S. coelicolor*, through precise removal of the genes for actinorhodin biosynthesis. A low-copy plasmid tailored exactly to this host organism functions as the vector, that is, the gene donor system, permitting sections of the removed genes coding polyketide synthase to be reintroduced (control experiment) or analogous foreign PKS genes to be introduced (actual experiment). The following flexible, exchangeable gene cassettes were constructed: the poly-β-ketosynthase/acyltransferase genes (ORF1), the still unspecified ORF2 genes, and the acyl carrier protein genes (ORF3). Some components of the actinorhodin polyketide synthase gene cluster were established as constant domains, among others the activating genes for polyketide biosynthesis, which guarantee that the polyketide biosynthesis begins at its "natural" starting point (during the logarithmic growth phase of the streptomycetes). Initially the shuttle plasmid contained actinorhodin ketoreductase (ORF5), which reduces the 9-C=O group of the polyketide to the corresponding secondary alcohol. This reaction may be followed by elimination of water, resulting in removal of the oxygen atom at C-9. The plasmid also contains the cyclase (ORF4) responsible for the closure of the second ring. All these genes combined represent a minimal PKS, in other words, construction of a functional PKS would be impossible with fewer genes.[7a] For the control experiment, receptor organism CH999 was transformed with a plasmid containing the "standard" actinorhodin ORF1/ORF2/ORF3 genes, designated plasmid pRM5. The host–vector system was shown to function. The major product was 3,8-dihydroxy-1-methylanthraquinone-2-carboxylic acid (DMAC, **5**); the only minor product was its presumably nonenzymatically decarboxylated analogue aloesaponarin II (**6**) (Scheme 2). These results fulfill the expectations for the utilized gene set: the C_{16} polyketide is formed through correct first (cf. **4**) and second ring closures and one 9-C=O reduction (and subsequent dehydra-

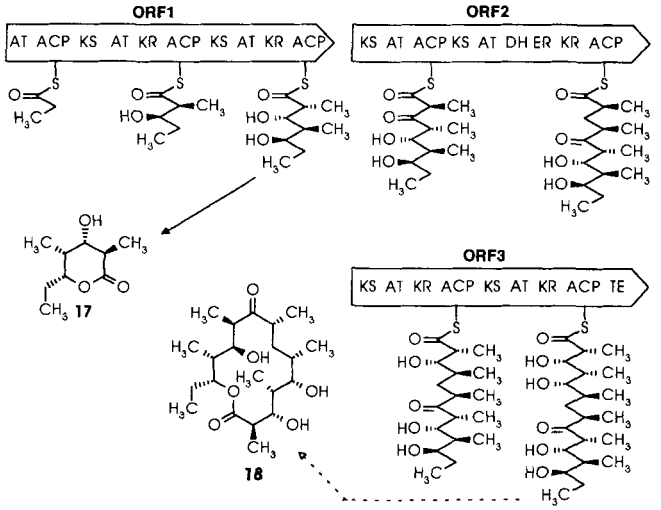
Scheme 2. The natural biosynthesis of the octaketide actinorhodin (*act*, **4**) (top) in comparison with the control experiments with Khosla's host–vector system. Middle: Minimal *act*-PKS with functional ketoreductase (KR) yields the anthraquinones **5** (major product) and **6**; these products are also formed when the octaketide PKS of the granaticin producer (all possible combinations of ORF1, ORF2, and ORF3) or when only ORF1 of the tetracenomycin (a decaketide) producer is combined with *act*-PKS. Bottom: Minimal *act*-PKS without KR yields SEK4 **7**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0808-0882 $ 10.00+.25/0

tion). Thus DMAC **5** is the product of the "normal" minimal actinorhodin (*act*) polyketide synthase. Consequently, all possible ORF1/ORF2/ORF3 variants of control plasmid pRM5 were systematically constructed by using hetero PKS genes of the well-studied producers of tetracenomycin C (*S. glaucescens*) and granaticin (*S. violaceoruber*). In addition, partially characterized polyketide synthase genes, for example from the frenolicin/nanaomycin producer *S. roseofulvus* and the oxytetracyclin producer *S. rimosus*, were used. In two more cases, analogous plasmids were constructed with deactivated ketoreductase (KR) genes (ORF5).

Scheme 4. Combinations with nonaketide PKS. Top: Natural biosynthesis of frenolicin B (**13**) and nanaomycin (**15**). Below: Minimal frenolicin PKS/actinorhodin PKS with *act*-KR yields the hybrid products RM18 **14** and RM18b **16**.

It could be demonstrated that the control products **5** and **6** were always obtained whenever any KS/AT gene (ORF1) had been combined with an actinorhodin (*act*; C_{16}) ORF2 gene. The acyl carrier protein gene (ORF3) could be varied without visible consequences. In contrast, when both ORF1 and ORF2 genes of a foreign PKS were unified with the actinorhodin PKS genes, novel polycyclic compounds with completely different frameworks were produced (RM20 **9**, RM20b **10**, RM20c **11**, RM18 **14**, RM18b **16**; Schemes 3, 4). As in the natural actinorhodin biosynthesis, the 9-C=O group in these compounds is reduced to a secondary alcohol. Generally, the foreign organisms had to be producers of longer (nona-, deca-) polyketides (C_{18}, C_{20}).[9a] Dehydration usually took place after reduction of 9-C=O (→ **9**, **14**, and **16**), but not always (→ **10** and **11**[9b]). In the latter case a different, novel ring skeleton was formed. To explain the results it was proposed that actinorhodin cyclase, the enzyme responsible for the closure of the second ring, operates "chain length specifically" and is unable to convert polyketides with chain lengths differing from that specified in the natural biosynthesis, which yields an octaketide. The novel ring systems presumably result from spontaneous reactions.



Scheme 3. Natural biosynthesis of tetracenomycin C (*tcm*, **8**) (top) and PKS combination products of the decaketide *tcm*-PKS (ORF1/ORF2) and octaketide *act*-PKS. Middle: The minimal *tcm*-PKS/*act*-KR hybrid yields the major product RM20 **9** and minor products RM20b **10** and RM20c **11**. The latter are also produced from tetracyclin/actinorhodin hybrid organisms. Bottom: Minimal *tcm*-PKS without *act*-KR yields SEK15 **12**.

The transformant organisms, which are completely identical to those described above except for the lack of functional ketoreductase (KR), assembled further types of molecular frameworks, namely the octaketide SEK4 **7** (Scheme 2, bottom) and the decaketide SEK15 **12** (Scheme 3, bottom). As expected, these molecules are constructed without reduction of CO groups and are therefore characterized by further types of folding and intramolecular cyclizations. The regioselectivities of these reactions are again presumably the result of nonenzymatic reactions, that is, with thermodynamic control. Retention or removal of the ketoreductase is therefore another degree of freedom for gene combinatorial polyketide constructions.

New information about the functions of the type II PKS subunits was gained. Since the length of the polyketide formed always coincides with that of the natural molecule, from the biosynthesis of which the ORF2 genes are derived, it could be concluded that ORF2 contains a chain length determining factor (CLF).[7a] The reduction of the CO groups occurs at this point (in contrast to with the type I polyketides) after the biosynthesis of the entire polyketide chain, possibly even after the first cyclization,[10] since hybrid organisms without functional KR still promote cyclization between C-7 and C-12 of the original polyketide chain.

In comparison with type II PKSs, type I PKSs are considerably larger and more complex (**A** in Fig. 1, Scheme 5). They catalyze a stepwise assembly of molecules such as macrolides which is analogous to the fatty acid biosynthesis. But the β-keto group resulting from each condensation step may either remain unchanged or is reduced to some degree.[2d] The modular open reading frames of gene clusters of type II PKSs can contain the necessary gene fragments for all possible variants in 1:1 correspondence to the programmed biosynthetic step. Thus there are ketoreductases (KR), dehydratases (DH), and enoyl reductases (ER) located after the β-ketosynthase/acyltransferase (KS/AT) genes necessary for the polyketide chain assembly. A number of

Scheme 5. Biosynthesis of 6-deoxyerythronolide B (**18**) with modular type I PKS. The complete biosynthesis (including the lactonization) also functions in the *S. coelicolor* host–vector system after transformation of the ORF1/ORF2/ORF3 genes shown here. Lactone **17** is produced when only the ORF1 genes are transformed into the host organism. AT = acyltransferase, ACP = acyl carrier protein, KS = β-keto ACP synthase, KR = β-keto ACP reductase, DH = dehydratase, ER = enoyl reductase, TE = thioesterase/cyclase).

acyl carrier proteins (corresponding to the number of the building blocks) successively bear the growing polyketide chain until it is finally cleaved by a thioesterase (TE) (Scheme 5).[11a,b] Through selective inactivation of individual subactivities of this type of PKS, specifically modified macrolide analogues have already been obtained.[11a,c–e] Recently, Khosla et al. successfully performed the heterologous expression of type I PKS genes, for instance the entire gene cluster of 6-deoxyerythronolide B (**18**) synthase, into the *S. coelicolor* CH999 host organism described above, and thus could direct the production of macrolides.[8a] In addition, it was possible to express only the genes of the first open reading frame (ORF1), resulting in the production of δ-lactone **17**, if only in low yields.[8b] **17** contains exactly the expected functionalities programmed by the two modules of ORF1 (Fig. 1, Scheme 5). These results pave the way for the combination of macrolide-PKS with other PKS (type I or II). Surprisingly, the cyclic lactone is formed rather than the expected open-chain molecules. Whereas deoxyerythronolide B (**18**) is apparently cyclized directly by the thioesterase, a nonenzymatic reaction has to be considered for the formation of **17**. Alternatively, the intermediates are activated as lactones, which are passed on from subunit to subunit of the PKS. Analogous lactones were previously identified as shunt products of other macrolide producers.[12]

The results are encouraging, although the number of different ring systems obtained—in principle three novel carbon frameworks—is less than one would expect if nonenzymatic reactions were responsible for their formation. The resulting type of molecular framework seems to be chiefly dependent on the degree of reduction of the 9-C=O group (and the possible consequent dehydration). Clearly, all of the controlling factors of this gene combinatorial approach are not yet understood. For instance, what is the controlling factor for the first cyclization of type II polyketides? Why do the novel hybrid molecules often undergo decarboxylation (at C-1 of the polyketide chain)? This occurs rarely in the natural biosyntheses and only to a small extent in the control experiment. Model calculations might be useful in this context.[6a] All gene sets (ORFs) of different organisms could not be intercombined at random successfully, but there are many more examples of positive than of negative intercombinations, in which no polyketides were produced. There is already evidence that it will be possible in future to combine polyketide biosynthesis genes with various "post-polyketide" biosynthetic genes such as oxygenases or glycosyltransferases from foreign organisms.[13] In such an approach the formation of novel molecules depends on the substrate tolerance of the post-polyketide enzymes, and an even greater palette of genetically engineered hybrid products may be produced. The vision of constructing hybrid organisms in which only desired biosynthetic genes are combined, permitting a direct access of certain structural moieties, may become reality in the near future. The work described here paves the way for such a prospect, showing that many more combinations of biosynthetic genes are possible than one could have expected. This flexibility may be extended by using organisms with genetically modified primary metabolism capacities,[14] such that a broader range of building blocks can be used in natural product biosyntheses.

Control of Ion–Molecule Reactions in the Gas Phase

Karl-Heinz Gericke*

Chemists dream of selecting reaction channels by manipulating starting materials. Simply heating the reaction system will, in general, increase the rate of all reactions and side reactions, and may even open new channels, but real control of the outcome of a reactive encounter is not obtained. Most chemical reactions are statistical in nature, and heat is thus, in general, the only (and appropriate) way to influence the formation of products. However, there are outstanding exceptions to this general rule. For example, studies of the reaction of hydrogen or chlorine atoms with HOD confirm our expectations that the products formed depend on the bond that is vibronically excited: the stretched bond reacts. Therefore, we can control the product ratio OH + HD vs. OD + H_2 in the reaction H + HOD (or OH + DCl vs. OD + HCl in the reaction Cl + HOD) by activating different sides of the HOD reactant.[1, 2] Thus, motio along the reaction coordinate promotes the reaction.

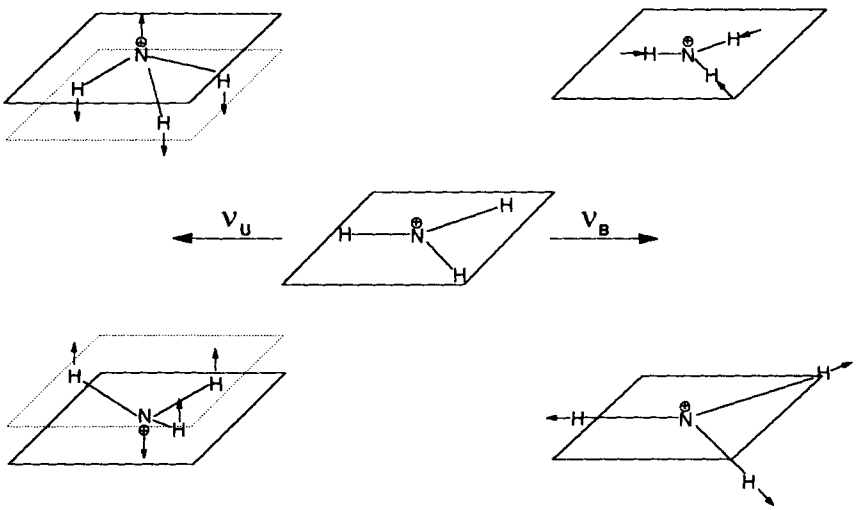

Fig. 1. Illustration of the ν_U umbrella mode (left) and the ν_B breathing mode (right) of the planar NH_3^+ ion (center). These modes have a strong influence on the branching ratio of the $NH_3^+ + ND_2$ reaction.

Unfortunately our experimental knowledge is very limited (the scientific way of saying we know almost nothing) in the case of more complex reactions: Does the reagent's type of internal motion still direct the outcome of the reactive encounter or does everything become statistical when larger reaction systems are involved?

The research group of Zare has recently demonstrated that in case of the reaction of NH_3 with ND_3, the branching ratio for these three different product channels (a)–(c) can be influenced

$$NH_3^+(v_R v_S) + ND_3 \xrightarrow{\text{charge transfer}} NH_3 + ND_3^+ \quad \text{(a)}$$

$$NH_3^+(v_R v_S) + ND_3 \xrightarrow{\text{proton transfer}} NH_2 + ND_3H^+ \quad \text{(b)}$$

$$NH_3^+(v_R v_S) + ND_3 \xrightarrow{\text{deuterium abstraction}} NH_3D^+ + ND_2 \quad \text{(c)}$$

by the choice of the internal NH_3^+ motion, although the energy of the different type of motions, that is, different ν_U or ν_B vibrational modes, is approximately the same.[3]

Two of the six vibrational modes of NH_3^+ are important for the course of the reaction (Fig. 1). In contrast to neutral NH_3, the positive ion is planar, and the so-called umbrella mode (ν_U) corresponds to an out-of-plane, totally symmetric, bending mode, while the breathing mode (ν_B) corresponds to an in-plane, totally symmetric, stretching mode of the hydrogen atoms.

With multiphoton ionization of NH_3 the NH_3^+ reactant is prepared in two nearly isoenergetic states, either with two quanta of the umbrella mode and one quantum of the breathing mode ($2\nu_U 1\nu_B$) or with five quanta of umbrella motion and no breathing excitation ($5\nu_U 0\nu_B$). A strong dependence of the product branching ratio is observed. For example, if two quanta of the umbrella mode (and one quantum of the breathing mode) are excited, roughly 47% of the total amount of products are generated by the proton transfer channel and 47% by the charge transfer channel. Roughly 6% of the products are generated by the deuterium abstraction channel. If five quanta of umbrella mode are excited, the contribution of the charge transfer chan-

nel increases to 56%, while the contribution from the proton transfer channel decreases to 36%. The deuterium abstraction channel is enhanced to 8%. The branching ratio also depends on the collision energy. In any case, the importance of the charge transfer and the deuterium channels is enhanced at the expense of the proton transfer channel when the umbrella motion is more strongly activated.[4, 5] However, it is still possible that the breathing motion influences the branching ratio, because the experimental runs also differ by one quantum of the v_B mode.

In another experiment Zare and co-workers compared identical amounts of umbrella mode excitation ($2v_U$) with ($1v_B$) and without ($0v_B$) breathing mode excitation. The important result is that breathing motion does not influence the branching ratio for the $NH_3^+ + ND_3$ reaction, whereas umbrella motion plays a large role in this polyatomic ion–molecule reaction over the studied collision energy range (1 eV to 5 eV).

The good news is that the reagent's type of internal motion can direct the outcome of a reactive encounter, which confirms the assumption that all three product channels are a result of a direct and fast reaction in which there is not enough time for complete energy redistribution. The bad news is that such polyatomic systems are so complicated that simple models that successfully treat the mode selectivity in small systems like H/Cl + HOD cannot completely explain the outcome of this ion–molecule reaction. Small systems told us that vibrational motion along the reaction coordinate enhances reactivity, whereas motion perpendicular to the reaction coordinate hinders reactivity or is ineffective. For example, the reaction rate of $H_2 + OH \rightarrow H_2O + H$ hardly changes if OH is vibrationally excited, whereas vibrational excitation of H_2 increases the reaction rate by almost two orders of magnitude. This model explains why deuterium abstraction in the $NH_3^+ + ND_3$ reaction is promoted but proton transfer is hindered by umbrella motion. However, we do not understand why the breathing motion does not favor the proton transfer channel, although this type of motion is directed along the reaction coordinate. Obviously a more detailed theoretical treatment than the simple reduction to a three particle model system is necessary.

Octadecanuclearity in Manganese Carboxylate Chemistry: $K_4[Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ ($phthH_2$ = phthalic acid)**

Rachel C. Squire, Sheila M. J. Aubin, Kirsten Folting, William E. Streib, David N. Hendrickson,* and George Christou*

Our efforts in manganese carboxylate chemistry over the last several years have been stimulated by 1) the desire to prepare models of the Mn_4 aggregate responsible for photosynthetic water oxidation,[1] and 2) the search for molecular species with large values of spin S in the ground state to provide information on the factors responsible for the photosynthetic water oxidation and to find potential precursors to molecular ferromagnets.[2] Our results to date have been most gratifying, because we have come across both a wide variety of high nuclearity carboxylatomanganese aggregates with aesthetically pleasing structures and complexes with large values of S and other highly unusual magnetic properties.[3] For example, $[Mn_8O_6Cl_6(O_2CPh)_{12}(H_2O)_2]$ has an $S = 11$ ground state,[3e,f] whereas the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^z$ complexes have $S = 9$ or 10 ($z = 0$) or $S = 19/2$ ($z = -1$) *and* exhibit superparamagnet-like behavior when examined by AC susceptometry—the only *molecular* species to do so.[3c,d,f] The latter complexes are also the highest nuclearity carboxylatomanganese species observed to date. However, we herein report a remarkable octadecanuclear Mn carboxylate aggregate, and describe its structure and magnetic properties.

The synthesis involved the reaction of **1**,[3e] which contains a $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ butterfly-like core, with the monopotassium salt of phthalic acid ($phthH_2$; benzene-1,2-dicarboxylic acid). A dark red-brown MeCN solution of complex **1** was stirred for five days with one equivalent of potassium hydrogen phthalate and yielded a similarly colored solution and an off-white precipitate of KO_2CPh. The solution was filtered, and the filtrate allowed to concentrate at ambient temperature over 10 days to give essentially black crystals of **2**·10MeCN in about 30% yield.[4] Increase of the storage time by a factor of 2 leads to further product crystallization (total yield about 40%).

$(NnBu_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ **1**

$K_4[Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]\cdot 10MeCN$ **2**·10MeCN

The structure of **2** (Fig. 1)[4] has crystallographically imposed C_2 symmetry and idealized D_2 symmetry. Charge considerations indicate that the Mn centers are all in the Mn^{III} oxidation state. There is a central, almost linear Mn_4 unit (Mn1, Mn1′, Mn2, Mn2′) and seven Mn atoms above and below this unit, all held together by 16 μ_3-O^{2-} ions. The peripheral ligation is provided by 22 $PhCO_2^-$ groups in their familiar *syn,syn*-bridging mode, two terminal H_2O groups on each of two Mn atoms (Mn4 and Mn8), and two μ_4-$phth^{2-}$ groups whose O atoms each coordinate to different Mn atoms; the latter represents an unprecedented binding mode for this group. The two $phth^{2-}$ groups ligate to a total of six Mn atoms. The 16 μ_3-O^{2-} ions can be divided into four types: 1) O15, O15′, O20, and O20′ have distinctly pyramidal geometry with a sum-of-angles (SOA) of about 316°; 2) O11, O11′, O16, and O16′ (SOA ca. 345.5°) and O13, O13′, O18, O18′ (SOA ca. 355°) are also pyramidal, but

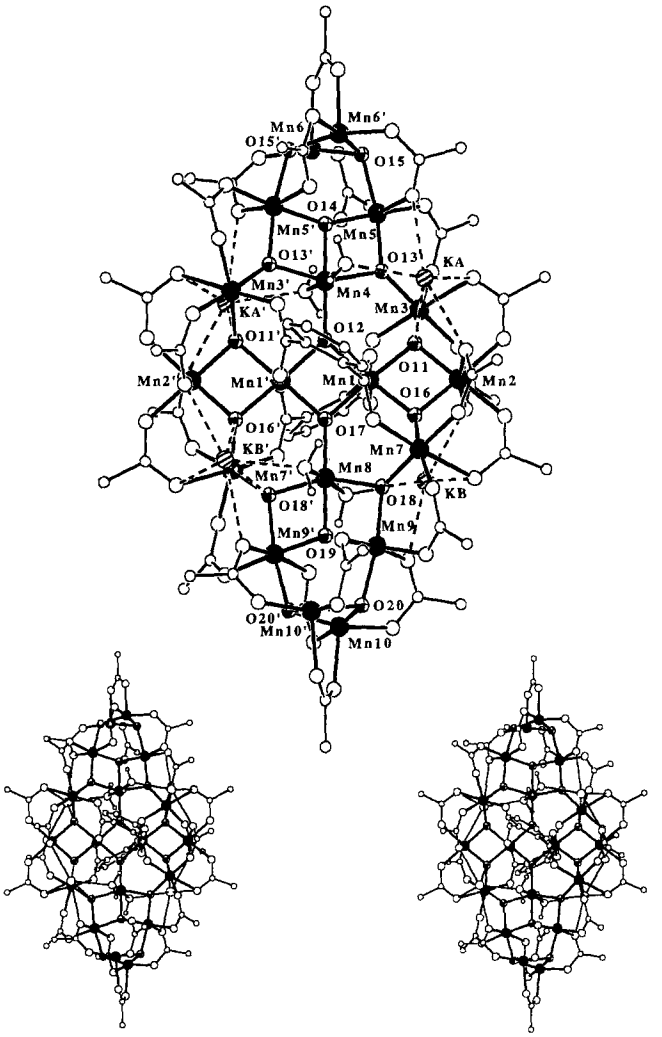

Fig. 1. ORTEP representation and stereoview of the structure of **2**; all but one of the benzoate-phenyl C atoms have been omitted for clarity. The terminal MeCN groups on the K^+ ions (KA and KB, diagonally shaded) are also omitted.

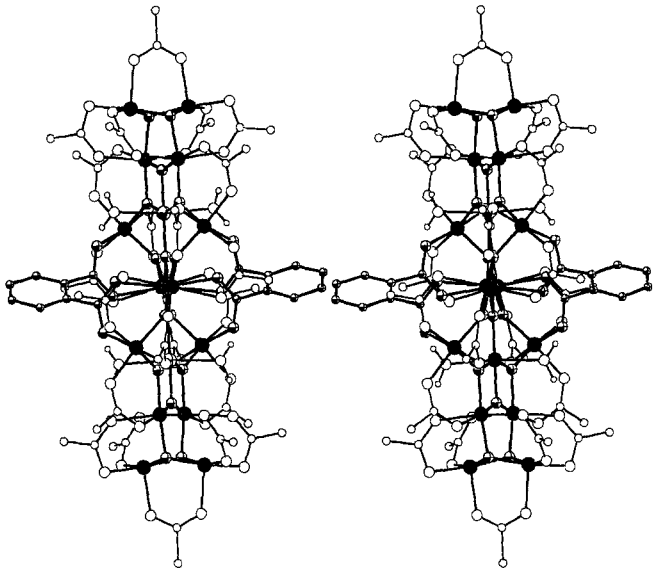
with a more flattened geometry as indicated by the SOA; 3) O12 and O17 are planar (SOA about 360°) and very approximately trigonal; and 4) O14 and O19 are planar (SOA 360°) but with an almost T-shaped geometry (Mn5-O14-Mn5′ and Mn9-O19-Mn9′ are 151.5(3)° and 150.9(4)°, respectively). The Mn atoms are either five-coordinate, square-pyramidal (Mn6, Mn6′, Mn10, Mn10′), or distorted octahedral displaying the Jahn–Teller axial distortion (elongation) expected for a high-spin d^4 ion in near-octahedral geometry. The $[Mn_{18}O_{16}]$ core has a somewhat sheet-like appearance and is twisted slightly about the real C_2 (vertical) axis; these points are emphasized by the stereoview in Figure 2. The K^+ ions are tightly ion-paired with the tetraanion, and their positions are indicated in Figure 1; each also has a terminal MeCN ligand (not shown).



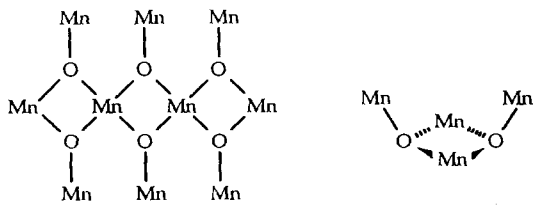


Fig. 2. ORTEP stereoview of complex **2** (without the K^+ ions) from a viewpoint essentially perpendicular to that in Figure 1 and approximately along the almost linear Mn_4 central unit. This view emphasizes the twist of the almost planar $[Mn_{18}O_{16}]$ core along the C_2 (vertical) axis.

An alternate and convenient description of **2** is as the result of fusing five $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ units with either a planar or bent ("butterfly") Mn_4 unit (the latter as found in **1**).[3e, 5] The central $[Mn_{10}O_{16}]$ unit (**A**) represents the fusion of three such units

by sharing of "hinge" Mn atoms (Mn1 and Mn1′). Two additional $[Mn_4O_2]$ units (**B**) are then attached to the "wing-tip" positions of the central unit by atoms O13, O13′, O14 and O18, O18′, O19.

Variable-temperature, solid-state magnetic susceptibility studies were performed on powdered samples of complex **2** in the temperature range 2.00–320 K and in an applied magnetic field of 10 kG (1 T). The $\xi_M T$ value (ξ_M is the molar DC magnetic susceptibility per Mn_{18} complex) slowly decreases from 28.67 $cm^3 K mol^{-1}$ (15.14 μ_B per molecule) at 320.0 K to 0.376 $cm^3 K mol^{-1}$ (1.73 μ_B) at 2.00 K (Fig. 3). The spin-only value for an aggregate of eighteen noninteracting Mn^{III} ($S = 2$) ions is 54.00 cm^3 $K mol^{-1}$ (20.78 μ_B). Thus, there are appreciable antiferromagnetic exchange interactions within **2**.

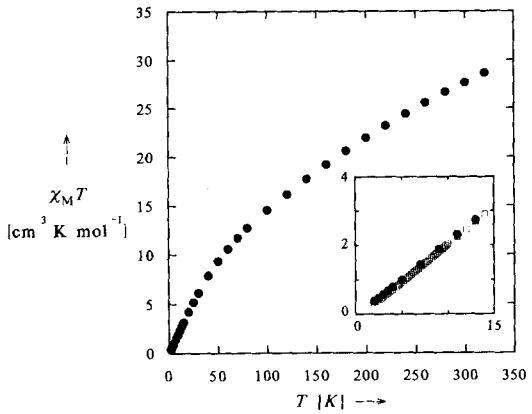

Fig. 3. Plot of $\xi_M T$ vs T data for complex **2** collected in an applied magnetic field of 10 kG. Corresponding μ_{eff} values are given in the text. The inset shows the $\xi_M T$ data in the 2–15 K range; DC data (•) measured at 10 kG and AC data (□) measured in zero DC field and 1.0 G AC field (500 Hz frequency) are shown.

AC magnetic susceptibility data were also collected for a polycrystalline sample of **2** in the 2.00–60.0 K range. These data were run in zero DC field with a 1.0 G AC field oscillating at 500 Hz. The AC susceptibility data nearly superimpose on the DC data. At the lowest temperatures (see inset in Figure 3) both $\xi_M T$ vs T plots extrapolate to $\xi_M T = 0$ at $T = 0$. Clearly, complex **2** has a $S = 0$ ground state.

Interestingly, Mn_x ($x > 3$) carboxylate complexes with ground states $S = 0$ are the exception rather than the rule. As stated earlier, one of the objectives of our program is to elucidate the various factors that lead to large S values in the ground state, and it is becoming apparent that one of these is spin frustration within certain topological arrangements.[6] That complex **2** with its large ensemble of paramagnetic ions should have an $S = 0$ ground state is thus somewhat surprising and of importance to this continuing search for an understanding of what is beneficial to obtaining large values of S and what is detrimental. A more detailed discussion will be presented in a full paper. From a synthetic inorganic viewpoint, the preparation of **2** shows that it is possible to generate Mn aggregates with nuclearities significantly greater than those known to date by relatively minor perturbations to the reaction system, in this case, the introduction of a dicarboxylate ligand. Further work along these lines is in progress, with the objective of increasing even further the number of high nuclearity Mn carboxylate aggregates available for study.

A Nickel(II) Azide Cubane: Characterization of the Magnetic Exchange Interactions Mediated by a Triply Bridging Azide Group Bound End-On**

Malcolm A. Halcrow, John C. Huffman, and George Christou*

We have a long-standing interest in manganese carboxylate aggregates as models for the Mn_4 cluster in the active center of green plants and cyanobacteria for photosynthetic water oxidation.[1] We prepared several $Mn^{III}_3Mn^{IV}$ complexes containing the distorted cubane $[Mn_4O_3X]^{6+}$ core (X = halide, carboxylate),[2] and also the cubane $[Co_4O_4]^{4+}$ core, together with protonated versions of the latter.[3] As an extension to this work, we recently turned our attention to cubane complexes containing other metal ions, to investigate the electronic and magnetic properties of this interesting class of compound further. We report here the cubane complex **1**; this is the first paramagnetic

$[Ni_4(\mu_3\text{-}N_3)_4(dbm)_4(EtOH)_4]$ **1** dbmH = dibenzoylmethane

molecule to contain end-on-coordinated, triply bridging azide ligands,[4-6] and thus provides an opportunity to characterize the magnetic exchange interactions mediated by azide in this rare bridging mode. The structure of one other $[M_4(N_3)_4]^{n+}$ cubane species is known, namely diamagnetic $[Pt_4(N_3)_4(CH_3)_{12}]$.[5]

A one-pot reaction of $Ni(ClO_4)_2 \cdot 6H_2O$, NaN_3, and Na(dbm) (in a 1:1:1 molar ratio) in EtOH at room temperature yields a bright green precipitate containing **1** and a little $NaClO_4$. Recrystallization from CH_2Cl_2/EtOH affords large green crystals of pure **1** in 78% overall yield. The IR spectrum of **1** as a Nujol mull shows, in addition to bands arising from dbm^- and coordinated EtOH, a very strong absorption at 2087 cm^{-1} attributable to the ν_{asym}(N-N-N) stretching vibration of coordinated azide;[7] this band appears at 2089 cm^{-1} in $CHCl_3$ solution. The ν_{sym}(N-N-N) and δ(N-N-N) vibrations also expected from a metal-bound azide[7] were masked by absorptions from the dbm^- ligand and could not be positively identified. The UV/Vis spectrum of **1** in $CHCl_3$ is typical of an octahedral Ni^{II} complex,[8] while the ^1H NMR spectrum of **1** in $CDCl_3$ shows the paramagnetically shifted resonances of only a single environment for dbm^- and EtOH.

The structure of the bis(toluene) solvate of **1** (Fig. 1)[9] contains a tetranuclear $[Ni_4(\mu_3\text{-}N_3)_4]^{4+}$ cubane core; the molecule has virtual C_2 symmetry and lies on a general position within the unit cell. Each Ni ion is octahedrally coordinated by three end-on-coordinated, triply bridging azide ligands, one chelating dbm^- ligand, and one ethanol ligand. Each ethanol ligand is intramolecularly hydrogen-bonded to an O atom in a dbm^- ligand that is

[**] This work was supported by the U.S. National Science Foundation (CHE 9311904). We thank Prof. K. R. Dunbar and J.-S. Sun (Michigan State University) for collection of magnetic susceptibility data, and Prof. J. Ribas (University of Barcelona) for a preprint of ref. [18].

bound to a neighboring Ni atom (averaged $O\cdots O = 2.703$ Å); this results in a distortion of the $[Ni_4(N_3)_4]^{4+}$ core from T_d to D_{2d} symmetry which results in the four faces of the cubane spanned by hydrogen bonds having shorter Ni–Ni distances and more acute Ni-N-Ni angles and Ni-N-N-Ni dihedral angles than the two faces not bridged in this fashion (average values for Ni1-N5-N8-Ni2, Ni1-N5-N14-Ni3, Ni2-N8-N11-Ni4, and Ni3-N11-N14-Ni4: $Ni\cdots Ni = 3.162$ Å, Ni-N-Ni = 96.1°, Ni-N-N-Ni = 167.1°; for Ni1-N8-N14-Ni4 and Ni2-N5-N11-Ni3: $Ni\cdots Ni = 3.235$ Å, Ni-N-Ni = 99.6°, Ni-N-N-Ni = 175.5°). This feature is also exhibited by several $[Ni_4(OR)_4]^{4+}$ cubanes that contain coordinated alcohol ligands intramolecularly hydrogen bonded in this manner.[10, 11] The azide ligands are each symmetrically coordinated to three Ni ions, and the Ni–N distances and Ni-N-N angles about each azide show only small differences with no discernable pattern. The Ni–N and Ni–O bond lengths for **1** are unremarkable, while the N–N distances within the azide ligands display the same "long–short" pattern shown by Ni^{II} complexes containing end-on-coordinated, doubly bridging azides.

Variable-temperature magnetic susceptibility measurements were performed on a powder sample of **1** between 320 and 5.00 K. The observed effective magnetic moment μ_{eff} for **1** rises from a value of 6.46 μ_B at 320 K to a maximum of 9.66 μ_B at 20 K, before slightly decreasing below 9.00 K (Fig. 2); the value at 20 K may

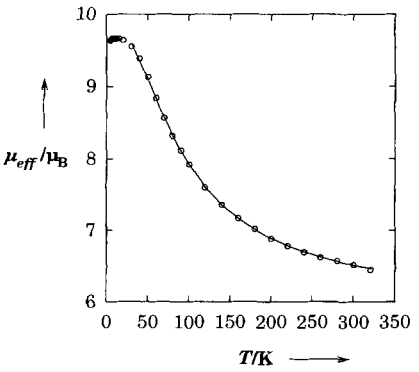

Fig. 2. A plot of effective magnetic moment μ_{eff} per Ni_4 unit vs. temperature T for complex **1**. The solid line represents the least-squares fit to a one-J (T_d symmetry) model; see the text for the fitting parameters. Only data for $T \geq 30$ K were employed to avoid problems at lower temperature arising from zero-field splitting of the $S = 4$ ground state.

be compared with the spin-only ($g = 2$) value of 8.94 μ_B calculated for an $S = 4$ ground state expected for four ferromagnetically coupled high-spin Ni^{II} ions. The data for temperatures ≥30 K were fit according to a one-J model (T_d symmetry) incorporating a Weiss constant θ to account for intermolecular interactions in the solid state[11] (fitting parameters $J = +11.9 \pm 0.5$ cm^{-1}, $g = 2.05$, $\theta = +3.0$ K; $\mathcal{H} = -2JS_1 \cdot S_2$; Fig. 2); utilization of a two-J model (D_{2d} symmetry) did not result in improved fits or in significant splitting (<0.1 cm^{-1}) of the two J parameters.

It is interesting that the distortions within the cubane core noted above are not reflected in the magnetic properties of **1**; this contrasts with the behavior of alkoxide-bridged cubanes, which show J values that are very sensitive to the Ni-O-Ni bridging angles within the faces of the cubane structure.[11–13] Specifically, the complex $[Ni_4(OMe)_4(dbm)_4(MeOH)_4]$, which exhibits similar patterns of MeOH···dbm hydrogen bonding and structural distortions within the $[Ni_4(\mu_3\text{-}OMe)_4]^{4+}$ unit, is best described by a two-J model incorporating both ferromagnetic and antiferromagnetic contributions.[12] The observed J value for **1** is weaker than any reported for coupling across a $[Ni_2(\eta^1,\mu\text{-}N_3)_2]$ bridge, consistent with the presence of triply, as opposed to doubly bridging azides in **1**.[14]

Two mechanisms for the transmission of superexchange interactions through azide ligands bridging end-on have been proposed, which involve accidental orthogonality[15] or spin polarization[16] as the dominant factor determining the sign of the observed coupling; both of these models predict ferromagnetic coupling between metal ions bridged by azide in end-on fashion in most (accidental orthogonality) or all (spin polarization) cases. In particular, a theoretical study of accidental orthogonality in Cu^{II} complexes containing a planar $[Cu_2(\eta^1,\mu\text{-}N_3)_2]^{2+}$ bridge predicted a switch from ferromagnetic to antiferromagnetic coupling for Cu-N-Cu angles greater than 103°.[15] In this regard, it is noteworthy that the average Ni-N-Ni bridge angle in **1** is 97.3°, which is unusually small for an azide bridging end-on in a dinuclear metal complex and is substantially below the predicted crossover value. While the use of Ni^{II} rather than Cu^{II} as metal center and the nonplanarity of the $[Ni_2(\mu\text{-}N_3)_2]$ bridges in **1** might be expected to cause small deviations from the published model,[17] the nature of the magnetic interactions present should be similar in the two types of compound, since both Ni^{II} and Cu^{II} only possess magnetic orbitals of σ symmetry. The lack of dependence of the coupling constant J on the Ni-N-Ni angle in **1** is difficult to reconcile on the basis of the accidental orthogonality model, but is consistent with the spin polarization model.[16] However, *antiferromagnetic* coupling mediated by end-on-coordinated, doubly bridging azide groups with an even more acute Ni-N-Ni angle of 84° was reported.[18] Clearly, the mechanism of superexchange coupling through end-on azide bridging ligands deserves further study, and the present work has provided an additional bridging mode for inclusion in these considerations.

Experimental Procedure

Solid NaN_3 (0.30 g, 4.9 mmol) and Na(dbm) (1.2 g, 4.9 mmol) were added to a solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (1.8 g, 4.9 mmol) in EtOH (100 mL), and the mixture was stirred at room temperature for 4 h. The resultant green precipitate was filtered off, washed with EtOH, and dried in air. Recrystallization from CH_2Cl_2/EtOH afforded deep green blocks, which were not of X-ray quality (1.4 g, 78%); crystallization from toluene/EtOH gave a lower yield of crystals suitable for an X-ray diffraction study. Correct C,H,N,Ni analysis for $C_{68}H_{68}N_{12}O_{12}Ni_4$. IR (Nujol): $\tilde{\nu}$ = 3586 (w), 3270 (br), 3061 (w), 2087 (vs), 1618 (w), 1595 (s), 1554 (s), 1516 (s), 1454 (m), 1442 (w), 1402 (m), 1383 (s), 1312 (s), 1292 (m), 1267 (w), 1242 (m), 1229 (w), 1183 (w), 1157 (w), 1129 (w), 1086 (w), 1073 (w), 1057 (m), 1047 (m), 1024 (m), 1001 (w), 941 (m), 882 (w), 785 (w), 754 (m), 725 (s), 691 (m), 637 (m), 530 (m) cm^{-1}. IR ($CHCl_3$) $\tilde{\nu}$ = 2089 cm^{-1}. Complexes with Polar W–W Multiple Bonds: $[W_2(O\mathit{i}Pr)_4L(dmpe)_2]$ (L = $(H)_2$, CO) and $[W_2(O)_4(\mu\text{-}O)\{W(CO)(dmpe)_2\}_2]$**

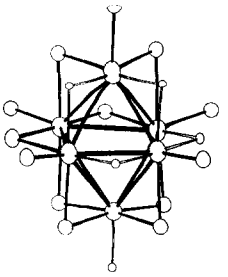
Malcolm H. Chisholm,* Keith S. Kramer, and William E. Streib



Dedicated to Professor F. A. Cotton on the occasion of his 65th birthday

The recent highlight by Herberhold and Jin[1] focused attention on heterometallic complexes with unbridged, polar metal–metal bonds. We describe here reactions in which a symmetric homonuclear complex containing a W–W triple bond yields asymmetric complexes with polar W–W bonds. One of the products described is a novel water-soluble tetranuclear complex involving nonbridged W–W bonds between tungsten atoms in oxidation states + 5 and 0.

[**] This work was supported by the Department of Energy, Office of Basic Sciences, Chemistry Division. dmpe = bis(dimethylphosphano)ethane.

The compound $[W_2(i\mathrm{Bu})_2(O\mathit{i}Pr)_4]$ and dihydrogen react in hydrocarbon solvents to give the hexanuclear hydridotungsten cluster $[W_6(H)_5(O\mathit{i}Pr)_{13}]$,[2] whose $W_6H_5O_{13}$ core is shown pictorially by **A** in Scheme 1. We reasoned that $[W_6(H)_5(O\mathit{i}Pr)_{13}]$ was formed stepwise from the coupling of reactive $[W_2(H)_2(O\mathit{i}Pr)_4]$ fragments. Ligand scrambling may account for the odd number of hydrido and alkoxido ligands in the product, and the formal oxidation state of each tungsten atom is maintained at + 3.

A

Scheme 1. The $W_6H_5O_{13}$ core **A** in $[W_6(H)_5(O\mathit{i}Pr)_{13}]$.

Consequently in an attempt to trap $[W_2(H)_2(O\mathit{i}Pr)_4]$ we have carried out the hydrogenation of $[W_2(i\mathrm{Bu})_2(O\mathit{i}Pr)_4]$ in the presence of chelating diphosphanes.[3] In the presence of bis(dimethylphosphano)ethane (dmpe), the dinuclear complex **1**

$[W_2(\mu\text{-}H)_2(O\mathit{i}Pr)_4(dmpe)_2]$ **1**

was obtained as a dark brown crystalline solid. The solid-state structure of **1** (Fig. 1) reveals that one W atom is coordinated to four O*i*Pr ligands and the other to two dmpe ligands. The structure is superficially similar to that of $[Mo_2(O\mathit{i}Pr)_4(dmpe)_2]$,[4] but the M–M distance in **1** (M = metal) is notably longer and

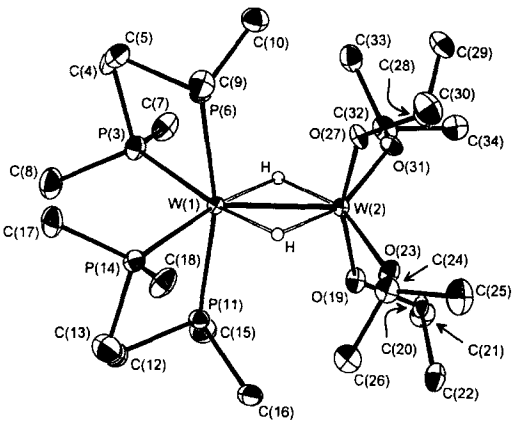

Fig. 1. ORTEP drawing showing the crystal structure of **1** (50% probability ellipsoids). Pertinent bond lengths [Å] and angles [°], averaged where appropriate: W-W 2.496(1), W-O 1.96(1), W-P(6,11) 2.424(2), W(1)-P(3,14) 2.486(2), W-W-P(6,11) 97.5(1), W-W-P(3,14) 130.3(1), W-W-O(23,31) 120.3(2), W-W-O(19,27) 99.4(2).

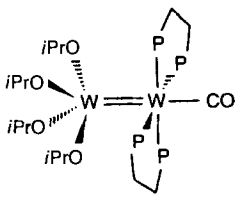
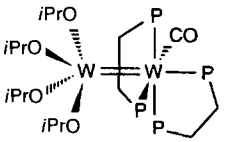


The coordination of the $M(dmpe)_2$ units is different. In $[Mo_2(O\mathit{i}Pr)_4(dmpe)_2]$ all the Mo-Mo-P bond angles range from 98.0(1) to 100.8(1)°, and the Mo–Mo bond length of 2.236(1) Å is typical for a Mo–Mo triple bond. In compound **1**, however, the W–W bond length of 2.496(1) Å is in the range expected for a W–W double bond, and two sets of W-W-P bond angles 97.5(1) and 130.3(1)°] define four positions of the octahedral coordination about W(2). In the structure shown in Figure 1 the two μ-H ligands are placed in proposed positions (hydride locating program XHYDEX),[5] and compound **1** is therefore formulated as $[W_2(\mu\text{-}H)_2(O\mathit{i}Pr)_4(dmpe)_2]$. In solution compound **1** is fluxional; at low temperatures at least two isomers are present, as is evident from the hydride and phosphorus signals. Owing to the broadness of the ^{31}P NMR signals at −80 °C, the

^{1}H-coupled ^{31}P spectrum did not provide any useful information. However, the presence of two hydrido ligands is further supported by the overall 1:2 ratio of hydride to methine resonances observed at $-60\,^{\circ}C$ in the ^{1}H NMR spectrum.



Compound **1** reacts in hydrocarbon solvents with carbon monoxide to evolve H_2 and form complex **2**. The reaction

$[W_2(O\mathit{i}Pr)_4(CO)(dmpe)_2]$ **2**

proceeds in two stages as monitored by ^{1}H NMR spectroscopy in [D$_6$]benzene. In the first step H_2 is liberated ($\delta = 4.5$), and the NMR spectra indicate the formation of a complex with the proposed structure **B** [^{31}P{^{1}H} NMR: $\delta = 26.2$, s, $J_{W\text{-}P} = 272$ Hz, intensity of the satellites corresponds to 14% of the peak intensity; ^{1}H NMR: $\delta = 2.1$ and 1.6, one set of proximal and distal methyl resonances for the dmpe ligands]. With time the kinetic product **B** slowly isomerizes to form **C** which has been crystallographically characterized.

B

C

The structure of the thermodynamically stable form of **2** is given in Figure 2. The CO ligand is *cis* to the W–W bond, which with a length of 2.524(1) Å is in the expected range for a

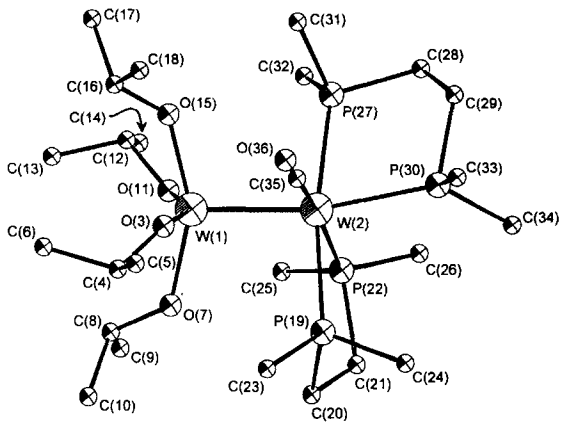


Fig. 2. Ball-and-stick drawing showing the crystal structure of **2** (enantiomer A in the asymmetric unit). Atoms C(21), P(22), C(29), and P(30) are unique to enantiomer A and were weighted only half. All other atoms are common to both enantiomers. Pertinent bond lengths [Å] and angles [°], averaged where appropriate: W-W 2.524(1), W-O 1.93(1), W-P 2.43(1), W-C 1.96(1), W-W-O 104.0(3), W-W-P(30) 166.0(4), W-W-P 95.4(1), W-W-C 94.4(4).

W–W double bond. The tungsten atoms are assigned oxidation states of +4 and 0. The arrangement of ligands about the W(CO)(dmpe)$_2$ unit leads to an ABMX spin system for the P nuclei in the ^{31}P NMR spectrum. It can also be seen that a d^6-W^0 center with one CO ligand [ν(CO) = 1827 cm^{-1}] has two electrons available for forming a W–W double bond with the d^2-W(OR)$_4$ center.

Compound **2** reacts with water to give the novel tetranuclear, water-soluble tungsten complex **3**, whose solid-state structure

$[W_2O_4(\mu\text{-}O)\{W(CO)(dmpe)_2\}_2]$ **3**

is given in Figure 3. The tungsten atoms in the central linear W-O-W moiety are each in a pseudotetrahedral environment with bonds to two terminal oxo groups and a further tungsten

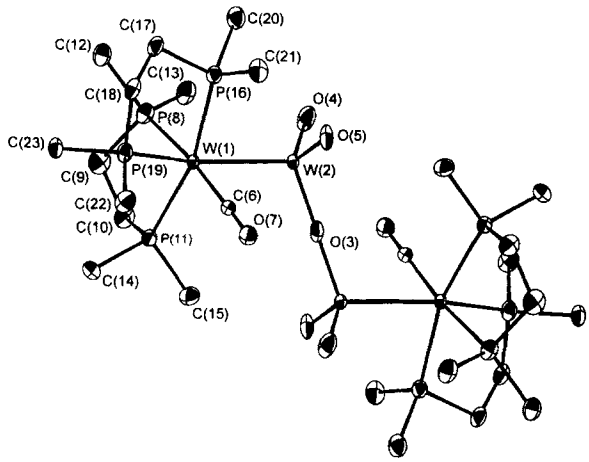

Fig. 3. ORTEP drawing showing the crystal structure of **3** (50% probability ellipsoids). Pertinent bond lengths [Å] and bond angles [°], averaged where appropriate: W-W 2.648(1), W- O(3) 1.88(1), W-O(4)(5) 1.73(1), W-C 1.95(1), W-P 2.490(1), W-W-O(3) 110.7(2), W-W-O(4,5) 109.8(2), W-W-C 72.8(2), W-W-P(19) 147.5(1), W-W-P 89.1(1).

atom. The two W(dmpe)$_2$(CO) units are mutually *anti* in what is an essentially ethane-like X$_2$(Y)W–O–W(Y)X$_2$ core. Since we can find no evidence for the existence of hydrido ligands in compound **3**, we propose that it contains unsupported metal–metal bonds between metal atoms having oxidation states of 0 and +5. Compound **3** is diamagnetic and in solution shows a complex ^{31}P NMR spectrum consistent with the presence of more than one rotamer in solution. The diamagnetism of compound **3** presumably arises from spin pairing of the oxo-bridged d^1-d^1 tungsten centers. The asymmetry of the complex removes the degeneracy of the d_{xz} and d_{yz} orbitals (the W-O-W axis is defined as the z axis), thus allowing spin pairing by occupation of a nonbonding three-center molecular orbital of π symmetry. The W–W single bond (2.648 Å) would then be the result of a dative interaction between the W^0 and the W^V centers.

In summary compounds **1**, **2**, and **3** reveal the remarkable ability of tungsten to form M–M bonds between metal atoms in very different oxidation states. This is in marked contrast to all of the chemistry that we have previously seen for so-called d^3-d^3 tungsten dimers.[6] We believe that the present compounds with W–W bonds between tungsten atoms in different oxidation states arise because the metal shows both class a and b character in liking both hard and soft ligands. Thus in each of the complexes **1**–**3** one tungsten atom coordinates all of the oxo substituents, while the other binds four P atoms as well as an additional carbonyl ligand in **2** and **3**. It may well therefore be possible that the results anticipated for early–late transition metal complexes can also be achieved with homometallic com-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0808-0892 $ 10.00+.25/0

plexes with polar M–M bonds involving disparately hard and soft ligands. Clearly there is a need to explore this area of chemistry further.

Experimental Procedure

All reactions were carried out under N_2 using standard glovebox and Schlenk-line techniques. ^{1}H NMR spectra were recorded on a Varian XL-300 spectrometer at 300 MHz, and ^{31}P NMR spectra were recorded on a Nicolet NT-360 spectrometer at 146 MHz. NMR solvents were dried and deoxygenated prior to use.

1: In a 30 mL capacity Kontes brand solvent seal flask $[W_2(i\mathrm{Bu})_2(O i\mathrm{Pr})_4]$ (0.900 g, 1.25 mmol) was dissolved in roughly 15 mL of toluene, and dmpe (0.376 g, 2.51 mmol) was then added from a µL syringe. The mixture was frozen in liquid nitrogen and the flask evacuated and closed. Next, the flask was transferred to a gas-addition manifold where it was immersed in liquid nitrogen, and hydrogen (600 Torr, ca. 3 atm at 22 °C) was added. The Kontes tap was closed and the contents warmed to room temperature with stirring. After 24 h the excess hydrogen was released and the reaction mixture transferred to a standard Schlenk flask. The solvent volume was reduced in vacuo until crystallization began, and the mixture was warmed to regain homogeneity. The flask was left standing at room temperature for several hours and then cooled to −20 °C for another 24 h. Two crops of crystals were isolated in this manner; the mother liquor was removed and the crystals washed with cold hexane (yield: 0.985 g, 87%); Anal. calcd (found) for $C_{24}H_{62}O_4P_4W_2$: C 31.81 (31.94), H 6.89 (6.95); ^{1}H NMR (+ 60 °C, [D$_8$]toluene): δ = 4.65 (m, 4H, OC(*H*)(CH$_3$)$_2$), 1.41 (d, 24H, OC(H)(C*H*$_3$)$_2$), 1.62 (br. s, 32H, (CH$_3$)$_2$PCH$_2$CH$_2$P(CH$_3$)$_2$); ^{1}H NMR (− 60 °C, [D$_8$]toluene, W-H): δ = −12.4 (m), −1.60 (m), −1.04 (m); ^{31}P{^{1}H} NMR (+ 60 °C, [D$_8$]toluene): δ = 14.9 (br. s, dmpe); ^{31}P{^{1}H} NMR (− 80 °C, [D$_8$]toluene): δ = 18.12 (br. s, $J_{^{183}W-^{31}P}$ = 224.8 Hz), 14.02 (br. s, $J_{^{183}W-^{31}P}$ = 275.5 Hz), 5.37 (br. s, $J_{^{183}W-^{31}P}$ = 167.0 Hz); IR (KBr): ν_{H} = 1755, ν_{D} = 1250 cm^{-1}; crystal data for **1**: T = −160 °C; a = 9.841(1), b = 20.478(3), c = 17.280(3) Å, β = 95.70(1)°, Z = 4, ρ_{calcd} = 1.734 g cm^{-3}, space group $P2_1/n$; R(F) = 0.033, Rw(F) = 0.035 [7].

2: In a 20 mL capacity Kontes brand solvent seal flask $[W_2(H)_2(O i\mathrm{Pr})_4(\mathrm{dmpe})_2]$ (0.200 g, 0.221 mmol) was dissolved in roughly 10 mL of hexane. The solution was then frozen in liquid nitrogen and the flask evacuated. One atm of CO was added by way of a gas-transfer manifold, the flask closed. The reaction mixture was warmed to room temperature and stirred for 24 h. The reaction mixture was filter transferred to a standard Schlenk flask where the volume of solvent was then reduced to about 1 mL. After 3 to 4 d at −20 °C, brown crystals were isolated by cannulating off the mother liquor (yield: 0.190 g, 92%). Anal. calcd. (found) for $W_2P_4O_5C_{25}H_{60}$: C 32.21 (31.88), H 6.49 (6.27); ^{1}H NMR (22 °C, C_6D_6): δ = 4.63 (sept, 4H, OC(*H*)(CH$_3$)$_2$), 1.56 (d, 12H, OC(H)(C*H*$_3$)$_2$, 1.41 (d, 12H, OC(H)(C*H*$_3$)$_2$), 2.24, 2.14, 2.05, 1.86, 1.29, 1.26, 0.801, 0.468 (8d, 24H, (C*H*$_3$)$_2$PCH$_2$CH$_2$P(C*H*$_3$)$_2$); ^{13}C{^{1}H} NMR (22 °C, C_6D_6): δ = 224.0 (m, 1C, CO, $J_{^{183}W-^{13}C}$ = 158.6 Hz, $J_{^{13}C-^{31}P(trans)}$ = 27.3 Hz, $J_{^{13}C-^{31}P(cis)}$ = 4.8 Hz); ^{31}P{^{1}H} NMR (22 °C, C_6D_6): δ = 15.7 (AB quartet, 2P, dmpe), 6.8 (dd, 1P,dmpe), −3.0 (dd, 1P, dmpe); simulated coupling constants (Hz) for the ABMX system: J_{AB} = 85, J_{AM} = 16, J_{AX} = 0, J_{BM} = 0, J_{BX} = 13, J_{MX} = 23.5, $J_{\mathrm{W\text{-}P(A)}}$ = 370, $J_{\mathrm{W\text{-}P(B)}}$ = 260, $J_{\mathrm{W\text{-}P(M)}}$ = 190.5, $J_{\mathrm{W\text{-}P(X)}}$ = 130; IR (Nujol): ν_{CO} = 1827, $\nu_{^{13}\mathrm{CO}}$ = 1784 cm^{-1}; crystal data for **2**·0.5 toluene: T = −170 °C; a = 19.546(3), b = 21.745(4), c = 18.114(3) Å, Z = 8, ρ_{calcd} = 1.688 g cm^{-3}, space group *Pbca*; R(F) = 0.051, Rw(F) = 0.046 [7].

3: In a Kontes brand solvent seal flask complex **1** (0.200 g, 0.221 mmol) was dissolved in roughly 10 mL of toluene. One atm of CO was added to generate **2** as described previously. The solution of **2** was then transferred to a standard Schlenk flask, and a 1.11 M solution of H_2O in THF (600 µL, 0.662 mmol) was added by µL syringe. The reaction mixture was left at room temperature without stirring for 24 h, whereupon orange needles deposited on the sides of the flask. The mother liquor was removed by cannula and the orange solid washed twice with 5 mL of hexane and dried in vacuo (yield: 0.148 g, 97%). Compound **3** can also be generated directly from crystalline **2** in comparable yield. X-ray quality crystals were grown from CH_2Cl_2. Anal. calcd (found) for $W_4P_8O_7C_{26}H_{64}$: C 21.21 (20.83), H 4.38 (4.43); ^{1}H NMR (22 °C, [D$_5$]pyridine): δ = 0.900–2.23 (16 doublets consistent with the presence of two rotamers in a ratio of ca. 1.0–1.2); ^{31}P{^{1}H} NMR (22 °C, D_2O): δ = 13.9 (m, 1P), 8.5 (m, 1P), 0.767 (m, 2P); IR (KBr): ν_{CO} = 1800, $\nu_{^{13}\mathrm{CO}}$ = 1755 cm^{-1}; crystal data for **3**·4CH$_2$Cl$_2$: T = −169 °C; a = 13.282(2), b = 14.308(3), c = 15.319(3) Å, β = 97.88(1)°, Z = 4, ρ_{calcd} = 2.105 g cm^{-3}, space group $P2_1/n$; R(F) = 0.0245, Rw(F) = 0.027 [7].

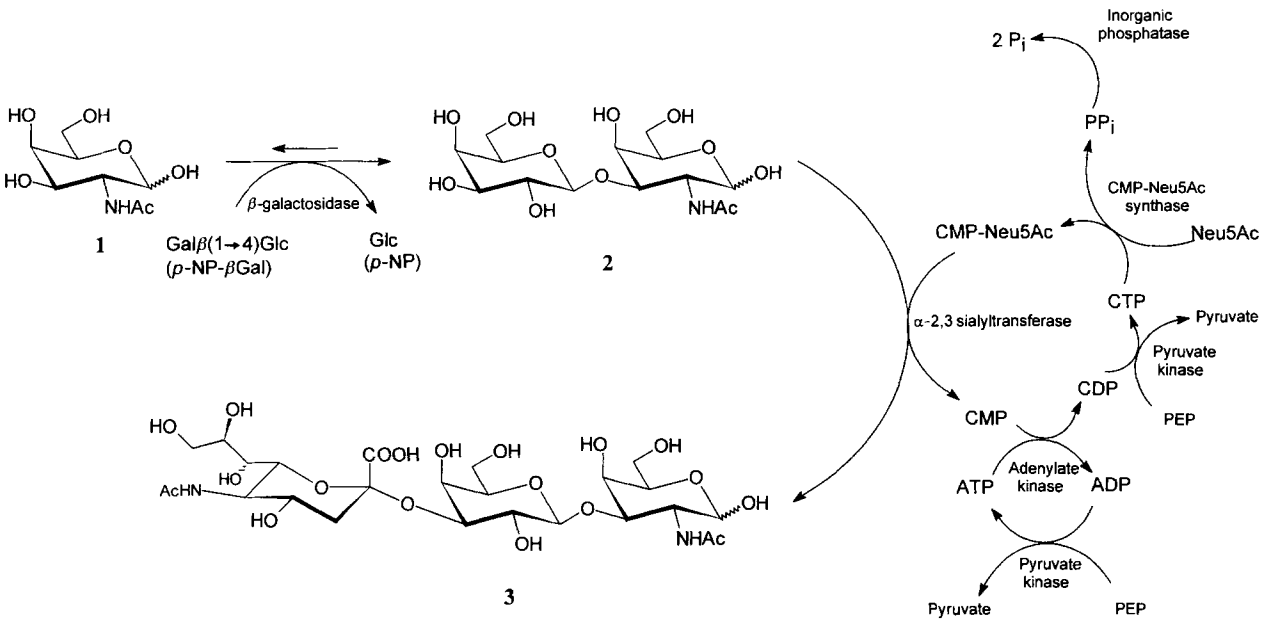
A Multienzyme System for a One-Pot Synthesis of Sialyl T-Antigen**

Vladimír Křen* and Joachim Thiem

The diverse roles of carbohydrates in biological recognition are increasingly a topic of research.[1] Sialic acid, a common structure in glycoconjugates, is particularly important because sialylated structures are involved in a variety of biological processes,[2] for example, cell surface communication,[3] immunogenicity, and circulation half-life of glycoproteins;[4] moreover, they are recognized as crucial structural elements of some antigenic determinants in tumors.[5]



Thomsen–Friedenreich antigen (T-antigen), (Galβ(1 → 3)-GalNAcα-O-Ser), belongs to the antigens that are related to blood group determinants and is expressed in epithelial cancers.[6] A sialylated epitope, Neu5Acα(2 → 3)Galβ(1 → 3)GalNAc (**3**, Scheme 1) can be found in GM_1 glycolipids, human erythrocytes,[5, 7] and a bone marrow macrophage lectin.[7] The synthesis of this epitope is of considerable importance for immunological studies and for the preparation of, for example, synthetic antitumor vaccines.[8]

Enzymatic approaches to the synthesis of these epitope structures and their derivatives proved to be useful,[9, 10] in particular, those based on glycosyltransferases coupled with in situ regeneration of sugar nucleosides.[11, 12] The starting material for the preparation of **3**, Galβ(1 → 3)GalNAc (**2**), could be obtained either by a complicated multistep synthesis[13] or by an enzymatic transglycosylation employing β-galactosidases from bovine testes and *E. coli*, which, however, gave only 21% yield.[14] Both methods are rather complicated, and this is reflected in the extremely high price of the commercial product (approximately DM 100 per mg).

A combined sequential use of glycosyltransferases,[12] or glycosidase together with glycosyltransferase and a cofactor regeneration,[16] transforms the complicated multistep reactions into a one-pot reaction, thus avoiding laborious purification of the intermediates. Reverse hydrolysis of the disaccharide intermedi-

Scheme 1.

ate is blocked by its glycosyltransferase-mediated conversion into an oligosaccharide, which is no longer a substrate for the glycosidase. An analogous approach has been employed recently for a chemoenzymatic synthesis of Neu5Acα(2 → 6)-LacNAc using commercial β-galactosidase from *Bacillus circulans* and α-2,6-sialyltransferase from rat liver.[16] We have now developed a sequential multienzyme one-pot system (Scheme 1) with cofactor regeneration for the preparation of the sialylated antigen T-epitope.

In the case of the above model compound[16] the optimal pH of the enzymes used lie in a narrow range, which substantially facilitated the operation as a multienzyme system. The optimal pH of CMP-Neu5Ac synthase (CMP = cytosine monophosphate) from calf brain is 9.0,[17, 18] that of α-2,3-sialyltransferase (ST) from porcine liver 6.5, and that of β-galactosidase from bovine testes (BTG) 4.3.[15] Although the optimal pH of α-2,3-ST is 6.5, it is usually synthesized at pH 7.5 to prevent decomposition of CMP-Neu5Ac at lower pH. This pH is still suitable for CMP-Neu5Ac synthase and for most of other enzymes required for CTP regeneration. The crucial question was whether BTG would be able to operate at a pH quite far from its optimal value to synthesize the intermediate disaccharide.

According to Distler and Jourdian[15] the activity of BTG at pH 7.5 for the substrate lactose is about 19% of its maximum activity. When *p*-nitrophenyl β-D-galactopyranoside (*p*-NP-Gal) is used, the rate of galactose release can be raised to about 30%. The transglycosylation activity of glycosidases in synthesis is quite often pronounced at more basic conditions than at the pH optimum.[19] Therefore, such a shift should support the transglycosylation reaction. Furthermore, the activity of BTG is about twice as high in the presence of *N*-acetylgalactosamine,[15] which most plausibly serves as an acceptor for galactose released, thus shifting the equilibrium of the reaction.

These phenomena should both be of advantage. The hypotheses were tested under real conditions (Na-cacodylate 25 mM, $MnCl_2$ 20 mM, NaCl 75 mM, Triton X-100 1.4% w/v) and *p*-NP-Gal as a substrate. At pH 6.5, 7.0, and 7.5 the BTG activity was 42%, 30%, and 26% of that at pH 4.3, respectively. GalNAc in the final concentration of 250 mM at pH 7.5 elevated the activity 3.6-fold. TLC (*n*-propanol: 1 M NH_3:H_2O = 6:2:1) confirmed the fast formation of the desired disaccharide component **2** in the reaction mixture.

To investigate the course of the ST reaction in the presence of *p*-nitrophenol released from *p*-NP-Gal, and the coupling of transgalactosylation of GalNAc with the transfer of Neu5Ac to the acceptor disaccharide, we used radioactively labeled CMP-Neu5Ac. When lactose was the Gal-donor instead of *p*-NP-Gal, the (analytical) yield of **3** was 20% higher. However, we decided to use *p*-NP-Gal for preparative purposes to simplify the purification procedure. This part of reaction sequence without CMP-Neu5Ac regeneration was optimized with the radioactively labeled substrate. It was shown that CMP-Neu5Ac is not hydrolyzed in the BTG preparation used.[14]

This part of the reaction sequence was then coupled to a modified multienzymatic system that regenerates CMP-Neu5Ac[12] (Scheme 1). The final composition of the reaction mixture for a semipreparative scale is given in the experimental section. The analytical yield of the trisaccharide **3** based on Neu5Ac was 45%, the isolated yield 36%.

The reaction was followed by a new colorimetric system that enabled the determination of the proportion of free Neu5Ac, CMP-Neu5Ac, and the product (**3**) at any time. The course of reaction and reactant additions could therefore be optimized (Fig. 1).

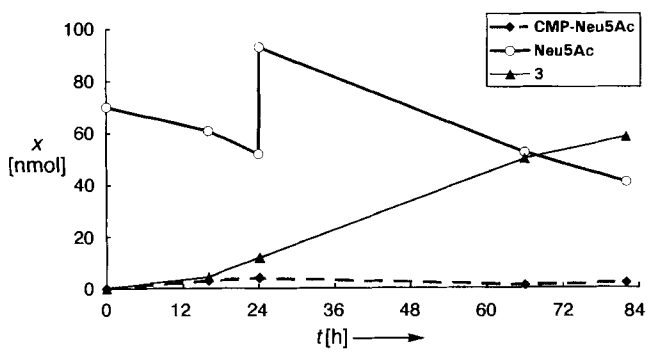

Fig. 1. Synthesis of **3** by incorporation of Neu5Ac into **2** (see Scheme 1) during the multienzyme one-pot reaction (*x* is the amount of substance, *t* the reaction time).

Neu5Ac is present in the reaction mixture in three forms: free, as CMP-Neu5Ac, and incorporated into the trisaccharide **3**. Total Neu5Ac can be determined after hydrolysis of the sample (pH 1, 80 °C, 1 h) by the thiobarbituric acid method.[21] The amount of Neu5Ac incorporated into the product **3**, that is, the analytical yield of the reaction, can be determined after passing the sample, diluted in phosphate buffer (5 mM, pH 6.9), through a Pasteur pipette filled with Dowex 1 × 8, 200–400/(PO_4^{3-}). The ion exchange resin retains both Neu5Ac and CMP-Neu5Ac so that the amount of the product can be assayed by the thiobarbituric acid method after acid hydrolysis. The sum of the Neu5Ac incorporated into the product **3** and into the CMP-Neu5Ac can be determined after treatment of the reaction mixture with $NaBH_4$, followed by acid hydrolysis and the thiobarbituric acid assay. Free Neu5Ac is reduced to the Neu5Ac-alditol that does not give a color reaction with thiobarbituric acid. This system is applicable to the optimization of the course of the reaction and the determination of the analytical yield of any other transsialylation reactions employing both sialyltransferases and sialidases.

In summary, the concept of multienzyme reactions with integrated cofactor regeneration was shown to be useful for sequential synthesis of rather complicated heterooligoglycosides. Furthermore, enzymes with rather widely separated optimal pH values can be employed when the reaction conditions carefully rationalized and optimized. These results open new perspectives for one-pot syntheses of glycosides having as many as three to four different glycosyl units.

Experimental Procedure

Enzymatic synthesis of **3**: Neu5Ac (70 μmol; 0.7 mL of 0.1 M solution neutralized to pH 7.5 by $NaHCO_3$), CMP (50 mg, 100 μmol), ATP (5 μmol), CTP (0.5 μmol), phosphoenolpyruvate (K salt, 300 mg, 200 μmol), **1** (150 mg, 0.7 mmol), *p*-nitrophenyl β-D-galactopyranoside (300 mg, 1 mmol), $MnCl_2$ (60 μmol; 60 μL of 1 M solution), $MgCl_2$ (0.12 mmol; 120 μL of 1 M solution), KCl (0.2 mmol; 200 μL of 1 M solution), and Na-cacodylate buffer (1 mL; 0.25 M, pH 7.5 containing 2% of Triton X-100) were mixed and adjusted to approximately 5 mL with H_2O. The pH was adjusted to 7.5 (NaOH). The enzymes myokinase from porcine muscle ([EC 2.7.4.3], 600 U), pyruvate kinase ([EC 2.7.1.40], 1200 U), inorganic phosphatase ([EC 3.6.1.1], 5 U), CMP-Neu5Ac synthase from calf brain immobilized on the CNBr Sepharose [20] ([EC 2.7.7.43], 1 U), β-galactosidase from bovine testes [14] ([EC 3.2.1.23], 1.5 U), α-2,3-sialyltransferase (porcine liver) ([EC 2.4.99], 0.1 U)[9, 17, 22] were added, and the mixture was made up to 10 mL. After 16 h of incubation at 37 °C more *p*-NP-Gal (300 mg, 200 μmol) and β-galactosidase (0.7 U) were added (pH was adjusted to 7.5), and after another 24 h Neu5Ac (40 μmol), CMP-Neu5Ac synthase (0.2 U), and sialyltransferase (0.07 U). After a further 24 h, sialyltransferase (0.07 U) was again added, and the reaction was terminated after a total of 82 h. The reaction mixture was diluted with water to twice its volume, and approximately 7 mL of Dowex 1 × 2 (200–400 mesh)/PO_4^{3-}, equilibrated in 5 mM NaP_i buffer, pH 6.9) were added. After 20 min the supernatant was collected, and the ion exchange resin was washed with 15 mL of the equilibration buffer. This treatment removes all free Neu5Ac, CMP-Neu5Ac, and *p*-nitrophenol. The pooled elutes were concentrated by lyophilization to approximately 2 mL and applied to the column (4 × 100 cm) of BioGel P2 (200–400 mesh) with water as eluent. The fractions containing the trisaccharide (refractometric detection, thiobarbiturate assay[21]) were pooled and lyophilized to give 27 mg of the product **3** (isolated yield 26 mg, 36%; analytical yield determined at the end of the reaction 45% based on Neu5Ac).

3: ^{1}H NMR (400 MHz, D_2O; equilibrium in water: α:β ratio 5:4): $\delta = 1.72$ (t, 0.56 H, $J_{3'''a,4'''} = J_{3'''a,3'''e} = 12.2$ Hz, H-3‴*a* β-anomer), 1.73 (t, 0.44 H, $J_{3'''a,4'''} = J_{3'''a,3'''e} = 12.2$ Hz, H-3‴*a* α-anomer), 1.97 (s, 3 H, 5′-NAc), 1.99 (s, 1.7 H, 2-NAc β-anomer), 1.99 (s, 1.3 H, 2-NAc α-anomer), 2.69 (dd, 1 H, $J_{3'''e,4'''} = 4.1$ Hz, H-3‴*e*), 4.44 (d, 0.44 H, $J_{1',2'} = 7.6$ Hz, H-1′ β-anomer), 4.51 (d, 0.56 H, $J_{1',2'} = 7.6$ Hz, H-1′ α-anomer), 4.63 (d, 0.44 H, $J_{1,2} = 9.2$ Hz, H-1 β-anomer), 5.17 (d, 0.56 H, $J_{1,2} = 4.1$ Hz, H-1 α-anomer). The data are in agreement with the previously published spectrum (250 MHz) [9] of **3**.

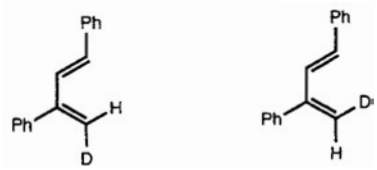
The Dimerization of (*E*)-1,3-Diphenyl-1,3-butadiene Proceeds Suprafacially with Respect to Both Components: Evidence for a Concerted [4 + 2] Cycloaddition

Johann Mulzer* and Katja Melzer



The stereochemistry of the dimerization of 1,3-butadiene and its derivatives has been studied intensively over the past two decades, with contradictory results. For instance, Stephenson et. al.[1] found that the stereochemical purity of the product was reduced by 10%. They interpreted this as the result of competing pathways, the allowed [$4_s + 2_s$] and forbidden [$4_s + 2_a$] pathways in a ratio of 9:1. According to a recent analysis by Klärner et. al.,[2, 3] the reaction actually proceeds with 97% stereoselectivity! An analogous result was obtained by Berson and Malherbe for the dimerization of piperylene.[4] Based on these findings a concerted mechanism was postulated as the dominant path-

[*] Prof. Dr. J. Mulzer, Dipl.-Chem. K. Melzer

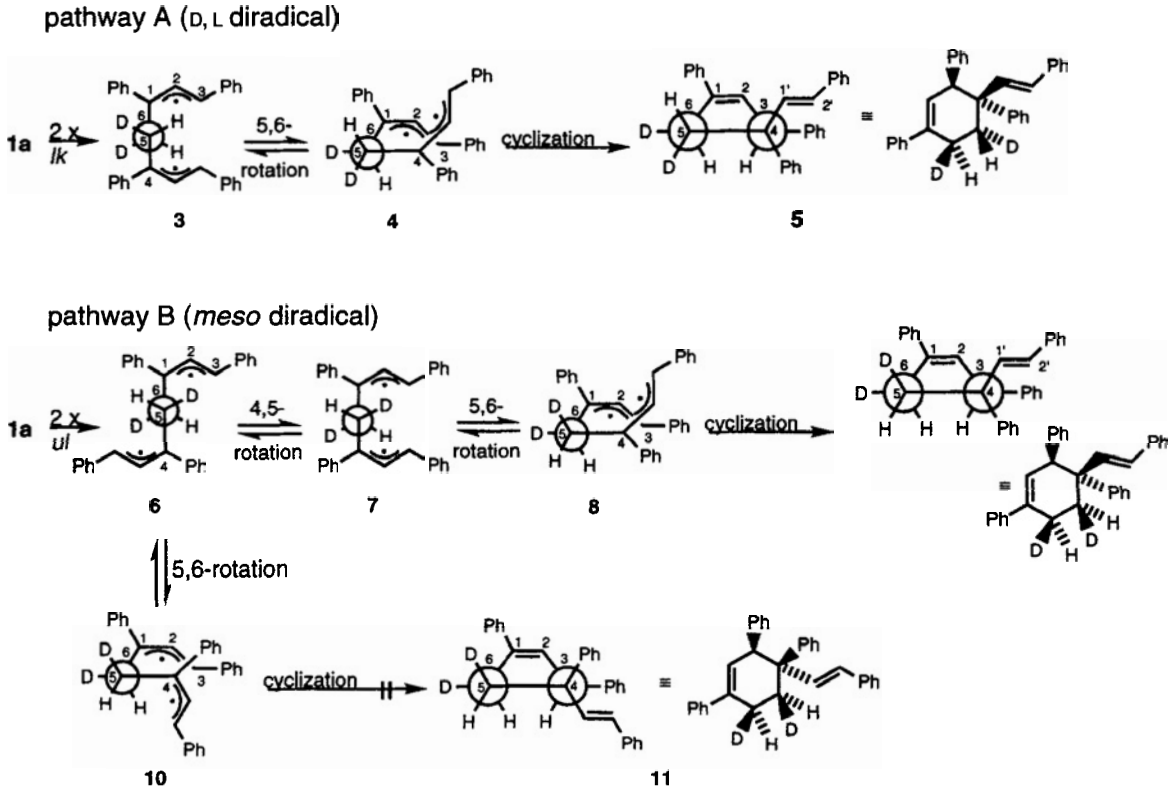
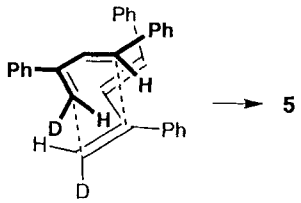
way for the dimerization of butadiene in competition with the stepwise mechanism. In the dimerization of 2,3-dimethyl-1,3-butadiene a two-step mechanism with a diradical intermediate competes with a concerted mechanism in a similiar way,[5] and a diradical mechanism was proved for one of the [4 + 2] dimers of chloroprene.[3] Ab initio calculations for 1,3-butadiene by Li and Houk showed a preference for the stepwise mechanism over the concerted one by 1.3 kcal mol^{-1}.[6] We found previously[7] that the dimerization of (*E*)-1,3-diphenyl-1,3-butadiene (**1**) significantly differs from the butadiene dimerizations studied to

1 **2**



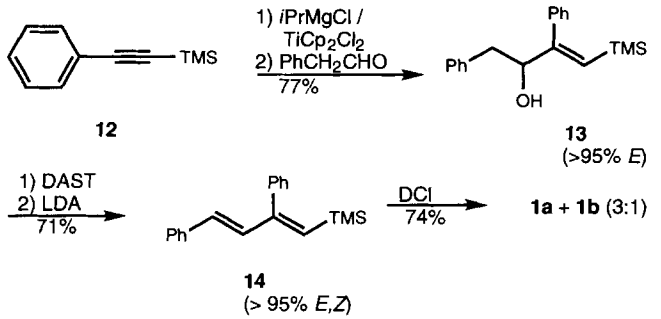
1a **1b**



date. The reaction proceeds at 22 °C in condensed media and provides exclusively the [4 + 2] *endo* dimer **2** with high regio- and stereocontrol (both >97%). The reaction shows an significant substituent effect; for instance (*E*)-1,3-diphenyl-1,3-butadiene (**1**) dimerizes 10^6 times faster than 1,3-butadiene or its alkyl derivatives. For this reason and because of the low solvent effect the dimerization of **1** was regarded as a clearcut example of a diradical Diels–Alder-type cycloaddition.[7, 8]

To further support or disprove the diradical mechanism we decided to study the faciality of the reaction with respect to both the diene and the dienophile by using the monodeuterated butadienes **1a** and **1b**. In the diradical dimerization of **1a** (Scheme 1) the first bond forms between the terminal C atoms in 4-position. Bond formation proceeds with about equal rates by either pathway because of the low difference in energy between the diastereomeric diradicals **3** and **6**.[9] In pathway A the terminal C atoms are joined in a *Re–Re* or *Si–Si* fashion (*lk* arrangement) to give the D,L diradical **3**, which after rotation about the C5–C6 bond cyclizes to dimer **5** (*3r,4t,5t,6c* configuration). On the other hand, the initiating step in pathway B proceeds through a *ul* arrangement to give the *meso* diradical **6**. Rotation about the C5–C6 bond then leads to **10**, which obviously cannot cyclize owing to steric repulsion between the phenyl substituents, and the corresponding dimer **11** is not formed in the reaction. Cyclization is possible only after rotation about the C4–C5 bond giving **7**, followed by rotation about the C5–C6 bond yielding **8**. Cyclization then leads to dimer **9** (*3r,4t,5c,6c* configuration). Since no change in the deuterium distribution of the starting material was detected during the reaction, formation of both C–C bonds must be irreversible. Cyclization of the diradical intermediate proceeds equally well regardless of whether one (pathway A) or two rotations (pathway B) occur. Therefore if a diradical mechanism is involved, dimers **5** and **9** should be formed in equal amounts, whereas a concerted mechanism would lead to dimer **5** as the only product (Scheme 2).

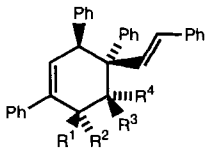
For the synthesis of **1a** (Scheme 3) phenyl(trimethylsilyl)acetylene (**12**) was submitted to a *cis*-selective hydromagnesation.[10]



Scheme 1. Conceivable mechanisms for the diradical dimerization of **1**. The numbering of the C atoms corresponds to that of the product

Scheme 2. Concerted dimerization of **1**.

The resulting Grignard species was immediately quenched with phenylacetaldehyde to give alcohol **13** with (*E*) configuration. Treatment of **13** with *N*,*N*-diethylaminosulfur-trifluoride (DAST) and subsequently with LDA furnished the stereochemically pure (*E*,*Z*) silyldiene **14**. Deuteriolysis of **14** with DCl[11] led to a 3:1 mixture of the monodeuteriobutadienes **1a** and **1b**.[12] The dimerization of the **1a**/**b** mixture was performed without a solvent as described[7] to give the



Scheme 3. Synthesis of **1a**, **b**.

crystalline dimers (see Table 1) in quantitative yield. NOE measurements (500 MHz) of undeuteriated **2** allowed the unambiguous assignment of the ^{1}H NMR signals of the protons in 5- and 6-position (Fig. 1). The intensities of these signals relative to that of the signal of 3-H were determined with a maximum error of $< 5\%$, and the ratio of 5-H_α:5-H_β:6-H_α:6-H_β was found to be 0.26:0.74:0.72:0.26.

On calculating the expected distribution of the deuterium label at the four positions, it must be considered that **1a** and **1b** (ratio 3:1) dimerize statistically. Table 1 shows how the expected relative intensities of the 5-H and 6-H signals for the products

Table 1. Calculated and experimental relative intensities for the ^{1}H NMR signals of the protons at C5 and C6 in the products arising from pathways A and B (e.g. rel. probability for **1a** + **1a** → **5** is $0.75 \times 0.75 = 0.56$; for **1a** + **1b** → **9**, $0.75 \times 0.25 = 0.19$ and so on).

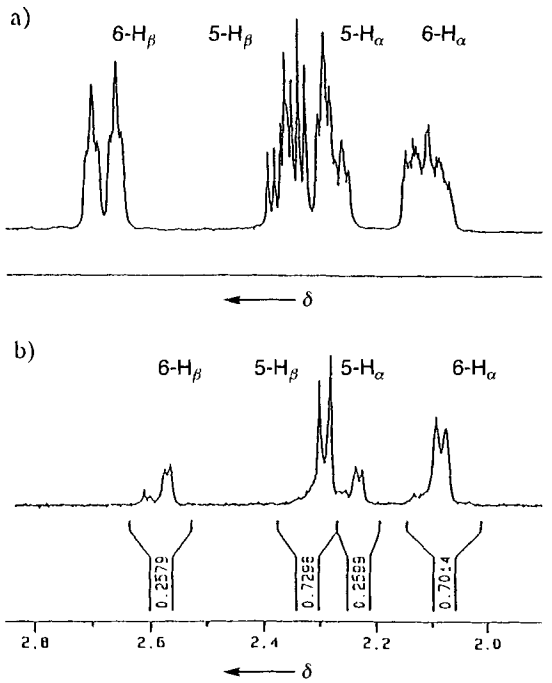

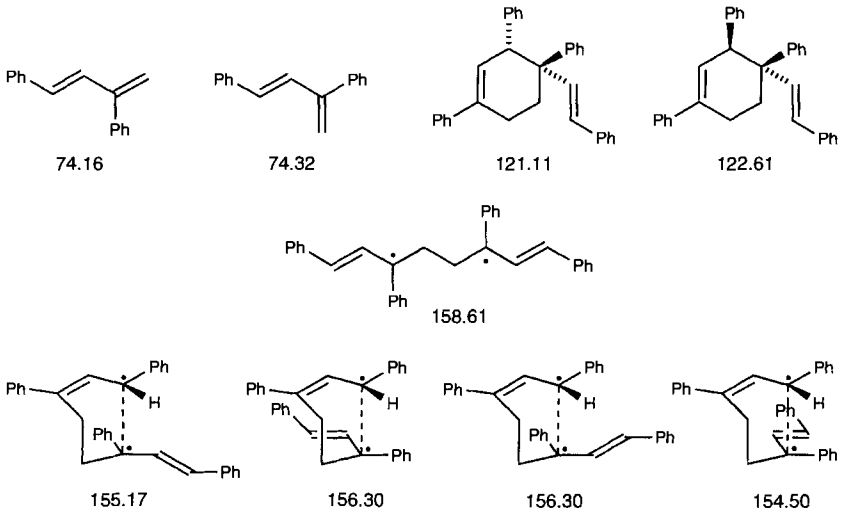

Fig. 1. a) Section of the ^{1}H NMR spectrum of **2**; b) section of the ^{1}H NMR spectrum of the mixture of deuterated regioisomers **5**, **9**, **15**, and **16** obtained from dimerization of **1a**,**b**.

of pathways A and B are calculated from the relative probabilities of the four combinations (**1a** + **1a**, **1a** + **1b**, **1b** + **1a**, **1b** + **1b**). The ratio of the signal intensities 5-H_α:5-H_β:6-H_α:6-H_β is 2:2:3:1 for the diradical mechanism and 1:3:3:1 for the concerted mechanism. The difference in the two mechanisms is reflected in the ratio of the relative intensities of the 5-H_α and 5-H_β signals, which is 1:1 for the diradical mechanism and 1:3 for the concerted mechanism. The experimentally determined ratio (Table 1, Fig. 1) indicates unequivocally that only the concerted mechanism is in effect in the dimerization. These conclusions are confirmed by force field calculations (MMEVBH).[13] The energy level diagram for the dimerization shows that the transition state in the diradical mechanism is 10 kcal mol^{-1} higher in energy than that in the concerted one (Fig. 2). The energies given in Figure 2 are mean values; the exact values are listed in Scheme 4. The high barrier for 1,6-cyclization with formation of the C3–C4 bond (13.4 kcal mol^{-1}) is remarkable. A comparable barrier for redissociation must be assumed to explain the irreversibility of the formation of the first C–C bond (between C1 and C6). This may be rationalized by a *cisoid* comformation of the diradical in the ground state (e.g. **4** and **8**) stabilized by π–π interactions between the allyl units, but this might be farfetched. In calculations on the dimerization of 1,3-butadiene Li and Houk found formation of the first C–C bond to be irreversible.[6]

We have shown that the dimerization of (*E*)-1,3-diphenylbutadiene follows a concerted mechanism, even though a diradical

intermediate would be stabilized. Doering et al. reached similar conclusions in studies of the Cope rearrangement: phenyl substituents facilitated the concerted mechanism.[14]

[9] In a [4 + 2] dimerization one butadiene moiety must be in *s-cis* conformation; the second may be either *s-cis* or *s-trans*. If both partners are in *s-trans* conformation, only [2 + 2] cycloaddition can occur. Since we did not detect the corresponding product, we assume that **1** adopts mainly the *s-cis* conformation in the ground state. For simplicity we will consider this the sole conformation, although this point is not essential for our discussion.

$Li_5Pt_2H_9$, a Complex Hydride Containing Isolated $[Pt_2H_9]^{5-}$ Ions**

Welf Bronger* and Lothar à Brassard

In the area of alkali-metal platinum hydrides, we have previously reported the syntheses and the determination of the crystal structures of the compounds A_2PtH_4 (A = Na, K, Rb, or Cs)[1–3] and A_3PtH_5 (A = K, Rb, or Cs).[4] The structures of these ternary hydrides are all characterized by square-planar $[PtH_4]^{2-}$ ions. Because of the high thermal mobility of the hydrogen atoms, in each high-temperature modification of these compounds the averaged structure shows an octahedral coordination of each platinum atom with an occupation factor of 2/3.

The synthesis of these ternary hydrides entailed the conversion of the binary alkali-metal hydrides with platinum sponge in an atmosphere of highly pure hydrogen gas. The required reaction temperatures lay between 580 and 700 K while the hydrogen pressures varied between 1 and 10 bar.

Recently we have shown that it is possible, using high pressures of hydrogen, to oxidize platinum beyond the + II oxidation state and up to the + IV oxidation state, so obtaining hydrides of the composition A_2PtH_6 (A = Na, K, Rb, or Cs).[5–7] The determination of the structures of these compounds revealed that they are isotypic with that of K_2PtCl_6.

[**] This work was supported by the Bundesministerium für Forschung und Technologie, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the ICDD Grant-in-Aid Programme, and by the Large Installation Plan of the European Community Commission. We would like to thank Dr. Gudrun Auffermann and Dr. Paul Müller for carrying out the neutron diffraction experiments. Grateful thanks are also extended to the Hahn Meitner Institute (HMI) in Berlin and the Risø National Laboratory for allocating measurement time to us.

In the lithium/platinum/hydrogen system, only the compound $LiPtH_{0.66}$ has been hitherto synthesized and structurally characterized.[8] The structure of this compound corresponds to that of a metallic hydride in which lithium and platinum form alternate layers of hexagonal closest packed atoms. Dependent upon the temperature, the hydrogen atoms can reversibly occupy the available tetrahedral holes in this structure. The possibility remained that, under high hydrogen pressures, platinum could be oxidized further to yield saltlike, ternary lithium platinum hydrides. Our experiments now show that this is indeed possible. With a reaction pressure of 1250 bar of hydrogen at a temperature of 820 K and a reaction duration of one hour, a hitherto unknown hydride results, structural analysis of which yielded the composition $Li_5Pt_2H_9$. In this experiment a mixture of LiH (Alfa Products; stated purity 98%) and platinum (Degussa; stated purity 99.9%) in the respective molar ratio of 2.8:1 were employed, and the ternary hydride resulted as a finely crystalline, anthracite-colored caked solid, which was very air- and moisture-sensitive.

X-ray investigations using the Guinier method (Huber diffractometer G644) revealed a tetragonal unit cell in which the positions of the platinum atoms could be determined. In order to facilitate a complete structural elucidation, the corresponding deuteride, which could be synthesized by an analogous method to that used for the hydride, was subjected to elastic neutron diffraction studies. The first experiment was carried out at the reactor of the HMI in Berlin and yielded the complete structural determination. Further confirmation was provided by the data from a later experiment on the TAS III site of the DR3 reactor in the Risø National Laboratory (Denmark), which uses neutrons associated with a shorter wavelength than those generated at the HMI. An aluminum tube (diameter 10 mm, length 40 mm, wall thickness 0.05 mm) into which a second thin-walled aluminum tube (diameter 4.5 mm) was fitted to reduce the absorption effects further, served as the sample container for these studies. The substance was added to this hollow cylinder under argon, and the vessel sealed with a Viton gasket. The resulting data were analyzed with the program Fullprof (Rietfeld method).[9]

The lattice constants for the hydride and deuteride, determined from the Guinier diagrams, are reproduced in Table 1. The neutron diffraction diagram obtained on TAS III and that calculated for the refined structure are shown in Figure 1. The data are also collated in Table 1. When the refinement was complete, the occupation parameters of the atoms were allowed to vary. However, deviations from the $Li_5Pt_2H_9$ composition were not observed. The structure of the ternary hydride is depicted in Figure 2, but only half of the unit cell ($c/2$) is shown to retain clarity.

Table 1. Lattice constants of $Li_5Pt_2H_9$ and $Li_5Pt_2D_9$ (Guinier process, $Cu_{K\alpha_1}$ radiation) and the results of the elastic neutron diffraction experiments on workstation TAS III at room temperature (space group $I4/mcm$, $Z = 4$).

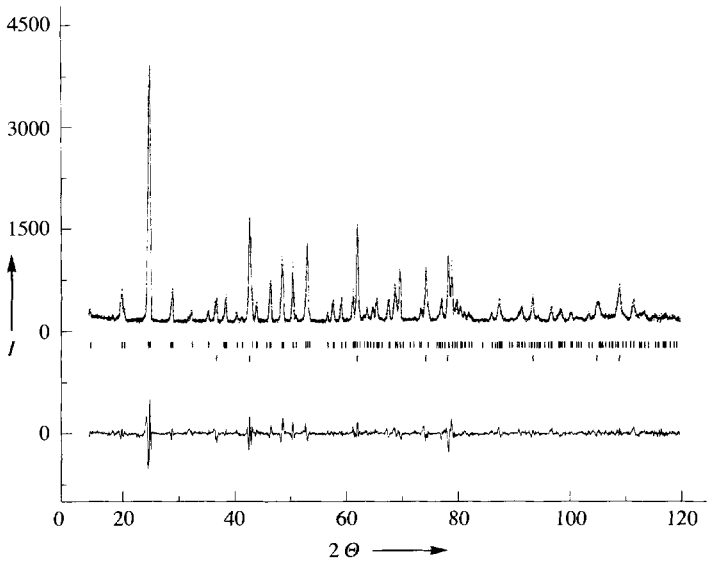

Fig. 1. The neutron diffraction diagram of $Li_5Pt_2D_9$, the measured (·), calculated (—), and difference profiles are depicted. In addition, the line diagrams of the reflections of $Li_5Pt_2D_9$ and of the aluminum tube, which was also refined, are shown.

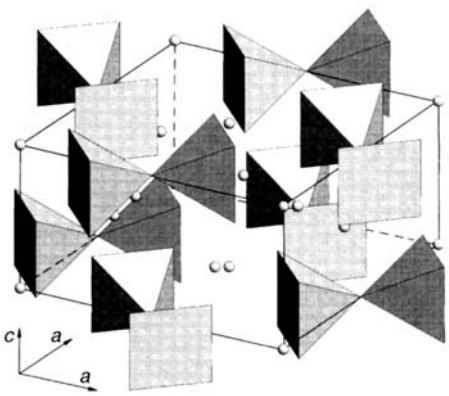

Fig. 2. The structure of $Li_5Pt_2D_9$. The square double pyramids formed by the deuterium atoms and centered by the platinum atoms are shown as well as the positions of the lithium atoms. The half unit cell ($c/2$) is indicated.

The atomic arrangement of $Li_5Pt_2D_9$ contains the surprisingly novel anionic complex $[Pt_2D_9]^{5-}$ (Fig. 3), in which the platinum atoms are each coordinated by five deuterium ligands. Four of these ligands form, within the experimental accuracy, a square plane. The platinum atom is displaced 0.196 Å from the center of the plane in the direction of the fifth, apical deuterium atom. The fifth deuterium atom acts simultaneously as the bridge to the second, identical coordination polyhedron such that the two planar pyramids are connected to each other through a common vertex. The Pt-D-Pt bridge is linear and the two square planes of deuterium ligands per anion are arranged in an eclipsed conformation with respect to one another. To our knowledge, an analogous structure has not hitherto been reported. Selected distances are compiled in Table 2. The Li2 atoms

are cubically coordinated by eight deuterium ligands while the Li1 atoms are sevenfold coordinated. The coordination polyhedron may be described as an extended, simple capped trigonal prism.

In order to obtain more information about the properties of this compound, its magnetic susceptibility was measured between 4 and 298 K by the Faraday method. A weak, virtually temperature-independent diamagnetism of $-90(10)\times 10^6\,cm^{-3}mol^{-1}$ was observed. The value calculated per formula unit from the diamagnetic increments is $-94\times 10^6\,cm^{-3}mol^{-1}$ when one substitutes the values -40 for Pt^{2+}, -0.6 for Li^+, and $-1.2\times 10^6\,cm^{-3}mol^{-1}$ for H^-.

Aldehyde-Appended Tetraphenylporphyrin: A New Building Block for Porphyrin Arrays**

Anthony K. Burrell, David L. Officer,* and David C. W. Reid

Photosynthesis is a marvelous but highly complex process that has intrigued researchers for many years.[1] It has been studied extensively by scientists from a variety of disciplines, with a view to increasing the understanding of the photosynthetic mechanism and utilizing this inexhaustible supply of energy. In the main, studies of the conversion of light to chemical energy have focused on the latter stages of the process, modeling the electron transfer processes involved with donor–acceptor molecules as models.[2] Much less attention has been paid to the mechanism of photon capture and the construction of the required light-harvesting porphyrin arrays. Viable syntheses of suitably large arrays have only recently become available with the development of "building block" methodologies as exemplified by the work of Anderson et al.,[3] Lin et al.,[1] and Lindsey et al.[4]. The building block approach is quick and inherently flexible since only small changes in the conditions give access to a variety of arrays. Herein we describe the synthesis and structure of a substituted tetraphenylporphyrin (TPP) **1** that has been used successfully in a building block approach to array construction.

Porphyrin **1** has a number of features that make it appealing as a building block. It is simple to prepare in high yield. The porphine ring can be metalated to alter the properties of the putative arrays. Aldehyde functionalities are well established in the syntheses of porphyrin systems. The synthesis of **1** relies on a Wittig reaction and is based on methodology developed by Bonfantini and Officer.[5] Reaction of phosphonium salt **2** and dialdehyde **3** under Wittig conditions gives a *cis*/*trans* mixture of **1** which is easily isomerized to *trans*-**1** in 80% overall yield (Scheme 1). Porphyrin **1** can be metalated[6] to give metalloporphyrins **1**-Cu, **1**-Ni, and **1**-Pd.[7]

Scheme 1. a) DBU, CH_2Cl_2, room temperature, 1 min; b) I_2, CH_2Cl_2, room temperature, 16 h.

Single crystals of **1**-Cu suitable for X-ray diffraction were obtained by slow diffusion of ethanol into a solution of **1**-Cu in chloroform, and the structural data were collected and refined by standard techniques.[8] We believe this to be the first 2-vinyl-substituted tetraphenylporphyrin to be characterized by X-ray crystallography. The crystal structure of **1**-Cu is shown in Figure 1, and several interesting features should be noted. The olefin unit and aldehyde are coplanar, while the torsion angle between the olefin and porphine ring[9] is small ($\approx 17°$). The overall planarity of this molecule (excluding the *meso*-phenyl substituents) and the fact that the solution UV/Vis spectra of **1** and **1**-Cu show red-shifted Soret bands (relative to TPP and CuTPP) lead us to believe that there is nothing preventing conjugation between the porphine and aldehyde moieties of **1**. This is contrary to previous postulations that conjugation of this kind is unlikely.[10] The existence of conjugation between porphine and aromatic aldehyde has important implications for the rate of electron transfer in oligomers and arrays containing this structural unit.

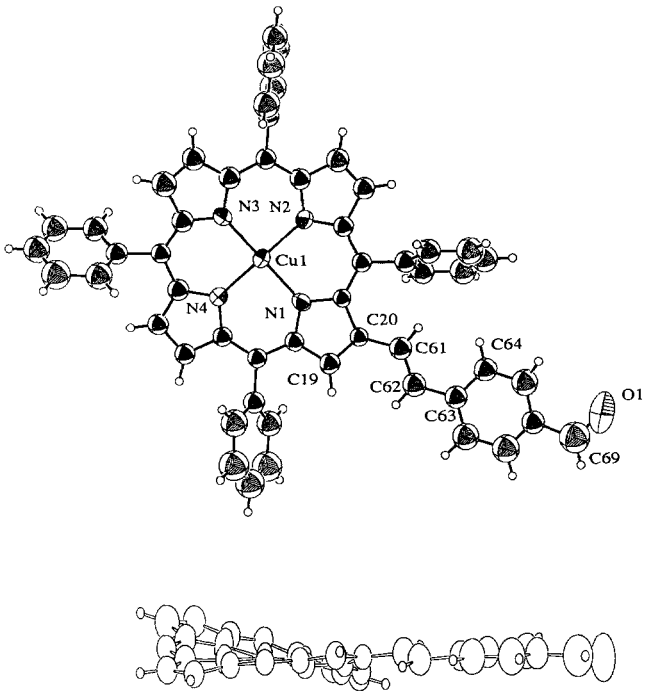

Fig. 1. Crystal structure of **1**-Cu. Top: Top view (torsion angle C19-C20-C61-C62 17(2)); bottom: side view (*meso*-phenyl rings omitted for clarity).

The stacking of the porphyrins in the crystal lattice (Fig. 2) is interesting. The $\pi-\pi$ interactions clearly present are typical of the kind predicted by Hunter and Sanders.[11] It should be noted, however, that they excluded tetraarylporphyrins from their calculations of porphyrin–porphyrin interactions in the solid state on the grounds that steric and electrostatic effects could disrupt these interactions. Figure 2 also shows a notable $\pi-\pi$ interaction between one porphine ring and the formyl-substituted aromatic ring of an adjacent molecule.

Scheme 2. a) Aqueous NaOH, CH_2Cl_2, room temperature, 1 h; b) CF_3COOH, CH_2Cl_2, room temperature, 4 h; c) *o*-chloranil, reflux, 8 h.

The utility of **1** as a building block for porphyrin arrays is demonstrated by the formation of dimeric and trimeric porphyrin systems. Thus, building block **1** undergoes a Wittig reaction with phosphonium salt **2** to give dimer **4** (Scheme 2). Given that the crystal structure and UV-Vis spectra of **1**-Cu imply conjugation between the porphine ring and the aldehyde group, dimer **4** is of interest because it has the potential to be fully conjugated across both porphine rings. Unfortunately the characterization of **4** is severely limited by poor solubility,[12] and therefore this issue remains unresolved until a more soluble analogue is available.[13] A similar Wittig reaction using **1**-Pd and **2**-Ni[14] gives the novel heterodimetallic complex **4**-PdNi. This illustrates the flexibility of this approach as well as the ease with which a variety of metals can be selectively incorporated into dimeric porphyrins by this methodology.

Facile condensation of **1** and dipyrrylmethane **5** gives the trimeric array **6** (Scheme 2).[15] Trimer **6** has better solubility than dimer **4** in organic solvents. If the condensation is repeated

with **1**-Ni, the trimer **6**-Ni_2 is obtained. Thus not only does this building block approach give access to arrays of different sizes but also systematic and controlled metalation is easily achieved.

Porphyrin **1** is an ideal building block for the synthesis porphyrin arrays. It is easily prepared on a large scale and in high yield, and can be metalated as required. The array-forming reactions (to form dimeric and trimeric porphyrins) are higher yielding than for comparable molecules prepared by linear synthetic strategies. Overall we believe that this building block approach has great promise, and our current research is directed towards using **1** and similar building blocks to construct larger arrays.

Experimental Procedure

1: Phosphonium salt **2** (113 mg, 0.12 mmol) and dialdehyde **3** (18 mg, 0.13 mmol) were dissolved in CH_2Cl_2 (20 mL) and stirred at room temperature before 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (0.5 mL) was added. After 1 min, the reaction mixture was chromatographed (silica gel, 1:1 CH_2Cl_2:hexane) to give a purple solid. The solid, a *cis/trans* mixture of products, was dissolved in CH_2Cl_2 (40 mL). I_2 (22 mg, 87 mmol) was added and the reaction mixture stirred at room temperature for 16 h. The reaction mixture was diluted with CH_2Cl_2 (20 mL), washed with aqueous $Na_2S_2O_3$ (1 M; 2 × 20 mL) and H_2O (2 × 20 mL), and dried ($MgSO_4$), and the solvent was removed under reduced pressure. Flash chromatography as described above yielded *trans*-**1** as a purple solid (80 mg, 88%). ^1H NMR (270 MHz, $CDCl_3$, TMS): $\delta = -2.59$ (br. s, 2H; NH), 7.13 (d, $^3J = 16.2$ Hz, 1H; $H_{ethenyl}$), 7.31 (d, $^3J = 16.2$ Hz, 1H; $H_{ethenyl}$), 7.37 (d, 2H; H_{Ar}), 7.71–7.83 (m, 14H; $H_{m,pPh}$ and H_{Ar}), 8.18–8.27 (m, 8H; H_{oPh}), 8.72-8.83 (m, 6H; $H_{pyrrole}$), 9.02 (s, 1H; $H_{pyrrole}$), 9.99 (s, 1H; CHO); UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 428 (5.31), 525 (4.32), 566 (4.13), 600 (3.95), 658 (3.69); FAB MS: *m/z*: 744 (M^+).

4: Aldehyde **1** (12 mg, 16 mmol) and phosphonium salt **2** (15 mg, 16 mmol) were dissolved in CH_2Cl_2 (3 mL), and a solution of NaOH (0.4 g) in H_2O (0.6 mL) was added. After 1 h of stirring at room temperature the reaction mixture was washed with H_2O (2 × 20 mL) and dried ($MgSO_4$), and the solvent removed under reduced pressure to give a purple solid [12]. FAB MS: *m/z*: 1356 (MH^+).

4-PdNi: This dimetalloporphyrin was prepared as for **4** with **1**-Pd as aldehyde and **2**-Ni as phosphonium salt [12]. FAB MS: *m/z*: 1517 (MH^+)

6: Dipyrrylmethane **5** (14 mg, 49 mmol) and aldehyde **1** (37 mg, 50 mmol) were dissolved in CH_2Cl_2 (5 mL) and the mixture bubbled with N_2 for 5 min. Trifluoroacetic acid (3.9 mL, 51 mmol) was added by syringe and the reaction stirred for 4 h at room temperature. *o*-Chloranil (19 mg, 77 mmol) was added and the reaction mixture heated to reflux for 8 h. The solvent was removed under reduced pressure and the resulting solid purified by column chromatography (silica gel, 5:1 CH_2Cl_2:hexane with 2% methanol). Trimer **6** was obtained as a purple solid (33 mg, 69%). ^1H NMR (270 MHz, $CDCl_3$, TMS): $\delta = -2.51$ (br. s, 4H; NH), −2.31 (br. s, 2H; NH), 1.15 (t, $^3J = 7.3$ Hz, 12H; $-CH_2CH_2CH_2CH_3$), 2.00–2.05 (m, 8H; $-CH_2CH_2CH_2CH_3$), 2.22–2.30 (m, 8H; $-CH_2CH_2CH_2CH_3$), 2.65 (s, 12H; $-CH_3$), 4.00–4.11 (m, 8H; $-CH_2CH_2CH_2CH_3$), 7.30 (d, $^3J = 16.2$ Hz, 2H; $H_{ethenyl}$), 7.64 (d, $^3J = 16.2$ Hz, 2H; $H_{ethenyl}$), 7.68 (d, $^3J = 7.9$ Hz, 4H; H_{Ar}), 7.79–7.88 (m, 24H; $H_{m,pPh}$), 8.06 (d, $^3J = 7.9$ Hz, 4H; H_{Ar}), 8.24–8.36 (m, 16H; H_{oPh}), 8.82–8.87 (m, 12H; $H_{pyrrole}$), 9.18 (s, 2H; $H_{pyrrole}$), 10.31 (s, 2H; *meso*-H); UV/Vis (CH_2Cl_2): λ_{max} (logε) = 426 (5.63), 518 (4.70), 566 (4.47), 598 (4.23), 654 (3.68); FAB MS: *m/z*: 2020 (MH^+).

6-Ni_2: This dimetalloporphyrin was prepared as for **6** with **1**-Ni as the aldehyde. Spectroscopic data for **6**-Ni_2 was consistent with the proposed structure.

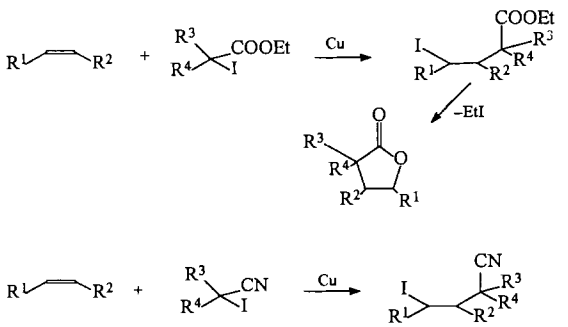
Radical Additions of Activated Haloalkanes to Alkenes Initiated by Electron Transfer from Copper in Solvent-Free Systems**

Jürgen O. Metzger* and Ralf Mahler

Dedicated to Professor Hansjörg Sinn on the occasion of his 65th birthday

The need to reduce the amount of toxic waste and by-products arising from chemical processes requires increasing emphasis on the use of less toxic and environmentally compatible materials in the design of new synthetic methods.[1] The time has now come for ecological factors to be considered in the development of synthetic procedures and for them to play an important role in the assessment of the quality of any new synthesis. Within this context, the reduced use of ecologically suspect solvents is of considerable significance. Thus the radical bromination of alkylarenes in supercritical carbon dioxide has been reported recently.[2] The polymerization of neat methacrylate is an important example of a solvent-free industrial process.[3]



For some time now intermolecular radical addition reactions have been powerful tools in preparative organic chemistry,[4] but the most widely used methods have a number of ecological disadvantages for widespread industrial use. This applies particularly to the frequently used organotin compounds.[5, 6] Transi-

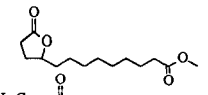
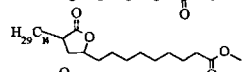
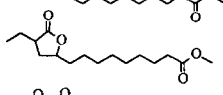
tion metal complexes and salts that initiate radical reactions by electron transfer processes[7] offer a viable alternative. Thus ethyl trichloroacetate and other compounds similarly activated by electron-withdrawing substituents may be induced to undergo radical addition to alkenes by copper(I) chloride[8] in acetonitrile, $[RuCl_2(PPh_3)_3]$,[9] $[CpMo(CO)_3]_2$,[10] $[CpFe(CO)_2]_2$,[10] and $[Co_2(CO)_8]$[10] in benzene and, in the latter example, without solvent.[10] These initiators,[11] as well as $[Pd(PPh_3)_4]$[12] in benzene and [Cu(bpy)Cl] in dichloromethane or 1,2-dichloroethane,[13] have been used successfully for the radical cyclization of esters of a number of suitable unsaturated α-halocarboxylic acids. Methyl α-iodo-(*Z*)-6-octadecenoate has been cyclized to cyclopentanecarboxylic acids by metallic silver in methanol.[14] Metallic copper has been used in the Ullmann reaction for the synthesis of diaryls from aryl halides,[15] and bromomalonodinitrile[16] and 2,2-dibromo-1,3-diones[17] have undergone addition to alkenes in benzene in the presence of copper as an initiator.

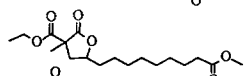
We now report the first radical addition of alkyl α-iodocarboxylates and α-iodoalkanenitriles to alkenes in the absence of solvent initiated by electron transfer from copper metal (Scheme 1). The alkenes most frequently used were the esters of

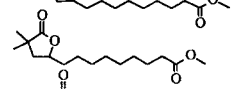
Scheme 1. Cu-catalyzed addition of alkyl α-iodocarboxylates and α-iodoalkanenitriles to alkenes. R^1, R^2, R^3, R^4 = H, alkyl, $(CH_2)_nCOOMe$.

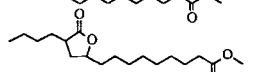


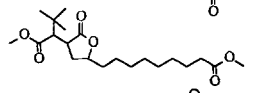


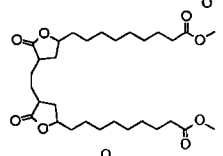


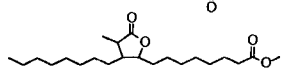


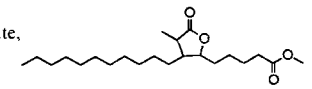


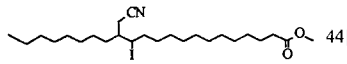










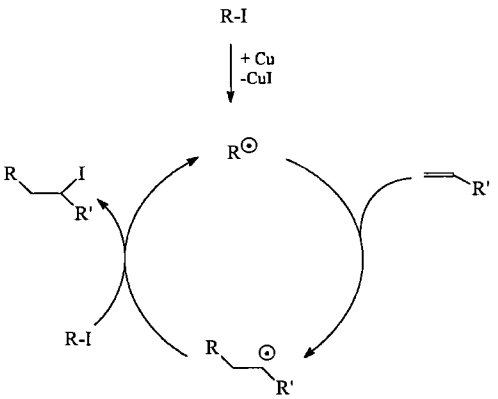


unsaturated carboxylic acids such as methyl 10-undecenoate (**1a**), methyl (*Z*)-9-octadecenoate (**1b**), methyl (*Z*)-13-docosenoate (**1c**), and methyl (*Z*)-6-octadecenoate (**1d**), which are of considerable interest as renewable raw materials.[18]

The reaction procedure is very simple: the alkene, iodo compound, and commercial copper powder are mixed without any pretreatment and heated at 100–130 °C in an inert atmosphere. After a simple workup procedure, the products are obtained analytically pure in satisfactory yields (Table 1).

The addition of alkyl 2-iodocarboxylates to 1-alkenes affords γ-lactones in high yields (entries 1, 2, 3b). The more readily

Table 1. Results of the copper-initiated addition of alkyl 2-halocarboxylates and 2-haloalkanenitriles to alkenes **1a–d**.



Entry	Alkene	Haloalkane	Product[a]	Yield [%]
1	**1a**	ethyl iodoacetate		70[b]
2	**1a**	methyl 2-iodopalmitate		79[b]
3a	**1a**	ethyl 2-bromobutyrate		41[b]
3b	**1a**	ethyl 2-iodobutyrate		80[b]
3c	**1a**	ethyl 2-bromobutyrate, NaI		72[b]
4	**1a**	diethyl 2-bromo-2-methylmalonate		87[b]
5	**1a**	ethyl 2-bromo-2-methylpropionate, NaI		54[b]
6	**1a**	methyl 2-bromohexanoate, NaI		70[b]
7	**1a**	dimethyl 2-bromo-3-*tert*-butylsuccinate, NaI		73[c]
8	**1a**	diethyl 2,5-diiodoadipate		60[c, e]
9	**1b**	ethyl 2-iodopropionate		51[b, d]
10	**1d**	ethyl 2-bromopropionate, NaI		60[b, d, f]
11	**1a**	2-bromohexanenitrile, NaI		55[b]
12	**1c**	iodoacetonitrile		44[b, d]

[a] All products were fully characterized by ^1H NMR and ^{13}C NMR spectroscopy and by mass spectrometry. [b] Isolated yield relative to starting alkene. [c] Isolated yield relative to starting haloalkane. [d] Regioisomeric mixture, ca. 1:1. [e] *c*(**1a**):*c*(iodoalkane) = 6:1. [f] The analogous additions of **1b** and **1c** gave the corresponding products in 58 and 59% yield, respectively.

available alkyl 2-bromocarboxylates also undergo copper-initiated addition to alkenes (entries 3a, 4). High yields are achieved with the more strongly activated alkyl bromomalonates (entry 4), however, yields from reaction with alkyl 2-bromomonocarboxylates (entry 3a) are much lower than with the corresponding iodo compounds (entry 3b). If the iodo derivative is formed from the corresponding bromo compound in situ by the addition of a stoichiometric amount of sodium iodide to the reaction mixture (entries 3c, 5–7), the products are obtained in high yields, similar to those obtained by direct use of the iodo derivatives. In this way primary, secondary, and tertiary alkyl 2-halocarboxylates were added to 1-alkenes. Of particular interest is the example of diethyl 2,5-diiodoadipate, which adds to two equivalents of **1a** to form a di-γ-lactone (entry 8). Radical addition to 1,2-dialkylethenes with extended alkyl groups such as methyl (*Z*)-9-octadecenoate (**1b**) using traditional methods frequently provides the products in only poor yields.[4] Thus in the benzoyl peroxide initiated addition of ethyl bromoacetate (in a tenfold excess) to methyl (*Z*)-9-octadecenoate the product is obtained in only 10% yield.[19] Moreover, using several variants of the tin procedure we were still unable to achieve satisfactory additions.[20] In contrast, with

copper initiation we were able to achieve yields in excess of 50% without any difficulty (entries 9, 10), which could be improved by very slow addition of the halo compound. 2-Iodo- and 2-bromoalkanenitriles add to 1-alkenes such as **1a** and to 1,2-dialkylethenes such as **1c** in an analogous manner (entries 11, 12). In these cases, the iodo functionality is retained, offering interesting possibilities for further transformations.

The reaction is initiated by electron transfer from copper to the activated haloalkane (Scheme 2). The electrophilic radical

Scheme 2. Mechanism for the Cu-initiated addition of iodoalkanes to alkenes. RI = alkyl 2-iodocarboxylates, 2-iodoalkanenitriles, R' = alkyl, $(CH_2)_nCOOMe$.

formed after cleavage of the halide adds to the electron-rich double bond of the alkene, and subsequent halogen abstraction affords the product, which in the case of alkyl 2-halocarboxylates cyclizes to a γ-lactone. About 30% of the copper is oxidized to copper(I) iodide during the reaction and about 20% of the haloalkane is reduced by halogen–hydrogen exchange. It is thus a radical chain reaction with a relatively short chain length. The C–I bond must be activated by an electron-withdrawing substituent. Iodine transfer onto the adduct radical by 1,3-induction is only slightly diastereoselective; the ratio of diastereoisomers is typically *cis*/*trans* = 1.5/1 (entry 2). The same stereoisomeric ratio was also obtained in the corresponding benzoyl peroxide initiated addition[22] and in Curran's iodine transfer method.[23] This confirms that like in these two reactions, the iodoalkane is also the iodine donor in the copper-initiated addition (Scheme 2). When the reaction is carried out with a bromoalkane and sodium iodide, the corresponding iodoalkane is formed as the intermediate, which was confirmed by gas chromatography. Key features of the reaction described here: no solvent is used, the workup procedure is simple in comparison to other methods since the copper powder initiator is unproblematic for workup and separation,[24] the reagents are used in essentially stoichiometric quantities, the yields are comparably high, even with 1,2-dialkylethenes, and the initiator can be reused (after total oxidation of the copper it is readily recovered by reduction).

Experimental Procedure

General method: A 50 mL, two-necked flask equipped with a magnetic stirrer, reflux condenser, and a gas inlet tube was charged with 1.3 equiv of iodoalkane, 1 equiv of alkene, and 1.3 equiv of copper powder (purum, Merck). The mixture was heated with constant stirring at 130 °C in an inert atmosphere [28]. The reaction was monitored by thin-layer chromatography and was usually complete within 3–7 h. The product was isolated by distillation; alternatively, the reaction mixture was taken up into diethyl ether and after removal of the copper salts by filtration and evaporation of the solvent on a rotary evaporator, the product was isolated by Kugelrohr distillation and recrystallization or flash chromatography.

[24] The copper content of the products is about 1 ppm [25], in other words, of the same order of magnitude as the copper content of foodstuffs [26]. Copper is an essential trace element for humans and within certain limits is regarded as being physiologically safe. The method should therefore be suitable for the synthesis of pharmaceuticals.
[25] We thank Dr. I. Block, Staatliches Untersuchungsamt, Oldenburg, for determination of the copper content of our samples by atom absorption spectroscopy.

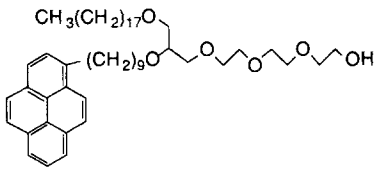
[28] We used a small excess of copper, whereby the reaction rate is increased. About 30% of the copper is oxidized during the reaction. The copper/copper iodide mixture can be reused twice as an initiator. The use of 1.3 equivalents of copper appears high from an ecological viewpoint, even though one batch can be used three times. With respect to both price and weight, however, the amount of copper used is low in comparison to that of the metal complexes mentioned in the text [9–13] such as $[Pd(PPh_3)_4]$. Furthermore, while the separation and recovery of homogeneous catalysts is often difficult if not impossible, that of the copper in our reactions is straightforward. Even the reaction temperature of 130 °C is ecologically acceptable when one considers that foods are cooked at about this temperature.

Metal-Induced Dispersion of Lipid Aggregates: A Simple, Selective, and Sensitive Fluorescent Metal Ion Sensor**



Darryl Y. Sasaki, Deborah R. Shnek, Daniel W. Pack, and Frances H. Arnold*

Lipid reorganization induced by specific ligand binding is a feature intrinsic to biological processes such as signaling,[1] membrane fusion,[2] cell docking,[3] and endocytosis.[4] Often the ligand is a protein, which generates lipid reorganization through multiple lipid–ligand interactions.[5] Lipid reorganization, however, can also be driven with small ions.[6] For example, calcium can induce phase separation of phosphatidylserine lipids in vesicles of phosphatidylcholine lipids[7] or alter the packing phase of cardiolipin from bilayer to inverted hexagonal.[8] In the course of studying substrate binding to metal-complexing lipids and their subsequent reorganization in membrane assemblies,[9] we discovered that metal ions can strongly affect the distribution of the metal-chelating lipid. Lipid **1a**, a pyrene-labeled lipid functionalized with iminodiacetic acid (IDA), forms aggregates when placed in vesicles of distearoyl phosphatidylcholine (DSPC), as evidenced by pyrene excimer formation in steady-state fluorescence measurements. Addition of divalent metal ions essentially instantaneously results in a dramatic reversal of the ratio of emission intensities of excimer and monomer, which is believed to coincide with dispersion of the pyrene-lipid into the gel phase of the matrix DSPC lipid. This process, which is highly sensitive and selective for Cu^{2+}, offers a particularly simple approach to Cu^{2+} detection and quantification.

1a R = H

1b R = CH_2CH_3

2

Lipids **1** and **2** can be co-sonicated in aqueous solution with various phosphatidylcholine lipids to prepare stable mixed bilayer vesicles. The steady-state fluorescence spectrum of 5 mol% lipid **1a** in vesicles of DSPC shown in Figure 1 (curve a) includes

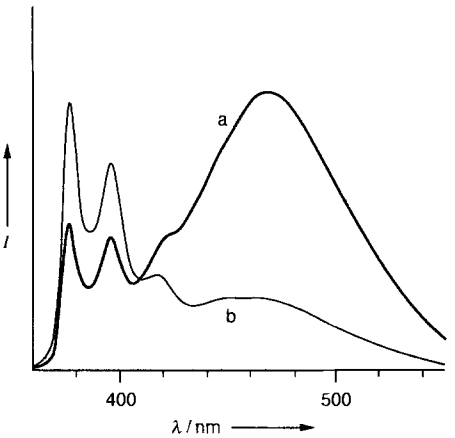


Fig. 1. Fluorescence emission spectra of a) 5% lipid **1a**/95% DSPC and b) 5% lipid **1a**/95% SOPC in a MOPS buffer at 25 °C. MOPS = 3-(4-morpholinyl)-1-propanesulfonic acid.

the monomer emission (maximum at 377 nm) and a broad featureless band with emission maximum at 470 nm, which is attributed to pyrene excimer. The large ratio of the fluorescence intensities of excimer and monomer (E/M) reflects a high local pyrene concentration in the bilayer assembly.[10] The E/M value of vesicles containing 5% lipid **1a** and 95% DSPC is 1.8 (curve a), but drops to only ≈ 0.2 or less in vesicles composed of 5% lipid **1a** in 1:1 DSPC–cholesterol (data not shown) or SOPC (2-oleoyl-1-stearoyl-*sn*-glycero-3-phosphocholine) (curve b). At 25 °C SOPC and DSPC–cholesterol matrix bilayers exist in the fluid phase, while DSPC is in the solid gel phase. The markedly different E/M values suggest that lipid **1a** aggregates or phase separates from the gel matrix of DSPC, but is dispersed in the two fluid bilayers.

The pronounced effect of divalent metal ions on the E/M value of lipid **1a** in DSPC vesicles is illustrated in Figure 2. With increasing metal ion (Mn^{2+}) concentration, the excimer emis-

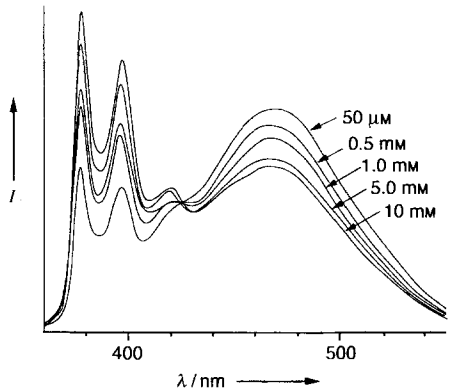

Fig. 2. Fluorescence emission spectra of 5% lipid **1a**/95% DSPC vesicles in a MOPS buffer at 25 °C with increasing concentrations of $MnCl_2$.

sion intensity decreases while the monomer emission increases. Other metal ions have a similar effect, but at different concentrations, as shown in Figure 3. The E/M curves generally parallel the metal ion binding constants to IDA, with the exception that Co^{2+} has a stronger affect than Ni^{2+}.[11] If the observed changes in the E/M values correspond to metal complexation by IDA, however, the metal binding affinity of the IDA headgroup appears to be attenuated by a factor of 100–1000 when incorpo-

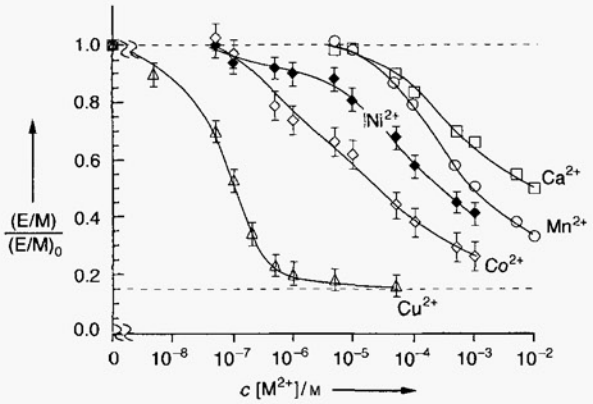

Fig. 3. E/M values (normalized by E/M values without added metal) for 5% lipid **1a**/95% DSPC vesicles, 0.11 mM total lipid, in the presence of various metal ions at 25 °C. The metals were added as the chloride salts in 0.1 M NaCl. Solid curves are drawn in for clarity.

rated into vesicles, relative to that of free *N*-(2-methoxyethyl)-iminodiacetate in solution.[12]

Sensitivity to lower concentrations of metal ions can be obtained by using more dilute vesicles (lower lipid concentrations). Figure 4 shows how titration with Cu^{2+} affects the E/M value of 5% lipid **1a**/95% DSPC vesicle solutions at three lipid concentrations, the lowest of which is 650 nM total phospholipid

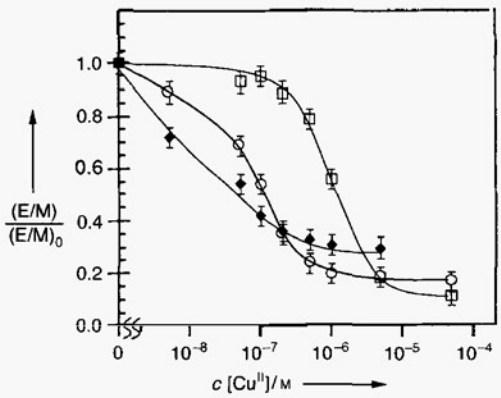

Fig. 4. E/M values (normalized by E/M values without added metal) for 5% lipid **1a**/95% DSPC vesicles in the presence of Cu^{2+} at 25 °C: Total phospholipid 65 μM (□), 6.5 mM (○), and 650 nM (●). The metal was added as the chloride salt in 0.1 M NaCl. Solid curves are drawn in for clarity.

(35 nM lipid **1a**). This system is sensitive to Cu^{2+} at concentrations of 5 nM (less than 1 ppb) in 0.1 M NaCl. It is conceivable that even greater sensitivity can be achieved by using even lower lipid concentrations and a pyrene-labeled lipid with a chelating headgroup with a higher affinity for the metal ion than IDA (e.g., nitrilotriacetate). The changes in E/M values shown in Figures 2–4 occur within seconds of metal ion addition and are completely reversible with the addition of excess ethylenediaminetetraacetate (EDTA).

Owing to the strong affinity of IDA for Cu^{2+}, this bilayer system is highly sensitive and selective for Cu^{2+}. Thus micromolar concentrations of Cu^{2+} ions can be detected in a 0.1 M NaCl solution containing millimolar concentrations of Ca^{2+}. Moreover, the fluorescence effects of submicromolar Cu^{2+} concentrations can be detected by the naked eye in black light (365 nm).

Metal titration studies performed with the non-metal-chelating pyrene lipids **1b** and **2** in DSPC vesicles confirm that the observed E/M change is a consequence of metal chelation by the IDA headgroup, rather than fluorescence quenching or a metal-induced perturbation of the membrane. The fluorescence E/M values of 5% lipid **1** and **2** in DSPC vesicles are shown in the form of a bar graph in Figure 5. While Cu^{2+} at 5 mM concentration induces a large change in the E/M value of the lipid **1a**/DSPC vesicles, it has very little effect on the E/M values of vesicles prepared with the nonchelating pyrene lipids. Even at Cu^{2+} concentrations 1000 times higher (mM), no significant change in fluorescence intensity or E/M value was observed for vesicles containing **1b** and **2**. Furthermore, metal ion addition to vesicles containing lipid **1a** in a fluid matrix (50% DSPC/50% cholesterol or SOPC) also induces only very small changes in the fluorescence E/M value (although quenching is observed for the more fluid SOPC matrix).

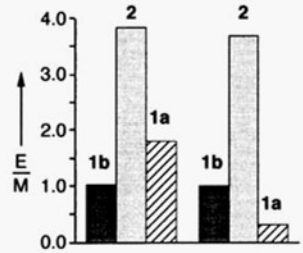

Fig. 5. Bar graph shows E/M values of DSPC vesicles containing 5 mol% lipid **1b**, **2**, or **1a** before (left) and after addition of $CuCl_2$ (5 mM) (right). All measurements done in a MOPS buffer at 25 °C.

It appears that complexation of the metal ion by the IDA headgroup induces the dispersal of lipid **1a** in the DSPC gel matrix, which results in the dramatic reduction in the rate of pyrene collisions, and therefore reduction of the E/M value. This process is illustrated in Figure 6.

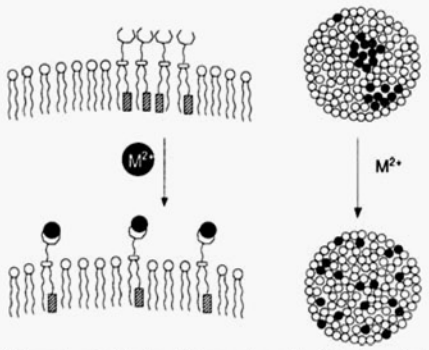

Fig. 6. Schematic representation of metal-induced dispersion of lipid **1a** in vesicles of 5% lipid **1a**/95% DSPC, as observed through fluorescence measurements at 25 °C. Lipid **1a** is believed to assemble into pyrene-rich aggregates which are dispersed upon chelation of a divalent metal ion by the lipid headgroup.

The reorganization of a lipid labeled with a light-emitting group induced by specific substrate binding provides a powerful method for detection of substrates in solution. As a sensing device, this extremely simple, two-component system offers some attractive features: its sensitivity for Cu^{2+} (nM) compares favorably to that of ion-selective electrodes[13] and other synthetic lipid-based sensors;[14] it is relatively insensitive to high concentrations of weakly binding metal ions such as Ca^{2+}; it can be regenerated by washing with a strong chelating agent (edta); and it has a rapid response time (seconds). Owing to its simplicity and essentially instantaneous signal transduction, this system could be readily adapted to continuous copper ion monitoring in a continuous flow fluorescence spectrometer. Studies

to understand the mechanism by which metal binding induces dispersion of the lipid aggregates and investigations of the generality of this type of sensor are underway.

Experimental Procedure

Stock lipid solutions were made by dissolving lipids and cholesterol (Sigma) in $CHCl_3$ (HPLC grade). Lipid **1** or **2** and a matrix lipid (DSPC, SOPC, or 1:1 DSPC:cholesterol) were combined (5 mol% lipid **1** or **2**, 95 mol% matrix lipid) to give 10 μmol total lipid in 12 mL volumetric centrifuge tubes. The lipid mixture was concentrated under aspirator vacuum, and 3 mL of MOPS buffer (20 mM MOPS, 0.1 M NaCl, pH 7.5) was added to the tubes. The tubes were heated above 55 °C and sonicated with a probe tip (Heat Systems model 375) for 15 min at 25–35% power under argon atmosphere in an ice bath. The vesicles were centrifuged at 11000 rpm for 20 min to remove titanium particles. The phosphate concentration was determined for selected samples [15]. Vesicle sizes were measured by quasi-elastic light scattering by using a Microtrac Ultrafine Particle Analyzer (Leeds & Northrop) at 25 °C in phosphate buffer. The mean diameter was 49 nm (59 nm distribution width) for unmetalated vesicles. Vesicles were diluted 167-fold in MOPS buffer for metal-binding studies. Steady-state fluorescence measurements were performed at 25 °C on a temperature-controlled Shimadzu RF-450 spectrofluorimeter, excitation at 346 nm, 5 nm excitation and emission slit width.

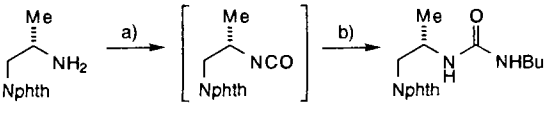
Solid-Phase Syntheses of Unnatural Biopolymers Containing Repeating Urea Units**

Kevin Burgess,* D. Scott Linthicum, and Hunwoo Shin

In medicinal chemistry, urea bonds have been used as critical structural elements in enzyme inhibitors[1] and as switching points in retro-inverso peptidomimetics.[2] The advent of "split syntheses"[3] in combinatorial methodology,[4, 5] however, opens an avenue for identification of many other urea-based compounds with potentially useful pharmaceutical properties. Consequently, there is a need for preparations of urea precursors, and for solid-phase syntheses of compounds with several urea functionalities incorporated in systematic fashion. This communication describes solid-phase syntheses of the two oligourea compounds CH_2G^u. CH_2F^u. CH_2F^u. CH_2A^u. A-amide (**8**) and YG. CH_2G^u. CH_2F^u. L-amide (**9**). These labels are based on the one letter codes for the amino acids from which the urea units are derived (vide infra).



Monomers for the oligourea syntheses were prepared by reducing the *N*-Boc protected amino acids to the corresponding amino alcohols **1**, which were then used as electrophiles in Mitsunobu displacements with phthalimide. Formation of regioisomeric products via undesired *N*-Boc aziridine intermediates is known,[6] and might have been problematic, but it was not. Removal of the *N*-Boc group gave the required monoprotected diamines **2**.

Scheme 1. R = Me, CH_2Ph, H. a) 1) ClCOO*i*Bu, NEt_3, 0 °C, THF; 2) $NaBH_4$, H_2O. b) 1) Phthalimide (HNphth), PPh_3, EtOCON=NCOOEt, THF, 25 °C, 3 h; 2) $HCl_{(aq)}$, THF.

Trial reactions in solution were performed to determine whether urea derivatives like **4** arise from isocyanate intermediates of type **3** formed in situ. To do this, the monoprotected diamine from alanine (**2a**, R = Me) was treated with "triphosgene" (bis(trichloromethyl)carbonate)[7] and then with 1-aminobutane. NMR analysis of the crude material indicated that the only detectable product was the anticipated urea **4a**.

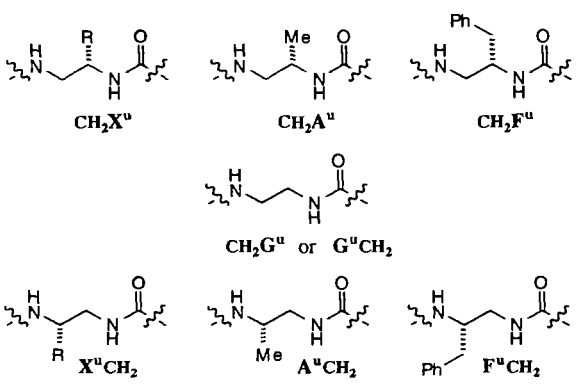
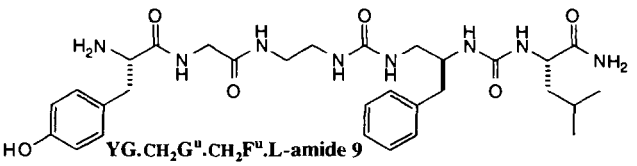
[**] Financial support for this work was obtained from the National Institutes of Health and The Robert A. Welch Foundation. K.B. is a NIH Research Career Development Awardee and an Alfred P. Sloan Scholar.



The next step was to extend the urea formation reactions to the solid phase. Fmoc-Ala was coupled to Rink's amide resin[8] (represented as a sphere in the following diagram) and deprotected[9] to give resin **5** with approximately 0.44 mmol of amino acid per gram of support. This was then treated with five equivalents of isocyanate **3a** generated in situ. Kaiser's ninhydrin test



Scheme 3. Treatment with 5 equiv of **3a**, CH_2Cl_2, 1.5 h. a) 60% $N_2H_4 \cdot H_2O$/DMF, 15 h, 25 °C. b) Repeated addition and removal of protecting groups. c) Cleavage from the resin with TFA (see text). d) Purification with RP-HPLC.

showed the coupling to be complete after 1.5 h.[10] Removal of the phthaloyl group with 60% hydrazine hydrate in DMF was slow; HPLC studies indicated that the reaction was essentially complete only after approximately 10 h. Consequently, overnight deprotection steps were used in this synthesis, and modifications of the deprotection conditions are currently being investigated to improve the time efficiency. Four repetitions of the isocyanate addition/deprotection cycle gave a product which was then cleaved from the resin with a mixture of phenol, 1,2-ethanethiol, thioanisole, water, and trifluoroacetic acid (TFA) [3:1:2:2:40 (w/v/v/v/v)] for 12 h at 25 °C. Cation scavengers may be unnecessary in this particular cleavage reaction, but they were included as a precaution in this preliminary study. Purification of the crude product by RP-HPLC gave the product **8** as a colorless hygroscopic solid in 46% yield,[11] which corresponds to an average yield of 86% in each coupling step.

We abbreviate the structure of urea analogs using nomenclature of the type "CH_2X^u", where the superscript u denotes a urea-derived fragment, the one letter code X identifies the amino acid from which the isocyanate reagent was prepared, and the "CH_2" label precedes the chiral center. Alternative structures in which the chiral center precedes the CH_2 group are being investigated in our laboratories; following the nomenclature described above, these are denoted as "X^uCH_2". In this system the urea side chains correspond to those of the parent amino acid from which the urea is derived.[12]

A solid-phase approach almost identical to that described above also was used to prepare the Leu-enkephalin analog **9** (YG. CH_2G^u. CH_2F^u. L-amide).[13] In this case the isolated yield of product was only 17%, but this procedure has not yet been optimized.

As far as we are aware, this work constitutes the first solid-phase syntheses of oligourea derivatives, but indications in the recent literature suggest increasing interest in unnatural biopolymers containing ureas. Nowick et al. are investigating systems they call "molecular scaffolds", in which urea functionalities link side chains to polyamine backbones.[14] Simultaneously, Hutchins and Chapman demonstrated that simple isocyanates (for example, PhNCO) could be added to solid-supported amino acids, then cleaved to give compounds with one urea group per molecule.[15] The "capping" of solid-supported peptides with aryl and alkyl isocyanates is also known and has been applied in Kent's ladder sequencing method.[16]

Oligoureas have several attractive features with respect to potential roles in biological systems. They are structurally similar to polyamides, yet they should not be as vulnerable to proteolytic cleavage as peptides. Ureas tend to be water soluble, but the physical (and chemical) properties of oligoureas can be modified by appending different side chains. With suitable protection, all the side chains found in the protein amino acids could be incorporated into oligoureas of the type illustrated in this paper, and some unnatural side chains as well. The focus of our future research will be on preparing encoded combinatorial libraries based upon oligoureas of the type described in this paper.

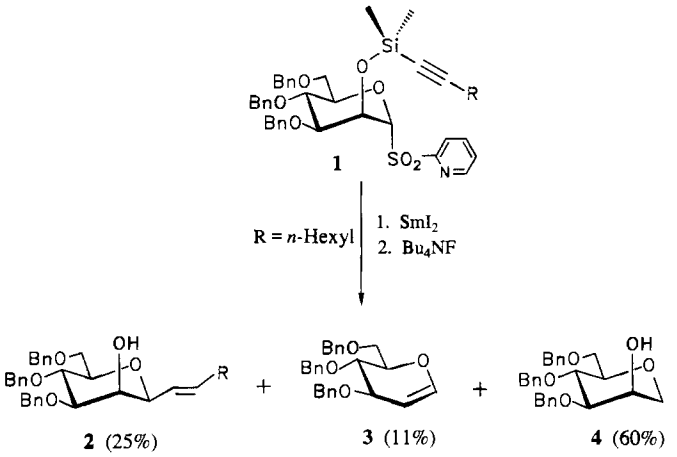
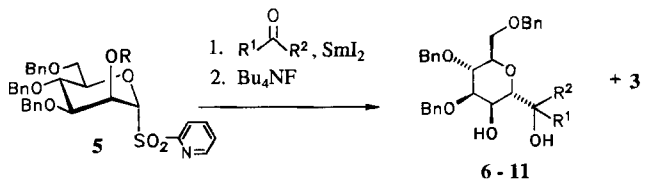
A Highly Stereoselective Synthesis of 1,2-*trans*-C-Glycosides via Glycosyl Samarium(III) Compounds



Daniel Mazéas, Troels Skrydstrup,* and Jean-Marie Beau*

C-Glycosides[1] are an important class of hydrolytically stable mimics of O- and N-glycosides usable as biological tools, particularly as potential artificial ligands for carbohydrate receptors in biological systems[2] as well as glycoenzyme regulators.[3] The interest in their construction was further intensified by the important discovery by Kishi et al.[4] that simple and complex C-glycosides adopt exoanomeric conformations similar to those of the parent O-glycosides.



There are many possible approaches to the direct carbon–carbon bond formation at the anomeric center of carbohydrates, including the use of anomeric carbocations, radicals and carbenes.[1] The utility of anionic anomeric species, however, has been chiefly confined, until recently, to 2-deoxysugars[5, 6] or glycals,[1] since β-eliminations of the C-2-functionality[5a] occur even when a stabilizing substituent[7] is present at the anomeric center.[8] Exceptions have been provided with the α- and β-lithio reagents derived from D-glucopyranosyl units only when the unprotected C-2-hydroxyl group is lithiated before C-1[9] and the reactions are performed at low temperature[10] (≤ -78 °C) to prevent elimination of Li_2O, conditions under which these tetrahedral anionic species are configurationally stable.[11] Similar transformations using anomeric anionic species derived from α-D-mannopyranosyl units were never attempted, based on the assumption that *anti*-elimination of the axially disposed oxy function at C-2 would be an easy process. This is indeed what happened with a presumed α-lithio reagent of a 2-*O*-trimethylsilyl derivative of mannopyranose.[12]

In this work we report our findings of an extremely mild method for the stereoselective preparation of 1,2-*trans*-C-glycosides by reductive samariation of mannosyl and glucosyl 2-pyridyl sulfones and the coupling of the correspondingly formed glycosyl samarium(III) reagent under Barbier conditions with carbonyl compounds.[13] This coupling at room temperature obliterates the prior alkoxide formation at C-2.

We were led to this method while attempting the SmI_2-induced free radical cyclization of **1**.[14] Instead of forming the anticipated β-C-mannoside **2** and glucal **3** (the latter resulting

from a two-electron reduction process and elimination) as major products, the 1,5-anhydro derivative **4** was surprisingly isolated in 60% yield. This implied that the intermediate organosamarium(III) species displayed exceptional stability towards β-elimination and suggested further the possibility of a condensation of the 2-pyridyl sulfone **5** protected at O-2 (R = $SiMe_3$) with a

carbonyl compound. When a solution of **5** and cyclohexanone (1.5 equiv) in THF at 20 °C was treated with slightly more than two equivalents of SmI_2, an almost instantaneous reaction ensued leading to the α-C-mannoside **6** in 86% overall yield after desilylation[15] and only 1% of glucal **3** (Table 1, entry 1); the β-C-mannoside was not detected. Entries 2–4 in Table 1, exemplify that the reaction appears general with both alkyl ketones and aldehydes.[16]

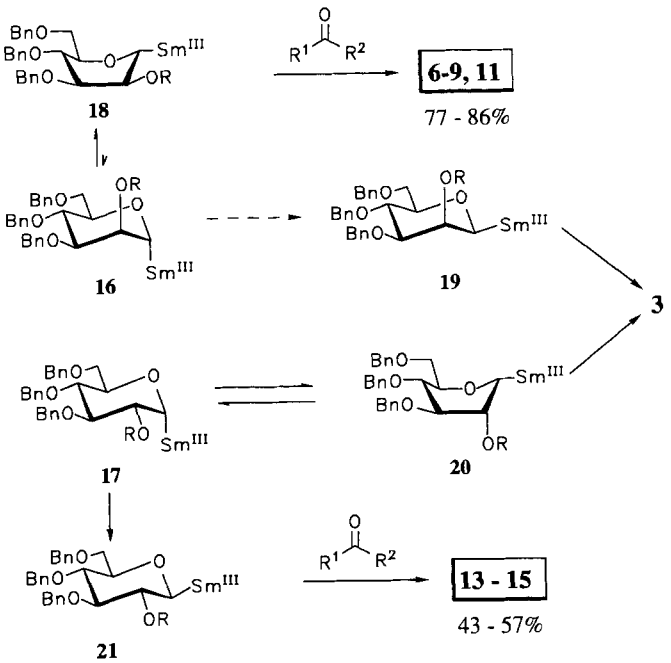
2	$SiMe_3$		**14** 43 (7:2)	36
3	$SiMe_3$	—	[e] 23	60
4	$SiMe_2tBu$		**13** 57	21
5	$SiMe_2tBu$		**15** 55 (3:2) [f]	22

[a], [b], and [c], see Table 1. [d] Isomeric α-2-pyridyl sulfone gave the same stereochemical results. [e] The yield corresponds to 1,5-anhydro-3,4,6-tri-*O*-benzyl-D-glucitol. [f] Known compound, see ref. [9b].

These results are remarkable for two reasons. First, the bimolecular organosamarium–carbonyl condensation is favored over the unimolecular elimination process, even though a favorable *trans*-diaxial relationship exists between the C-1–Sm and C-2–$OSiMe_3$ units. Second, although the α-tetrahydropyranyl anionic species are kinetically formed from a stepwise one-electron reduction pathway and exhibit substantial stereochemical stability at low temperature (−78 °C), the presumably thermodynamically more stable β-glycosyl samarium(III) species would be expected to dominate at higher temperatures providing the corresponding β-C-mannosides.[11]

These reactions must be performed under Barbier conditions, since addition of the carbonyl compound, even 20 s after SmI_2, did not lead to any condensation products. Again, it was surprising to observe the organosamarium reagent's preference for protonation from THF rather than elimination (Table 1 entry 6). The coupling reaction proceeded well (78%, entry 7) even when MeO group (instead of the $OSiMe_3$ group) is bound to the C-2 atom of the sulfone **5** (R = Me). With a C-2-acetoxy group, elimination finally took over (entry 8). Competitive reduction of benzaldehyde by SmI_2 explains the low yield for entry 5, although we have no explanation for the increased yield of the glucal formation.



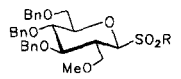
In contrast, β-C-glucosides **13**–**15** were formed exclusively from the corresponding glucosyl sulfones **12** giving moderate yields due to the competing elimination process (Table 2, entries 1 and 2). Acceptable yields were produced, however, when the trimethylsilyl group was substituted by a $SiMe_2tBu$ group; the yields of glycal decreased accordingly (entries 4 and 5).

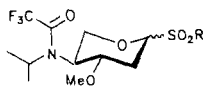
12 **13 - 15**

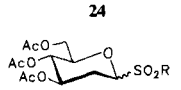
Noteworthy is the dominance of glucal **3** in the absence of a carbonyl substrate (entry 3), in contrast to that observed for **5** (R = $SiMe_3$).[16]

This stereochemical discrepancy between the *manno* and the *gluco* series is tentatively explained in Scheme 1. Upon sulfone reduction, the kinetic α-oriented organosamarium species **16** or

Scheme 1.







17 are produced by the reductive samariation of the corresponding anomeric radicals. In the *manno* series, rather than anomerization to **19**, **16** can undergo a facile conformational change to a possible boat or skew-boat conformer **18**, placing the C-1 and C-2 substituents in the sterically and energetically more favored equatorial positions, hence leading to the α-C-mannosides **6** to **11**. In the *gluco* series, this is probably a higher energetic process for **17**, since the already equatorially oriented C-2–O-2 bond must go through an eclipsed conformer with the C-1–Sm bond, hence anomerization to the β-species **21** may dominate. The

high 1,2-*trans* selectivity of the coupling process is therefore tentatively explained by a strong preference for a hitherto unknown *syn*-elimination mechanism operating with a β-heteroatom substituted organosamarium compound at room temperature which can only occur with **20** or possibly **19**. As observed experimentally, only the 1,2-*trans* species (e.g., **18** and **21**) would then give a productive C–C bond formation under the conditions used. In the *gluco* series, the higher yields obtained for the sterically more demanding $SiMe_2tBu$ (in place of the $SiMe_3$) C-2-protected sulfone **12** lend evidence for this hypothesis, although further confirmation is required. The behavior of these organosamarium(III) species is in high contrast to that of their lithium counterparts since, at −78 °C, the latter undergo either fast β-elimination (*manno* series) or 1,3-O-2 to C-1 silyl migration (*gluco* series).[12]

These assumptions were further supported by complementary experiments conducted on 2-deoxyglycosyl sulfones **22**–**25** (Table 3). The coupling products were obtained in good yields;

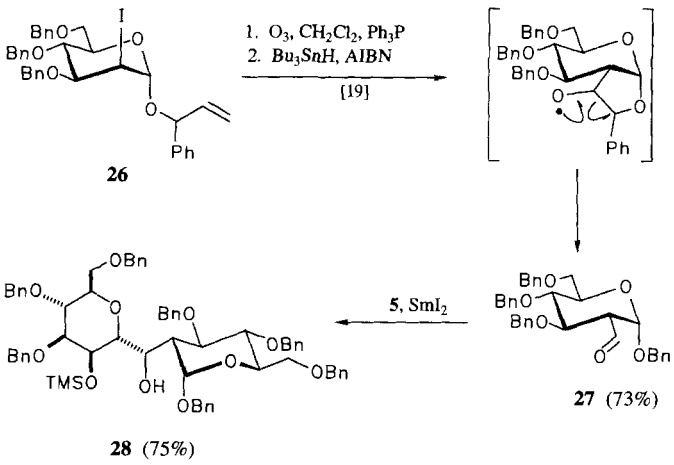

Table 3. Synthesis of the 2-deoxy-C-glucoside **22**–**25**.

Entry	Sulfone (R = 2-pyridyl)	Carbonyl compound [a]	Yield [%] C-glycoside (α:β) [b]
1	 **22**		82 (1:1)
2	 **23**		73 (1:4)
3	 **24**		80 (1:1.3) [17]
4	 **25**		88 (1:1)

[a] See [b], Table 1. [b] Isolated yields after chromatography on silica gel, α:β ratio was determined by ^1H NMR spectroscopy.

however no stereochemical preferences were displayed at the anomeric center for all 2-deoxyglycosides except for sulfone **23** (entry 2) with a carbon substituent at C-2. Placing a bulky substituent at position 2 (CH_2OCH_3 in **23** versus H in **22**) would disfavor a conformational change (as for **17** to **20**), thus decreasing the relative amount of the α-product. This suggests that the energy barrier for anomerization is close to that for a conformational change placing the C-1–Sm bond in an equatorial position. Noteworthy are the good yields obtained with the sulfone possessing trifluoroacetamide (**24**, entry 3) or even acetyl groups (**25**, entry 4).[17]

Finally, a carbon-linked disaccharide of a protected form of an α-D-mannopyranosyl(1 → 2)-D-glucopyranose was assembled efficiently by using the above procedure. Aldehyde **27** was prepared from the iodoglycoside **26**[18, 19] using a stereoselective transfer of a formyl group by a 5-*exo*cyclization-fragmentation procedure recently reported by Jung and Choe.[19] Reductive samariation of sulfone **5** (R = $SiMe_3$) in the presence of **27** gave the expected α-C-disaccharide **28** in 75% yield (isomeric ratio of 2:1 at the *exo*cyclic asymmetric center).

The preliminary results discussed herein suggest a viable and convenient way to 1,2-*trans*-C-glycosides which complements our recently reported SmI_2-induced 1,2-*cis*-C-glycoside methodology.[14] Further studies are currently underway concerning the mechanistic aspects of these reactions.

Experimental Procedure

C-Mannoside formation **6**: A 0.1 M solution of SmI_2 in THF (2.7 mL, 0.27 mmol) was added to a stirred solution of sulfone **5** (R = $SiMe_3$; 85 mg, 0.13 mmol) and cyclohexanone (20 μL, 0.19 mmol) at 20 °C. After stirring for 10 min, saturated aq. NH_4Cl was added to the reaction mixture which was then extracted twice with CH_2Cl_2. The combined organic phases were washed twice with water, dried with Na_2SO_4, and evaporated to dryness. The residue was redissolved in THF (5 mL), cooled to 0 °C, and 1.0 M Bu_4NF in THF (135 μL, 0.135 mmol) was added. After stirring for 5 min, water and CH_2Cl_2 were added, and the organic phase was washed twice with water, dried (Na_2SO_4) and evaporated to dryness. Flash chromatography (heptane: EtOAc, 7:1 → 3:1) gave first tribenzyl-D-glucal **3** (0.4 mg, 1%) and then **6** (60.5 mg, 86%); $[\alpha]_D^{20} = 8.0$ ($c = 0.80$, $CHCl_3$). ^1H NMR ($CDCl_3$, 300 MHz) (numbering of atoms is that of carbohydrate numbering): $\delta = 1.47-1.71$ (m, 10H, 5 CH_2), 2.50 (s, 1H, OH), 2.73 (d, 1H, $J = 5.2$ Hz, OH-2), 3.48 (d, 1H, $J = 7.7$ Hz, H-1), 3.62 (dd, 1H, $J = 10.2$, 5.0 Hz, H-6), 3.71 (dd, 1H, $J = 10.2$, 5.9 Hz, H-6'), 3.72 (dd, 1H, $J = 5.7$, 4.1 Hz, H-4), 3.87 (dd, 1H, J 5.7, 3.9 Hz, H-3), 4.11 (ddd, 1H, $J = 5.9$, 5.0, 4.1 Hz, H-5), 4.16 (ddd, 1H, $J = 7.7$, 5.2, 3.9 Hz, H-2), 4.49 (s, 2H, CH_2Ph), 4.51, 4.56, 4.60, 4.61 (4 d, 4H, $J = 12.0$ Hz, 4 CHPh), 7.32–7.38 (m, 15H, 3 Ph).

Rev.* **1992**, *92*, 29–68.

[14] D. Mazéas, T. Skrydstrup, O. Doumeix, J.-M. Beau, *Angew. Chem.* **1994**, *106*, 1457–1459; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1383–1386.

[15] All α-C-mannosides **6** to **11** described in this study adopt a conformation close to that of $^{O}S_2$, e.g., $J_{1,2} = 7.4–7.8$, $J_{2,3} = 3.1–3.9$, $J_{3,4} = 5.3–5.7$, and $J_{4,5} = 3.2–4.1$ Hz. That these products are indeed the α-anomers was confirmed by a nuclear Overhauser effect between the C-1 and C-6 hydrogens in **6**. The 2-deoxy-C-glycosides display the following coupling constants: β-anomers, $J_{1,2} = 9.6–12.0$, $J_{1,2'} = 2.1–2.2$, $J_{3,4} = 8.2–9.3$ Hz; α-anomers, $J_{1,2} = 2.6–3.4$, $J_{1,2'} = 10.3–11.5$, $J_{3,4} = 2.8–4.0$ Hz.

[16] Reactions of **5** and **12** with aldehydes led to some selectivity (up to 6.5:1) at the newly created stereogenic center C-7 (compounds **8**–**10**, **14**, **15**). Although the major isomer in the *gluco* series was identified possessing the C-7 (*R*) configuration [9b], we have not yet determined the C-7 configuration in compounds **8**–**10**. Significant ^{1}H NMR data for the major isomers of these compounds are as follows: **8** (diacetate): $\delta = 3.79$ (H-1), 5.24 (H-2), 5.13 (H-7), $J_{1,2} = 2.6$, $J_{1,7} = 5.4$ Hz; **9** (diacetate): $\delta = 3.80$ (H-1), 5.20 (H-2), 4.95 (H-7), $J_{1,2} = 2.8$, $J_{1,7} = 6.1$ Hz; **10**: $\delta = 3.89$ (H-1), 3.83 (H-2), 4.81 (H-7), $J_{1,2} = 3.7$, $J_{1,7} = 7.8$ Hz.

[17] The anomeric composition of the C-glycosides derived from sulfone **24** was determined by derivatization to their corresponding imidazole thiocarbamates and chromatographic separation. Unfortunately, the composition of the C-7 diastereomers could not be determined due to the trifluoroacetamido group giving rise to rotameric mixtures.

[18] Compound **26** was obtained by NIS-assisted iodoglycosylation (J. Thiem, H. Karl, J. Schwenter, *Synthesis* **1978**, 696–698) of tri-*O*-benzyl-D-glucal with racemic 1-phenyl-3-propenol [19].

Synthesis, Chemical Trapping, and Dimerization of 3,7-Dimethyltricyclo[3.3.0.0^{3,7}]oct-1(5)-ene: [2 + 2] Retrocycloaddition of the Cyclobutane Dimer**

Pelayo Camps,* Mercè Font-Bardia, Francesc Pérez, Xavier Solans, and Santiago Vázquez

"Pyramidalized" alkenes have attracted much attention since Weinshenker and Greene[1] published the synthesis of the first alkene of this kind. Szeimies published a review[2] on this topic in 1981, which was updated by Borden[3] in 1989 and by Luef and Keese[4] in 1991. Pyramidalized alkenes containing cubane,[5] homocubane,[6] dodecahedrane,[7] and other cage structures[8] have been recently described. Pyramidalized bridged cyclopropenes[9] and tribenzodihydroacepentalene[10] have also been prepared.

In particular, Borden at al.[8] synthesized several members of a series of tricyclo[3.3.*n*.0^{3,7}]alk-3(7)-enes and some derivatives for $n = 3, 2, 1$. The most pyramidalized member of this series[11] with $n = 0$ (tricyclo[3.3.0.0^{3,7}]oct-1(5)-ene) is as yet unkown, but a bis(ethano) derivative has been recently described.[8b] In this communication we describe the synthesis of 3,7-dimethyltricyclo[3.3.0.0^{3,7}]oct-1(5)-ene (**4**), its trapping with 1,3-diphenylisobenzofuran (**5**) and 11,12-dimethylene-9,10-dihydro-9,10-ethanoanthracene[12] (**7**), and its dimerization to the cyclobutane derivative **9**, which undergoes thermal conversion to diene **10** (Scheme 1).

Scheme 1. Synthesis, trapping, and dimerization of **4** and [2 + 2] retrocycloaddition of the cyclobutane dimer.

Our synthesis started with diester **1**[13] which on saponification gave the corresponding dicarboxylic acid **2**. Diodo compound **3** was obtained in 65% yield by iododecarboxylation of **2** with

[**] We thank Dr. C. Rücker (Institut für Organische Chemie und Biochemie, Universität Freiburg) for a copy of the POLCYC program used for naming the adducts and dimers derived from **4**. We thank Dr. M. Feliz and Dr. A. Linares for NMR analyses, Dr. A. Marín for mass spectra, and Dipl.-Chem. P. Domenech for elemental analyses.

iodosobenzene diacetate, following the Moriarty[14] modification of the Suárez[15] procedure. Reaction of **3** with *tert*-butyllithium in THF at −78 °C in the presence of diene **5** allowed us to isolate the corresponding Diels–Alder adduct **6** in 75% yield. Similarly, when the reaction was carried out in the presence of diene **7**, adduct **8** was obtained in 67% yield. The structure of these adducts was established by spectroscopic means, and in the case of **8** by X-ray diffraction analysis[16] (Fig. 1).

Table 1. Selected physical data for **2**, **3**, **6**, **8**, **9**, and **10** [20]: ^{1}H NMR and ^{13}C NMR spectra measured in $CDCl_3$; assignments given in the NMR spectra are based on DEPT, ^{1}H/^{1}H, and ^{1}H/^{13}C COSY experiments (HMQC and HMBC sequences); for the numbering of the atoms see Scheme 1. The elemental analyses (C, H, and I) of compounds **2**, **3**, **6**, **8**, and **10** agreed with calculated values within ±0.3.

10 (4,5,10,11-Tetramethylpentacyclo[8.2.1.1^{2,5}.1^{4,7}.1^{8,11}]hexadeca-1,7-diene): M.p. 156–157 °C; MS (70 eV): *m/z* (%): 269 (15), 268 (68) $[M]^{+}$, 253 (12), 199 (39), 187 (28), 186 (34), 185 (33), 171 (20), 159 (18), 157 (17), 155 (11), 145 (11), 143 (15), 142 (10), 141 (14), 135 (29), 134 (54) $[C_{10}H_{14}]^{+}$, 133 (19), 131 (18), 129 (18), 128 (21), 120 (12), 119 (51), 117 (21), 115 (23), 107 (28), 106 (14), 105 (46), 103 (12), 95 (26), 94 (21), 93 (35), 92 (17), 91 (100), 81 (11), 79 (61), 78 (18), 77 (68), 69 (32), 67 (24), 65 (34), 57 (12), 55 (54), 53 (38), 52 (10), 51 (18); ^{1}H NMR (200 MHz): δ = 1.09 (s, CH_3), 2.00 (d, J = 12.0 Hz), 2.50 (d, J = 12.0 Hz, CH_2); ^{13}C NMR (50.3 MHz): δ = 24.9 (CH_3), 42.1 (C), 48.4 (CH_2), 130.4 (C).

The reaction of **3** with *tert*-butyllithium in THF at −78 °C, in the absence of a trapping agent, gave a complex mixture. The presence of a cyclobutane dimer (**9**) and products derived from the addition of *tert*-butyllithium to **4** was established by coupled gas–liquid chromatography and mass spectrometry (GLC/MS), and by ^{1}H and ^{13}C NMR spectroscopy. Attempts to isolate **9** by column chromatography or crystallization provided the diene dimer **10** in low yield.

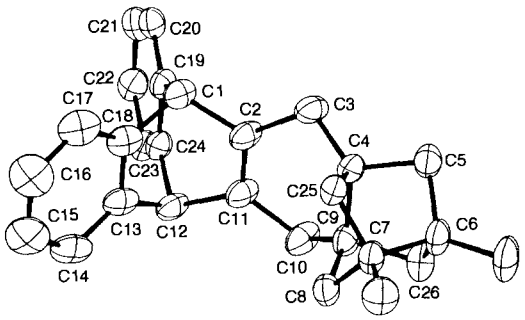

Fig. 1. Crystal structure (ORTEP) of adduct **8**. Selected distances [Å] and angles [°]: C4-C5 1.532(3), C4-C9 1.626(4), C5-C6 1.535(3), C6-C7 1.617(4); C3-C4-C5 119.7(2), C3-C4-C9 115.54(11), C4-C5-C6 95.0(2), C5-C4-C9 102.79(12), C5-C4-C25 95.9(2), C5-C6-C7 102.1(2), C5-C6-C26 96.2(2), C5-C6-CH_3 117.2(2), C6-C7-CH_3 116.5(3).

Reaction of **3** with a large excess of sodium (10 equiv) in dioxane at reflux for 4 h gave diene **10** as the only detectable product, which was isolated in 77% yield in crystalline form. Probably the initially formed cyclobutane dimer **9** is completely transformed into **10** under the reaction conditions. The formation of cyclobutane dimers from highly pyramidalized alkenes has been previouly observed,[10, 17] but a bis(ethano) derivative of tricyclo[3.3.0.0^{3,7}]oct-1(5)-ene[8b] failed to dimerize, probably because of steric hindrance. Cubene[5] and homocub-1(7)-ene[6a, b] also failed to dimerize. In addition, the opening of cyclobutane derivatives to dienes in very strained compounds has been described,[18] but such a reaction has never been reported for a cyclobutane dimer derived from a tricyclo[3.3.n.0^{3,7}]alk-3(7)-ene derivative with $1 \leq n \leq 3$.

Work is in progress to fully characterize the cyclobutane dimer **9** and apply this methodology to dimethyl tetracyclo[5.2.1.0^{2,6}.0^{3,8}]decane-7,8-dicarboxylate[19] in order to develop a convergent synthesis of dodecahedrane.

Experimental Procedure

Generation and trapping of **4**: To a solution of diiodide **3** (388 mg, 1.0 mmol) and the trapping agent (1.1–1.2 mmol) in anhydrous THF (15 mL) at −78 °C was added dropwise a 1.7 M solution of *tert*-butyllithium in pentane (1.0 mL, 1.7 mmol) under argon. The mixture was stirred for 0.5 h at −78 °C, quenched with methanol (5 mL), and allowed to warm to room temperature. Water (30 mL) was added, the mixture was extracted with diethyl ether (2 × 50 mL), and the combined organic extracts were dried with Na_2SO_4 and concentrated in vacuo. Column chromatography of the residue (silica gel, hexane/ethyl acetate) and crystallization from 2-propanol afforded the corresponding Diels–Alder adduct. Yields: **6**, 74%; **8**, 67%.

10: A mixture of freshly cut sodium (230 mg, 10 mmol) and anhydrous dioxane (10 mL) was heated under reflux until the sodium melted. Diiodide **3** (388 mg, 1.0 mmol) was added, and reflux was maintained for 4 h. The resulting suspension was allowed to warm to room temperature and filtered through Celite. The filtrate was concentrated in vacuo and the residue was crystallized from pentane to give **10** in 77% yield.

Synthesis, Structural Investigation, and Ligand Properties of Isocyanoacetonitrile**

Jürgen Buschmann, Dieter Lentz,* Peter Luger, Genivaldo Perpetuo, Dirk Scharn, Stefan Willemsen

Small molecules are favorite subjects for spectroscopic and structural investigations, because comparisons with theoretical calculations may contribute to a better understanding of the bonding. Malononitrile is the only well characterized and stable compound of the three isomeric compounds $CH_2(CN)_2$,[1] $CH_2(CN)(NC)$,[2, 3] (**1**) and $CH_2(NC)_2$.[4] Isocyanoacetonitrile, which is especially favorable for comparative investigations of the structural characteristics and ligand properties of the nitrile group and the isocyanide group, is insufficiently characterized, although it is mentioned in some patents and appears in a publication as a intermediate that was not isolated. The same is true for diisocyanomethane[4], the only known but poorly characterized geminal diisocyanide.

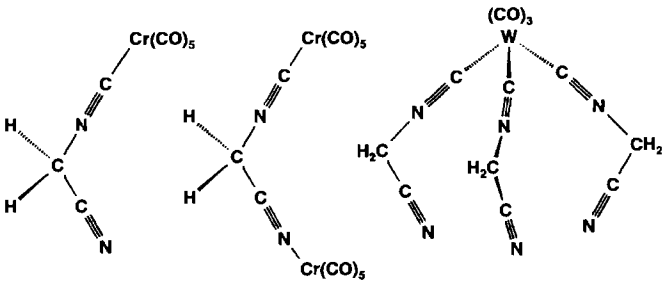
Here we present the synthesis of pure isocyanoacetonitrile (**1**), its spectroscopic characterization, its crystal structure analysis, and the first investigations of its complex chemistry. Starting with (formylamino)acetonitrile, which is prepared in good yields from aminoacetonitrile and acetylformate, an Ugi-reaction in dichloromethane gives a solution of isocyanoacetonitrile (**1**). [Eq. (a)]. Fractional condensation under high vacuum yields the colorless **1**, which is crystalline at $-30\,°C$ and melts at $-15\,°C$ to give a colorless liquid. Above $-10\,°C$ this liquid turns brown and decomposes rapidly.

1 (a)

The ^{14}N NMR spectrum [$\delta = -122$ ($\nu_{1/2} \approx 400$ Hz, $-CN$), -255 ($\nu_{1/2} \approx 18$ Hz, $-NC$)] and the ^{13}C NMR spectrum [$\delta = 29.9$ $\{^1J(^{14}N,^{13}C) \approx 7$ Hz; $CH_2\}$, 110.9 ($-CN$), 162.9 ($-NC$)] show the characteristic resonances for the isocyano group and the nitrile group in confirmation of the structure. Despite its instability we were able to grow a single crystal of **1** by zone melting and to determine the crystal structure by X-ray diffraction. Compound **1** crystallizes in the monoclinic space group *Pn* with two crystallographically independent molecules in the asymmetric unit. The unit cell (Fig. 1) also shows that the nitrile group and the isocyano group should be disordered if the centrosymmetric space group $P2_1/n$ is assumed.

Fig. 1. Unit cell (ORTEP plot [7]) of **1**.

In Table 1 the most important geometric parameters are summarized and compared with the results of an ab initio calculation.[6] The CN triple bond is significantly longer for the isocyano group than for the nitrile group, and both the nitrile group and the isocyano group are linear. According to ab initio calculations (HF/3-21G) the isocyano acetonitrile is less stable than malononitrile by 19.8 kcal mol^{-1}.



Pentacarbonyl(η^2-*cis*-cyclooctene)chromium or tricarbonyl(η^6-cycloheptatriene)tungsten both react with an excess of isocyanide **1** cleanly to give the complexes **2** and **4**, respectively (Scheme 1). The exclusive coordination of the metals to the isocyanide group is evident from the spectroscopic data, especially the $^1J(^{183}W,^{13}C)$ coupling constant of 116 Hz for the isocyanide carbon atom of the tungsten complex **4**, and from the

Scheme 1. Products of the reaction of **1** with $[(CO)_5Cr(\eta^2\text{-}C_8H_{14})]$ in CH_2Cl_2 (**2**), with $[(CO)_5Cr(thf)]$ in THF (**3**), and with $[(CO)_5W(\eta^2\text{-}C_7H_8)]$ in CH_2Cl_2 (**4**).

crystal structure analysis of **2** (Fig. 2). In **2** the chromium atom is almost octahedrally coordinated by five carbonyl ligands and the isocyanide ligand. A short Cr–C bond to the carbonyl ligand in *trans* position and a long bond to the isocyanide ligand demonstrate that this isocyanide ligand acts as a good σ-donor ligand. This finding is also reflected in the IR spectrum of **2**. The tungsten complex **4** exihibits only one set of signals in the ^1H and the ^{13}C NMR spectra as anticipated for a facial arrangement of the ligands.

Although the nitrile group can also be coordinated to a metal center in the reaction of **1** with excess of pentacarbonyl(tetrahydrofuran)chromium, **3** is so unstable that its formation was only proven by its mass spectrum.

Experimental Procedure

1: (Formylamino)acetonitrile (6.93 g, 90 mmol) and triethylamine (45.81 g, 454 mmol) were dissolved in dichloromethane (250 mL) and cooled to 0 °C under steady stirring. During the next 75 min phosphoryl chloride (14.13 g, 92 mmol) was added to the well-cooled mixture. After 5 min of additional stirring the solution was washed once with a 30% sodium carbonate solution (250 mL) and twice with distilled water (200 mL). The yellow solution was stirred with sodium sulfate for 15 min. The by-products of the reaction and the solvent were removed from the organic phase by fractional condensation at room temperature. In the trap, which is cooled to −30 °C, **1** separates as a colorless crystalline solid. Yield: 1.45 g (24%). ^1H NMR: = 4.49; ^{13}C NMR: δ = 29.9 (t, CH_2, $^1J(^{14}N,^{13}C) \approx 7$ Hz), 110.9 (–CN), 162.9 (br, -NC); ^{14}N NMR (NO_3^-, ext. standard): $\delta = -122$ (-CN, $\nu_{1/2} \approx 400$ Hz), −225 (–NC, $\nu_{1/2} \approx 18$ Hz); IR (film): $\tilde{\nu}$ = 2975 s, 2943 m, 2160 vs, 1613 s, 1418 s, 1348 m, 982 s, 900 s, 800 w cm^{-1}; MS: *m/z*: 66 $[M^+]$, 40 $[NC_2H_2^+]$, 39 $[NC_2H^+]$, 38 $[NC_2^+]$, 28 $[NCH_2^+]$.

2: **1** (0.125 g, 2 mmol) was dissolved in dichloromethane under an argon atmosphere, and pentacarbonyl(*cis*-cyclooctene)chromium (0.462 g, 1.5 mmol) was added. The solution was stirred at room temperature for 45 min and then concentrated. The reaction products were separated by preparative TLC (eluent: dichloromethane/pentane 1:1). Complex **2** is eluted from the stationary phase by dichloromethane, and the solution crystallized at −20 °C; pale yellow crystals, m.p. 143 °C. Yield: 0.078 g (20%). ^1H NMR: δ = 4.65; ^{13}C NMR: δ = 110.0 (–CN), 32.8 (CH_2), 215.8 (s, CO_{trans}), 214.3 (s, CO_{cis}); IR (KBr): $\tilde{\nu}$ = 2983 vw, 2950 vw, 2174 m, 2067 m, 1986 s, 1974 s, 1926 vs, 1411 w, 1347 w, 1020 vw, 901 w, 653 s, 533 vw, 482 w, 447 w, 303 vw cm^{-1}; IR (CH_2Cl_2): $\tilde{\nu}$ = 2157 m, 2063 s, 1957 vs cm^{-1}; Raman: $\tilde{\nu}$ = 2989 vw, 2957 vw, 2272 vw, 2175 m, 2068 m, 1996 w, 1985 s, 1947 w, 1926 w, 1416 vw, 1351 vw, 958 vw, 904 vw, 677 vw, 651,vw, 541 vw, 462 w, 393 s, 361 vw, 227 vw, 117 vs cm^{-1}; MS: *m/z*: 258 $[M^+]$, 230 $[M^+-CO]$, 202 $[M^+-2CO]$, 174 $[M^+-3CO]$, 146 $[M^+-4CO]$, 118 $[M^+-5CO]$, 78 $[CrCN^+]$, 52 $[Cr^+]$.

4: Tricarbonyl(η^6-cycloheptatriene)tungsten (0.36 g, 1 mmol) in dichloromethane (5 mL) was added to a solution of **1** (0.3 g, 5 mmol) in dichloromethane (5 mL) at −20 °C. On warming to room temperature a yellow-brown precipitate formed, and the solution turned brown by the part decomposition of the isocyanide. The precipitate was recrystallized from dichloromethane/pentane. Yield: 0.126 g (27%), pale yellow crystals, m.p. 173 °C. ^1H NMR: δ = 4.90; ^{13}C NMR: δ = 32.3 [CH_2], 113.4 [–CN], 159.3 [–NC, $^1J(^{183}W,^{13}C)$ = 116 Hz], 201.5 [CO, $^1J(^{183}W,^{13}C)$ = 134 Hz]; IR (THF): $\tilde{\nu}$ = 2160 (NC), 2100 (NC), 1945 (CO), 1893 (CO) cm^{-1}; MS: *m/z*: 466 $[M^+]$, 428 $[M^+-CO]$, 382 $[M^+-3CO]$, 372 $(W(CO)_2(CNCH_2CN)_2^+]$, 316 $[W(CNCH_2CN)_2^+]$, 249 $[W(CNCH_2CN)^+]$.

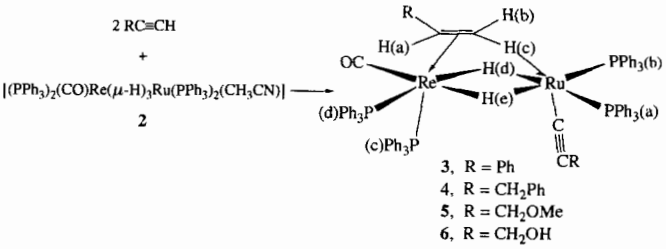
Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center



Zhongli He, Laurent Plasseraud, Isabel Moldes, Françoise Dahan, Denis Neibecker, Michel Etienne, and René Mathieu*

The study of the reactivity of bi- or polymetallic complexes toward unsaturated organic molecules has led to numerous examples of unusual modes of bonding and activation due to the proximity of the metal centers.[1] Here we report a new example of the synergy exerted by two different metal centers leading to an unprecedented mode of bonding for a monosubstituted alkene. In addition to a classical π bonding of the carbon–carbon double bond with one metal center, one of the sp^2 C–H bonds of the alkene experiences a static agostic interaction[2] with the second adjacent metal center.

This novel bonding situation was discovered during the course of the study of the reactivity of bimetallic polyhydride rhenium–ruthenium complexes[3] toward terminal alkynes. No reaction occurs between **1** and the terminal alkynes HC≡CR (R = Ph, CH_2Ph, CH_2OMe, CH_2OH, *t*Bu). Thus, we examined the reactivity of **2**, which was expected to be more reactive since it contains a labile nitrile ligand.[3b]

$[(PPh_3)_2(CO)HRe(\mu\text{-}H)_3RuH(PPh_3)_2]$ **1**

Except for the case of R = *t*Bu, **2** reacts at room temperature with an excess of each alkyne, leading to the formation of the complexes (**3** (R = Ph), **4** (R = CH_2Ph), **5** (R = CH_2OMe), and **6** (R = CH_2OH) in low to reasonable yields (Scheme 1).

Scheme 1.

The structure of these compounds was inferred by spectroscopic data (Table 1) and then confirmed by an X-ray study on a crystal of complex **5** (see Fig. 1).

Complex **3** can also be obtained in similar yield from the reaction of **1** and phenylacetylene at 50 °C in the presence of *tert*-butylethylene as a hydrogen acceptor. The lower thermal stability of the other complexes (**4**–**6**) prevents the extension of this method to the other alkynes used.

The IR spectra of the complexes (**3**–**6**) show characteristic absorptions for a σ-bound acetylide ligand,[4] (between 2103 and 2080 cm^{-1}), and for a terminal CO ligand (between 1830 and 1820 cm^{-1}); however the most informative data about their structure comes from a complete NMR analysis using homo- and heteronuclear decoupling experiments.

[a] Heteronuclear decoupling experiments have not been performed on this complex.

In the ^1H NMR spectra we observe, apart from the R and Ph resonances, five multiplets, each of which is for a single hydrogen, two at low field (H(a) and H(b)) and three (H(c), H(d) and H(e)) upfield from the TMS resonance (see Scheme 1).

The ^{13}C NMR spectra exhibit among other signals, one doublet at $\delta \approx 70$ (^1J(C–H) = 153–160 Hz) and a doublet of doublets at $\delta \approx 39$ (^1J(C–H) = 107–113 Hz and 160–166 Hz), attributable to the coordinated carbon atoms of an alkene. Moreover, $^{13}C\{^1H\}$ selective decoupling experiments show that the smaller coupling constant of the high-field signal is associated with H(c). These two observations, namely a reduced ^1J(C–H) and a high-field resonance for the corresponding hydrogen atom, are fully consistent with an agostic interaction of the sp^2 C–H(c) bond with one metallic center.[2, 5] Furthermore, $^{13}C\{^{31}P\}$ selective decoupling experiments in the case of **3** indicate that the coordinated carbon atoms of the styrene molecule exhibit a small, unresolved coupling with the phosphorus atoms attached to rhenium only. A similar narrowing of the H(c) resonance in the ^1H NMR spectrum is evident when the ruthenium-bound phosphanes are irradiated in selective ^{31}P decoupling experiments. These spectroscopic data are consistent with π coordination of the alkene on the rhenium center and a C–H agostic interaction with the adjacent ruthenium atom.

Definitive proof for the proposed structure comes from an X-ray study[6] on crystals of the complex **5** (R = CH_2OMe; Fig. 1). As expected, it consists of a bimetallic complex; the two

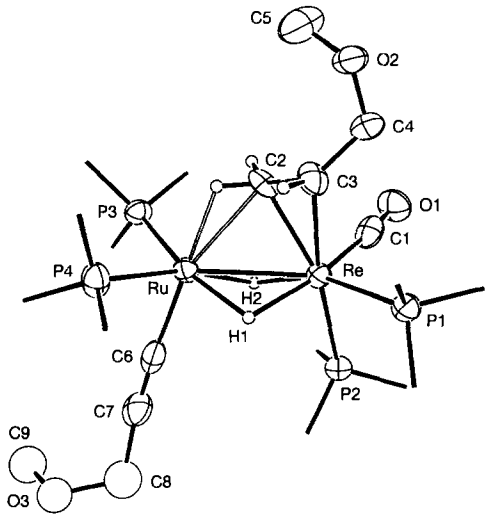

Fig. 1. Crystal structure of **5** (phenyl groups omitted). Selected distances [Å] and angles [°]: Re-Ru 2.7084(8), Re-C2 2.168(8), Re-C3 2.261(9), Ru-C2 2.357(7), Ru-H1(C2) 1.86(9). C2-C3 1.399(12), Ru-C6 1.985(11), C6-C7 1.179(15); P3-Ru-H1(C2) 84(2), P4-Ru-H1(C2) 96(2), C6-Ru-H1(C2) 177(2), Re-Ru-H1(C2) 72(2), Re-Ru-C2 50.1(2), P1-Re-C2 117.4(2), P1-Re-C3 81.1(2), C1-Re-C2 88.5(4), C1-Re-C3 90.0(4), P2-Re-C2 148.4(2), P2-Re-C3 173.1(2), Ru-Re-C2 56.4(2), Ru-Re-C3 84.3(2).

metal centers are bridged by two hydrido ligands, and the alkene is π bound to the rhenium atom. One hydrogen of the alkene methylene group is at bonding distance from the ruthenium atom. This hydrogen atom is *trans* to the acetylide ligand. In this way a potentially free apical coordination site at ruthenium is filled. The Ru–C2 distance is also consistent with a ruthenium–carbon interaction and compares well with the distance found (2.38(2) Å) for the carbon of the methylene group in agostic interaction in $[Ru(\eta^3\text{-butenyl})(PMe_2Ph)_3][PF_6]$.[7] The C–C double bond of the alkene is nearly parallel to the H2-Re-P1 axis, and the Re–C2 bond is significantly shorter than the Re–C3 bond. This situation is strongly reminiscent of the mode of bonding involving bridging, η^1,η^2-bound alkenyl groups.[8]

Hence, this bonding situation may be viewed as an arrested migration of a hydrido ligand from one metal center (ruthenium here) onto a bridging η^1,η^2-bound alkenyl group. This actually represents the last step of the hydrogenation of an alkyne leading to alkene formation at a heterobimetallic center. Considering the agostic interaction, the complex is formally a 32-electron bimetallic complex, that is two electrons short of saturation. This coordinative unsaturation certainly explains the stabilization of the unusual mode of bonding of the alkene in the complexes **3**–**6**.

To gain some insight into the mechanism of this reaction and to determine the origin of the hydrogen atoms transferred to the alkynes we have treated **2** with PhC≡CD. In the final product $[D_2]$-**3**, the H(b) and H(d) resonances represent less than 10% of the intensity of H(a) and H(c) resonances, which demonstrates that styrene formation occurs by hydride transfer from complex **2** and that one of the bridging hydrides in **3** originates from the oxidative addition of a second molecule in phenylacetylene, leading to the formation of the acetylide ligand.

Experimental Procedure

All manipulations were performed under argon. Complexes **1** and **2** were prepared according to published procedures [3]. General procedure: To **2** (0.2 g, 0.14 mmol) in CH_2Cl_2 (10 mL) was added 0.8 mmol of the alkyne and the solution was stirred at room temperature for 3 h. The solution was then evaporated to dryness under reduced pressure and the residue dissolved in CH_2Cl_2 (4 mL). Addition of methanol (4 mL) and cooling at −20 °C allowed the isolation of **3** (65%), **4** (26%), **5** (36%), and **6** (19%). Alternative procedure for **3**: To **1** (0.2 g) dissolved in THF (20 mL) was added phenylacetylene (0.1 mL) and *tert*-butylethylene (0.3 mL) and the mixture was heated at 50 °C for 5 h. The same purification procedure as above allowed the isolation of **3** in 75% yield.

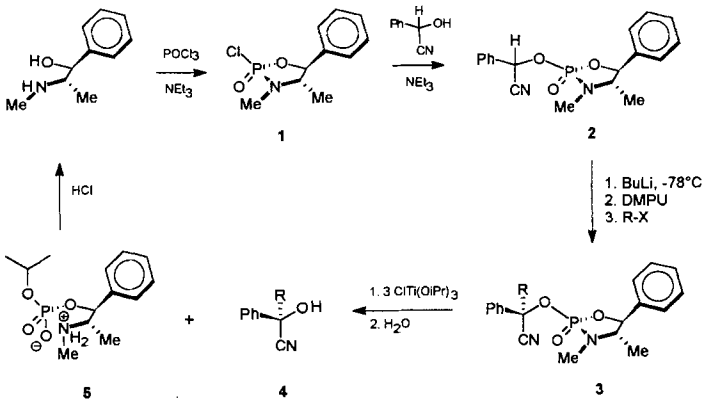
A Chiral Cyanohydrin Phosphate for Carbonyl Umpolung—Stereoselective Synthesis of Tertiary Cyanohydrins**

Thomas Schrader*



Cyanohydrins have been used for many years as umpoled carbonyl compounds.[1a] Their importance in organic synthesis as nucleophilic acyl anion equivalents increased significantly in the 1970s when Stork et al. introduced *O*-alkoxyalkylcyanohydrins[1b] and shortly afterwards Hünig et al. reported on *O*-silylcyanohydrins.[1c] These derivatives can be employed in the transformation of aldehydes into ketones,[2a] α-hydroxyketones,[2b] γ-oxoesters,[2c] and 1,4-diketones.[2d] Surprisingly, no enantio- and diastereoselective syntheses have been reported making use of cyanohydrins as umpoled carbonyl compounds.

[**] I thank Prof. Mootz, Düsseldorf, for the X-ray structure analysis.

In the related field of aminonitrile chemistry efficient asymmetric procedures are also very rare; the Michael addition of chiral aminonitriles developed by Enders et al. represents a milestone in this area.[3]

During the past few years several enantioselective syntheses have been reported that focus on the use of cyclic phosphonates or phosphonamides with a stereogenic phosphorus atom.[4] Although high inductions are achieved, the stable P–C bond restricts the final products of these reactions to almost exclusively phosphonic acid derivatives.[5] This paper describes the new chiral cyanohydrin phosphate, **2**, in which the OH group of the benzaldehyde cyanohydrin is linked to a chiral phosphate. The latter can be removed hydrolytically after metalation and diastereoselective alkylation of **2** (Scheme 1).

Scheme 1.

Precursor **1** is easily obtained from (+)-pseudoephedrine and phosphoryl chloride. Exocyclic substitution of chloride by the free racemic cyanohydrin proceeds smoothly with complete retention of configuration at phosphorus.[6] Thus, **2** can be prepared from (+)-pseudoephedrine in a one-pot procedure with 45% overall yield (Scheme 1). Deprotonation with butyllithium followed by addition of an electrophile affords the alkylated products **3** with high diastereomeric excesses (*de* = 82–94%) (Table 1).

Table 1. Diastereoselectively alkylated cyanohydrin phosphates (*R*)-**3** and resulting tertiary cyanohydrins (*R*)-**4**.

[a] Determined by cleavage of recrystallized, enantiomerically pure cyanohydrin phosphates **3**; in the case of **4b** and **4e** determined by NMR shift experiments.

The relative configuration of the cyanohydrin phosphates **3** was determined by X-ray structure analysis[7] of the benzylated product **3e**. (1*S*,2*S*)-(+)-Pseudoephedrine yields cyanohydrin phosphate **3e** with *R* configuration at the α-C atom, confirming that the metalated cyanohydrin phosphate **2** is preferentially attacked on its *Si* face. We developed a mild Lewis acid assisted method for selective removal of the auxiliary. Reaction of **3** with titanium chloride triisopropoxide and subsequent hydrolysis furnishes pure free cyanohydrin in the organic phase. (+)-Pseudoephedrine may be recovered in 68% yield from the aqueous phase after hydrolysis of intermediate **5**.

Cleavage of the phosphate proceeds with retention at the cyanohydrin, such that tertiary (*R*) cyanohydrins **4** are formed. This could be demonstrated with the methylated product **3b**, which was hydrolyzed to give atrolactamide and then cyclized with acetone to yield oxazolidinone **6**. The optical rotation of **6** after recrystallization was in agreement with the literature value for the (*R*) compound.[8]

The enantiomeric purity of the free tertiary cyanohydrins **4** was also determined by NMR spectroscopic analysis of their complexes with TADDOL (molar ratio 1:1 for TADDOL: cyanohydrin; TADDOL = (4*R*,5*R*)-α,α,α′,α′-tetraphenyl-1,3-dioxolane-4,5-dimethanol).[9] Hydrolysis of diastereomerically pure **3b** and **3e** leads in both cases to optically pure cyanohydrins with a signal ratio of >98:2.

The final products are key intermediates in the synthesis of pharmaceuticals such as 2,4-oxazolidinediones **7** (anticonvulsants, drugs for treatment of *diabetes mellitus*)[10a] and tetronic acids **8** (antibiotics, antitumor agents).[10b]

While numerous asymmetric syntheses[11] and enzymatic methods[11] have been developed for secondary cyanohydrins, a general approach to optically pure tertiary cyanohydrins has not been reported to date.[12] Preliminary experiments with aliphatic cyanohydrins and reactions of the new chiral acyl-anion equivalent **2** with other electrophiles such as Michael acceptors and acid chlorides show promising results.

Experimental Procedure

A solution of cyanohydrin phosphate **2** (5 g, 14.6 mmol) in 100 mL of dry THF was cooled to −78 °C, *n*-butyllithium (1.6 N solution in hexane, 11 mL, 17 mmol, 1.2 equiv) was added, and the reaction mixture was stirred for 20 min. *N*,*N*′-Dimethyl-*N*,*N*′-propylene urea (DMPU, 0.9 mL, 15 mmol, 1 equiv) [13] was added, and stirring was continued for another 20 min at −78 °C. The desired electrophile (1.3 equiv) was added and the resulting solution stirred for 3–6 h at −78 °C. After quenching with 50 mL of aqueous ammonium chloride, the organic phase was removed, the aqueous phase extracted with 50 mL of THF, and the combined organic phases dried over magnesium sulfate. The solvent was evaporated and the crude product purified either by recrystallization from toluene/acetone (10:1) or by chromatography over silica gel (0.04–0.063 mm). A solution of 10 mmol of the cyanohydrin phosphate **3** in 100 mL of dry THF was treated with titanium chloride triisopropoxide (1.0 M solution in hexane, 30 mmol, 3 equiv). The reaction mixture was stirred for 3 h at room temperature and subsequently quenched with 100 mL of water. The resulting two-phase system was stirred vigorously for another 3 h at room temperature. After the organic phase was removed and dried, the free cyanohydrin was obtained by simple concentration in vacuo and filtration through silica gel (toluene/acetone 10:1) [14]. From the aqueous phase the titanium salts were precipitated with NaOH, and the filtrate was hydrolyzed with 5 N HCl for 8 h at 80 °C. Neutralization and extraction with dichloromethane yielded free (+)-pseudoephedrine, which was extracted with the fourfold amount of water for 3 h to remove small amounts of (−)-ephedrine (68%, starting from **3**).

[14] Often cleavage of a small amount (ca. 5%) of the labile tertiary cyanohydrin to the ketone is observed, but racemization of the cyanohydrin never occurs.

Synthesis and Structure of Organometallic Compounds with $(Al_2Si)_2$ and Al_3Sb_2 Frameworks**

Stephan Schulz, Torsten Schoop, Herbert W. Roesky,* Ludger Häming, Alexander Steiner, and Regine Herbst-Irmer

Dedicated to Professor Dr. Peter Paetzold on the occasion of his 60th birthday

Little is known about the reactivity of organometallic compounds containing Group 13 elements in the oxidation state I. In the case of indium and thallium, this can be explained by the stability of the compounds containing monovalent metal atoms. As far as aluminum and gallium are concerned, monovalent compounds recently became preparatively accessible.[1-3] Since finding a straightforward synthetic route to $[(Cp^*Al)_4]$ ($Cp^* = C_5Me_5$), we have been involved in the thorough investigation of the reactivity of this compound.[3] As demonstrated by a few examples,[3, 4, 5] aluminum(I) compounds mostly react to give compounds with the metal in the oxidation state III. The next question is: how does $[(Cp^*Al)_4]$ behave towards compounds that contain thermodynamically very stable Si–F bonds (Si–F bond energy = 543 kJ mol^{-1} (exp.))?[6] In the course of such reactions, both the tendency of aluminum(I) to oxidize to aluminum(III) and the formation of the thermodynamically very stable Al–F bond (Al–F bond energy = 659–672 kJ mol^{-1} (exp.))[6] are decisive. We chose Ph_2SiF_2 as the reaction partner.

$[(Cp^*Al)_4]$ was treated with an excess of Ph_2SiF_2 under reflux for three days to give almost colorless solution. The colorless complex **1** [Eq. (a)] was obtained as a solid on cooling the solution and redissolved on warming.

$$[(Cp^*Al)_4] + 2\,Ph_2SiF_2 \longrightarrow \underset{\mathbf{1}}{[\{(Cp^*AlF)_2SiPh_2\}_2]} \qquad (a)$$

The ^1H and ^{13}C NMR spectra confirm conclusively that the Cp* ligands were not eliminated in this reaction ($\delta = 1.83$, and $\delta = 11.4$ and 115.5, respectively). Cp* was, however, eliminated in the reaction of $[(Cp^*Al)_4]$ with $[(MeC_5H_4)_2TiF_2]$, which results in the formation of $[\{(MeC_5H_4)_2TiF_2\}_3Al]$.[7] The mass spectrum of **1** shows the heaviest ion to be the fragment $[M-Cp^*]$ (m/z 953); the signal has a relative intensity of 10% and the expected isotopic pattern.

Single crystals suitable for X-ray structure analysis (Fig. 1) were obtained by slowly cooling a solution of **1** in toluene over a period of 20 h. Crystals with the space group $P\bar{4}2_1c$ were formed.[8] The silicon atoms lie on the crystallographic $\bar{4}$ axis; the molecule thus belongs to the point group S_4. Compound **1** contains an eight-membered Al_4F_4 ring. This means that fluorine atoms were inserted into four of the original six Al–Al bonds of the Al_4 tetrahedron. Two aluminum atoms are each connected by a Ph_2Si bridge. This indicates that both tetracoordinate aluminum and silicon atoms are present in **1**. This type of bridging silicon atom between two aluminum atoms has not previously been observed; there are only a few examples of compounds containing Al–Si bonds in which the silicon atom is part of a terminal $SiMe_3$ group.[9] The average Al–F bond length is 184.6 pm and lies within the range observed for the few structurally characterized covalent aluminum fluorides[10-12]

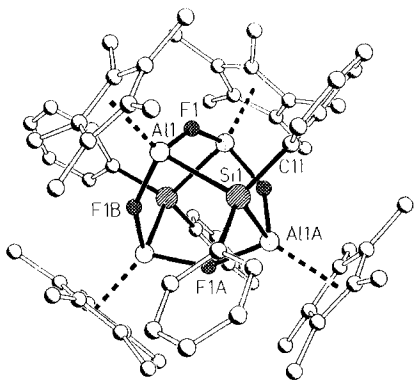

Fig. 1. Crystal structure of **1**. Selected distances [pm] and angles [°]: Al1-F1 184.3(1), Al1-F1B 184.8(1), Al1-C1 218.1(2), Al1-C2 217.2(2), Al1-C3 247.8(2), Al1-C4 267.2(3), Al1-C5 249.0(2), Al1-Cp*(center) 208.6(2), Al1-Si1 245.1(1); Al1-F1-Al1C 149.0(1), F1-Al1-F1B 88.3(1), F1-Al1-Si1 99.9(1), F1B-Al1-Si1 99.9(1), Al1-Si1-Al1A 99.7(1), C11-Si1-C11A 110.5(1), Al1-Si1-C11 110.7(1), Al1A-Si1-C11 112.5(1).

[**] This work was supported by the Fonds der Chemischen Industrie, the Bundesministerium für Forschung und Technologie, the Volkswagen-Stiftung, and the Deutsche Forschungsgemeinschaft. T. S. thanks the Fonds der Chemischen Industrie for a doctoral grant.

(190 pm). The good agreement of the Al–F bond length and the Al–F–Al angle (149°) of **1** with the corresponding values in tetrameric Me_2AlF (181.0 pm and 146°), which also contains an eight-membered Al_4F_4 ring,[13] is very striking. This structural type is obviously a stable form of organometallic aluminum fluorides. The Al–Si bond lengths (245.1 pm) lie in the range of those reported in the literature.[9]

The [Cp*Al] monomer can be regarded as a carbene analogue. This simplifies our understanding of the formation of **1**, in which the aluminum atom of the [Cp*Al] is inserted in the Si–F bond. We then asked ourselves whether coupling reactions with other carbene analogues are possible and whether novel aluminum–element compounds can be built up from these. We chose $(t\mathrm{BuSb})_4$ as the reaction partner.[14]

The reaction of $[(Cp^*Al)_4]$ with $(t\mathrm{BuSb})_4$ was carried out in toluene in a molar ratio of 1:1 (60 °C). The solvent was slowly removed under vacuum, and from the orange-brown solution crystals of the composition $[(Cp^*Al)_3Sb_2]$ (**2**) [Eq. (b)] were

$$[(Cp^*Al)_4] + (t\mathrm{BuSb})_4 \longrightarrow Cp^*Al\begin{array}{c}Sb\\ \diagdown\\ Cp^*Al\\ \diagup\\ Sb\end{array}AlCp^* + \ldots \qquad (b)$$

2

formed as orange-brown hexagonal needles. The reaction did not proceed stoichiometrically with respect to **2** and $t\mathrm{Bu_3Sb}$; elemental antimony and other decomposition products were formed as well.[15] $(t\mathrm{BuSb})_4$ decomposes by eliminating *t*Bu groups. This reaction has been observed during the preparation of this compound as well as on warming $(t\mathrm{BuSb})_5$.[16]

The ^{1}H and ^{13}C NMR spectra of **2** show only signals of the Cp* ligand. The heaviest ion in the mass spectrum is the molecular ion with the correct isotopic pattern and 20% relative intensity. In addition, fragmentation also occurred. The elemental analysis confirms the composition of **2**. An X-ray diffraction experiment yields a model for **2** in which positions of the heavy atoms are consistent with the atomic arrangement given in Equation (b).[17]

The reaction of $[(Cp^*Al)_4]$ with elemental phosphorus leads to the formation of $[P_4(Cp^*Al)_6]$.[4] In the formation of **2**, $(t\mathrm{BuSb})_4$ functions as a source of antimony. No reaction was observed between $[(Cp^*Al)_4]$ and elemental antimony.

Experimental Procedure

1: A solution of $[(Cp^*Al)_4]$ (0.16 g, 0.25 mmol) and Ph_2SiF_2 (0.66 g, 3 mmol) in toluene (60 mL) was heated under reflux for three days and then allowed to cool slowly to room temperature. Colorless triangular crystals of **1** (0.21 g, 0.22 mmol, 88%) were obtained. M.p. 292 °C; ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): $\delta = 1.83$ (s, C_5Me_5, 60 H), 7.02–7.95 (m, C_6H_5, 20 H); ^{13}C NMR (100 MHz, C_6D_6, 25 °C, TMS): $\delta = 11.4$ (s, $C_5\mathit{Me}_5$), 115.5 (s, C_5Me_5), 131.4 (s, *ortho*-arene-C), 132.1 (s, *para*-arene-C), 134.7 (s, *meta*-arene-C), 136.3 (s, Si-C); IR (CsI): $\tilde{\nu}$[cm^{-1}] = 1261 s, 1152 s, 1094 vs, 1028 s, 998 s, 799 vs, 729 vs, 700 vs, 636 s, 599 s, 465 vs, 370 vs, 310 vs, 273 s; MS (EI, *m/z* (%)): 953 (10) [$M^+ - Cp^*$], 525 (100) [$M^+/2 - F$], 181 (15) [Cp*AlF], 162 (80) [Cp*Al]. Correct elemental analysis.

2: $[(Cp^*Al)_4]$ (0.16 g, 0.25 mmol) was dissolved in toluene (40 mL). A solution of $(t\mathrm{BuSb})_4$ (0.18 g, 0.25 mmol) in toluene (20 mL) was added dropwise. The mixture was heated to 60 °C for 6 h, which caused the solution to turn orange-brown. The solvent was then slowly removed under reduced pressure. Orange-brown crystals of **2** (0.16 g, 0.22 mmol, 65% with respect to $[(Cp^*Al)_4]$) were obtained. M.p. 199 °C (decomp.); ^{1}H NMR (250 MHz, C_6D_6, 25 °C, TMS): $\delta = 2.07$ (s, C_5Me_5); ^{13}C NMR (63 MHz, C_6D_6, 25 °C, TMS): $\delta = 11.9$ (s, $C_5\mathit{Me}_5$), 116.1 (s, C_5Me_5); IR (CsI): $\tilde{\nu}$[cm^{-1}] = 1261 s, 1146 s, 1098 vs, 1022 vs, 800 vs, 751 w, 726 w, 697 w, 588 w, 447 vs, 405 s; MS (EI, *m/z* (%)): 730 (20) [M^+], 568 (20) [$M^+ - Cp^*Al$], 406 (25) [$M^+ - 2Cp^*Al$], 162 (100) [Cp*Al]. Correct elemental analysis.

[8] Crystal structure data of **1**: $C_{64}H_{80}Al_4F_4Si_2 \cdot 2C_7H_8$, $M_r = 1273.65$, space group $P\bar{4}2_1c$, $a = b = 1586.7(2)$, $c = 1418.8(2)$ pm, $V = 3.5720(8)$ nm^3, $\rho_{calcd} = 1.184$ Mg m^{-3}, $F(000) = 1360$, $\lambda = 71.073$ pm, $\mu(Mo_{K\alpha}) = 0.151$ mm^{-1}. Intensities were determined at 193 K with a shock-cooled crystal in an oil drop [18] according to the $2\theta/\omega$ method in the range $8 \le 2\theta \le 50°$ on a STOE-Siemens-AED diffractometer. The colorless octahedral crystal measured $0.8 \times 0.6 \times 0.6$ mm. 10773 reflections were measured, 3122 independent ($R_{int} = 0.03$). A semiempirical absorption correction was carried out on 208 ψ-scanned reflections. The structure was solved by direct methods (SHELXS-90) [19] and refined using the least-squares method on F^2 (SHELXL-93) [20]. Hydrogen atoms were calculated on their ideal geometrical positions and refined according to a riding model in which the methyl groups were able to rotate around their local axes. The phenyl group was refined on two slightly twisted positions with respect to the position of C11 with occupation factors of 0.64/0.36 to account for its disorder. The disordered toluene molecule on the twofold axis was refined on two positions with occupation factors of 0.29/0.21. 545 restraints were used for the final refinement of the 346 parameters. The Flack parameter refined to 0.1(2) [21]. A minimum of -237 e nm^{-3} and a maximum of 209 e nm^{-3} were obtained for the last difference Fourier synthesis. $R1 = 0.0343$ ($F > 4\sigma(F)$), $wR2 = 0.0954$ (all data). $R1$ and $wR2$ are defined as follows: $R1 = \sum||F_o| - |F_c||/\sum|F_o|$ and $wR2 = \{[\sum w(F_o^2 - F_c^2)^2]/[\sum w(F_o^2)^2]\}^{1/2}$. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Paul R. Raithby, and Ronald Snaith

Lithium alkyls and amides are used to effect key deprotonation steps in numerous organic syntheses.[1] In this they are often so specific that subsequent electrophilic substitution of Li^+ gives a particular derivative of the organic precursor. Much is known about the structures of these lithium reagents,[2] but far less about how they operate, the origin of their selectivity, and the natures of lithiated organic compounds produced prior to work-up. We are therefore studying some well-established specific organic syntheses that use lithium reagents. Here we report preliminary results on the protocol established by Katritzky for specific α-substitution of NH-containing heterocycles in which the NH group is protected by carbon dioxide.[3] The Katritzky method has been applied to indoles,[3a] isoquinolines,[3b] phenothiazines,[3c] and related compounds. The one-pot method is illustrated for phenothiazine (**1**, Scheme 1). The amine **1** is converted first into the lithium amide **2**, which gives the lithium carbamate **3** on treatment with CO_2. Further lithiation is then held to afford specifically the α-lithio derivative **4**, whose treatment with an electrophile gives **5**. Acidification and decarboxylation give **6** and then the final α-substituted product **7**. Two key points are relevant to the mechanism of this synthetic strategy: 1) as well as preventing substitution at the nitrogen atom, it has been suggested that the CO_2 acts also as a directing group, possibly by "chelating" with the added *t*BuLi in the conversion of **3** to **4**; 2) to our knowledge, the lithium species of types **2**, **3**, **4**, **5** have not been isolated, identified, and structurally examined. To explore these points we have studied some of the key steps and intermediates along the conversion of **1** (Scheme 1)[3c] into its α-substituted derivatives. We have also examined the lithiation of a model system, diphenylamine (**1a**).

Scheme 1. The Katritzky method for the conversion of phenothiazine (**1**) into an α-substituted product (**7**).

Treatment of **1** in THF with *n*BuLi affords an amber-orange solution from which orange crystals of **2** · 3 thf were isolated (see Experimental Procedure). X-ray crystallography[4] shows that **2** · 3 thf is monomeric in the solid (Fig. 1), with Li–N and mean Li–O distances of 2.011(9) and 1.972(9) Å, respectively. There is nothing unusual about such a structure (five $R_2NLi \cdot 3$ thf monomers are in the Cambridge Crystallographic Data Base), although it is interesting that the phenothiazine anion is nonplanar. If CO_2 is bubbled through a chilled THF solution of **2** · 3 thf, its color lightens to pale yellow. Removal of solvent and recrystallization of the residue from toluene gives a microcrystalline material, identified as $(\mathbf{3} \cdot \text{thf})_n$ by elemental analysis and NMR and IR spectroscopy (in particular, a strong carboxylate stretch is seen at 1670 cm^{-1}). In addition, cryoscopic relative molecular mass (CRMM) measurements on solutions of $(\mathbf{3} \cdot \text{thf})_n$ in benzene give association state (n) values of 2.01 ± 0.09; the dominant species in solution is thus the dimer. Unfortunately, it proved impossible to get X-ray quality crystals of this complex, so we cannot confirm its suspected dimeric nature in the solid also. This failure made us switch our attention to systems based on diphenylamine (**1a**, Scheme 1); it contains all the essential features (NH unit, several aromatic CH units) of **1** and similar heterocycles.

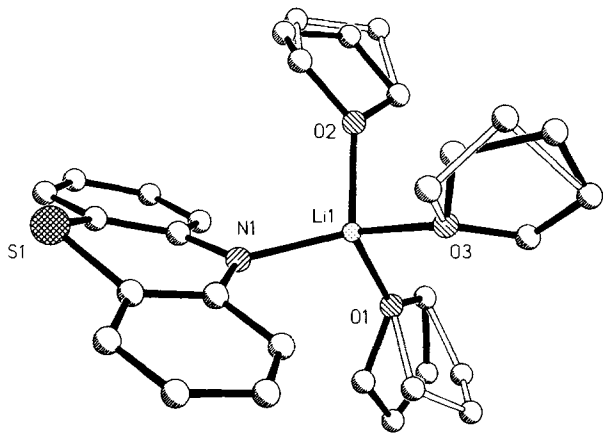

Fig. 1. The molecular structure of **2** · 3 thf (hydrogen atoms omitted for clarity). The disordered THF molecules are pictured in the two most highly refined positions.

Reaction of **1a** with *n*BuLi and then CO_2 in THF, followed by solvent removal and recrystallization of the residue from toluene/TMEDA (TMEDA = *N,N,N',N'*-tetramethylethylenediamine) afforded crystals of $(Ph_2NCO_2Li \cdot \text{tmeda})_n$, $(\mathbf{3a} \cdot \text{tmeda})_n$ (see Experimental Procedure). This is dimeric ($n = 2$) in the solid state.[5] The main structural feature (Fig. 2a) is the central, eight-membered $(LiOCO)_2$ ring [Li–O distances in Å range from 1.862(10) to 1.914(10); mean 1.886(10)]. Such a feature has been observed before in three dimeric lithium carboxylate structures,[6] but never for a lithium carbamate. The ring itself is formed from two near-planar monomeric units (Li1O3C2O4 and

L-S.). We thank also Dr. D. Reed (University of Edinburgh), and Dr. J. Barker and Dr. D. Barr (Associated Octel Co. Ltd) for assistance with NMR spectroscopic and synthetic aspects of the work.

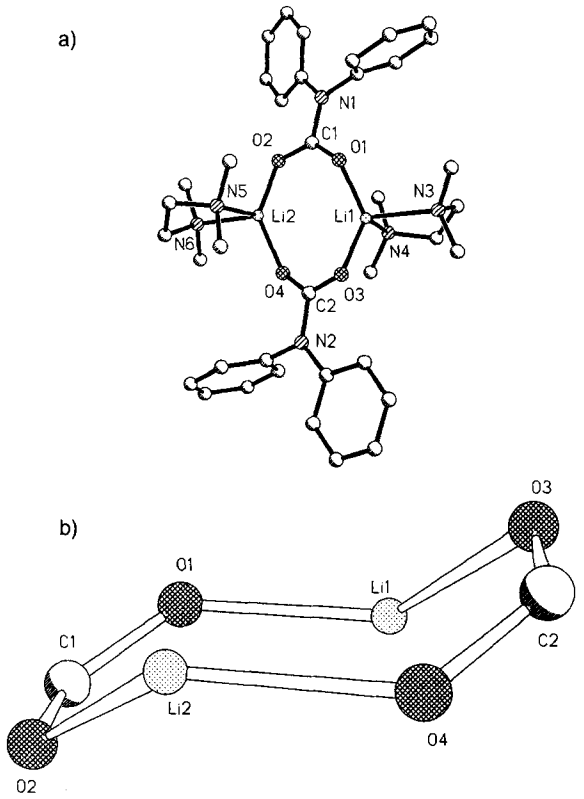

Fig. 2. a) The molecular structure of $(\mathbf{3a} \cdot \text{tmeda})_2$. b) The chair-shaped central $(LiOCO)_2$ ring of $(\mathbf{3a} \cdot \text{tmeda})_2$.

Li2O2C1O1), which link to give a chair-shaped dimer (Fig. 2b). Coordination around each Li^+ ion is completed by a TMEDA molecule [mean Li–N distance, 2.156(10) Å].

In $(\mathbf{3a} \cdot \text{tmeda})_2$, therefore, dimerization occurs even though each Li^+ ion is coordinated to two centers (from one TMEDA ligand). This supports our assertion that $(\mathbf{3} \cdot \text{thf})_n$ will be a dimer also. Since two THF molecules are (roughly) electronically equivalent to one TMEDA molecule, but are more demanding sterically, the implication is that incorporation of two THF complexants per Li^+ ion might lead to a monomeric structure. To probe this point, we treated **1a** in THF with *n*BuLi and the resulting solution with CS_2; this has also been used as a protecting group in the specific α-substitution of amines.[7] The crystalline product isolated from such a system is $Ph_2NCS_2Li \cdot 2\,thf$ (see Experimental Procedure), and it is indeed a monomer in the solid state (Fig. 3).[8] In this structure—the first of a lithium dithiacarbamate—the CS_2 unit chelates the Li^+ ion [mean Li–S 2.469(5) Å], whose tetrahedral coordination is completed by two THF molecules [mean Li–O 1.936(5) Å]. Surprisingly, this is the first example of definite CS_2–Li^+ chelation: in the only other related structure, that of the lithium trithiocarbonate complex $[Li(dme)_2]_2 \cdot (S_2CSCH_2CH_2SCS_2)$,[9] dme = $MeOCH_2CH_2OMe$, the Li–S contacts are understandably very long [mean 2.747(6) Å], since the complexed Li^+ ion is already four-coordinate.

Presumably, in $Ph_2NCS_2Li \cdot 2\,thf$ the larger S atoms allow the space for each Li^+ ion to accommodate two THF complexants, so dictating retention of a monomer, whereas in $(\mathbf{3} \cdot \text{thf})_n$ the smaller O atoms prevent incorporation of more than one THF molecule per Li^+ ion, and dimerization is then preferred. The balance between monomers and dimers is a fine one, as re-emphasized by studies on benzene solutions of $(\mathbf{3a} \cdot \text{tmeda})_n$. CRMM measurements give *n* values of 1.02 ± 0.04 in dilute solution

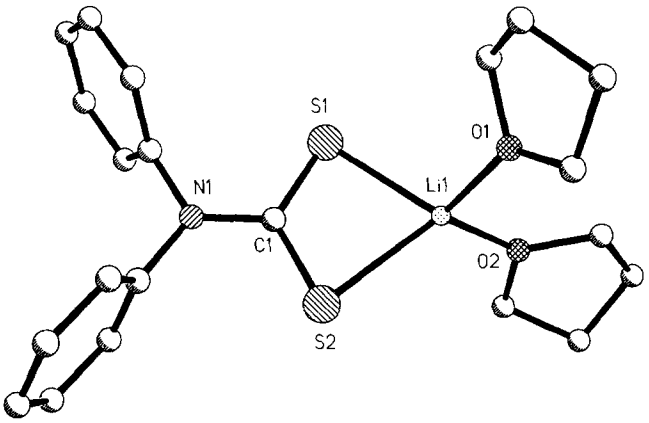

Fig. 3. The molecular structure of $Ph_2NCS_2Li \cdot 2\,thf$.

(0.008 M), increasing to 1.14 ± 0.08 with increasing concentration (0.018 M). Unusually, distinct resonances are observable close to room temperature in ^7Li NMR solution spectra. For a 0.048 M solution at 10 °C, there are two dominant singlets at $\delta = -1.38$ and -1.82 (relative to PhLi as external standard in benzene) and a much smaller one at $\delta = -2.08$. The same three signals occur at lower concentration (0.012 M) at 10 °C ($\delta = -1.36$, -1.80, -2.16), but the lowest frequency one ($\delta = -2.16$) is the largest. Therefore we assign this resonance to monomeric $\mathbf{3a} \cdot$ tmeda. This assignment, and others, are supported by variable-temperature studies on the more concentrated solution. Thus at 25 °C, the highest frequency signal (now at $\delta = -1.42$) has diminished and the other two (at $\delta = -1.87$, -2.10) have grown. By 45 °C, only these latter two resonances (now at $\delta = -1.90$, -2.17) are present. The highest frequency signal can therefore be attributed to dimeric $\mathbf{3a} \cdot$ tmeda. The intermediate resonance (at about $\delta = -1.8$) is possibly due to an "open-dimer" (as detected recently for certain lithium amides[10]) formed by cleavage of one Li–O bond in the dimer and thus the intermediate stage between monomer and dimer, that is, $(tmeda)Li^+ - OC(NPh_2)O - Li(tmeda) - OC(NPh_2)O^-$.

We return finally to the question of how the CO_2 unit in a lithium carbamate—or indeed the CS_2 unit in a lithium dithiacarbamate—might direct the position of a second lithiation (step **3** → **4** in Scheme 1). Our results show that the suggested[3e] "chelation" of added $(t\text{BuLi})_n$ ($n = 4$ in the solid[11]) by a complexed R_2NCX_2Li monomer or by a complexed $(R_2NCX_2Li)_2$ dimer (X = O or S) is unlikely. Any complexation of $(t\text{BuLi})_n$ would need to be external to the CX_2Li chelate ring in the former (as found in solid $Ph_2NCS_2Li \cdot 2\,thf$, Fig. 3) or to the larger $(CX_2Li)_2$ ring in the latter [as found in solid $(\mathbf{3a} \cdot \text{tmeda})_2$, Fig. 2a]. Indeed, this is a crucial point. It is precisely such *external* initial complexation of added $(t\text{BuLi})_n$ to a (merely two-coordinate) O center of, for example, dimeric $(\mathbf{3a} \cdot \text{tmeda})_2$ (see Fig. 2a, O2, O3) which would hold this reagent (presumably with $n < 4$) close to aromatic α-CH units (C22, C42). However, while such a scenario seems fine in theory, we have obtained some puzzling experimental results in attempting to carry out a second lithiation. Thus, treatment of THF solutions of $(\mathbf{3} \cdot \text{thf})_n$ and of $(\mathbf{3a} \cdot \text{tmeda})_n$ with $(t\text{BuLi})_n$ give solutions from which it has proved impossible to isolate any dilithiated products, even at room temperature (note from Scheme 1 that conversion **3** → **4** is held to occur at −20 °C). To explore this further, a solution of $(\mathbf{3} \cdot \text{thf})_n$ was prepared in $[D_8]$THF. To one half of this was added two equivalents of *t*BuLi (that is, two moles of *t*BuLi as a monomer to every one mole of **3** · thf as a monomer) at −70 °C, and this mixture was then transferred to a chilled

NMR tube. ^{1}H NMR spectra were recorded from $-60\,^\circ$C to $60\,^\circ$C. There was no discernible reaction. All eight aromatic protons of **3** · thf (including both α-CH protons) remained intact, and two *t*Bu singlets ($\delta = 0.94$, 0.90) of relative integrals for 9H and 9H (that is, 2 *t*BuLi) were apparent at all temperatures. To the other half of the solution of **3** · thf at $-70\,^\circ$C were added two equivalents of *t*BuLi *and* one of Me_3SiCl. ^{1}H NMR monitoring shows that now reaction does occur, starting at $-60\,^\circ$C: the α-CH proton resonances begin to diminish (fewer than 2H) as do the two singlet *t*Bu ones (fewer than 18H), and several Me_3Si singlets are apparent (total relative integral for 9H). At $60\,^\circ$C, α-Me_3Si substitution of **3** · thf appears complete: aryl resonances sum to 7H, *t*BuLi ones to 9H (that is, one of the two added equivalents of *t*BuLi remains) and there is one Me_3Si singlet (9H, $\delta = 0.36$). Remarkably, therefore, it seems that **3** will not react to any significant extent with *t*BuLi alone, but that the presence of the electrophile (here, Me_3SiCl) is needed. The deduction is that steps **3** → **4** and **4** → **5** in Scheme 1 are not consecutive, but are in some way interdependent. Explanations must be speculative, but include 1) that $(t\text{BuLi})_n$, held in **3** between an O atom of the CO_2 unit and an α-CH, is first complexed further by added Me_3SiCl (through Cl), which reduces the degree of aggregation *n* further and increases its reactivity; 2) that $(t\text{BuLi})_n$ reacts with Me_3SiCl to produce a "mixed-anion" lithiating reagent[12] of general form $(t\text{BuLi} \cdot \text{ClLi})_{n'}$, again of enhanced reactivity; or 3) that **3** does react with $(t\text{BuLi})_n$ to give **4**, but only in trace amounts, and the equilibrium **3** ⇌ **4** is driven forward by a fast reaction between **4** and added Me_3SiCl. We are investigating these possibilities.

Experimental Procedure

Synthesis of **2** · 3thf: Solid **1** (0.496 g, 2.5 mmol) was dissolved under nitrogen in dry THF (6 mL), the solution chilled in an acetone/dry ice bath, and *n*BuLi solution (2.5 mmol in hexane) added. The resulting orange solution and precipitate was heated to 60 °C to dissolve the solid. After cooling to room temperature over 2 h large orange crystals of **2a** · 3thf were isolated. First batch yield 0.48 g, 45%; m.p. > 300 °C; satisfactory analysis for $C_{24}H_{32}LiNO_3S$, ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): $\delta = 6.95$ (t, 4H), 6.6 (t, 4H), 3.5 (m, 12H, THF), 1.3 (m, 12H THF).

Synthesis of **3** · thf: An orange solution of **2** · 3thf was chilled in an acetone/dry ice bath and CO_2 gas bubbled through for two minutes, which caused decolorisation to pale yellow. Removal of solvent and addition of toluene (8 mL) gave a pale yellow solution. After storage at room temperature for 1 d, small white crystals of **3** · thf were isolated. First batch yield 0.46 g, 57%; m.p. > 250 °C; satisfactory analysis for $C_{17}H_{16}LiNO_3S$; ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): $\delta = 7.1$–6.6 (m, 8H), 3.35 (s, 4H, THF), 1.37 (s, 4H, THF).

Synthesis of **3a** · tmeda: Solid **1a** (0.423 g, 2.5 mmol) was dissolved under nitrogen in dry THF (6 mL), the solution chilled, and *n*BuLi solution (2.5 mmol, in hexane) added. The resulting pale yellow solution was warmed to room temperature before being chilled in an acetone/dry ice bath. CO_2 gas was bubbled through the solution for two minutes, causing decolorization. Removal of solvent under reduced pressure, followed by addition of toluene (5 mL), hexane (5 mL), and TMEDA (0.38 mL, 2.5 mmol), gave a pale yellow solution, which was refrigerated at $-20\,^\circ$C for 7 d, whereupon small white crystals of **3a** · tmeda were isolated. First batch yield 0.65 g, 77%; m.p. 117–120 °C; satisfactory analysis for $C_{19}H_{26}LiN_3O_2$, ^{1}H NMR (C_6D_6, 360 MHz, 10 °C): $\delta = 7.4$ (m, 3H), 7.1 (m, 4H), 6.9 (m, 3H), 2.1 (s, 4H, $Me_2N(CH_2)_2NMe_2$), 2.0 (s, 12H, $Me_2N(CH_2)_2NMe_2$).

Synthesis of Ph_2NCS_2Li · 2thf: A solution of **1a** (0.846 g, 5 mmol) in dry THF (6 mL) was chilled, and *n*BuLi solution (5 mmol, in hexane) added. The resulting pale yellow solution was warmed to room temperature before being slightly chilled. CS_2 (0.3 ml, 5 mmol) was then added, giving a thick orange precipitate. Removal of solvent, addition of toluene (10 mL), and gentle heating gave an orange solution. After cooling to room temperature over 2 h a large crop of small orange crystals of Ph_2NCS_2Li · 2thf was isolated. First batch yield 1.52 g, 77%; m.p. 290–295 °C; satisfactory analyis for $C_{21}H_{26}LiNO_2S_2$, ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = 7.7 (d, 6H), 7.12 (d, 2H), 6.97 (d,2H), 3.6 (m, 8H, THF), 1.3 (m, 8H, THF).

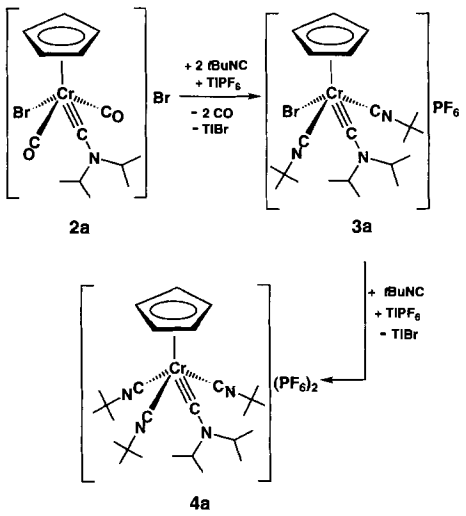
Aminocarbyne Complexes of Chromium in a High Oxidation State—Synthesis, Structure, and Reactivity**

Alexander C. Filippou,* Bernhard Lungwitz, Klaus M. A. Wanninger, and Eberhardt Herdtweck

In 1975 R. R. Schrock et al. reported the synthesis of [Li(dmp)][(tBuCH$_2$)$_3$Ta≡CtBu] (dmp = *N*,*N*′-dimethylpiperazine), the first carbyne complex of a transition metal in a high oxidation state.[1] Since then numerous second- and third-row transition metal carbyne complexes of this type have been prepared.[2] Among them, the molybdenum and tungsten carbyne complexes [(RO)$_3$M≡CR′] (R,R′ = alkyl, aryl; R′ = amino) have been extensively studied because of their catalytic activity in alkyne metathesis.[3] Two principal methods have been developed for the synthesis of these compounds. The first involves the reaction of Mo^{VI} and W^{VI} halides with alkyllithium compounds,[4] the second is the oxidative decarbonylation of Fischer-type carbyne complexes.[5] In comparison, analogous carbyne complexes of first-row transition metals have not yet been reported. Attempts to prepare Schrock-type carbyne complexes of chromium have so far been unsuccessful owing to the oxidation of alkyl transfer reagents by Cr^{VI} halides[6] or the oxidative cleavage of the chromium–carbon triple bond of Fischer-type carbyne complexes.[7] Here we report the synthesis, structure, and reactivity of the first carbyne complexes of chromium in a high oxidation state.

Oxidation of **1a** and **1b**[8] with bromine in CH_2Cl_2 at −78 °C leads selectively to the cationic aminocarbyne complexes in **2a** and **2b** [Eq. a]. Similarly, the cationic chloro complex in [Cp(Cl)(CO)$_2$Cr≡CN^{i}Pr$_2$]Cl (**2c**) is obtained from **1a** and $PhICl_2$,

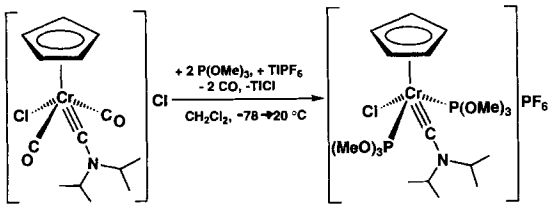


(a)

1a, 1b **2a, 2b**

a: R = H; b: R = Me

while oxidation of the analogous molybdenum and tungsten complexes [(η^5-C$_5$R$_5$)(CO)$_2$M≡CNEt$_2$] with halogens affords the neutral aminocarbyne complexes *cis*-[(η^5-C$_5$R$_5$)(X)$_2$(CO)M≡CNEt$_2$] (R = H, Me; X = Cl, Br, I), bearing one carbonyl ligand.[5b, e, f]

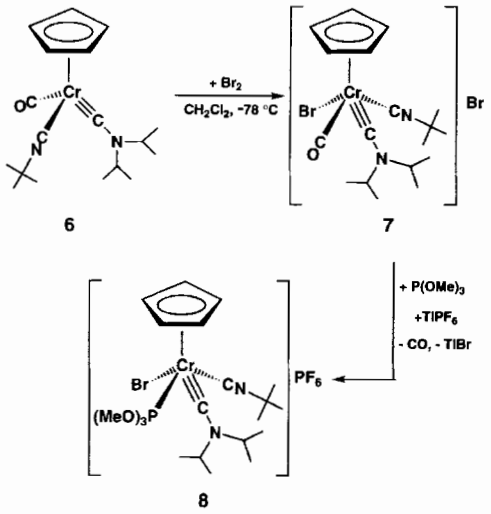


The salts **2a**–**2c** were isolated as ocker-yellow, very thermolabile solids (decomposition of the solids above ca. −50 °C). Their low thermal stability can be ascribed to the labile chromium–carbonyl bonds.[9] Thus, thermal decomposition of these compounds in solution leads after elimination of both CO ligands to blue paramagnetic products of yet unknown structure. However, thermally stable aminocarbyne complexes of chromium in a high oxidation state can be obtained after CO substitution, if the halide counterion of **2a**–**2c** is removed by reaction with TlPF$_6$. Thus, treatment of **2a** with TlPF$_6$ and tBuNC leads to the salt **3a** containing a monocationic aminocarbyne complex, which can be subsequently converted with additional TlPF$_6$ and tBuNC to the dicationic aminocarbyne complex in **4a** (Scheme 1). In contrast, reaction of **2b** with TlPF$_6$ and tBuNC leads directly to the analogous pentamethylcyclopentadienyl (Cp*) derivative [Cp*(tBuNC)$_3$Cr≡CN^{i}Pr$_2$] (PF$_6$)$_2$ (**4b**).

2a **3a** **4a**

Scheme 1.

Similarly, the salt **5** containing a cationic aminocarbyne complex is obtained from **2c** after treatment with TlPF$_6$ and P(OMe)$_3$ [Eq. b]. Also mixed-substituted aminocarbyne derivatives are accessible following this route, as demonstrated by the selective oxidation of **6**[8] with bromine to give the thermolabile, light-brown aminocarbyne complex in **7** (m.p. = ca. −50 °C (decomp.)), followed by the transformation of this complex in **7** to the cation in **8** after treatment with TlPF$_6$ and tBuNC (m.p. = 83 °C (decomp.)) (Scheme 2).



(b)

2c **5**

The amine carbyne complexes of chromium are isolated as yellow (**4a**), orange-red (**3a**, **8**), red (**4b**), and brown (**5**) solids, which, unlike the salts **2a**–**2c**, and **7** with their carbonyl-containing cationic precursor complexes show a surprising thermal stability (m.p.: 83–141 °C (decomp.)). The salts **2a**–**5**, **7**, and **8** were characterized by elemental analyses, IR, NMR, and mass spectra (Table 1). All aminocarbyne

7: IR (CH_2Cl_2, −60 °C): $\tilde{\nu}$[cm^{-1}] = 2194 s [ν(C≡NtBu)], 2057 vs [ν(CO)], 1621 s [ν(C$_{carbyne}$···N)].

8: IR: $\tilde{\nu}$[cm^{-1}] = 2173 s [ν(C≡NtBu)]; 1589 m, sh, 1575 s [ν(C$_{carbyne}$···N)]; ^{1}H NMR: δ = 1.31 (d, 6H; 2 × CHMe_AMe$_B$), 1.36 (d, 6H; 2 × CHMe$_A$$Me_B$), 1.58 (s, 9H; Me_3C), 3.76 (sept, 2H; 2 × CHMe$_2$), 3.93 (d, ^3J(H,P) = 10.4 Hz, 9H; P(OMe)$_3$), 5.36 (d, ^3J(H,P) = 3.7 Hz, 5H; C_5H_5); ^{13}C{^{1}H}-NMR: δ = 21.8 (2 × CHMe_AMe$_B$), 22.6 (2 × CHMe$_A$$Me_B$), 30.4 ($Me_3$C), 56.0 (d, ^3J(C,P) = 6.1 Hz; 2 × CHMe$_2$), 57.1 (d, ^2J(C,P) = 6.7 Hz; P(OMe)$_3$), 60.3 (Me_3C), 97.6 (Cp), 161.1 (Me_3CNC), 319.6 (d, ^2J(C,P) = 95.2 Hz; Cr≡C); ^{31}P{^{1}H} NMR: δ = 158.7; FD-MS (CH_2Cl_2): m/z 517 [M]$^+$.

[a] Correct elemental analyses were obtained for **3a–5** and **8**. [b] IR spectra (FT-IR spectrometer Perkin Elmer 1650) in CH_2Cl_2 at room temperature, unless otherwise stated; NMR spectra (Jeol-JMX-GX-400 spectrometer) in CD_2Cl_2 at room temperature, unless otherwise stated; the δ_H and δ_C values are referenced to residue solvent signals and the δ_P values to a 85% H_3PO_4 solution (external standard); the ^{3}J(H,H) coupling constant of the N(CHMe$_2$)$_2$ group is 6.1 Hz; mass spectra: m/z values relative to the ^{52}Cr and ^{81}Br isotopes.

complexes of chromium in a high oxidation state are distinguished by an intense IR absorption of the ν(C$_{carbyne}$···N) vibration in the range 1560–1637 cm^{-1} (Table 1). This vibration is slightly lower in frequency than that of the immonium ions [R$_2$C=NR$'_2$]$^+$ (1640–1690 cm^{-1})[10] revealing a strong π conjugation of the amino group with the chromium–carbon triple bond.[8, 9] The ν(C$_{carbyne}$···N) absorption of the aminocarbyne complexes of chromium in a high oxidation state appears at higher wavenumbers than that of the starting materials **1a**, **1b**, and **6** [ν(C···N) = 1519–1552 cm^{-1}].[8] There is a shift of this frequency towards lower wavenumbers in the series **2a**, **2c** > **7** > **3a** > **8** > **5** as a result of the increasing electron density at the metal center and the strengthening of the chromium–carbyne back bonding.[5b–f] The number and relative intensity of the ν(CO) and ν(C≡NtBu) absorptions of the complexes in **2a–2c** and **3a** indicate the diagonal arrangement of these ligands in the coordination sphere. The weak chromium–carbonyl and chromium–isocyanide back bonding in these compounds is displayed by the frequencies of these absorptions. In the ^{1}H NMR spectra of **2a–5** one doublet is observed for the methyl protons and one septet for the methine protons of the aminocarbyne ligand, confirming the C_s symmetry of these complexes and the fast rotation of the amino group about the C$_{carbyne}$–N bond (Table 1).[11] In contrast, two doublets are found in the ^{1}H NMR spectrum of the C_1-symmetric complex in **8** for the diastereotopic methyl protons of the aminocarbyne ligand. The carbyne–carbon resonances of the complexes in **2a–5**, **7**, and **8** appear at a considerably lower field (δ = 311.7–325.8) than those of the starting materials **1a**, **1b**, and **6** (δ = 276.6–281.7).[8] The same trend is observed on comparing Schrock-type with Fischer-type carbyne complexes of molybdenum and tungsten.[2, 5]

The proposed structures of the carbyne complexes in **3a** and **4b** were confirmed by single-crystal X-ray diffraction studies (Figs. 1 and 2).[12] Interesting structural features of **3a** and **4b**

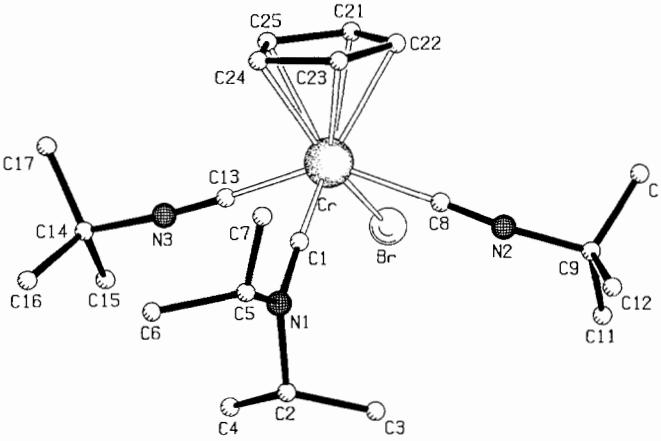

Fig. 1. Structure of the cation in **3a** (PLUTON plot) in the crystal. Selected bond lengths [pm] and angles [°]: Cr-C1 174.5(3), Cr-Br 255.7(1), Cr-Cp$_{centroid}$ 186.2, Cr-C8 197.6(3), Cr-C13 197.4(3), C1-N1 130.0(4); Cr-C1-N1 177.0(3), Br-Cr-C1 109.5(1), Br-Cr-C8 75.0(1), Br-Cr-C13 79.6(1), C1-Cr-C8 81.3(1), C1-Cr-C13 81.4(1), C8-Cr-C13 142.1(1), C8-N2-C9 164.1(3), C13-N3-C14 174.8(3).

are a) the unusual high coordination number observed for half-sandwich chromium complexes bearing a Cp ligand (C.N. = 5, if the complexes in **3a** and **4b** are considered as distorted square pyramids with the Cp or Cp* ligand, respectively, on the apex)[13]; b) the very short Cr–C$_{carbyne}$ bonds of **3a** and **4b** (174.5 and 173.5 pm respectively), which are however of similar

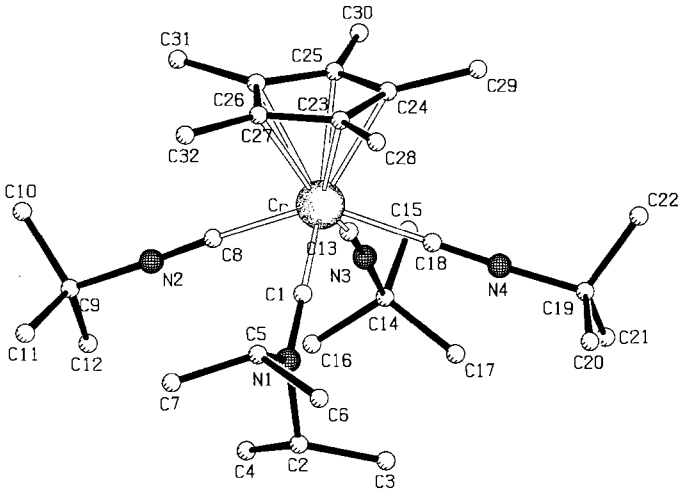

Fig. 2. Structure of the cation in **4b** · CH_3CN (PLUTON plot) in the crystal. Selected bond lengths [pm] and angles [°]: Cr-C1 173.5(4), Cr-$Cp^*_{centroid}$ 186.7, Cr-C8 197.2(4), Cr-C13 199.1(5), Cr-C18 194.9(5), C1-N1 127.8(5); Cr-C1-N1 179.3(4), C1-Cr-C8 78.0(2), C1-Cr-C13 109.5(2), C1-Cr-C18 80.7(2), C8-Cr-C18 141.9(2), C8-N2-C9 176.6(5), C13-N3-C14 174.9(5), C18-N4-C19 177.1(6).

length to the $Cr-C_{carbyne}$ bonds of aminocarbyne complexes of chromium in a low oxidation state;[14] c) the trigonal-planar coordination of the amino-nitrogen atom (the sum of angles around nitrogen is 360° for both **3a** and **4b**), and the short $C_{carbyne}-N$ bonds of 130.0 and 127.8 pm, respectively, which together with the spectroscopic data demonstrate the π-conjugation of the amino group with the chromium–carbon triple bond,[10, 14] and d) the almost perpendicular orientation of the aminocarbyne ligand plane, defined by the atoms C1, N1, C2, and C5, relative to the Cp or Cp* ring plane (dihedral angle between the best planes: **3a** 92.2°; **4b** 93.4°).[11]

The cations in **2a–5**, **7**, and **8** are the first isolated and characterized carbyne complexes of chromium in a high oxidation state. Protonation of these compounds may provide a route to carbene complexes of chromium in a high oxidation state. Further studies are necessary to demonstrate whether the synthetic concept presented here can be extended to Cp-free carbyne complexes of chromium and other first-row transition metals, and to investigate the reactions of these compounds with unsaturated hydrocarbons.

Experimental Procedure

2a: A precooled (−78 °C) solution of Br_2 (0.496 g, 0.16 mL, 3.11 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of **1a** (0.93 g, 3.26 mmol) in CH_2Cl_2 (30 mL) at −78 °C and the reaction mixture stirred for 2 h. The resulting brown-yellow solution was reduced in volume at −78 °C and the product precipitated with a cold (−78 °C) Et_2O/pentane mixture (1/5). The precipitate was washed repeatedly with cold Et_2O (−78 °C). Yield 1.31 g (90%), yellow powder, m.p. = ca. −50 °C (decomp.).

3a: A solution of **2a** (0.93 g, 2.09 mmol) in CH_2Cl_2 (50 mL) was treated at −78 °C with a cold (−78 °C) solution of *t*BuNC (0.698 g, 0.95 mL, 8.40 mmol) in CH_2Cl_2 (10 mL) and $TlPF_6$ (0.90 g, 2.58 mmol). The mixture was then allowed to warm to room temperature and stirred for 1 h. The resulting brown reaction mixture was treated with a small amount of Et_2O and filtered from the insoluble thallium salts. The filtrate was reduced in volume and the product precipitated with a Et_2O/pentane (1/1) mixture. The precipitate was recrystallized from THF/Et_2O. Yield 0.70 g (54%), orange-red, microcrystalline powder, m.p. = 117 °C (decomp.).

4b: A solution of **2b** (0.57 g, 1.11 mmol) in CH_2Cl_2 (50 mL) was treated at −78 °C with a precooled (−78 °C) solution of *t*BuNC (1.25 g, 1.70 mL, 15.04 mmol) in CH_2Cl_2 (20 mL) and $TlPF_6$ (0.77 g, 2.20 mmol). The mixture was allowed to warm to room temperature and stirred for 3 h. The resulting red reaction mixture was treated with a small amount of Et_2O and filtered from the insoluble TlBr. The filtrate was concentrated and the product precipitated with Et_2O. The precipitate was dissolved in a few mL of CH_2Cl_2 and the solution filtered from a small amount of a red-purple by-product. The filtrate was reduced in volume and the product precipitated with Et_2O/pentane. Yield 0.56 g (60%), red, microcrystalline solid, m.p. = 141 °C (decomp.).

[9] The aminocarbyne ligand bears, other than alkyl or arylcarbyne ligands, only one low-lying π-acceptor orbital, which is oriented in the plane of the amino group [2]. Therefore only one filled metal-centered orbital of π symmetry is primarily used for the metal-carbyne back bonding in the complexes in **2a–5**, **7**, and **8**. The other π-acceptor orbital of the aminocarbyne ligand is raised in energy due to overlap with the p-type orbital of the amino-nitrogen atom. This orbital interacts in **2a–2c** with the other metal-centered π-orbital, competing with the two π*-acceptor orbitals of the CO ligands. This specific electronic situation is the reason for the lability of the chromium–carbonyl bonds in **2a–2c**, the high frequency of the $\nu(C_{carbyne}\cdots N)$ vibration found in the IR spectra of the aminocarbyne complexes of chromium in a high oxidation state and the "upright" conformation of the aminocarbyne ligand found in the crystal structures of **3a** and **4b**.
[10] C. Sandorfy in *The Chemistry of the Carbon-Nitrogen Double Bond* (Ed.: S. Patai), Interscience, London, **1970**.
[11] Molybdenum and tungsten aminocarbyne complexes of the type *cis*-[(η^5-C_5R_5)$(X)_2(CO)M{\equiv}CNR'_2$] (X = Cl, Br; R = H, Me; R' = Et, *i*Pr, cyclohexyl), which are related with the chromium compounds in **2a–5**, **7** and **8**, show temperature-dependent ^1H NMR spectra due to a restricted rotation of the amino group about the $C_{carbyne}-N$ bond. The free activation enthalpy of ca. 10 kcal mol^{-1} for this rotation, was determined from the coalescence temperature of the inequivalent alkyl groups attached to the amino-nitrogen atom. The rotational barrier is of electronic origin. Thus, EHMO calculations of the model compound $[Cp(Br)_2(CO)W{\equiv}CNH_2]$ show, that the conformer, in which the amino and the Cp ring plane are perpendicular to each other, is more stable (by ca. 10 kcal) than the conformer, in which the amino group is rotated by 90°. The crystal structures of **3a**, **4b**, and [(η^5-C_5Me_4Et)$(Br)_2(CO)W{\equiv}CNEt_2$] show, in full agreement with these calculations, that the amino and the Cp or Cp* ring plane are perpendicular to each other: A. C. Filippou, B. Lungwitz, H. Berke, T. Bürgi, unpublished results.
[12] X-ray structure analysis of **3a**: $C_{22}H_{37}BrCrF_6N_3P$, M = 620.4; orange-red needles (0.36 × 0.08 × 0.04 mm) from CH_2Cl_2/*n*-pentane at −30 °C by diffusion; monoclinic, $P2_1/c$ (no. 14), a = 977.5(1), b = 1328.8(1), c = 2198.2(2) pm, β = 95.93(1)° (25 reflections at high scattering angles, $2\theta_{min/max}$ = 69.8°/94.0°), $V = 2840 \times 10^6$ pm^3, Z = 4, ρ_{calcd} = 1.451 g cm^{-3}; $F(000)$ = 1272; μ = 60.7 cm^{-1}; CAD4, $Cu_{K\alpha}$ radiation, λ = 154.184 pm; $\theta/2\theta$ scan, 8.8° < θ < 70.0°; t_{max} = 90 s. 5951 reflections were collected at $T = -110 \pm 5$ °C. After LP and decay correction (135.5 h, −7.5% decay), and an empirical absorption correction (5 Psi-scan-data, $C_{min/max}$ = 0.902/1.000), 4534 independent reflections remained with R_m = 0.020 (F). Solution of the structure was carried out using a combination of Patterson and difference-Fourier-methods and full matrix least-squares refinement (STRUX-IV, SHELXS-86, SDP). One isopropyl group of the aminocarbyne ligand is disordered in two locations with different probability (2:1). All non-hydrogen atoms except those for the disordered group were refined anisotropically. Hydrogen atoms were calculated on ideal positions (d_{C-H}: 95 pm; B_H: 1.3 B_C) and included in the structure factor calculations. The calculations converged at R = 0.056 and R_w = 0.038 for 3678

reflections with $I > 2\sigma(I)$ and 305 parameters. Subsequent difference-Fourier synthesis led to a final electron density of $e_{min/max} = +0.65/-0.78\ e\text{Å}^{-3}$. Because of the high thermal parameters of the PF_6 anion, the distances P–F seem to be shortened. X-ray structure analysis of **4b** · CH_3CN: $C_{34}H_{59}CrF_{12}N_5P_2$, $M = 879.8$; red needles (crystal dimensions $0.20 \times 0.20 \times 0.60$ mm) from CH_3CN/Et_2O by diffusion at $-30\,^{\circ}C$; orthorhombic, $P2_12_12_1$ (no. 19), $a = 1150.4(1)$, $b = 1663.2(2)$, $c = 2378.6(2)$ pm (48 reflections at high scattering angles, $2\theta_{min/max} = 31.8/37.6^{\circ}$), $V = 4551 \times 10^6$ pm^3, $Z = 4$; $\rho_{calcd} = 1.284$ g cm^{-3}; $F(000) = 1840$; $\mu = 3.8$ cm^{-1}; CAD4; $Mo_{K\alpha}$ radiation, $\lambda = 71.073$ pm; ω scan, $1.0^{\circ} < \theta < 25.0^{\circ}$; $t_{max} = 90$ s. 4468 reflections were collected at $T = -50 \pm 3\,^{\circ}C$. After LP correction 4063 independent reflections remained with ($R_m = 0.020(F)$). Structure solution was carried out using a combination of direct and difference-Fourier methods and full matrix least-squares refinement (STRUX-IV, SHELXS-86, SDP). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were calculated on ideal positions with $d_{C\ H}$: 95 pm; B_H: 1.3 B_C) and included in the structure factor calculations. All calculations converged at $R = 0.075$ and $R_w = 0.054$ for 3476 reflections with $I > 2.0\,\sigma(I)$ and 470 parameters. Subsequent difference-Fourier synthesis led to a final electron density of $e_{min/max} = +0.65/-0.78\ e\text{Å}^{-3}$. Because of the high thermal parameters of the PF_6 anion, the distances P–F seem to be shortened. Compound **4b** exists also in a solvent-free pseudo-tetragonal brown phase. The chromium atom lies on a fourfold axis, and thus the ligands are highly disordered. Apparently acetonitrile stabilizes the orthorhombic phase. That means high thermal parameters for the PF_6 anions, disordered solvent, and unoccupied sites in the lattice with space for 9 Å^3 and 7 Å^3. It is possible that the solvent does not properly occupy sites in the crystal or is exchanged by Et_2O. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-58816.

[13] Halfsandwich complexes of chromium, bearing a Cp ligand, are mostly four-coordinate. In contrast, only few five-coordinate compounds are known such as the carbonyl complexes $[CpCr(CO)_3X]$ (X = H, halogen Me, $SnPh_3$) and $[CpCr(CO)_2L_2]$ $[CpCr(CO)_3]$ (L_2 = bis(diphenylphosphano)methane (dppm), 1,2-bis(diphenylphosphano)ethane (dppe): a) A. 2-[*p*-(*N*-*tert*-butyl-*N*-oxyamino)phenyl]-4,4,5,5-tetramethyl-4,5-dihydroimidazol-3-oxide-1-oxyl, a Stable Diradical with a Triplet Ground State**

Katsuya Inoue and Hiizu Iwamura*

Stable triplet diradicals with additional functionalities such as donor/acceptor properties and ligating capabilities to transition metal ions are of great interest for the construction of molecular magnets by assembling electron spins (radical centers) in more than one dimension.[1] Except for Yang's biradical,[2] *meta*-phenylenebis(nitroxide)s,[3] and the stabilized "Schlenk hydrocarbon",[4] there are not very many examples that satisfy both the requirements of kinetic stability and a large energy gap between the triplet ground and singlet excited states. We have prepared the title diradical **1** that, in spite of its formal *para*-substitution pattern of Ullman's nitronyl nitroxide[5] and *tert*-butyl nitroxide moieties, is a stable and robust ground-state triplet species.

p-[*N*-*tert*-Butyl-*N*-(*tert*-butyldimethylsilyloxy)amino]benzaldehyde[6] was condensed with 2,3-bis(hydroxyamino)-2,3-dimethylbutane, and the resulting bis(hydroxylamine) was oxidized with lead dioxide to give oxyl **2**. Deprotection by treatment with tetrabutylammonium fluoride followed by oxidation with silver oxide gave bis(nitroxide) **1** as violet needles (Scheme 1).

Scheme 1. Synthesis of the diradical **1**. TBDMS: *tert*-butyldimethylsilyl, DMF = dimethylformamide.

The results of the X-ray crystal structure analysis of **1**[9] are reproduced in Figure 1. The molecular structure is characterized by the presence of three approximately planar units: the dihydroimidazole ring, the *para*-phenylene ring, and the C, N, O unit of the *tert*-butylnitroxide group. The dihedral angle between the first two planes is about 27° (N_1-C-C-C = 27.5° and N_2-C-C-C = 27.2°) and that of the last two is 22° (C-C-N-O = 21.6°). Typical values for the corresponding dihedral angles in unbiased monoradicals are 35–39° and 30–40°, respectively; that is, **1** is closer to a coplanar structure than these monoradicals. The N–O bonds are slightly elongated. The *para*-phenylene ring appears to deviate from a regular hexagon toward a slightly bond-alternating quinonoidal structure, but only by 0.01–0.02 Å.

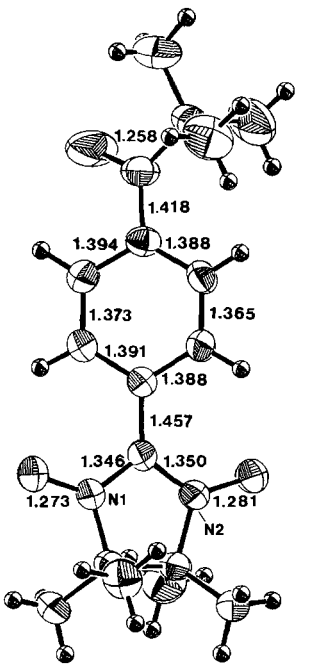

Fig. 1. ORTEP representation of **1** with 50.0% probability ellipsoids [9].

A degassed solution of **1** in 2-methyltetrahydrofuran (MTHF) at room temperature showed a seven line EPR hyperfine structure (a = 3.5 G (2 N) and 4.4 G (1 N) by simulation) at $g = 2.0061$, which suggests that the exchange interaction is greater

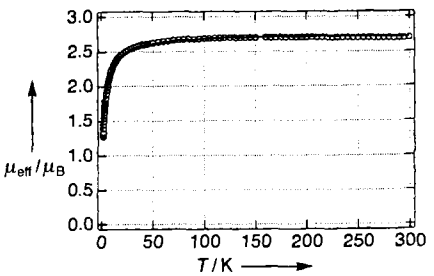
than the hyperfine coupling. A frozen solution of **1** in MTHF gave a broad singlet (width 20.0 G) at $g = 2.0073$ and a $\Delta m_S = \pm 2$ transition at 168 mT, showing that the dipole–dipole interaction between the two unpaired electrons is rather weak. Temperature dependence of the broad $\Delta m_S = \pm 1$ signal followed a Curie law in the range 14–55 K.

The temperature dependence (2–300 K) of the paramagnetic susceptibility of a microcrystalline sample of **1** was measured at 5000 Oe, and the data are expressed by the effective magnetic moment μ_{eff} vs. temperature plot in Figure 2. The μ_{eff} value of



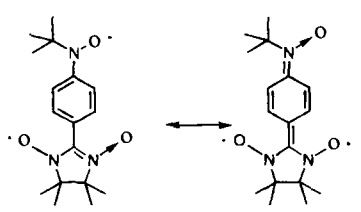


Fig. 2. The temperature dependence of the magnetic moment μ_{eff} of polycrystalline **1** measured at 5000 Oe.

2.71 μ_B at 300 K is close to a theoretical value of 2.83 μ_B for a triplet species. Since there is no specific short contact found between the diradical molecules in the X-ray crystal structure, the contribution of a strong ferromagnetic intermolecular interaction, which is operative even at room temperature, is a remote possibility. The magnetic data were analyzed in terms of a Bleany–Bowers-type singlet–triplet model for the diradical molecule[7] with a weak intermolecular interaction, which is treated by the Weiss field [Eq. 1], in which the magnetic exchange coupling constant J corresponds to a Hamiltonian of the

$$\chi_m = \frac{2fNg^2\mu_B^2}{k_B(T-\theta)\{3 + \exp(-2J/k_BT)\}} \quad (1)$$

form $\mathcal{H} = -2JS_1S_2$. Since μ_{eff} remained constant in the range 100–300 K, only the lower limit of J ($J/k \geq 450$ K) was obtained. By fixing J at 450 K, the other parameters were optimized by means of a least squares analysis to give $\theta = -5.64 \pm 0.063$ K, and f (purity of the diradical) $= 94.9 \pm 0.2\%$.

A preliminary study on the suitability of **1** as a ligand was not satisfactory. Thus when **1** was mixed with $[Mn^{II}(hfac)_2]$, (hfac = hexafluoroacetylacetonato) a two-to-one complex was formed in which only the *tert*-butylnitroxide moiety takes part in complexation.[10] The basicity of the nitronyl nitroxide moiety appears to have decreased somewhat, which supports the canonical structure **1a**. A study employing more acidic transition metal centers is in progress.

1 **1a**

It is concluded that diradical **1** is a kinetically stable and robust triplet diradical. A contribution of resonance structure **1a**, a heteroatom analogue and vinylogue of trimethylenemethane,[2b, 8] may be evoked for the strong intramolecular exchange coupling between the two radical centers separated by several π bonds (about 7 Å), but the bond alternation toward the quinonoidal structure **1a** revealed by the X-ray molecular structure is limited.

Experimental Procedure

Protected nitronyl nitroxide **2** was obtained by condensation of 2,3-dihydroxyamino-2,3-dimethylbutane sulfate with *p*-[*N*-*tert*-butyl-*N*-(*tert*-butyldimethylsiloxy)amino]benzaldehyde [5] in the presence of potassium carbonate followed by oxidation with lead(IV) oxide in dichloromethane at 0 °C. Recrystallization from CH_2Cl_2 gave **2** as black crystals: mp. 140.0–140.8 °C.

1: Compound **2** was deprotected by treatment with tetrabutylammonium fluoride in THF at 0 °C for 30 min. Deprotected **2** was not stable and therefore was oxidized with silver oxide in dichloromethane at 0 °C without purification. Purification of the oxidized crude product by chromatography (SiO_2, CH_2Cl_2/hexane (1:1)) and recrystallization from hexane/ether gave **1** as stable, deep violet needles: m.p. approximately 180 °C (decomp.); UV/Vis [$CHCl_3$, $\lambda(\varepsilon)$] 574.0 (1.30×10^3), 354 nm (3.72×10^4).

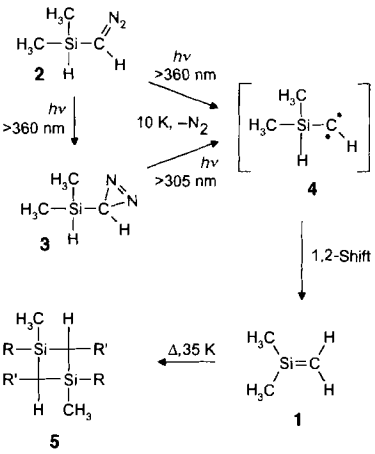
Reaction of 1,1-Dimethylsilene with Formaldehyde**

Martin Trommer, Wolfram Sander,*
Carl-Henrik Ottosson, and Dieter Cremer*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

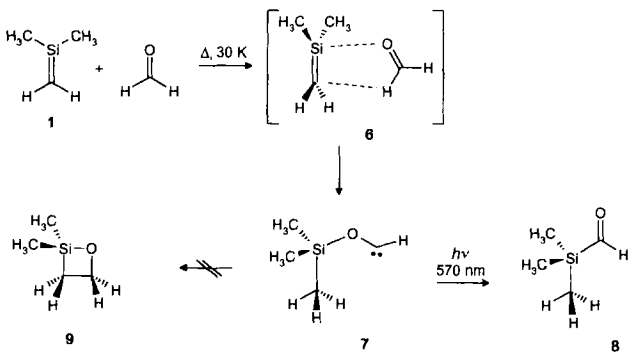
In contrast to C–C double bonds, Si–C double bonds are strongly polar and labile and thus undergo reactions with polar molecules that are unknown in olefin chemistry.[1] For example, silenes react with carbonyl compounds (in particular aromatic carbonyl compounds) in a Wittig-type reaction to give olefins (Scheme 1).[2–4] 1,2-Oxasiletanes have been postulated, and in some cases demonstrated, as intermediates in the formation of olefins.[4–6] The extremely unstable silanones formed in the fragmentation of the 1,2-oxasiletanes immediately react further to give cyclosiloxanes.



Scheme 1.

According to the results of our CCSD(T)/6-31G(d,p) calculations the reaction of silene with formaldehyde leading to formation of 1,2-oxasiletane is exothermic by 67 kcal mol^{-1}. The overall reaction, including fragmentation to ethene and silanone, is still exothermic by 30 kcal mol^{-1},[6] but the 1,2-oxasiletane lies in such a deep energy well that it can be detected as an intermediate.

The reaction of silenes with carbonyl compounds having an α-H atom follows another route. Here, the main product is a silyl enol ether formed by migration of an H atom (Scheme 1).[1a, 7]



We report here on the reaction of 1,1-dimethylsilene (**1**) with formaldehyde. This silene can be synthesized[8] in high yield by photolysis of (dimethylsilyl)diazomethane (**2**) and is very suitable for the investigation of simple silenes that are not stabilized by bulky substituents (Scheme 2).

Irradiation (λ = 360 nm) of **2** in an argon matrix at 10 K[9] led to formation of the silene **1** and the diazirine **3**. The carbene **4** was too short lived to be detected by IR or UV/Vis spectroscopy, even under conditions of matrix isolation. Irradiation at shorter wavelength (λ > 305 nm) also resulted in elimination of N_2 from **3**, and **1** was formed in almost quantitative yield (IR detection). When the matrix was annealed at 30–40 K, **1** dimerized within a few hours to give disiletane **5** as the main product.[10–13]

Scheme 2.

In the photolysis of **2** (λ > 305 nm, 10 K) in a matrix containing 0.6% formaldehyde, **1** was still formed as the main product, but small amounts of other reaction products were now observed by IR spectroscopy. When the matrix was warmed to 30–35 K after photolysis of **2** at 10 K, the reaction between **1** and CH_2O could then be followed directly by IR spectroscopy: the intensity of the bands of CH_2O and **1** decreased markedly within a few hours, and the new product **7** was formed in addition to small amounts of dimer **5** (Scheme 3). After about 70% conversion the reaction stopped. The new product formed by warming the matrix was extremely photolabile and rearranged quantitatively to 2,2-dimethyl-2-silapropanal (**8**) within a few minutes' irradiation (λ > 570 nm) (Fig. 1). Comparison of the most intense bands at 2624 (aldehyde C–H str.), 1661 (C=O str.), 1252, and 851 cm^{-1} with those of an authentic matrix-isolated sample[8, 14] allowed **8** to be identified.

Scheme 3.

The photolabile compound **7** shows an intense IR absorption at 2605 cm^{-1}, the position and intensity of which resemble that of the OC–H stretching vibration of aldehydes.[15] However, this functional group can be excluded because of the absence of a C=O vibration. Other bands of high intensity are found at 1306, 1254, and 850 cm^{-1} in the range of Si–O and Si–C stretching vibrations. Ab initio calculations of the vibrational spectra of a series of $C_4H_{10}SiO$ isomers carried out at the MP2/6-31G(d,p) level shed light on the identity of **7**. The calculated

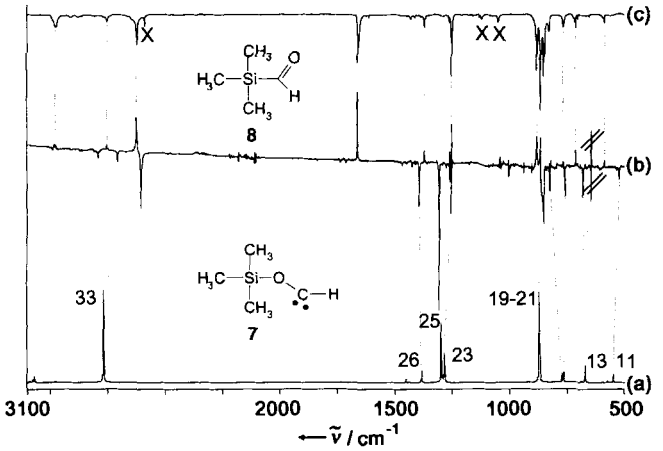

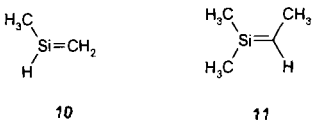

Fig. 1. a) IR spectrum of trimethylsiloxycarbene (7) from ab initio calculations at the MP2/6-31G(d,p) level. b) IR difference spectrum of the photoisomerization **7** → **8** (λ = 570 nm) at 10 K; bands of **7** (pointing downwards) disappear to be replaced by bands of **8** (pointing upwards). c) IR reference spectrum of **8** at 10 K. To match the experimental spectrum, the calculated spectrum was scaled with a factor of 0.95 and simulated with a Lorentz band form with a half-bandwidth of 2 cm^{-1}. Bands marked X are due to residual solvent.

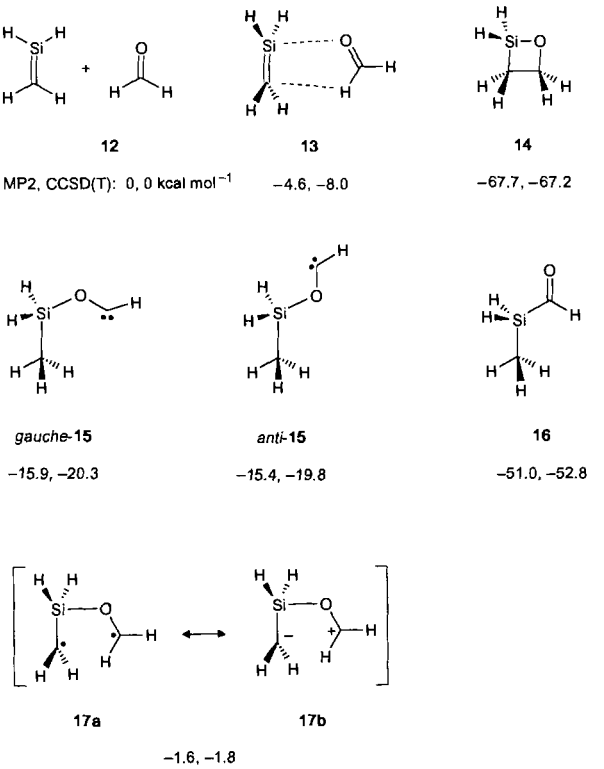
spectrum of trimethylsiloxycarbene was in very good agreement with that of **7** (Fig. 1), whereas no correlation was found for 2,2-dimethyl-1,2-oxasiletane (**9**).



The formation of siloxycarbenes as short-lived intermediates in the irradiation of silylcarbonyl compounds has frequently been postulated,[16, 17] but hitherto only been observed directly in one case by time-resolved spectroscopy.[18, 19] Under the conditions of matrix isolation (T < 40 K) **7** is thermally stable.

For comparison, 2-silapropene (**10**) and 2-methyl-2-sila-2-butene (**11**)[12, 13] were treated with formaldehyde under similar conditions. Whereas the silapropene reacted with formaldehyde analogously to **1**—although quantitatively and markedly faster at 35 K—no thermal reaction was observed with the silabutene. The reactivity of the silene towards formaldehyde therefore drops with increasing number of methyl substituents. Because of the large kinetic isotope effect, reaction of silapropene with [D_2]formaldehyde could not be measured (no reaction after 12 h at 35 K).

Results from CCSD(T)/6-31G(d,p)//MP2/6-31G(d,p) calculations for the system SiH_2CH_2 + CH_2O show that the thermal reaction to form carbene **15** takes place via the van der Waals complex **13** and the intermediate diradical or zwitterion **17** (Scheme 4). The van der Waals complex[20] resembles the complex between silanones and CH_2O,[8] but the bonding is considerably weaker than that in the latter complex (8 kcal mol^{-1}, Scheme 4). Intermediate **17** sits in an extremely shallow well (0.3 kcal mol^{-1} deep) on the energy hypersurface 6.2 kcal mol^{-1} above the van der Waals complex **13**, so that **17** effectively corresponds to a transition state, from which carbene **15** is formed by a proton shift.[21]

The transformation of complex **13** via **17** to carbene **15** also takes place at low temperature, as a result of the excess energy of 8 kcal mol^{-1} and slow dissipation of energy in the argon matrix. On the other hand, the remaining excess energy of the van der Waals complex **13** is insufficient to allow access to the transition state for formation of the oxasiletane **14**, which lies 7.8 kcal mol^{-1} above **13** and is formed by a 90° rotation of the

Scheme 4. Energies of some C_2OSiH_6 isomers, relative to the energy of **12**, calculated at the MP2/6-31G(d,p) and CCSD(T) levels.

CH_2O group in **17**. An energy difference of 1.6 kcal mol^{-1} in the respective barriers is therefore responsible for the fact that carbene **15** is formed rather than silaoxetane **14**.[22]

Carbene **15** can exist as C_1-symmetrical *gauche* or C_s-symmetrical *anti* conformer, although the former is more stable by 0.5 kcal mol^{-1}. The energy barrier for the rearrangement **15** → **16** is 4.7 kcal mol^{-1}; the reaction is exothermic by 33 kcal mol^{-1} and therefore irreversible. The results of the ab initio calculations are consistent with the experimental results and explain the formation of the carbene **15** in place of the anticipated oxasiletane **14**. Further experiments will show to what extent the new type of reaction between silenes and formaldehyde reported here is restricted to a matrix environment or whether it can also take place in solution.

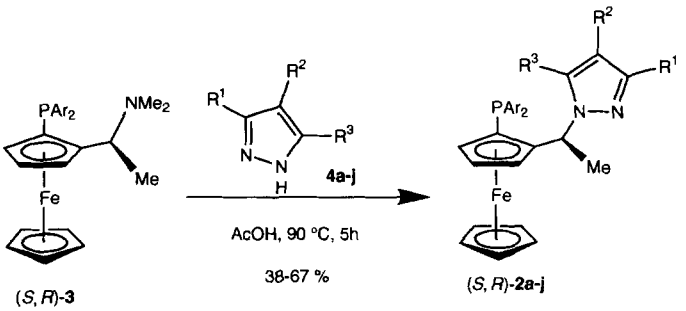
Strong Electronic Effects on Enantioselectivity in Rhodium-Catalyzed Hydroborations with Novel Pyrazole-Containing Ferrocenyl Ligands

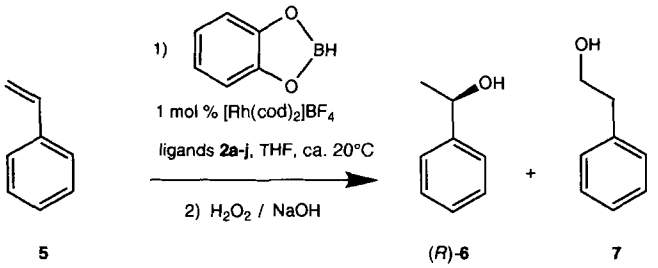
Anita Schnyder, Lukas Hintermann, and Antonio Togni*



We have recently shown that chiral bidentate ferrocenyl phosphanes of type **1**, which contain two sterically and electronically different ligating fragments, are able to ensure high enantioselectivities in a variety of transition-metal-catalyzed reactions.[1] Our two-step methodology for the synthesis of such ligands allows the incorporation of phosphano groups with virtually no limitations. This ligand system provides an opportunity for studying steric and electronic effects due to the chiral inducing agent on stereoselectivity.

(*S*,*R*)-**1**

We then extended our concept to P,N-ligands[2] of type **2**, incorporating a phosphane and a pyrazole, an unprecedented combination in asymmetric catalysis,[3] and now report their use in the Rh-catalyzed hydroboration of styrenes with catecholborane.[4] The most striking finding relates to the observation of large electronic effects on the enantioselectivity of this reaction.[5] Furthermore, the different electronic properties of the pyrazole and phosphane fragments exert opposite influences: high enantioselectivities are obtained when both the N-ligand is a good σ-*donor* and the P-ligand a good π-*acceptor* (vide infra).



The new ligands **2** were easily prepared in moderate yields starting from ferrocenyl amines of type **3**[6] and the corresponding pyrazoles **4** in glacial acetic acid (Scheme 1). The results of

the catalytic hydroboration experiments (Scheme 2) are summarized in Table 1. The reactions were conducted at room temperature in THF, with 1 mol% of the catalyst (formed in situ from $[Rh(1,5\text{-cod})_2]BF_4$ and 1.1 equiv of the ligand). Complete conversion of the substrate styrene was found to take place within

5 (*R*)-**6** **7**

3 to 5 h. Workup and product analysis were carried out as previously reported.[1a] Compared to some known systems,[4] our catalysts proved to be less regioselective and afforded relatively high amounts of the achiral linear alcohol. On the other hand, in some cases the enantioselectivity for the desired branched product **6** reaches very high and unprecedented values (up to 98.0% *ee*). Thus, the ligand containing the 3,5-dimethylpyrazolyl fragment (**2a**) affords an *ee* of 95.1% (Table 1, entry 1). Similar values were obtained with ligands **2c** and **2f**, which contain the extra substituent 4-methyl and 4-bromo, respectively (entries 3 and 6). Increasing the size of the groups in positions 3 and 5 from methyl to isopropyl lead to a lower enantioselectivity (91.6%, entry 5); the *steric* properties of those substituents are therefore crucial.

Replacement of the methyl groups by the strong σ-accepting trifluoromethyl fragments at positions 3 and 5 of the pyrazole should engender an *electronic* modification of the ligand, whilst only marginally altering its steric properties.[7] Thus ligand **2b** led to a drastically different stereochemical outcome when used under the exact same conditions. Whereas the regioselectivity dropped by only a few percent (from 66:34 to 61:39 branched to linear), the enantioselectivity dropped to 33.4% *ee* (from

[a] Not optimized.

95.1% *ee*, entry 2). This corresponds to a difference of more than 1.5 kcal mol^{-1} in $\Delta\Delta G^{\neq}$ for the two diastereomorphous transition states in the reactions with the two different ligands. The 3-trifluoromethyl-5-methyl derivative **2d**, for which it is reasonable to assume electron-donating properties intermediate between those of **2a** and **2b**, also gave an intermediate *ee* of 43.8% (entry 4). A similar comment applies to the result obtained with ligand **2h** (3-phenyl-5-methyl derivative, 79.6% *ee*, entry 8). However, the comparison is not completely justified solely in *electronic* terms, because there is also an important *steric* difference between **2h** and **2a**,**b**,**d**.

Since the 3,5-dimethylpyrazolyl fragment was assumed to be the best suited for the reaction under study both from an electronic and a steric point of view, the electronic properties of the phosphane fragment of this derivative were modified. The introduction of *para*-substituents on the phenyl rings is easily achieved.[6b] Again a significant increase of enantioselectivity is obtained with ligand **2i**, which bears the electron-accepting trifluoromethyl group. The obtained value of 98% *ee* (entry 9) is the highest so far reported for this particular reaction and indicates a gain of about 0.5 kcal mol^{-1} in $\Delta\Delta G^{\neq}$ in going from **2a** to **2i**. When the electron-donating substituent OMe is used instead (ligand **2j**), a loss of enantioselectivity is observed (90.0% *ee*, entry 10). This is comparable, in terms of $\Delta\Delta G^{\neq}$, to the gain mentioned above.[8]

The ligands affording lower selectivities contain pyrazolyl fragments that are relatively electron-poor. Therefore one could argue that the observed low enantioselectivity yielded by, for example, **2b** could be due to partial dissociation of this ligand from rhodium during catalysis. Such dissociation to yield a monodentate phosphane ligand would reduce the selectivity of the catalyst. We addressed the problem of *thermodynamic* stability of the Rh complexes containing the ligands **2a**,**b**,**d**,**g**, and **h** by simple NMR competition experiments. Mixing equivalent amounts of a) $[Rh(1,5\text{-cod})_2]BF_4$ and two different ligands of type **2**, or b) of the complex [Rh(1,5-cod)(ligand 1)]BF_4 and ligand 2, and analyzing the equilibrium mixture by ^1H and ^{31}P NMR allowed us to establish the following relative stability series of the species [Rh(1,5-cod)(**2**)]BF_4, depending on the ligand: **2g** ≈ **2a** > **2h** > **2d** > **2b**. According to these experiments the difference in stability constant for the complexes containing **2g** and **2b** (the most and the least stable, respectively) is at least four orders of magnitude.[9] Thus, stability partially correlates with the observed enantioselectivity. However, we were not able to observe partial dissociation of the pyrazolyl moiety, even upon addition of less than one equivalent of a monodentate phosphane (PEt_3 or PPh_3) to the corresponding complex. The monodentate ligand was incorporated into the complex $[Rh(1,5\text{-cod})(PR_3)_2]BF_4$ quantitatively, thus indicating that under thermodynamic control the ferrocenyl ligands either dissociated completely or not at all. Furthermore, a large excess of the substrate of the catalytic reaction, styrene, is not able to induce any observable dissociation of any of the pyrazolyl ligands under study. From these experiments we conclude that dissociation of the ligands from the catalytically active species most likely is not taking place and that the effects on enantioselectivity we report are indeed predominantly electronic in nature.[10]

Since the effects we observed are ultimately an expression of a subtle change in the electronic structure of the transition metal complexes involved in the catalytic reaction, and hence of their reactivity, they elude any treatment according to current views on electronic effects in organic chemistry.[11] The observed phenomena can be tentatively explained as follows, taking into account a comparison between ligands **2a** and **2b** explicitly: In the two ligands the phosphane group is both a good σ-donor and a moderate π-acceptor. The pyrazolyl nitrogen in **2a** will be a very good σ-donor with almost no π-accepting properties, whereas in **2b** its σ-donor capability will be reduced, in favor of a moderate π-accepting propensity, by virtue of the aromatic system in which it is imbedded. In this respect it will behave similarly to an electron-poor phosphane. Thus, because of the pure σ-character of the Rh–N bond in the complex containing ligand **2a**, this ligand will induce a higher "*electronic asymmetry*" at the metal center than **2b**, which will be reflected in the enhanced enantioselectivity observed. This electronic asymmetry seems to be maximized in ligand **2i**, in terms of further enhancing the π-acceptor qualities of the phosphane, relative to the situation in **2a**. In order to turn these conjectures into a more sound argument, detailed mechanistic and structural studies are required. These are currently in progress and will be reported in due course.

Experimental Procedure

A typical preparation for the pyrazolyl ligands, that of 1-{(*S*)-1-[(*R*)-(diphenylphosphano)ferrocenyl]ethyl}-3,5-di-methylpyrazole (**2a**), is described: A solution of (*S*)-(*R*)-**3** (2.5 g, 5.6 mmol) and 3,5-dimethylpyrazole (0.65 g, 6.8 mmol, 1.2 equiv) in glacial acetic acid (10 mL) was stirred at 90 °C for 3 h. The red reaction mixture was quenched with saturated, aqueous $NaHCO_3$ and extracted with hexane. The combined organic layers were washed with saturated, aqueous NaCl and dried over $MgSO_4$. Removal of the solvent and recrystallization from hexane afforded **2a** as yellow crystals (1.52 g, 55%). m.p. 127 °C (decomp.); $[\alpha]_D^{20} = 329$ ($c = 0.42$, $CHCl_3$); ^1H NMR ($CDCl_3$, 250 MHz): $\delta = 6.68$–7.53 (m, 10H), 5.58 (dq, 2 Hz, 1H), 5.06 (s, 1H), 4.79–4.81 (m, 1H), 4.35–4.37 (m, 1H), 4.05 (s, 5H), 3.72–3.74 (m, 1H), 2.13 (s, 3H), 1.95 (s, 3H), 1.70 (d, 7 Hz, 3H); ^{31}P NMR ($CDCl_3$, 101 MHz): $\delta = -24.1$ (s, PPh_2); elemental analysis: calcd for $C_{29}H_{29}FeN_2P$: C, 70.72; H, 5.94; N, 5.69; found: C, 70.74; H, 6.01; N, 5.59. The ligands **2b**–**j** were prepared analogously.

[6] a) T. Hayashi, T. Mise, M. Fukushima, M. Kagotani, N. Nagashima, Y. Hamada, A. Matsumoto, S. Kawakami, M. Konishi, K. Yamamoto, M. Kumada, *Bull. Chem. Soc. Jpn.* **1980**, *53*, 1138–1151. b) T. Hayashi, A. Yamazaki, *J. Organomet. Chem.* **1991**, *413*, 295-302.

[7] For a discussion of the steric bulk of aliphatic groups in terms of cone angles, see a) D. Datta, D. Majumdar, *J. Phys. Org. Chem.* **1991**, *4*, 611–617. b) D. White, N. J. Coville, *Adv. Organomet. Chem.* **1994**, *36*, 95–158. The cone angle of a methyl group is 112°, whereas that of the trifluoromethyl substituent is 135°, identical to the value for isopropyl.

[8] Substrate electronic effects were also observed (see also [4]). Thus, compared to styrene and in the presence of ligand **2a**, *para*-chlorostyrene and *para*-methoxystyrene both gave lower *ee*'s (93.5 and 79.2% *ee*, respectively). With ligand **2b** the same two substrates afforded 13 and 77.6% *ee*, compared to 33.4% *ee* for styrene.

[9] Assuming a conservative NMR detection limit of 100:1 for two different compounds, such a difference in stability constant between the complexes containing **2g** and **2b** is inferred by comparing different pairs of ligands. These stability measurements, carried out on catalyst precursors, do not necessarily reflect the stabilities of the actual complexes involved in the catalytic cycle, but may be reasonably taken as an indication of the trend.

[10] However, the existence of a catalytically active complex containing the ferrocenyl ligand acting in a monodentate fashion under kinetic control cannot be excluded by these experiments.

What's in a Name

Instrumental Methods for Determining Elements. By *L. R. Taylor, R. B. Papp* and *B. D. Pollard.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1994. 322 pp., hardcover DM 128.00, $ 51.50.—ISBN 3-527-28096-0/1-56081-038-6

This book is intended for the analytical chemist who has to choose the most suitable method for a given problem. It treats in detail all the most important modern instrumental methods of elemental analysis: atomic absorption spectroscopy (AAS), atomic emission spectroscopy (AES), voltammetry, potentiometry, chromatography, X-ray fluorescence, and combustion methods. For each method there is a brief description of the basic physical principle and the construction of the instrument. This information is intended only as a short introduction, and not as a substitute for a thorough study of the fundamentals of the method concerned. References to detailed specialist literature in the form of monographs or original papers are provided.

The authors then compare the various methods with regard to their practical application, placing special emphasis on the needs of the user who must decide on a particular analytical method for the problem in hand. They consider questions about the sample itself, including the nature of the matrix, sample size, and sample preparation, economic factors such as the capital and running costs of the instrument, its complexity, sample throughput rate, and possibilities for automation. A clear distinction is made between, on the one hand, purely instrumental factors such as limits of detection, sensitivity, operating range, precision, and selectivity, and on the other hand element-related matters such as capabilities for multielement detection, for quantitative analysis, and for distinguishing between different species of the same element. The authors also discuss questions such as how widespread is the use of the instruments concerned (as this affects the availability of information about applications), and whether the method can be used for on-line process analysis. Each chapter is rounded off by giving examples (in the form of tables) of typical applications of the method, and information about the main instrument manufacturers, which is useful for requesting promotional and technical information. As well as the methods mentioned above, the authors also briefly discuss capillary electrophoresis, flow injection analysis, mass-spectrometric techniques, neutron activation analysis, and spectrophotometry.

The detailed discussions of the various methods are helpful to the reader both in choosing suitable analytical methods for specific problems and, if the question arises, in purchasing a new analytical instrument. In this respect the book differs from conventional texts in this field, which are usually confined to treating in detail the theoretical background and the areas of application of each analytical method. *Instrumental Methods for Determining Elements* is therefore a valuable additional resource for the practical analyst.

Namen- und Schlagwortreaktionen der Organischen Chemie. By *T. Laue* and *A. Plagens.* Teubner, Stuttgart, 1994. 338 pp., paperback DM 36.80.—ISBN 3-519-03526-X

Organic Syntheses Based on Name Reactions and Unnamed Reactions. By *A. Hassner* and *C. Stumer.* Pergamon, Oxford, 1994. 452 pp., paperback £ 28.00.—ISBN 0-08-040279-8

The Noyori homogeneous catalytic reaction for asymmetric hydrogenation will certainly mean something to you. But are you also familiar with the Perkow synthesis of vinyl phosphates? What do you know about the Neber rearrangement? Would you like to be able to quickly find out something about the Stork enamine reaction? The two books reviewed here can help with such questions, rapidly and at little cost. For the average reader it is still just as important as ever to have rapid access to information without using CD-ROM or on-line services. Although summaries of important reactions already exist—for example, in the relevant section of the Merck Index—these two books by Hassner and Stumer and by Laue and Plagens bring together information on important reactions of organic chemistry in a very handy form that is convenient to use. Although they are very similar in layout, some clear differences emerge. The book by Laue and Plagens, in the Teubner series of student textbooks, has a striking external appearance with a somewhat more careful standard of production, the typeface and the formulas being well matched in size and pleasingly arranged. On the other hand the book by Hassner and Stumer, in the Tetrahedron Organic Chemistry Series, is a compilation of pages produced directly from the computer, and one is struck by the large areas of empty space.

The Laue and Plagens book is intended for students of chemistry, pharmacy, and related disciplines, and contains clear descriptions, in alphabetical order, of some 130 important reactions of organic chemistry. These include both important name reactions and others ("Schlagwortreaktionen", key-word reactions) that are known by descriptive names rather than being linked to the name of a scientist, e.g. the di-π-methane rearrangement. As well as classical examples such as the Finkelstein and haloform reactions, which are to be found in any traditional textbook of organic chemistry, the compilation also includes many of more recent origin, such as the Pauson–Khand reaction, the Bergman cyclization, and the Dötz reaction. In each case the title is followed by a one-sentence description of the reaction and a generalized formula scheme. Next there is a brief discussion in which the main emphasis is on the reaction mechanism. Other relevant information is also given; for example, in

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995* *0570-0833/95/0808-0935 $ 10.00+.25/0*

describing the Cope rearrangement it is pointed out that it should not be confused with the Cope elimination reaction. The cross-references to other reactions described in this book are very helpful. The book also contains a short list of selected literature references, giving not only the first publication in which each reaction is described, but also important review articles enabling the reader to find out about a reaction of interest in greater depth. It is pleasing that the authors appear to have made an effort to include some quite recent citations extending into the 1990s. Brief name and subject indexes are provided at the end of the book.

The book by Hassner and Stumer covers about 450 reactions, including some lesser known ones, again arranged alphabetically. In the preface the authors rightly point out that for reasons of space alone it is not possible to include every reaction, and that some whose mechanisms are likely to be well known to every chemist have been purposely omitted. Nevertheless, in view of the fact that many reactions of a highly specialized nature have been included, it is surprising to find no mention of the mechanistically important and highly topical Bergman cyclization. In many cases several closely similar reactions have been included. Each reaction is first described in a single sentence, which is then followed by a formula scheme for a specific example of the reaction, giving the reaction conditions and in many cases also the yield. A few relevant literature references are listed, including the first paper describing the reaction and at least one review article. Lastly the experimental details for carrying out the example reaction are given. At the end of the book are indexes according to names, reagents, and reaction types, as well as a fold-out "Functional Group Transformations Index" similar to those provided in the *Compendium of Organic Synthetic Methods*.

What are the main differences, and which book should be recommended? The book by Laue and Plagens is certainly aimed more at the needs of students, and from that standpoint the inclusion of brief summaries of the mechanistic background is an important advantage. By cleverly limiting the coverage to about 130 reactions the authors have allowed themselves sufficient space to do justice to the didactic quality expected from a book intended for students. The book by Hassner and Stumer is clearly intended rather for the research chemist in academia or industry. For this readership, although it may still be important to give mechanistic information, the main need seems to be for rapid access to typical experimental conditions for the reaction of interest. Whereas Laue and Plagens can best serve to complete the reader's knowledge, Hassner and Stumer on the other hand is more in the nature of a resource for solving preparative problems. For the latter purpose one is not necessarily looking for a named reaction, but it is a fact that many of the most important reactions carry the names of their originators. What is meant in the title by "Unnamed Reactions"? There are none of these in the book—by definition they cannot even appear in the "Names Index". The authors have given every reaction (at least) one name in its heading. Probably the purpose of this part of the book's title is just to attract the attention of potential readers.

Both books are well suited to their different purposes and can be recommended—this reviewer is glad to have them both. However, a word of caution is in order. These books and others like them are eminently suitable for quickly learning about a large number of reactions of organic chemistry, and many readers will certainly find them very useful, for example when preparing for examinations. Nevertheless, both the readers and their teachers must always bear in mind that knowing about a reaction is no substitute for understanding it. These books are not intended as alternatives to more detailed textbooks, but are for quick reference, and are best treated as an extension of the textbooks to be used judiciously. No well-constructed examination can be limited to merely asking about named reactions, and equally the memorizing of a "data bank" of reactions is not sufficient to enable one to succeed as a scientist.

Chemical Generation and Reception of Radio- and Microwaves. By *A. L. Buchachenko* and *E. L. Frankevitch*. VCH Verlagsgesellschaft, Weinheim, 1994. 180 pp., hardcover DM 135.00.—ISBN 3-527-89630-9.

"Spin chemistry", i.e. the investigation and utilization of magnetic field effects and spin effects in chemical reactions, enjoys increasing popularity. The authors of the present book like to distinguish between two generations of spin chemistry. The first was concerned with the influence of static magnetic fields, typical examples being magnetic field effects (MFE) or chemically induced dynamic nuclear and electron spin polarizations (CIDNP and CIDEP). In this book the emphasis is on spin chemistry of the second generation, which comprises the interactions with additional oscillating fields. These cause radio-induced magnetic isotope effects (RIMIE), stimulated nuclear polarization (SNP), and microwave-stimulated quantum beats, and are exploited in reaction yield detected magnetic resonance (RYDMR). In addition, the authors deal with the reversal of such processes, namely the emission of coherent microwave radiation from chemically reacting systems.

In the first chapter, "Magnetic Scenario of Chemical Reaction", numerous examples are given to drive home the principle of spin conservation during chemical transformations and thus spin selectivity of chemical reactions. The second chapter is a discussion of the radical pair mechanism, despite its misleading title, "Magnetic Interactions in Chemical Reactions". The title of the third chapter, "Magnetic Effects in Chemical Reactions", also slightly misrepresents its actual content: except for a few introductory sentences, it only deals with spin chemistry of the first generation. "Chemically Induced Radio-Frequency Emission" is only touched upon in the short (15 pp.) fourth chapter, although from the title of the book one would have expected this to be a central topic. Four chapters on RYDMR ("Reaction Yield Detected Magnetic Resonance—RYDMR", "RYDMR in Solids", "RYDMR in Liquid Solutions", and "RYDMR in Photosynthetic Systems") are followed by two others ("Radio-Induced Magnetic Isotope Effect" and "Microwave-Stimulated Nuclear Polarization") about spin chemistry of the second generation. The authors focus on examples and applications rather than on detailed quantitative explanations of the theory of these effects. In Chapter 11 ("Coherence in Spin Dynamics and Chemical Reactivity") quantum beats are discussed. At the end of the volume we find a very short chapter (3 pp.) on "The Action of Electromagnetic Waves on Biological Processes".

The most striking impression one receives when going through the book for the first time is that it is written in alarmingly bad English. A few examples, quoted verbatim, may illustrate this; there are numerous others of this kind. There are frequent misspellings of proper names—"Plank constant" (p. 3), "Schrodinger equation" (p. 18), "Gann-diode" instead of Gunn-diode (p. 76), "Abraham" instead of Abragam (consistently on p. 125 and p. 127), and chemical names—"vinilene" (p. 100), "acetonitryl" (p. 125), "dinucleatide" (p. 130).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0808-0936 $ 10.00+.25/0

Often though, not only the laws of the English language but also those of logic are violated, and the reader is slowed down trying to figure out the likely meaning: "The term $(1-\Lambda)F$ takes into account the unfavorable chance that the pair, being transformed from triplet to singlet and being ready to react, avoids the reactions since $\Lambda < 1$" (p. 22); "If in the course of the reaction some products may be produced that have the same spin as that of the pair, then the reaction proceeds" (p. 62); "The kinetic scheme gives a qualitatively good picture of a spectrum of resonant variations in the rate constants away from crossing of intermediate pair levels" (p. 113); "The spin of ion radical D^+ at the moment of its recombination was conditioned by its evolution as the spin of the hole while it was in a state M^+ that was a precursor of D^+" (p. 120). The third of the foregoing examples is utterly incomprehensible (at least to the present reviewer), both with and without its context.

At times, the formulations verge on the absurd:—page 11: "Radical pair is a dynamic system from which the radicals can diffuse apart, traveling randomly in space and time, and then return and reencounter"—page 126: "A small internal size of a micelle where radicals can diffuse makes us believe that the prominent part of their lifetime will be spent suffering on exchange interaction".

Looking more closely into the book, one detects a good many errors in figures and formulas. Again, some examples: In Figures 1.1, 2.3, and 5.4 (bottom), vector representations of the triplet states $|T_{+1}\rangle$ and $|T_{-1}\rangle$ are given, in which the phase difference between the two vectors is 180°. On the other hand, in the vector models of Figures 2.2 and 5.4 (top) there is a phase difference of 0°. What is the reader to think if the same state is depicted in two ways that are obviously quite different? But in addition, even within the limitations of vector models, *both* these representations are wrong. In the first, the resultant spin coincides with the z-axis, which is a violation of the uncertainty principle. In the second, combination of two vectors representing spin-1/2 particles would give a vector of wrong total length ($\sqrt{3}\hbar$ instead of $\sqrt{2}\hbar$). The correct way to draw the diagrams for $|T_{+1}\rangle$ and $|T_{-1}\rangle$ is with a 90° phase difference.

For the magnetic moment of the nucleus, we find $\mu_n = -g_n(\beta_n/\hbar)\boldsymbol{J}$, i.e. the wrong sign (p. 4). The same mistake appears in the expression for the z-component of μ_n. On page 13, the dependence of the sign of the electron Zeeman energies on the electron spin state is ignored. In the expression on page 42 for the ratio of the equilibrium populations of adjacent nuclear energy levels, the denominator of the Boltzmann term should have kT instead of $2kT$. Anyone working in the field of magnetic resonance will probably spot these and similar errors at once. However, the book aims at the non-specialist, for instance at chemical physicists and physical organic chemists, as we read on its cover.

In the equation for the $S-T_0$-mixing matrix element (Eq. 2.12 on p. 18), the sign of the second term is wrong. The third term of the expression for the spin-independent probability of geminate recombination (Eq. 2.27 on p. 20) should have p^2 instead of p. Et cetera; it is to be doubted that a reader trying to get acquainted with spin chemistry will detect such errors at a glance.

The later parts of the book contain more than 50 equations, many of them very specialized, and the derivations of most of them are not given. The above examples do not inspire great confidence in their correctness.

Analyzing the references, some 200 in number, and eliminating duplicate entries and conference proceedings that are not generally available, the reviewer found only about 30 publications that were concerned with the main subjects of the book and had appeared after 1987. One cannot help noticing that the most recent reference pertaining to "Chemically Induced Radio-Frequency Emission" dates back to 1983, and that this was itself a review, written by one of the authors of the present book. Obviously, nothing of importance has happened in the latter field during the last ten years, so why review it anew? The cover text "...first critical overview in a decade..." seems almost ironical under these circumstances.

Finally, one puts aside the book with the impression that the efforts of the two authors have not always been well coordinated and that their treatment of the subject matter is somewhat imbalanced. For instance, vector models and intersystem crossing in radical pairs are discussed at the beginning of Chapter 2 and are explained in just as much detail a second time in Chapter 5. Also, many formulas appear in duplicate (Eqs. 2.4 and 2.11, 2.5 and 2.12, 2.6 and 2.34, 2.7 and 2.35, etc.); the contents of Figures 1.1, 2.2 (top), and 5.4(a) are identical, apart from the inconsistencies mentioned above; the same holds for Figures 2.3 and 5.4(b); and so on. Basic concepts which should be known to the group of scientists the book is intended for, such as singlet and triplet states and spin conservation in chemical reactions, are treated at length (three pages of examples to illustrate the latter principle) and repeated frequently. In contrast, throughout the book practically all derivations and details of the calculations are skipped, and there are abrupt jumps to rather specialized results. Is it not one of the very purposes of a monograph to *bridge* the gaps between the fundamentals and the end results?

In summary, this book is probably of little value for a "chemical physicist, physical organic chemist, material scientist, radio- or biophysicist" (press release) in general. Maybe the expert in the field of spin chemistry could profit from it in some points.

Combinatorial Synthesis and Multidimensional NMR Spectroscopy: An Approach to Understanding Protein–Ligand Interactions

James K. Chen and Stuart L. Schreiber*

Combinatorial chemistry is a laboratory emulation of natural recombination and selection processes. Strategies in this developing discipline involve the generation of diverse, molecular libraries through combinatorial synthesis and the selection of compounds that possess a desired property. Such approaches can facilitate the identification of ligands that bind to biological receptors, promoting our chemical understanding of cellular processes. This article illustrates that the coupling of combinatorial synthesis, multidimensional NMR spectroscopy, and biochemical methods has enhanced our understanding of a protein receptor used commonly in signal transduction, the Src Homology 3 (SH3) domain. This novel approach to studying molecular recognition has revealed a set of rules that govern SH3–ligand interactions, allowing models of receptor–ligand complexes to be constructed with only a knowledge of the polypeptide sequences. Combining combinatorial synthesis with structural methods provides a powerful new approach to understanding how proteins bind their ligands in general.

Keywords: combinatorial chemistry · molecular recognition · NMR spectroscopy · proteins

1. Introduction

Chemistry has profoundly influenced the development of modern biology. Since the pioneering work of Emil Fischer, chemists have explored the molecular realm of life and reconstructed its basic elements. Biological cofactors, metabolites, and hormones have been characterized and resynthesized using the tools of organic chemistry. Similarly, X-ray crystallography and NMR spectroscopy have been used to elucidate the primary macromolecules of nature: proteins, DNA, and RNA. These advances have transformed our understanding of biology, allowing cellular processes to be analyzed at the molecular level.

The complementary impact that biology has had on chemistry, however, should not be overlooked. Many chemical strategies have been inspired and guided by biological phenomena. This reciprocal relationship between chemistry and biology is exemplified by recent advances in the areas of ligand discovery and molecular recognition. Traditional approaches in these disciplines have utilized the powerful tools of computer modeling and organic synthesis, but have been limited by our incomplete understanding of molecular interactions and the inefficiency of evaluating individual lead compounds. As a result, new strategies for ligand discovery that emulate biological processes have emerged. These approaches draw from the genetic recombination and selection mechanisms that yield specific receptor–ligand interactions in nature. Similar mechanisms regulate the humoral immune response, in which antigen-binding receptors are selected from large combinatorial pools of antibodies. Guided by these biological models, chemists have developed an alternative strategy for ligand discovery: molecular libraries generated by combinatorial synthesis.

Like its biological counterpart, combinatorial chemistry relies on the efficient synthesis of large, diverse libraries of compounds and the facile selection of molecules that have a desired property. Its success as a strategy for ligand discovery also requires the unambiguous characterization of these molecules, which often are present in minute quantities. Significant progress has been made on both fronts, especially in the past five years. Many initial applications of combinatorial synthesis have focused on the discovery of therapeutic agents, paralleling the development of traditional organic synthesis. Medicinally important targets such as the human platelet fibrinogen receptor have been studied with synthetic libraries, providing chemical leads in drug discovery efforts. Indeed, one important objective in combinatorial chemistry is the development of libraries that contain bioavailable compounds and their application in medical research.

Especially when coupled to neighboring disciplines, combinatorial synthesis also has enormous potential to elucidate fundamental problems in basic research. In particular, combinatorial chemistry can advance our understanding of cellular processes, completing the synergistic cycle of chemistry and biology. This review highlights the recent application of combinatorial syn-

thesis to the study of Src (pronounced "sark") Homology 3 (SH3) domains, a family of protein modules involved in intracellular signal transduction pathways. By combining this technique with multidimensional NMR spectroscopy and site-directed mutagenesis, it has provided insights into the molecular recognition of SH3 domains, revealing a unique biological mechanism for protein association. These advances have culminated in a detailed understanding of SH3–ligand interactions involving two distinct binding modes and allow for the straightforward molecular modeling of SH3–ligand complexes using only a knowledge of polypeptide sequences.

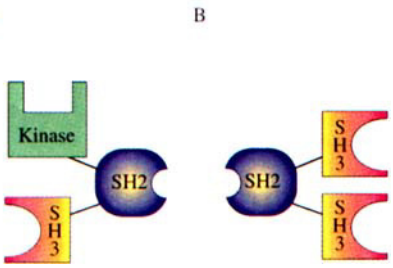

Fig. 1. Schematic representation of two classes of SH3-containing proteins: A) proteins with catalytic domains (e.g. a kinase), B) macromolecular adaptors for protein association.

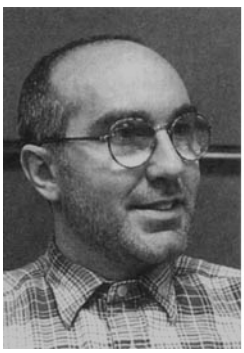
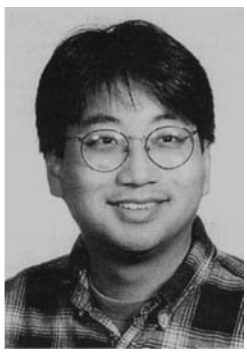
2. Background



2.1. Biochemical Studies

SH3 domains are small receptor modules of approximately 60 amino acids.[1, 2] Initially observed in the Src family of tyrosine kinases, these conserved domains have been found in a variety of proteins that mediate signal transduction, the biological mechanism by which extracellular molecules influence intracellular events. SH3-containing signaling molecules are structurally and functionally diverse, ranging from phospholipase C-γ (PLC-γ) to the p85 subunit of phosphatidylinositol 3-kinase (PI3K). SH3 domains have also been identified in cytoskeletal proteins and are often accompanied by receptor modules called SH2 domains, which recognize tyrosine-phosphorylated proteins in a sequence-specific manner (Fig. 1). These observations have suggested that SH3 domains mediate protein–protein interactions in signal transduction pathways and cytoskeletal structures (Fig. 2). Biochemical studies have subsequently implicated SH3 domains in subcellular localization,[3] enzymatic regulation,[4] substrate recognition,[5] and the regulation of guanosine triphosphate (GTP) binding proteins.[6]



Our investigations have focused on understanding the molecular recognition of SH3 domains, using the cellular Src (c-Src) and PI3K SH3 receptors as model systems. Src is a nonreceptor tyrosine kinase with one SH2 and one SH3 domain, both of which are essential for normal cellular signaling.[7] The mutation or deletion of either domain activates the catalytic and oncogenic potential of Src and abrogates the association of at least one kinase substrate, p110.[4a–c, e, 8] PI3K is a heterodimeric complex composed of a 110 kDa catalytic subunit that contains a lipid (phosphatidyl inositol) kinase domain and an 85 kDa regulatory subunit that contains one SH3 domain, two SH2 domains, and a region with homology to Rho/Rac ("row" and "rack") GTPase-activating proteins (GAPs).[9] The SH2 domains of PI3K mediate its interaction with the phosphorylated cytoplasmic tails of activated growth factor receptors,[9a–c, 10] whereas the cellular function of the SH3 domain is unknown. Like their parent proteins, the SH3 domains of Src and PI3K are structurally diverse, sharing only 21% sequence identity.[2c] The two protein modules contain highly dissimilar regions, including a 15 amino acid insert in PI3K p85 that is absent in the SH3 domain of Src. By studying these two structurally unique SH3 domains, we hoped to elucidate the general principles of SH3–ligand interactions as well as the origins of ligand specificity.

The first insights into the molecular recognition of SH3 domains were provided by Baltimore et al. The SH3-binding proteins 3BP1 and 3BP2 were identified by screening a cDNA expression library, using the Abl ("able") SH3 domain fused to glutathione *S*-transferase (GST) as a probe.[11, 12] Comparative searches of protein sequence data bases revealed that 3BP1 shares homology with the GTPase-activating protein GAP-Rho

Stuart L. Schreiber was raised and educated in Virginia. He obtained a B. A. in chemistry in 1977 at the University of Virginia, and earned his Ph.D. at Harvard University under the direction of R. B. Woodward and Y. Kishi. He is currently an Investigator at the Howard Hughes Medical Institute and a Professor at Harvard University, where he is a Member of the Chemistry Department and an Associate Member of the Department of Molecular and Cellular Biology. His research integrates several disciplines, including synthetic organic chemistry, protein and structural biochemistry, and molecular and cellular biology. His research group has been using chemical methods to understand and control signaling pathways.

S. L. Schreiber

J. K. Chen

James K. Chen was born in Rolla, Missouri in 1969. He received his A. B. degree in 1991 from Harvard University. He is currently a graduate student in Professor Schreiber's research group at Harvard, pursuing the chemistry and biology of immunosuppression, the molecular recognition of SH3 domains, and the development of nonpeptidic combinatorial libraries.

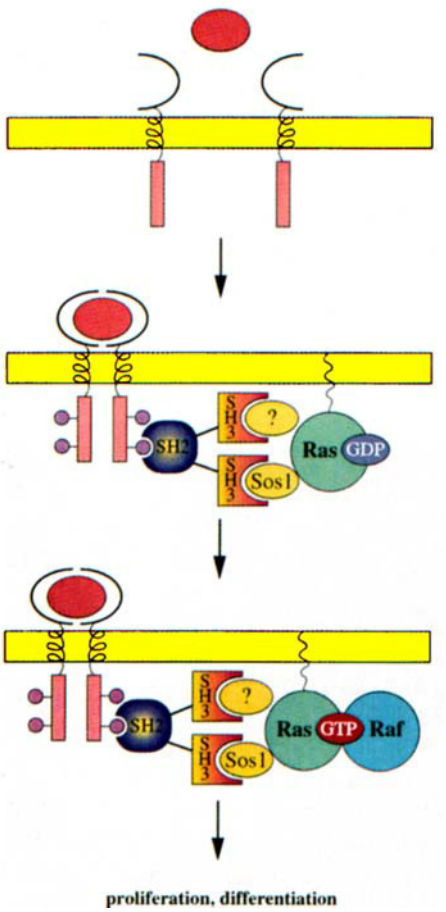


Fig. 2. Schematic representation of the Grb2-mediated activation of Ras, a prototypical signaling cascade involving SH3-containing proteins. In quiescent cells the adaptor protein Grb2, which comprises one SH2 and two SH3 domains, is complexed to the guanine nucleotide exchange factor Sos1 through one or both of its SH3 domains. This complex is recruited to the cellular membrane following stimulation by a growth factor (red) and activates Ras. Purple circles on the activated receptor represent phosphorylated tyrosine residues which are potential docking sites for SH2 domains.

and that 3BP2 contains an SH2 domain. The ability of both 3BP1 and 3BP2 to interact selectively with the Abl SH3 domain was further demonstrated by filter binding assays of GST-3BP1, GST-3BP2-40 (a GST fusion protein containing a 40 amino acid fragment of 3BP2), and several biotinylated GST-SH3 fusion proteins. Colorimetric detection of the 3BP1- and 3BP2-SH3 complexes using streptavidin alkaline phosphatase yielded similar intensities for the SH3 domains of Abl, Src, and Grb2 ("grab-two"), suggesting that they have comparable affinities for the SH3-binding proteins. In contrast, the neural Src, Nck ("nick"), and Crk ("crack") SH3 domains produced much weaker signals. Related experiments also localized the SH3-binding sites of 3BP1 and 3BP2 to the sequences APTMPPPLPP (3BP1-10) and PPAYPPPPVP (3BP2-10), respectively. The proline-rich character of these sequences was intriguing but provided few clues about the molecular origins of SH3–ligand interactions, whereas the absence of conserved non-proline residues in these sequences seemingly contradicted the specificity of 3BP1 and 3BP2. Mutational analysis of 3BP1-10 revealed that only Pro2, Pro7, and Pro10 are essential for Abl SH3 binding, suggesting a PXXXXPXXP consensus motif for SH3 ligands. It was proposed, however, that non-proline residues are still important for SH3–ligand interactions since the Abl SH3 domain cannot bind to a poly-L-proline peptide like Pro_{10}.[12]

This mosaic understanding of SH3–ligand interactions has been gradually clarified in the past two years. In collaboration with George Whitesides and co-workers, we carried out subsequent investigations of 3BP1-10 using affinity capillary electrophoresis,[13] a technique that can quantitatively evaluate receptor–ligand interactions in solution. These studies demonstrated that although the substitution of Pro2 with alanine (P2A) and the P7A and P10A mutations significantly diminish the affinity of the peptide for the Abl SH3 domain, they have little effect on its interactions with the SH3 domain of Src. Moreover, a VPPQ sequence that is C-terminal to 3BP1-10 was found to be critical for Src SH3 binding. These results indicated that 3BP1 has at least two distinct SH3-binding sites, raising the possibility that the PXXXXPXXP motif of 3BP1 and 3BP2 might not be universal for all SH3 ligands. The differential binding of the Abl and Src SH3 domains to 3BP1 was also consistent with the hypothesis that non-proline residues are important determinants of SH3 recognition. These issues were addressed, in part, by the identification of other SH3-binding proteins by affinity chromatography. For example, the motor protein dynamin was isolated from cellular extracts by using affinity columns containing immobilized GST-PI3K SH3 fusion protein[2d, 4d] and the cytoskeletal protein paxillin was similarly extracted with immobilized GST-Src SH3.[14] Both SH3-binding proteins contain proline-rich regions, confirming the general preference of SH3 domains for these motifs. Sequences from these and other reported SH3 ligands, however, failed to elaborate the optimal number of proline residues in SH3-binding motifs or their relative spacing. Analysis of these regions is complicated by the plurality of proline residues, many of which are ostensibly unimportant for SH3 binding. The repetitive, proline-rich nature of these sequences also indicated that these SH3-binding motifs might interact with multiple SH3 domains or contain two or more overlapping binding sites. Accordingly, it has become increasingly apparent that many reported SH3-binding proteins can bind to several different SH3 domains in vitro. Dynamin itself has several overlapping SH3-binding motifs, and at least one of these sites can interact with the SH3 domains of PI3K, PLC-γ, and Grb2.[4d]

The physiological relevance of these particular SH3–ligand associations, therefore, is uncertain. Although they can occur in vitro, several of them involve proline-rich ligands that have low specificities and affinities for their putative SH3 receptors. One SH3-mediated interaction, however, has been shown with certainty to be a component of intracellular signaling pathways. Investigations in several laboratories have elucidated the molecular targets of Grb2, a cytoplasmic protein containing one SH2 domain and two SH3 domains.[6] This signaling protein is representative of the class of SH3-containing proteins that have no catalytic domains and function as molecular adaptors or protein dimerizers. The discovery of its physiological SH3 ligand provided the first cellular model of SH3-mediated events and illustration of non-proline determinants for SH3 binding. As demonstrated by immunoprecipitation and binding studies, either one or both Grb2 SH3 domains bind to Son of sevenless 1 (Sos1, "sauce-one"), a guanine nucleotide exchange factor for the GTPase Ras. Upon growth factor stimulation, this cytosolic complex is recruit-

ed to activated, membrane-bound receptors through Grb2 SH2–phosphotyrosine interactions, thereby localizing Sos1 to the plasma membrane. There, the guanine nucleotide exchange factor can then activate Ras, initiating signaling cascades that promote cellular growth and differentiation (see Fig. 2).

To identify the SH3-binding sites in Sos1, fragments of the nucleotide exchange factor were tested for their ability to bind to the Grb2 protein.[6b, d–f] These experiments localized the SH3-binding region of Sos1 to its C-terminal tail, which contains multiple PX(L/V)PPR motifs. Sos1-derived peptides that contain these residues can inhibit Grb2–Sos1 association in vitro, corroborating their role in SH3 binding. The presence of a conserved C-terminal arginine residue in these regions also suggested that the guanidinium side chain makes specific contacts with the Grb2 SH3 domain(s). Indeed, an arginine-to-lysine mutation in one of these proline-rich peptides abolishes its ability bind Grb2.[6d] Like previously reported SH3-binding motifs, however, the C-terminal region of Sos1 provided few additional insights into the molecular basis of SH3–ligand interactions. Multiple consensus motifs for SH3 ligands were proposed,[4d, 11] but the molecular recognition of proline-rich sequences by SH3 domains remained enigmatic.

2.2. Structural Studies

Sequence alignments of SH3 domains provided early clues about their secondary structure (Fig. 3). The delineation of the SH3 core was facilitated by the independent, modular nature of the domain, which is occasionally located at the extreme N- or C-termini of proteins. Conserved residues in SH3 domains are scattered throughout the primary sequence, including an N-terminal ALYDY motif and several groups of hydrophobic residues. Since many of these hydrophobic amino acids are interspersed with hydrophilic residues, Musacchio et al. initially proposed that SH3 domains are primarily composed of β-strands.[1b] Putative loop regions were also assigned based on the distribution of glycine and proline residues in SH3 sequences. Other attempts to predict the SH3 structure de novo were independently reported by Benner et al.[15] and by Rost and Sander.[16] Although both groups concluded that the domain comprises multiple β-strands and one α-helix, different protein folds were proposed.

The first structural elucidations of two SH3 domains verified many of these conclusions but invalidated others, illustrating the current limitations of de novo structure predictions. The crystal structure of α-spectrin SH3[2a] determined by Saraste et al. and the c-Src SH3 solution structure[2b] determined by Hongtao Yu in our laboratory revealed a conserved topology composed of two three-stranded antiparallel β-sheets that pack against each other at approximately right angles (Fig. 4; an alternative description of the SH3 fold has been proposed by Musacchio et al.,[2a] but the global structures of the two SH3 domains are essentially identical). The interface of these two β-sheets is mediated by several conserved hydrophobic residues, exemplified by Phe86, Leu100, Phe102, Leu108, Ile110, Ile132, and Val137 of Src. Loop regions between the β-strands are conformationally flexible and exhibit a preference for charged residues. Other common motifs in the α-spectrin and Src SH3 domains include a type II β-turn between strands S2 and S3 and a 3_{10} helix after strand S5 that is initiated by a highly conserved proline residue (Pro133 of Src). The general topology of SH3 domains therefore represents a unique protein fold structurally unrelated to the β-sheet- and amphipathic helix-containing SH2 domain.[17] As in SH2 modules, however, the N- and C-termini of SH3 domains

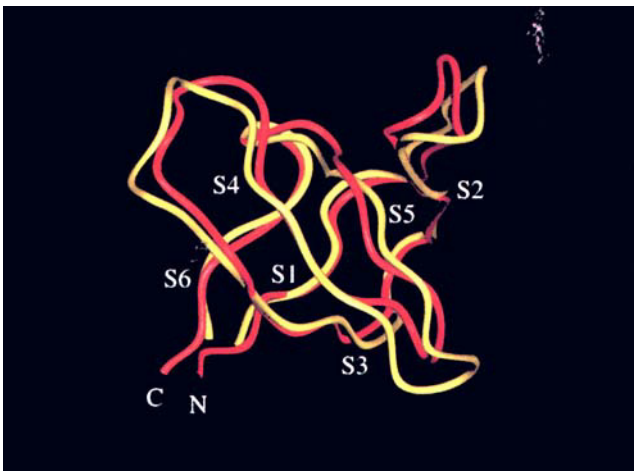

Fig. 4. Superposition of the SH3 domains of Src (yellow) and α-spectrin (red). The α-carbon traces are shown. The β-strands that represent the conserved topology of SH3 domains are labeled S1–S6.

Fig. 3. Sequence alignment of SH3 domains. Conserved residues corresponding to β-strands are colored green, and the C-terminal 3_{10} helix region is violet. Abbreviations for the proteins are based on their species of origin: H (human), C (chicken), V (viral), Ce (*Caenorhabditis elegans*).

converge on one protein face and are relatively disordered. These structural characteristics allow the SH3 domain to exist as an independent entity in proteins with minimal disruption of the surrounding structure.

NMR experiments with ^{15}N-labeled Src SH3 also provided insights into its ligand-binding site.[2b] Several residues exhibited perturbations in their ^{15}N or ^{1}HN chemical shifts upon the addition of 3BP1-derived peptides, suggesting that they either constitute or border the receptor–ligand interface (Fig. 5). One

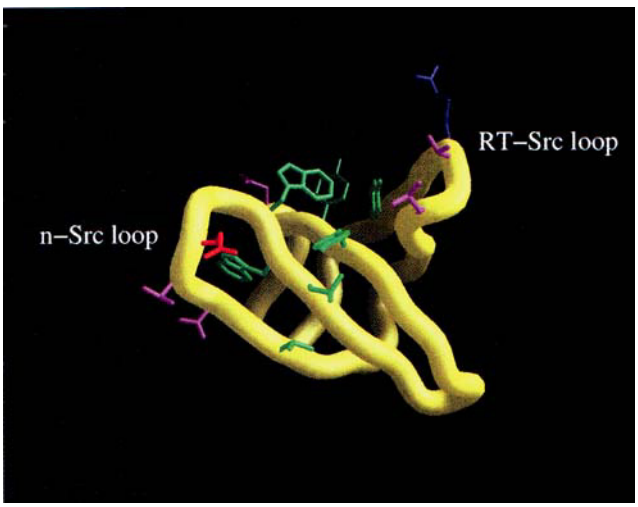

Fig. 5. The α-carbon trace of the Src SH3 domain depicting side chains of residues that show a change in their amide ^{15}N and/or ^{1}HN chemical shifts after the binding of 3BP1-derived peptides. Chemical shifts of the residues Tyr92, Arg95, Thr96, Thr98, Val111, Asn113, Thr114, Glu115, Trp118, Trp119, Leu120, Tyr131, Asn135, and Tyr136 changed by $\Delta\delta > 0.1$ (^{1}H) or > 0.5 (^{15}N) upon peptide binding, whereas others remained unaffected. Hydrophobic residues are shown in green, acidic residues are red, basic residues are blue, and neutral polar residues are purple [51].

subset of these residues (Tyr92, Val111, Trp118, Trp119, Leu120, Tyr131, and Tyr136) forms a smooth, hydrophobic patch on the protein surface that is lined with aromatic side chains. Since many of these amino acids are highly conserved, we were able to propose that this aromatic platform is the core binding site for SH3 ligands. Other perturbed residues (Arg95, Thr96, Thr98, Asn113, Thr114, and Glu115) are not conserved in the SH3 family and are located in variable loop regions. One of these regions, which is located between strands S1 and S2, has been named the RT-Src loop since mutations of either Arg95 or Thr96 cause cell transformation.[4a, b, e] The other ligand-contacting loop is the site of 6 and 17 amino acid insertions that are found in alternatively spliced variants of the Src SH3 domain found in neurons.[18, 19] This region is located between strands S3 and S4 and is commonly called the n-Src loop.

Subsequent investigations of other SH3 domains confirmed the generality of these structural elements.[2e–h] All known SH3 structures share a common global topology although additional β-strands or helices can be tolerated by the SH3 fold. In particular, the residues that correspond to Tyr90, Tyr92, Trp118, and Tyr136 of the Src SH3 domain have a conserved spatial arrangement, with similar side-chain orientations. These four residues are conserved in nearly all SH3 domains and form a gearlike composite surface in the ligand-binding site. In contrast, the RT- and n-Src loops are structurally diverse and can accommodate significant architectural changes. One dramatic example of this structural flexibility is the PI3K SH3 domain, whose structure was shown by Satoshi Koyama in our laboratory to contain a 15 amino acid insert in its n-Src loop, composed of one α-helix and two 3_{10} helices (Fig. 6).[2c] Chemical shift perturbation studies were also conducted on this unique SH3 domain using a proline-rich peptide derived from dynamin.[2d] Although these ex-

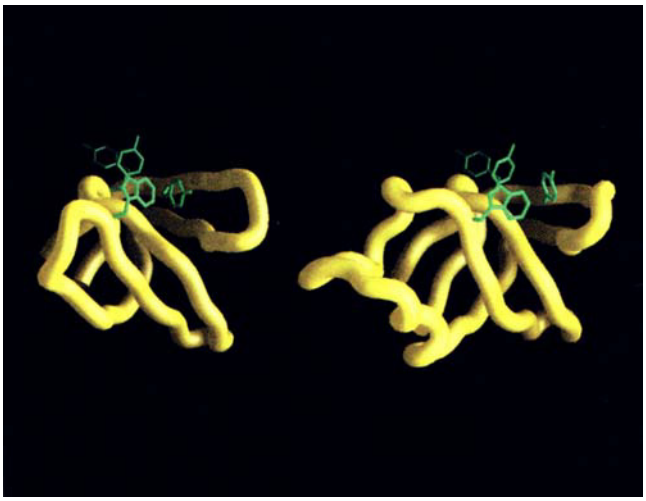

Fig. 6. Comparison of the solution structures of the SH3 domains of Src (left) and PI3K (right). The side chains of the conserved aromatic residues that line the binding site are in green [51]. The residues that are shown are: Tyr90, Tyr92, Trp118, and Tyr136 (Src), and Tyr12, Tyr14, Trp55, and Tyr73 (PI3K).

periments monitored side-chain proton resonances rather than ^{15}N and ^{1}HN chemical shifts of the SH3 backbone, the putative binding site residues of PI3K SH3 are identical or analogous to those elucidated in the Src SH3 perturbation studies. These results supported earlier speculations that the conserved, hydrophobic surface of SH3 domains is a general platform for proline-rich ligands, with specificity conveyed by the RT- and n-Src loops.

Unfortunately, these investigations shed little light on the structure of SH3 ligands. The identification of a putative binding site provided topographical clues, but the bound conformation of SH3 ligands remained a mystery. One major obstacle to further structural studies was the lack of high-affinity SH3-binding peptides. The chemical shift perturbation studies of the Src and PI3K SH3 domains utilized ligands with low specificity and affinity for their respective receptors. For example, the dynamin-derived peptide binds to the PI3K SH3 domain with a dissociation constant (K_D) of 300 μM.[2d] Although these peptides facilitated the delineation of the ligand-binding site (the solution structural studies were carried out at ca. 2 mM concentrations of receptor and ligand), their weak affinity and nonspecific nature precluded a meaningful evaluation of SH3–ligand interactions. Thus, fundamental questions about the molecular recognition of SH3 domains remained unanswered. How do SH3 domains bind proline-rich ligands? Why are certain proline residues critical for SH3 binding? What structural elements in SH3 ligands confer specificity? The remainder of this review will focus on the scientific advances that ultimately resolved these issues. In particular, we will discuss the discovery of SH3 ligands through combinatorial chemistry and the structure elucidation of SH3–

ligand complexes by NMR spectroscopy and X-ray crystallography. The insights provided by these studies will then be used to construct a general model for SH3–ligand interactions.

3. Combinatorial Studies of the PI3K and Src SH3 Domains

Several strategies for ligand discovery that involve combinatorial synthesis and molecular selection have recently emerged.[20] Libraries of peptides,[21] oligonucleotides,[22] and other linear polymers[23] have been synthesized in soluble forms and on a variety of solid supports. Complementary approaches have applied combinatorial synthesis to the generation of benzodiazepines[24] and azinomycin analogues,[20a, 25] demonstrating the compatibility of many synthetic transformations with library construction. Our investigations of the PI3K and Src SH3 domains have utilized combinatorial peptide libraries on beads in analogy to that described by Lam et al.[21d] These libraries are synthesized by a "split-and-pool" procedure[26] which rapidly generates millions of peptides, each covalently attached to a unique bead. Beads that contain high-affinity ligands are then identified by their ability to interact with a labeled receptor. Accordingly, the success of bead-based strategies requires the careful consideration of certain variables: 1) the size and basic structure of the molecular library, 2) the chemical composition of the solid support, 3) the derivatization of the target receptor, 4) the bead selection conditions, and 5) the method of bead characterization. The application of combinatorial libraries to the study of SH3–ligand interactions illustrates the roles of these factors in ligand discovery.

Our initial attempts to discover SH3 ligands used two random libraries: one containing two million linear hexapeptides and another containing two million cyclic heptapeptides.[27] The general structure of the hexapeptide library was XXXXXX, in which X represents any amino acid other than cysteine; the heptapeptide library had the form CXXXXXC and was intramolecularly cyclized by disulfide bond formation. Investigations using these libraries failed to yield suitable SH3 ligands; the amino acid sequences of SH3-binding beads followed general trends, but no clear consensus sequences were apparent. Furthermore, the SH3-binding affinities of synthetic, soluble versions of these ligands were found to be weak ($>100\,\mu M$). These results were both disappointing and puzzling. At the time of these experiments, no SH3 ligands were known and it was uncertain that SH3 domains even recognized polypeptides. The subsequent discovery of 3BP1, 3BP2, and other putative SH3-binding proteins revealed the preference of SH3 domains for proline-rich sequences. Although the minimal consensus motif of SH3 ligands remained elusive and controversial, these proline-rich regions provided the foundation for a modified approach: *biased* combinatorial libraries.

Recognizing that several reported SH3 ligands contain the sequence PPXP, we designed and constructed a biased combinatorial library of the form XXXPPXPXX.[27, 28] The biasing element was incorporated to orient the ligands in a uniform manner and to increase the average affinity of the ligands to the target receptor. Cysteine was again excluded from variable positions to avoid intra- and intermolecular disulfide bonds that would complicate library synthesis and characterization. Analogous to our previous libraries, approximately ten million peptides with this structural bias were synthesized on polydimethylacrylamide beads with a molecular spacer composed of β-alanine, ε-aminocaproic acid, and ethylenediamine. This particular solid support was used since it is well solvated and chemically stable in both the organic solvents necessary for peptide synthesis and the aqueous buffers that solubilize biological receptors. The linker was included to minimize steric interactions between the SH3 domains and the polydimethylacrylamide matrix. The PI3K and Src SH3 domains were then site-specifically derivatized at their N-termini through the coupling of fluorescein thiosemicarbazide to glyoxalamides, which can be introduced to peptides and proteins by cleavage of N-terminal serine residues with sodium periodate (Fig. 7).[29] Fortuitously, the PI3K SH3 domain expressed in *E. coli* already contains an N-terminal serine

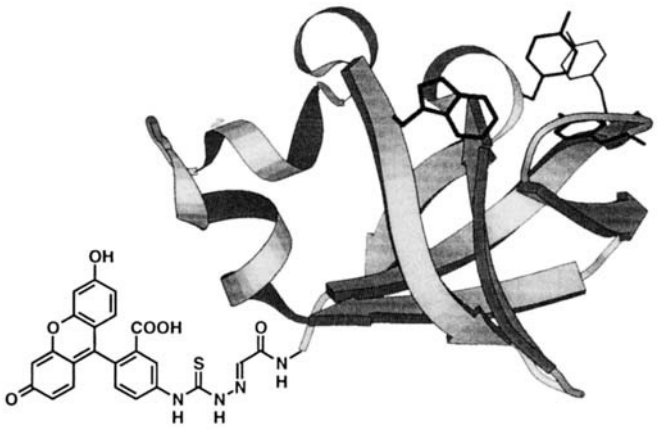

Fig. 7. Ribbon drawing of the N-terminally derivatized, semisynthetic PI3K SH3 domain used to probe the peptide libraries. Conserved aromatic residues that constitute the binding site are outlined with thick lines [52].

since posttranslational modifications remove its initiating methionine. Although this is not the case for the Src SH3 domain, an N-terminal serine was easily incorporated into the protein module by PCR mutagenesis and Factor Xa proteolysis. This selective and mild tagging procedure was chosen since the N-terminus and ligand-binding site of an SH3 domain are on opposite faces of the receptor, thereby preventing any interference with ligand binding by the fluorescent reporter. Aliquots of approximately two million beads from the XXXPPXPXX library were mixed with the fluorescein-conjugated PI3K and Src SH3 domains to allow receptor–ligand complexation, and the matrix was washed extensively with detergent-containing high ionic strength buffers to abrogate nonspecific interactions. SH3 ligand-containing beads were subsequently identified by fluorescence microscopy. In each library screening 60–70 beads were intensely fluorescent, and a subset of the brightest beads were isolated (Fig. 8). Because each bead is approximately $100\,\mu m$ in diameter and contains at least 50 pmol of peptide, resin-bound ligands can then be characterized by automated Edman degradation.

Two distinct classes of SH3 ligands emerged from these library-based studies (Table 1). Class I ligands have the consensus sequence RXLPPΦPXX (Φ represents arginine for PI3K SH3

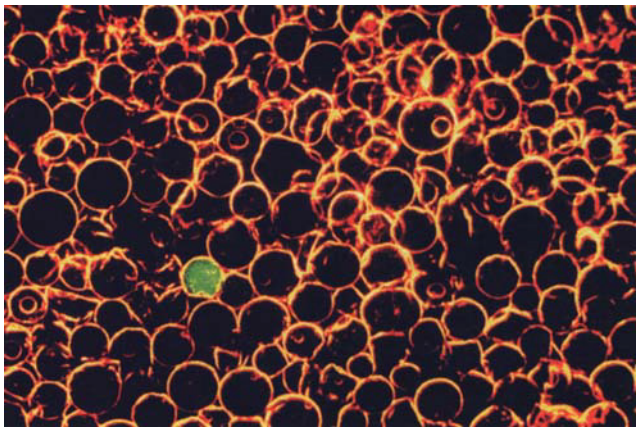

Fig. 8. Random subset of a bead-based library that has been probed with a fluorescein-conjugated SH3 domain. The 100 μm beads were viewed through a microscope using both transmitted light and incident fluorescence.

and leucine for Src SH3; X represents a nonconserved residue), and class II ligands have the consensus XXXPPLPXR. Spectroscopic analysis of several receptor–ligand complexes revealed that the tryptophan fluorescence of SH3 domains changes in intensity and shifts to shorter wavelengths upon ligand binding (Fig. 9). These fluorescence perturbations are presumably caused by ligand-induced desolvation of a conserved tryptophan in the SH3 binding site corresponding to Trp118 of Src. Consequently, representative ligands were synthesized as carboxamide peptides, and their affinities for the SH3 domains were evaluated by fluorescence titration assays (Table 2). Dissociation constants for both classes of ligands are in the micromolar range, with the highest affinity ligands having K_D values that are less than 10 μM. The peptides also bind selectively to their respective receptors, reflecting different residue preferences at certain randomized sites. For example, the PI3K SH3 ligand RKLPPRPSK (RLP1) binds to the PI3K and Src SH3 domains with K_D values of 9.1 and 52 μM, respectively. The Src SH3 ligand RALPPLPRY (RLP2) is somewhat less selective, binding to the PI3K and Src SH3 domains with K_D values of 17 and 7.8 μM, respectively. These affinities are comparable to and in general greater than those reported for peptides derived from SH3-binding proteins. One of the strongest SH3–peptide interactions known to date is that between the N-terminal SH3 domain of Grb2 and a Sos1-derived peptide, VPPPVPPRRR, with a K_D of 5.6 μM (the C-terminal SH3 domain of Grb2 binds to this peptide with a K_D of 39 μM).[27] In comparison, the 3BP1-derived peptide APTMPPPLPP binds to the Abl SH3 domain with a K_D of approximately 37 μM.[13, 30]

Table 1. Amino acid sequences of bead-bound peptides that interact with the SH3 domains of PI3K and Src.

SH3 Domains	Class I		Class II
PI3K SH3	RKLPPRPSK	RMLPPKPRV	PWHPPLPLR
	RDLPPRPAA	RKLPPKPKW	VWKPPLPKR
	RYLPPRPMY	RPLPPHPRR	LNKPPLPKR

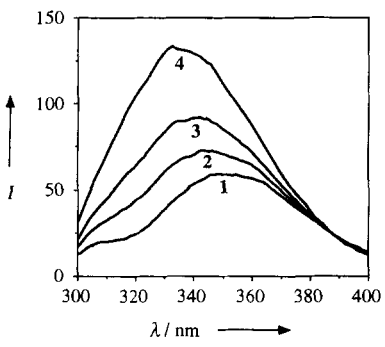

Fig. 9. Effect of ligand binding on the fluorescence spectra of an SH3 domain. 1: = PI3K SH3 (0.5 μM); 2, 3, and 4: PI3K SH3 with 4.3, 13, and 110 equivalents of the peptide RKLPPRPSK, respectively. λ = emission wavelength [nm], I = fluorescence intensity (in arbitrary units).

The discovery of two ligand classes was intriguing because it indicated that SH3–ligand interactions involve two distinct binding modes. Since there is a conserved N-terminal arginine in class I ligands and a conserved C-terminal arginine in class II ligands, we proposed that these peptides bind to SH3 domains in reverse orientations even though we were not aware of any precedent for this behavior in a protein receptor.[27, 28] The preponderance of RXL-containing ligands apparently reflected an inherent preference for class I ligands, yet the tight binding ligand of the N-terminal Grb2 SH3 domain, VPPPVPPRRR, resembles class II peptides and was predicted to bind in a similar manner.[28, 31] These molecular recognition issues were further clarified by mutational analyses of two SH3 ligands (Fig. 10). The class I peptide RLP1[28] and the class II peptide AFAPPLPRR (PLR1)[32] were systematically mutated to determine the relative importance of each residue for SH3 binding. As expected, conserved residues are generally important for SH3 recognition; alanine or glycine substitutions of these amino acids significantly attenuate binding. Nonconserved residues that are not critical for SH3–ligand interactions can be grouped into two categories. One group comprises Lys2 and Pro5 of RLP1, and Pro5 and Arg8 of PLR1, which are interspersed with conserved

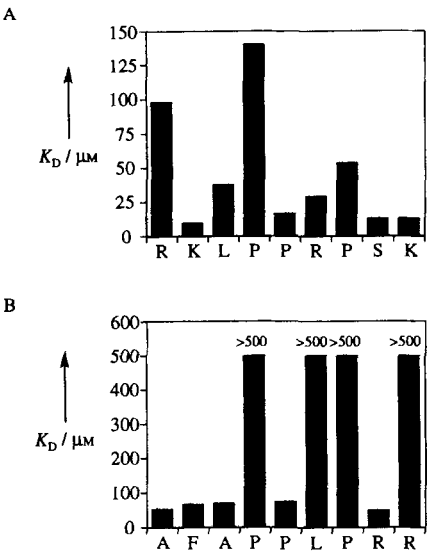

Fig. 10. Mutational analysis of the class I ligand RLP1 and the class II ligand PLR1. A) Effects of alanine substitutions of individual RLP1 residues on the dissociation constant K_D of the PI3K SH3–RLP1 complex. Values for residues Ser8 and Lys9 represent the affinity of the truncated peptide RKLPPRP for the SH3 domain of PI3K. B) Effects of alanine or glycine substitutions (at original alanine sites) of individual PLR1 residues on the dissociation constant K_D of the SrcSH3–PLR1 complex.

SH3-contacting residues. The second group of residues includes terminal amino acids in the two peptides, suggesting that the minimum length of these ligands is approximately seven amino acids. This localization of nonessential residues at the C-terminus of class I ligands and at the N-terminus of class II ligands supported our hypothesis that the two classes of peptides adopt opposite binding orientations. Moreover, we observed a palindromic PXXP motif that is universally conserved; Pro4 and Pro7 of both ligands contribute to SH3 binding. In retrospect, this conserved PXXP motif and the relative spacing of noncontacting residues suggested that SH3 ligands form highly organized structures with an unique spatial relationship between i and $i + 3$ residue positions. These results also revealed why our original molecular libraries failed to contain SH3 ligands. Nonencoded libraries on beads are restricted to five or six random positions owing to synthetic and screening limitations, but SH3 domains require ligands that contain at least seven amino acids. Our proline-rich bias therefore not only incorporated an SH3-binding element, but also allowed for the synthesis of larger ligands which contact the protein receptor more extensively.

Comparative searches of the EMBL/SwissProt data base using class I and class II ligands identified similar proline-rich regions in several cellular and viral proteins. For example, class I-like sequences can be found in the tyrosine kinase v-Fgr,[33] the potassium channel protein HK2,[34] and human proacrosin.[35] Class II-like sequences exist in the proto-oncogene c-Cbl ("sybil"),[36] Sos1,[37] and the N-terminal regulatory domain of the progesterone receptor.[38] Interestingly, there is also a class I-like sequence RPLPVAP in the p85 subunit of PI3K, approximately ten amino acids after the SH3 domain.[9a, b] Recent investigations have determined that the binding of Lyn ("lin") or Fyn ("fin") SH3 domains to this region activates the lipid kinase activity of PI3K.[39] In addition, we have shown that this region can mediate the dimerization of a recombinant p85 fragment in vitro by intermolecularly associating with the SH3 domain.[40] The physiological significance of these putative SH3-binding motifs is uncertain since the length of the PI3K and SrcSH3 ligands precludes the unambiguous identification of endogenous targets. The discovery of these SH3 ligands through combinatorial chemistry, however, laid the groundwork for our structural investigations that would ultimately unravel the molecular basis for SH3–ligand interactions.

4. Structural Studies of SH3–Ligand Complexes

Now equipped with the ligands we sought, we next undertook the structural determination of several SH3–ligand complexes using multidimensional NMR spectroscopy. The PI3K SH3 domain complexed with RLP1[28] and the c-SrcSH3 domain complexed with RLP2 and PLR1[32] were studied by H. Yu and Sibo Feng in our laboratory, revealing a novel molecular architecture for protein–ligand interactions. These studies illustrate how the mode of ligand binding by a protein receptor can be revealed by coupling combinatorial synthesis with protein structure determination techniques. In addition, Musacchio et al. recently reported the crystal structure of the AblSH3–3BP1-10 complex,[30] and Eck et al. determined the provocative structure of an SH3–SH2 fragment of the tyrosine kinase Lck in which the SH2 domain was complexed with a phosphotyrosine peptide.[29] These investigations have yielded valuable insights into the molecular origins of SH3–ligand interactions and the structural determinants of specificity. They also provide fundamental guidelines for the structure-based design of non-peptidic SH3 ligands, which could have important roles in medicinal and biological research.

4.1. Overview of the Structures

The structures of the four SH3–peptide complexes (Figs. 11–16) are generally consistent with early proposals about SH3–ligand interactions and reveal a remarkable structural mechanism for protein–protein interactions. The conserved, hydrophobic patch flanked by the variable RT- and n-Src loops constitutes the ligand-binding site of the SH3 domain, as previously demonstrated by NMR experiments. The overall structure of the SH3 domain does not significantly change upon ligand binding; for example, the root-mean-square deviation of the backbone in the minimized average structures of the free and ligand-bound PI3K SH3 domain is 0.85 Å.[28] Thus, the highly conserved aromatic residues that correspond to Tyr90, Tyr92, Trp118, and Tyr136 of the Src SH3 domain form a preorganized, gearlike template that binds the SH3 ligand. These amino acids and other neighboring residues form three uniformly spaced pockets in the SH3 domain that accommodate specific side chains from the proline-rich ligands. The binding pockets are primarily hydrophobic in character although charged residues from peripheral loops can contribute to the composite receptor surface. Ligand complexation can also significantly retard the cooperative unfolding of the SH3 domain in solution, as exemplified by the observation of eleven slowly exchanging amide protons for the RLP2-bound SH3 domain.[32] Only three are observed in the unbound state.[2b]

The solution structure of the PI3K SH3–RLP1 complex (Fig. 11) clearly revealed that the peptide forms a left-handed polyproline type II (PPII) helix which spans the receptor binding site, and this mode of binding has been confirmed in the three subsequent structures of SH3–peptide complexes. Two complete helical turns contact the SH3 domain, and in the Abl SH3–3BP1-10 complex additional N-terminal residues adopt an extended conformation. This unique PPII helix motif is well suited

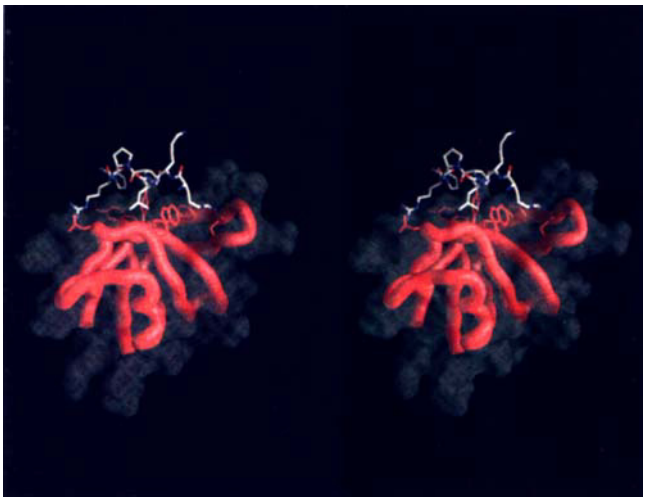

Fig. 11. Stereoview of the PI3K SH3–RLP1 complex. SH3 residues that participate in binding interactions are shown in red [51]. C-terminal ligand residues that do not contact the SH3 domain are omitted.

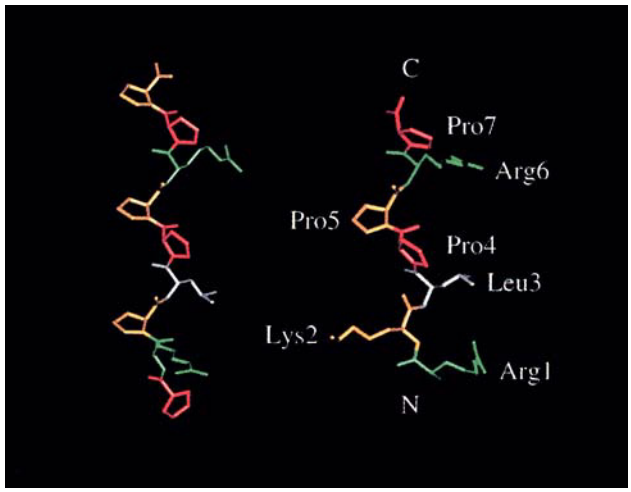
for the molecular recognition of SH3 domains. Polypeptides in this conformation form an extended molecular scaffold that complements the long, narrow surface of the SH3 ligand-binding site. In comparison, right-handed α-helixes that contain an equivalent number of residues are approximately half the length of these structures. PPII helices in globular proteins are also ideal mediators of protein–protein interactions because these motifs are usually exposed to solvent; lacking internal hydrogen bonds, PPII helices depend on backbone solvation for thermodynamic stability.[41] The most striking features of PPII helices are their left-handedness and their regular, repeating architecture (Fig. 12). There are three residues per helical turn, and amino acids at the i and $i + 3$ positions extend from the same face of the helix with nearly identical orientations. This conformation restricts the peptide to an elongated structure, in which the backbone and side chains form evenly spaced grooves like the threads of a screw. The width and depth of these grooves match the van der Waals surfaces of the aromatic side chains that line the SH3 ligand-binding site. The SH3–ligand complex therefore resembles the mechanical worm gear, in which a threaded, extended shaft interdigitates the teeth of a gearwheel.

Since the side chains of a PPII helix protrude from the peptide backbone every 120° (as viewed along the axis of the helix), one solvent-exposed residue and two adjacent SH3-contacting residues compose each helical turn (Fig. 13). Solvent-exposed amino acids point away from the SH3 ligand-binding site and do not make enthalpic contributions to SH3–ligand interactions. It is these residues in RLP1 (Lys2 and Pro5) and PLR1



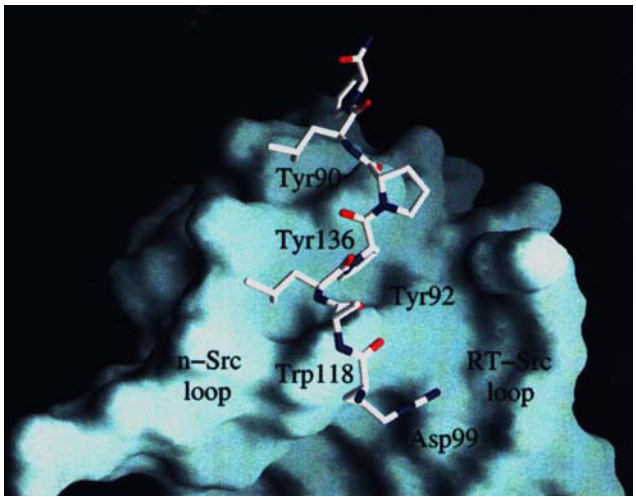


Fig. 12. Comparison of the conformation of bound RLP1 (partial structure RKLP-PRP, right) and a regular PPII helix (left) containing the RLP1 residues critical for SH3 binding. Prolines that contact the SH3 domain are shown in red, non-proline residues that participate in binding interactions are shown in white or green, and residues that do not contact the SH3 domain are shown in yellow.

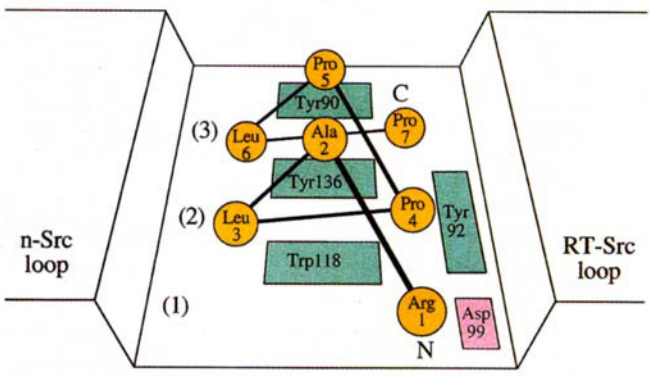

Fig. 13. Detailed view of a representative SH3–ligand complex. Top: Molecular surface of the Src SH3 domain with the bound RLP2 peptide, as viewed along the axis of the PPII helix [51]. Src SH3 residues that are critical for binding are labeled; C-terminal ligand residues that do not contact the SH3 domain are omitted. Bottom: Schematic representation of the Src SH3–RLP2 complex. Numbers in parentheses represent the three hydrophobic pockets in the SH3 binding site.

(Pro5 and Arg8) that can be mutated to alanine without significant attenuation of binding affinity. There is, however, a preference for proline residues in these positions, as demonstrated by

a slight increase in PI3K SH3 binding affinity for a mutant of RLP1 containing a proline residue for lysine at position 2 (the K2P mutant of RLP1, RPLPPRPSK).[28] Although proline residues in these positions do not contact the SH3 domain, they contribute to SH3 binding by conformationally restricting the polypeptide and promoting PPII helix formation. The remaining PPII helix residues interact extensively with the receptor, occupying the three hydrophobic clefts in the ligand-binding site. The first cleft is exemplified by the arginine-binding pocket in the Src SH3–RLP2 complex (see Fig. 15, middle). This pocket is formed by the indole ring of Trp118 and neighboring hydrophobic elements, and accommodates the aliphatic chain of the arginine residue, which caps one end of the PPII helix. (A discussion of the guanidinium-binding component of this pocket follows in Section 4.2.) The second and third binding pockets are also composed of hydrophobic residues in the SH3 domain, corresponding to Tyr90, Tyr92, Trp118, Pro133, and Tyr136 of Src. Each of these aromatic clefts binds an XP dipeptidyl moiety in the PPII helix. A noncontacting residue links these two XP structural elements, yielding the consensus SH3-binding motif **XPXXP**. Thus, the two aromatic pockets and their dipeptidyl ligands provide the structural basis for previous observations of critical PXXP motifs in SH3 ligands.

The molecular basis for the recognition of XP elements is evident from the SH3–ligand complexes. The alkyl substituents of these residues are in close proximity to each other since the $C_\alpha-C_\beta$ bond of X and the $N-C_\delta$ bond of proline are only two backbone bonds apart (Fig. 14). The compact nature of these

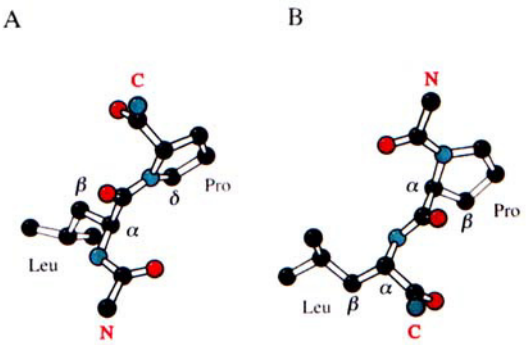

Fig. 14. Comparison of the dipeptidyl moieties XP (A) and PX (B) (X = leucine). Backbone directionality is indicated by N and C in red. Carbon atoms are shown in black, nitrogen atoms are blue, and oxygen atoms are red [52].

XP elements and their spatial relationship in a PPII helix allows them to intercalate between the aromatic residues of the SH3 binding site, maximizing hydrophobic interactions at the protein–ligand interface. In comparison, other dipeptidyl moieties such as XX and PX are less suitable for SH3 binding since their larger composite van der Waals surfaces are not complementary to the receptor binding pockets. Alkyl substituents in these dipeptidyl structures are juxtaposed by the two $C_\alpha-C_\beta$ bonds and are therefore separated by three instead of two backbone bonds. XX and PX elements are also more conformationally flexible than XP dipeptidyl moieties, which are restricted by potential 1,3-allylic interactions involving the $N-C_\delta$ bond of the pyrrolidinyl ring and either the $C_\alpha-C_\beta$ or $N-C_\alpha$ bond of X. Consistent with these observations, when the XP motifs in RLP2 and PLR1 were replaced with PX structural elements, we found that the resultant peptides bind to the Src SH3 domain with significantly diminished affinities.[32] There are, however, special cases in which one or both SH3-contacting moieties has the sequence PP such as in the Abl SH3–3BP1-10 complex. The $C_\alpha-C_\beta$ bond of the N-terminal proline and the $N-C_\delta$ bond of the C-terminal proline are separated by two backbone bonds, and this rigid dipeptidyl element is tolerated by the SH3 binding site. Indeed, recent phage display studies by Rickles et al. have shown that the second hydrophobic pocket of the Abl SH3 domain selectively binds PP elements, whereas the third pocket prefers (I/V)P motifs.[42] Our studies of the Src and PI3K SH3 domains demonstrate that the second and third binding pockets of these SH3 domains have preferences for XP sequences, in which X is an acyclic, aliphatic residue. This propensity for non-proline residues may reflect the ability of N-terminal acyclic residues and C-terminal prolines to form composite binding surfaces that maximize attractive interactions in SH3–ligand complexes.

The SH3–ligand complex therefore represents an extraordinary biological apparatus for protein–protein association. By iteratively combining aromatic and pyrrolidinyl elements, nature has created a molecular framework that is both functional and structurally elegant. In particular, ligands for SH3 domains fully exploit the molecular peculiarities of proline residues, which are structurally compact and conformationally restricted. These unique cyclic amino acids provide a solvent-accessible, hydrophobic surface, and the rigid PPII helix conformation imposed by these residues orients and spaces potential SH3-contacting elements. Such interactive elements have composite surfaces that are both spatially compact and conformationally rigid owing to the $N-C_\delta$ side chain substituents of proline residues. Pyrrolidinyl rings are also apparently ideal structures for contacting aromatic functionalities, as demonstrated by the frequency of proline–arene interactions in protein structures[43] and the selective binding of proline residues by synthetic receptors with aromatic groups.[44] This remarkable optimization of receptor–ligand interactions is the result of molecular evolutionary processes that govern biological systems. It is likely that a similar structural mechanism is involved in the recognition of poly-L-proline (PLP) sequences by the multifunctional receptor profilin. In analogy to SH3 domains, this structurally distinct protein contains an array of conserved aromatic residues that have been recently implicated in PLP binding.[45]

4.2. Ligand Specificity

The core recognition motif of SH3 ligands is the XPXXP sequence, which is functionally equivalent to the phosphotyrosine residue in SH2–ligand interactions. These key recognition elements anchor the ligands in the receptor binding sites, allowing neighboring amino acids to confer binding specificity. In SH2–phosphopeptide complexes, residues that flank the phosphotyrosine extend across the receptor surface and contact specific hydrophobic and electrostatic sites.[2g, 17a, d–f, 46] Similarly, variable residues in and surrounding the XPXXP core confer specificity in SH3–ligand interactions. These differences in receptor-contacting residues parallel topographical and elec-

trostatic variations in SH3 binding sites that are primarily conveyed by the RT- and n-Src loops.

All three hydrophobic pockets in the SH3 domain are subject to structural modifications that alter their ligand preferences (Fig. 15). As demonstrated by our combinatorial studies, the first binding pocket in the PI3K and Src SH3 domains selectively binds arginine residues in proline-rich ligands. The methylene groups of the arginine side chain pack against the surface-exposed cleft composed of hydrophobic residues (including Trp118 in Src and Trp55 in PI3K), whereas the guanidinium group contacts a highly conserved acidic residue in the pocket corresponding to Asp99 of the Src SH3 domain (Asp21 of PI3K). The existence of a salt bridge involving Asp99, which resides at the end of the RT-Src loop, is confirmed by NMR experiments and site-directed mutagenesis. The amide proton chemical shift of Asp99 is significantly perturbed upon ligand binding, and the D99N mutant of the Src SH3 domain binds to RLP2 and PLR1 with greatly diminished affinity.[32] Similar results were observed with the PI3K SH3 domain and RLP1.[28] Phage display[42] and cDNA expression library[11, 12] studies reveal, however, that the analogous binding pocket in the Abl SH3 domain prefers hydrophobic residues such as tyrosine and methionine. This difference in ligand specificity can be attributed to the relatively hydrophobic character of Thr100, which is structurally equivalent to Asp99 of Src.[2c] Indeed, the Abl SH3 domain is unique in its lack of an acidic residue at this site. The absence of a negatively charged residue in the first binding pocket alters its electrostatic potential and enables the Abl SH3 domain to bind aliphatic or aromatic side chains. This structural mechanism for ligand discrimination is reminiscent of the substrate specificity pockets of serine proteases, in which Ser189 and Asp189 modulate the side-chain preferences of chymotrypsin and trypsin, respectively.[47]

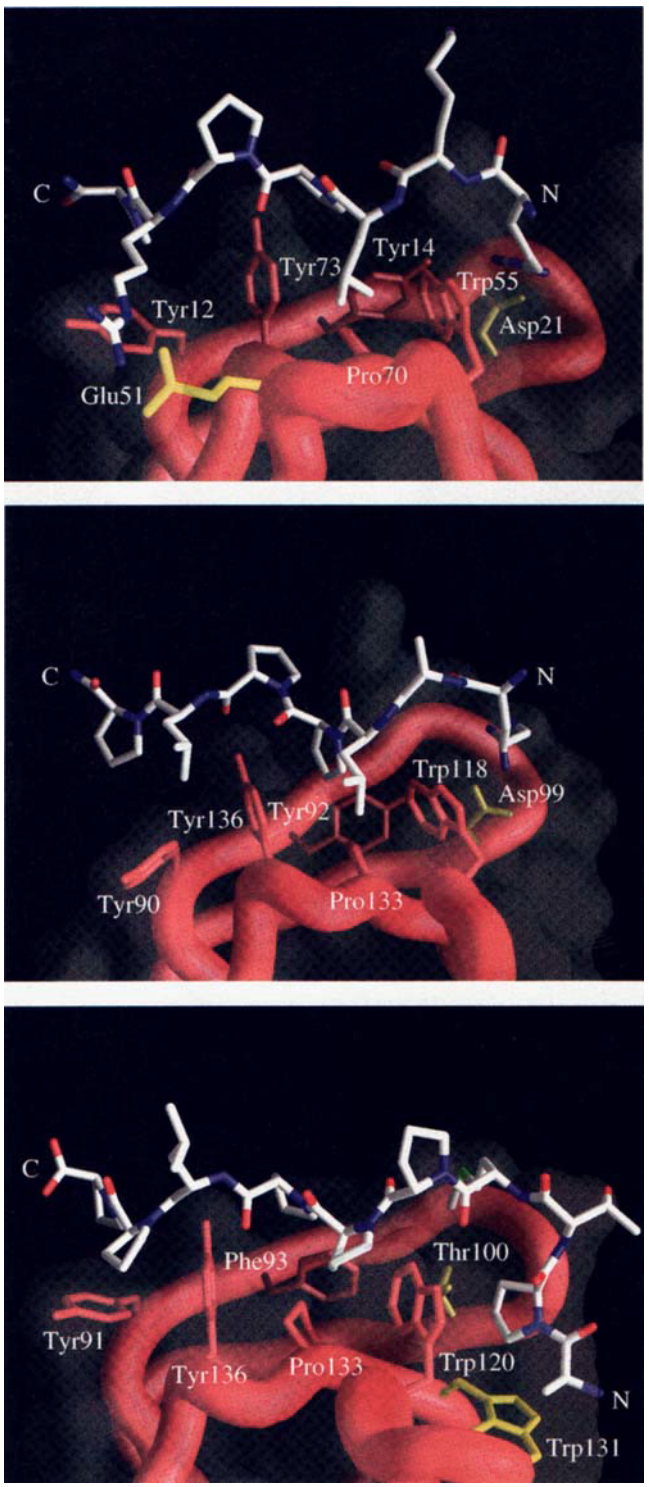

Fig. 15. Molecular determinants of specificity in the PI3K SH3–RLP1 (top), Src-SH3–RLP2 (middle), and Abl SH3–3BP1-10 complexes (bottom). SH3 residues that make conserved contacts in the three complexes are shown in red, and residues that mediate ligand specificity are shown in yellow [51]. C-terminal ligand residues that do not contact the SH3 domains are omitted.

Architectural variations in the second and third SH3 binding pockets regulate other aspects of ligand specificity. Whereas our investigations have revealed that the PI3K and Src SH3 domains prefer LP dipeptidyl moieties in their second binding pockets, complementary studies using phage display libraries have demonstrated that the Abl SH3 domain recognizes PP sequences in this site. The structural basis for this selectivity is not obvious since the SH3 residues in this region are well conserved. It is likely therefore that this binding specificity reflects subtle topographical differences in the SH3 domains, perhaps involving residue changes in the neighboring n-Src loop. Accordingly, the aromatic residues (Trp120 and Tyr136) that form the second binding pocket of the Abl SH3 domain are slightly further apart than the corresponding residues in PI3K and Src, and the n-Src loops of the Abl and Src SH3 domains have different conformations even though they are similar in length. The potential role of this variable loop in ligand discrimination is epitomized by SH3–ligand interactions involving the third binding pockets of the PI3K and Src SH3 domains. Class I ligands selected by the PI3K SH3 domain in combinatorial studies exhibit a preference for arginine residues at the variable site between the prolines (X of PPXP). In contrast, the SH3 domain of Src prefers ligands that contain leucine at this position. These results can be attributed to the 15 amino acid insert in the PI3K SH3 n-Src loop that is absent in the Src SH3 domain. This acidic, helical insert borders the third binding cleft, positioning Glu51 at the end of the pocket. Consequently, the dipeptidyl recognition site-selectively binds RP sequences in class I ligands; the aliphatic portion of the arginine side chain contacts hydrophobic elements in the ligand binding site, while the guanidinium group forms a salt bridge with the carboxylic acid. The importance of this electrostatic interaction for ligand recognition is illustrated by the

E51Q mutant of PI3K SH3, which binds to RLP1 with a threefold loss in affinity.[28] Because the Src SH3 domain lacks this acidic insert, its third binding pocket is primarily hydrophobic and therefore binds LP elements in class I ligands. In comparison, the SH3 domains of neural Src variants contain basic n-Src loop inserts and may prefer ligands containing XP motifs, in which X is aspartic or glutamic acid. One possible target for these neural Src isoforms or structurally related SH3 domains is Burton's tyrosine kinase (Btk), which contains the adjacent proline-rich sequences KPLPPTP and KPLPPEP. The KPLPPTP region binds selectively to the SH3 domains of Fyn, Lyn, and Hck ("hick"), but the KPLPPEP motif interacts weakly with these SH3 receptors.[48] This latter region contains an acidic EP moiety, which might interact specifically with basic residues in the n-Src inserts.

These three binding pockets and their peptidyl ligands represent the core recognition elements of SH3–ligand complexation. A number of studies indicate, however, that additional contacts can be made that increase the affinity and specificity of these interactions. Early mutagenesis experiments on the peptide 3BP1-10 demonstrated that Pro2 in the APTMPPPLPP sequence is essential for Abl SH3 binding,[12] and the Abl SH3–3BP1-10 complex reveals the molecular basis for this structural requirement (Fig. 15, bottom). Although residues Met4–Pro10 adopt a PPII helix conformation, the peptide kinks at Thr3 and places Pro2 in a critical pocket formed by Trp120 and Trp131. Residues in the SH3 family corresponding to or neighboring Trp131 are structurally diverse, suggesting that this general region plays a role in ligand specificity. Phage display studies of several SH3 domains also indicate that additional N-terminal residues in class I-like ligands can contribute to SH3 binding.[42] Based on the known structures of SH3–ligand complexes, these N-terminal residues may be major determinants of molecular specificity since they extend from the conserved aromatic core of the SH3 domain and flank the variable loops. The SH3 domain therefore may contain a fourth binding pocket that is an important mediator of ligand selectivity.

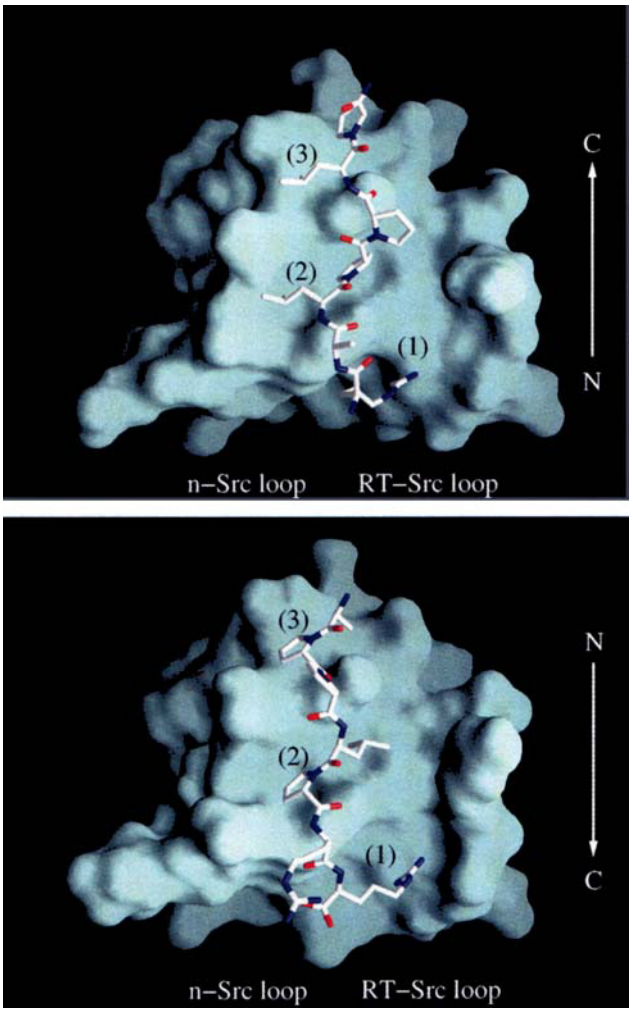

Fig. 16. Two binding modes in SH3–ligand interactions: the Src SH3–RLP2 complex (top) and the Src SH3–PLR1 complex (bottom) [51]. The backbone directionalities of the ligands are denoted by the arrows. Numbers shown on the SH3 domain represent the three hydrophobic pockets in the ligand-binding site. N- and C-terminal ligand residues that do not contact the SH3 domain are omitted.

4.3. Ligand Orientation

The discovery of two SH3 ligand classes through combinatorial synthesis provided the first evidence of dual binding modes. Intrigued by the structural similarities between the two groups of ligands, we initially proposed that SH3 domains can bind proline-rich peptides in two opposing orientations. The structures of the SH3–ligand complexes confirm and elucidate this unprecedented receptor–ligand interaction. The first mode of SH3–ligand interactions is exemplified by the Src SH3–RLP2 complex, in which the peptide amide backbone transverses the ligand binding site with its N-terminus adjacent to Trp118 and its C-terminus adjacent to Tyr90 (Fig. 16, top; see also Fig. 13). The N-terminal Arg1 of RLP2 contacts the first SH3 binding pocket and forms a salt bridge with Asp99 of the Src SH3 domain. The remaining two hydrophobic clefts in the receptor site accommodate LP dipeptidyl moieties from the proline-rich ligand, such that the leucine side chains abut the n-Src loop region of the domain and the proline pyrrolidinyl rings neighbor the RT-Src loop. This binding mode is generally adopted by class I ligands, as demonstrated by the PI3K SH3–RLP1 and Abl SH3–3BP1-10 complexes; peptides in both structures have identical backbone directionalities, and in the PI3K SH3–RLP1 complex the XP structural elements are similarly oriented.

The second mode of binding was uncovered by S. Feng in our laboratory when he determined the structure of the Src SH3 domain complexed with the class II ligand PLR1 (Fig. 16, bottom). The peptides PLR1 and RLP2 interact with the same three binding pockets on the Src SH3 domain, yet the two proline-rich ligands bind with opposite amide backbone directionalities. Thus, SH3 domains can recognize PPII helices in two orientations just as a gear can interdigitate a screw in two directions. The C-terminal Arg9 of PLR1 occupies the first binding cleft and forms a salt bridge with Asp99 of the receptor (again confirmed by mutagenesis and binding studies[32]). The second and third SH3 binding pockets contact XP sequences in PLR1, but the relative positions of non-proline and proline residues in these binding sites are exchanged owing to the reverse orientation of the ligand. Specifically, the acyclic side chains of XP elements face the RT-Src loop, and the pyrrolidinyl rings are

proximal to the n-Src loop in the Src SH3–PLR1 complex and vice versa in the Src SH3–RLP2 complex. The ability of the SH3 domain to accommodate this positional interchange underscores two important aspects of SH3–ligand recognition. First, the second and third binding pockets of the SH3 domain recognize the composite van der Waals surfaces of dipeptidyl XP motifs rather than proline residues alone. Second, the structural tolerance of SH3 domains for both orientations of XP sequences necessitates a mechanism for establishing ligand backbone directionality. Binding mode specificity is apparently mediated by structural asymmetries in the SH3 receptor site. For example, Asp99 of the first Src SH3 binding pocket orients the arginine-containing ligands RLP2 and PLR1. The backbone directionality of the 3BP1-derived ligand APTMPPPLPP is similarly dictated by specific interactions between the Abl SH3 domain and ligand residues N-terminal to the PP recognition elements such as Pro2 and Met4.

It is unclear whether SH3 domains have inherent structural preferences for either binding mode. A bias for class I ligands is suggested by the differential affinities of RLP2 and PLR1 for the Src SH3 domain and the preponderance of RXL-containing ligands in our combinatorial studies. Furthermore, two hydrogen bonds have been proposed in the Abl SH3–3BP1-10 structure based on the intermolecular distances between potential hydrogen bond donors and acceptors: one between the main-chain carbonyl oxygen atom of the ligand residue Met4 and the indole NH group of Trp120 and another involving the carbonyl oxygen atom of Pro7 and the side-chain NH group of Asn135. If real, these attractive interactions could play a role in ligand orientation, although their relative contributions to SH3–ligand interactions are unknown. It is apparent, however, that both classes of ligands can be found in nature. Sequence alignments of reported SH3-binding proteins reveal class I- and class II-like regions, which presumably bind in reverse orientations (Table 3)[4d, 6e, 11, 12, 48, 49]. In order to test our prediction that the Sos1-derived peptide VPPPVPPRRR binds in a class II orientation, we evaluated the ability of VPPPVPPRRR mutants to bind the N-terminal SH3 domain of Grb2.[32] In analogy to Arg9 of PLR1, Arg8 of this Sos1-derived peptide is essential for interactions with the Grb2 SH3 domain.[6d] This C-terminal arginine is expected to form a salt bridge with Glu16 of the Grb2 SH3 domain, which is structurally equivalent to Asp99 of Src.[31] Our additional binding experiments revealed that Pro3 and Pro6 of this peptide are critical for Grb2 SH3 binding, whereas Pro4 and Pro7 can be mutated to alanine with less than a twofold attenuation of affinity.[32] These results strongly support a class II-like binding mode since Pro3 and Pro6 constitute the critical PXXP motif in this orientation and Pro4 and Pro7 correspond to noncontacting prolines that point away from the SH3 domain (Fig. 17). The slight effect of P4A and P7A mutations on SH3 binding is characteristic of ligand proline residues, whose role in complexation is to stabilize the PPII helix conformation without interacting with the receptor.[28, 32] Arg9 and Arg10 of the Sos1-derived peptide also contact the Grb2 SH3 domain, as demonstrated by successive decreases in binding affinity upon their removal.[32] Thus, residues C-terminal to the class II consensus sequence, like residues N-terminal to the class I consensus, can contribute to SH3-binding affinity. Based on the structures of SH3–peptide complexes, these additional N- and C-terminal amino acids probably deviate from the PPII helix conformation in order to contact the SH3 surface. Analogous residues are not well conserved in known SH3 ligands and may be important determinants of ligand specificity.

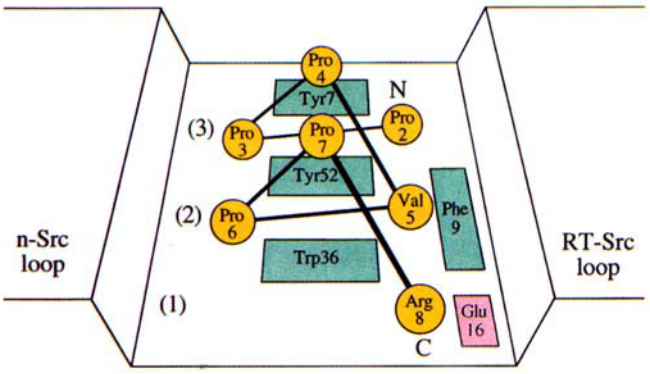

Fig. 17. Schematic representation of the Sos1-derived peptide VPPPVPPRRR bound to the N-terminal SH3 domain of Grb2 in an orientation analogous to that of class II ligands. Numbers in parentheses represent the three hydrophobic pockets in the SH3 binding site.

[a] Capital letters represent amino acid residues in the SH3-binding motifs. X_i and X_i' represent SH3-contacting residues that may confer ligand specificity, Z represents flanking residues that may participate in additional SH3–ligand interactions, and lowercase p represents scaffolding residues, typically proline. Proline residues that are completely conserved are in boxes. In the case of 3BP1, the amino acid position numbers start at the beginning of the partial cDNA sequence reported by Cicchetti et al. [11].

4.4. Insights from the SH3–SH2 Fragment of Lck

Since the discovery of 3BP1 and 3BP2, most studies of SH3 recognition have focused on linear, contiguous epitopes in polypeptide ligands. The structures described above indicate that single peptide chains are optimal SH3 ligands, but it is possible that noncontiguous epitopes in an SH3-binding protein could mimic the hydrophobic and electrostatic elements of a proline-rich peptide. Evidence for such an interaction is provided by the crystal structure of the Lck regulatory domains, in which an SH3–SH2 fragment dimerizes in a bivalent, "head-to-tail" fashion. The SH3 and SH2 domains in this intriguing complex make extensive intermolecular contacts that involve the SH3 binding pockets and SH2 residues flanking the phosphopeptide recognition site (Fig. 18). In particular, the second binding cleft

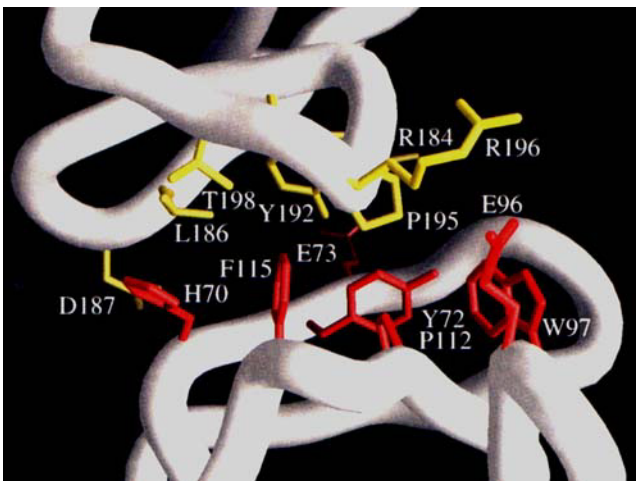

Fig. 18. The intermolecular interface of the Lck SH3–SH2 dimer. The α-carbon traces of the two domains are shown in white. SH3 and SH2 residues that participate in hydrophobic or electrostatic interactions are shown in red and yellow, respectively [51].

of the Lck SH3 domain interacts with Pro195, which protrudes from the SH2 surface. The pyrrolidinyl ring of this residue partially emulates the XP moiety of PPII helix ligands, although its orientation is orthogonal to that of analogous prolines in SH3–peptide complexes. Leu186 and Thr198 of the SH2 domain form another XP mimic and contact the third SH3 binding pocket, while SH2 residue Tyr192 makes additional hydrophobic contacts with aromatic residues in the SH3 domain. Other SH2 and SH3 residues including Glu73, Glu96, Asp187, Arg184, and Arg196 participate in salt-bridge interactions that stabilize the dimer interface. In contrast, intramolecular contacts between the SH3 and SH2 domains are limited to a single hydrogen bond from the backbone NH group of Lys118 in the SH3 domain to the side chain of Glu204 in the SH2 domain and hydrophobic contacts involving Leu69, Ala117, and Pro200.

The crystal structure of the SH3–SH2 fragment complexed to a phosphotyrosyl peptide (sequence TEGQ[pY]QPQPA; pY represents phosphotyrosine) reveals a similar arrangement of domains, in which the SH2 ligand binds at the SH3–SH2 interface (Fig. 19). This phosphorylated peptide corresponds to a region in the Lck C-terminal regulatory tail that presumably in-

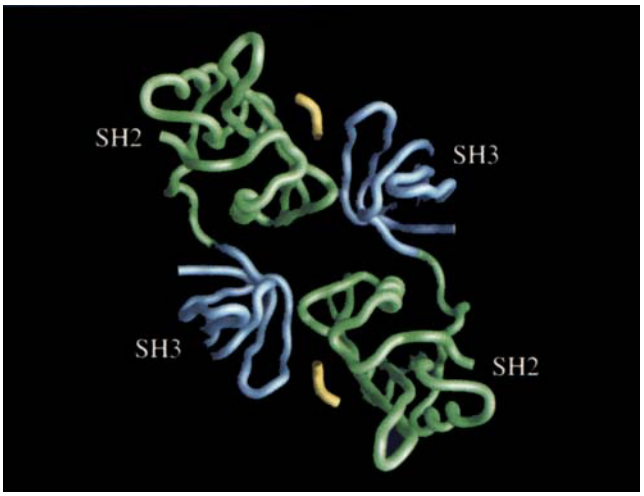

Fig. 19. The Lck SH3–SH2 dimer complexed with a phosphotyrosyl peptide. The α-carbon traces of the SH2 domains are shown in green, the SH3 domains are blue, and the phosphopeptide is yellow [51]. Peptide residues N-terminal to the phosphotyrosine are omitted.

hibits tyrosine kinase activity by intramolecularly binding to the SH2 domain.[4e, 50] The binding of the C-terminal tail appears to stabilize the dimeric complex since the peptide contacts both domains, including the RT-Src loop of the SH3 domain. On the basis of these observations, Harrison et al. have proposed a general model for the regulation of Src-family tyrosine kinases.[2g] In this structural model the SH3–SH2 dimer complexed with the C-terminal region of Lck represents the "closed" catalytically inactive state of tyrosine kinases. The binding sites of SH3 and SH2 domains are thus concealed and unable to recognize heterologous targets. Molecular events that disrupt this dimeric structure may trigger an "open" state and activate the kinase domain, initiating signal transduction cascades. Possible activating events include the dephosphorylation of the regulatory C-terminal tail, the binding of the SH3 or SH2 domains to other endogenous ligands, or mutations in either domain that destabilize the "closed" conformation of tyrosine kinases. The validity of this mechanistic model awaits testing by biochemical methods, since it is possible that the SH3–SH2 dimer is simply the result of crystal packing forces. No association has yet been detected in solution or in cellular lysates. Protein dimerization, however, may occur in intact cells because Src-family tyrosine kinases are localized to the membrane.

5. A General Model for SH3–Ligand Interactions

As demonstrated by combinatorial synthesis and methods of structure elucidation, there are recurring structural features in SH3 domains and their proline-rich ligands. These conserved architectural elements and the structure-based analysis of putative SH3-binding sequences allow for a detailed understanding of SH3–ligand interactions. The molecular recognition of SH3 domains is therefore governed by a common model which we describe below:

1) The SH3 domain contains three core binding pockets formed by conserved hydrophobic residues corresponding to Tyr90, Tyr92, Trp118, Pro133, and Tyr136 of c-Src SH3.

Residues in the RT- and n-Src loop regions contribute to the composite surface of these sites, providing structural elements for binding specificity.

2) SH3 domains recognize PPII helices in two distinct binding modes that differ in the directionality of their amide backbones. Hydrophobic contacts are the primary driving force of complexation, although specific electrostatic and hydrogen bond interactions may also play a role in ligand binding.

3) The core consensus motif for class I ligands is X_1-p-X_2-P-p-X_3-P; the class II consensus motif is X_3'-P-p-X_2'-P-p-X_1' (see Table 3). (X_i and X_i' represent SH3-contacting residues that may confer ligand specificity. The lower case p denotes a scaffolding residue that does not contact the SH3 domain but tends to be proline for PPII helix stabilization.) For both classes of ligands, a critical XPpXP sequence intercalates into the SH3 receptor site. Additional N-terminal residues in class I ligands or C-terminal residues in class II ligands can also contribute to SH3 binding and may play a major role in receptor–ligand specificity.

With these general guidelines, one can predict the molecular structure of an SH3–ligand complex using only the primary sequences of the receptor and ligand. For example, two components of the phagocyte NADPH oxidase complex are associated through an SH3-mediated interaction.[49d] The C-terminal SH3 domain of $p67^{phox}$ specifically binds to a proline-rich region in $p47^{phox}$ (QPAVPPRPS, residues 362–370). Based on the sequences of this SH3 binding motif and the $p67^{phox}$ SH3 domain, we can make the following predictions (Fig. 20). The proline-rich region of $p47^{phox}$ binds to the $p67^{phox}$ SH3 domain as a PPII helix, with its N-terminus adjacent to Phe466 of the receptor and its C-terminus adjacent to Trp494. Arg368 of the ligand contacts the first SH3 binding pocket and forms a salt bridge with Asp475, while dipeptidyl moieties formed by Val365–Pro366 and Gln362–Pro363 interact with the second and third binding clefts, respectively. As in the Sos1-derived ligand VPPPVPPRRR, the two most C-terminal residues (Pro369 and Ser370) may make additional contacts with the SH3 surface, increasing ligand affinity and specificity. Other ligand residues such as Ala364 and Pro367 point away from the SH3–ligand interface and may pack against the surface of $p47^{phox}$. The precise details of these structural predictions are a testament to our current understanding of SH3–ligand interactions. They also illustrate the collective power of combinatorial synthesis and structural methods in receptor–ligand investigations.

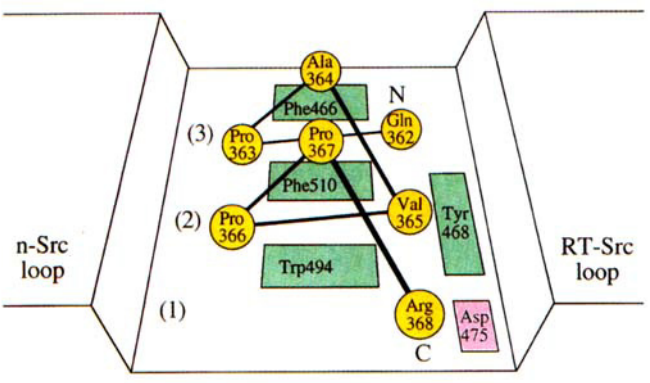

Fig. 20. Schematic representation of the $p47^{phox}$-derived peptide QPAVPPRPS bound to the C-terminal SH3 domain of $p67^{phox}$. Numbers in parentheses represent the three hydrophobic pockets in the SH3 binding site.

6. Summary and Outlook

The determination of the three-dimensional structures of SH3 domains complexed to ligands discovered through combinatorial synthesis has provided a remarkably clear picture of SH3 recognition. In only a short period of time, our view of these receptors has been transformed into one that involves specific molecular interactions between a PPII helix and a spatial array of aromatic SH3 residues. This global understanding of SH3–ligand interactions is the result of a two-step research strategy. Combinatorial synthesis yielded two familes of peptide ligands, filling a critical gap in our knowledge of SH3 recognition. Multidimensional NMR spectroscopy then completed this discovery process, providing a molecular understanding of SH3–ligand complexes that has significant predictive capabilities. The combination of these two techniques embodies a new approach to studying protein–ligand interactions that should be applicable to other systems.

The insights we have obtained through combinatorial synthesis and NMR spectroscopy lead to a number of fundamental questions concerning SH3–ligand interactions. For example, why would nature invent a mechanism for protein–protein association that involves dual orientations? Do individual SH3 domains utilize both binding modes in cellular systems, or do they each have a specific preference for a single class of ligands? The resolution of these biological issues will depend on more traditional strategies, which have gradually dissected the myriad of signal transduction pathways into their molecular components. Fundamental issues of molecular recognition are also highlighted by the structural elucidation of SH3–ligand complexes. In many respects, the PPII helix represents an ideal SH3-recognition motif that has been optimized by countless evolutionary cycles. It is interesting, however, to consider the outcome of selection processes that are not limited to natural amino acids. Can combinations of other functional groups provide suitable SH3 ligands? Will such non-peptidic ligands mimic the structural elements of the PPII helix, or are unique solutions for SH3 binding possible? Answers to these questions await the structure-based design of non-peptidic ligands or perhaps even better, the structure-based design of new combinatorial libraries, including ones that remove the peptide backbone entirely. The chemical leads provided by these strategies, their structural elucidation by NMR spectroscopy or X-ray crystallography, and the redesign of new ligands or libraries constitute an iterative process of discovery that promises to expand our knowledge of molecular recognition and the biological processes it governs.

We would like to thank our friends and colleagues who have contributed to our investigations of SH3 domains. Our success in the application of combinatorial synthesis to SH3 recognition would have been impossible without the patience and efforts of Andrew Brauer of ARIAD Pharmaceuticals, Inc., Bill Lane of the Harvard Microchemistry Facility, and Akito Tanaka of our laboratory. Our accomplishments in the structural elucidation of SH3–ligand complexes are due to the hard work and critical insights of Hongtao Yu, Sibo Feng, and Satoshi Koyama of our laboratory and David Dalgarno of ARIAD Pharmaceuticals, Inc. We would also like to thank Professor George Whitesides and Frank Gomez of Harvard University for their collaboration in our initial studies of SH3–ligand interactions using affinity capillary

electrophoresis. Thanks go out to H. Y., S. F., and Tae Bum Shin for critiquing the manuscript, Professor Stephen Harrison of the Harvard Molecular and Cellular Biology Department for providing coordinates of the SH3–SH2 fragment of Lck, and Andrea Musacchio of EMBL for providing the coordinates of the Abl SH3–3BP1-10 complex. Finally, we are indebted to our colleagues at ARIAD Pharmaceuticals, Inc., including Ricky Rickles and Joan Brugge, and current and former members of the Schreiber group, including T. B. S. and Julian Simon, whose enthusiasm and helpful discussions have made the SH3 project in the laboratory exciting and successful. J. K. C. would like to thank the National Science Foundation, the American Chemical Society Division of Organic Chemistry, and Zeneca for financial support in the form of graduate fellowships. SH3 research in the S. L. S. group is supported by the National Institute of General Medical Sciences (GM-44993) and the Howard Hughes Medical Institute.

The Catalytic Oxidative Coupling of Methane

Jack H. Lunsford*

One of the great challenges in the field of heterogeneous catalysis is the conversion of methane to more useful chemicals and fuels. A chemical of particular importance is ethene, which can be obtained by the oxidative coupling of methane. In this reaction CH_4 is first oxidatively converted into C_2H_6, and then into C_2H_4. The fundamental aspects of the problem involve both a heterogeneous component, which includes the activation of CH_4 on a metal oxide surface, and a homogeneous gas-phase component, which includes free-radical chemistry. Ethane is produced mainly by the coupling of the surface-generated $CH_3^{\bullet}$ radicals in the gas phase. The yield of C_2H_4 and C_2H_6 is limited by secondary reactions of $CH_3^{\bullet}$ radicals with the surface and by the further oxidation of C_2H_4, both on the catalyst surface and in the gas phase. Currently, the best catalysts provide 20% CH_4 conversion with 80% combined C_2H_4 and C_2H_6 selectivity in a single pass through the reactor. Less is known about the nature of the active centers than about the reaction mechanism; however, reactive oxygen ions are apparently required for the activation of CH_4 on certain catalysts. There is spectroscopic evidence for surface O^- or O_2^{2-} ions. In addition to the oxidative coupling of CH_4, cross-coupling reactions, such as between methane and toluene to produce styrene, have been investigated. Many of the same catalysts are effective, and the cross-coupling reaction also appears to involve surface-generated radicals. Although a technological process has not been developed, extensive research has resulted in a reasonable understanding of the elementary reactions that occur during the oxidative coupling of methane.

Keywords: catalysis · methane · oxidations · radicals · reaction mechanisms

1. Introduction

Methane, a principal component of natural gas, is an abundant hydrocarbon resource that is mainly used as a relatively inexpensive and clean-burning fuel. Certain chemicals such as methanol are indirectly derived from methane through a reforming reaction, in which methane reacts with water at elevated temperatures to form hydrogen and carbon monoxide. Because of the enormous proven reserves of natural gas in the world (1.4×10^{14} m^3),[1] there is a strong economic incentive to develop a process that would convert methane into more valuable chemicals and fuels. The quest for such a process and the associated scientific challenge has stimulated a large amount of research over the last decade on methods for the direct conversion of methane into ethylene, methanol, formaldehyde, etc. This research has focused on gas-phase reactions (noncatalytic and usually at high pressures),[2, 3] as well as on catalytic reactions in solution and on solid surfaces. The recent report by Lin and Sen[4] describes one of the few homogeneous catalytic systems in which methane has been converted into another organic molecule. In this case, methane was converted into acetic acid over a rhodium complex.

Most of the research on the direct conversion of methane has been devoted to the oxidative coupling reaction, which involves the catalytic conversion of methane and oxygen to ethane and water. The ethane is converted in situ into ethylene, and other sequential reactions produce small amounts of higher hydrocarbons. The hydrocarbon products (ethane, ethylene, and higher hydrocarbons) often are reported as C_{2+} products. The target molecule is ethylene, not only because of price but because of the size of the market. Ethylene is by far the largest volume organic chemical; 6×10^{10} kg was produced in 1992. In addition to these desirable products, CO_x (CO and CO_2) products are formed nonselectively. The conversion of CH_4 to CO_x is undesirable since it represents a reduced yield of hydrocarbons. Moreover the formation of CO_2 is a highly exothermic reaction, and the dissipation of heat would be a formidable engineering problem for commercial operation. The goal of the technical research is to produce, in a single pass through a catalyst, high ethylene selectivity at moderate levels of methane conversion. One might hope to achieve, for example, 90% selectivity for ethylene at 40% methane conversion. As the subsequent sections will show, this goal has certainly not been achieved.

At a more fundamental level the research on the oxidative coupling of methane has provided insight into an unusual type of oxidation catalysis, which involves both surface and gas-phase free-radical chemistry. In many cases the catalysts are uncommon in oxidation catalysis, as they do not contain transi-

[a] v: flow rate. [b] The C:O:X ratio refers to mole percentages of CH_4, O_2, and inert gas in the feed stock; total pressure: 1 atm. [c] $C(CH_4)$: conversion of methane. [d] S: selectivity. [e] The C_2H_4/C_2H_6 ratio was 25.

tion metal ions. Oxidative coupling reactions generally take place at 650–880 °C, at the limits of catalytic combustion where the availability of oxygen largely dictates the C_{2+} selectivity.

In this introduction to oxidative coupling, attention will be given to the mechanistic details and the nature of the centers that are responsible for the activation of methane. The scope of oxidative coupling will be broadened somewhat to include a limited amount of material on cross-coupling reactions; that is, reactions in which a methyl radical couples with another type of hydrocarbon radical. At least two other recent reviews provide a detailed summary of the catalysts that have been employed and the results obtained.[5–6] Likewise, other reviews and at least one book address other aspects of the research and provide alternative viewpoints on oxidative coupling.[7–10]

2. Catalysts and Catalytic Results

The possibility of attaining reasonable C_2 yields through oxidative coupling of CH_4 first became evident with the publication of Baerns and co-workers in 1984[11] and those of Ito et al. in 1985.[12] Baerns achieved 58% C_2 selectivity at 5% CH_4 conversion over a PbO/Al_2O_3 catalyst, whereas Ito et al. reported that a lithium-promoted MgO catalyst (Li/MgO) resulted in 50% C_2 selectivity at 28% conversion. Since these early results were reported, hundreds of catalysts have been found to be more or less active and selective for the coupling reaction. Several of the better catalysts are listed in Table 1, along with the conversions and selectivities that have been achieved.

In earlier studies the goal of the applied research was often to maximize C_2 yield by varying catalyst composition, reagent partial pressures, etc.; however, economic evaluations have shown that C_2 selectivity is more important than yield, provided, of course, one can obtain a modest level of CH_4 conversion. The maximum selectivity and conversion that can be achieved are related, and it is often useful to consider the sum of the two. For the best catalysts known at this time the sum of selectivity and conversion is about 100. Specific activity is a less important factor because of the problems associated with heat removal. Moreover, it often is difficult to ascertain specific activities from published results, because the reactions are carried out under severely oxygen-limited conditions to maximize selectivity. Nevertheless, from the specific flow rates listed in Table 1, one can qualitatively judge the activity. Still another factor in evaluating a catalyst is the need of a diluent. The conversion and selectivity generally increases as the partial pressure of the reagents decreases, but the separation of C_2H_4 from a large excess of a diluent gas is undesirable. Therefore, the better catalysts are capable of promoting high C_{2+} selectivities in the absence of a diluent.

The more effective catalysts may be divided into five groups: a) highly basic pure oxides, of which the early members of the lanthanide oxide series (excluding CeO_2) are the best; b) Group IA or IIA ions supported on basic oxides (for example, Li/MgO, Ba/MgO and Sr/La_2O_3); c) monophasic oxides; d) a few transition metal oxides that contain Group IA ions; and e) any of these materials that are promoted with chloride ions. Dubois and Cameron[21] have concluded that good oxidative coupling catalysts are strongly basic oxides that are p-type semiconduc-

Jack Lunsford, born in 1936 in Houston, Texas, received his undergraduate degree at Texas A & M University (1957) and his Ph.D. degree from Rice University (1962). In 1966 he returned to Texas A & M University as Assistant Professor of Chemistry, and in 1971 he was appointed Professor. He was a Guggenheim Fellow in 1985 and an Alexander von Humboldt Senior Scientist in 1992. He has maintained an active research program in the field of heterogeneous catalysis, with emphasis on the use of spectroscopic techniques to identify active centers and reaction intermediates. His research on surface-generated, gas-phase radicals has provided a basis for understanding the mechanism of oxidative coupling reactions.

tors at elevated temperatures and have oxygen anion mobility. Moreover, they are free of reducible surface cations. Many exceptions to the requirement of strong basicity are now known. For example, the $Mn(2\,wt\%)/Na_2WO_4(5\,wt\%)/SiO_2$ catalyst does not react with CO_2 at elevated temperatures, which usually is taken as measure of strong basicity. It also is surprising that this catalyst is highly selective, because transition metal oxides usually favor the formation of CO_x. We have confirmed the excellent behavior of the $Mn(2\,wt\%)/Na_2WO_4(5\,wt\%)/SiO_2$ catalyst and have found that at a $CH_4:O_2$ ratio of 8:1 without diluent and at 800 °C, the C_{2+} selectivity was 81% at 20% CH_4 conversion.[22] Moreover, as shown in Figure 1, the CH_4 selectivity decreased only a modest amount upon increasing the total

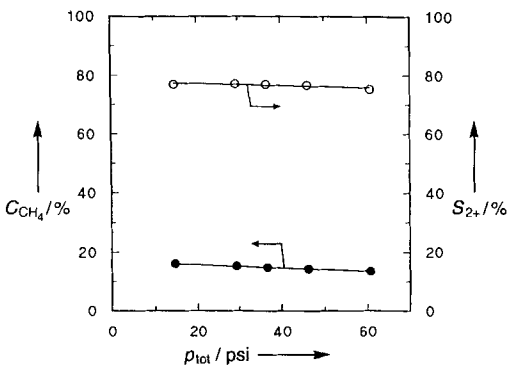

Fig. 1. Oxidative coupling of CH_4 over a $Mn(2\,wt\%)/Na_2WO_4(5\,wt\%)/SiO_2$ catalyst at pressures p greater than 1 atm: 0.1 g (0.22 mL) catalyst, $T = 785$ °C, $p(CH_4)/p(O_2) = 10$, contact time = 0.13 s (1 psi = 6.89 kPa). The y axes represent the methane conversion (C_{CH_4}) and the selectivity with respect to C_{2+} (S_{2+}).

pressure from 1 to 4 atm (1 atm = 101.3 kPa). The mass flow rate was varied so that the residence time of the feed gas in the catalyst bed remained constant at all pressures. This is believed to be the first example of a catalytic system that provides favorable conversions and selectivities at elevated pressures.

The $NaMnO_4/MgO$ catalyst, developed by Sofranko and coworkers,[19] is interesting, because it can be operated either in the usual co-feed or in a cyclic mode. In the latter mode the catalyst is oxidized with air, which eliminates the need for an oxygen separation facility. Moreover, for a given level of conversion, one can achieve approximately 10% greater C_{2+} selectivity. The specific activity for CH_4 conversion, however, is much less in the cyclic mode.

Several mixed-metal monophasic oxides have been studied as coupling catalysts, but these materials are subject to phase separation under the severe conditions employed in the coupling reaction. Of the Ba–Pb, Ba–Bi, and Ba–Sn perovskites that were examined by Dissanayake et al.,[23] only the Ba–Sn perovskite resisted phase separation, and this material was not selective. With the other two catalysts, barium segregated to the surface, and this presumably was the active component. Surface transformation is a common problem with all but the pure oxides, and the loss of an active component can adversely affect the performance. The loss of lithium from Li/MgO or lead from PbO/Al_2O_3 would be a serious impediment to the use of these catalysts in commercial operation.

3. Mechanism

3.1. Methane Activation

Product distributions as a function of residence time in the reactor show that most, if not all, of the initial hydrocarbon produced is C_2H_6, which suggests that ethane is formed by the coupling of $CH_3^{\bullet}$ radicals. This hypothesis is strongly supported by results obtained with a mixture of CH_4 and CD_4 in the reagent stream. Both Nelson et al.[24] and Mims et al.[25] showed that the main product of the coupling reaction was CH_3CD_3. Moreover, there is both qualitative and quantitative evidence for the coupling of the methyl radicals in the gas phase, after activation of CH_4 on the catalyst. Using a matrix isolation electron spin resonance (MIESR) system, we have detected surface-generated, gas-phase radicals over Li/MgO,[26] Li-MgO-Cl,[27] Na/CaO,[28] Na/CeO_2,[29] Sr/La_2O_3,[30] $LiNiO_2$,[31] Li/ZnO,[32] La_2O_3,[33] and other lanthanide oxide catalysts.[34] The results of Figure 2 are typical of the agreement between the $CH_3^{\bullet}$ radical production rate and that of C_2 product formation.

Although the MIESR system normally operates at pressure of about 2 Torr (1 Torr = 133 Pa), it was modified so that both the $CH_3^{\bullet}$ radical production rate and the C_2 production rate over a catalyst could be determined simultaneously at 760 Torr. By locating a leak into the MIESR system at the exit side of a thin catalyst bed, it was possible to minimize coupling within the voids of the bed. The results demonstrated that over a Li/MgO catalyst more than 40% of the C_2H_6 was derived from the coupling of $CH_3^{\bullet}$ radicals in the gas phase.[35] Using an entirely different system based on mass spectrometric detection and photoionization of $CH_3^{\bullet}$ radicals, Gutman and co-workers[36] concluded that greater than 75% of the C_2H_6 resulted from the coupling of $CH_3^{\bullet}$ radicals in the gas phase when the catalyst was Sr/La_2O_3. It may seem unlikely that the gas-phase coupling would exceed the surface coupling; however, one should recall that the binding energy (that is, heat of adsorption) of $CH_3^{\bullet}$ radicals on a closed shell oxide would be small and the entropy factor would favor desorption at the high temperatures used in these reactions.

These results convincingly show the importance of gas-phase reactions in the oxidative coupling reaction. A number of factors influence the production rate of $CH_3^{\bullet}$ radicals, and likewise, the conversion of CH_4 to C_2 products. The results of Figure 2 demonstrate maxima at about 3 wt% Li, whereas in a previous study we reported a maximum at about 13 wt% Li.[26] The difference between the two studies was the temperature at which the Li/MgO was calcined prior to forming $CH_3^{\bullet}$ radicals. By calcining the catalyst at a higher temperature (750 °C) the lithium was apparently more evenly distributed on and in MgO. Thus, less lithium was required to achieve maximum activity. Carbon dioxide likewise has a strong negative effect on $CH_3^{\bullet}$ radical production, but this will be discussed in more detail in Section 3.2.

Once the $CH_3^{\bullet}$ radicals enter the gas phase, they may either couple or enter into chain branching reactions that ultimately result in the formation of CO_x. Several groups have attempted to model these heterogeneous–homogeneous reaction systems with modest success.[37–39] A major difficulty in constructing such a model is in accounting for reactions of radicals or other

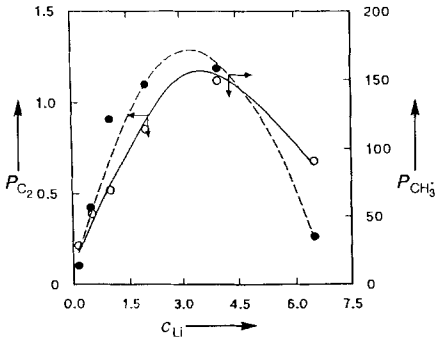

Fig. 2. Variation in C_2 productivity P_{C_2} [μmol m^{-2} s^{-1}] (○) and $CH_3^\bullet$ radical productivity $P_{CH_3^\bullet}$ [arbitrary units m^{-2}] (●) as a function of lithium content c_{Li} [wt%] in a Li/MgO catalyst. The reactions were carried out at 700 °C. The C_2 productivity was determined in a flow of 200 Torr CH_4 and 100 Torr O_2 (1 Torr = 133 Pa); the $CH_3^\bullet$ radical productivity was determined in a flow of 0.2 Torr CH_4 and 0.004 Torr O_2.

intermediates with the surface. For example, the gas-phase reaction (1) is a source of OH$^\bullet$ radicals, which serve as a major chain carrier in the temperature range of interest. But on a surface the facile decomposition reaction (2) occurs, and OH$^\bullet$ radicals do not enter the gas phase.

$$H_2O_2 + M \longrightarrow 2OH^\bullet + M \quad (1)$$

$$H_2O_2 \xrightarrow[\text{surface}]{} H_2O + 1/2\,O_2 \quad (2)$$

A model based on the original scheme proposed by Ito et al.[12] for heterogeneous reactions [Eqs. (3)–(5)] in addition to 156 gas-phase reactions has been used to explain most of the

$$CH_4 + O_s^- \rightarrow CH_3^\bullet + OH_s^- \quad (3)$$

$$2OH_s^- \rightarrow H_2O + O_s^{2-} + \square \quad (4)$$

$$O_s^{2-} + \square + 1/2\,O_2 \rightleftharpoons 2O_s^- \quad (5)$$

kinetic data over the Li/MgO catalyst,[37] including the variation in kinetic isotope effect on changing CH_4 and O_2 partial pressures.[40] The symbol □ denotes an oxide ion vacancy, and the subscript s an adsorbed species. The model can be extended to include N_2O as an oxidant by replacing reaction (5) with (6) and by adding the heterogeneous reactions (7), (8), and (9) as

$$O_s^{2-} + \square + N_2O \longrightarrow 2O_s^- + N_2 \quad (6)$$

$$N_2O + O_s^- \rightarrow O_{2s}^- + N_2 \quad (7)$$

$$N_2O + O_{2s}^- \rightarrow O_{3s}^- + N_2 \quad (8)$$

$$O_{3s}^- \rightleftharpoons O_2 + O_s^- \quad (9)$$

well as relevant gas-phase reactions.[41] Reactions (3) and (7) account for the inhibiting effect that CH_4 has on N_2O decomposition. At a given level of conversion, much greater C_{2+} selectivities were observed with N_2O than with O_2. One might think that this was due to differences in the gas-phase chemistry; however, the model indicates that surface reactions are largely involved. The ozonide ion, formed by reaction (8) or the reverse of reaction (9), might be responsible for the nonselective oxidation of C_2H_4 (see Section 3.3). In general, at temperatures less than 700 °C and at CH_4/O_2 ratios greater than 2, most of the chemistry occurs on the catalytic surface except for the coupling of the $CH_3^\bullet$ radicals.

There have been attempts to model the reaction in terms of Langmuir–Hinshelwood kinetics, which assumes that *adsorbed* CH_4 reacts with some form of surface oxygen,[42] or that $CH_3^\bullet$ radicals couple on the surface.[43] But several studies involving transients have confirmed that CH_4 is not adsorbed on coupling catalysts in the temperature range of interest.[44–46] With the small amount of C_2H_4 and C_2H_6 formed in these transient experiments, it is more difficult to make definitive conclusions about these hydrocarbons, and hence the location for $CH_3^\bullet$ radical coupling. Peil et al.[44] found evidence for a delay in C_2H_6 evolution from Li/MgO at 645 °C, but van der Wiele and co-workers[38] concluded that no C_2H_4 was adsorbed on Li/MgO at 800 °C. Recent studies by Baerns and co-workers,[47] who used a temporal analysis of products (TAP) reactor, confirm that over Sm_2O_3 methyl radicals are formed by the direct reaction of gaseous CH_4 with surface oxygen species in an Eley–Rideal type of mechanism.

Kinetic isotope effect (KIE) studies, first carried out by Cant et al.[48] and more recently by others as well,[49–52] indicate that a C–H bond is broken in the rate-limiting step [reaction (3)], with O_2 as the oxidant. We have found, however, that the KIE for methane conversion over a Li/MgO catalyst was a function of the CH_4/O_2 ratio and perhaps the total pressure.[40] Thus, there is no unique rate-limiting step; reactions (3) and (5) have comparable rates. Only when N_2O is the oxidant is it possible to find evidence for a clearly defined rate-limiting step. At a ratio of $CH_4/N_2O = 0.33$, a value of KIE = 1.1 was observed, which confirms that reaction (6) was rate-limiting.[41]

Our model calculations for the reaction of CH_4 and O_2 over Li/MgO indicate that the orders of reaction are determined by the forward and reverse rates of reaction (5) relative to the rate of reaction (3).[27] One may show analytically that the reaction is first order with respect to CH_4 and half order with respect to O_2 if reaction (3) is rate-limiting and reaction (5) is at equilibrium. As the forward and reverse rates of reaction (5) decrease with respect to the rate of reaction (3), the orders can become half with respect to CH_4 and 1 with respect to O_2. In the limit as the forward reaction (5) becomes rate limiting, the orders will become 0 with respect to CH_4 and 1 with respect to O_2 (or other oxidant). Again, the latter case has been observed only with N_2O as the oxidant.[41]

Another controversial mechanistic question concerns the mode of C–H bond activation. According to reaction (3), the C–H bond is broken homolytically by the abstraction of a hydrogen atom. Other investigators[53–56] focus on the basicity of the catalyst, and propose that the C–H bond is broken heterolytically as indicated in (10) where CH_4 is the acid. For certain catalysts the relationship between C_2 formation and basicity appears to correlate;[56] however, there are many examples for which it does not.

$$CH_4 + M^{n+}{-}O^{2-} \longrightarrow \overset{CH_3^-\ H^+}{M^{n+}{-}O^{2-}} \xrightarrow{O_2} \overset{O_2^-\ H^+}{M^{n+}{-}O^{2-}} + CH_3^\bullet \quad (10)$$

Since hydrogen–deuterium isotopic exchange of reactions among alkanes is believed to occur by heterolytic dissociation of C–H and C–D bonds, the isotopic exchange reaction between

CH_4 and CD_4 can be used independently to probe the circumstances under which the heterolytic dissociation might occur. Lapszewicz and Jiang[55] followed the isotopic exchange reaction between D_2 and CH_4 over Sm_2O_3, MgO, and γ-Al_2O_3, and concluded that no direct correlation exists between C–H bond activation and methane conversion. Moreover, Nelson et al.[57] found that during the oxidative coupling with CH_4/CD_4 mixtures very little hydrogen isotope exchange occurred over a Li/MgO catalyst. We have recently studied both the extent of hydrogen isotope exchange between CH_4 and CD_4 and the conversion of CH_4 during the oxidative coupling reaction over a Ba/MgO catalyst that contained 0.5 mol% Ba.[58] The results of Figure 3 show that the addition of CO_2, which poisons basic sites, has a much greater effect on the exchange reaction than on the activation of CH_4 for coupling. This catalyst apparently contains at least two distinguishable kinds of surface sites. One type is sufficiently basic to promote the heterolytic C–H bond cleavage, but under normal oxidative coupling conditions these would be poisoned by CO_2. The less basic set of sites is capable of catalyzing only the homolytic C–H bond cleavage in methane, directly producing $CH_3^{\bullet}$ radicals that result in C_2H_6 formation.

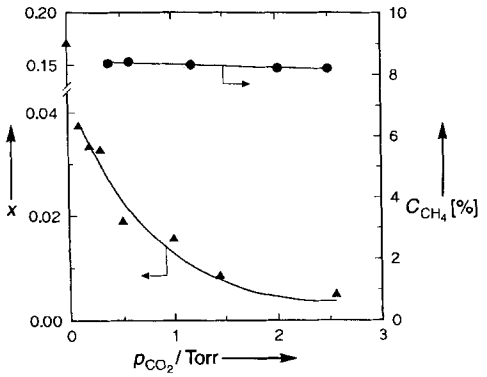

Fig. 3. Effect of CO_2 partial pressure on the isotope exchange between CH_4 and CD_4 (▲) and the oxidation of CH_4 (●) at 850 °C over 0.5 mol% Ba/MgO [58]. x = number of exchanged H or D atoms per molecule.

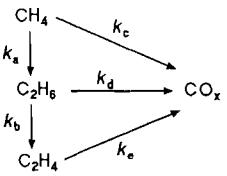
3.2. Ethene Formation



As noted previously, ethene is the desired product in the oxidative coupling of methane, although most mechanistic studies demonstrate that ethane is the initial C_2 product. Hutchings and co-workers[5] have reported that small amounts of C_2H_4 are observed, even at short residence times, but the direct formation of C_2H_4, for example by coupling of CH_2, would only be a minor pathway. Several of the better oxidative coupling catalysts also have been investigated for the oxidative dehydrogenation (OXD) of ethane, and in each case the catalyst has been shown to be effective for this reaction.[59–62] In fact, the best OXD catalysts are also good methane oxidative coupling catalysts. The initial activation step for both CH_4 and C_2H_6 is believed to be the same—the formation of alkyl radicals. The $C_2H_5^{\bullet}$ radicals also have been identified with the MIESR system.[59] The dominant subsequent pathways for methyl and ethyl radicals, however, are different. In the presence of O_2 reaction (11) prevails over coupling or the unimolecular loss of

$$C_2H_5^{\bullet} + O_2 \longrightarrow C_2H_4 + HO_2^{\bullet} \quad (11)$$

$H^{\bullet}$. For $CH_3^{\bullet}$ radicals there is no analogous route to the formation of a stable product. Consequently, the yields of C_2H_4 from the OXD reaction are more than twice as large as those from oxidative coupling of CH_4. Over a Li/MgO catalyst containing chloride ions a C_2H_4 selectivity of 77% has been achieved at a C_2H_6 conversion of 75%, which corresponds to a yield of 58%.[62] Moreover, because the C–H bond strength in C_2H_6 (422 kJ mol^{-1}) is less than that in CH_4 (439 kJ mol^{-1}), the rates of reaction are substantially greater with C_2H_6.

3.3. The Origin and Effects of CO_2

Since the development of a practical oxidative coupling process for methane is limited largely by the undesirable formation of CO_2, it is of interest to determine its origin. Both CO and CO_2 are produced as by-products during CH_4 coupling, but CO is converted into CO_2 over most of the catalysts. These oxides of carbon, which will be collectively referred to as CO_x, may be derived from all of the three hydrocarbons according to the generalized Scheme 1.

Scheme 1.

The three hydrocarbons in Scheme 1 compete for a common set of sites; it is therefore misleading to consider the oxidation of each hydrocarbon separately. The most definitive experiments to determine the origin of CO_x have been carried out by adding $^{13}C_2H_4$ or $^{13}C_2H_6$ to the $^{12}CH_4$ reagent and observing the fraction of $^{13}CO_x$ that appears as a product. Ekstrom et al.[63] were the first to use this method to demonstrate that oxidation of C_2H_6 and C_2H_4 were responsible for much of the CO_x formed over a Sm_2O_3 catalyst. Nelson and Cant[64] carried out similar experiments over Li/MgO catalysts and concluded that at $T > 740$ °C, most of the CO_x is derived from C_2 oxidation, and at $T < 700$ °C most is derived directly from CH_4. In evaluating these results it is important to recognize that both the rate constants (k_c, k_d, or k_e) and the respective hydrocarbon concentrations affect the rate of CO_x production.

It would be useful to separate out the intensive and the extensive factors in the formation of CO_x. In an effort to achieve this, we have defined a parameter R as the ratio of the percentage of ^{13}C in the CO_x products to that in the feed gas.[65] If the amount of CO_x derived from C_2H_6 is small (that is, the conversion of C_2H_6 to C_2H_4 is very selective), R is approximately the ratio of k_e/k_c. In Table 2 values of R are compared for several catalysts over a range of temperatures. Clearly, the values of R are significantly greater than 1. Even at 650 °C over Li/MgO a value of $R = 3.4$ was obtained. Thus, at all temperatures studied CO_x would be derived mainly from C_2H_4, provided the partial pressures of CH_4 and C_2H_4 are comparable. Higher temperatures, however, increase the formation of CO_x from C_2H_4, probably as a result of increased gas-phase oxidation.

Table 2. Origin of CO_x over various catalysts [a].

Catalyst	T [°C]	C_{CH_4} [%] [b]	S_{C_2} [%] [c]	$^{13}C_2H_4$ added [Torr]	CO_x from C_2 cmpds [%]	R
Li/MgO [d]	700	6.7	70.1	2.2	22.5	4.7

	800	9.4	50.8	3.9	40.6	4.0
CeO_2 [f]	800	10.5	3.8	1.1	7.8	7.7

[a] $p(CH_4) = 200$ Torr (1 Torr = 133 Pa); molar ratio $CH_4/O_2 = 10$; balance helium. [b] CH_4 conversion. (c) S_{C_2} = selectivity with respect to C_2 products. [d] 200 mg. [e] 5 mg. [f] 100 mg, diluted to 1 cm^3 with quartz chips.

Nevertheless, when operating at low conversions to achieve high C_2 selectivities, much of the CO_x would be derived directly from CH_4. The mechanism for this direct oxidation should therefore be considered. A simple calculation shows that a $CH_3^{\bullet}$ radical would collide with the surface of the catalyst approximately 10^5 times before it reacts with another $CH_3^{\bullet}$ radical in the gas phase. Some radicals react with species on the surface. By using a modified form of the MIESR system it has been found that for this interaction of $CH_3^{\bullet}$ radicals with selected metal oxides, the reactive sticking coefficients may range between 1×10^{-7} and 2×10^{-5}.[66] Moreover, the reactive sticking coefficients may be directly related to the O_2 pressure.[67] The larger sticking coefficients are found with oxides that have multiple oxidation states, making them accessible to reduction by $CH_3^{\bullet}$ radicals. Thus, reaction may occur through electron transfer, with the concomitant formation of a methoxide ion [Eq. (12)].

$$M^{(n+1)+}O^{2-} + CH_3^{\bullet}(g) \longrightarrow M^{n+}(OCH_3)^- \quad (12)$$

Methoxide ions function as surface intermediates in formation of CO_x under oxidative coupling conditions. Even on nonreducible oxides, which constitute most of the oxidative coupling catalysts, the electron may be transferred to oxide ion vacancies on the surface, forming F-type centers. In the presence of O_2, electron transfer may result in the formation of surface oxide or superoxide ions.

The catalytic behavior of a nonselective oxide (for example, CeO_2) may be completely altered by the addition of an alkali metal ion which forms a surface oxide/carbonate phase. In the case of CeO_2, which reacted extensively with $CH_3^{\bullet}$ radicals and produced only CO_2 during oxidation, the addition of a monolayer of Na_2CO_3 resulted in an active and reasonably selective coupling catalyst.[29, 68] Apparently the Na_2O/Na_2CO_3 layer inhibits electron transfer from $CH_3^{\bullet}$ to the CeO_2, and thus prevents $CH_3^{\bullet}$ radicals from reacting with the surface.

Since the early work of Lin et al.[33, 69] it has been suggested that $CH_3O_2^{\bullet}$ radicals in the gas phase, formed in the equilibrium reaction (13), may be responsible for CO_x formation. This

$$CH_3^{\bullet} + O_2 \rightleftharpoons CH_3O_2^{\bullet} \quad (13)$$

hypothesis is attractive, because the equilibrium $CH_3O_2^{\bullet}$ concentration decreases with increasing temperature, and up to a certain point, the selectivity for C_2 formation increases with temperature. Our model calculation, however, demonstrated that the role of $CH_3O_2^{\bullet}$ in the homogeneous component of the reaction is not important,[37] but it is possible that reactions of $CH_3O_2^{\bullet}$ with the surface may be significant.[64] Even so, it is difficult to understand the effect of O_2 on the reactive sticking coefficient at the low partial pressures of the MIESR experiment. We have suggested that a surface oxygen species, such as O_3^-, may be responsible for the conversion of $CH_3^{\bullet}$ to CO_x,[41] but it also is possible that an electron transfer reaction, analogous to reaction (12), may be involved, but with the reduction of O_2 instead of metal oxide according to reaction (14). Indeed, there was ESR evidence for the O_2^- ions on CeO_2 after the sample had been exposed to $CH_3^{\bullet}$ radicals and O_2.[66]

$$M^{n+}O^{2-} + CH_3^{\bullet}(g) + O_2(g) \longrightarrow M^{n+}(OCH_3)^- + O_2^- \quad (14)$$

At this point we turn our attention to the effect that CO_2 has on activity and selectivity during the catalytic oxidation of methane. The extent of the CO_2 effect depends very much on the basicity of the catalyst. Marcelin and co-workers[70] found that methane conversion over Li/MgO decreased dramatically with the addition of CO_2; however, CO_2 had less effect on methane conversion over Sm_2O_3. Similarly, differences were observed over these same two catalysts with respect to $CH_3^{\bullet}$ radical formation.[71] In poisoning the centers responsible for CH_4 activation, CO_2 has a profound effect on the kinetics of the coupling reaction. For example, over Li/MgO the order of reaction with respect to O_2 is largely determined by the increased amount of CO_2 that is formed.[72] As the O_2 partial pressure is increased, more CO_2 is produced. Moreover, the poisoning effect of CO_2 is manifested in the apparent activation energy for $CH_3^{\bullet}$ radical formation and CH_4 conversion over basic oxide catalysts. Because CO_2 is a poison, the rate equation for $CH_3^{\bullet}$ radical formation may be expressed as shown in Equation (15).[73] If $K[CO_2] \gg 1$, then the conditions in (16) are valid, where λ

$$\frac{d[CH_3^{\bullet}]}{dt} = \frac{k f([CH_4], [O_2])}{1 + K[CO_2]} \quad (15)$$

$$k_a = k/K \quad \text{and} \quad E_a = E + \lambda \quad (16)$$

is the heat of adsorption of CO_2. Upon increasing the amount of added CO_2 from 0 Torr to 0.75 Torr, the activation energy for $CH_3^{\bullet}$ formation increased from 96 kJ mol^{-1} to 201 kJ mol^{-1}, which suggests a value for λ of about 105 kJ mol^{-1} (Fig. 4). A

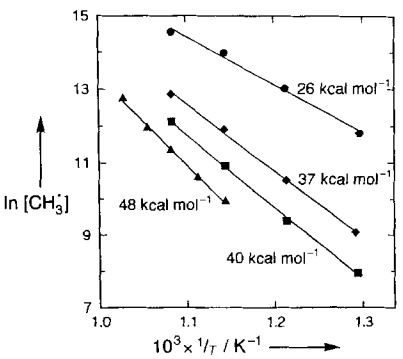

Fig. 4. Arrhenius plots of $CH_3^{\bullet}$ radical formation rate over Li/MgO as a function of the partial pressure of CO_2 added to the reagent stream. $p(CO_2)$: 0 Torr ●, 0.04 Torr ◆, 0.2 Torr ■, 0.75 Torr ▲. The pressures of CH_4 and O_2 were 0.22 and 0.02 Torr, respectively [73].

similar increase in E_a from 134 kJ mol^{-1} to 218 kJ mol^{-1} was found for methane conversion when CO_2 was added to the reagents during oxidative coupling.

The role of CO_2 in improving C_2 selectivity from CH_4, or C_2H_4 selectivity from C_2H_6, is illustrated by the results in Table 3. At a constant level of 5% CH_4 conversion, the C_2 selectivity increased from 45% to 64% upon the addition of

Table 3. Effect of CO_2 poisoning on selectivity S during the partial oxidation of methane and ethane over Li/MgO catalyst.

[a] Hydrocarbon conversion. [b] Li content = 4 wt%, $p(CH_4) = 200$ Torr, $p(O_2) = 100$ Torr, total flow rate = 80 mL min^{-1}, T = 650 °C. [c] Numbers in parentheses are the amounts of CO_2 produced by the reaction, in Torr. [d] Li content = 4 wt%, $p(C_2H_6) = p(O_2) = 290$ Torr, total flow rate = 60 mL min^{-1}, $T = 650$ °C.

23 Torr CO_2. MIESR results indicated that CO_2 inhibited secondary reactions between the $CH_3^{\cdot}$ radicals and the Li/MgO catalyst.[71] As the conversion level is increased by increasing the amount of catalyst, and a larger fraction of the CO_2 is derived from C_2H_4, one might expect that the positive effect of CO_2 on C_2 selectivity would become less evident. However, the results of Table 3 clearly show that CO_2 also enhanced the selectivity for C_2H_4 during the OXD of C_2H_6. The origin of this effect is not obvious, but the results suggest that CO_2 may poison sites that are uniquely capable of promoting the further oxidation of C_2H_4 to CO_2.

One of the manifestations of this role of CO_2 is the effect of residence time on selectivity. Usually in oxidation catalysis the conversion increases, but selectivity to a partial oxidation product decreases as the residence time in the catalyst bed increases. But in the oxidative coupling reaction it is often found that short residence times result in low C_2 selectivity because an insufficient amount of CO_2 has been formed. As a result of this effect, comparisons between results obtained in integral and differential reactors can be misleading.

4. Nature of the Active Center

4.1. Surface Oxygen Ions

The diversity of catalysts used in the oxidative coupling reaction makes it unlikely that a single type of center is responsible for the activation of CH_4. Therefore, the potential active centers will be discussed with respect to classes of catalysts. Li/MgO is the most thoroughly investigated. One of the challenges in identifying active centers results from the fact that most characterization methods are applicable only at conditions far removed from those used in the actual catalytic reaction. Nevertheless, rational hypotheses can be made concerning the species that might exist on the surface of a functioning catalyst. With one notable exception, which will be discussed subsequently, the attention has focused on different types of oxygen ions, for example, O^-, O_2^-, O_2^{2-}, or O^{2-} in a state of low coordination. This attention to oxygen ions results because only metal oxides are effective in the coupling reaction and because the CH_4 reactivity is generally much greater in the presence of a gas-phase oxidant (O_2 or N_2O). Even those catalysts that function in a cyclic mode are much more active when CH_4 and O_2 are co-fed to the system.

The effect of the simultaneous presence of CH_4 and O_2 over the catalyst is illustrated by the results of Figure 5, which were obtained over a Mn(2 wt%)/Na_2WO_4(5 wt%)/SiO_2 catalyst

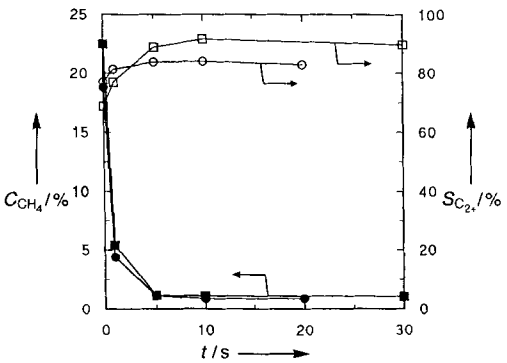

Fig. 5. CH_4 conversion C_{CH_4} and C_{2+} selectivity $S_{C_{2+}}$ obtained during pulse experiments. The time t is the delay between the 1 mL CH_4 pulse and the 0.2 mL O_2 pulse. Catalyst Mn(2 wt%)/Na_2WO_4(5 wt%)/SiO_2 (0.068 g): ● CH_4 conversion, ○ C_{2+} selectivity; catalyst $NaMnO_4$(5 wt%)/MgO (0.133 g): ■ CH_4 conversion □ C_{2+} selectivity.

and a $NaMnO_4$(5 wt%)/MgO catalyst.[22] The latter is similar to the one used in the cyclic experiments described above.[19] The catalysts were first treated with pure O_2 at 800 °C and briefly flushed with a stream of He. The first results, corresponding to zero time, were obtained by passing a pulse of CH_4 and O_2 in a 5:1 ratio over the catalysts. Thereafter a pulse of O_2 was followed by a pulse of CH_4. The periods between the O_2 pulse and the CH_4 pulse are indicated by the times given on the abscissa. During the initial CH_4/O_2 pulse over the $NaMnO_4$(5%)/MgO catalyst, 23% of the CH_4 was converted with a 69% selectivity into C_{2+} products. When the delay between the O_2 pulse and the CH_4 pulse was only one second, the CH_4 conversion decreased to 6%. After a delay of five seconds the conversion decreased to 1% and remained constant at this level. Similar results were obtained for the Mn(2 wt%)/Na_2WO_4(5 wt%)/SiO_2 catalyst. When the CH_4/O_2 mixture was added after several sequential CH_4 and O_2 pulses, the conversion increased to its original high value. These results indicate that a surface form of oxygen is responsible for the activation of CH_4. Bulk lattice oxygen may participate, but it does so at a rate that is slow compared to the rate of CH_4 activation by oxygen derived from the gas phase.

The early discovery of Li/MgO as an effective oxidative coupling catalyst focused attention on [Li^+O^-] centers as possible sites for the activation of CH_4.[26] These centers were known to be present in Li-doped MgO crystals at high temperatures, and they form only in an O_2 atmosphere.[74] Subsequent ESR studies on quenched catalyst samples revealed that [Li^+O^-] centers

were present, but they were mainly in the bulk of the crystallites.[75] It was proposed that surface O^- ions, in equilibrium with bulk $[Li^+O^-]$ centers, were responsible for the activation of CH_4. The $[Li^+O^-]$ centers have also been observed in Li/ZnO catalysts, and the analogous $[Na^+O^-]$ centers have been found in Na/CaO.[32, 69] All three of these catalysts function well at the lower end of the temperature range for oxidative coupling. At least two groups[76, 77] have carried out theoretical studies on the interaction of $[Li^+O^-]$ centers with CH_4, and the most refined calculation indicates a barrier height of only 25 kJ mol^{-1} for the hydrogen atom abstraction reaction, which is considerably less than the experimental value of 96 kJ mol^{-1} for $CH_3^\bullet$ radical formation.[73] The small barrier height is consistent with the gas-phase reaction of O^- ions with CH_4 to form $CH_3^\bullet$ radicals and OH^- ions, which occurs with an 8% probability at 25 °C.[78] Thus, while $[Li^+O^-]$ centers and O_s^- ions undoubtedly exist in and on the surface of Li/MgO catalysts, and they are capable of activating CH_4, it remains to be demonstrated that they are present in sufficient concentrations to account for the oxidative coupling results.

Based upon high resolution electron energy loss spectroscopy (HREELS) of model Li/MgO catalysts, Goodman and coworkers[79] concluded that F-centers (an oxide ion vacancy with two trapped electrons) or F-center aggregates function as the active centers on Li/MgO. Their model catalysts consisted of 20 monolayers of Li/MgO formed on a Mo(100) crystal. After heating the films to progressively higher temperature from 1000 to 1300 K and then cooling to 900 K for the catalytic measurements or 80 K for the HREELS measurements, they found that the activity for C_2H_6 production correlated better with the formation of F-centers and F-center aggregates than with that of $[Li^+O^-]$ centers. It is important to note, however, that the HREELS spectra were obtained after heating the model catalyst in only 5×10^{-7} Torr O_2, whereas the catalytic experiments were carried out in 1 Torr of O_2. Since the $[Li^+O^-]$ concentration is a function of the O_2 pressure,[74] a comparison of spectroscopic and catalytic results obtained after exposing the samples to very different O_2 pressures is problematic.

There also is considerable evidence that peroxide ions play a role in the activation of CH_4 over certain catalysts. It was pointed out by Sinev et al.[80] and Otsuka et al.[81] that Na_2O_2 and BaO_2 are capable of converting CH_4 into C_2H_6 at temperatures above 500 °C. The reactions were stoichiometric rather than catalytic, because both sodium and barium form stable carbonates at these temperatures. Nevertheless the results show that peroxide ions, if they existed at considerably higher temperatures, could activate CH_4. Because of the propensity of sodium to form a stable peroxide, the catalytic behavior of the Na/CeO_2 catalyst, as well as other sodium-promoted lanthanide oxide catalysts, has been explained by the existence of a supported Na_2O_2 phase.[68, 82] But there was no spectroscopic evidence to confirm the presence of this phase.

More recently, both X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy have been used to support the role of BaO_2 in the activation of CH_4. The initial XPS experiment to characterize a barium-containing coupling catalyst was carried out by Yamashita et al.[83], who studied Ba/La_2O_3. From the O(1s) binding energy they concluded that BaO_2 was present on the surface and O_2^- ions, or O^- ions derived from the peroxide, were responsible for the catalytic activity. We subsequently demonstrated that phase separation occurs during catalysis over $BaPbO_3$ and $BaBiO_3$ perovskites (see Section 2) and that the barium-enriched surface contains peroxide ions.[23] Since the O(1s) binding energies in O_2^-, CO_3^{2-} and OH^- are very similar, care must be taken in distinguishing between the three surface species. The contribution from CO_3^{2-} ions can be determined by separately measuring the carbonate C(1s) signal and then evaluating the amount of oxygen from this species. Hydroxide ions generally are removed by a thermal treatment at elevated temperatures, but this may be verified by carrying out an exchange experiment with D_2. If OH_s^- ions are present, HD will be detected in the gas phase.

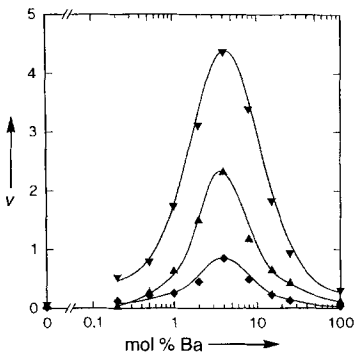

Fig. 6. Specific activities of Ba/MgO catalysts at a $CH_4:O_2$ ratio of 5:1. T = 750 °C ◆, 800 °C ▲, 850 °C ▼ [16]. The y axis represents methane conversion v [mmol min^{-1} m^{-2}].

The relationship between coupling activity and the presence of peroxide ions was even more convincingly shown with a series of Ba/MgO catalysts that contained from 0.2 to 25 mol% Ba.[16] As shown in Figure 6, the catalytic activity reached a maximum at about 4 mol% Ba. The decreasing activity at larger Ba loadings may result from a greater susceptibility to CO_2 poisoning, which indicates that the host oxide may influence the basicity of another surface phase, in this case BaO. The surface compositions for this same set of catalysts are depicted in Figure 7, where it is evident that the percentage of the surface covered by peroxide ions parallels the activity pattern shown in Figure 6.

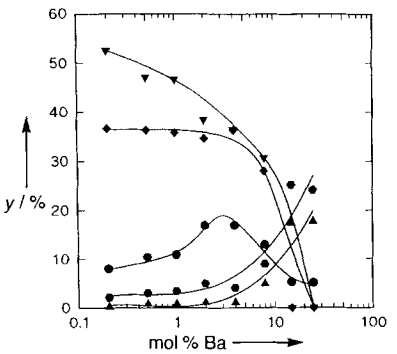

Fig. 7. Surface composition of Ba/MgO catalysts determined by XPS after exposure to a $CH_4:O_2$:He reaction mixture for 1 h at 800 °C and subsequent cooling to 25 °C in an atmosphere of O_2 and He: O^{2-} ▼, O_2^- ●, CO_3^{2-} ▲, Mg^{2+} ◆, and Ba^{2+} ● [16].

Although one might argue that the active centers are actually O^- ions in equilibrium with O_2^- ions, the O–O bond energy in a peroxide ion is about 205 kJ mol^{-1},[84] which is considerably greater than the E_a of 163 kJ mol^{-1} for the coupling reaction over the 4 mol% Ba/MgO catalyst. Moreover, there is evidence that CH_4 reacts with peroxides at relatively low temperatures.

The use of XPS to detect peroxide ions suffers from the fact that it is an ex situ method. By contrast, with Raman spectroscopy results can be obtained in the presence of the reagents and the catalyst at temperatures up to 800 °C. The Raman spectra for the 0.5 mol% Ba/MgO catalyst at progressively higher temperatures are shown in Figure 8.[85] The major band at

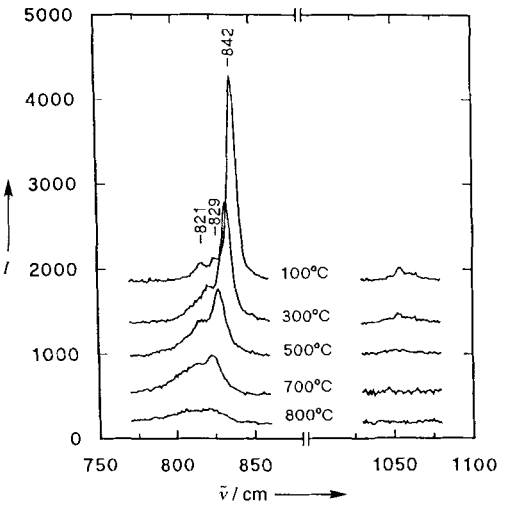

Fig. 8. Raman spectra of Ba(0.5 mol%)/MgO with the sample at the indicated temperatures. The sample had been cooled from 800 °C in a stream of O_2 [85]. *I* in arbitrary units.

842 cm^{-1} is due to the O–O stretch in BaO_2, while the weak band at about 1050 cm^{-1} is due to carbonate ions. The frequency shift with respect to temperature is a well-known phenomenon in Raman spectroscopy of solids, and it is related to the thermal expansion of lattice parameters. Although the Raman signal due to peroxide ions broadens and decreases in area with increasing temperature, there is evidence for the species even at 800 °C. No Raman band was observed around 1150 cm^{-1}, which is the position expected for O_2^- ions. In the presence of CH_4 and O_2 at temperatures greater than 700 °C, the carbonate bands quickly formed as a result of CO_2 produced during reaction, and the peroxide signal decreased below detection limits.

The involvement of peroxide ions in the oxidative coupling of CH_4 over these supported barium catalysts is reasonably convincing; however, the more general role of these ions has yet to be demonstrated. Earlier we reported the presence of a Raman band at 863 cm^{-1} on La_2O_3, which we attributed to O_2^{2-} ions, but subsequent experiments in an externally heated fused-quartz cell failed to reproduce this result.[86] Similarly, XPS results indicate the presence of only oxide ions on La_2O_3, provided the O_2 used to treat the sample is entirely free of H_2O.

4.2. Chloride-Containing Catalysts

The addition of chloride ions to an oxidative coupling catalyst can have a marked effect on its properties, particularly with respect to the C_2H_4/C_2H_6 product ratio. The chlorine may be introduced either initially as part of the catalyst or through organo chlorine compounds that are added to the reagents. Thomas et al.[17] studied a family of alkali-metal bismuth oxychloride catalysts, of which $LiCa_2Bi_3O_4Cl_6$ was an example, and they found C_2H_4/C_2H_6 ratios as great as 35. However, these materials generally lost activity within a few hours, which is a common problem with many of the chlorided catalysts. Typically, the properly chlorided catalysts give C_2H_4/C_2H_6 ratios between 3 and 5, which is still attractive since C_2H_4 is the desired product.

Because chlorine is known to dehydrogenate C_2H_6 in the gas phase, it has been suspected that homogeneous reactions may be responsible for the large C_2H_4/C_2H_6 ratios that are observed in these chlorine-containing systems.[87, 88] Perhaps the most definitive evidence against a substantial gas-phase component is found in the transient studies of Burch and co-workers,[89] who observed that the positive effect of chlorine addition to a catalyst persisted long after the flow of CH_3Cl over the catalyst had ceased. Moreover, we have shown that there is no correlation between the rate of chlorine loss from a Li^+-MgO-Cl^- catalyst and its ethane OXD activity.[90]

Most of the chlorine is lost as HCl in the reaction of water with the catalyst. The rate of chlorine loss can be minimized by operating a catalyst at lower temperatures. For example, Hinson et al.[91] found that a Li^+-MgO-Cl^- catalyst prepared by a sol–gel process was effective for periods up to 238 h at 640 °C; C_2 yields up to 20% and C_2H_4/C_2H_6 ratios of about 5 were achieved.

The favorable C_2H_4/C_2H_6 ratio over the Li^+-MgO-Cl^- catalyst, and presumably over all of the effective chlorided catalysts, results from the fact that the OXD of C_2H_6 is faster than the oxidative coupling of CH_4. In a series of studies on this catalyst we have demonstrated that a separate set of sites is largely responsible for the OXD reaction.[27, 90–92] It has been postulated that these sites consist of Li_2O on a molten film of LiCl. The LiCl modifies the basicity of the catalyst in such a way that neither the CH_4 conversion nor the C_2H_6 conversion is affected by CO_2. This is a particularly nice system with which to obtain kinetic data, because the CO_2 poisoning effect does not complicate the results (Section 3.3). With respect to selectivity, Cl^- ions appear to play the same role as CO_2 did on the Li/MgO catalyst. The unique behavior of the chlorided Li/MgO is found only at Cl/Li ratios ≥ 0.9. At lower Cl/Li ratios Li_2CO_3 is formed and the characteristics of a typical Li/MgO catalyst are observed.

Ruckenstein and Khan[93] found that the addition of pairs of alkali metal chlorides to MgO resulted in good oxidative coupling catalysts; the best additive was 5 mol% NaCl + 5 mol% CsCl on MgO. At 750 °C a C_2 yield of 20% and a C_2H_4/C_2H_6 ratio of 2.2 was attained. Because of the higher reaction temperature, there was a modest decrease in C_2 yield with time on stream. Contrary to the results obtained with the Li^+-MgO-Cl^- catalysts, these authors found that the catalysts promoted with alkali metal chlorides adsorbed CO_2 strongly, and therefore were highly basic. The reason for this large difference in basicity is not evident.

5. Cross-Coupling

If one considers cross-coupling, the scope of methane coupling reactions is considerably expanded. Perhaps the most important of these, and certainly the most thoroughly studied, is

the oxidative coupling of methane with toluene to produce ethylbenzene. While in the catalyst bed, a portion of the ethylbenzene is converted into the desired product, styrene. In addition, small amounts of stilbene, biphenyl, propylbenzene, and xylene are also detected. The initial experiments were carried out by Khcheyan, et al.;[94-96] however, other investigators have continued to pursue the problem.[97-100] Many, though not all, of the CH_4 coupling catalysts are effective for this cross-coupling reaction. For example, Sm_2O_3 is a nonselective catalyst, whereas Li/Sm_2O_3 gave a C_8 (ethylbenzene plus styrene) yield of 16.5%, based on the amount of toulene converted.[99] Khan and Ruckenstein[100] found that the same (Na + Cs)/MgO catalyst that was effective in the CH_4 oxidative coupling reaction also produced the largest C_8 yield (24.2%) in the cross-coupling reaction. They concluded that the superior performance of this catalyst was related to its high (super)basicity.

Although most investigators point out that the mechanism involves the coupling of methyl and benzyl radicals, it is not certain whether the reaction occurs on the surface or in the gas phase. Using the MIESR system, we have identified gas-phase benzyl radicals that were formed when toluene and nitrous oxide were passed over a Li/MgO catalyst.[101] The experimental spectrum and a simulated spectrum are compared in Figure 9. In view of the nonselective reaction over Sm_2O_3, it is significant that mainly $CH_3^{\bullet}$ radicals were produced when toluene and oxygen were passed over this catalyst. Apparently, Sm_2O_3 promotes the breaking of the C–C bond, rather than the abstraction of hydrogen from the methyl group.

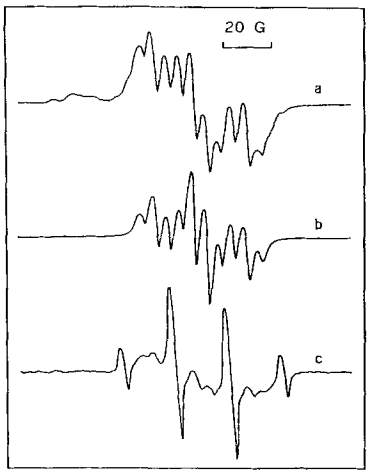

Fig. 9. ESR spectra of gas-phase radicals produced over catalysts: a) experimental spectrum of benzyl radicals formed from toluene over a Li/MgO catalyst, b) simulated spectrum of benzyl radicals, c) experimental spectrum of mainly methyl radicals formed from toluene over a Sm_2O_3 catalyst. Results were obtained with the catalysts at 650 °C in a flow of Ar (4.8 mL min^{-1}), toluene (0.10 mL min^{-1}), and N_2O (0.10 mL min^{-1}), p_{total} = 0.9 Torr [101].

Yet another potentially important cross-coupling reaction occurs when methyl radicals react with allyl radicals formed from propylene. Sodesawa et al.[102] studied the production of C_4 hydrocarbons during the reaction of methane and propylene over several catalysts, including Na/La_2O_3. They concluded that the mechanism involved the oxidative methylation of propylene, followed by the loss of a hydrogen atom. Since the oxidative coupling catalysts are also capable of generating allyl radicals from propylene,[103] it seems more likely that the C_4 products are formed by a radical coupling mechanism. In the allyl radical most of the spin density is on the terminal carbons. Thus it is not surprising that the major C_4 products were linear butenes and butadiene, rather than isobutylene.

6. Summary and Conclusions

Although research on the oxidative coupling of methane has not resulted in a commercial process, it has provided insight into an interesting class of heterogeneous–homogeneous radical reactions. Catalysts have been developed which are capable of generating methyl and other hydrocarbon radicals, but which do not react extensively with these radicals once they are formed. The mechanism for the formation and reactions of these radicals is reasonably well understood; however, less is known about the sites that are responsible for the activation of CH_4 and the hydrocarbon products. The identification of the active forms of surface oxygen on the Group IA and IIA metal oxides remains as one of the significant challenges in this area of research. At a practical level, the oxidation of the desired product, ethylene, must be overcome before larger ethylene yields can be attained. Advances in catalyst development are continuing, but additional research is needed to integrate advanced separation technology with novel reactor designs.

The author is indebted to a large group of graduate students and research associates who contributed significantly to the field of methane oxidation during their time at Texas A & M University. These individuals include K. D. Campbell, S. J. Conway, D. Dissanayake, D. J. Driscoll, M. Hatano, P. G. Hinson, T. Ito, K. C. C. Kharas, C.-H. Lin, W. Martir, E. Morales, C. Shi, Y. Tong, Z. Yu, D. Wang, J.-X. Wang, X. Wang, M. Xu, and H. S. Zhang. In addition, M. P. Rosynek was involved in many aspects of the research. Financial support was provided by the U. S. National Science Foundation and the Gas Research Institute.

Filled Buckyballs: Recent Developments from the Endohedral Metallofullerenes of Lanthanides

Frank T. Edelmann*

Over the past several years, significant progress has been made in the exploration of fullerene chemistry, especially that of C_{60}.[1-7] Multifunctionalized fullerenes and transition metal complexes with fullerenes as ligands have become quite common. The extent to which organic fullerene chemistry has already developed is exemplified by recent reports on fullerene sugars,[8] fullerene dendrimers,[9,10] and fullerene-substituted acetylenic polymers.[11] One of the most unusual classes of fullerene derivatives is endohedral metallofullerenes, $M@C_{2n}$, which have been intensively studied for M = lanthanide.[12] Initial evidence for the existence of carbon cages with encapsulated lanthanide ions was first published in 1985.[13,14] However, it was not until 1991 that a "lanthanofullerene", $La@C_{82}$, could be isolated on a macroscopic scale (i.e. a few milligrams!).[15,16] A more detailed investigation of these fascinating molecules was hindered by limited preparative accessibility and low reaction yields. Furthermore, the isolation of pure samples proved to be a major experimental challenge as no method existed for separating endohedral complexes from concurrently formed "empty" fullerenes. In addition, in contrast to metal-free carbon cages, endohedral metallofullerenes were found to be air-sensitive. Several papers published during the past two years are suggestive of a major breakthrough: Not only has it proven possible to dramatically increase the reaction yield,[17] but new procedures for the chromatographic purification have also been devised.[18,19] At last, a full investigation of the chemistry of lanthanofullerenes appears within reach, and one can even start to consider future applications.

The synthesis of endohedral metallofullerenes of encapsulated lanthanides is in principle identical to that employed for the synthesis of empty carbon cages. Mixtures of graphite and lanthanide oxide are pressed into rods and these are then arc-vaporized in a helium atmosphere. Several metallofullerenes of scandium, yttrium, and lanthanum were produced by this technique; unfortunately, the yields were rather low (approximately 0.1% of the produced soot) and the products were found to be contaminated with metal-free fullerenes.[14-16,20-26] In view of the known pronounced oxophilicity of lanthanides, the main reason for the poor yields might be attributed to the use of lanthanide oxides as starting materials; elements such as oxygen and nitrogen are known to also interfere with the synthesis of empty fullerenes using electric arcs.[27] Thus, all physical measurements such as mass spectrometry, ESR spectroscopy as well as EXAFS, and XPS studies had to be carried out initially on mixtures.

The following compounds were identified by mass spectrometry: $Ln@C_{2n}$ (Ln = Sc, Y, La, Ce, Gd; $n = 37-45$), $Ln_2@C_{80}$ (Ln = Sc, La), $Sc_2@C_{2n}$ ($n = 37, 41, 42$), and $Sc_3@C_{82}$. The relative distribution of products varies with the method of preparation; for example, higher ratios of La:C favor the formation of $La_2@C_{80}$,[22] whereas $La@C_{76}$ could only be detected if the samples were isolated under anaerobic conditions.[23] Little has been reported about the colors of isolated metallofullerenes; solutions of $La@C_{82}$ in toluene have been described as greenish-yellow.[16] From a valence-theoretical viewpoint all products with a caged metal atom can be formulated as $Ln^{3+}@C_{2n}^{3-}$.[20,26,28-33]

Scandium derivatives with encapsulated Sc_2 or even Sc_3 moieties are highly remarkable, but have so far been relatively little studied.[30-32] Scandium preferentially forms endohedral fullerene complexes with two atoms trapped inside the fullerene cage ($Sc_2@C_{74}$, $Sc_2@C_{82}$, and $Sc_2@C_{84}$). Other major species that form during the course of the reaction are $Sc@C_{82}$ and $Sc_3@C_{82}$. ESR spectroscopic studies on $Sc_3@C_{82}$ revealed the presence of an encapsulated Sc_3 molecule in which the three Sc atoms form an an equilateral triangle.[30-32] Isolated metallofullerenes of scandium are soluble in benzene, toluene, and CS_2. Surprisingly, these compounds are air-stable in the solid state.[32]

Bandow et al. showed that significant improvements in the yield could be achieved by doping the graphite rods with lanthanum *carbide* instead of the previously employed lanthanum *oxide*.[17] In the case of $La@C_{82}$ this resulted in a tenfold (ca. 1% of the produced soot!) increase in the yield. In the same study, the authors also employed a newly constructed arc generator that allows for the isolation of lanthanofullerenes under anaerobic conditions. Lanthanofullerenes[29] are generally less air-sensitive than most other organolanthanide complexes:[33] for example, $La@C_{82}$ and $Y@C_{82}$ react only slowly with atmospheric oxygen to give insoluble products.[34]

The best-studied lanthanofullerene, $La@C_{82}$, is soluble in a number of solvents such as toluene, CS_2, and pyridine. High-pressure extraction with toluene has proven to be an especially efficient means of separating insoluble soot.[23] Further enrichment of the metallofullerene fraction can be accomplished by extraction with pyridine.[35] This leads to the second major

problem associated with the isolation of pure lanthanofullerenes, their chromatographic separation and purification. Conventional HPLC techniques are rather demanding when applied to endohedral metallofullerenes and often give pure fractions only after repeated purification steps. The complete separation of empty fullerenes from metallofullerenes is, due to their structural and sterical similarities, barely possible by conventional methods. A method recently developed by Meyerhoff, Francis et al. might provide a solution.[35]

This method has already proven its worth in the separation of polycyclic hydrocarbons.[35, 36] It employs silica-packed HPLC columns in which tetraphenylporphyrin moieties are anchored to the silica surface through carboxyl groups ("CPTPP silica", CPTPP = (*para*-carboxyphenyl)triphenylporphyrin). The tetraphenylporphyrin units are present either as free ligands or as zinc complexes. Using these HPLC columns and with toluene as the mobile phase it was possible to separate $Y@C_{82}$ and $La@C_{82}$ from metal-free fullerenes (C_{60}, C_{70}, C_{76}, C_{78}, C_{82}, and C_{84}) in a single step! The ability of CPTPP silica-gel columns to effect separation of metallofullerenes has been rationalized by Meyerhoff et al. in terms of the three-dimensional interaction between the silica-anchored porphyrin and the fullerenes. As depicted in Figure 1, the four phenyl rings are almost

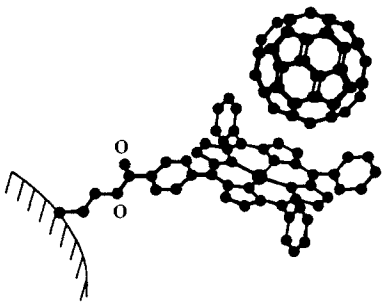

Fig. 1. Interaction between a fullerene (C_{60}) and a silica-anchored zinc(II) tetraphenylporphyrin [35].

perpendicular to the porphyrin ring and form a pocket which can serve as a receptacle for fullerene molecules of up to the size of C_{100}. The formation of C-H π interactions between the fullerene on the one hand and the aromatic rings and the porphyrin system on the other hand provides a plausible explanation for the unusual selectivity of silica-anchored porphyrins for fullerenes and metallofullerenes.

How can one explain the increased retention times of metallofullerenes on CPTPP columns compared to the retention times of metal-free fullerenes of similar size? For example, $La@C_{82}$ has a markedly longer retention time than C_{82}. As previously mentioned, the electronic structure of $La@C_{82}$ can be represented as $La^{3+}@C_{82}^{3-}$. For other lanthanides the transfer of only two electrons from the metal atom to the surrounding carbon framework is conceivable. However, in each case the endohedral metallofullerenes should show a higher π-electron density on the surface than the empty fullerenes. Hence, C–H π interactions with the phenyl rings are strengthened, leading to an increased affinity of the metallofullerenes for the column material and, thus, resulting in longer retention times. The separation is mainly effected by electronic factors and not by size-selectivity of the CPTPP phase.

Another remarkable development in the field of metallofullerenes is the encapsulation of radioactive lanthanide ions in fullerene cages, as recently reported by Kikuchi, Achiba et al.[37] More exactly, this work reports on the encapsulation of nonradioactive lanthanide ions and their subsequent transmutation by neutron activation. In analogy to the yttrium and lanthanum derivatives the novel metallofullerene $Gd@C_{82}$ was first prepared and isolated in pure form by two-stage HPLC. A sample of the crude extract was then irradiated with neutrons (neutron flux: 1.5×10^{12} n cm^{-2} s^{-1}) which by transmutation led to the formation of the isotopes ^{153}Gd, ^{159}Gd, and ^{161}Tb (Scheme 1).

$$^{152}\mathrm{Gd} \xrightarrow{(n,\gamma)} {}^{153}\mathrm{Gd} \xrightarrow[t_{1/2} = 241.6\ \mathrm{d}]{\mathrm{EC}} {}^{153}\mathrm{Tb}$$

$$^{158}\mathrm{Gd} \xrightarrow{(n,\gamma)} {}^{159}\mathrm{Gd} \xrightarrow[t_{1/2} = 18.6\ \mathrm{h}]{\beta^-} {}^{159}\mathrm{Tb}$$

$$^{160}\mathrm{Gd} \xrightarrow{(n,\gamma)} {}^{161}\mathrm{Gd} \xrightarrow[t_{1/2} = 3.2\ \mathrm{min}]{\beta^-} {}^{161}\mathrm{Tb} \xrightarrow[t_{1/2} = 6.90\ \mathrm{d}]{\beta^-} {}^{161}\mathrm{Dy}$$

Scheme 1. Nuclear reactions of Gd isotopes upon neutron activation. EC = electron capture.

Radioactive endohedral metallofullerenes can also be isolated and separated by HPLC. By comparison to normalized solutions the authors were able to show that the C_{82} cage remains intact under the experimental conditions of neutron capture and β decay. These compounds are an unprecedented type of molecular "tracers" with well-defined size and shape. Even though it is still too early to speculate about possible applications, for example in medicine, it is evident that metallofullerenes with encapsulated radioactive metal atoms open up a whole new area of scientific research.

Closely related to fullerenes are the so-called carbon nanotubes.[38, 39] Nanomaterials currently play an ever increasing role in such areas as chemistry, physics, optics, electronics, and material science.[40, 41] Promising applications are found in the manufacture of electronical, optical, and mechanical devices,[40–45] in new methods for the administration of pharmaceuticals,[46] and in the field of bio-encapsulation.[47] Nanotubes are hollow, fiber-like particles with nanometer dimensions. Carbon-based nanotubes are produced in the same way as fullerenes, namely, by arc-vaporization of graphite.[39–41, 48] The nanotubes prepared in this way are generally closed and rounded at the ends. Perfect tubes are expected to comply with Euler's theory, which states that for spherical closure exactly twelve five-membered rings must be present (hence the obvious analogy to fullerenes). Six of these rings should be located at each of the polar caps of these tubes and are thought to be responsible for the observed curvature.[49]

Nanotubes can exhibit considerable structural and electronic variations.[50–57] They can consist of a single or multiple carbon layers and may even exhibit helical symmetry, giving rise to chiral tubes.[49, 54] Single-shell nanotubes typically have diameters of 1–2 nm,[55, 56] whereas multiple-shell tubes are 4–30 nm in diameter, and the tubes can be up to 1 μm in length. It has not yet been possible to control the factors that influence properties such as the number of layers and the tube length. Several tubes

can aggregate to form bundles, threads, or even voluminous nets which cover the inside of the electric arc generator.[57] Depending on the structure, the tubes were found to show semiconducting or metallic conducting properties.[44] Besides tubular arrangements, polyhedral carbon particles with onionlike structure (diameter: 5–20 nm) are also known. Ugarte was able to show that tubes can be transformed into onions by electron bombardment (200 kV).[58] Transmission electron microscopy (TEM) allows for a more detailed characterization of carbon nanotubes. Figure 2 depicts the TEM image of a multilayered tube. The polar caps at the ends and inside the tube are readily discernible.

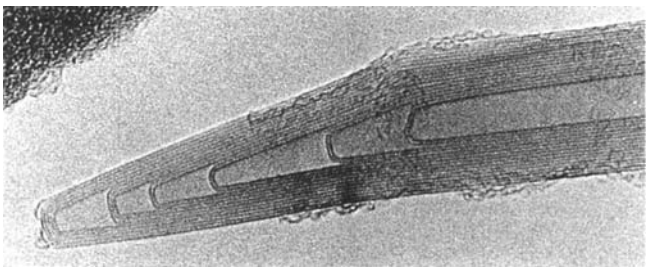

Fig. 2. TEM image of a multi-shell carbon nanotube [70].

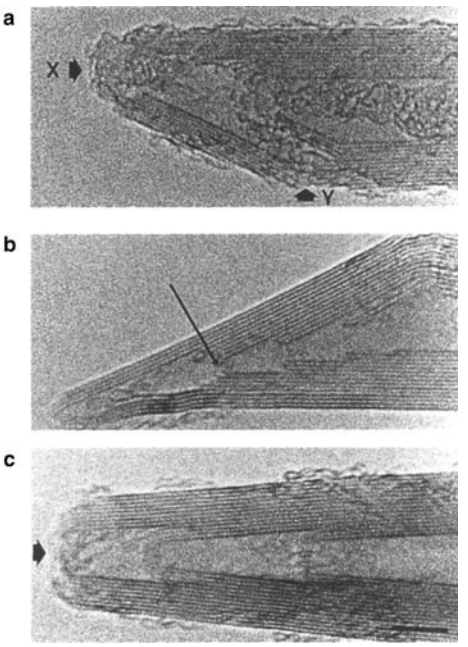

Fig. 3. TEM image of a carbon nanotube after treatment with concentrated nitric acid [70]. a) The attack takes place at positions X and Y; in these positions six-membered rings are not present. b, c) The arrows point to positions where the inside caps of the tubes have been destroyed by treatment with acid.

Macroscopic quantities of carbon nanotubes first became available in 1992.[39] Ever since then researchers have been fascinated by the prospect of opening nanotubes at the ends so as to allow for encapsulation of specific materials in the tubes. Initial experiments met with only limited success. The techniques were either applicable to only a small number of materials or the yields were extremely low. For example, arc-vaporization of metal-doped carbon electrodes resulted in most cases in the formation of free metal carbides as the main product. Only very small amounts of metal or metal carbide were encapsulated in the nanotubes that had concurrently formed.[60–68] In another attempt, nanotubes were heated in air in the presence of molten lead. Closer inspection revealed that under the experimental conditions about 1% of the tubes were opened at the ends and filled with lead. More recently it was found that carbon dioxide[48] or oxygen[69] can selectively oxidize nanotubes at elevated temperatures (ca. 700 °C); the ends of the tubes are removed in these reactions. Again, this procedure only leads to a small amount of uncapped tubes (yield: 2–10%). Also, in oxidative processes such as these the outer carbon layers are attacked, making the resulting tubes thinner and thinner.[48, 69] As an additional complication the nanotubes tend to clog due to the deposition of amorphous carbon.[69]

An extremely simple method to open and fill carbon nanotubes has recently been reported by Green and coworkers.[70a] Uncapped nanotubes were formed in about 80% yield by boiling samples in concentrated nitric acid for 4.5 h at 140 °C. Prolonged heating (24 h) was shown to increase the yield of opened tubes to 90%; however, the formation of amorphous carbon places an upper limit on the reaction time. Figure 3 shows electron micrographs of nanotubes after treatment with nitric acid. Additional studies revealed that the tubes are attacked in places with curvature, that is, those locations where five-membered rings are expected to be present. Interestingly, the caps inside the tubes are also attacked providing particles that are completely open. The high yield of open tubes implies that in most cases opening occurs at both ends.

Filling opened tubes with metals or metal oxides is an amazingly simple process too. Samples containing encapsulated nickel oxide (NiO) (Fig. 4) can be obtained in 60–70% yield (relative to the amount of open nanotubes) by treatment with nitric

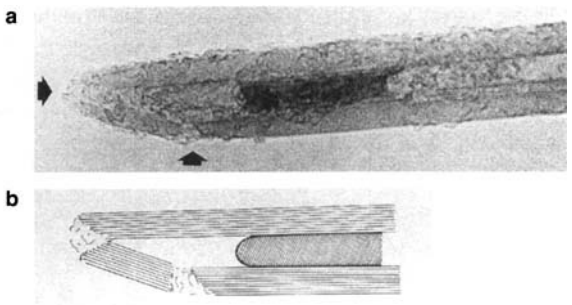

Fig. 4. a) TEM image and b) schematic representation of a nanotube encapsulating NiO [70].

acid in the presence of an aqueous solution of nickel(II) nitrate. NiO crystallites form upon drying and calcination at 450 °C. Most NiO crystallites are typically 10–30 nm long and have diameters of 3–6 nm, and thus almost completely fill the tube cavity wall-to-wall. Incorporation of nickel-containing material in the carbon layers of the tube wall was not observed. The formation of NiO-filled nanotubes can readily be explained by a two-step process: on opening, the tubes fill with a solution of nickel nitrate which upon calcination transforms into crystalline nickel oxide.

The opening and in situ filling of the carbon nanotubes can be easily extended to other metals such as cobalt, iron, and uranium. In another impressive experiment, Green et al. were able to fully reduce the encapsulated metal oxide particles to the corresponding metal (Fe, Co, Ni). Heating the NiO-filled nanotubes to 400 °C for 2 h in a hydrogen atmosphere changed the appearance of the crystallites noticeably. The ends of the particles showed facets typically observed for metal crystals (Fig. 5). This successful production of encapsulated nickel crystals has opened up interesting perspectives for the manufacture of nanomagnets.

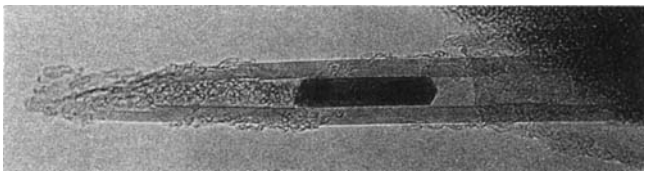

Fig. 5. TEM image of a nanotube after reduction of the encapsulated NiO with hydrogen. The facets are indicative of a nickel single crystal [70].

It should prove possible to extend the approach by Green et al. to other materials. A compelling advantage of this procedure is that the precursors are used directly as aqueous solutions. This work has undoubtedly provided a major thrust to the study of carbon nanotubes.[70b]

The deposition of metals onto the *surface* of carbon nanotubes is another promising area of research. Planeix et al. have recently shown that a novel heterogeneous catalyst is obtained by the deposition of metallic ruthenium onto nanotubes.[71] Tubes with 0.2 wt% of Ru are obtained by treating metal-free nanotubes with a solution of ruthenium acetylacetonate in toluene. The adduct is then dried and the ruthenium is reduced to the metal with hydrogen (3 h, 250 °C). TEM images of this material show the presence of homogeneous ruthenium particles (diameter: 3–7 nm) on the tube surface. These Ru/C nanotubes were shown, for example, to catalyze the hydrogenation of cinnamaldehyde to cinnamyl alcohol (selectivity: 92%). In contrast, a Ru/Al_2O_3 catalyst comprised of ruthenium particles of similar size showed only a selectivity of 20–30%.

Chemical Engineering Dynamics

Modelling with PC Simulation

1994. XX, 701 pages with 430 figures.
Hardcover. DM 276.-/
öS 2153.-/ sFr. 256.-.
ISBN 3-527-28577-6

In this book, the reader is guided through the complex study of dynamic chemical engineering systems by the unique combination of a simplified presentation of the fundamental theory (Part 1) and direct hands-on computer experimentation with the provision of 85 accompanying computer-based simulation examples (Part 2) supplied on diskette.

The ISIM digital simulation language is very simple to use and its powerful interactive nature enables the readers to create their own simulations, based on their own specific problems. This powerful dynamic ISIM software is ready to run on any DOS personal computer.

The treatment employed in this book is well tried and tested, based on over 20 years experience in teaching an international post-experience course. Whether for the teacher, the student, the chemist or engineer, this book serves as the key to a greater understanding of chemical engineering dynamics through the fun and enjoyment of active learning.

Formal Oxidation State versus Partial Charge—A Comment

Martin Kaupp* and Hans Georg von Schnering

In a communication in this journal,[1] Snyder recently claimed that the oxidation state of the copper atom in the square-planar anion $[Cu(CF_3)_4]^-$ is Cu^I, and not Cu^{III} as inferred by Naumann et al.[2] from synthesis and properties, and from structural arguments which up to now have been generally accepted. Snyder based his conclusion on NBO population analysis from ab initio pseudopotential calculations. These gave charges on copper of only $q \approx +1$.

Evidently, there must be a gross misunderstanding. Snyder has confused two important but fundamentally different concepts: the formal oxidation state, and partial charges as obtained, for example, from population analyses. To derive a formal oxidation state, a completely ionic bonding description is chosen deliberately; that is, the bonding electron pairs are assigned exclusively to the more electronegative bonding partner. Thus, if one accepts that the CF_3 ligand is more electronegative than the copper atom, that each CF_3 ligand is bound to the central atom, that there are no additional bonds between the ligands, and that all CF_3 ligands are equivalent, there is no way around an assignment of an oxidation state of III to the copper atom. (An alternative, completely homolytic distribution of the bonding electrons would lead to the unrealistic oxidation state −I.) The validity of none of the above assumptions has been touched in any way by Snyder's calculations.

Snyder's population analysis yields a significant electron population in the $d_{x^2-y^2}$ atomic orbital of copper. This merely tells us that significant covalent interactions contribute to the Cu–C bonds. Therefore, the formal oxidation state III differs appreciably from the calculated partial charge in this case. However, this holds generally true for significantly covalent bonds.

The square-planar structure also clearly supports the original description[2] as a Cu^{III} complex. A four-coordinate Cu^I complex should be tetrahedral. The examples for square-planar Cu^I species erroneously quoted by Snyder turn out to be either obviously Cu^{II} complexes[3] or (slightly distorted) tetrahedrally coordinated systems.[4, 5]

Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State

James P. Snyder*

Since Pauling's introduction of the concept over 40 years ago,[1] assignment of *formal* oxidation numbers and oxidation states has proved to be useful for teaching elementary chemical concepts and for cataloguing trends in the periodic table.[2] Nonetheless, apart from isolated monoatomic ions, designation of a formal oxidation state is entirely arbitrary and often accompanied by assumptions as underscored by Kaupp and von Schnering.[3] Assignment is accomplished by employing one of the many predefined but not entirely consistent electron-counting schemes.[4] Unfortunately, uncritical application of the resulting oxidation values can lead to confusing and physically unrealistic descriptions for organic, organometallic, and inorganic species alike.[5]

The report by Naumann et al.[6] classified the metal in **1** as Cu^{III} and designated it as d^8, suggesting an intimate link between

$[Cu(CF_3)_4]^-$ **1** $[CH_3-Cu-CH_3]^-$ **2**

oxidation state and electron distribution. The critical question concerns the filling of copper's d orbitals in the complex. Partial charges alone are not sufficient to address this issue. Among others, atomic and bond orbital populations not dependent on basis set, as provided by natural population analysis (NPA),[7] provide useful additional tools. Two comparisons place our initial analysis[8] in a broader context.

First, both monoanions **1** and **2** exhibit less than 5% (less than 20%) NPA contribution to the localized Cu–C bonding orbitals at the reported[8] MP2 (SCF) levels. The resulting ionic bonding (greater than 80–95%) implies that the valence electrons reside primarily as pairs either with Cu or CF_3/CH_3. The largely ionic character implies further that it should be possible to assign the metal oxidation state in **1** as readily as for monoatomic ions given knowledge of the electron partition. Examination of the total metal d-orbital populations for anions **1** and **2** illustrates that they are very similar (9.7 (9.4) and 9.6 (9.9) electrons, respectively). Accordingly, copper is ascribed a d^{10} configuration and a *nonformal* Cu^{I} oxidation state in both complexes. The calculated charges and orbital populations at the CF_3/CH_3 ligands are fully consistent.

The second comparison concerns the ability of the NPA analysis to treat complexes in which the metal is unambiguously d^8. The square-planar complexes **3**–**5** were treated analogously to **1** and **2** at the MP2/LANL2DZ level of theory.[9] Total d-orbital populations of 8.8, 8.6, and 8.9 electrons were obtained for **3**, **4**, and **5**, respectively. Ligand electron donation gives rise to the metal d^{8+} constitution.

$[RhCl(PH_3)_3]$ **3** $[Pt(NH_3)_4]^{2+}$ **4** $[Ni(CN)_4]^{2-}$ **5**

One qualitative heuristic explanation for the d^{10} result for **1** is to view it as a combination of two complementary effects. First, the crystal field splitting for Cu^{III} is maximized both by the strong-field effect of CF_3 and by its negative charge.[10] Raised to high energy, the $d_{x^2-y^2}$ orbital experiences the transfer of two electron from the surrounding anionic ligands. Second, the electron-depleted CF_3 moieties are internally stabilized by π-type F–X interaction analogous to that for BF_3,[11] CF_3^+,[12] and other fluorinated cations.[13] MO correlation is an alternative but equivalent interpretation in which the square-planar geometry arises from a stabilizing donor–acceptor interaction between the filled $d_{x^2-y^2}$ of Cu^{I} and the four CF_3 ligands sharing three lone electron pairs.[8]

In conclusion, while a broader examination of the ideas outlined herein is required, novel mechanistic insights are already evident from the above analysis. Furthermore, at the very least it can be expected that square-planar tetracoordinate silver and gold centers in anionic complexes will exhibit electronic properties similar to copper in **1**.[14]

Tetrakis[bis(trimethylsilyl)methyl]dialuminoxane with a Linear Al-O-Al Group**

Werner Uhl, Matthias Koch, Wolfgang Hiller, and Maximilian Heckel*

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

Aluminoxanes[1] of general formula $R_2Al\text{-}O\text{-}AlR_2$ or $(RAlO)_n$ are important as cocatalysts in the polymerization of ethene or propene; the investigation of their properties is an area of current interest in organoaluminum chemistry.[1-3] Whilst tetraalkyldialuminoxanes are usually dimers or trimers, the monoalkyl compounds exhibit oligomeric polyhedral structures, and cages with up to nine RAlO formula units have been identified by crystal structure analysis for *tert*-butyl derivatives. Monomeric dialuminoxanes $R_2Al\text{-}O\text{-}AlR_2$ with only twofold coordination of O atoms and threefold coordination of Al atoms were hitherto unknown. The bonding in their Al-O-Al unit is of particular interest on account of the possible π interaction between the unoccupied p orbitals on Al and the free electron pairs on O. Starting with the corresponding dialuminum(4) compound **1**,[4] we recently synthesized derivatives containing Al-S-Al,[5] Al-Se-Al,[6] and Al-Te-Al fragments,[7] which are monomeric in the solid state because of the high steric shielding by four bulky $CH(SiMe_3)_2$ groups. There are no significant π contributions in these derivatives because of the staggered conformation of the substituents and an angle of between 117 and 110° on the central atom.

Tetraalkyldialuminoxane **2** is produced by the reaction of **1** with the oxygen donors trimethylamine oxide, *N*-sulfinylaniline

(H_5C_6—N=S=O), or DMSO.[8] However, the crystals of **2** so obtained include 10–20% of the μ-hydroxo derivative $R_2Al(\mu\text{-}OH)_2AlR_2$, which has already been synthesized as a pure compound by another method,[9] and which could not be removed by recrystallization of **2**. Because DMSO is easy to handle, it was used as the oxygen donor in the subsequent investigations. Pure **2** can be obtained if the raw product is treated with isobutyllithium which traps the hydroxide.[10] The optimum amount of isobutyllithium is determined by ^1H NMR.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Compound **2** crystallizes as a monomer in the centrosymmetric space group *C2/c*. The oxygen atom lies on a crystallographic inversion center,[11] and the Al-O-Al group is therefore linear. The frequently observed averaging out of two positions that are in reality separate, thus feigning a linear arrangement of symmetrical atomic groups, can be excluded on account of the low anisotropic displacement parameters of the central atom. To date there are only a few compounds known with a monomeric Al-O-Al group; however, in these the oligomerization is prevented by the coordination of a Lewis base to an Al atom. These include linear[2, 12] and bent[13] molecules, without a discernible correlation between Al-O-Al angles and Al-O bond lengths. In adducts of trimethylamine oxide with **2** ($2\cdot Me_3NO$ and $2\cdot 2Me_3NO$)[9] the linearity is lost, and we observe Al-O-Al angles of 162.30° and 161.4°, respectively. In aluminum suboxide, Al_2O, a linear structure was verified both experimentally and theoretically,[14] and also in $H_2Al\text{-}OR$,[15] which has not yet been synthesized, the approximately linear environment of the oxygen atom has been predicted to give an optimal π overlap of Al and O orbitals.

The very short Al–O bond (168.8 pm) is characteristic for the participation of π interactions (p_π–p_π or n–σ^*);[16, 17] the Al–C distances of 195.6 pm are, as in compounds with Al-S-Al or Al-Te-Al units,[5, 7] shorter than those in the starting material **1** (198.2 pm).[4] The Al atoms in **2** project only 0.6 pm out of the plane of the surrounding atoms. As a result of the interaction of both lone pairs of electrons on the oxygen atom with the Al atoms, the valence electron configuration in **2** would be the same as that of allenes, and the substituents in the 1,3 position should be staggered. This conformation was recently observed in $Cp^*_2Sc\text{-}Te\text{-}ScCp^*_2$, which has an almost linear (172°) Sc-Te-Sc group.[18] In diboroxanes the substituents are also staggered; however, in the gas phase and in the solid state the B-O-B angles range from 144 to 166°.[19] As shown in Figure 1, all the substituents on the Al atoms in **2** are coplanar, which is in agreement with the presence of an inversion center. The α-C–H bonds

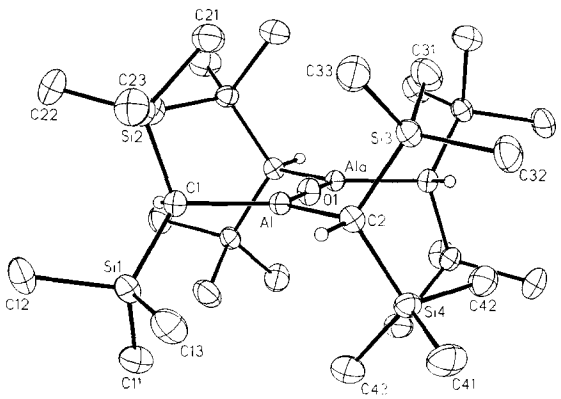

Fig. 1. Molecular structure of **2** in the crystal (vibrational ellipsoids with 40% probability). Only the methine hydrogen atoms are drawn (radius not to scale). The atom Ala is produced by the symmetry operation $-x+0.5, -y+0.5, -z+1$. Selected bond lengths [pm] and angles [°]: Al–O1 168.77(4), Al–C1 195.7(1), Al–C2 195.4(1); Al-O1-Ala 180, O1-Al-C1 117.54(5), O1-Al-C2 119.83(5), C1-Al-C2 122.63(6).

only deviate slightly from the $C_2AlOAlC_2$ plane; each hydrogen atom projects into the space between the two trimethylsilyl groups of the neighboring carbon atom.

The fast rotation about the Al–C bond in solution results in only one NMR signal for the methyl and methine groups. These signals remain virtually unchanged on cooling a solution of **2** in toluene to −80 °C. The methine protons of **2** ($\delta = -0.54$) resonate far upfield from the corresponding protons in the starting material **1** ($\delta = 0.36$), and lie in the range between the values of threefold ($\delta = -0.20$ to -0.45) and fourfold ($\delta < -0.55$) coordinated bis(trimethylsilyl)methylaluminum compounds.[20] The resonance of the C atom bonded to Al ($\delta = 9.0$) also lies at a higher field than that in compounds with Al atoms having threefold coordination (R_2Al-S-AlR_2:[5] $\delta = 16.6$; R_2Al-Te-AlR_2:[7] $\delta = 17.3$); this corresponds to an increase of the charge density on the Al atoms. In analogy to the situation in organoboron compounds (Me_2BOR or Me_2BNR_2),[21] these data possibly verify the participation of a mesomeric structure with Al–O π interactions between the lone pairs of electrons on oxygen and the empty p orbitals on Al.[16]

Experimental Procedure

1 (1.24 g, 1.8 mmol) was dissolved under argon in *n*-hexane (50 mL, freshly distilled over butyllithium) and treated with dimethyl sulfoxide (0.127 mL, 1.8 mmol, distilled over BaO) at room temperature with vigorous stirring. After about 30 min the solution had completely decolorized. The volume of the solution was reduced by half (in vacuo) and the optimal amount of isobutyllithium added (experimentally predetermined; here: 0.84 mL (0.72 mmol) of a 0.857 M solution in *n*-pentane). Colorless crystals of **2** were obtained on cooling to −50 °C. Yield: 0.95 g (75%). M.p. (under Ar): 173 °C; M_r (cryoscopically determined in benzene) [g mol^{-1}]: found 683, calcd 707.6. ^{1}H NMR (C_6D_6): $\delta = 0.30$ (72 H, $SiMe_3$), −0.54 (4 H, AlCH); ^{13}C NMR (C_6D_6): $\delta = 9.0$ (AlC), 4.8 ($SiMe_3$). IR (Nujol, CsBr plates): $\tilde{\nu}$ [cm^{-1}] = 1262 s, 1248 s δCH_3; 1017 s δCH; 930 m, 909 m, 843 vs, 777 s, 756 s, 748 s, 731 m ρCH_3(Si); 704 w, 687 m, 673 s ν_{as}SiC; 642 w, 611 w ν_sSiC; 559 vw, 534 w, 500 w νAlC; 376 vw, 339 vw, 316 vw δSiC; ν_{as}AlO probably lies hidden under the ρCH_3 absorptions.

[8] Compound **1** does not react with a stoichiometric amount of oxygen, whilst excess oxygen destroys the starting material. Bis(trimethylsilyl)peroxide, dinitrogen monoxide, and cyclohexene oxide do not react with **1**; benzophenone and trialkylphosphane oxide gave indeterminate product mixtures. We also attempted to synthesize **2** from the corresponding dialkylaluminum chloride R_2Al-Cl with Ag_2O, Li_2O, hexamethyldisiloxane, and R_2Al-O-$SiMe_3$ [9] but there was no reaction, even in a melt.

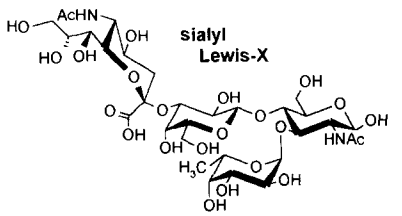
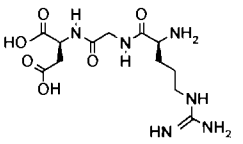
Synthesis of an RGD-Sialyl-Lewis^X Glycoconjugate: A New Highly Active Ligand for P-Selectin**

Ulrich Sprengard, Gerhard Kretzschmar,* Eckart Bartnik, Christoph Hüls, and Horst Kunz*



Dedicated to Professor Richard R. Schmidt on the occasion of his 60th birthday



The circulation of blood cells such as leucocytes, neutrophils, granulocytes, and monocytes is a multistep, complex process at the molecular level, and only some steps are known.[1] Current research results show that the molecular mechanism of lymphocyte circulation, which is vital for immune control, and the mechanism of localization of neutrophils and monocytes at sites of inflammation are very similar. During acute and chronic inflammation processes this leads to adhesion of leucocytes to endothelial cells, and to migration to the site of inflammation or to the secondary lymphatic organs.

Many specific signaling molecules, such as interleukins, leukotrienes, tumor necrosis factor (TNF-α), and especially tissue-specific adhesion molecules, are involved in these process-

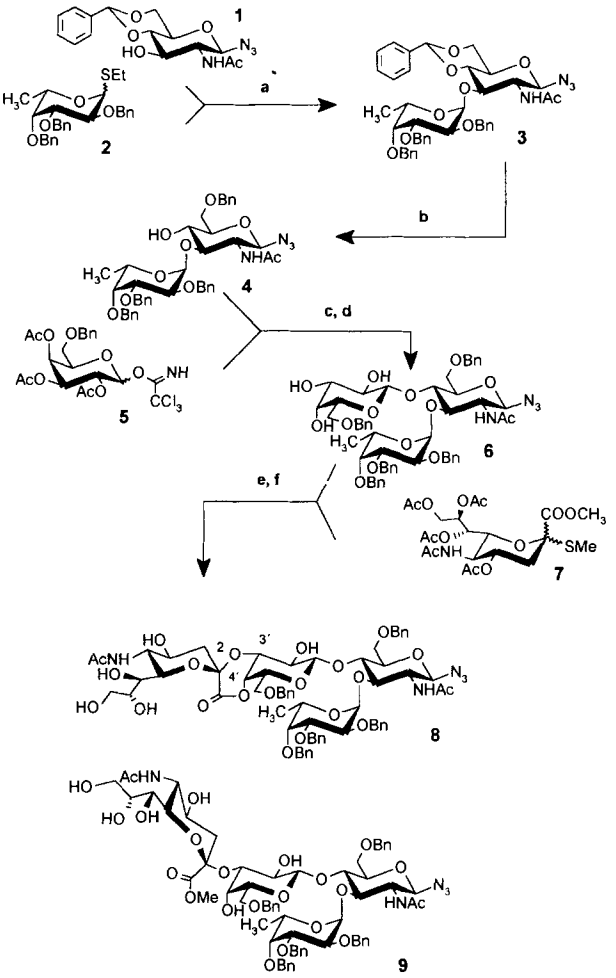
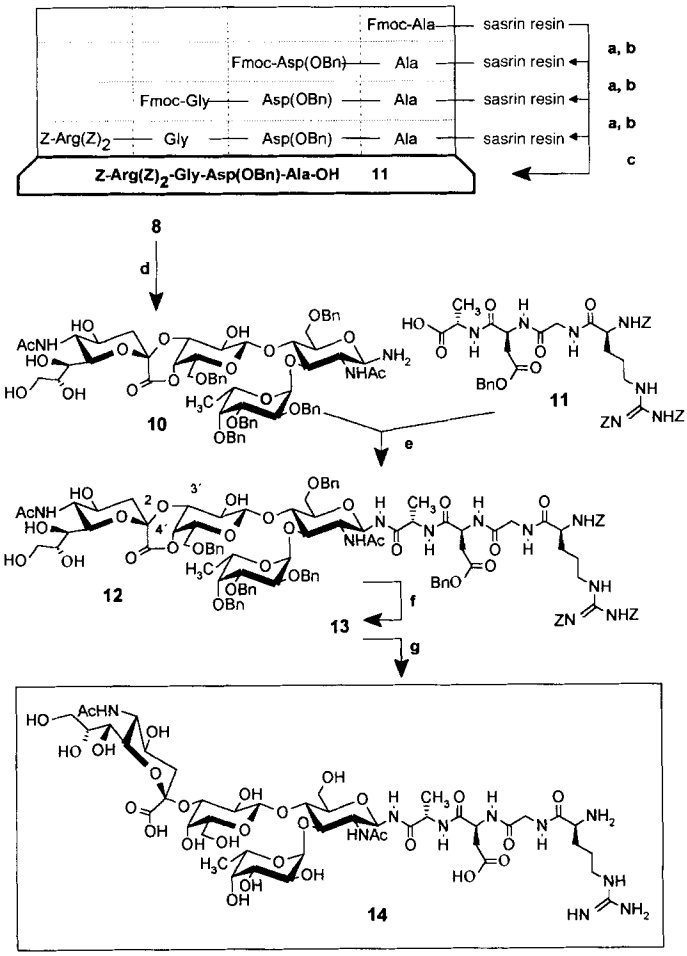
es and are recognized by receptors. In addition to integrins and glycoproteins of the immunoglobulin superfamily, the selectins (E-, P- and L-selectin)[2] are amongst the most important adhe-



sion molecules, playing a vital role in the initial phases of leucocyte adhesion. It is generally recognized that the tetrasaccharide sialyl Lewis^X,[3] which occurs as a partial structure of glycosphingolipids and glycoproteins on cell membranes, functions as a ligand with a weak affinity for all three selectins in cell culture assays.[4]

The tripeptide Arg-Gly-Asp (RGD) corresponds to the minimal sequence of many adhesion molecules, including the α-chain of fibrinogen that binds to integrin receptor GpIIb/IIIa, and it frequently serves as a model structure for antiadhesive peptide mimetics.[5] However, no peptido- or glycomimetics are known that bind with a high affinity to selectins. Here we describe the synthesis of the adhesion hybrid **14**, which combines the structural elements of the RGD motif with those of the sialyl Lewis^X ligand and is a highly active ligand for P-selectin in cell assays. During the synthesis of **14**, a partially blocked sialyl Lewis^X unit is produced on a multigram scale through a coordinated protective-group strategy, and this is finally converted into **14** by using the presynthesized peptide:[6] a) The azido functional group acts as an anomeric protective group for the glucosamine unit during the saccharide synthesis. It can be selectively reduced to the β-glycosylamine. b) Condensation of only partially O-protected oligosaccharide amines with C-terminal deblocked peptides enables an efficient synthesis of the conjugate, whereby the anomeric amino groups are selectively acylated in the presence of free OH functions by modern peptide chemistry linkage methods. c) The lactone of neuraminic acid **8** is used as an internal protective group to mask the carboxyl function, which renders blocking of the methyl ester superfluous. d) The coordinated protective-group protocol enables mild terminal deblocking of the glycopeptide by catalytic hydrogenation.



Glycosylation of the 4,6-(benzylidene)-protected *N*-acetylglucosaminylazide **1**[7, 8] with the perbenzylated thiofucoside **2** and tetrabutylammonium bromide/copper (II) bromide[9] stereoselectively produces α-glycoside **3** (Scheme 1) with 92% yield. Regioselective opening of the benzylidene acetal ring is achieved with sodium cyanoborohydride/HCl.[10] However, the yield of 81% is only obtained by titrimetric addition of HCl in ether, because of the acid lability of the fucose. Linkage of the disaccharide **4** with the galactosyl trichloracetimidate **5**[11] on the sluggishly reactive, sterically hindered 4-OH function followed by Zemplen hydrolysis produces β-glycoside **6** in 44% yield. Because of the acetamide group a large amount of Lewis acid is required, which promotes side reactions. Alternatively, trisaccharide **6** can be synthesized with a yield of 16% from **4** and methylthiogalactoside with *N*-iodosuccinimide (NIS)/trifluoromethanesulfonic acid (TfOH). Following deacetylation, the Lewis^X trisaccharide **6** can be derivatized at the galactose unit. Sialylation is performed with the methylthioglycoside of neuraminic acid **7**[12] (1.8 equiv) at -40°C in dichloromethane/acetonitrile, in the presence of methylsulfenyl bromide (MSB)/silver

Scheme 1. a) **2** (1.4 equiv), $Bu_4NBr/CuBr_2$, CH_2Cl_2/DMF (1:1), molecular sieve 3 Å, **3**: 92%; b) $NaCNBH_3$, HCl/Et_2O, molecular sieve 4 Å, **4**: 81%; c),d) **5** (1.5 equiv), TMSOTf (0.15 equiv), CH_2Cl_2; $NaOCH_3$ in MeOH, Amberlite IR 120, **6**: 44%; e),f) MSB/AgOTf, CH_2Cl_2/CH_3CN (5:1), molecular sieves 3 Å, -40°C; $NaOCH_3$ in MeOH, Amberlite H^+ IR 120, **8**: 42% relative to **6**.

trifluoromethanesulfonate as promoter.[13, 14] The sialylation products can be separated chromatographically following deacetylation of the crude products on a multigram scale, and the unconverted trisaccharide can be recovered. The partially deblocked sialyl Lewis^X **8** is formed by intramolecular esterification to give the 1-4′-lactone and can be isolated as the main product with a yield of 42% (based on **6**).[15] The 1-2′-lactone and the methyl ester **9** of the tetrasaccharide can only be detected in trace amounts.[16] The lactone remains as an internal protective group to mask the carboxyl function during subsequent synthesis of the saccharide–peptide conjugate. It can be hydrolyzed using mild conditions, which reduces the risk of racemization during subsequent deblocking.[14, 17, 18] Hydrogenation of the anomeric azide over neutral, washed Raney nickel in isopropyl alcohol/water (9:1) produces the sialyl Lewis^X amine unit **10** (Scheme 2).[19] Alternative methods in which the glycosyl amine is generated from the anomeric unprotected oligosaccharide often lead to salt-containing products.[20]

The second synthetic unit, the RGDA peptide in the form of the C-terminal deblocked Z-Arg (Z_2)-Gly-Asp(OBn)-Ala-OH **11**, is synthesized using the Fmoc solid-phase strategy[21] on acid-labile sasrin resin (Scheme 2).[22] Fragment condensation of the sialyl Lewis^X amine unit **10** with the RGDA peptide **11** using TBTU/HOBT/DIPEA[23] produces the *N*-glycosyl-

Scheme 2. a) 20% piperidine in DMF; b) 3 equiv amino acid, TBTU/HOBT/DIPEA 3 equiv each, DMF; c) 1% TFA in CH_2Cl_2, yield after cleavage from sasrin resin and purification: 49%; d) Raney nickel (neutral washed), 2-propanol (10% H_2O), 1 h, 95%; e) **11** (1.25 equiv), TBTU/HOBT/DIPEA (3:1.25:0.25 equiv), DMF, **12**: 65%; f) H_2, Pd on activated charcoal, methanol/dioxane/acetic acid (2:1:1); g) NaOH in methanol/water pH 10, Amberlite H^+ IR 120, **14**: 66%.

RGDA conjugate **12** in 65% yield.[24] This process enables complex saccharide–peptide conjugates to be accessed whilst the 4′-lactone is maintained as a stable internal protective group for neuraminic acid derivatives. Hydrogenolytic cleavage of the benzyl ether groups over Pd/C to give the 4′-lactone **13**[25] is followed by lactone opening by mild hydrolysis with sodium hydroxide solution. The sialyl-Lewis^X-RGDA glycopeptide **14** was purified by gel chromatography on Biogel P2 and characterized by NMR spectra and FAB mass spectra.[26]

In a cell adhesion test in which competitive binding of **14** was measured on recombinant human P-selectin-immunoglobulin fusion proteins (P-selectin-IgG)[27] relative to tumor cells (HL 60), **14** proved to be the most active synthetic ligand in this test system to date[28], with an IC_{50} value of 26 μM. Three alternative recognition models are discussed for the binding of carbohydrate ligands to selectins.[2] In the Carbohydrate Recognition Model, discrete saccharide structures are assumed to be recognition regions. The Cluster Model assumes that polyvalent carbohydrate clusters are ligands, which bind to neighboring selectins with high avidity. For glycoproteins, the binding epitope can be made up of a carbohydrate and a protein portion, which is considered in the Carbohydrate Protein Recognition Model. The IC_{50} value in the submillimolar region observed for **14** relative to P-selectin suggests the involvement of the N-glycosidically linked peptide in the binding of sialyl Lewis^X to P-selectin. Investigation of further variants of glycopeptide ligands should lead to even more active and selective inhibitors of leucocyte adhesion.

Synthesis and Structure of Tetra- and Octanuclear Chelate Complexes—Exohedral Guest Exchange in Tetrahemispheraplexes **

Rolf W. Saalfrank,* Roman Burak, Stefan Reihs, Norbert Löw, Frank Hampel, Hans-Dietrich Stachel, Jochen Lentmaier, Karl Peters, Eva-Maria Peters, and Hans Georg von Schnering

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

Biomimetic processes have gained significance over the past few years. One of the topics with relevance to this field is that of tailor-made host compounds, which in solution selectively bind complementary guest molecules or incorporate them in concave cavities, similar to biological receptors or enzymes. In the process, host–guest complexes that depend on the formation of ion pairs or on hydrogen bonding require a smaller conformational adjustment of the receptor (induced fit) than systems that are based on van der Waals or charge-transfer interactions between π-electron donors and π-electron acceptors. In addition to studies of the special bonding between host and guest, the specific catalytic properties that characterize these systems as synthetic enzymes are of particular interest.[1]

Tetranuclear adamantanoid chelate complexes are well suited to be tetrahemispherands. The complexes $[(Mg_4L_6^1 \cap (4NH_4)]$ (**1**) and $[(Co_4L_6^1 \cap (4NH_4)]$ (**3**) are not salts in the usual sense, but tetrahemispheraplexes. This is confirmed pictorially by the crystal structure of **3**:[2] The four imaginary tetrahedral surfaces of the tetranuclear adamantanoid framework of **3** are not planar, but each form a half shell. In the center of each shell are three keto oxygen atoms in ideal positions to bind an ammonium ion through three hydrogen bonds (Fig. 1). The length of the hydrogen bonds range from 1.928 to 2.021 Å.

We were then interested in replacing the four exohedrally bound ammonium ions in **1** by alkylammonium groups to influence the physical and chemical properties of the "spherical surface" in $[(Mg_4L_6^1 \cap (4H_3NR)]$ (**2**). The exchange of the ammonium in **1** for alkylammonium to form the new tetrahemispheraplexes **2** (yield: 70–90%, see experimental section) is achieved by addition of alkylamines **4** in excess. Ammonia is set free. The assumption that no structural change takes place on exchange

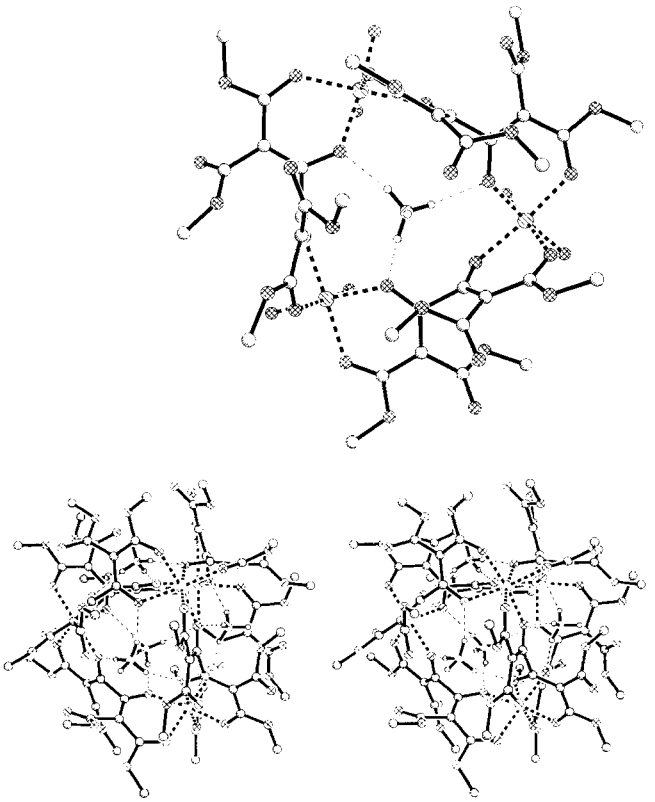

Fig. 1. Top: View into a concave half-shell of **3** with an ammonium ion held in the center by hydrogen bonds (thin dashed lines) to three keto oxygen atoms in ideal geometric positions. For clarity only one "tetrahedral face" with three cobalt ions is represented, and the H atoms have been omitted. Bottom: Stereoview of **3** (H atoms of the ligands omitted; O atoms: ⊗; N atoms: ⊘; H atoms of the NH_4^+ ion: ○.

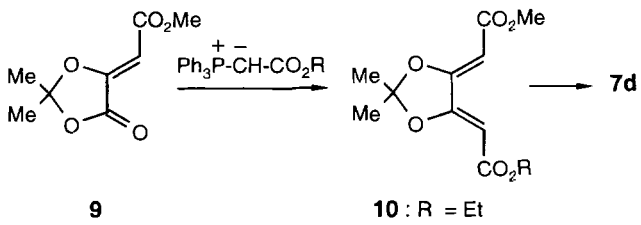
[**] "Adamantanoid" Chelate Complexes, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. F. Vögtle and Dr. S. Schuth, University of Bonn, Prof. Dr. K.-P. Zeller, University of Tübingen, and Dr. R. Fröbe, University of München, for the FAB mass spectra. Part 4: [3].

of the four ammonium ions in **1** for four alkylammonium groups in the formation of **2** is clearly confirmed by the NMR data of **2**. For example, the ^1H and ^{13}C NMR spectra of **2b** and **1** are virtually superimposable, except for the additional signals that are attributable to the pentyl groups in **2b**. The explanation is that the two compounds have the same chelate (4−) ions that show only two ^1H and six ^{13}C NMR signals on account of the high molecular symmetry (T in an idealized view). A characteristic difference between free and bound pentylammonium is the appearance of two multiplets at $\delta = 2.74$ and 2.45 for the two α-aminomethylene protons, since these protons become diastereotopic when the pentylammonium guest is fixed to the chiral chelate framework and therefore form an AB system.



However, reaction of **1** with 1,ω-diaminoalkanes instead of primary alkylamines yields microcrystalline products, which are virtually insoluble in common organic solvents and which are also tetrahemispheraplexes according to solid-state NMR studies. The microanalysis of these complexes proves that the ratio of host to guest is exactly 1:2. This finding indicates the formation of three-dimensional, diamandoid polymers in which the tetranuclear chelate (4−) ions serve as bridgeheads.

The tetrahemispheraplexes **1**–**3** and the mixed-valent endoreceptor complex $[NH_4 \subset Fe_4L_6^1]$ **(5)**[3] are interesting from the point of view of their cage architecture as well as their electrochemistry. We therefore intended to tune both the structure and the properties of the anticipated tetranuclear chelate complexes by varying the ligands. The one-pot process with the *intermolecular* coupling of two malonate anions through oxalyl chloride as key step which allowed the synthesis of the complexes **1**, **3**, and **5** could not be extended to acetylacetonate. We did not succeed in linking two acetylacetonate ions *intermolecularly* with oxalyl chloride to form the required bridging ligand. In general with 1,3-diketones and oxalyl chloride in the presence of catalytic amounts of magnesium chloride we obtained furan-2,3-diones through *intramolecular* ring closure.[4] Consequently we changed our synthesis strategy for the construction of tetranuclear chelate complexes. The required bis(bidentate) chelate ligand has now been generated directly from the tetramethyl 2,2′-terephthaloyldimalonate by double deprotonation with sodium hydride. This chelate ligand forms the spacer complex $[Fe_4L_6^2]$ **(6)**[5] with iron(III) chloride solution.

Our attempts to prepare spacer-free tetranuclear systems of the type **1**–**3** and **5** analogously starting from the ketipinic acid esters **7a**–**c**,[6] have so far remained unsuccessful. Instead, after workup we obtained colorless (**8a, c**) or yellow (**8b**) crystals on treatment of the dialkyl ketipinate **7** with aqueous ammonia and cadmium chloride solution. According to the microanalysis and FAB-MS data (FAB = fast atom bombardment), the resulting products **8** are octanuclear cadmium chelate complexes of the composition $[Cd_8L_8^3] \cdot 4H_2O$ (see experimental section).

The ^1H and ^{13}C NMR spectra of **8** (S_4 symmetry, **8a**: nine ^1H and sixteen ^{13}C NMR signals) indicate that in each case four ligands in these complexes are identical. The two halves of each ligand are in different magnetic environments. For an unambiguous characterization of **8** we tried to grow crystals suitable for X-ray analysis. This was unsuccessful for **8a**–**c**.[7] To obtain a crystal structure nevertheless, based on more favorable packing effects, we synthesized the C_s-symmetric, mixed ethyl methyl ketipinate (**7d**) from 1,3-dioxolane (**9**)[8] and ethoxycarbonylmethylenetriphenylphosphorane via the ketipinic acid derivative **10** and thus prepared the corresponding octanuclear complex **8d**.

It is remarkable that from the resulting mixture of isomers (see experimental section) one pure isomer could be obtained as single crystals suitable for X-ray analysis.[9] The results show that isomer **8d** exists as tetrahydrate $[Cd_8L_8^3] \cdot 4H_2O$ in the crystal (Fig. 2). Of the eight cadmium ions, four are crystallographically identical and form the corners of two squares of different sizes, which have the same center. The smaller square is turned 45° relative to the larger one. The four outer cadmium ions are linked in a μ_1 fashion through the two ester carbonyl

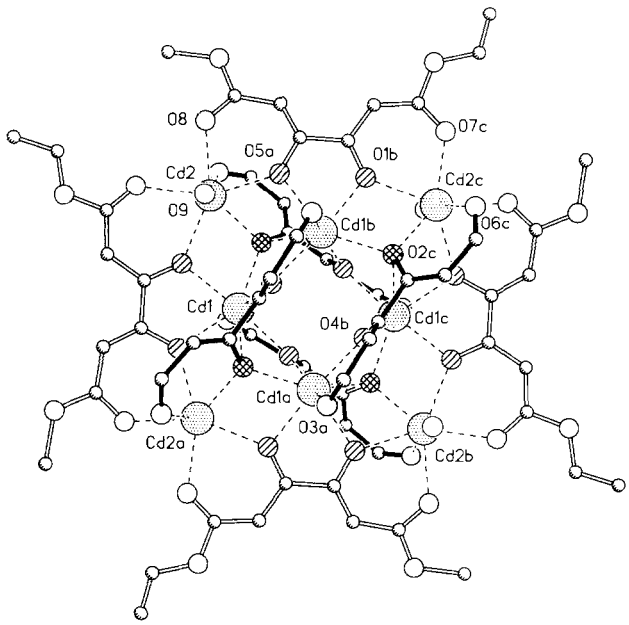


Fig. 2. Structure of **8d** in the crystal. View along the crystallographic S_4 axis: μ_1-bound ester carbonyl atoms empty, μ_2-bound keto oxygen atoms hatched, μ_3-bound oxygen atoms double hatched, cadmium ions dotted. For clarity the H atoms were omitted and the methoxy and ethoxy groups included only on the ligands lying in the illustrated plane.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-0994 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 9

oxygen atoms of a set of four ketipinic acid diester dianions, which lie almost in a plane (E^1). The two keto oxygen atoms of these four ligands are μ_2-bound and bridge inner and outer cadmium ions. Furthermore, a water molecule is coordinated to each of the four outer cadmium ions alternately above and below E^1. In two sets of parallel planes above and below E^1 and perpendicular to it lie four ligands, which are shifted pairwise relative to each other such that $[(E^2 \parallel E^3) \perp (E^4 \parallel E^5)]$. These four ketipinic acid diester dianions are each bound in a μ_1 fashion through the ester carbonyl oxygen atoms to one outer and one inner cadmium ion. One of the keto oxygen atoms forms a μ_2 bridge between two inner cadmium ions, and the other a μ_3 bridge to two inner and an outer cadmium ion. Thus all eight cadmium ions are sevenfold coordinated.

Cadmium is one of the physiologically important metals whose ions, for example, stimulate a reactivation of latent *Herpes simplex* viruses.[10] Suitable chelate-forming species could block this effect.

Experimental Procedure

2: General procedure: An excess of amine **4** (**4a**: 6 mmol (0.35 g); **4b**, **c**: 3 mmol (0.26 g, 0.56 g)) was added to a solution of **1** (0.5 mmol, 1.03 g) [2] in dichloromethane (50 mL) and stirred for 5 h at about 40 °C. The volatile components were removed in a rotary evaporator (30 °C, water-jet vacuum). The unchanged remainder of the amines **4a**, **b** evaporated without leaving any residue. Amine **4c** was removed by washing three times with 50 mL portions of diethyl ether. The crude product was recrystallized from chloroform/hexane (1:1) and dried under vacuum (oil pump). All new compounds gave correct elemental analyses. However, no interpretable FAB mass spectra have yet been recorded for **2a**–**c**. – **2a**: yield: 0.86 g (78%) colorless microcrystals; decomp. above 166 °C; IR ($CHBr_3$): $\tilde{\nu} = 1710\ cm^{-1}$ (C=O), 1650 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.87$ (br., 8H; NH_3), 7.68 (br., 4H; NH_3), 3.79, 3.55 (s, each 36H, OCH_3), 2.66, 2.43 (m, 4H, NCH_A; NCH_B), 1.30 (m, 8H; CH_2), 0.56 (m, 12H, CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 184.3$, 170.9, 167.2 (24 C=O, 12 C=O), 95.3 (12 =C), 52.0, 51.2 (24 OCH_3), 42.7 (4 NCH_2), 20.0 (4 CH_2), 11.1 (4 CH_3). – **2b**: yield: 1.08 g (92%) colorless microcrystals; Decomp. above 181 °C; IR ($CHBr_3$): $\tilde{\nu} = 1710\ cm^{-1}$ (C=O), 1640 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.69$ (br., 12H; NH_3), 3.78, 3.59 (s, each 36H; OCH_3), 2.74, 2.45 (m, 4H; NCH_A, NCH_B), 1.31, 1.04, 0.91 (m, each 8H; CH_2), 0.75 (t, 12H; CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 184.4$, 170.9, 167.2 (24 C=O, 12 C=O), 95.4 (12=C), 51.9, 51.2 (24 OCH_3), 41.6 (4 NCH_2), 29.0, 25.9, 21.6 (12 CH_2), 13.7 (4 CH_3). – **2c**: yield: 0.87 g (68%) colorless microcrystals; Decomp. above 197 °C; IR ($CHBr_3$): $\tilde{\nu} = 1690\ cm^{-1}$ (C=O), 1630 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.68$ (br., 12H; NH_3), 3.78, 3.55 (s, each 36H; OCH_3), 2.73, 2.45 (m, 4H; NCH_A, NCH_B), 1.29–0.99 (m, 80H; CH_2), 0.87 (t, 12H; CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 184.4$, 170.8, 167.3 (24 C=O, 12 C=O), 95.3 (12 =C), 52.0, 51.2 (24 OCH_3), 41.5 (4 NCH_2), 31.9, 29.7, 29.6, 29.4, 29.3, 28.7, 26.9, 26.3, 22.7 (36 of 40 CH_2, two signals per alkylamino group overlap), 14.1 (4 CH_3).

7: **7a**–**c** according to ref. [6]. **7d**: **10** (2 mmol) was stirred in conc. H_2SO_4 (5 mL) for 1 h at room temperature. The solution was then diluted with diethyl ether (100 mL) and stirred into 100 mL of water. The organic phase was separated, washed several times with water, and dried over sodium sulfate. The solvent was removed under vacuum. yield: 0.15 g (35%) colorless crystals (from diethyl ether); M.p. 77 °C; IR (KBr): $\tilde{\nu} = 1646\ cm^{-1}$ (C=O); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 11.66$, 11.57 (s, each 1H; OH), 5.30 (s, 2H; =CH), 4.19 (q, $^3J(H,H) = 7$ Hz, 2H; OCH_2), 3.75 (s, 3H; OCH_3), 1.25 (t, $^3J(H,H) = 7$ Hz, 3H; CH_3); EI-MS (70 eV): $m/z = 216\ [M^+]$.

8: General procedure: Aqueous ammonia (12%) was added dropwise to a solution of cadmium chloride (0.5 mmol, 92 mg) and the appropriate dialkyl ketipinate **7a**–**d** (0.5 mmol) in ethanol (1:1, 100 mL) until no more turbidity formed. The precipitates were filtered off, dried under vacuum (oil pump), and recrystallized from hot methanol (**8a**) or ethanol (**8b**–**d**). yield: 133 mg (83%) colorless needles; Decomp. above 220 °C; IR (KBr): $\tilde{\nu} = 3400\ cm^{-1}$ (OH), 1640 (C=O), 1620 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.44$, 5.32, 5.10, 4.94 (s, each 4H, =CH), 3.75, 3.73, 3.57, 3.46 (s, each 12H, OCH_3), 1.88 (s, 8H; H_2O); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 177.66$, 175.17, 175.10, 174.26, 173.89, 173.20, 172.74 (32 C=O, two signals overlap), 87.82, 87.73, 84.42, 83.35 (16 =CH), 51.52, 50.79, 50.68, 50.43 (16 OCH_3); FAB-MS (3-nitrobenzyl alcohol matrix = *m*-NBA): m/z 2500 $[Cd_8L_8^{3a}]$.

8b: yield: 145 mg (83%) yellow crystals; Decomp. above 210 °C; IR (KBr): $\tilde{\nu} = 3400\ cm^{-1}$ (OH), 1630 (C=O), 1620 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.43$, 5.30, 5.10, 4.95 (s, each 4H; =CH), 4.27–4.07 (m, 8H; OCH_2) [11], 4.21 (q, $^3J(H,H) = 6.9$ Hz, 8H; OH_2) [12], 4.07–3.94 (m, 8H; OCH_2) [11], 3.80 (q, $^3J(H,H) = 7.2$ Hz, 8H; OCH_2) [12], 2.47 (br. s, 8H; H_2O), 1.39, 1.28, 1.19, 1.11 (t, each 12H, CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 177.99$, 177.06, 175.21, 174.26, 173.84, 173.16, 172.47 (32 C=O, two signals overlap), 88.74, 88.34, 84.92, 83.75 (16 =CH), 59.96, 59.60, 59.38, 59.27 (16 OCH_2), 14.63, 14.54, 14.32, 14.20 (16 CH_3); FAB-MS (*m*-NBA): m/z 2724 $[Cd_8L_8^{3b}]$. – **8c**: yield: 126 mg (62%) colorless microcrystals; Decomp. above 230 °C; IR (KBr): $\tilde{\nu} = 3450\ cm^{-1}$ (OH), 1645 (C=O), 1635 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.75$, 5.40, 5.25, 5.10 (s, each 4H, =CH), 2.36 (br. s, 8H; H_2O), 1.58, 1.44, 1.32, 1.26 (s, each 36H; CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 177.38$, 177.13, 175.37; 173.97, 173.87, 173.51, 173.27, 172.56 (32 C=O), 90.09, 89.83, 85.91, 85.12 (16 =CH), 79.95, 79.36, 78.78, 78.51 (16 O–C), 28.68, 28.30, 28.21, 28.12 (48 CH_3); FAB-MS (*m*-NBA): m/z 3173 $[Cd_8L_8^{3c}]$. – **8d**: Only as single crystal from ethanol was **8d** obtained isomerically pure. The following data refer to a mixture of isomers. yield: 111 mg (66%) colorless microcrystals; Decomp. above 208 °C; IR (KBr): $\tilde{\nu} = 3445\ cm^{-1}$ (OH), 1652 (C=O), 1636 (C=C); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.45–4.90$ (m, 16H; =CH), 4.22–3.90 (m, 16H; OCH_2), 3.74–3.45 (m, 24H; OCH_3), 1.74 (br. s, 8H; H_2O), 1.31–1.10 (m, 24H; CH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 178.46$, 178.42, 178.17, 178.08, 177.22, 177.18, 177.04, 175.26, 175.14, 174.39, 174.30, 174.09, 173.75, 173.42, 173.05, 172.92, 172.63, 172.29 (C=O), 88.43, 88.37, 88.30, 88.17, 87.70, 84.85, 84.61, 84.42, 84.35, 83.68, 83.51, 83.29 (=CH), 59.98, 59.60, 59.30 (OCH_2), 51.41, 50.83, 50.66, 50.39 (OCH_3), 14.71, 14.65, 14.62, 14.54, 14.49, 14.30, 14.21 (CH_3); FAB-MS (*m*-NBA): m/z 2612 $[Cd_8L_8^{3d}]$.

10: **9** (9.3 g, 0.05 mol) [8] was heated for 24 h with ethoxycarbonylmethylenetriphenylphosphorane (0.15 mol) in xylene (100 mL) under reflux. Synthesis and Structural Characterization of a Stereospecific Dinuclear Gallium Triple Helix: Use of the *trans*-Influence in Metal-Assisted Self-Assembly

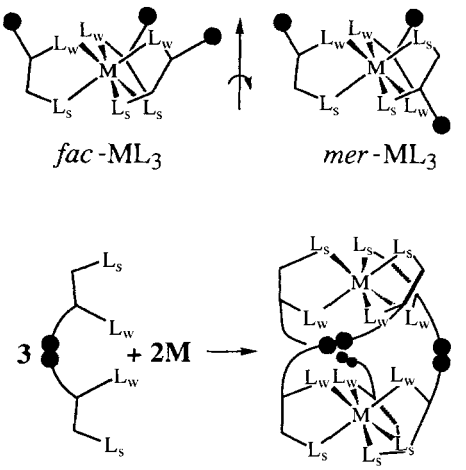
Eric J. Enemark and T. D. P. Stack*

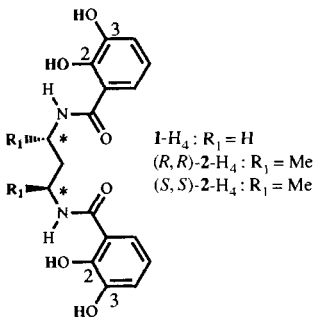


A great interest exists in metal-assisted self-assembly of helical supramolecular complexes because of the prevalence of this structural motif in nature and the cooperative behavior in such systems.[1, 2] The most successful and efficient systems have relied on a labile metal center and well-designed, semi-rigid, polynucleating ligands.[3–6] The lability of the metal allows a system to readily achieve the most thermodynamically stable state, while ligand design is necessary to exploit the stereochemical preferences of such metals to align the organic fragments in a self-complementing framework. Entropy provides a principle driving force to discrete complexes, which maximize the number of particles.

Though supramolecular helical complexes are intrinsically chiral, most investigations have focused on racemic mixtures because of the achiral nature of the polynucleating ligands and the lability of the metals used in their assembly.[7–9] Stereospecific triple[10–12] and double[13] helices have been obtained from labile metals either by the use of enantiomerically pure ligands[10, 13] or by spontaneous resolution during crystallization.[11, 12] The former approach provides additional energetic differentiation between products that would not be possible under racemic or achiral conditions.[13]

To date, most of the ligating subunits used in metal-assisted self-assembling systems have been effectively electronically symmetric, aromatic nitrogenous ligands.[3, 4, 6, 14] Electronic asymmetry within bidentate ligating subunits can potentially provide additional enthalpic drive to discrete, dinuclear triple-helical species. This enhanced thermodynamic bias results from an electronic organizational preference of ligating atoms on an octahedral metal, a phenomenon known as the *trans*-influence.[15] Assuming no steric constraints, the ligand with the stronger donor properties (the "stronger ligand") will orient *trans* to that with the weaker donor properties, lengthening the weaker ligand's bond to the metal.

For a monomeric tris-chelate complex of three electronically nonsymmetric bidentate ligands, two configurations, *fac* and *mer*, are possible (see Scheme 1). Only in the *fac* configuration are all the stronger donors (s) *trans* to the weaker ones (w). The *fac* configuration is enthalpically preferred, generating inherent structural directionality in the complex not possible with electronically symmetric, bidentate ligands. Incorporation of two electronically nonsymmetric, bidentate units in a twofold symmetric, dinucleating tetradentate ligand yields a system that should be enthalpically and entropically biased towards assembly of a 2:3 metal:ligand complex (see Scheme 1, bottom). Cooperative behavior[16] of such systems is a consequence of the ligand design.



A well-characterized type of nonsymmetric, bidentate ligand is the 2,3-dihydroxybenzamide **L** (catecholamide), a chelating agent found in many bacterial siderophores.[17] The 3-hydroxyl group

Scheme 1. Top: *fac* and *mer* isomers of a mononuclear ML_3 complex. The arrow indicates the direction of the pseudo-C_3 axis. L_w = weak donor ligand, L_s = stronger donor ligand. Bottom: Formation of a dinuclear triple helix.

is a stronger donor than the 2-hydroxyl group as reflected in the difference in their pK_a values (pK_a(2-OH) ≈ 7, pK_a(3-OH) ≈ 12).[18] Spectroscopic studies of a $[GaL_3]^{3-}$ complex have suggested that a *fac* configuration predominates in solution.[19]

The bis-catecholamide ligands used in this study are presented in Scheme 2 and differ only in the nature of the bridging propyl

Scheme 2.

unit. These ligands are designed to bind two separate metals because the bridges do not allow a single metal to be ligated in a tetradentate fashion. The ^{1}H NMR spectra in D_2O and [D$_6$]DMSO of the reaction mixture of three equivalents of **1**, (*R*,*R*)-**2**, or (*S*,*S*)-**2** with two equivalents of Ga^{3+} and twelve equivalents of base (KOH or R_4NOH) are consistent with the formation of a single, D_3-symmetric species. ^{1}H NMR titrations of basic solutions of **1** or (*R*, *R*)-**2** with incremental addition of Ga^{3+} are consistent with the presence of only two species, free ligand and the 2:3 complex. The absence of other species in the presence of excess ligand indicates that the gallium atoms are bound cooperatively.

$(Et_4N)_6[Ga_2\{(R,R)\text{-}2\}_3]\cdot 2.25\,H_2O$ **3**

The structure of **3** confirms the existence of a stereospecific dinuclear triple helix. A simple line drawing of the structure is presented in Figure 1. Views of the hexaanion both perpendicular and parallel to the pseudo-threefold axis are presented in Figures 2 and 3. Each metal is bound by a pseudo-octahedral array of oxygen atoms provided by three catecholamide groups, and the metals are separated by 10.78 Å. Twist angles[20] of

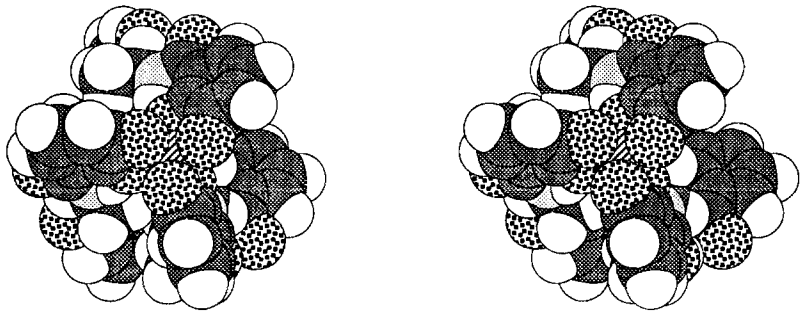

Fig. 3. Stereoview of the hexaanion of **3**, parallel to the pseudo-threefold axis.

44(4)° and 48(3)° at the metal centers are consistent with other characterized gallium catecholate structures.[21–23] The molecule has a 59(1)° helical pitch.[24] Presumably, the large gallium–gallium distance and the near-perfect staggering of the coordination spheres minimize charge repulsion between the formally triply negative metal coordination spheres. Strong hydrogen bonds are maintained between amide protons and deprotonated 2-hydroxyl oxygens, generating planar catecholamide subunits as previously observed in other metal structures.[22, 23, 25, 26] The gallium–oxygen bond lengths range from 1.96 to 2.00 Å; the average Ga–O3 distance is slightly shorter than that of Ga–O2 (Fig. 1). A comparison of the six pairs of *trans*-related ligating oxygens show that all the Ga–O3 distances are equal to or shorter than the Ga–O2 distances, consistent with a *trans*-influence. The distortion of the overall structure from threefold symmetry is apparent from the stereoview (Fig. 3). This distortion results primarily from the attempt of the bridging units to fill the void between the two metal coordination spheres. One of the six methyl groups is rotated inward and affects the positions of the other chains. The result is that one groove of the helix is more open than the other two.

The most interesting feature of **3** is its helical nature; both metal centers have the same absolute configuration, *Λ*, as defined by the absolute chirality of the enantiomerically pure diamine used in the synthesis of ligand **2**.[27] Assessing whether the metals retain this *Λ,Λ* configuration in solution by circular dichroism spectroscopy is not possible, because gallium lacks the necessary optical transitions. The distinct and sharp ^{1}H NMR resonances in the methyl and methylene regions of **3** in D_2O and [D_6]DMSO suggest either the existence of a single species in which both metals adopt the same configuration, or rapid racemization at the metal centers. The ^{1}H NMR spectrum of the less sterically demanding $[Ga_2(\mathbf{1})_3]^{6-}$ complex shows that the methylene protons adjacent to the amide nitrogens are diastereotopic, which is only possible if the metals do not racemize faster than the NMR time scale. Thus, the anion of **3** must retain its helical structure in solution.

To probe the importance of enantiomeric purity on stereospecific helix formation, the product distribution of a 2:3 metal–ligand complex from racemic **2** and Ga^{3+} was examined. Initially, the ^{1}H NMR resonances in D_2O correspond to the statistically predicted 3:1 mixture of heterochiral and homochiral isomers, respectively.[28] An equilibrium mixture of about 6:1 (heterochiral:homochiral) is attained after several hours at 297 K, indicating that the heterochiral isomer is energetically more stable by about 1.0 kcal mol^{-1}. The same equilibrium ratio is observed after mixing equal molar amounts of the preformed, enantiomerically pure triple helices, $[Ga_2\{(R,R)\text{-}\mathbf{2}\}_3]^{6-}$ and $[Ga_2\{(S,S)\text{-}\mathbf{2}\}_3]^{6-}$. These ligand exchange reactions show that these metal–ligand systems are at thermodynamic equilibrium, a fact not evident when enantiomerically pure or achiral ligands are used. This data further supports the idea that **3** exists as a single, stereospecific *Λ,Λ*-helix in solution and that *Δ,Δ*-side-by-side[13] and *Δ,Δ*-helical configurations are each energetically destablized by at least 2.0 kcal mol^{-1} at 297 K.[29]

This study of chiral and achiral dinucleating catecholamide ligands with gallium reveals a number of interesting aspects of metal-assisted self-assembly. First, cooperative polynucleating ligands can be rationally designed to utilize the thermodynamic preferences present in mononuclear species, such as a *trans*-influence. Secondly, enantiomerically pure polynucleating ligands can greatly constrain helical direction producing a stereospecific helix even when the ligand is relatively flexible.

Experimental Procedure

The ligands were synthesized as previously described from an activated form of 2,3-dimethoxybenzoic acid and half an equivalent of diamine followed by deprotection with BBr_3 [22]. The enantiomerically pure diamines used in the syntheses of (*R,R*)-**2** and (*S,S*)-**2** were prepared and resolved according to literature procedures [30].

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-0997 $ 10.00+.25/0

Crystal data for **3**: The complex crystallized by slow diffusion of ether into an acetonitrile solution in space group $P2_1$ (no. 4) with the following cell constants based on 25 reflections ($19° < 2\theta < 36°$): $a = 15.029(3)$, $b = 18.050(2)$, $c = 26.561(4)$ Å, $\beta = 94.55(2)°$, $V = 5830(1)$ Å^3, $Z = 2$. A total of 9160 reflections ($\pm h, +k, +l$) were collected at 203 K using ω scans on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $5° < 2\theta < 47°$, of which 9015 were unique. The structure was solved by the Patterson method. The water molecules were disordered, and modeled by oxygen atoms at reduced occupancies. Four of the tetraethylammonium ions were well-defined, but the remaining two were significantly disordered and were modeled with additional carbon atoms at reduced occupancies. All gallium and nitrogen atoms were refined anisotropically. Oxygen atoms in the anion were refined anisotropically, and oxygen atoms present as solvent were refined isotropically. All carbon atoms were refined isotropically. Full matrix refinement of 768 variables based on 4757 reflections ($|F_o| > 3\sigma(F_o)$, $8.24° < 2\theta < 47°$) and sigma weights converged with final residuals of $R = 0.072$, $R_w = 0.063$. The absolute configuration of the space group was assigned by the chirality of the ligand (*R,R*)[27]. Inversion of the structure and refinement significantly increased the residuals supporting this assignment. All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[28] Excluding each metal's coordination configuration, four possible 2:3 (M:L) isomers exist with racemic **2**. Two isomers that are D_3-symmetric enantiomers, *R,R,R* and *S,S,S* will be referred to as homochiral. The homochiral isomers display a single set of ^{1}H NMR resonances. The two isomers that are C_2-symmetric enantiomers, *R,R,S* and *S,S,R*, will be referred to as heterochiral. The heterochiral isomers display three sets of ^{1}H NMR resonances consistent with the C_2 symmetry. In a statistical mixture, the heterochiral isomers are present at three times the concentration of the homochiral isomers.
[29] Assuming that purity of 97% can be assessed by a "clean" NMR spectrum.

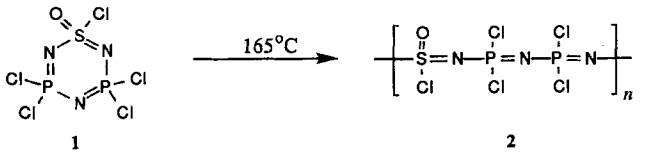
The First Sulfur(VI)–Nitrogen–Phosphorus Macrocycles**



Yizeng Ni, Alan J. Lough, Arnold L. Rheingold, and Ian Manners*

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

Cyclic compounds which contain skeletons of inorganic elements are of considerable interest with respect to structure and bonding, solid-state properties, and use as precursors to new polymer systems.[1–6] Over the past two decades six-membered cyclic thionylphosphazenes such as **1** (1,3,3,5,5-pentachloro-1λ^6,2,4,6,3λ^5,5λ^5-thiatriazadiphosphophorin-1-one) have been well-studied, and the skeleton present in these compounds, which consists of four-coordinate sulfur(VI), nitrogen, and phosphorus atoms, has been shown to be robust and stable.[2] We have recently described the thermal ring-opening polymerization of **1** to yield **2**, the first member of the potentially extensive poly(thionylphosphazene) system.[5, 6] These sul-

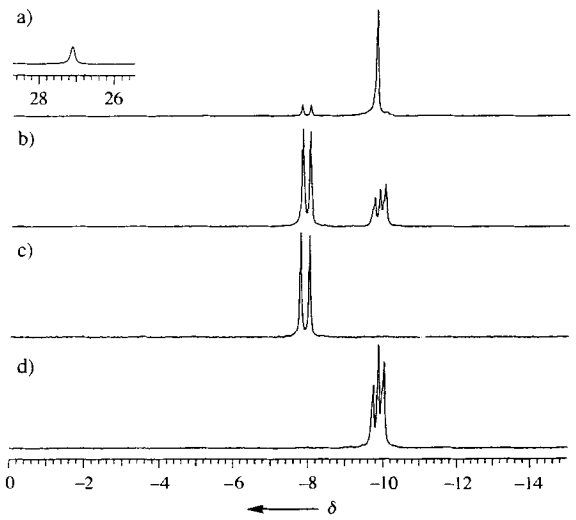
1 2

fur–nitrogen–phosphorus polymers show interesting differences from classical polyphosphazenes[7] in terms of material properties, substitution patterns, and the types of polymer structures that are accessible.[6, 8] In this paper we report on our attempts to identify the by-products formed during the polymerization of **1**, which have yielded the first examples of macrocyclic species with a sulfur(VI)–nitrogen–phosphorus skeleton.[9, 10]

A ^{31}P NMR spectrum (in CH_2Cl_2) of the reaction products derived from heating **1** for 4 h at 165 °C is shown in Figure 1a.



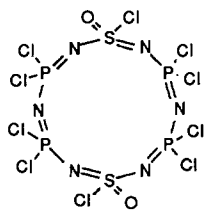


Fig. 1. ^{31}P NMR spectra (121.4 MHz) of the reaction products from the thermolysis of **1** (in CH_2Cl_2).

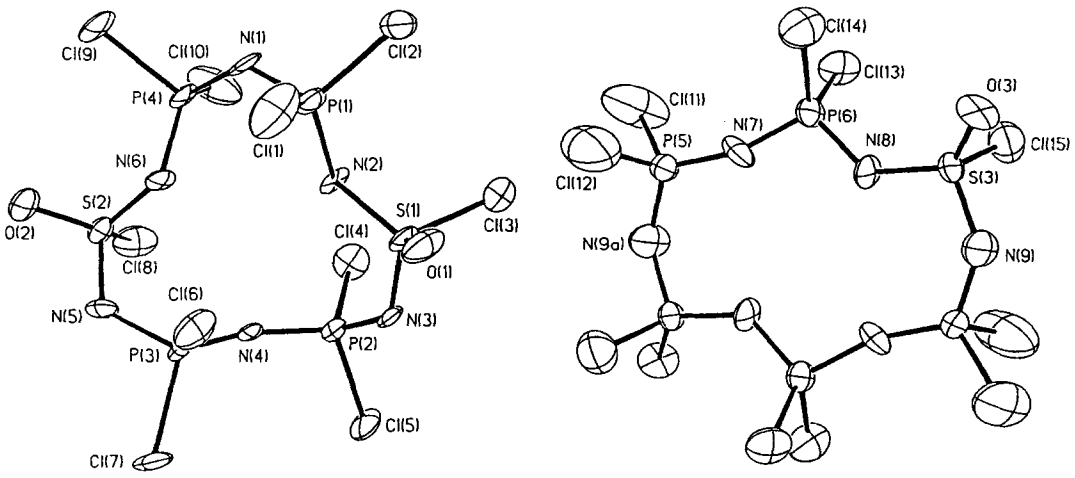
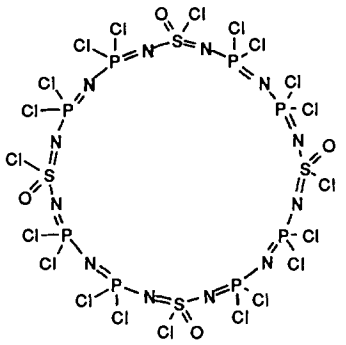


The singlet resonances at $\delta = 27.08$ and $\delta = -9.77$ are assigned to unchanged **1** and the poly(thionylphosphazene) **2**, respectively.[5] In order to isolate the by-product(s) giving rise to the resonances at $\delta = -7.76$ and $\delta = -8.00$, the polymer **2** and then the unreacted **1** were sequentially removed by precipitation and by vacuum sublimation, respectively. The remaining moisture-sensitive products gave the ^{31}P NMR spectrum shown in Figure 1b with the desired resonances at $\delta = -7.76$ and $\delta = -8.00$ (ratio 1.1 to 1.0) and, in addition, a group of poorly resolved peaks at higher field clustered around the original location of the singlet resonance for **2** at $\delta = -9.77$. Analysis by Fast Atom Bombardment (FAB) mass spectrometry indicated that this mixture consisted of the 12-, 18-, 24-, 30-, and 36-membered rings $[(NSOCl)(NPCl_2)_2]_x$ ($x = 2$–6); the strong peaks detected corresponded to the molecular ion minus a chlorine atom for each species.[11] Careful vacuum sublimation of this mixture yielded a white crystalline solid, which afforded the ^{31}P NMR spectrum (in CH_2Cl_2) shown in Figure 1c. The mass spectrum identified this product as the 12-membered ring **3**. The presence of two singlet ^{31}P NMR resonances suggested that both *cis* and *trans* isomers were present.

A block shaped crystal of **3** was selected for a single-crystal X-ray diffraction study.

3

The X-ray analysis showed that the crystals comprised a 2:1 mixture of the *cis* and *trans* isomers of the symmetrical 12-membered ring **3**. Molecules of the *trans* isomer were located at crystallographic inversion centers.[12, 13] The molecular structures of **3a** (*cis*) and **3b** (*trans*) are shown in Figure 2. The sulfur(VI)–nitrogen–phosphorus rings in each isomer are significantly nonplanar, and the bond angles and bond lengths are different. The most dramatic difference in geometry between the 12-membered rings and the six-membered ring **1** is in the P-N-P bond angles, which are substantially expanded to values of 134.1(16)–163.4(13)° in the former relative to the value of



3a 3b

Fig. 2. Molecular structures of the isomers of **3**: **3a** (*cis*) and **3b** (*trans*). Selected bond lengths [Å] and angles [°] (estimated standard deviations in parentheses). **3a** (*cis*): S1-N3 1.554(18), N3-P2 1.583(13), P2-N4 1.544(14), N4-P3 1.526(17), P3-N5 1.632(17), N5-S2 1.531(22), S2-N6 1.543(13), N6-P4 1.592(20), P4-N1 1.530(13), N1-P1 1.578(19), P1-N2 1.543(20), N2-S1 1.602(18); S1-N3-P2 126.3(13), N3-P2-N4 120.3(9), P2-N4-P3 149.4(11), N4-P3-N5 116.9(10), P3-N5-S2 122.9(10), N5-S2-N6 109.7(8), S2-N6-P4 132.5(11), N6-P4-N1 113.9(10), P4-N1-P1 134.1(16), N1-P1-N2 112.3(9), P1-N2-S1 128.5(8), N2-S1-N3 109.6(8). **3b** (*trans*): N9-S3 1.555(17), S3-N8 1.558(19), N8-P6 1.562(13), P6-N7 1.557(26), N7-P5 1.470(25), P5-N9A 1.575(26); P5A-N9-S3 128.6(18), N9-S3-N8 109.2(12), S3-N8-P6 131.9(13), N8-P6-N7 106.2(10), P6-N7-P5 163.4(13), N7-P5-N9a 118.8(11).

122.0(2)° in the latter.[14] The S-N-P angles are also slightly larger in the 12-membered rings **3** (122.9(10)–132.5(11)° compared to an average of 120.9(2) in **1**). In contrast, the N-S-N angles are significantly smaller in **3** (109.2(12)–109.7(8)°) than in **1** (115.2(2)°), whereas the N-P-N angles are similar (106.2(10)–120.3(9)° in **3**, 116.7(2)° in **1**). The 12-membered ring **3** possesses S–N and P–N bond lengths that range from 1.53(2) to 1.60(2) Å and from 1.47(3) to 1.63(2) Å, respectively. The ranges include the values found in **1** (S–N 1.557(3)–1.559(3) Å, P–N 1.571(3)–1.613(3) Å), and the bond lengths are closer to those expected for double rather than single bonds.[15]

After the separation of the 12-membered ring **3**, the remaining products in CH_2Cl_2 gave the ^{31}P NMR spectrum shown in Fig. 1d. Bearing in mind the results of the mass spectrometric analysis mentioned above,[11] this multiplet suggested that the products giving rise to the ^{31}P NMR resonance clustered at $\delta \approx -9.7$ to -10.0 in Figure 1b and d are the higher cyclics $[NSOCl(NPCl_2)_2]_x$ ($x > 2$). Fractional recrystallization from hexanes over three weeks yielded colorless crystals. Analysis of these by mass spectrometry showed a molecular ion minus chlorine for the 24-membered ring **4**, whereas removal of solvent from the mother liquors yielded a mixture of mainly 18-, 24-, and 30-membered rings. One of the crystals of **4** proved to be suitable for an X-ray diffraction study.[16]

4

The single crystal X-ray diffraction analysis indeed identified **4** as a 24-membered ring (Fig. 3), and this molecule is, to our knowledge, the largest discrete inorganic heterocycle to be crystallographically characterized to date.[17] The crystal contained only the *cis*, *trans*, *cis*, *trans* isomer although the molecule was rotationally disordered.[18] Interestingly, the sets of two P–Cl bonds at each phosphorus atom are alternately exo- and endocyclic, whereas in the 12-membered ring **3** all of the P–Cl bonds are exocyclic. This is probably a consequence of the larger cavity in **4** than in **3**. The P-N-P angles in **4**, which vary from 134.8(6) to 138.9(5)°, are similar to the smallest values found in the 12-membered ring **3** and are substantially larger than those in the six-membered ring **1**. The S-N-P, N-S-N, and N-P-N angles vary from 119.9(7) to 131.5(6)°, 109.9(6) to 112.8(9)°, and 109.0(5)° to 114.0(5), respectively. These values are similar to those found in **3** and are not dramatically different from the values found in **1**. The spread in the S–N and P–N bond lengths in **4** is similar to that found in the isomers of **3**, and the ranges contain the values found in **1**. Inspection of the bond-length and bond-angle data for **3**, **4**, and **1** therefore suggests that the ring strain in **1**, which presumably provides the thermodynamic driving force for the ring-opening polymerization to yield **2**, is mainly manifest in a structurally enforced contraction of the P-N-P angles.

The formation of macrocycles, which only correspond to oligomers of the six-membered ring **1**, during the polymerization of this species contrasts with the situation for the ring-opening polymerization of the cyclic phosphazene $[NPCl_2]_3$ which yields mainly the eight-membered ring $[NPCl_2]_4$ together with

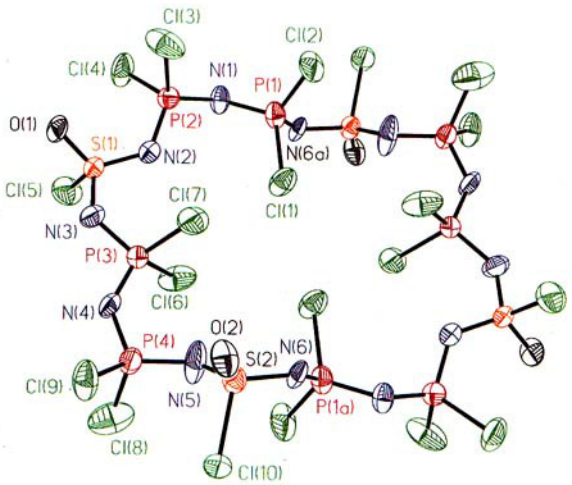


Fig. 3. Molecular structure of **4**. Selected bond lengths [Å] and angles [°] (estimated standard deviations in parentheses): P1-N1 1.570(8), N1-P2 1.538(7), P2-N2 1.595(11), N2-S1 1.532(8), S1-N3 1.546(11), N3-P3 1.575(11), P3-N4 1.541(10), N4-P4 1.566(11), P4-N5 1.579(9), N5-S2 1.617(10), S2-N6 1.551(13), N6-P1A 1.653(13); N6A-P1-N1 106.1(5), P1-N1-P2 138.9(5), N1-P2-N2 114.0(5), P2-N2-S1 127.4(7), N2-S1-N3 110.7(5), S1-N3-P3 131.5(6), N3-P3-N4 106.9(5), P3-N4-P4 134.8(6), N4-P4-N5 113.7(5), P4-N5-S2 130.8(7), N5-S2-N6 109.9(6), S2-N6-P1A 128.1(8).

very small quantities of higher cyclics $[NPCl_2]_x$ ($x = 5$, 6 etc.) in addition to the high polymer $[NPCl_2]_n$.[19] Furthermore, the isolation of 12- and 24-membered rings that exclusively possess SNPNPN sequences provides excellent evidence that molecules of **1** can add to both themselves and to molecules of **3** in a regioselective manner under the thermolysis conditions. The large macrocycles are possible models for the conformations of polymers such as **2** and are also of possible interest as inorganic crown ether type ligands for the complexation of metal ions. In addition, an investigation of the polymerization behavior of the macrocycles should provide additional insight into the processes that can occur when cyclic thionylphosphazenes are heated at elevated temperatures.

Experimental Procedure

3: Monomer **1** (10.0 g) was heated in an evacuated Pyrex tube at 165 °C for 4 h. The tube contents were then dissolved in approximately 40 mL of CH_2Cl_2. The solution was concentrated to about 10 mL, and then added dropwise to 200 mL of stirred hexanes by cannula. Polymer **2** precipitated out of the solution. The polymer was reprecipitated twice, and the mother liquors from all three precipitations were collected, and the solvent removed to leave a white solid (2.1 g). Unconverted **1** was removed from the products by high vacuum sublimation (55–60 °C, 0.008 mmHg, 24 h). The residue was redissolved in hexanes, filtered, and the solvent removed. Small additional amounts of unreacted **1** were removed by vacuum sublimation under the same conditions. High vacuum sublimation at higher temperature (80 to 85 °C, 0.008 mmHg) for 48 h yielded a white crystalline sublimate (**3**). The residue was dissolved in hexanes, the resulting solution filtered, and the solvent removed. Another sublimation under the same conditions yielded a small additional amount of **3**. Total yield of **3**, 0.27 g (3%). ^{31}P NMR: $\delta = -7.76$, -8.00 (1.1:1.0). MS (EI, 70 eV): *m/z* (%): 623 (100, $[M^+ - Cl]$, correct isotope pattern for 9 Cl atoms), 588 (6, $[M^+ - 2\,Cl]$), 553 (85, $[M^+ - 3\,Cl]$), 516 (55 $[M^+ - 4\,Cl]$).

4: The oily residue remaining after the removal of **3** by vacuum sublimation was dissolved in warm hexanes. This solution was filtered and cooled to -14 °C for 24 h. The resulting oily precipitate was redissolved in warm hexanes. At ambient temperature a white powder precipitated over 24 h period. This was isolated and redissolved in warm hexanes. Colorless crystals of **4** formed over 3 weeks at ambient temperature. Yield 15 mg. ^{31}P NMR: $\delta = -9.86$. MS (EI, 70 eV): *m/z* (%): 1282 (100, $[M^+ - Cl]$, correct isotope pattern for 19 Cl atoms), 1210 (38, $[M^+ - 3\,Cl]$), 1140 (15, $[M^+ - 5\,Cl]$), 1068 (7, $[M^+ - 7\,Cl]$). Removal of the solvent from the mother

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1000 $ 10.00+.25/0

liquors yielded an oily residue. ^{31}P NMR: $\delta = -9.76, -9.86, -9.96, -10.01$. MS: m/z 1615, 1282, 952 assigned to $[M^+ - Cl]$ for the 30-, 24-, and 18-membered rings, respectively.

Synthesis of Rodlike Distellenes**

Rolf Gleiter* and Oliver Borzyk

Dedicated to Professor Franz Effenberger on the occasion of his 65th birthday

The interaction of nonconjugated π systems can be described either by a through-space or a through-bond mechanism.[1] The latter is of interest with respect to long-range electron transfer processes.[2] In our studies on exomethylene derivatives of tricyclo[3.3.0.0^{3,7}]octane (stellenes) such as **1**–**3**[3] we realized that

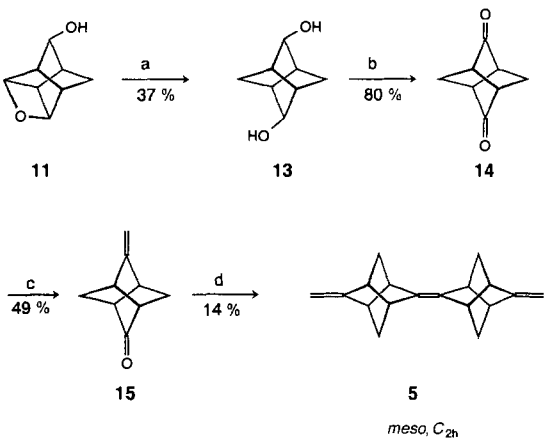
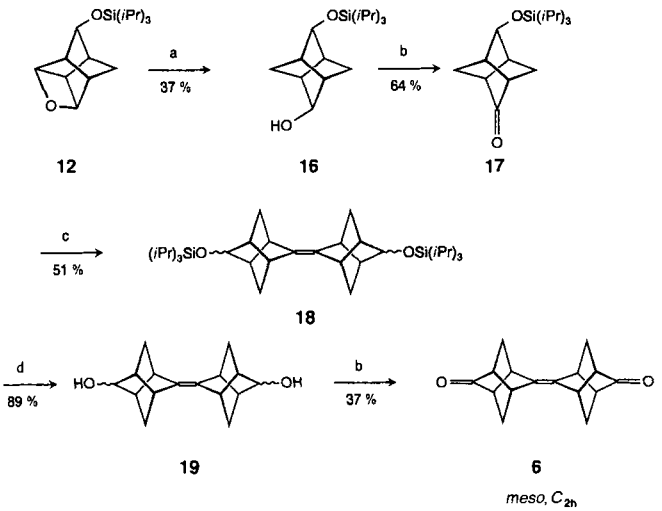
not only the twisted six-membered ring but also the whole tricyclo[3.3.0.0^{3,7}]octane (stellane) skeleton can provide a good relay for through-bond interactions. We therefore concluded that two or more stellane units are not only good building blocks for rodlike molecules but might be of interest with respect to electron transfer processes when they can be placed between acceptor and donor groups. In this paper we report on the synthesis of the rodlike molecules **4**–**6** which incorporate two stellane units (distellenes).

Compound **4** was synthesized by coupling the known ketone **7**[4] with the titanium trichloride/dimethoxyethane (DME) complex described by McMurry et al. (Scheme 1).[5] The starting

Scheme 1. a) $TiCl_3 \cdot DME/Zn-Cu/DME$, 40 °C, 19 h.



compound **8** for the synthesis of **5** and **6** could be prepared readily by the Diels–Alder addition of acrolein to 6,6-dimethylfulvene.[6] Conversion of **8** to the oxetane **10** was accomplished by irradiation and subsequent ozonization (Scheme 2). The re-



Scheme 2. a) *hν* (285 nm)/Et_2O; b) $O_3/CH_2Cl_2/DMS$; c) $LiEt_3BH/THF$; d) TIPS triflate/CH_2Cl_2.

gioselective reduction of **10** yielded **11** which could be converted to **12** by reaction with triisopropylsilyl (TIPS) triflate. The oxetane rings in **11** and **12** were cleaved as described by Sauers et al.[7] with Li in ethylenediamine (EDA) to yield the alcohols **13** (Scheme 3) and **16** (Scheme 4), respectively. The next steps in the route to **5** were a Swern[8] oxidation (**13** → **14**) and a Wittig reaction (**14** → **15**). This route also comprises a new and efficient synthesis of compounds **14** and **15**.[9] The McMurry coupling of **15** afforded **5**. The preparation of distellene **6** (Scheme 4) relied on the same procedures as in Scheme 3. The key reactions were also the Swern oxidation[8] of **16** to **17** and **19** to **6**.

A salient feature of the synthetic approach to **5** and **6** was the discovery of an efficient high-yielding synthesis of alcohols **13** and **16** by the reductive cleavage of the oxetane rings in **11** and **12**. This reaction sequence is part of a seven-step synthesis of **15** and **17** which provides these key intermediates in gram quantities (Scheme 3 and 4). A previous synthesis yielding small amounts of **14** and **15** required several additional steps.[9]

Scheme 3. a) Li/EDA; b) $(COCl)_2/DMSO/NEt_3$; c) $[Ph_3PCH_3]Br/NaNH_2/THF$; d) $TiCl_3 \cdot DME/Zn-Cu/DME$.

Scheme 4. a) Li/EDA; b) $(COCl)_2/DMSO/NEt_3$; c) $TiCl_3 \cdot DME/Zn-Cu/DME$; d) nBu_4NF/THF.

Three stereoisomers (*meso*, C_{2h}-symmetric; racemate, D_2-symmetric) are possible for compounds **4**, **5**, and **6**. The isomers of **4** (racemate **4'** and *meso* **4**) could be separated on an analytical cyclodextrin column. The ratio of the isomers **4'**:**4** was found to be 5:1. The assignments of the NMR signals are based

Table 1. Selected physical and spectroscopic data of **4**–**6**.

on this ratio. Separation of the isomers of **5** and **6** has not yet been achieved. Relevant spectroscopic data of **4**–**6** are presented in Table 1.

To elucidate the relay properties of the stellane skeleton we recorded the photoelectron (PE) spectra of **5**, **6**, and **14**. In **14**, in which the oxygens are separated by five bonds (5.6 Å), the first two ionization energies I_v are found at 8.86 and 9.90 eV. These two peaks are assigned to ionizations from the two linear combinations of the two 2p AOs at the oxygen centers and the σ skeleton ($6b_3(n^+)$ and $6b_2(n^-)$; Fig. 1). It is evident that the

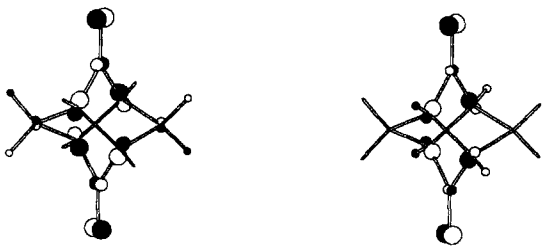

Fig. 1. Drawing of the two highest occupied MOs of **14**; left: $6b_3(n^+)$, right: $6b_2(n^-)$.

2p–σ interaction in $6b_3(n^+)$ is larger than in $6b_2(n^-)$. In **5** the split between the ionization energies from the terminal π bonds (π_o^+, π_o^-) amounts to 0.43 eV (Table 1). In **6** the energy difference between the first two bands (n^+, n^- linear combination) amounts to 0.28 eV (Table 1). Similar efficient relay properties were encountered with the bicyclo[1.1.1]pentane skeleton.[10]

Al,Ti Avoidance in the Microporous Titanoaluminosilicate ETAS-10**

M. W. Anderson,* A. Philippou, Z. Lin, A. Ferreira, and J. Rocha

Recently the structure of the microporous, crystalline titanosilicate ETS-10 was solved and found to be highly disordered.[1, 2] The framework can be described in terms of an intergrowth of two end member structures termed polymorphs A and B, both of which consist of a three-dimensional 12-ring structure. Polymorph A belongs to a chiral space group and like zeolite β possesses a spiral channel. ETS-10, therefore, constitutes a very interesting new microporous material with wide pores and a chemical composition very different from that of zeolites.

The structure of ETS-10 contains corner-sharing TiO_6 octahedra and corner-sharing SiO_4 tetrahedra. Consequently, in the anionic framework every titanium atom is associated with a -2 change in the structure. This charge is compensated by cations not in the framework, which in the case of the ETS-10 produced by the method described here is a mixture of Na^+ and K^+ ions. It appears that the K^+ ions are the most important components for directing the synthesis towards ETS-10 rather than towards other titanosilicate phases. The anhydrous formula of ETS-10 is $M^{m+}_{2/m}TiSi_5O_{13}$, where M is a cation with charge m. The cation density in ETS-10 is, therefore, approximately equivalent to that in a zeolite with Si/Al = 2.5 such as zeolite Y. This makes ETS-10 potentially a very interesting material both for cation exchange and catalysis. With regards to catalysis, the high framework charge and cation exchange ability should impart basic properties. On the other hand, acidic properties could be introduced by forming bridging hydroxyl groups such as Ti-(OH)-Si. To improve the acid chracteristics further, aluminum may be incorporated into tetrahedral silicon sites, thus generating sites for zeolite-type acidity. The formation of ETAS-10 (*E*ngelhard *t*itano*a*luminos*i*licate) has already been described.[3, 4] We have synthesized a number of different ETAS-10 samples and report here on the location of the aluminum atoms and general considerations for titanoaluminosilicates.

When aluminum is incorporated in tetrahedral framework sites in a zeolite, a negative framework charge is introduced. Owing to this negative charge and the consequent electrostatic repulsion, the Al atoms, tend to avoid each other. This behavior is described by the Al, Al avoidance principle of Loewenstein's rule.[5] This precludes the existence of Al-O-Al linkages, and implies that all Al atoms have the same chemical environment, Al(4Si). When Loewenstein's rule holds, Si/Al ratios in the frameworks of structurally simple zeolites such as zeolite may be calculated from ^{29}Si magic-angle spinning (MAS) NMR spectra according to Equation (a).[6] Here $I_{Si}(n\text{Al})$ is the integrated intensity of the resonance corresponding to silicon atoms bonded through oxygen to n Al neighbors.

$$\text{Si/Al} = \frac{\sum_{n=0}^{4} I_{\text{Si}(n\text{Al})}}{0.25 \sum_{n=0}^{4} n I_{\text{Si}(n\text{Al})}} \qquad \text{(a)}$$

One consequence of Loewenstein's rule is that the lowest Si/Al ratio possible is 1, and strict alternation of silicon and aluminum atoms in the framework must apply (such as in zeolite A and sodalite). Interestingly, it was shown recently[7] that in pyrolytically prepared ultramarines (with the sodalite structure) disorder of the aluminum atoms results in breaking of Loewenstein's rule. However, in hydrothermally prepared sodalites Loewenstein's rule is obeyed. We wondered whether titanoaluminosilicates follow such avoidance rules, in other words whether Al-O-Ti units are found exclusively.

Figure 1 shows the framework connectivity for ETS-10 as reported previously.[1] For the ensuing arguments the choice of

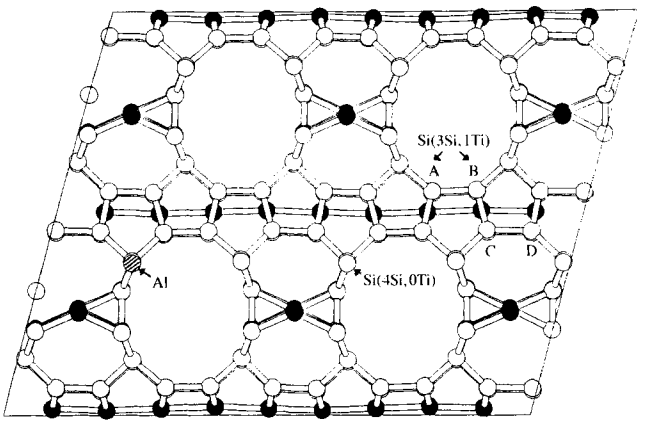

Fig. 1. Framework of ETS-10 (Si: white, Ti: black). Oxygen atoms are not shown; they lie approximately in the middle of the atom connections. One aluminum atom is shown (shaded) incorporated at a tetrahedral site which avoids neighboring titanium.

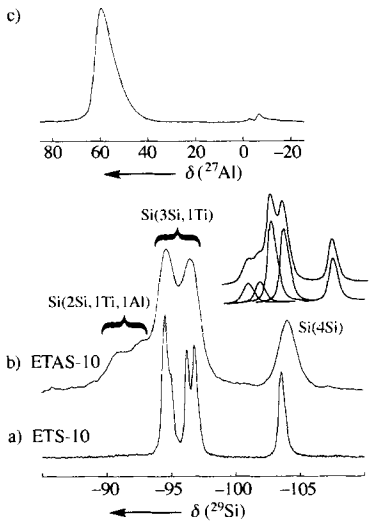
polymorph is irrelevant as is the disorder in ETS-10; in all cases local environment of the tetrahedral sites remains unaffected. There are only two types of chemical environment for silicon atoms in ETS-10, Si(3Si, 1Ti) and Si(4Si, 0Ti). The ratio of these two environments is 4:1; this can be seen in the structure (Fig. 1) and is supported experimentally in the ^{29}Si MAS NMR spectrum (Fig. 2a). This spectrum reveals a further crystallographic splitting of the Si(3Si, 1Ti) environment into three or four sites, which are labeled A–D in Figure 1. For most of the following discussion this crystallographic inequivalence can be ignored, in other words, it suffices when only chemical environments are considered.

The ^{29}Si and ^{27}Al MAS NMR spectra of ETAS-10 are shown in Figures 2b and 2c, respectively. The ^{27}Al NMR spectrum reveals that 98% of the aluminum is incorporated in tetrahedral sites ($\delta = 60$ relative to $[Al(H_2O)_6]^{3+}$). A small contribution from aluminum centers in octahedral sites (ca. 2%) is evidenced by resonances between $\delta = 0$ and $\delta = -10$, which could be due to aluminum atoms within or not in the framework of ETAS-10. The ^{29}Si MAS NMR spectrum is more complicated. First, the resonances for ETAS-10 are all considerably broader than for ETS-10. Such a phenomenon is also observed in zeolites and is generally regarded to be due to second nearest neighbor effects. Second, all the resonances for ETS-10 appear in the spectrum for ETAS-10, but there is an additional set of resonances roughly 4 ppm downfield from the Si(3Si, 1Ti) signal. We ascribe these signals to Si(2Si, 1Al, 1Ti) environments. A 4 ppm downfield shift is expected upon exchange of a silicon neighbor by aluminum.[6] Importantly, though, there is no signal 4 ppm downfield fom the Si(4Si,0Ti) signal, indicating that there is no aluminum substitution neighboring this silicon site. These arguments are summarized in Scheme 1. This is direct proof of Al, Ti avoidance in ETAS-10. Aluminum only substitutes into



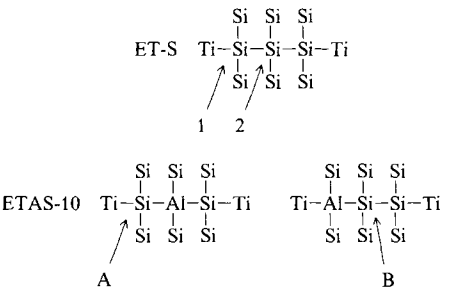


Fig. 2. ^{29}Si MAS NMR spectra of a) ETS-10 and b) ETAS-10. Inset shows deconvolution of the overlapping signals. c) ^{27}Al MAS NMR spectrum of ETAS-10.

Scheme 1. In the representation of ETS-10 the arrows labeled 1 and 2 point to silicon centers having different chemical environments. In the representation of ETAS-10 the arrow labeled A points to a silicon center Si(2 Si, 1 Ti, 1 Al) which gives rise to an NMR signal; the arrow labeled B points to a silicon center Si(3 Si, 1 Al) which does not give rise to an NMR signal.

Si(4Si, 0Ti) sites, thereby avoiding neighboring titanium (O atoms are discounted). The ^{27}Al MAS NMR spectrum also supports this conclusion, as only one signal for an aluminum environment is observed with a chemical shift similar to that found for Al(4Si) sites in zeolites.

Detailed analysis of signal intensities in the spectra, which will be reported in full separately, allows framework Si/Al and Si/Ti ratios to be calculated with Equations (b) and (c), respectively. These calculations reveal that at higher concentrations of aluminum, slight deviations from the Al, Ti avoidance rule are observed. For the sample reported in this study Si/Al = 20.3 and Si/Ti = 4.8 is found. This is in close agreement with the results of an independent chemical analysis by ICP atomic emission spectroscopy.

$$\mathrm{Si/Al} = \frac{\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} I_{\mathrm{Si}(n\mathrm{Al},m\mathrm{Ti})}}{0.25\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} nI_{\mathrm{Si}(n\mathrm{Al},m\mathrm{Ti})}} \qquad \text{(b)}$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1004 $ 10.00+.25/0

$$\mathrm{Si/Ti} = \frac{\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} I_{\mathrm{Si}(n\mathrm{Al},m\mathrm{Ti})}}{0.25\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} mI_{\mathrm{Si}(n\mathrm{Al},m\mathrm{Ti})}} \qquad (c)$$

It is too early to say whether Al, Ti avoidance is a general phenomenon in titanoaluminosilicates; however, it seems logical that, when possible, aluminum and titanium will not be neighbors. This has implications for aluminum incorporation in ETS-4.[3] Although a full structural study has not been performed on ETS-4, the structure is believed to be related to that of zorite.[8] All silicon sites in the structure of zorite neighbor titanium, and consequently aluminum atoms cannot avoid being adjacent to titanium atoms. We have been unsuccessful in our attempts to incorporate aluminum into ETS-4, possibly because the Al,Ti avoidance principle holds.

In conclusion ETAS-10 displays Al, Ti avoidance when low to medium concentrations of aluminum are incorporated. This preference of certain sites for aluminum is maintained at higher aluminum concentrations, although the avoidance rule does not hold strictly.

Experimental Procedure

ETAS-10 with Si/Al = 20: An alkaline solution was made by mixing 11.78 g sodium silicate solution (Na_2O: 8 wt%, SiO_2: 27 wt%), 2.5 g H_2O, 0.48 g NaOH, and 0.45 g KF. A mixed Ti/Al solution was made by adding 5.72 g $TiCl_3$ (1.9 M solution of $TiCl_3$ in 2.0 M HCl) to a solution made from 5.08 g H_2O, 0.48 g NaOH, 0.46 g KF, 0.49 g KCl, and 0.36 g $NaAlO_2$. The alkaline silicate solution and the mixed Ti/Al solution were combined with thorough stirring. A seed crystal of ETS-10 (0.1 g) was added to the resulting gel. The gel with a Ti/Al molar ratio of 2 was autoclaved under autogenous pressure for six days at 200 °C. The crystalline product was filtered, washed with distilled water at room temperature, and dried at 120 °C. ^{29}Si MAS NMR: $\delta = -90.8$ [Si(1Al, 1Ti)], -92.9 [Si(1Al, 1Ti)], -94.8 [Si(0Al, 1Ti)], -96.7 [Si(0Al, 1Ti)], -104.4 [Si(0Al, 0Ti)]. The Si(1Al, 1Ti) and Si(0Al, 1Ti) sites are crystallographically distinct. MAS NMR spectra were recorded on a Bruker MSL400 spectrometer. For ^{29}Si NMR spectra a 3.5 μs 45° pulse was used with an interpulse delay of 35 s. For the ^{27}Al NMR spectrum a 0.6 μs π/18 pulse was used with an interpulse delay of 0.5 s.

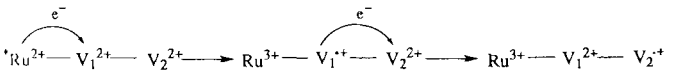
Effective Charge Separation in Intermolecular Complexes of an Electron Donor and a Doubly Branched Triad Assembly: A Model System for Environmental Effects Controlling Electron Transfer**

Eran Zahavy, Martin Seiler, Sharon Marx-Tibbon, Ernesto Joselevich, Itamar Willner,* Heinz Dürr, Donald O'Connor, and Anthony Harriman

Photosensitized electron transfer in diad, triad, and tetrad assemblies has been extensively examined as a model of the photosynthetic reaction center.[1–3] It was found that charge separation and stabilization of the intermediate redox products occurs by stepwise vectorial electron transfer within the multiacceptor triads and tetrads. Recently, we showed that effective photoinduced electron transfer takes place in donor–photosensitizer–acceptor assemblies stabilized by intermolecular charge transfer interactions.[4] The protein in which the photosynthetic reaction center is embedded plays a major role in controlling electron transfer and charge separation.[5] Alignment of the electron acceptors within the protein spatially separates the photogenerated photoproducts, thereby supporting efficient charge separation. Similarly, the protein backbone facilitates the vectorial electron transfer through the L-branch within the almost symmetrical M,L-branched photosynthetic reaction center.[6, 7] We report here on the photoinduced electron transfer reactions in a difunctionalized photosensitizer–triad assembly which serves as a functional model for the photosynthetic reaction center. We recently prepared the triad assembly **1** (Cl^- counterion),[8] in which a tris(4,4′-di-

1



methyl-2,2′-bipyridine)ruthenium(II) component functions as a light-harvesting center. In this triad one of the bipyridine ligands is linked covalently to two acceptor units. We found that formation of intermolecular complexes between the triad and an externally added electron donor such as **3** substantially affects the charge separation within the supramolecular assembly. In this way the electron donor mimics possible effects of protein-linked electron donor units on the charge separation in the photosynthetic reaction center.

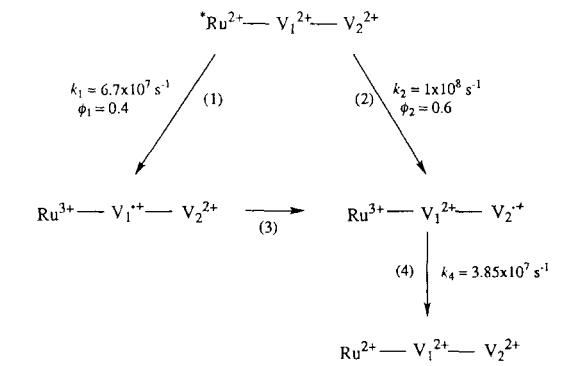
The components in the difunctional triad **1** were chosen such that their reduction potentials are in the appropriate order for a vectorial stepwise electron transfer. The cyclic voltammogram of triad **1** in the potential range -1.6 to $+2.0$ V (vs. Ag/AgCl) reveals four quasi-reversible reduction waves at -0.405, -0.61, -0.75, and -0.97 V, corresponding to the stepwise reduction of the triad Ru^{2+}-V_1^{2+}-V_2^{2+} (V = electron acceptor unit, see structural formula) to the species Ru^{2+}-V_1^{2+}-$V_2^{\bullet+}$, Ru^{2+}-$V_1^{\bullet+}$-$V_2^{\bullet+}$, Ru^{2+}-$V_1^{\bullet+}$-V^0, and Ru^{2+}-V_1^0-V_2^0, respectively.[9] Since the redox potential of excited Ru^{II} center is -0.638 V (vs. Ag/AgCl), the stepwise vectorial electron transfer summarized in Scheme 1 is feasible.



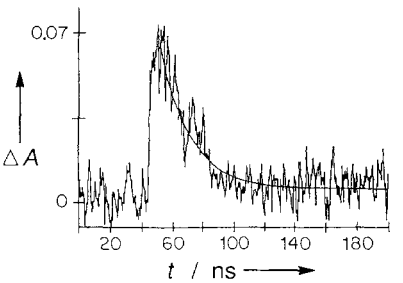
Scheme 1. Vectorial electron transfer in triad **1**.

Photoexcitation of the Ru^{II}–polypyridine center of **1** results in an emission with a lifetime of 6 ± 0.1 ns. For comparison, the lifetime of tris(4,4′-dimethyl-2,2′-bipyridine)ruthenium(II) dichloride is 0.33 μs. Thus, effective quenching of the excited state occurs in the difunctional triad assembly **1**. Further examination of the reference diad assembly **2** reveals that the excited Ru^{II} center has a lifetime of 15 ± 0.3 ns. The shorter lifetime of the excited state of **1** implies that an additional quenching route is operating (Scheme 2).

2

Assuming that electron transfer from the Ru^{II} center in **1** to the first acceptor (V_1) has a similar rate constant to that of the reference compound **2**, $k_1 = (6.7 \pm 0.1) \times 10^7\ s^{-1}$, then the direct electron transfer from Ru^{II} to the second electron acceptor (V_2) proceeds with a rate constant of $k_2 = (1 \pm 0.1) \times 10^8\ s^{-1}$.[10] The quenching of the luminescence ϕ_L of the excited Ru^{II} complex results only in a redox product that corresponds to the charge-separated triad Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$. This implies that the intermediate redox product Ru^{3+}-$V_1^{\bullet+}$-V_2^{2+} decays to Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ [Eq. (3) in Scheme 2] faster than it forms. The charge-separated triad Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ decays by back electron transfer to the ground state [Eq. (4) in Scheme 2]. Figure 1 shows the decay of the photogenerated radical cation intermediate Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ ($\lambda = 620$ nm) to the ground state. The decay curve is monoexponential and corresponds to a lifetime of 26 ± 0.5 ns. Thus, the recombination rate constant in the triad assembly is $k_4 = (3.8 \pm 0.1) \times 10^7\ s^{-1}$. The species Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ was characterized by its transient absorption spectrum; the absorption bands characteristic of the $V_2^{\bullet+}$ unit were identical to those of *N,N′*-dialkyl-4,4′-bipyridinium radical cations.

Scheme 2. Vectorial electron transfer and back-reaction in triad **1**.



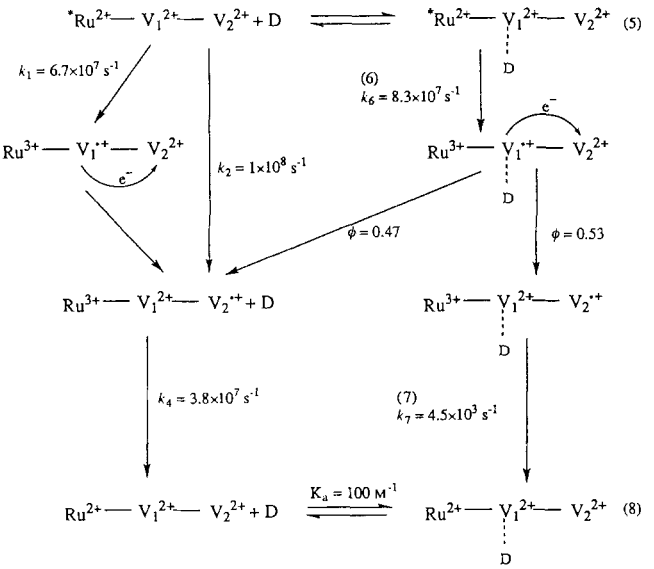


Fig. 1. Transient decay of the photogenerated redox product, Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$. In this system **1**, $c = 1.5 \times 10^{-4}$ M, $\lambda_{exc} = 532$ nm, $\lambda_{analysis} = 620$ nm.

Addition of 8-(4-anisoxy)-3,6-dioxaoctane-1-ol (**3**), $c = (2.2 \pm 0.2) \times 10^{-2}$ M, to the difunctional triad **1**, $c = 1.5 \times 10^{-4}$ M, substantially influences the electron transfer within the supra-

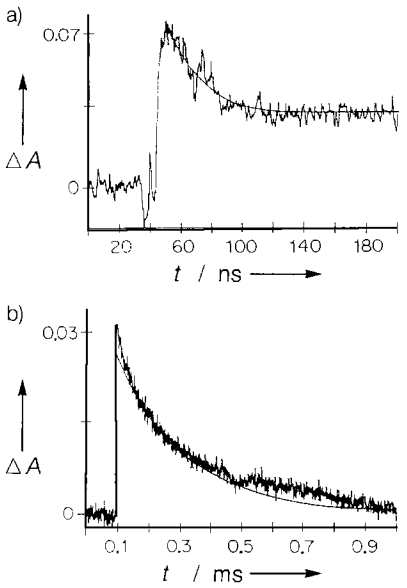
3

molecular assembly. Dialkoxybenzenes are known to form intermolecular donor–acceptor complexes with *N,N′*-dialkyl-4,4′-bipyridinium salts,[4, 11, 12] and hence the formation of such a supramolecular assembly could structurally distort the difunctional triad. The emission curve of photoexcited **1** in the presence of **3** exhibits a biexponential decay, implying two distinct populations of excited species that are being quenched (Scheme 3).[13]

Scheme 3. Vectorial electron transfer, back-reactions, and charge separation in triad **1** in the presence of added **3**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1006 $ 10.00+.25/0

One population (25%) has a lifetime of 6 ± 0.1 ns, identical to that of **1** in the absence of added electron donor. The second population (75%) has a lifetime of 12 ± 0.1 ns. Thus, we suggest that in the presence of **3** the difunctional triad exists in two configurations [Eq. (5) in Scheme 3]. The free triad $*Ru^{2+}$-V_1^{2+}-V_2^{2+} decays within 6 ns, whereas the supramolecular donor–triad complex $*Ru^{2+}$-V_1^{2+}(···D)-V_2^{2+} decays within 12 ns.[14] The redox products detected after the laser pulse contain, however, the oxidized Ru^{3+} center and the reduced second acceptor $V_2^{\bullet+}$ as a radical cation. Figure 2a shows the depletion of the reduced acceptor $V_2^{\bullet+}$ by the intramolecular back-reaction. The decay curve is monoexponential with a time constant τ of 26 ns,



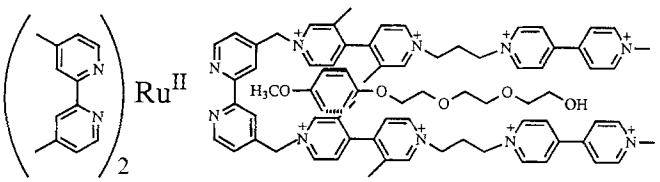


Fig. 2. Transient decay of the photogenerated redox product, Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ in the presence of added **3**. $c = 2.25 \times 10^{-2}$ M. a) Transient for fast recombination. b) Transient for slow recombination.

identical to that of the Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ radical cation in the absence of **3**. Nonetheless, on this time scale the decay curve of the redox photoproduct does not reach zero, and 40% of the initial redox intermediate remains. Figure 2b shows the decay curve of this stabilized fraction. *We see that this redox intermediate has a lifetime of 220 μs. Thus, in the presence of* **3**, *40% of the generated redox product is stabilized by a factor of roughly* 10^4 *as compared to the redox photoproduct* Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ *in the absence of* **3**. We attribute the slow decay to a redox product consisting of the radical cation triad intermolecularly associated with the electron donor **3** [Eq. (7) in Scheme 3].[15]

Previous studies revealed that stable intermolecular complexes are formed between electron donors such as xanthene dyes[16] or dialkoxybenzene[11, 12] and layered bipyridinium salts. Intercalation of **3** between the two bipyridinium branches of triad **1** provides the driving force for the formation of such an intermolecular complex. Further insight into the structure of the intermolecular complex formed between **1** and **3** was obtained by ^{1}H NMR spectroscopy. The ^{1}H NMR spectrum of **1** (400 MHz) was fully analyzed, and the signals of all of the protons associated with the difunctional triad branches were assigned. The two branches are symmetrical. When different concentrations of donor **3** are added to triad **1** in D_2O, the ^{1}H NMR spectra indicate that the symmetry of the triad branches is retained. The signal of proton H_a of the bipyridine ligand is shifted downfield, whereas the signals of protons H_b, $H_{b'}$, H_c, $H_{c'}$, H_d, and $H_{d'}$, associated with the first electron acceptor V_1^{2+}, are shifted upfield. It should be noted that the signals of the protons of the second electron acceptor V_2^{2+} are not affected by the addition of **3**. From the ^{1}H NMR shifts and the titration curves a 1:1 stoichiometry is deduced for the intermolecular complex of **1** and **3**, and the association constant $K_a = 100\ M^{-1}$ was derived.[17] Thus, we suggest that the electron donor intercalates into the groove formed by the photosensitizer ligand and the two electron acceptor units as schematically outlined in structure **4**. The

4

resulting intermolecular complex is stabilized by donor–acceptor charge transfer interactions.[11, 12, 16] The reduction potentials of the electron acceptors indicate that association of the electron donor **3** to the second bipyridinium electron-relay V_2^{2+} should be favored. We believe that the photosensitizer bipyridine ligand acts synergetically in the association of **3** with the less favored position by secondary π–π interactions.

We have found that the formation of the intermolecular complex between **3** and the difunctional triad **1** controls the photoinduced charge separation within the supramolecular assembly. The resulting redox products are 10^4 times more stable to back electron transfer than the system lacking **3**. It is reasonable to assume that the flexibility of the difunctional triad allows the redox centers in Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ to be closer together, thus enhancing back electron transfer. The association of the electron donor **3** with the difunctional triad could rigidify the conformation of the triad and align it in a stretched structure, whereby the increased distance between the generated redox species retards back eletron transfer. Such a mechanism could also operate in the natural photosynthetic reaction center. Intermolecular complexes between protein donor units such as histidine or tyrosine and the electron acceptors involved with the reaction center could be aligned in an optimal conformation for effective charge separation.

[9] The reduction waves were assigned to the corresponding redox intermediates by comparison of the cyclic voltammogram of **1** to that of tris(4,4'-dimethyl-2,2'-bipyridine)ruthenium(II) and reference compound **2**.
[10] Although V_2 is spatially separated from the excited Ru^{II} center, electron transfer to the second acceptor is slightly faster than to the first acceptor V_1. This is attributed to the higher free energy associated with the electron transfer to the second acceptor (V_2) ($\Delta G^\circ = -22.5\ kJ\,mol^{-1}$).

[13] All experiments were performed in H_2O at 298 K. No quenching of **2** or of the reference compound tris(4,4'-dimethylbipyridine)ruthenium(II) by **3**, $c = 2.2 \times 10^{-2}$ M, could be detected.
[14] Using the value of the association constant ($K_a = 100\ M^{-1}$) for the complex and the respective concentrations of **1** and **3** (150-fold excess), we estimate the ratio of the ground state reactants Ru^{2+}-V_1^{2+}-V_2^{2+} and Ru^{2+}-V_1^{2+}(···D)-V_2^{2+} to be 3:7. This ratio is very similar to the populations of the quenched photosensitizers **1** and **4**, respectively. Thus, the association constant between **3** and excited **1** has a similar value to the ground state association constant. The quenching rate constant for $^*Ru^{2+}$-V_1^{2+}(···D)-V_2^{2+} is identical to that observed for reference compound **2**. Accordingly, the primary electron transfer in the supramolecular triad–donor complex occurs only to the first acceptor (V_1^{2+}) to generate Ru^{3+}-$V_1^{\bullet+}$(···D)-V_2^{2+}.
[15] Note that although 75% of the excited triad in the supramolecular assembly $^*Ru^{2+}$-V_1^{2+}-V_2^{2+} undergoes electron transfer quenching, only 40% of the photoproduct recombines by the slow route through the intermolecular complex intermediate Ru^{3+}-V_1^{2+}(···D)-$V_2^{\bullet+}$. This is attributed to the fact that the primary electron transfer product is Ru^{3+}-$V_1^{\bullet+}$(···D)-V_2^{2+}. In this intermediate the donor **3** is poorly associated to the triad owing to reduction of one of the bipyridinium components that stabilize the complex. Hence, dissociation of the complex structure competes with the intermolecular vectorial electron transfer, whereby the supramolecular complex is restabilized. Thus, the enriched fraction of Ru^{3+}-V_1^{2+}-$V_2^{\bullet+}$ originates from the dissociation of the complex Ru^{3+}-$V_1^{\bullet+}$(···D)-V_2^{2+} that competes with intramolecular electron transfer generating the stable intermediate, Ru^{3+}-V_1^{2+}(···D)-$V_2^{\bullet+}$ (Scheme 3).

$[Cp^*(Me_3P)_2Ru(\eta^2\text{-}O{=}SO_2)]PF_6$, the First Complex between a Transition Metal and Sulfur Trioxide**

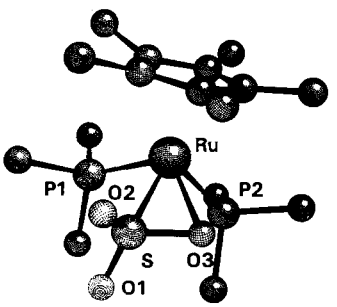
Eberhard Dombrowski and Wolfdieter A. Schenk*

Dedicated to Professor Peter Paetzold on the occasion of this 60th birthday

The reactivity of unsaturated molecules is distinctly modified by coordination to transition metal fragments. This aspect of the coordination chemistry of sulfur dioxide has also attracted increasing attention.[1, 2] Nucleophilic additions at sulfur[3, 4] on one hand, and reduction to SO and other species[2, 5] on the other have been priorities in these studies. Now we report an oxidation of metal-coordinated sulfur dioxide that leads to the first example of a transition metal complex of sulfur trioxide.

Recently we obtained complex **2**,[4b] a stable complex of sulfene, which cannot exist in the free state, from $[Cp^*Ru(PMe_3)_2(SO_2)]PF_6$ (**1**) by nucleophilic methylene transfer. It therefore seemed feasible to synthesize an SO_3 complex in an analogous way. As reagent we selected iodosobenzene, which has previously proved useful for nucleophilic oxygen transfers to coordinated CO and CH_2.[6] From **1** the ionic compound **3** is indeed obtained (Scheme 1) and could be identified as the first sulfur trioxide complex by spectroscopy and X-ray structure analysis.[7]

The structure of **3** (Fig. 1) clearly underscores the close relationship to the sulfene complex **2**.[4b] Thus, **2** and **3** have nearly



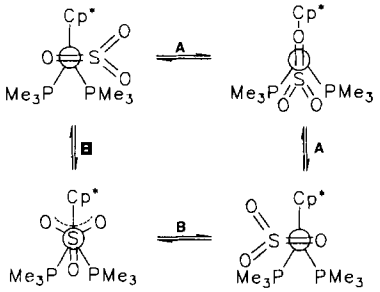


Fig. 1. Structure of the cation of **3** · Me_2CO. Bond lengths [pm]: Ru-P1 237.0(1), Ru-P2 238.1(1), Ru-S 227.15(8), Ru-O3 218.2(2), Ru-Cp (ring centroid) 192.4(0), S-O1 144.1(3), S-O2 145.4(3), S-O3 152.3(3); bond angles [°]: P1-Ru-P2 86.81(3), P1-Ru-S 87.00(3), P1-Ru-O3 118.02(8), P2-Ru-S 103.15(3), P2-Ru-O3 80.26(7), S-Ru-O3 39.94(8), O1-S-O2 113.7(2), O1-S-O3 112.4(2), O2-S-O3 112.7(2).

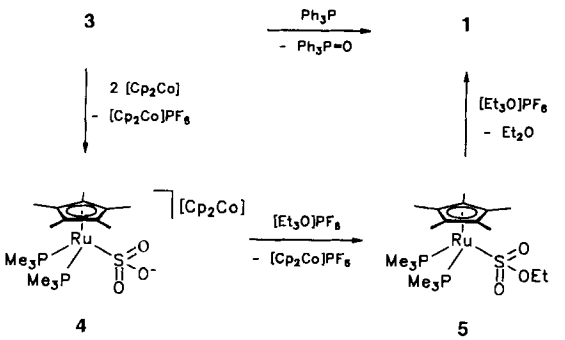
[**] Sulfur(IV) Compounds as Ligands, Part 22. This work was supported by the Fonds der Chemischen Industrie. Part 21: W. A. Schenk, J. Frisch, W. Adam, F. Prechtl, *Angew. Chem.* **1994**, *106*, 1699; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1609.

equal Ru–S lengths, the Ru–O distance of **3** is 15 pm smaller than the Ru–C distance of **2**, which approximately corresponds to the difference between the covalent radii of O and C. The S–O(3) bond is 10 pm longer than in uncoordinated SO_3 (142.0 pm[8]) but still distinctly shorter than a S–O single bond (for example, 158 pm in sulfonic acid esters[9]). The difference between endocyclic and exocyclic S–O distances in **3** equals that in η^2-SO_2 complexes, for example in $[Mo(CO)_2(PMe_3)_3(\eta^2\text{-}O{=}SO)]$.[10] Accordingly the bonding in **3** can best be described in terms of the Dewar–Chatt–Duncanson model as a side-on coordination of a S–O double bond of SO_3 to a 16-valence electron complex. Thus, sulfur trioxide can, unexpectedly,[1] act as a ligand in transition metal complexes despite its pronounced Lewis acidity.



In solution **3** exhibits dynamic behavior: its ^1H and ^{31}P NMR signals are broadened by an exchange process ($\Delta G^{\neq}$ = 61 kJ mol^{-1}) which renders the two PMe_3 ligands magnetically equivalent. Two different processes might be envisioned, a rotation of the SO_3 ligand by 180° (route A, Scheme 1), or a 60°

Scheme 1. Exchange processes leading to equivalence of the PMe_3 ligands in the ^1H and ^{31}P NMR spectra.

rotation concomitant with a 1,2-shift of the metal atom (route B).

Preliminary investigations into the reactivity of **3** document the facile reducibility of the coordinated sulfur trioxide. With a stoichiometric amount of triphenylphosphane, **3** is converted

back into the starting material **1**. An excess of phosphane has to be avoided since this would cause decomposition with phosphane exchange and further reduction of the coordinated SO_2.

Cobaltocene reduces **3** to the sulfito complex **4**; this can be converted back into the starting material **1** by double alkylation via the ethylsulfito complex **5**. Hence the identity of **3** has also been unequivocally proved by chemical means.

Experimental Procedure

3: To a solution of **1** (95 mg, 0.16 mmol) in dichloromethane (5 mL) was added iodosobenzene (88 mg, 0.40 mmol) at −20 °C. After 5 h at 20 °C the slightly turbid brown solution was filtered through celite, and the product precipitated on addition of hexane (15 mL) at 0 °C. Yield 86 mg (88%), yellow-brown crystalline powder (correct elemental analysis for C, H, and S). IR (Nujol) $\tilde{\nu}$(SO) = 1224, 1124 cm^{-1}. ^1H NMR ([D$_6$]acetone, 400 MHz) δ = 1.82 (vt, N = 11.2 Hz, PCH_3), 1.93 (t, J = 0.7 Hz, CCH_3); ^{31}P NMR (CD_2Cl_2, 162 MHz, −70 °C) δ = 9.6, 7.6 (AB system, J(AB) = 55 Hz).

1 from **3**: **3** (7 mg, 11 μmol) was dissolved in CD_2Cl_2 (0.5 mL) in an NMR tube and treated with PPh_3 (2.6 mg, 10 μmol). After 30 min at 20 °C the ^{31}P NMR spectrum consisted predominantly of the signals of **1** (δ = 0.8) and Ph_3PO (δ = 27.5).

4: To a solution of **3** (74 mg, 0.12 mmol) in THF (15 mL) was added cobaltocene (46 mg, 0.24 mmol) at 20 °C. After 3 h the solvent was removed under vacuum, and the residue extracted with benzene. The product was isolated from the evaporated extract by crystallization from dichloromethane/ether. Yield 52 mg (66%), yellow crystalline powder. IR (Nujol) $\tilde{\nu}$(SO) = 1154, 1036 cm^{-1}. ^1H NMR (CD_2Cl_2, 400 MHz) 1.43 (vt, N = 8.9 Hz, PCH_3), 1.71 (s, $C_5(CH_3)_5$), 5.72 (s, $(C_5H_5)_2Co$). ^{31}P NMR (CD_2Cl_2, 162 MHz): δ = 9.3 (s).

1 from **4**: To a solution of **4** (52 mg, 0.08 mmol) in dichloromethane (20 mL) was added Et_3OPF_6 (40 mg, 0.16 mmol) at 20 °C. The yellow solution discolored immediately; precipitation with diethyl ether yielded 45 mg (95%) of **1**.

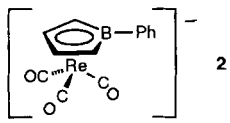
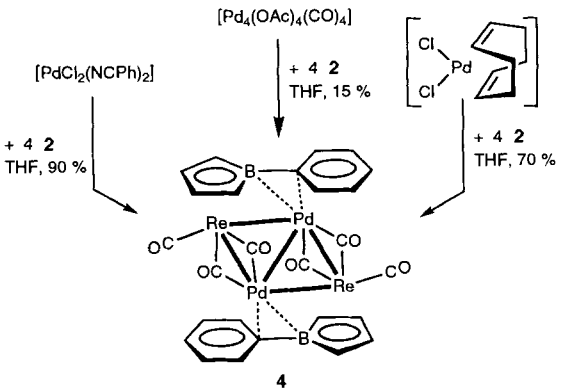
The First Mixed-Metal Borole Cluster; Stabilization of Formally 14e Pd Centers in the Re_2Pd_2 Electron-Deficient $[\{[(\eta^5\text{-}C_4H_4BPh)(CO)_3Re]Pd\}_2]$ Cluster**



Pierre Braunstein,* Ulli Englert,
Gerhard E. Herberich,* and Mark Neuschütz

Carbonylmetalates have long been used for the synthesis of metal cluster complexes and have proved particularly useful in mixed-metal cluster chemistry. The HOMO of 18-electron reagents such as $[CpMo(CO)_3]^-$ ($Cp = \eta\text{-}C_5H_5$) has mostly metal d orbital character, accounting for its propensity to form metal–metal bonds. For the isosteric reagent $[CpMn(CO)_2(CN)]^-$, in contrast, the HOMO is centered on the cyano nitrogen atom, which explains the tendency of this anion to form linear Mn-CN-M′ arrays.[1] In 1990 we found that this cyanometalate is simultaneously involved in both Mn-CN-Pd and direct Mn–Pd bonding in the unprecedented octanuclear, double-helix-type cluster **1**.[2] We have begun an investigation of the reactivity of electronically related borole-containing metalates such as **2**, where the negative charge is very much delocalized, and **3**, where it is mostly associated with the cyano ligand.[3] We also hoped that these compounds would allow the synthesis of the first cluster complexes containing a borole ligand. This was actually achieved and we present here our first results with anion **2** and the characterization of an unprecedented Re_2Pd_2 cluster **4**.

$[\{(\eta^5\text{-}C_5H_4Me)(CO)_2Mn(CN)Pd\}_4]$ **1** $[(\eta^5\text{-}C_4H_4BPh)Re(CO)_3]^-$ **2**



$[(\eta^5\text{-}C_4H_4BPh)Fe(CO)_2(CN)]^-$ **3**

In contrast to the strong nucleophile $[Re(CO)_5]^-$, **2** showed surprisingly little reactivity towards Pt^{II}, Pd^{II}, or Pd^{I} complexes. Neither with *cis*-$[PtCl_2(PEt_3)_2]$, $[PtBr_2(\gamma\text{-picoline})_2]$, $[PtCl_2(NCPh)_2]$, $[PtCl_2(cod)]$ (cod = 1,5-cyclooctadiene), nor $[Pd_2Cl_2(\mu\text{-dppm})_2]$ (dppm = bis(diphenylphosphano)methane) or $[PdCl_2(PPh_3)_2]$ was any product formed and no decomposition of **2** was observed. However, the reactions of **2** with *cis*-$[PdCl_2(NCPh)_2]$, $[PdCl_2(cod)]$, or $[Pd_4(\mu\text{-}OAc)_4(\mu\text{-}CO)_4]$ always afforded the same product **4**. This compound is deep blue-green, owing to the presence of a strong absorption band in the visible region at 640 nm, and is soluble in THF but only slightly soluble in toluene and dichloromethane. It is suprisingly air stable, even in solution. This complex was identified as the Re_2Pd_2 title cluster **4**, in which the palladium centers are in the formal oxidation state +1.

2

The metal core of **4** consists of a planar, triangulated rhombus with an inversion center in the middle of the Pd–Pd′ bond

4

(Fig. 1).[4] This bond is rather long (2.899(2) Å) when compared with those in other clusters,[5–8] in particular the series of planar, triangulated clusters **5**, in which the Pd–Pd′ distance ranges from

$[\{Cp(CO)_3MPd(PEt_3)\}_2]$ **5**, M = Cr, Mo, W

2.573(3) (M = W) to 2.582(1) Å (M = Mo).[5b] The fact that one of the Pd–Re bonds in **4** is very short (2.666(1) Å) is most probably because it is doubly spanned by carbonyl ligands. An average Pd–Re bond length of 2.872 Å has been found in the only other structurally characterized Pd–Re cluster known to us.[9]

[**] This work is based on the Ph.D. thesis of M. N. We are grateful to the Deutsche Akademische Austauschdienst for a grant to M. N., the Centre National de la Recherche Scientifique (Paris) for financial support, and Johnson Matthey PLC for a generous loan of $PdCl_2$.

A remarkable feature of the crystal structure of **4** is the short distance between the *ipso* carbon atom of the phenyl ring and the corresponding palladium atom (2.27(1) Å), which is, however, not accompanied by a pyramidalization of this carbon. The p(π) orbital at C14, which is perpendicular to the phenyl ring and points toward the palladium atom, must be involved in this interaction. Very few crystal structures contain aryl rings η^1-coordinated to a transition metal center in which all the C atoms are sp^2-hybridized.[10] Neither the interaction of the phenyl group with Pd nor the short Pd–B distance of 2.59(2) Å lead to an important slip distortion (0.07 Å).[11] The slight folding of the borole ligand about the C10–C13 axis shifts the boron atom away from the rhenium atom, but its distance to the best plane passing through the borole carbon atoms is only 0.10 Å. These values may be taken as evidence for η^5-coordination of the borole ligand to rhenium and the interaction of the palladium atom with both the boron and the phenyl *ipso* carbon atom.

Whereas the planar, triangulated cluster anion $[Re_4(CO)_{16}]^{2-}$[12] with 62 cluster valence electrons (CVE) satisfies both Wade–Mingos and the Effective Atomic Number (EAN) rules, clusters containing platinum or palladium generally have fewer CVEs. For example the planar, triangulated cluster **5**, M = Mo, has 58 CVE corresponding to five metal–metal bonds between 16-electron palladium and 18-electron molybdenum centers.[5a, b] A localized electron count was not possible, and the $CpMo(CO)_3$ fragment was best considered as a 3e donor metalloligand. The structural similarity (and differences) between Mo_2Pd_2 cluster **5** and **4** ($CpMo(CO)_3$ and (η^5-C_4H_4BPh)$Re(CO)_3$ are isoelectronic fragments) emphasize the origin of the electronic unsaturation in our new Re_2Pd_2 54 CVE cluster **4** (neglecting the Pd-B-C14 interaction): the two electron donor phosphane ligands present in the Mo_2Pd_2 cluster **5** are "missing" in **4**. The fragment (η^5-C_4H_4BPh)$Re(CO)_3$ should be considered as formally donating 3e to the Pd_2 unit, which results in formally 14e Pd centers. The nature and stabilizing role of the interaction of these Pd centers with the B–Ph σ bonds is being further analyzed.[13]

$$2 \times 18(Re) + 2 \times 14(Pd) = 54(CVE) + 5 \times 2\ (2c\text{–}2e\ bonds)$$

Preliminary extended Hückel calculations on **4**[14] give a MO scheme with a small HOMO–LUMO gap (0.676 eV) and a much larger gap between the LUMO and the next unoccupied orbital (1.409 eV). This confirms that cluster **4** is electron deficient and is consistent with the cyclic voltammogram of **4** (THF/TBAH, platinum electrode), which shows two reduction steps, at −0.47 V and −0.85 V vs. SCE, but no oxidation up to +1.0 V. In contrast, the related 58 CVE planar, triangulated clusters **5** and **6** are difficult to reduce (−0.85 V to −1.57 V vs. SCE) but are easily oxidized to dications.[15]

$[\{Cp(CO)_3MPt(PEt_3)\}_2]$ **6**, M = Cr, Mo, W

Experimental Procedure

Reactions were performed under purified nitrogen, using standard Schlenk techniques. Satisfactory elemental analyses were obtained for all complexes. Experiments were carried out in both [D_8]THF (to determine the yields by ^{1}H NMR spectroscopy with NMe_4^+ as internal standard) and toluene.

4: Toluene was added to a mixture of $NMe_4 \cdot$ **2** [3] and the corresponding palladium complex. The reaction mixture was stirred, the deep blue suspension of **4** was filtered and the solvent removed under vacuum.

Reaction of **2** with *cis*-$[PdCl_2(NCPh)_2]$: A solution of $NMe_4 \cdot$ **2** (16 mg, 0.03 mmol) and *cis*-$[PdCl_2(NCPh)_2]$ (6 mg, 0.015 mmol) in [D_8]toluene (0.3 mL) was stirred at ambient temperature for 10 min. The dark blue residue of **4** was identified by NMR spectroscopy (yield by spectroscopy: ca. 90%).

The reactions of **2** with $[PdCl_2(1,5\text{-cod})]$ (stirring at 60 °C for 45 min) and $[Pd_4(OAc)_4(CO)_4]$ (stirring at ambient temperature for 5 min) afforded **4** in yields of ca. 70% and 15%, respectively, by NMR spectroscopy. Monitoring of the reactions by NMR showed that one equivalent of **2** was used to reduce the Pd^{II} complexes to Pd^{I} species, the second equivalent to form cluster **4**.

Selected data for **4**: IR (toluene): $\tilde{\nu}$(CO) = 1978(s), 1894(s) cm^{-1}; IR (KBr): $\tilde{\nu}$(CO) = 1961(s), 1888(s) cm^{-1}; FIR (polyethylene): $\tilde{\nu}$ = 488(m), 478(s), 466(s), 437(m), 413(s), 370(m), 329(m), 296(m) cm^{-1}; UV (THF): λ = 640 nm; ^{1}H NMR (300 MHz, [D_8]toluene): δ = 7.74, 7.47 (m, 10H; phenyl), 4.87 (m, 4H, $N = {}^3J_{23} + {}^4J_{24} = 6.4$ Hz; 3,4-borole), 3.83 (m, 4H, $N = 6.4$ Hz; 2,5-borole); ^{1}H NMR (80 MHz, [D_8]THF): δ = 7.57, 7.02 (m, 10H; phenyl), 5.39 (m, 4H, $N = 6.4$ Hz; 3,4-borole), 3.89 (m, 4H, $N = 6.4$ Hz; 2,5-borole); MS (SIMS, DMBA): *m/z* (%): 1034 (13) [M^-], 950 (4) [$M^- - 3CO$], 411 (100) [**2**]$^-$.

[13] Considering the B–C14 bond as a 2e donor toward the Pd center, as suggested by a reviewer, would of course lead to 16e Pd, but this does not appear justified on the basis of the ligand geometry and preliminary extended Hückel calculations.

[14] a) The calculations were performed using the extended Hückel method [14b] with a weighted H_{ij} approximation [14c]. The programs used were FORTICON [14d] for the complete molecule and CACAO [14e] for the naked cluster. The geometry used corresponds to the structure of **4** in the crystal, the values for the H_{ii}s and orbital exponents were taken from literature [14f–h], and the Hückel constant was set to 1.75. b) R. Scheme 1.

A low-temperature crystallographic study[5] shows **1** to be a twenty-membered polyhedral cage in which a central planar $[K(\mu_2\text{-}OtBu)]_3$ ring is sandwiched between the intact neutral halves of the parent cage $[\{(cyNLi)_3Sb\}_2]$ (Fig. 1, top).[1] Two of the K^+ ions (K(2) and K(3)) within the core are loosely π-bonded to toluene ligands and two additional toluene ligands are found within the lattice, giving a total of four toluene molecules ($x = 4$) for each molecule of **1** (Fig. 1, bottom). This composi-

Cage Expansion of $[\{(cyNLi)_3Sb\}_2]$; Synthesis and Structure of the Trimetallic Complex $[\{(cyNLi)_3Sb\}_2(tBuOK)_3 \cdot x\,C_6H_5CH_3]$**

Donald Barr, Andrew J. Edwards, Michael A. Paver, Paul R. Raithby, Moira-Ann Rennie, Christopher A. Russell, and Dominic S. Wright*

A range of polyamidoantimony anionic cage complexes can be prepared by "mixed-metalation" reactions of dimethylamidoantimony complexes with monometalated primary amines (RNHM).[1, 2] For instance, an $[Sb(NR)_3]^{3-}$ ion is present in the $[\{(PhCH_2CH_2NLi)_3Sb(thf)\}_2]$ complex, produced by the reaction of $Sb(NMe_2)_3$ with $[PhCH_2CH_2NHLi]_n$.[1] The complex has a fourteen-membered polyhedral $[Sb_2N_6Li_6]$ core, which can be regarded as being constructed from an "iminolithium-like" Li_6N_6 core capped at the open Li_3N_3 faces by two Sb atoms.[3] These polyamidoantimony anions can be used as durable ligands for other metals. Thus, the transmetalation reaction of $[Sb_2(Ncy)_4]_2Li_4$ with CuCl produces the mixed-metal complex $[Sb_2(Ncy)_4]_2Cu_4$ in which two $[\{Sb_2(Ncy)_4\}_2]^{2-}$ dianions coordinate to a central planar Cu_4 unit.[4]

We describe here an unexpected alternative in the coordination chemistry of these species towards other salts. Simply mixing the bimetallic $[\{(cyNLi)_3Sb\}_2]$ complex with KO*t*Bu results in cocomplexation of the neutral components. The product is the remarkable trimetallic complex **1** in which cage expansion of the bimetallic precursor to a twenty-membered cage has occurred (Scheme 1).

$[\{(cyNLi)_3Sb\}_2(KOtBu)_3 \cdot x\,C_6H_5CH_3]$ **1**

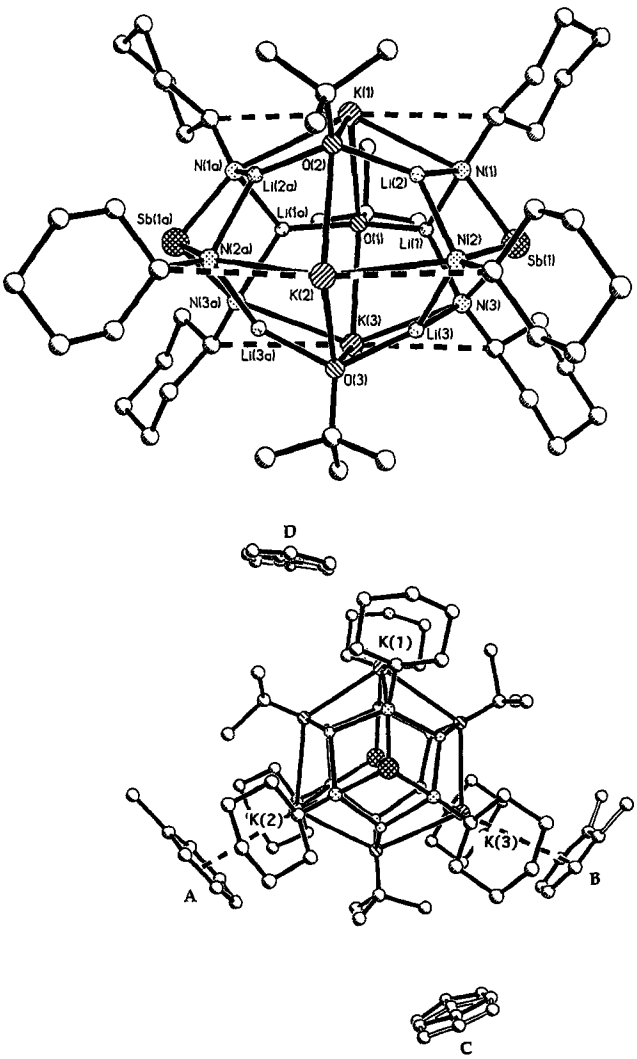

Fig. 1. Top: Molecular structure of **1**. Hydrogen atoms have been omitted for clarity. Selected average bond lengths [Å] and angles [°]: Sb–N 2.063, N–Li 2.01, K–N 2.854, K–O 2.90 (range 2.83–3.05), Li-O 1.90, cy α-C···K from 3.21(1) to 3.352(9); N-Sb-N 91.3, O-K-O 112.3, K-O-K 127.7, N-K-N 125.5, Li-O-Li 125.3, O-K-N 75.2. tion is consistent with analytical data on bulk samples of **1**, which indicate that there are about 3.5–4.0 molecules of toluene for each molecular unit. Although tripodal amide complexes of various main group metals[6] have been investigated, the structure of **1** and the cage expansion reaction involved in its formation are unpecedented.

Apart from a small compression in the N-Sb-N angles, the structure of the $[(cyN)_3Sb]^{3-}$ fragments of **1** are similar to that observed in $[\{(PhCH_2CH_2NLi)_3Sb(thf)\}_2]$ (average bond lengths and angles: Sb–N 2.063 Å, N-Sb-N 91.3° in **1**; Sb–N 2.063 Å, N-Sb-N 94.5° in $[\{(PhCH_2CH_2NLi)_3Sb(thf)\}_2]$[1]). A more noticeable difference is seen in the N–Li distances which are significantly shorter in **1** (average 2.01 Å in contrast to 2.10 Å in $[\{PhCH_2CH_2NLi)_3Sb(thf)\}_2]$[1]). Neither the K–O bonds nor the angles within the equatorial $[K(\mu\text{-}OtBu)]_3$ ring are completely symmetrical/average values: K–O 2.904 Å, O-K-O 112.3° and K-O-K 127.7°). This ring is planar, and attached symmetrically to the two $[(cyNLi)_3Sb]$ fragments by both K–N (average: 2.854 Å) and O–Li (average: 1.90 Å) bonds. Thus the terminal $[(cyNLi)_3Sb]$ units act both as donors and as acceptors in stabilizing this ring. The presence of a K_3O_3 fragment is a rare feature in the structure of **1**. Such a ring is seen in the salt complex $[(KNCS)_3 \cdot 5HMPA]$ (HMPA = hexamethylphosphoric triamide), which has a cage structure formed from the oxygen atoms of three HMPA ligands and three K^+ ions, capped by two μ_3-O atoms from HMPA ligands.[7]

All the K^+ ions in **1** are pseudo square-pyramidally surrounded by the O centers of the K_3O_3 ring and the N centers of the two $[(cyNLi)_3Sb]$ fragments (average angles: N-K-N 125.5°, Li-O-Li 125.3°, O-K-N 75.2°). This geometry leaves the K^+ ions open to loose coordination by toluene in the equatorial plane of the cage. The ion–dipole interaction of aromatic ligands with K^+ ions is now well-documented: typical $arene_{(centroid)} \cdots K^+$ distances lie in the range 3.18–3.59 Å[8] (cf. 3.43 and 3.79 Å for the π-bonded $C_6H_5CH_3$ ligands in **1**). Additionally, moderately short agostic interactions between cyclohexyl α-C-H and K^+ apparently further satisfy the coordination sphere of the K^+ centers of **1** (range α-C $\cdots$ K 3.21(1)–3.352(9) Å). These lengths are typical for organopotassium complexes.[9]

The unusual cocomplexation of $[\{cyNLi)_3Sb\}_2]$ and [KO*t*Bu] producing **1** is presumably driven largely by the formation of strong Li–O bonds. We are investigating other reactions of $[\{(cyNLi)_3Sb\}_2]$ and related polyamidoantimony complexes with alkoxides and amides of main group metal and transition metals.

Experimental Procedure

$[\{(cyNLi)_3Sb\}_2]$ was prepared by step-wise metalation of $cyNH_2$ (8.91 g, 90 mmol) in $C_6H_5CH_3$ (50 mL) with first *n*BuLi (56.25 mL, 1.6 mol L^{-1} in hexanes, 90 mmol) and then $Sb(NMe_2)_3$ (7.59 g, 30 mmol) at 20 °C. After filtration of the yellow solution and reduction in vacuo (to about 10 mL), the complex was isolated as a light yellow powder (yield 10.4 g, 80%). To a white slurry of $[\{(cyNLi)_3Sb\}_2]$ (2.165 g, 2.5 mmol) in $C_6H_5CH_3$ (20 mL) was added KO*t*Bu (Aldrich, 0.841 g, 7.5 mmol). Stirring at 20 °C (0.5 h) produced a red-orange solution. The remaining solid was then filtered off, and the solution was reduced to about 5 mL under vacuum. The yellow solid that precipitated was heated back in to solution, and storage at 5 °C (24 h) produced yellow crystalline blocks in low, though reproducible, yield (0.20 g first batch, 10%; although we believe that the low yield is a consequence of the high solubility of **1** in toluene, the possibility of side reactions or equilibria cannot be discounted); the crystals darken at 155 °C and melt at 178–180 °C with liberation of toluene; ^1H NMR (C_6D_6, +25 °C): $\delta = 7.10$ (m, aryl C–H, $C_6H_5CH_3$), 3.63 (m, α-C-H of cyN), 2.10 (s, CH_3 of $C_6H_5CH_3$) 0.7–3.0 (br. m, CH_2 of cyN), 1.25 (*t*BuO); relative integrals could not be obtained due to the overlapping of the *t*BuO, CH_2 (from cyN), and CH_3 (from toluene) resonances; elemental analyses (C, H, N) confirm that ca. 3.5–4.0 $C_6H_5CH_3$ molecules are present per molecule of **1**.

Structure Determination of Vitamin A Acetate Isomers through Coupled HPLC and ^{1}H NMR Spectroscopy**

Klaus Albert,* Götz Schlotterbeck, Ulrich Braumann, Heidrun Händel, Manfred Spraul, and Gerhard Krack

Vitamin A (retinol) plays an important role in the human body as a growth and protection factor; after oxidation to the corresponding aldehyde (retinal), it is also an active component in rhodopsin. In the vision process the isomerization of 11-*cis*-retinal to all-*trans*-retinal is one of the important biochemical processes in the rhodopsin cycle. Naturally occurring vitamin A (all-*trans*-retinol) and synthetic vitamin A acetate often coexist with their *cis*–*trans* isomers (Fig. 1).[1, 2] Fast and unequivocal structure

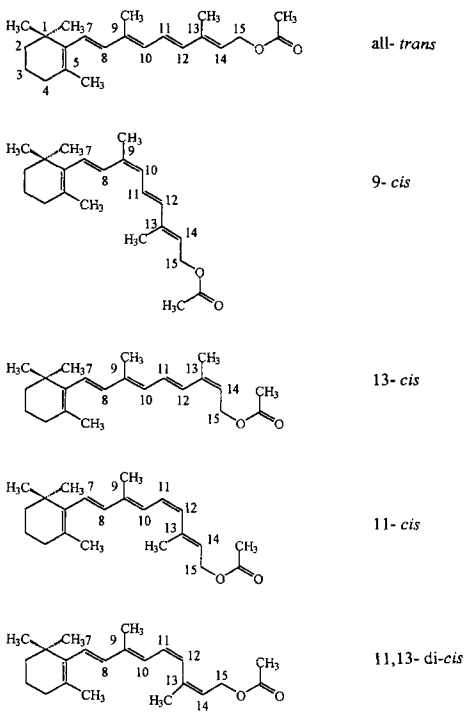

Fig. 1. Major isomers of vitamin A acetate.

determination of vitamin A acetate isomers prepared by different methods is of increasing importance because of the widespread use of these vitamins. Retinol and its derivatives are applied in medicine because of their antioxidative properties[3] and in tumor therapy because of their cytostatic activity.[4] In addition, these compounds are used as nutritional additives and in cosmetics. The separation of *cis*–*trans* isomers of carotinoids, in particular of vitamin A acetate, is possible by high-performance liquid chromatography (HPLC) with cyanopropyl- or *n*-alkyl-modified silica gel as the stationary phase.[5–7] Only hints to the structures of the separated isomers are given by the routine monitoring of the chromatographic separation by UV spectroscopy. Capacity factors derived from the chromatographic separation are not well suited for structure elucidation.[8] Structure assignment may be possible by comparative measurements, which require many experiments and are very time-consuming. Applying HPLC coupled with mass spectrometry for the present application is not feasible because the *cis*–*trans* isomers of vitamin A acetate have the same fragmentation pattern. Therefore we attempted to elucidate the structures of the different isomers by coupled HPLC and ^{1}H NMR spectroscopy.[9–15]

The vitamin A acetate isomers used as model compounds were prepared by briefly heating all-*trans* vitamin A acetate to 160 °C. Figure 2 shows the ^{1}H NMR spectrum (400 MHz) of the isomer mixture. Structure elucidation of distinct compounds is not possible because of signal overlap. Five main compounds are evident in the UV chromatogram for the separation of the isomer mixture on a cyanopropyl-modified silica gel phase with *n*-heptane as eluent (Fig. 3). Under the applied conditions (see Experimental Procedure) peaks 1 and 2 are not fully separated.

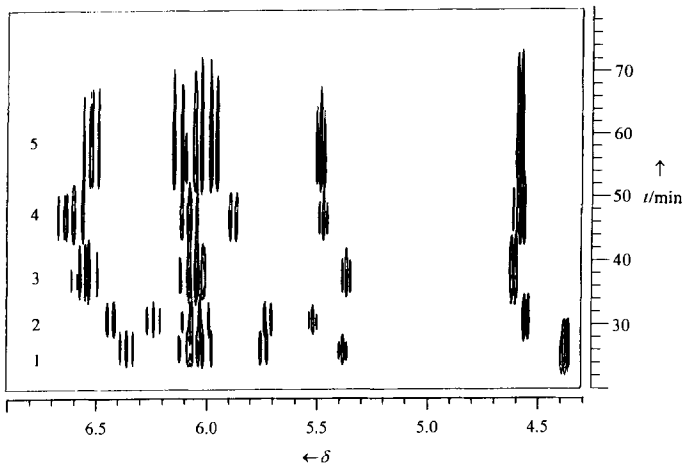

Fig. 4. Contour plot of the on-line HPLC NMR separation of a mixture of vitamin A acetate isomers (for parameters see Experimental Procedure). (1: 11,13-di-*cis*, 2: 11-*cis*, 3: 13-*cis*, 4: 9-*cis*, 5: all-*trans* vitamin A acetate).

Since *n*-heptane is used as eluent, the ^{1}H NMR signals of the aliphatic protons are not accessible for structure determination. Nevertheless, the contour plot (Fig. 4) of the on-line HPLC–NMR separation displays interesting details. Here the ^{1}H NMR signals of the olefinic protons of the separated compounds (x axis = ^{1}H chemical shift) are plotted against the retention times (y axis). The structure assignments will not be discussed in detail, but the two isomers (peaks 1 and 2), which were only poorly distinguished in the UV chromatogram, can be identified by their different ^{1}H NMR spectra.

The structures of the separated isomers were assigned based on the coupling constants, chemical shifts, and integration ratios from the continuous-flow ^{1}H NMR spectra. Figure 5 displays the olefinic region of the continuous-flow ^{1}H NMR spectra of the separated isomers recorded at the peak maximum. Routine and continuous-flow NMR spectra show the same resolution. The analysis of chemical shifts, coupling constants, and intergration ratios, which are not displayed because of lack of space, results in the structure assignments in Table 1.

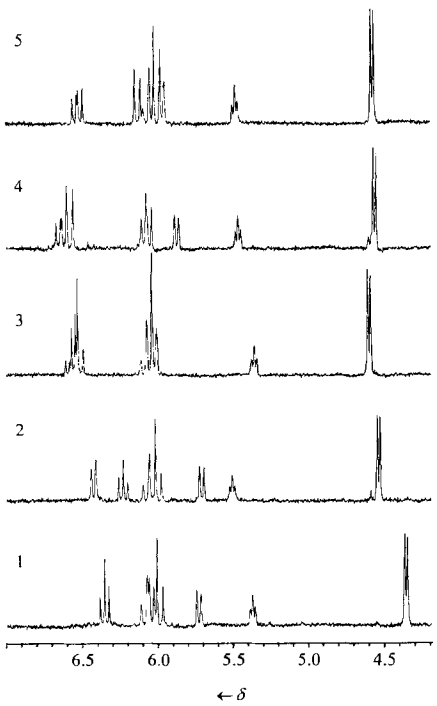

Fig. 5. Continuous-flow ^{1}H NMR spectra (400 MHz) of the separated vitamin A acetate isomers (1: 11,13-di-*cis*, 2: 11-*cis*, 3: 13-*cis*, 4: 9-*cis*, 5: all-*trans* vitamin A acetate).

Table 1. ^{1}H NMR spectroscopic data for vitamin A acetate isomers in *n*-heptane.

Isomer	Peak	Chemical shifts δ of the olefinic protons 7	8	10	11	12	14	Coupling constants J [Hz] ^3J (7,8)	^3J (10,11)	^3J (11,12)
11,13-di-*cis*	1	6.10	6.00	6.05	6.36	5.74	5.38	16.0	12.3	11.3
11-*cis*	2	6.08	6.00	6.43	6.24	5.71	5.51	15.8	11.7	11.7
13-*cis*	3	6.09	6.03	6.03 [a]	6.57 [a]	6.52 [a]	5.36	15.0	11.0 [a]	14.1 [a]
9-*cis*	4	6.09	6.58	5.88	6.64	6.06	5.47	16.1	11.7	14.1
all-*trans*	5	6.07	6.01	5.97	6.53	6.13	5.48	16.1	11.4	15.1

[a] ABX system, $^4J(10,12) < 0.3$ Hz.

Differences between these chemical shifts and previously reported values[16, 17] can be explained by the different solvents used, in our study, *n*-heptane. Whereas chemical shifts and coupling constants can be derived directly from the spectra of 11,13-di-*cis* and 9-*cis* isomers, the all-*trans*, 11-*cis*, and 13-*cis* isomers display more complex spectra. In these three isomers H7 and H8 are an AB system, and in the 13-*cis* isomer H10, H11, and H12 an ABX system. Assignment of the olefinic protons was confirmed by homonuclear correlated spectra (H,H COSY) acquired in the stopped-flow mode. Chemical shifts and coupling constants of the ABX system were determined with the simulation program WIN-DAISY.[18]

Our study of vitamin A acetate isomers shows that under unfavorable chromatographic conditions such as high concentrations[19] and slow flow rates, even coeluting compounds can be characterized unequivocally within a short analysis time. The great advantage of directly coupled HPLC and NMR spectroscopy is quite obvious. Due to the introduction of a second dimension, the ^{1}H NMR frequencies (chemical shifts and coupling constants), safe and unequivocal structure assignment is possible even when overlapping peaks are seen in conventional UV chromatograms.

Experimental Procedure

Two analytical Nucleosil 5 CN columns were connected for the separation of vitamin A acetate isomers. The original separation [20] was performed with a flow rate of 1 mL min^{-1}. From the viewpoint of NMR spectroscopy a lower rate is favorable: with a slower flow rate the number of coadded transients at a given sample volume is higher, which results in an improved signal/noise ratio (S/N). Taking into account a constant S/N and the same number of coadded transients, the number of spectra per peak elution volume can be increased. On the other hand, a reduced flow rate is below the optimal values derived from the van Deemter equation. As a practical compromise the normal flow rate of 1 mL min^{-1} was used at the beginning of the separation, and prior to the appearance of the peaks in the UV detector the flow rate was reduced to 0.2 mL min^{-1}, a more favorable rate for NMR measurements; generally longer retention times resulted.

For extended NMR measurements (e.g. stopped-flow experiments for homonuclear or inverse correlated spectra) a deuterium signal, typically from the deuterated solvent, is recommended for field-frequency stabilization. For economic reasons it is not possible to add enough deuterated eluent for a sufficiently intense deuterium signal. Therefore [D$_6$]benzene was added, because it neither alters the applied chromatographic separation conditions severely nor affects the absorption of the olefinic system at the detection wavelength of 325 nm, and [D$_6$]benzene yields a sufficient lock signal even at a concentration of only 1%.

Chromatographic parameters: Pump: Bruker LC 22; two columns: Macherey-Nagel 250 × 4.6 mm, Nucleosil 5 CN, 5 μm; eluent: *n*-heptane (dried over 0.3 nm molecular sieves); flow rate: 20 min at 1.0 mL min^{-1} (130 bar), later 0.2 mL min^{-1} (30 bar); UV detector: Hewlett Packard 1050, detection wavelength 325 nm. A

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1015 $ 10.00+.25/0

solution of 5 mg of the vitamin A acetate mixture in 50μL of *n*-heptane (10% solution) was used for the chromatographic separation.

NMR parameters: Bruker ARX 400 spectrometer, 120μL continuous-flow probe with an rf coil arrangement for inverse $^{13}C/^{1}H$ spectroscopy; 48 transients per FID; 8K time domain data points (TD2) with a spectral width (SW2) of 5618 Hz, acquisition time (AQ) = 0.73 s per transient, pulse width 90°, solvent presaturation over 0.5 s (alternating irradiation at the heptane signals at $\delta = 0.82$ and 1.22 for 5 ms each); 128 FIDs (TD1) with an acquisition time per FID of 60 s were recorded during the separation.

Data were treated like a 2D NMR matrix (t_1 direction = retention time) and processed with UXNMR software [21]; a phase-sensitive Fourier transformation was performed only in the t_2 direction: zero filling in t_2 to 32K data points; multiplication with a sine square apodization function.

[19] Separation and structure assignment is even possible at concentration levels at which UV detection fails. The detection limit of all-*trans* vitamin A acetate under stopped-flow conditions was determined to be 1.2 μg within the flow-cell with a signal/noise ratio of 4:1 for the doublet of H15 at $\delta = 4.8$. Solutions of different concentrations were directly injected into the flow-cell, and 512 transients were accumulated for each measurement. The *n*-heptane signals were suppressed by application of the above-mentioned presaturation sequence. Spectra were processed without using any filter function.

4c/3e Radical Cations with Cage-Directed Configurations**

Georg Gescheidt,* Rainer Herges,* Helfried Neumann, Jürgen Heinze,* Markus Wollenweber, Markus Etzkorn, and Horst Prinzbach*

Dedicated to Paul von Ragué Schleyer on the occasion of his 65th birthday

On the reaction coordinate of the symmetry-forbidden ethylene/ethylene [2 + 2]cycloaddition[1] with imposed D_{2h} symmetry, cyclobutane is the sole minimum ($r = 1.584$ Å, Fig. 1). What

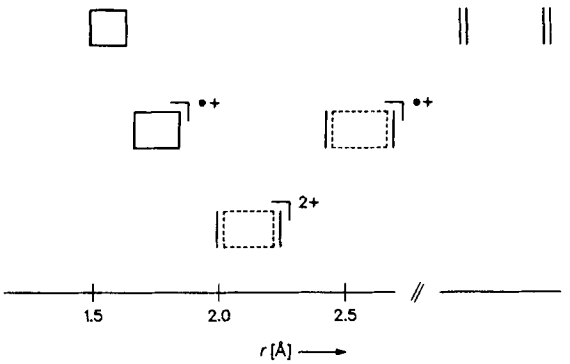

Fig. 1. Minima on the D_{2h} reaction coordinate of the cycloadditions ethylene/ethylene, ethylene/ethylene$^{\bullet+}$, and ethylene$^{\bullet+}$/ethylene$^{\bullet+}$ (ab initio 3-21G). r = distance between the ethylene units.

happens, when one electron is removed from the system? The [2 + 1]addition remains symmetry-forbidden, the activation barrier is lowered, however, in this case two minima exist: a π-complex-like ($r = 2.6$ Å, "extended") and a cyclobutanoid ($r = 1.75$ Å, "tight") species.[2] When a second electron is removed, there is only one (σ-bishomoaromatic) minimum[3] for the symmetry-allowed [1 + 1]addition—with $r = 2.15$ Å almost exactly at a distance where the two forbidden additions show their energy maximum. These nonclassical four-center–three-electron (4c/3e) and 4c/2e configurations are found not to be energy minima in calculations without symmetry restrictions; they are therefore only experimentally observable if structural provisions prohibit their transition into the respective global minimum configurations (open, localized ions).[4]

The rigid hydrocarbon cages of the (*iso*)pagodanes ([1.1.1.1]; [2.2.1.1]) and (bisseco-, seco)dodecahedradienes offer such "steric protection" and in addition allow the gradual modulation of the geometrical situation (r) in the central 4c core[5, 6] (cf. the PE spectroscopic characterization of "early" and "late" points on the D_{2h} reaction coordinate[7]). In this communication it is demonstrated that the radical cations generated from the [2.2.1.1] skeletons **1(2)**[2, 8] and the *iso*-skeletons **3(4)**[9]—one molecular half of **1(2)** is rotated by 90°—represent nonclassical, yet different configurations ("tight" and "extended", respectively); in contrast to the findings with the [1.1.1.1]skeletons,[2] the [2.2.1.1]pagodane cage stabilizes the "tight", and the [2.2.1.1]*iso*pagodane cage the "extended" minimum of the [2 + 1] reaction coordinate. MM2 calculations for the neutral molecules had suggested a relative preference for the *iso*-diene **4** ($\Delta\Delta H_f^\circ$ **1** → **2** = +15.0, **3** → **4** = +1.8 kcal mol^{-1});[10] this was confirmed by ab initio 3-21G calculations (Fig. 2).

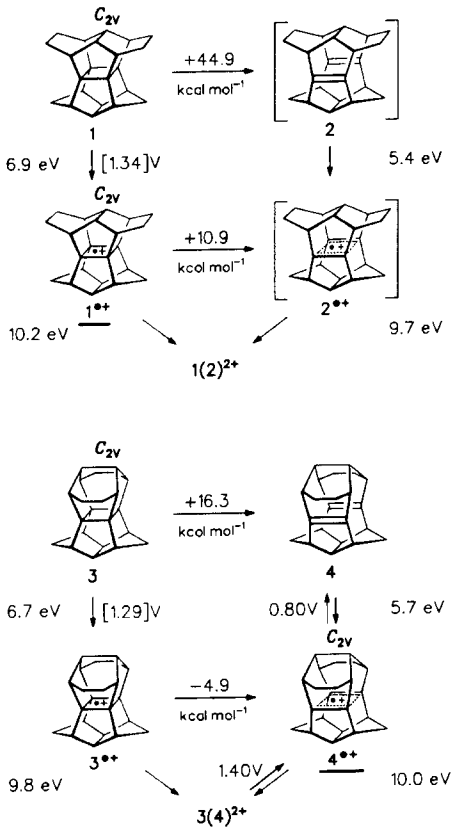

Fig. 2. Calculated nonvertical ionization energies [eV], reaction enthalpies (ab initio 3-21G, [kcal mol^{-1}]), and measured oxidation potentials ([E_p], E_o [V]) of the [2.2.1.1]structures **1(2)** and **3(4)**.

The course of the electrochemical oxidation[11] of **1** and **3** is strikingly different, as characterized by the cyclic voltammograms in Figure 3: For **1** even at very high scan rates and at temperatures as low as −70 °C only an irreversible wave is registered; after reversal of the scan no reduction is observed. For **3**, after a single scan, two oxidation waves, and after reversal of the scan, two reduction waves are revealed. In a multisweep experiment an additional oxidation wave appears which gains intensity at the expense of the first oxidation wave; a cyclic voltammogram has finally evolved which is identical with the one independently obtained from **4** and which, notably, demonstrates reversibility for the second oxidation step. In line with the reaction enthalpies (Fig. 2), the "tight" radical cation **1**$^{\bullet+}$ is not stabilized by opening to **2**$^{\bullet+}$ (speculations can be made about the nature of the obviously very fast follow-up reaction(s)), whilst **3**$^{\bullet+}$ rapidly expands to **4**$^{\bullet+}$. The latter is reversibly reduced to the diene **4** and oxidized to the dication **3(4)**$^{2+}$ (ECE process, the lifetime of **3(4)**$^{2+}$ in CH_2Cl_2, the most persistent σ-bishomoaromatic dication known to date, is about 0.8 s[12]).

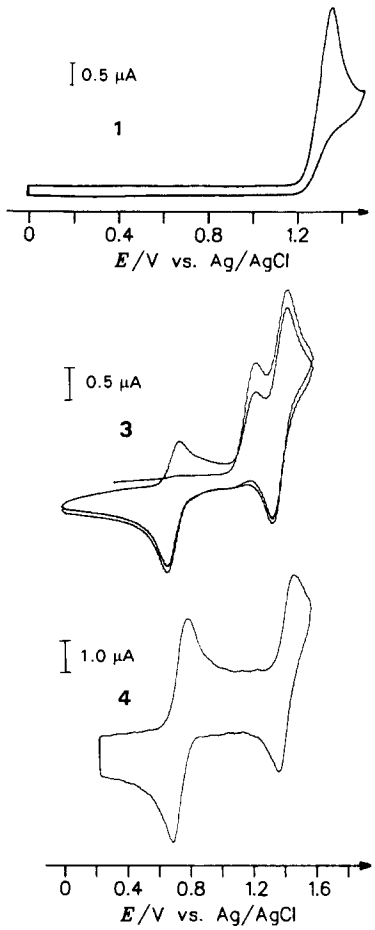

Fig. 3. Cyclic voltammograms of **1** (v = 200 mV s^{-1}), **3** (v = 1 V s^{-1}), and **4** (v = 5 V s^{-1}) in CH_2Cl_2/0.1 M nBu_4NPF_6 at 0 °C.

In agreement with the results of the cyclic voltammetric studies, the deeply colored radical cations generated under high vacuum from **1** and **3** in CH_2Cl_2 by electrolysis or with electron transfer reagents (tris(*p*)bromophenyl)-ammoniumyl-hexachloroantimonate, $AlCl_3$) are found to be of vastly different persistence: The ion from **1** (λ_{max} = 610 nm[13]) exists at −60 °C only for about 30 minutes, the ion from **3** (λ_{max} = 586 nm[13]), however, even at room temperature for more than 24 hours. The ESR spectra, registered at −40 °C in CH_2Cl_2 (Fig. 4), underscore the discrepancy: The spectrum of **1** is dominated by two ^{1}H-hyperfine coupling constants (a_H) of 1.76 and 0.96 mT for two sets of four β-protons. Additional a_H (6 sets) observed in the ENDOR spectrum are not resolved; an assignment cannot be made because of their similar and very small size and unknown multiplicity. The spectrum of **3** with its quintet splitting exhibits a large coupling constant of 1.63 mT for four equivalent β-protons. The multiplicities of the a_H which are additionally detected in the ENDOR spectrum can be determined by simulation of the ESR spectrum; an assignment remains unreliable because of their similar size. In ESR spectra measured after γ-irradiation (^{60}Co) of **1** and **3** at −196 °C in a Freon matrix ($CFCl_3$),[14] the a_H values are practically unchanged—the structures of both radical cations are static (C_{2v} symmetry) within the hyperfine time scale. With estimated dihedral angles between the (hypothetical[15]) $2p_z$ axis of the central C atoms and the C_β–H bonds of the [2.2] molecular parts of 10–0° for **1**$^{\bullet+}$ and **2**$^{\bullet+}$ and of 90–80° for **3**$^{\bullet+}$ and **4**$^{\bullet+}$ (the angles for the [1.1] molecular parts are 15–25° and 10–0°, respectively), however, like in the case of *iso* [1.1.1.1] ions,[2] only the "upper" ([2.2], 1.76, <0.08 mT)/"lower" ([1.1], 0.96, 1.63 mT) differentiation is unambiguous. Particularly in view of the varying hybridization of the quaternary C centers in the "tight" and "extended" configurations further interpretations on the basis of the McConnell equation are problematic.[2, 16]

Fig. 5. Structures of the radical cations $\mathbf{1}^{\bullet+}$–$\mathbf{4}^{\bullet+}$ optimized by ab initio (UHF/3-21G) calculations. Bond lengths and transannular distances in [Å], olefinic pyramidalization Φ in [°], ((−)/(+) inside (outside)), energies E_{rel} (relative to the most stable isomer $\mathbf{4}^{\bullet+}$) in [kcal mol^{-1}], and ESR coupling constants ($a_H\beta$) in [mT] (in each case the first value is for the [2.2] side).

The designation of the short-lived radical cation derived from **1** as "tight" ($\mathbf{1}^{\bullet+}$) and that of the longer lived ion from **3**(**4**) as "extended" ($\mathbf{4}^{\bullet+}$) is again[2, 5] corroborated by ab initio[18] and INDO[19] calculations. The geometries were optimized at the UHF/3-21G level and confirmed as minima by harmonic frequency analysis. The ESR coupling constants (a_H) calculated with the INDO method are based on the geometries determined by ab initio calculations (Fig. 5). According to these calculations both [2.2.1.1]pagodanes exhibit two minima (bond-length isomers $\mathbf{1}^{\bullet+}$, $\mathbf{2}^{\bullet+}$ and $\mathbf{3}^{\bullet+}$, $\mathbf{4}^{\bullet+}$)—for the pagodane cage the "tight" ($\mathbf{1}^{\bullet+}$), for the *iso*pagodane cage the "extended" structure ($\mathbf{4}^{\bullet+}$) is the more stable isomer. Indeed, the agreement between observed and calculated ESR coupling constants is better for $\mathbf{1}^{\bullet+}$ and $\mathbf{4}^{\bullet+}$.[19] The symmetrical (concerted) transition "tight" → "extended" is forbidden since both species in each system have different state symmetries ($\mathbf{1}^{\bullet+}$: $^2B_{2u}$; $\mathbf{2}^{\bullet+}$: $^2B_{1u}$; $\mathbf{3}^{\bullet+}$: $^2B_2$; $\mathbf{4}^{\bullet+}$: $^2B_1$). Nevertheless, the reaction may have a low barrier of activation through a symmetry-breaking process (e.g. a trapezoidal transition structure).[20]

[19] A "chemical" hint to the existence of a "tight" 4c/3e configuration is the finding that the dication produced from [1.1.1.1]*iso*pagodane [2] is reduced by methanol to the starting hydrocarbon (not to the [1.1.1.1]*iso*diene); the [2.2.1.1] dication $3(4)^{2+}$—like the [1.1.1.1] dication [3]—adds methanol (G. A. Olah, G. K. S. Prakash, personal communication). Remarkably, [2.2.1.1]isopagodane **3** (→ **4** [8]), but not [1.1.1.1]*iso*pagodane, can be transformed by PET into the respective diene (T. Voss, dissertation, University of Freiburg, **1995**).

[20] Note added in proof (March 11, 1995): The "tight" [1.1.1.1] radical cation [2] has recently been observed by FDMR (fluorescence detected magnetic resonance) in *n*-hexane (190 K – room temperature); at a lifetime of 0.2 μs at 293 K it is isomerized into the "extended" form. The measured $a_H\beta$ is remarkably close to the one calculated by the ab initio methods applied in this paper (1.02 vs. 1.05 mT) (A. D. Trifunac, D. Werst, personal communication).

Polar Interactions between Stacked π Systems in Fluorinated 1,8-Diarylnaphthalenes: Importance of Quadrupole Moments in Molecular Recognition**

Franco Cozzi,* Francesco Ponzini, Rita Annunziata, Mauro Cinquini, and Jay S. Siegel*

Interactions between aromatic units are invoked to rationalize a variety of molecular processes, such as stereoselective organic transformations[1] and molecular recognition,[2] and to explain the structure of many biologically relevant molecules.[3] Molecular recognition involving simple benzene derivatives has been modeled through a multicomponent equation with a strong electrostatic contribution to the energy of interaction,[4] and the experimentally observed effects are consistent with the quadrupole of the benzene ring playing an important part.[5] The sensitivity of phenyl stacking interactions to substitution can be revealed through a study of the dynamics of 1,8-diarylnaphthalenes.[6, 7] From this study, a simple model arises in which the electrostatic interaction between two benzene rings in the parallel stacked geometry is distinctly repulsive and sensitive to ring substitution such that electron donors heighten the electrostatic repulsion between the rings and electron acceptors diminish it.

A straightforward test for the electrostatic model, and an extension of the general analysis, is to reverse the charge distribution in the quadrupole of the ring and look for a commensurate change in the relative dynamics. Benzene and perfluorobenzene have quadrupole moments of similar magnitudes; however, in contrast to benzene, the individual bond dipoles of fluorobenzene point outward, to the highly electronegative fluorine atoms, resulting in a quadrupole in which the outer torus is negative.[8] Therefore, the electrostatic interaction between benzene and perfluorobenzene in the parallel stacked arrangement should be attractive and the substituent effects should be reversed.[9]

Continuing our investigations into 1,8-diphenylnaphthalene systems, we prepared three new series of 1,8-diphenylnaphthalenes (Fig. 1). In two series an "electron-rich" phenyl ring (ring A, phenyl or tolyl) was held constant as the variable ring (ring B) became progressively more fluorinated (**1a–d** and **2a–e**). In the third series ring A was made "electron-deficient" by perfluorination and ring B varied by different monosubstitutions (**3a–e**).[10] Standard Ullmann coupling methods were used to prepare these compounds.[11] The dynamics of phenyl group rotation were monitored by 2D EXSY NMR experiments;[12, 13] for compounds **2a, b** and **2d, e** barriers were estimated from both ^1H and ^{19}F exchange data.

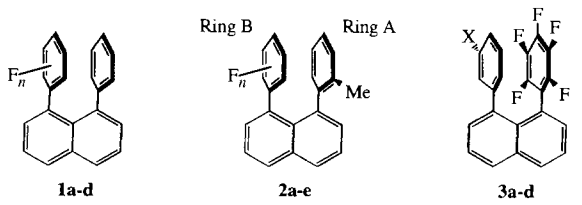

Fig. 1. Structure of compounds **1a–d**, **2a–e**, and **3a–d**; ring A is the phenyl ring on the right.

The barriers determined for **1a–d** and **2a–e** are in line with fluorine's general action as an electron-withdrawing group (Table 1). Progressive addition of fluorine to one phenyl ring correlates with an increase in the barrier to rotation, indicating a decrease in the stacked repulsion due to a removal of electron density from the center of the ring. The effect is approximately additive at 0.5 kcal mol^{-1} per fluorine atom; thus, the direction and magnitude of the slope as a function of Hammett parameter are in accord with our earlier work. In series **2a–e**, *syn*/*anti* isomerism occurs. The ratio of isomers is constant across the series, and *syn*–*anti* barriers are correspondingly 0.5 kcal mol^{-1} lower than *anti*–*syn* barriers. This effect shifts the line but does not change the nature of the correlation.

Table 1. Barriers to rotation for compounds **1a–d** (at 24 °C), **2a–e** (at 120 °C), and **3a–d** (at 80 °C).

Compound	Substituent	Position	ΔG^* [a]
1a	F	2	17.1
1b	F	2,3	17.6
1c	F	2,5	17.7
1d	F	2,3,4	18.1
2a	F	2	21.9 (21.8)
2b	F	2,3	22.3 (22.5)
2c	F	2,4	22.4
2d	F	2,5	22.0 (22.2)
2e	F	2,3,4	22.6 (22.6)
3a	NO_2	3	19.5
3b	CO_2Me	3	19.8
3c	Me	3	20.2
3d	NH_2	3	–

[a] Determined from ^1H NMR spectra; the values in parentheses were determined from ^{19}F NMR spectra.

In the series **3a–d**, ring A is perfluorinated and the electron donor/acceptor character of a single substituent on ring B varies. The symmetry of the perfluorinated ring mandates that

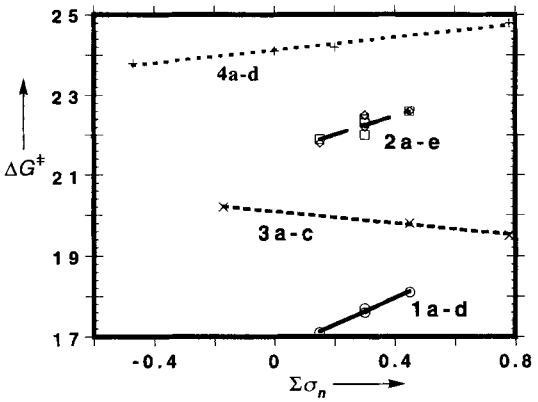
ring B be substituted in an unsymmetrical manner in order to make 2D NMR EXSY analysis possible. Because of the variability of steric effects from substituents in the 2-position, the 3-position was derivatized. The amino compound **3d** was not sufficiently stable to withstand the long times necessary to run the EXSY experiment.

For the series **3a–c**, the highest barrier is observed when methyl occupies the 3-position of ring B; the lowest barrier is observed for the nitro derivative. A plot of $\Delta G^{\ddagger}$ vs. $\Sigma\sigma_n$ displays a negative slope for the series **3a–c** (Fig. 2), in contrast to the



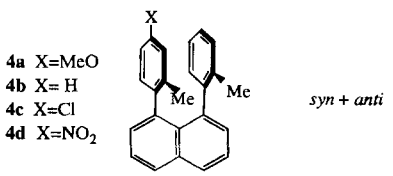


Fig. 2. Plot of the free energy of activation for phenyl group rotation vs. $\Sigma\sigma_n$ for 1,8-diarylnaphthalenes **1a–d**, **2a–e**, **3a–c**, and **4a–d**. For *syn*/*anti* mixtures the thermodynamic ratio of conformers is constant over all substituents; the barriers to the conversion of the *anti* to the *syn* conformer are plotted.

positive slope manifest by **1a–d**, **2a–e**, and the previously investigated series of 1,8-ditolylnaphthalenes **4a–d**. The trend for **3a–c** is exactly the reverse of that seen for the simple phenyl series, but completely compatible with the simple quadrupole

moment model.[14] Thus, from comparison of the trends from these three series with the trend from series **4a–d** (Fig. 2) one can conclude that a) a progressive depletion of the negative core of the benzene ring is associated with consecutive fluorine substitutions, and b) perfluorination can reverse the orientation of the benzene ring quadrupole, and therefore, reverse the electronic interaction with a given molecular electrostatic probe.

The present observations redirect existing avenues in the design of new molecular complexands and synthetic reagents by clearly pointing out the electronic prerequisites for two phenyl rings to interact with either a favorable π-stacked or T-shaped arrangement.[15] Indeed, if this model holds true, perfluorinated molecular hosts should be capable of complexing even unsubstituted benzene. Hosts prepared from a combination of both fluorinated and unfluorinated arenes should be capable of capitalizing on polar π interactions through the face and edge of an aromatic guest simultaneously, thus inducing a favored binding orientation as well as free energy.[16] Control of the degree and orientation of attraction between receptor and substrate translates to control of selectivity in reagent chemistry. Given the ease with which perfluorinated arenes can be prepared, we see this as a rich area for further exploration.

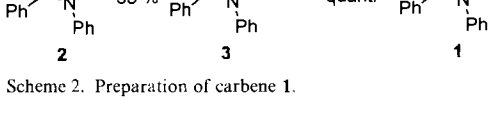
Preparation, Structure, and Reactivity of 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene, a New Stable Carbene**

Dieter Enders,* Klaus Breuer, Gerhard Raabe, Jan Runsink, J. Henrique Teles,* Johann-Peter Melder, Klaus Ebel, and Stefan Brode

Carbenes are among the most intensively investigated reactive species in organic chemistry.[1] For many decades chemists accustomed to the quadrivalence of carbon were intrigued by their divalent nature, so there were many attempts to prepare carbenes and to "store them in bottles".[2] Despite this effort, access to these compounds was impossible for a long time because of their high reactivity. The isolation of carbenes was only seldom accomplished in inert matrices at low temperatures.

However, Bertrand et al.[3] and Arduengo et al.[4] recently reported the preparation of compounds stable at ambient temperature, which can be formulated as carbenes.[5] Yet doubts were raised about the extent of the carbene character of Bertrand's phosphinocarbene,[6] since it reacts distinctly like a phosphaacetylene.[7]



We wish to report a new heterocyclic carbene, the 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene (**1**, Scheme 1), which is stable up to 150 °C—according to DSC/TG experiments (DSC/TG = differential scanning calorimetry/thermogravimetry) unspecific decomposition begins at 150 °C—and has the typical reactivity of a nucleophilic carbene stabilized by heteroatoms in the 1,3-positions.[1, 8]

1

Scheme 1. Triazolinylidene **1** and its resonance structures.

Carbene **1** was prepared by reaction of 1,3,4-triphenyl-1,2,4-triazolium perchlorate (**2**) with sodium methoxide in methanol, affording 5-methoxy-1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazole (**3**). Upon heating to 80 °C **3** decomposes endothermically (ΔH = 33 kJ mol^{-1} by DSC/TG) with concomitant elimination of methanol to form carbene **1** (Scheme 2).

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (SFB 380, Leibniz-Preis). We are obliged to Dr. Nigel Walker, BASF AG, for the X-ray structure determination of **3**.

In the ^{13}C NMR spectrum of **1** the carbene carbon gives rise to a characteristic[4] strongly low-field shifted signal at δ = 214.[9] The chemical shifts of **1** were calculated by the GIAO-SCF method. For the parent heterocyclic system, the 4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene (**1'**, $C_2N_3H_3$; the three phenyl groups were replaced by hydrogen atoms), a GIAO-MP2 calculation with an extended basis set was carried out.[10] This was used to correct the chemical shifts of the carbon atoms in the heterocyclic moiety, since electron correlation was neglected in the calculation of the chemical shifts of **1**. A very good agreement between experimental and calculated chemical shifts was found (Table 1).

Table 1. Selected experimental and calculated ^{13}C NMR chemical shifts for triazolinylidene **1**.

Carbon atom	δ(HF/dzp) [a]	δ (MP2/tzp-corr.) [b]	δ (exp.)
C1	238.7	213	214.6
C3	149.3	148	152.1
C1A	142.8	–	142.5
C1B	128.2	–	127.3
C1C	140.5	–	139.8

[a] The chemical shifts for **1** were calculated with the GIAO method at the HF/DZP level on an ab initio HF-optimized geometry [10]. [b] The correction was carried out by calculation of the chemical shifts of **1'** with the GIAO method at the HF/DZP level on a HF/DZP-optimized geometry and at the MP2/TZP level using a MP2/TZP-optimized geometry [10]. The difference attributable to electron correlation was subtracted from the corresponding chemical shifts of **1** calculated at the HF/DZP level of theory.

In the ^{1}H NMR spectrum no significant line broadening of the signals of the aromatic hydrogen atoms was found at temperatures as low as −100 °C. The rotation of the phenyl groups appears to be unhindered at this temperature. Yet the HF/SCF optimized geometry of **1** shows that the two adjacent phenyl groups are twisted out of the plane of the triazoline ring, which makes a geared rotation of these phenyl groups likely. Single crystals of **1** suitable for X-ray structure determination were obtained by layering a solution of **1** in toluene with pentane; crystals of **3** were prepared by crystallization from methanol. An ab initio calculation at the MP2(full)/6-31 + G* level of theory[13] was carried out for the parent heterocyclic system **1'** in order to gain some insight into the equilibrium structure of **1** unperturbed by the crystal field.[14] Furthermore, the structure of 1,2,4-triazolium ion **2'** ($C_2N_3H_4^+$) derived from **1'** was determined at the MP2(full)/6-31 + G* level of theory.[15]

The structure of **1** in the solid state (Fig. 1) features a bond angle of about 100° at the carbene carbon C1, which is typical of singlet carbenes.[16] This angle is significantly smaller than the corresponding one calculated for **2'** (105.0°). The phenyl groups at N3 and C2 are twisted out of the plane of the triazoline ring, while the phenyl ring at N1 is virtually coplanar with the heterocyclic ring. The C1–N1 and C1–N3 bond lengths (1.351(3) and 1.373(4) Å, respectively) are considerably shorter than expected for single bonds, which suggests a significant interaction of the occupied 2p orbitals of nitrogen atoms and the unoccupied 2p orbital of the adjacent carbene carbon atom in **1** (see Scheme 1). This stablizing interaction should be rescinded by coordinative saturation of the carbene carbon and should cause a lengthening of the bonds. In fact, the corresponding bonds in **3** (1.443(7) Å for both C2–N3 and C2–N1) are clearly longer (Fig. 2) than those in **1**. On the other hand, the C2–N2 bond (1.304(3) Å) in **2** is only negligibly longer than a typical C–N double bond,[17] be-

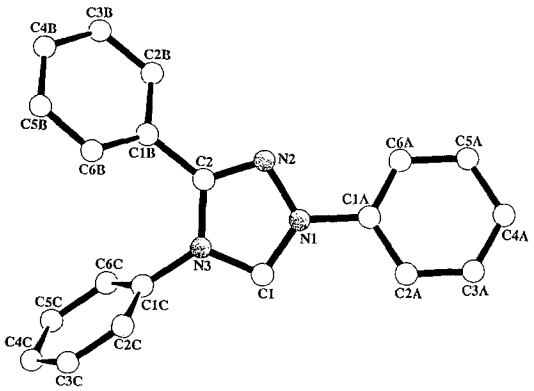

Fig. 1. Crystal structure of **1** (SCHAKAL representation) [11]. Selected bond lengths [Å] and angles [°]: C1–N1 1.351(3), C1–N3 1.373(4), C2–N2 1.304(3), N1–N2 1.398(3), C2–N3 1.391(2), N1-C1-N3 100.6(2).

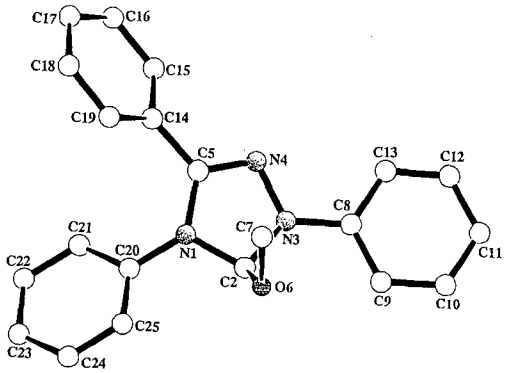

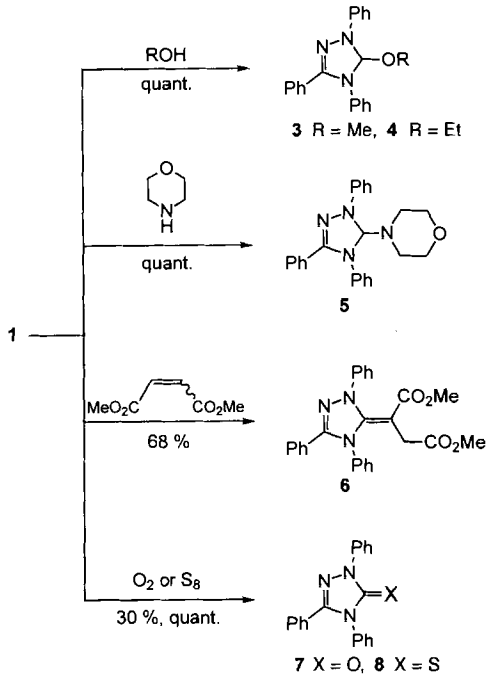

Fig. 2. Crystal structure of **3** (SCHAKAL representation) [12]. Selected bond lengths [Å] and angles [°]: N1–C2 1.443(7), C2–N3 1.443(7), N4–C5 1.296(6), N3–N4 1.394(6), N1–C5 1.391(6), N1-C2-N3 100.1(4).

ing barely longer than the C5–N4 bond in **3** (1.296(6) Å). Furthermore the N1–N2 and C2–N3 bond lengths in **1** are very similar to the corresponding bond lengths in **3**. As a rule, bond lengths determined by X-ray crystallography tend to be apparently shorter than their theoretical values.[18] Provided that this effect is negligible or comparable both for **1** and **3**, one can conclude that the interaction of the C2–N2 bond and the N1-C1-N3 unit in **1** and the corresponding unit in **3** is weak for both systems. Meanwhile the ab initio calculations yield a slightly longer N2–C2 bond for **2'** than for **1'**, while the C1–N1 and the C1–N3 bonds in **2'** are shorter by 0.2–0.3 Å. One should be wary of overrating these results given the positive charge of **2'**, yet they suggest an increased interaction of the lone pairs at the nitrogen atoms with the empty 2p AO at C1. Arduengo et al. attributed the stability of similar systems to kinetic factors, namely, to a hindered attack of nucleophilic species due to the accumulation of electron density at the carbene carbon atom itself and in its vicinity.[19] Neither our crystallographic nor our theoretical results permit us to judge the significance of these factors for the stability of the system examined in this work. Yet the differences between the bond lengths in the N1-C1-N3 unit in **1** and those in the corresponding unit in **3** indicate that 2p–2p interactions between the carbene carbon atom and the adjacent nitrogen atoms play a significant role in the stabilization of carbene **1**.

Triazolinylidene **1** reacts with alcohols such as methanol and ethanol by insertion into the O–H bond to form the 5-alkoxytri-

Scheme 3. Typical reactions of carbene **1**.

azolines **3** and **4** (Scheme 3). Insertion into the N–H bond of amines occurs similarly. Thus the reaction of **1** with morpholine yields the 5-morpholinotriazoline **5**. The carbene **1** reacts with ethyl fumarate or ethyl maleate to give methylenetriazoline **6**.[20] A cyclopropane system is presumably formed as the primary intermediate of the [2 + 1] cycloaddition, leading to the more stable allyl system by ring opening and subsequent 1,2-H shift.[21] The instability inherent in the cyclopropane spiro system can be traced back to the considerable ring strain and the "push–pull"-type substitution pattern of the cyclopropane ring. AM1 calculations[22] yield a strongly negative reaction enthalpy ($\Delta H = -76\ \mathrm{kJ\,mol^{-1}}$) for the rearrangement of the primary cyclic product to the methylenetriazoline **6** and therefore confirm the experimental results. Triazolinylidene **1** also reacts with oxygen with formation of the corresponding triazolinone **7**. Reaction with sulfur analogously leads to the triazolinethione **8**.

The X-ray data, ab initio calculations, and the reactions presented in this work show that compound **1** is a new stable carbene displaying a marked nucleophilic reactivity.

Experimental Procedure

3: Sodium methoxide (1.4 g, 26 mmol) dissolved in methanol (30 mL) was slowly added to a solution of 1,3,4-triphenyl-1,2,4-triazolium perchlorate (10.0 g, 25 mmol) in methanol (150 mL). The methanol was removed under reduced pressure at ambient temperature, and the residue extracted several times with ether. The solvent was removed from the combined ether layers under reduced pressure at ambient temperature. Crystallization from methanol yielded **3** as pale yellow crystals. Yield: 5.2 g (63%); m.p. 80 °C (decomp.); analysis calculated for $C_{21}H_{19}N_3O$: C 76.6, H 5.8, N 12.8, found C 76.5, H 5.8, N 12.6; ^{1}H NMR (300 MHz, C_6D_6, 25 °C, TMS): δ = 7.70–6.80 (m, 15H, arom. H), 6.58 (s, 1H, OC(H)N), 3.02 (s, 3H, OCH_3); ^{13}C NMR (75.4 MHz, C_6D_6, 25 °C, TMS) [23]: δ = 145.1 (C-5), 142.7 (*ipso*-C), 140.7 (*ipso*-C), 129.5 (C_{ar}), 129.2 (C_{ar}), 129.1 (C_{ar}), 128.6 (C_{ar}), 127.8 (C_{ar}), 125.0 (C_{ar}), 123.1 (C_{ar}), 120.5 (C_{ar}), 113.5 (C_{ar}), 101.0 (C2), 46.9 (C7); IR (KBr): $\tilde{\nu}$ = 3049 (m), 3000 (m), 2952 (m), 2928 (m), 2905 (m), 2816 (m), 1597 (s), 1567 (s), 1554 (s), 1505 (s), 1494 (s), 1458 (s), 1446 (m), 1408 (s), 1382 (s), 1358 (s), 1287 (m), 1261 (s), 1160 (m), 1069 (m), 1053 (s), 1038 (s), 1011 (s), 914 (s), 773 (s), 747 (s), 693 (s) cm^{-1}; MS (70 eV): *m/z* (%): 329 (0.21) [M^+], 298 (2.73) [$M^+ - CH_3OH$], 83 (100).

1: **3** (1.0 g, 3.0 mmol) was heated at 80 °C in vacuo for 16 h. Yield: 0.9 g (100%); m.p. 150 °C (decomp.); analysis calculated for $C_{20}H_{15}N_3$: C 80.8, H 5.1, N 14.1, found C 80.5, H 5.2, N 14.0; ^{1}H NMR (500 MHz, C_6D_6, 25 °C, TMS): δ = 8.68 (d,

2H, $^3J(H,H) = 7.5$ Hz), 7.35 (m, 2H), 7.25 (br.t, 2H, $^3J(H,H) = 8$ Hz), 7.21 (m, 2H), 7.06 (tt, 1H, $^3J(H,H) = 7.4$ Hz and $^4J(H,H) = 1.2$ Hz), 6.98–6.89 (m, 6H); ^{13}C NMR (125.6 MHz, C_6D_6, 25 °C, TMS) [24]: $\delta = 214.6$ (C1), 152.2 (C2), 142.5 (C1A), 139.8 (C1C), 129.9 (C4B), 129.5 (C2B, C6B), 129.4 (C3A, C5A), 129.1 (C3C, C5C), 128.6 (C3B, C5B), 127.9 (C4C), 127.3 (C1B), 127.0 (C4A), 126.7 (C2C, C6C), 120.2 (C2A, C6A); IR (KBr): $\tilde{\nu} = 3046$ (w), 1596 (s), 1552 (w), 1494 (s), 1460 (w), 1448 (m), 1359 (s), 1317 (m), 1307 (m), 1215 (m), 1152 (m), 1074 (s), 987 (s), 949 (m), 933 (m), 914 (m), 782 (s), 769 (s), 760 (s), 711 (s), 694 (s) cm^{-1}; MS (70 eV): m/z (%): 297 (56) [M^+], 296 (73) [$M^+ - 1$], 194 (100) [$M^+ - PhNC$], 180 (7), 104 (7), 91 (28), 77 (51); calculated for $C_{20}H_{15}N_3$ [M^+] 297.1266, found 297.1267.

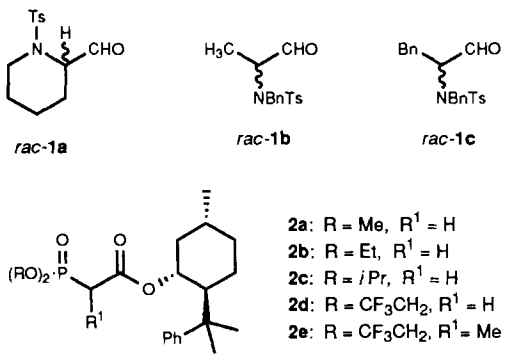
First Dynamic Kinetic Resolution of Racemic α-Amino Aldehydes**



Tobias Rein,* Reinhard Kreuder, Paultheo von Zezschwitz, Christian Wulff, and Oliver Reiser*

The versatility of α-amino aldehydes in synthesis of biologically important compounds has been amply documented.[1] Nevertheless, because α-amino aldehydes are easily racemized, special precautions are necessary for their synthesis, handling, and storage.[2] This undesirable property might be turned to advantage, however, since it offers possibilities for converting racemic α-amino aldehydes to enantiomerically pure derivatives by means

of a chiral reagent that reacts at different rates with the two enantiomers under conditions in which the aldehyde is configurationally unstable.[3] We report here that such dynamic kinetic resolutions can be successfully achieved by treating racemic aldehydes *rac*-**1** (Bn = CH_2Ph, Ts = $H_3CC_6H_4SO_2$) with the chiral phosphonates **2** in the presence of a slight excess of base.

To date, relatively few reports on dynamic kinetic resolutions by chemical[4] methods have appeared, whereas this principle has more frequently been successfully applied to enzymatic[5] methods. Recently, dynamic resolution of 2-substituted cycloalkanones by reaction with a chiral phosphonate derived from mannitol has been demonstrated.[6] We previously reported that classical kinetic resolution of aldehyde *rac*-**3** by reaction with appropiate phosphonates **2a–d** could give either (*S*,*Z*)-**4** (R* = (−)-8-phenylmenthyl) or the corresponding (*R*,*E*)-alkene with good *E*/*Z* selectivity and diastereoselectivities [Eq. (1)].[7]

(1)

In these reactions, use of at least two equivalents of the aldehyde substrate was necessary, since compound **3** epimerizes only slowly in the presence of base. As an extension of these studies, we investigated asymmetric Horner–Wadsworth–Emmons (HWE) reactions with α-amino aldehydes *rac*-**1**,[8, 9] to find reaction conditions under which (*R*)-**1** and (*S*)-**1** would be in fast equilibrium, thus making dynamic resolution possible. Moreover, the corresponding HWE products appeared to be attractive precursors to non-proteinogenic amino acids[10] as well as to various alkaloids.

To establish whether dynamic resolution was possible in these reactions, we performed both classical kinetic resolutions (≥2 equiv aldehyde) and, for comparison, experiments in which only 1.3–1.4 equivalents of the aldehyde substrate were used, either with or without an excess of base over the amount of phosphonate reagent (Table 1). The results from classical resolutions of *N*-tosyl-protected aldehyde **1a**[11] (nos. 1, 2, and 4) showed, as expected, that phosphonates **2a–c** mainly gave the *E* product **5a**[12] (**2c** afforded the highest diastereoselectivity: no. 4), while reagents **2d** and **2e** predominantly gave the *Z* alkenes **6a**[12] and **8a**, respectively (nos. 8 and 12).[12] The experiments in which an excess of base was used (nos. 3, 5, 7, 9, 11, 14) then provided evidence that dynamic resolution is possible with all four reagents **2b–e**. A comparison of the classical resolutions and the reactions in which no excess of base and less than two equivalents of substrate were used (nos. 6, 10, 13) shows that selectivities as high as in the classical resolutions, or even higher, were generally observed when an excess of base was used. This becomes especially evident by comparison of nos. 8–11: While the (*Z*)-alkene (*S*)-**6a** is formed with a diastereoselectivity of 5:1 with 2.2 equivalents of **1a** without an excess of base, the selectivity dramatically improves to 16:1 in the presence of a slight excess of potassium hexamethyldisilazide (KHMDS), with either 2.2 equivalents (no. 9) or only 1.3 equivalents (no. 11) of **1a**. Without excess base, however, interconversion of (*R*)-**1a** and (*S*)-**1a** is too slow to allow dynamic resolution to operate. This is reflected in decreased *E*/*Z* selectivity and diastereoselectivity (no. 10). Under dynamic resolution conditions (*E*)-alkene

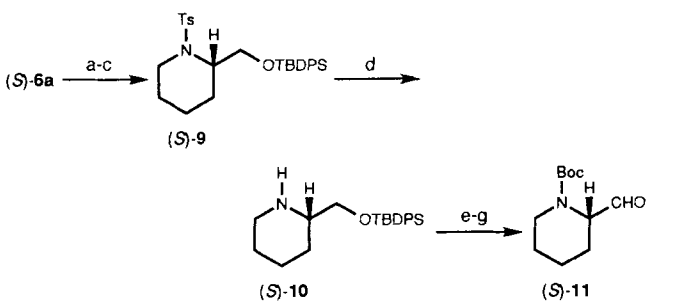
(*R*)-**5a** could be obtained with 70% *de*, and the (*Z*)-alkenes (*S*)-**6a** and (*S*)-**8a** with 88 and 94% *de*, respectively. In analogy to our results from reactions with *rac*-**3**, the diastereoselectivities and yields obtained in nos. 10 and 13 can only be explained by the fact that the major diastereomers of **5a** and **6a**, and **7a** and **8a**, respectively, must have opposite absolute configuration at the allylic stereocenter (cf. Scheme 1).



Scheme 1. Dynamic kinetic resolution of aldehydes *rac*-**1** by reaction with chiral phosphonates **2** in the presence of a small excess of base. With **2a–c** the major products are (*R*)-**5a–c**, with **2d–e** (*S*)-**6a–c** and (*S*)-**8a–c**, respectively. P^1, P^2 = protecting group; R* = (−)-8-phenylmenthyl.

To confirm that the improved selectivities were indeed due to dynamic kinetic resolution rather than to subsequent equilibration of the products, samples of **5a** or **6a** of low diastereomeric purity in mixture with *rac*-**1a** were subjected to KHMDS under the same reaction conditions. In no case was a change of the diastereomeric ratio observed.

Also in our studies of reactions with acyclic α-amino aldehydes, the choice of protecting group for the amino functionality turned out to be important. Of the alternatives investigated so far, the combination of one *N*-benzyl and one *N*-tosyl group was the best. Nevertheless, reactions of the alaninal derivative *rac*-**1b** with phosphonate **2d** gave disappointing results (nos. 15–17): while high *Z*:*E* ratios were observed, the *Z* product **6b** was formed with almost no diastereoselectivity, either under classical or under dynamic resolution conditions. To our delight, however, reactions of **2d** with aldehyde *rac*-**1c**, derived from phenylalanine,[13] gave (*S*)-**6c**[12] with diastereoselectivities up to 90% *de* (nos. 18–20). Again, excess of KHMDS not only allowed a decrease of the amount of aldehyde to 1.3 equivalents but also significantly improved the diastereoselectivity by a factor of 2.

The absolute configurations of *Z* products (*S*)-**6a** and (*S*)-**8a** were determined by correlation with the known compound (*S*)-*N*-Boc-piperidine-2-carbaldehyde[14] (**11**; Scheme 2). In analogy with these assignments, the major *Z* diastereomer produced from **1c** is tentatively assigned as (*S*)-**6c**.

Scheme 2. Determination of absolute configuration for compound (*S*)-**6a** by correlation with the known aldehyde (*S*)-**11**: a) OsO_4, NMO (73%). b) 1. H_5IO_6; 2. $NaBH_4$ (80%). c) 1. KHMDS; 2. *tert*-Butyldiphenylsilyl chloride (TBDPSCl) (78%). d) $NaC_{10}H_{10}$ (80%). e) Boc_2O (73%). f) Bu_4NF (97%). g) $(COCl)_2$, DMSO (83%).

To conclude, we have demonstrated that dynamic kinetic resolution of aldehydes *rac*-**1** by reaction with the chiral phosphonates **2** in the presence of a slight excess of base can give selectivities as high as, or even higher than the corresponding classical kinetic resolutions. Use of only 1.3–1.4 equivalents of the aldehyde substrate is sufficient, and both disubstituted and trisubstituted alkenes are accessible with high diastereoselectivities. Furthermore, this technique will also allow the synthesis of compounds derived from amino acids with unnatural configuration. The strategy described should be useful not only in HWE reactions, but should also be of general importance for the use of amino aldehydes in doubly stereodifferentiating reactions. Further extensions of this methodology are currently under investigation.

Experimental Procedure

The dynamic kinetic resolutions were performed as follows: To a solution of the phosphonate reagent **2** (1.0 equiv, 0.01–0.02 M) and [18]crown-6 (5 equiv) in THF at −78 °C under argon was added $KN(SiMe_3)_2$ (1.2 equiv, 0.5 M in toluene). After 30 min the resulting reaction mixture was added by cannula to a precooled (−78 °C) solution of *rac*-**1** (1.3–1.4 equiv) in THF. The reaction mixture was stirred for 2–19 h at −78 °C (monitoring by TLC) and then quenched with water or phosphate buffer (pH 7). Extractive workup (ethyl acetate), drying ($MgSO_4$), and concentration gave the crude condensation product, which was purified by flash chromatography or MPLC [15] on silica gel with EtOAc in hexanes (for example, **6a**: $R_f = 0.18$ in hexanes:ethyl acetate 9:1; **5a**: $R_f = 0.13$ in hexanes:ethyl acetate 9:1).

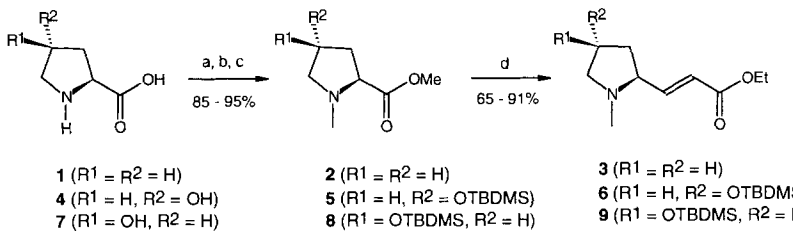
Synthesis of Optically Active Nine-Membered Ring Lactams by a Zwitterionic Aza-Claisen Reaction**

Michel Diederich and Udo Nubbemeyer*



The ketene-Claisen reaction was first described by D. Belluš in 1978 as an intermolecular variant of the [3.3] sigmatropic rearrangement of allyl and thioallyl ethers.[1] Recently, it was reported that allyl sulfides, in particular, can be rearranged under very mild conditions chemoselectively with the expected 1,3-chirality transfer from the C–S to a C–C bond. Furthermore, excellent 1,2-asymmetric induction was found when an optically active C–O functionality was located α to the nascent C–C bond.[2] The reaction was also employed in the syntheses of medium-sized rings (7–13 ring atoms).[3] Until now the rearrangement was restricted to activated ketenes like chloroalkyl- and dichloroketene. Allyl amines have been used in ketene-Claisen reactions only rarely. The few reported cases focused on conformationally fixed bicyclic systems or amines bearing an unhindered terminal olefinic unit.[4] Here, we report on the synthesis of optically active[5] hexahydroazoninones by a zwitterionic aza-Claisen reaction with complete 1,3-chirality transfer from chiral allyl amines.[5]

As starting compounds we used the allyl amines **3**, **6**, and **9**. The proline methyl ester **2** was synthesized from L-(−)-proline (**1**) by Clarke–Eschweiler methylation[6] and subsequent esterification (Scheme 1).[7] In a one-pot reaction **2** was reduced with diisobutylaluminum hydride (DIBAH) in situ to give the aldehyde; Horner olefination provided amino ester **3**. Amino esters **6** and **9** were prepared by analogous sequences starting from *trans*- and *cis*-4-hydroxy-L-proline (**4**) and (**7**), respectively. Prior to the one-pot reduction/chain extension reaction, the free OH group was protected as a *tert*-butyldimethylsilyl (TBDMS) ether in **5** and **8**.[8] The diastereomeric purity of amino esters **3**, **6**, and **9** was determined by ^1H and ^{13}C NMR spectroscopy (see Table 1) and by HPLC analysis.[9]

Special two-phase conditions were developed for the Claisen rearrangement of allyl amines **3**, **6**, and **9**. A slurry of the amine and solid potassium carbonate in anhydrous chloroform at 0 °C was treated with acetyl chloride and 20 to 30 mol% of trimethylaluminium. The corresponding partially hydrogenated azoninones **14**, **15**, and **16** were isolated in 65 to 84% yield (Scheme 2).

Scheme 2. Zwitterionic aza-Claisen reaction: a) AcCl, K_2CO_3, Me_3Al, $CHCl_3$, 0 °C, 72 h (65–85%). Selective reduction of the ester function: b) $NaBH_4$, *t*BuOH, MeOH, reflux, 2 h (46%).

Scheme 1. Synthesis of amino esters **3**, **6**, and **9**. a) 98% HCO_2H, 37% CH_2O/H_2O, reflux, 7 h; b) $SOCl_2$, MeOH, reflux, 6 h; c) **4** and **7**: TBDMSCl, imidazole, CH_2Cl_2, 20 °C, 12 h; d) 1. DIBAH, Et_2O, −78 °C, 16 h, 2. $(EtO)_2P(O)CH_2CO_2Et/NaH$, Et_2O, −78 → 20 °C, 4 h.

In considering the reaction mechanism it seemed reasonable to assume that the acyl ammonium salt **10** forms initially. This intermediate could be attacked either by the nucleophilic halide ion in a von Braun type S_N reaction[10] generating the chlorides **11** and/or **12**, or by a base (e.g. the chloride ion) which could deprotonate the α-position of the activated carbonyl group. The resulting zwitterionic intermediate **13** could then undergo [3.3] sigmatropic rearrangement resulting in the azoninones **14** to **16**.

The postulated reaction path via **10** and **13** is based on the following observations.

1) Acyl ammonium salt **10** was detected in the reaction mixture at low temperatures by ^1H and ^{13}C NMR spectroscopy.

2) Halides of type **11** and **12** were isolated in yields of 0 to 10% and characterized as by-products of the rearrangement. Apparently the reaction path taken is determined by the bulk of the alkyl substituent on acyl ammonium salt **10**: N-benzylated amino esters underwent the von Braun reaction to yield amides **11** and **12**, whereas the N-methylated esters **3**, **6**, and **9** rearranged as described above.[11]

3) The chloride ion served as the essential base under the reaction conditions. After the generation of acyl ammonium salt

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

10 with acetyl trifluoroacetate[12] the rearrangement was started by the addition of tetraalkylammonium chloride. Acetic anhydride did not react. Numerous bases (Li and K amides, alcoholates, amidines, etc.) destroyed the acyl ammonium salt regenerating the allyl amines **3**, **6**, and **9**.

4) Ketenes did not react with **3**, **6**, and **9** under widely varied reaction conditions,[13] since ketenes are apparently not electrophilic enough to attack the allyl amines.[14]

5) The Lewis acid increases the acidity of the α-protons by interacting with the carbonyl group of the acyl ammonium salt **10** and/or stabilizing the zwitterionic intermediate **13**, thus suppressing the elimination of ketene.[15] Without Lewis acid the reaction rate decreased severely (ca. 25% conversion after three days); von Braun type substitution products were isolated in yields of 20 to 50%.

If the azoninones are formed by the postulated path, acyl ammonium salt **10** might be (partly) racemized, because the acidity of H_a is increased by the ester group (and the Lewis acid) and the ammonium function. The structure assignments of lactams **14**–**16** proved the complete chirality transfer from the C–N to the C–C bond. Furthermore the results support the mechanism proposed by Pombo-Villar et al.[4b] in which a [3.3] sigmatropic rearrangement is postulated as the key step. The alternate mechanism, formation of an allyl cation followed by attack of the enolate, seems to be disfavored. On the one hand, generation of a cation adjacent to an acceptor function is improbable; on the other hand, rearrangement of amino esters **6** and **9** should result in mixtures of diastereomers because of increased rotational freedom after the cleavage of the C–N bond.

The ester group of lactam **14** was reduced selectively with $NaBH_4$ in *tert*-butyl alcohol and methanol to give alcohol **17**,[16] which was protected as a Mosher ester.[17] According to HPLC analysis, and ^1H and ^{13}C NMR spectra of the derivative, only one diastereomer had formed, which indicates that the enantiomeric purity of **17** is >90%.

That the 1,3-chirality transfer was complete could be proved directly by analyzing the structures of lactams **15** and **16**. The *syn*-configurated amino ester **9** gave exclusively the *syn* azoninone **16**. The relative configuration was determined unequivocally by NOE difference spectroscopic analysis. Because the double bond and the amide function of azoninone **16** fix the ring system in one conformation at room temperature, all protons are in fixed positions and could be assigned exactly to the ^1H NMR signals.

The configuration of azoninone **15** (synthesized from the *anti* amino ester **6**) was determined only indirectly owing to the occurrence of two stable conformations at 23 °C. In the ^1H NMR spectrum in DMSO at 130 °C complete coalescence was not achieved. Two nonoverlapping peaks were evident by HPLC analysis, but preparative separation by HPLC failed. After separation the two fractions had the same distribution of the compounds as that originally found by HPLC. However, since both conformers of azoninone **15** are distinctly different from lactam **16**, epimerization of the chiral center can be excluded (complete 1,3-chirality transfer!). Relevant spectroscopic data are given in Table 1.

The zwitterionic aza-Claisen reaction allows the stereospecific rearrangement of allyl amines such as **3**, **6**, and **9** to the corresponding γ,δ-unsaturated lactams **14**, **15**, and **16** under very mild conditions. Thus this reaction offers the following advantages:

1) The high temperatures (>120 °C) of the Johnson, Eschenmoser, and the amide enolate reactions are not necessary.[18]

2) Superbases (LDA, etc.) like that employed in the Ireland type process are avoided.[19]

3) The reaction is not restricted to activated ketenes, which are essential in the rearrangement of thioallyl ethers.[2]

The method described allows the generation of optically active nine-membered ring lactams in high yields in only five or six steps (three steps with isolated products). The reaction can be carried out in the presence of acidic protons without epimerization.[20] This easy approach to hexahydroazoninones should encourage their application in the synthesis of pharmaceutically active compounds and natural products.[21]

Experimental Procedure

1) One-pot procedure for the DIBAH reduction and Horner olefination: A solution of 50 mmol of amino ester **2**, **5**, or **8** in 50 mL of anhydrous Et_2O under argon was cooled to −78 °C. During the addition of 1.3 equiv of DIBAH (20% in toluene) the temperature was kept below −75 °C. After 16 h at −78 °C, the reaction mixture was treated with 60 mmol of triethyl phosphonoacetate (deprotonated with NaH) in 100 mL of anhydrous THF. The mixture was stirred for 5 h and allowed to warm to room temperature. Then the reaction was quenched with 5 mL of MeOH. After 15 min 10 g of K/Na tartrate was added, and after a further 15 min the mixture was hydrolyzed with 30 mL of 10% aqueous $NaHCO_3$. The organic layer was decanted and the residue extracted with EtOAc. The combined organic phases were dried ($MgSO_4$) and concentrated to dryness. The resulting crude material was purified by column chromatography on silica gel.

2) Aza-Claisen reaction: A suspension of 50 mmol of dry Na_2CO_3 in 200 mL of anhydrous $CHCl_3$ under argon was treated with 60 mmol of amino ester **3**, **6**, or **9**. The reaction mixture was cooled to 0 °C and 90 mmol of AcCl was added with stirring. After a further 20 min, 10–20 mmol of Me_3Al (2 M in hexane) was injected by syringe. The reaction was stopped after 2–5 d by careful hydrolysis of Me_3Al with ice water. The layers were separated and the aqueous phase was extracted with $CHCl_3$. The combined organic phases were dried ($MgSO_4$) and concentrated to dryness. The resulting crude product, **14**, **15**, or **16**, was purified by column chro-

matography on silica gel. Note: When more than 10 to 20% of the amino ester remained after the workup, the crude material was subjected to the reaction conditions again. After the second cycle the reaction was complete without a decrease in the yield.

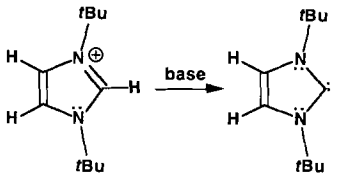
N-Confused Porphyrins and Singlet Carbenes: Is There a Connection?**

Abhik Ghosh*

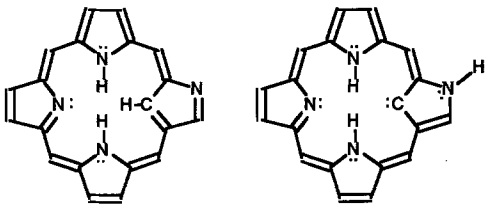


The isolation of 2-aza-21-carba-5,10,15,20-tetraarylporphyrins as by-products of a standard preparative method for tetraarylporphyrins was an important and unexpected development in porphyrin chemistry.[1, 2] Interest in these novel compounds (e.g. **1**), also dubbed N-confused porphyrins, centers on their remarkable ability to act as tetracoordinate ligands and form complexes (e.g. **2**) with metal–carbon bonds (Scheme 1).[1]

Scheme 1. Ar = *p*-tolyl; a) $NiCl_2 \cdot 6H_2O$, $CHCl_3$/EtOH, reflux, 0.5 h.

However, neither the original report[1] on this discovery nor a critical commentary[3] on these compounds proposed a rationale for the unexpectedly labile central C–H bond of **1**.

Here we point out a striking analogy between the remarkable carbon acidity of N-confused porphyrins and the properties of completely different organic compounds, namely stable "bottleable" carbenes such as **4** synthesized by Arduengo et al. by the deprotonation of *N*,*N*-dialkylimidazolium ions **3**.[4] Thus, complex **2** may be formally regarded as a nickel(II)-stabilized carbene. In addition, we propose that the stability and aromaticity of the ligand in **2** may account for the hitherto unexplained carbon acidity of **1** and its N-protonated form, **1**-H$^+$.



Our proposal, if essentially correct, should have far-reaching implications for the electronic structure and chemical reactivity of N-confused porphyrins. Accordingly, we carried out high-quality ab initio[5] and local density functional (LDF)[6] calculations on compounds **5**–**9** to test the validity of the proposed analogy as well as to develop the first theoretical picture of the electronic structure of N-confused porphyrins. Compounds **5** and **8** are the unsubstituted analogues of **1** and **2**, respectively. Species **6** is the free base form of the ligand in complex **8** and the carbenic tautomer of **5**. The zinc complex **7** was selected for studying the interaction of the carbenic ligand **6** with a closed-

shell Lewis acid such as a Zn^{2+} ion. LDF calculations on **5**–**8**, including geometry optimizations, used double-zeta plus polarization (DZP) basis sets, the von Barth–Hedin exchange-correlation functional,[7] and a C_s symmetry constraint. Ab initio calculations using Hartree–Fock (HF) and second-order Møller–Plesset perturbation theories were carried out on LDF-optimized geometries of the organic molecules **5** and **6** and the unsubstituted free base porphyrin **9** with generally contracted double-zeta (DZ) basis sets[8, 9] and direct electronic structure methods[10] that obviate the need for storing prohibitive volumes of electron repulsion integrals. In the optimized geometry of **6** the C-C-C angle subtended at the carbenic center is only 104.2°, which is extremely small for dicoordinate carbon and highly characteristic of singlet carbenes. Table 1 presents the calculated Hartree–Fock orbital energies of the six highest occupied molecular orbitals (MOs) of the purely organic compounds **5**, **6**, and **9**. Table 2 presents calculated LDF values of the lowest singlet–triplet energy gaps (ΔE_{S-T}) for both the lowest $\pi^1\pi^{*1}$ and $\sigma^1\pi^{*1}$ triplet states, and the lowest σ and π ionization potentials (IPs) of **5**–**8**.

Table 1. Sign-reversed HF orbital energies [eV] of the six highest occupied MOs of **5**, **6**, and **9**.

5	**6**	**9**
10.41 (π)	9.74 (π)	10.25 (π)
10.31 (π)	9.11 (π)	10.20 (π)
9.55 (π)	8.54 (σ)	9.30 (π)
8.99 (π)	8.44 (π)	9.07 (π)
6.66 (π)	6.54 (π)	6.52 (π)
6.40 (π)	5.63 (π)	6.20 (π)

Table 1 shows that the values of the HF orbital energies of **5** and **9** are extremely similar,[11] at least for the six lowest IPs (according to Koopmans' theorem, KT), while the values of **6** are considerably different. Thus, none of the six lowest IPs of **5** and **9** corresponds to σ ionization, whereas the fourth lowest HF-KT IP of **6** corresponds to a σ-ionized final state. LDF calculations (using the ΔSCF method) also show that the lowest σ-IP of **6** is relatively low at approximately 7.31 eV compared to the lowest π-IP of 6.65 eV and to the lowest σ-IPs of **5** and **9** (for which the HF-KT values listed in Table 1 may serve as estimates). An LDF calculation on the lowest energy σ-ionized $^2A'$ state of **6** shows that the majority ($\approx 80\%$) of the unpaired spin density is localized in the region of the carbenic lone pair. This is indeed what one expects of a stable nucleophilic carbene of the type synthesized by Arduengo et al.[12] For instance, the lowest σ-IP of **4**, corresponding largely to ionization from the carbenic lone pair, is 7.68 eV,[12] which is quite close to the LDF value of 7.31 eV for **6**. One difference between **4** and **6** is that the aromatic framework of **6** may be regarded as a large annulene whose highest occupied π MOs have rather higher orbital energies (i.e. lower HF-KTs) than the π HOMOs of imidazole. Thus, it is understandable that the lowest LDF IP of **6** (7.31 eV, which corresponds to a π ionization) is significantly smaller than the lowest IP (7.68 eV) of **4**, which corresponds to σ ionization.

Conceptually, the lowest ΔE_{S-T} values of **5**–**8** are not directly comparable to the ΔE_{S-T} values of known carbenes, since the lowest triplet states of **5**–**8** do not arise through electronic excitation from the carbenic lone pair, but rather have have $\pi^1\pi^{*1}$ configurations. The LDF values of the lowest ΔE_{S-T} values of **6**–**8** range from 26.4 to 31.0 kcal mol^{-1}. As Table 2 shows, the lowest $\sigma^1\pi^{*1}$ triplet states of **6**–**8** are even higher in energy. These ΔE_{S-T} values may be compared to calculated values of 45 kcal mol^{-1} for CF_2,[13] a prototypical singlet carbene, and 79.4 kcal mol^{-1} for unsubstituted imidazol-2-ylidene.[14] Thus, the ΔE_{S-T} values of **6**–**8**, while substantial, are significantly lower than those of the stable imidazol-2-ylidene-type carbenes. Once again, this is a consequence of the relatively low energy of the lowest $\pi^1\pi^{*1}$ states of large-ring aromatic compounds such as porphyrins.

Table 2. LDF values of ΔE_{S-T} [kcal mol^{-1}] and lowest σ- and π-IPs [eV].

Molecule	Lowest ΔE_{S-T}		Lowest IP	
	$\pi^1\pi^{*1}$ triplet	$\sigma^1\pi^{*1}$ triplet	σ	π
5	[a]	[a]	[a]	7.22
6	26.4	41.2	7.31	6.65
7	29.6	34.9	6.96	6.76
8	31.0	56.3	7.79	7.72

[a] These values are not available since the calculations on the pertinent, highly excited states could not be converged.

Although **6** exhibits the salient structural and electronic attributes of a stabilized singlet carbene, it is still higher in energy than **5** by a substantial margin—30.4, 32.8, and 42.2 kcal mol^{-1} at the LDF, HF, and MP2 levels, respectively.[15] In view of the significant energy difference between tautomers **5** and **6**, how can we account for the activation of the central C–H bond in **1** (the known analogue of **5**) by a reagent as mild as $NiCl_2$? To probe this issue, we examined the interaction of **6** with a Zn^{2+} ion (a closed-shell Lewis acid) and with a Ni^{2+} ion by performing calculations on **7** and **8**, respectively.[16] Table 2 shows that the lowest σ-IPs of **6** and **7** are similar, as are the energies of the lowest $\sigma^1\pi^{*1}$ triplet states relative to the ground states. However, unlike the lowest cationic $^2A'$ (i.e. σ-ionized) state of **6**, the unpaired electron spin in the lowest $^2A'$ state of **7** is delocalized rather evenly on the carbenic carbon, the three central nitrogen atoms, and the zinc ion, suggesting a certain stabilization of the carbenic lone pair by covalent interactions with the zinc center.

The results on **8** are drastically different from those on **6** and **7**. Thus, the energies of both the lowest $\sigma^1\pi^{*1}$ triplet and cationic $^2A'$ states of **8**, relative to the neutral ground state, are much higher than the corresponding values for **6** and **7**. Indeed, in the lowest energy cationic $^2A'$ state of **8**, the nickel ion carries nearly all the unpaired spin density, leaving negligible spin density at the carbenic center. In other words, the carbenic lone pair does not contribute to the highest occupied σ MO of **8**, but to an MO with an even lower orbital energy. An examination of the high-lying σ MOs of **8** reveals that the stability of **2** or **8** stems significantly from a highly favorable covalent interaction between the carbenic lone pair and the empty d_σ atomic orbital of an Ni^{2+} ion (d^8) placed in a strong square-planar ligand field as well as from a metal–ligand π bond.

Both Arduengo-type carbenes and the carbenic tautomers of N-confused porphyrins feature a carbenic lone pair in the nodal plane of a highly stable aromatic π system. This stereoelectronic feature results in a substantial singlet–triplet energy gap. As in the case of Arduengo-type carbenes, significant fractions of the unpaired spin density in the lowest σ-ionized states of **6** and **7** reside on the carbenic center. The lowest σ IPs of **6** and **7** are also close to the lowest σ IPs of the imidazol-2-ylidene-based carbenes. Thus, our calculations lend strong support to the proposal that **6** is indeed an Arduengo-type aromatic carbene. The specially favorable covalent interactions between **6** and the Ni^{2+} ion provides additional insight into the surprising ease with which N-confused porphyrins form metal–carbon bonds.

Silicon Analogues of Grignard Compounds: Synthesis and Structure of Amine-Stabilized Trimethylsilylmagnesium Halides**

Richard Goddard, Carl Krüger, Nazmi A. Ramadan, and Alfred Ritter*

Dedicated to Professor Hubert Schmidbaur on the occasion of his 60th birthday

For a long time it has been suspected[1] that triorganosilyl Grignard compounds play a role as intermediates in the reaction of halo(triorgano)silanes with elemental magnesium to give hexaorganodisilanes. However, all attempts to synthesize members of this class of compounds in analogy to the classical methods of preparing carbon Grignard reagents have been unsuccessful.

Indirect evidence for the existence of triorganosilylmagnesium halides in ether has been recently obtained by Oehme and coworkers[2] during the metal exchange reaction of tris(trimethylsilyl)silyllithium $(Me_3Si)_3SiLi \cdot 3THF$ with magnesium bromide. The assumed intermediate, tris(trimethylsilyl)silylmagnesium bromide $(Me_3Si)_3SiMgBr$, was not isolated but immediately underwent further reaction in ether solution.

We have now synthesized Grignard analogous trimethylsilylmagnesium compounds easily as complexes with amine chelating ligands, directly from halo(trimethyl)silanes and magnesium, using the highly reactive pyrophoric magnesium (Mg*) of Bogdanović et al.[3]

So far we have observed that only bromo(trimethyl)silane and iodo(trimethyl)silane and not the usual chloro(trimethyl)silane react under our chosen reaction conditions to give trimethylsilyl Grignard compounds. In contrast to the classical Grignard synthesis, the reaction cannot be carried out in oxygen-containing solvents such as tetrahydrofuran or diethyl ether because of quantitative ether cleavage during the course of the reaction. Hence the reactions were carried out in dried toluene in the presence of tetramethylethylenediamine or pentamethyldiethylenetriamine as complexing ligands.

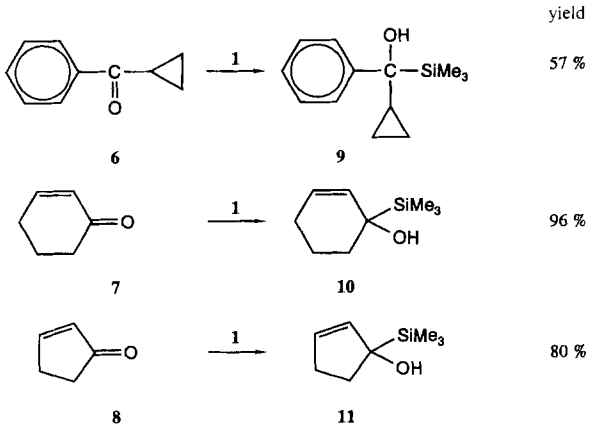
[**] We thank Prof. Dr. M. Demuth and Dr. J. Leitich for valuable discussions, Mr. P. Bayer and Mr. K. H. Claus for experimental assistance, as well as Prof. Dr. K. Schaffner for his kind support. N. A. R. thanks the DFG for financial support for his stay at the MPI für Strahlenchemie in 1992 and 1994.

Under these conditions it has been possible to isolate the trimethylsilylmagnesium compounds **1**–**4** as solids. Crystals of **1** and **2** suitable for X-ray structure analysis have also been obtained.

$$Me_3Si{-}Hal + Mg^* \xrightarrow{tert.\ amine} \underset{\mathbf{1-4}}{Me_3Si{-}Mg{-}Hal \cdot tert.\ amine}$$

$Me_3Si{-}Mg{-}Br \cdot Me_2N{-}CH_2{-}CH_2{-}NMe_2$ **1**

$Me_3Si{-}Mg{-}Br \cdot MeN(CH_2{-}CH_2{-}NMe_2)_2$ **2**



$Me_3Si{-}Mg{-}I \cdot Me_2N{-}CH_2{-}CH_2{-}NMe_2$ **3**

$Me_3Si{-}Mg{-}I \cdot MeN(CH_2{-}CH_2{-}NMe_2)_2$ **4**

The only by-product from the preparation of **1** is the known pyrophoric bis(trimethylsilyl)magnesium · tetramethylethylenediamine (**5**).[4] Bis(trimethylsilyl)magnesium is also known to form complexes with other ligands.[5] Compound **5** is evidently formed as a consequence of a Schlenk equilibrium.[6]

$Me_3Si{-}Mg{-}SiMe_3 \cdot Me_2N{-}CH_2{-}CH_2{-}NMe_2$ **5**

As first examples of the uses of **1**–**4**, **1** was treated with the ketone **6** and the enones **7** and **8** in toluene at −70 °C, and the compounds **9**, **10**,[7] and **11** were formed after hydrolysis. Replacement of **1** by trimethylsilyllithium in the reaction with **7** does not lead to **10**, but yields exclusively 3-(trimethylsilyl)cyclohexanone.[8]

The results of the crystal structure analysis of **1** are summarized in Figure 1.[15] It is particularly noteworthy that in the crystal **1** exists neither as a monomer nor as a symmetrically Br-bridged dimer, but rather as an associated complex. The complex lies on a crystallographic inversion center, but the two independent Mg–Br distances in **1** differ significantly from one another, in contrast to other Br-bridged Grignard compounds.[9–13] Whereas one of the Mg–Br bond lengths of 2.534(4) Å lies between the value observed in the monomeric ethyl((−)-isosparteine)magnesium bromide (2.506 Å)[14] and that in the symmetrical Br-bridged dimeric ethyl(triethylamine)magnesium bromide complex[11] (average 2.567 Å), the other Mg–Br* distance of 3.220(4) Å is clearly longer. It is 0.6 Å larger than the sum of the ionic radii of Mg^{2+} and Br^- (2.60 Å) and thus indicates no interaction between these atoms. Closer inspection of the local geometry of the Mg atoms reveals, however, that the geometry of the monomeric subunit deviates from the expected idealized C_s symmetry of the free monomer. The Mg atom is situated

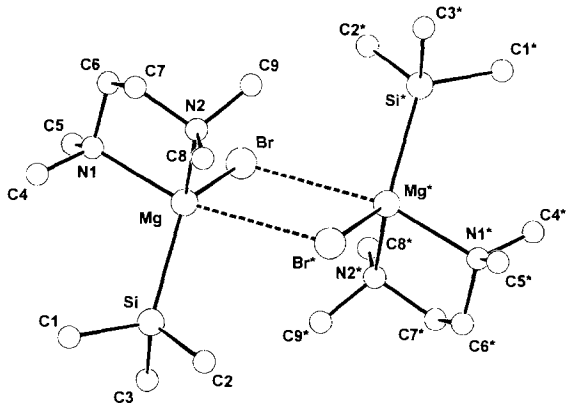


Fig. 1. Molecular structure of **1** in the crystal. Selected bond lengths [Å], angles [°], and torsion angles [°]: Mg-Si 2.630(4), Mg-Br 2.534(4), Mg–Br* 3.220(4), Mg-N1 2.265(8), Mg-N2 2.190(9), Si-C1 1.87(1), Si-C2 1.81(2), Si-C3 1.91(2), N1-C4 1.37(2), N1-C5 1.42(2), N1-C6 1.49(2), N2-C7 1.48(2), N2-C8 1.47(2), N2-C9 1.49(2), C6-C7 1.54(3); Br-Mg–Br* 81.0(1), Mg-Br–Mg* 99.0(1), Br-Mg-Si 128.7(2), Si-Mg–Br* 86.7(1), Br-Mg-N1 95.2(3), Br-Mg-N2 107.5(3), Si-Mg-N1 106.5(2), Si-Mg-N2 121.0(3), N1-Mg-N2 82.1(4), Si-Mg-Br–Br* -78.4(4) [15].

0.27 Å towards Br* from the mean plane through Br, Si, and the midpoint between N1 and N2. Apart from possible steric effects on the Mg atom, the influence of the neighboring Br* atom on the arrangement of the ligands around the Mg atom cannot be ignored. Whether the tendency to dimerize is caused by the acceptor ability of the Si atom cannot be judged without structural information on a corresponding alkyl Grignard compound. Crystal structures have been reported for [{η^5-1,2,4-tris(trimethylsilyl)cyclopentadienyl}magnesium bromide] · tetramethylethylenediamine[16] and the related (η^5-cyclopentadienyl)magnesium · tetraethylethylenediamine,[17] which each contain a π-bonded cyclopentadienyl ligand, but not from the corresponding alkyl Grignard compound with tetramethylethylenediamine as ligand. Ethyl((−)-isosparteine)magnesium bromide[14] is, however, monomeric in the crystal, and this has been attributed to the bulky isosparteine ligand. Interestingly, the Mg–Br bonds of bis-[(μ_2-bromo)(2-methoxymethyl-*o*-phenylene-*C*,*O*)(tetrahydrofuran-*O*)magnesium],[13] in which the Mg atom is pentacoordinate, differ in length [2.509(3) and 2.705(2) Å], but the difference is much smaller than that observed for **1**. The Mg–Si distance of 2.630(4) Å in **1** resembles that in bis(trimethylsilyl)magnesium · tetramethylethylenediamine.[4] Here the bond lengths are 2.624(4) and 2.631(4) Å [average 2.628(5) Å]. The Si-Mg-Br angle in **1** [128.7(2)°] is significantly larger than the Si-Mg-Si angle in bis(trimethylsilyl)magnesium [115.3(1)°].[4]

The molecular structure of **2** is depicted in Figure 2. The molecule is monomeric in the crystal and lies on a crystallographic mirror plane passing through Mg, Br, Si, C1, N2, and C7. Three coordination sites of the pentacoordinate Mg atom are occupied by the pentamethyldiethylenetriamine ligand. The Mg–Br and Mg–Si distances of 2.599(4) and 2.651(6) Å, respectively, are slighly longer than the corresponding distances in **1**, but the Si-Mg-Br angle is considerably smaller [105.0(2)°]. This may be a result of the larger steric requirements of the triamine ligand. Compounds **1** and **2** are the first examples of crystal structures of Si analogues of Grignard compounds.

Experimental Procedure

For the preparation of **1**, pyrophoric Mg* [3] (4.4 g, 0.183 mol), which was obtained by dehydrogenation of catalytically prepared (Ti catalyst) MgH_2, were placed under argon in a three-necked flask fitted with a reflux condensor, three-way tap, dropping funnel, and magnetic stirrer, and covered with 30 mL dried toluene. Then bro-

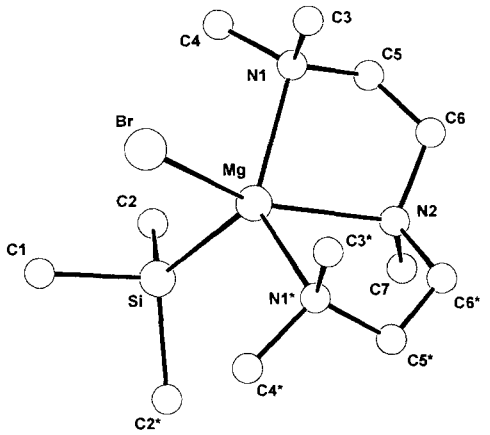

Fig. 2. Molecular structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Mg-Si 2.651(6), Mg-Br 2.599(4), Mg-N1 2.251(8), Mg-N2 2.35(1), Si-C1 1.81(2), Si-C2 1.85(1), N1-C3 1.49(1), N1-C4 1.49(2), N1-C5 1.41(2), N2-C6 1.44(2), N2-C7 1.46(2), C5-C6 1.47(2); Si-Mg-Br 105.0(2), Br-Mg-N1 92.8(3), Br-Mg-N2 151.8(4), Si-Mg-N1 113.4(2), Si-Mg-N2 103.2(4), N1-Mg-N2 76.0(4), N1-Mg-N1* 129.5(4) [18].

mo(trimethyl)silane (Fluka, 28.1 g, 0.184 mol) in dried toluene (65 mL) was added dropwise while stirring. A solution of tetramethylethylenediamine (21.3 g, 0.184 mol) in dried toluene (65 mL) was added dropwise over about 2 h. The reaction mixture was maintained at 50 °C for 24 h and then for a further 110 h at 70 °C. The flocculent, dark grey precipitate of $MgBr_2$·amine so formed was filtered off under argon on a glass scinter, washed 3 × with 20 mL portions of dry toluene, and the complete filtrate was dried under oil-pump vacuum. Repeated extractions of the residue with dry pentane and evaporation of the extracts to dryness yielded 7.06 g (13.5%) **5** as a white, air-flammable solid. The deposit that had been freed of **5** by elution of the residue with pentane was analytically pure **1** (20.41 g, 38%) with m.p. 135 °C [19]. Compound **1** decomposes in damp air with loss of trimethylsilane. Correct elemental analysis. MS (70 eV): *m/z*: 219 [*M*−$SiMe_3$], 213 [*M*−Br], 116, 73, 58. ^{1}H NMR (400 MHz, [D_8]toluene): δ = 0.35 (s, 9H, $Si(CH_3)_3$); 1.8–2.1 (br. s at 1.83, 1.92, 2.0, 16H, NCH_2, NCH_3); ^{13}C NMR (100 MHz, [D_8]toluene): δ = 6.1 ($Si(CH_3)_3$), 46.67–46.78 (br. d, $N(CH_3)_x$), 55.91 (NCH_2). All NMR spectra were recorded at room temperature.

The compounds **2**, **3**, and **4** were synthesized by the same experimental method as **1**. Deviations from this procedure were the reaction time of 20 h for **3** and **4** and the reaction temperature of 40 °C. **2**: Yield 15%; m.p. 159–161 °C [19]. Correct elemental analysis. MS (70 eV): *m/z*: 276 [*M*−$SiMe_3$], 270 [*M*−Br], 73. Compound **2** shows complex temperature-dependent NMR spectra, which indicate dynamic processes and equilibria between many species. ^{1}H NMR (400 MHz, C_6D_6): δ = 0.3–0.75 (br.), 0.48 (s, $Si(CH_3)_3$), 1.6–2.5 (many multiplets of differing intensity, among others a strong broad singlet at δ = 2.31 (NCH_3 and NCH_2); ^{13}C NMR (100 MHz, C_6D_6, BB-decoupled and DEPT): δ = 4.0–6.0 (br.), 7.25 (s, $Si(CH_3)_3$), 44.0–48.0 (br., NCH_3), 56.3, 56.5 (each s, NCH_2).

3: Yield 39%; m.p. 100–102 °C [19]. Correct elemental analysis. MS (70 eV): *m/z*: 340 [M^+], 325 [*M*−15], 267 [*M*−$SiMe_3$], 73. ^{1}H NMR (400 MHz, [D_8]toluene): δ = 0.32 (s, 9H, $Si(CH_3)$), 1.97–2.01 (br., 16H, NCH_3, NCH_2); ^{13}C NMR (100 MHz, [D_8]toluene): δ = 5.55 ($Si(CH_3)_3$), 47.23 (NCH_3), 56.39 (NCH_2).

4: Yield about 10%; m.p. 220–225 °C (decomposition) [19].
MS (70 eV): *m/z*: 324 [*M*−$SiMe_3$], 73.

9: MS (70 eV): *m/z*: 219 [*M*−H], 205 [*M*−CH_3], 147 [*M*−$SiMe_3$], 77, 75, 73. The constitution was established by analyses, NMR spectra (^{1}H, ^{13}C-BB, -DEPT, -gated, C/H-COSY), in particular in the aliphatic region from the C–H coupling constants of 147–163 Hz and the geminal H–H coupling constants of 4.8 Hz, which show the presence of the cyclopropane ring.

11: MS (70 eV): *m/z*: 155 [*M*−H], 83 [*M*−$SiMe_3$], 73. The constitution was established by analyses, NMR spectra (^{1}H, ^{13}C-BB, -DEPT, -gated, C/H-COSY).

[19] All melting points were determined under argon in sealed capillaries.

Corrigenda

A reinvestigation (Y. Yarovoy, M. M. Labes, *Mol. Cryst. Lig. Cryst.* **1995**, *264*, 201) of the cholesteric pitch data supporting the effect of cholesteric twisting on the chiral properties of solutes dissolved in liquid crystal solvents revealed that the effects reported in two publications are irreproducible (M. M. Labes, W. Shang, *J. Am. Chem. Soc.* **1991**, *113*, 2773; M. M. Green, D. Weng, W. Shang, M. M. Labes, *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 88). Therefore the authors withdraw the above-mentioned publication in *Angewandte Chemie*. The central hypothesis raised there remains unsupported by experiment.

In the communication "Formation and Structures of New Metallo- and Metallapolysulfanes, $[MS_y]^+$ (y = 2–16)" by I. Dance, K. Fisher, and G. Willett (*Angew. Chem. Int. Ed. Engl.* **1995**, *105*, 201) the phrase "that is, after all of the Mn^+ has reacted" should be deleted from the legend to Figure 1.

Mature Methods

Chemistry of Non-Stoichiometric Compounds. By *K. Kosuge*. Oxford University Press, Oxford, 1994. 262 pp., hardcover £ 55.00.—ISBN 0-19-855555-5

In this monograph Koji Kosuge, Professor of Solid-State Chemistry at Kyoto University, reviews a subject that is of fundamental importance to chemistry. It is only through understanding the internal processes of solid materials, i.e. the nature and behavior of the relevant particles or chemical stimuli, that one can apply chemistry to solids in analogy to the successes of the acid–base or redox concepts of "wet chemistry". The appearance of a book on this subject is therefore to be welcomed. Regrettably, however, it does not succeed very well in its aims.

The choice of topics seems promising at first. The starting point is the thermodynamics of mixtures, which is then applied to the equilibrium of defects, first in dilute systems, then in more concentrated systems, and finally in those that deviate greatly from the concentration of the ordered phase. However, there is no treatment of chemical diffusion. (In this book the term "diffusion coefficient" is used only in the sense of a tracer diffusion coefficient.) The last chapter can be recommended, dealing with extended defects, shear structures, Vernier structures, micro-twin structures, intergrowth structures, and adaptive structures, and containing a wealth of information that is chiefly useful to the chemist interested in crystallography. Unfortunately high-temperature superconductors, which would have nicely completed this chapter, are not covered.

The first of the three chapters, making up at least half the book, cannot be recommended. There are numerous inaccuracies and errors which will spoil the pleasure of reading the book. A few examples follow.

The nomenclature is not in accordance with conventions in the literature. Moreover, there is confusion between absolute and relative charges, and worse still, the symbols for these are confused. On page 45 the regular electronic state is denoted by "eh", whereas on page 85 it is correctly identified by the symbol "0" in the building elements notation. In the case of ionic equilibria a mixture of structure elements and building elements is used. The introduction to chemical equilibria and the configurational enthalpy (Ch. 1.2) is clumsy and often inaccurate. One could perhaps tolerate the frequent switching between differences and differentials, but not the identification of $-(\Delta G^0-\Delta G)/RT$ as an equilibrium constant. In the discussion of the formation of defects (p. 18) there is no mention of the vibrational entropy, which has an important influence on the free enthalpy of formation, especially in high-temperature chemistry. The fact that the temperature dependence of the equilibrium constant for the band–band transition is determined by the band gap is explained by the following curious statement: "The rate of ionization is believed to be roughly equal to that of the dissociation of water ... and therefore we put [eh] = 1." (?). This is just a small selection. The most annoying aspect of the errors is that they destroy the reader's faith in those parts of the text that are properly written.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Principles of Electron Spin Resonance. (Physical Chemistry Series.) By *N. M. Atherton*. Ellis Horwood, Chichester, 1994. 585 pp., hardcover $ 127.00.—ISBN 0-13-721762-5

This book is a revised and updated version of *ESR—Theory and Applications* which appeared in 1973, and the change in the title reflects the author's aim of placing greater emphasis on the fundamentals of ESR spectroscopy. Rapid changes are currently occurring in the experimental methods used in ESR spectroscopy, summed up by the key phrase "pulsed ESR spectroscopy", opening up entirely new possibilities in time-resolved and multidimensional measurements. In turning back to basic principles at this time the author is tapping a great potential but also running some risks.

As is to be expected for a method that has reached maturity, the literature contains a wide variety of notations for the treatment of special cases, making it difficult for students and users to relate the techniques to their specific problems by analogy with methods that are already familiar. Here we undoubtedly find one of the strengths of the book, as the author consistently treats spectral calculations and relaxation processes at a level suitable for the average reader. He also helpfully "translates" even very recently published papers, so that the reader who works consistently through the book gains a comprehensive insight into topical problems. However, the discussion of the possibilities opened up by pulsed ESR spectroscopy is less successful. Only 80 pages are devoted to recently developed methods such as pulsed ENDOR, 2D ESR spectroscopy, and optical spin polarization, and these are treated essentially at an introductory level, in contrast to the first ten chapters (440 pp.) which deal with continuous-wave (CW) forms of ESR and ENDOR spectroscopy, explaining their capabilities and describing many examples of a nontrivial kind.

A work that has the word "principles" in its title invites comparison with other books that make similar claims. Examples are: *Principles of Magnetic Resonance in One and Two Dimensions* (Ernst, Bodenhausen and Wokaun), *Principles of Magnetic Resonance* (Slichter), *Principles of Nuclear Magnetism* (Abragam), and *EPR of Transition Ions* (Abragam and Bleaney), all of which undoubtedly have the character of handbooks. In my view the present book is instead more accurately described as a "comprehensive introduction", although this classification in no

way detracts from its value and usefulness.

Against the background of constantly shrinking library budgets, one must look at any new book and ask whether its purchase is really essential. Here the needs of the specialists are less important than those of the advanced students who, in the course of their work, need to find quick solutions to practical problems without first having to make a deep and detailed study of the methods. This book offers a very good foundation for that purpose. It has the advantages of a detailed subject index and an up-to-date bibliography (although it is difficult to understand why, in the age of computer-aided text processing, all the umlauts have been consistently omitted from names such as Schrödinger, Hückel, and Möbius). To sum up, the book fulfills its aim of providing students and scientists whose main field is physical chemistry with an up-to-date and comprehensive basis for understanding ESR spectroscopy.

Computer Simulations of Biomolecular Systems. Theoretical and Experimental Applications. Vol. 2. Edited by *W. F. van Gunsteren, P. K. Weiner* and *A. J. Wilkinson*. ESCOM, Leiden (Netherlands), 1993, 589 pp., hardcover HFl 415.00.—ISBN 90-72199-15-4

About 18 years ago when J. A. McCammon, B. R. Gelin, and M. Karplus published the first molecular dynamics simulation of a protein (*Nature* **1977**, *267*, 585), the accepted picture of a biological molecule was essentially that of a rigid body. The molecular structures of several proteins and of DNA had already been successfully determined by X-ray crystallography, and the results were represented by a rigid wire model. The dynamic aspects that play an important role in all biological processes could not, and still cannot, be directly observed experimentally, at least down to atomic-scale resolution. When the results of molecular dynamics calculations first began to appear, it became possible to follow the molecular motions as if in a ciné film. These calculations were restricted to relatively small molecules, and the time intervals that could be simulated were very short, in the order of picoseconds. However, such simulations made an important contribution to revising the ideas based on the rigid wire model.

The book reviewed here shows how simulation methods have developed during the last 18 years and reflects the present-day importance of the subject. In 25 chapters, introduced in a very detailed preface by Martin Karplus, various authors review simulation techniques, force fields, and applications. The contents list alone occupies more space than is available for this review, and it will only be possible here to pick out some of the topics covered.

The first two sections of the book are concerned with fundamentals, namely simulation techniques (algorithms for molecular dynamics and Monte Carlo calculations) and force fields. A force field should on the one hand approximate as closely as possible to the real quantum-mechanical situation, while on the other hand allowing rapid and efficient calculations. Because of the need to keep the computing time within reasonable bounds, compromises are always necessary. Simplified force fields are necessary in order to study slow processes such as protein folding. However, even more detailed force fields are still only approximations, and it is important for the user to know how this can affect the results of the calculations.

One of the most important applications of molecular dynamics simulations is the calculation of free energies. The book offers an excellent introduction to this topic, with particular emphasis on possible difficulties and sources of error. Several examples of successful free energy calculations are given. On the other hand it is also clearly explained why the predictions from the calculations may not always be correct.

The three chapters on the use of molecular dynamics calculations in refining molecular structural data from X-ray crystallography and NMR spectroscopy can be regarded to some extent as occupying a special position in the book. Here one is using the molecular dynamics algorithm not to investigate the dynamics of a molecule but as an optimization method for the solution of a difficult nonlinear problem. The excellent convergence properties of the molecular dynamics method have revolutionized the process of structure refinement. The occasions when individual steps must be performed laboriously by hand are now increasingly rare, and the end result, the refined structure, is reached much more quickly than in the past. However, the close connection that exists between molecular dynamics and NMR spectroscopy especially is also mentioned here.

I learned much from reading this book, and it can be recommended as a thorough introduction to the simulation of macromolecules. It is a valuable source of practical information and an indispensable work of reference. In a multiauthor work such as this some degree of non-uniformity is perhaps unavoidable, as also is a certain amount of overlapping in chapters on related topics. However, I regard the latter as an advantage, since it means that important topics are seen from different points of view. All the aspects of the simulation of macromolecules discussed in the book are active areas of research, and as is made clear in the preface many questions still remain to be finally answered, even with regard to the methods. It is pleasing that many of the authors are able to view their own work critically from a distance. It is very useful, especially for a newcomer to the field, to be made aware of problems in the application of these methods.

Ideas in Chemistry. A History of the Science. By *D. Knight*. Athlone Press, London, 1992. 213 pp., hardcover £ 38.00.—ISBN 0-485-11390-2

What a splendid title! It promises a much needed book on the intellectual content of chemistry, and on its trade: by insemination, as with "reaction", borrowed in part from the action/reaction pair in physics; by dissemination, as with "affinity" or "catalysis," terms and concepts that have entered common language too; or as with "complementarity", which spawned molecular biology.

Is it because of the inheritance from alchemy? Chemistry is a conceptual science, rooted in material operations. Other sciences (astronomy, biology, or physics) do not transform their subject matter as a matter of course. But chemistry intellectualizes its metamorphoses, to an extent that is astounding, given the huge distance from the macroscopic to the microscopic that it entails: to think and to talk of molecular *objects*, reaction *paths*, molecular *orbitals*, atomic *hardness*, etc. demands temerity and insight.

What is needed is a thesaurus of key chemical notions. There are two or three dozen central concepts, such as acidity or coordination, plus a hundred or so more peripheral but also necessary notions, such as steric hindrance or chain reaction. Someone should provide such a compendium, with present-day definitions, capsule histories, and illustrative quotations.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1034 $ 10.00+.25/0

Professor Knight of Durham University indeed takes as his scope the whole of the history of chemistry. Not to worry, he has the scholarship to match! However, besides the misleading book title, which the subtitle corrects to some extent, the chapter titles are other irritants. Each chapter corresponds to a historical period, and is labeled in the manner of those books of yesteryear which had names such as "The Age of Enlightenment", "The Age of Revolutions", and so on. Here, chapters bear names such as "A teachable science", "A deductive science", etc. Of course each such label is questionable. Some—"A service science" for present-day chemistry—raise the blood pressure.

The philosophical bases appear as a little weak, for a book of this sort which aims at providing an intellectual history. Chapter 7, "The experimental science", is not one of the best. Somehow, it fails to convey what "thinking with one's hands" entails. "Experimental science" has two meanings. The jaded meaning is sociological, that of professionals spending their time in the laboratory and somehow, theorizing from their observations, producing novel knowledge. The stronger meaning is philosophical: the methodology, which we owe to Boyle and Bacon, of questioning matter through experiments, the results of which raise new questions, leading in turn to new experiments, so that truth is approached inquisitively rather than speculatively. Hence, some naive statements such as "observation with instruments is remote and theory-laden compared with the working with test-tubes and bottles, and seems somehow unchemical" are questionable.

This is a delightful introduction to the history of chemistry. The tone combines simplicity, down-to earthness, some of the flavor of speech, and erudition, worn lightly. It resembles in these respects some of the outstanding science programs of the BBC, never condescending, always explanatory. David Knight succeeds in making this slim historical volume into a popularization of chemistry. His trick is to talk to the layman as if he too were a layman. Here is just one example of such felicitous writing: "the texture of things get into the memory: the viscosity, mobility and viscidity of different liquids, and the gritty, unctuous or glassy feel of solids; the undescribable but unforgettable smell of things."

One can learn a lot from Professor Knight's learned conversation, and I did: Richard Watson's description of saturnism at the end of the eighteenth century; Lyon Playfair's 1852 prophetic tirade on recycling; or the phrase *glyptic formulae* to describe what we nowadays call molecular modeling.

The insularity is not totally unexpected. Sometimes the constant hagiography of British scientists rubs raw. But it is involuntary and unsystematic, for instance Laurent's ideas and methodology get the rich praise they deserve. A minor irritant is the abysmal typesetting, swarming with typos. Conversely, the jacket design is admirable. All in all, a highly recommended book, which any chemist would be well advised to own.

Palaiseau (France)

Transition Metals in the Synthesis of Complex Organic Molecules. By *L. S. Hegedus*. University Science Books, Mill Valley, CA (USA), 1994. 358 pp., paperback £ 27.95.—ISBN 0-935702-28-8

The use of transition metals has revolutionized organic synthesis in various ways. In many cases reactions that would otherwise have been simply classified as "impossible" can be carried out using transition metal compounds. Moreover, much of the modern armory of the preparative chemist, especially with regard to chemo-, regio-, and stereoselective methods, is based on transition metal-assisted reactions, so that synthetic chemistry without these has now become unthinkable. This situation has already been well recognized by the excellent treatment in Part III (*Applications to Organic Synthesis*) of the book *Principles and Applications of Organotransition Metal Chemistry* (2nd Edition), by J. P. Collman, L. S. Hegedus, J. R. Norton, and R. G. Finke (University Science Books, Mill Valley, 1987). The development of synthetically relevant organometallic processes has continued apace in recent years, and many new applications of transition metal-assisted reactions in the synthesis of complex organic molecules have been published, and therefore this updated survey by L. S. Hegedus, covering the literature up to January 1993, is very welcome.

The main contents of the book are arranged according to the well proven system used in Chapters 13–20 of Collman, Hegedus, Norton, and Finke. These are preceded by two short, well structured chapters (45 pp. in total) on formalisms, bonding situations, and organometallic reaction mechanisms, which equip the reader with the essential tools for understanding the following chapters on synthetic applications. Chapter 3 (transition metal hydrides) is mainly concerned with homogeneous hydrogenation reactions, now also including enantioselective reductions using ruthenium-BINAP catalysts. Chapter 4, on complexes containing metal–carbon σ-bonds, has been extensively revised (with over 100 new references), and gives the reader good insights into modern organocopper chemistry and the fascinating synthetic possibilities now opened up by palladium-catalyzed processes such as enyne cycloisomerizations, cross-couplings, and Heck reactions. The chapter also includes a new section on reductive cyclodimerizations of alkenes and alkynes based mainly on zirconium chemistry. In Chapter 5 (carbonyl complexes) the sections on coupling reactions, carbonylations, and decarbonylations correspond fairly closely to those in Collman et al., but the chapter also includes some more recent applications of chiral non-racemic metal acyl enolates. In contrast Chapter 6 (carbene complexes) consists almost entirely of recent examples of the various uses of electrophilic and nucleophilic transition metal carbene complexes in organic synthesis, with over 100 new references. Cyclopropanations, Dötz reactions, photochemical generation and subsequent reactions of ketene complexes, as well as metal-catalyzed decompositions of diazo compounds followed by insertion into C–H or X–H bonds or formation of ylides, are all described in detail. This chapter ends with a brief section on carbonyl-olefination using Schrock-type carbene complexes. Many new references also appear in Chapter 7 (alkene, diene, and dienyl complexes). The use of palladium(II) complexes to assist the attack on alkenes by O-, N-, and C-nucleophiles is thoroughly discussed, including cyclization-induced rearrangements. Other topics highlighted in this chapter are the use of iron complexes to protect alkenes and 1,3-dienes, and the regio- and stereoselective formation of carbon–carbon bonds by nucleophilic attack on molybdenum diene complexes, and especially on iron dienyl complexes. Chapter 8 (alkyne complexes) discusses the use of cobalt complexes for the protection of the alkyne function, and in this connection describes new applications of the Nicholas reaction and subsequently takes a closer look at the Pauson–Khand reaction. Cobalt-catalyzed cyclo-oligomerizations of alkynes provide another major topic of this chapter, which ends with a completely new section on zircono benzyne complexes. Chapter 9 (η^3-allyl complexes) begins with the telomerization of 1,3-dienes, with

special attention to recently developed intramolecular processes catalyzed by palladium, iron, or nickel. This is followed by a long section concerned mainly with regio- and stereoselective reactions of π-allyl palladium complexes using C-, N-, and O-nucleophiles, their reduction to olefins, and their elimination reactions yielding 1,3-dienes. Also covered in this chapter and supported by a wealth of new literature references are allylic alkylations using vinyl or aryl tin compounds, palladium ene reactions and cascades based thereon, and formal [3 + 2]-cycloadditions via trimethylenemethane intermediates. The chapter ends with a survey of other η^3-allyl metal complexes (of Mo, W, Fe, Co, and especially Ni). Chapter 10 (arene complexes) gives an up-to-date review of the synthetic applications of arene-chromium tricarbonyl complexes, including nucleophilic substitutions of aryl halides, regio- and stereoselective additions of C-nucleophiles, along with possible types of follow-on reactions, ring lithiations, and reactions involving activation of the benzylic position. Also the potential for using alternative metals that have not yet been thoroughly investigated in this context (Fe, Ru, Mn) is briefly considered at the end of this chapter.

With this updated survey of transition metal-assisted methods the author has succeeded in producing an independent and highly stimulating book, whose particular strengths lie in the carefully chosen examples, the excellent figures, and the succinct explanations. Apparently as a result of limiting the coverage to reactions of compounds containing transition metal–carbon bonds, as in Collman et al. (see p. 6), the enormously important catalytic epoxidations and dihydroxylations are unfortunately not included. Nevertheless, this book, which is intended both as the basis for a one-semester course for upper-level students and as an overview for practicing chemists, sets a new standard in the treatment of this subject matter. It is emphatically recommended for use by advanced students and by all academic and industrial chemists concerned with synthesis.

Bioinorganic Chemistry. Edited by *I. Bertini, H. B. Gray, S. J. Lippard* and *J. S. Valentine.* University Science Books, Mill Valley, CA (USA), 1994. 611 pp., hardcover £ 28.95.—ISBN 0-935702-57-1

Although this work is in fact a textbook on bioinorganic chemistry, it does not aim to compete in quite the same market as other recent introductory textbooks by W. Kaim and B. Schwederski, by J. A. Cowan, and by S. J. Lippard and J. M. Berg. It consists of nine chapters by a total of 15 authors, covering a wide variety of topics, mostly in considerable detail. The reader will not find here an introduction addressing the question "What is bioinorganic chemistry?", nor a systematic treatment of the basic principles of coordination chemistry, biochemistry, and physical methods. Instead the book aims to fill the gap between introductory textbooks (such as those mentioned above) and highly specialized review articles. The level of the contents would be more accurately reflected by a title such as "*Advanced* Bioinorganic Chemistry".

The chapters are of a fairly uniform length, with the exception of Chapter 1, a much shorter one in which E. C. Theil and K. N. Raymond give a clear and understandable description of the storage, transport, and biomineralization of transition metals (including zinc). In the second chapter I. Bertini and C. Luchinat discuss the reactions of zinc enzymes. Taking carbonic anhydrase as an example, they illustrate the importance of NMR spectroscopy and protein crystallography in this field. For some important zinc enzymes the authors describe possible catalytic cycles. The chapter also includes a short section on coenzyme and vitamin B_{12}.

The wide-ranging importance of calcium in the regulation of cell functions is recognized by devoting a separate chapter to this topic. After a short introduction (in which we also learn about the calcium content of a "good" beer), S. Forsén and J. Kördel describe the methods used to measure the concentration and distribution of calcium in cells. This is followed by sections on the transport and regulation of Ca^{2+} ions in higher organisms and on Ca^{2+} receptor proteins in cells. In Chapter 4 G. B. Jameson and J. A. Ibers contribute a review of both biological and synthetic dioxygen-transporting molecules. They begin by describing the thermodynamics of dioxygen transport and the biomolecules hemoglobin, hemocyanin, and hemerythrin, then go on to discuss some aspects of the chemistry of molecular oxygen, iron, copper, and cobalt. The chapter ends by describing the structural characteristics of dioxygen-binding biomolecules and synthetic complexes.

Chapter 5, by J. S. Valentine, is concerned with the reactions of the O_2 molecule that are of biological importance. After dealing with the chemistry and toxicity of O_2, the author discusses the relevant enzymes, namely cytochrome *c* oxidase, oxygenase, catalase, peroxidase, and Cu,Zn superoxide dismutase. Chapter 6 is devoted to electron transfer processes. H. B. Gray and W. R. Ellis Jr. describe the various electron transfer proteins and the types of biological processes in which electron transfer plays a part (e.g. photosynthesis). The emphasis is on theoretical aspects, especially with regard to long-range electron transfer in proteins.

In Chapter 7 E. I. Stiefel and G. N. George discuss proteins containing metal sulfide centers. They begin with iron sulfur proteins, concentrating appropriately on relevant (model) complexes of low molecular mass. Hydrogenases and nitrogenases are then discussed (including the recent crystal structure study by J. Kim and D. C. Rees). Chapter 8, by J. K. Barton, deals with interactions and reactions of metal ions and their complexes with nucleic acids. Topics covered include tris(phenanthroline) metal complexes, zinc-finger proteins, the MerR protein, and Fe^{II}-bleomycin.

In the last chapter S. J. Lippard discusses practical applications of bioinorganic chemistry, concentrating on the uses of metal compounds in medical diagnostics and chemotherapy. Cisplatin is treated at length (over 50 pages) as a case study. This chapter is also of interest in that the author broadens the discussion to include aspects beyond basic research, for example in drawing parallels between protagonists of new inorganic drugs and Hollywood film producers.

The inclusion of color plates and about 2000 (!) literature references add to the appeal of this excellent book, and there are few textual errors. It is unfortunate, however, that the IUPAC recommendation to enclose formulas of coordination compounds in square brackets has only been followed consistently in Chapter 9. I feel it is especially important in a student textbook to stick to the accepted rules of nomenclature.

Anyone who already has an elementary knowledge of bioinorganic chemistry, even if only from an introductory lecture course, will find this book useful and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/0909-1036 $ 10.00+.25/0

readily understandable. It should be in every departmental library, and I hope that it will also find its way into many personal collections, helped by the reasonable price.

Henry Strasdeit
Fachbereich Chemie
der Universität Oldenburg (FRG)

Destruction of Hazardous Chemicals in the Laboratory. 2nd edition. By *G. Lunn* and *E. B. Sansone*. Wiley, Chichester, 1994. 501 pp., hardcover £ 66.00.—ISBN 0-471-57399-X

It has always been one of the chemist's regular tasks to convert residues that are toxic, reactive, or harmful to the environment into products that can safely be disposed of. The methods for achieving this are becoming increasingly important as a consequence of strict legislation governing the handling of dangerous substances and properly disposing of them in environmentally acceptable ways. Although there is nowadays general agreement that certain substances should no longer be used in some situations, such as in teaching chemistry at elementary level, in modern research it is often impossible to avoid using reagents that present severe problems. This book contains over sixty short articles (an increase of about a third since the first edition in 1990), each giving well tested laboratory procedures for dealing with a particular substance or compound class, including critical evaluations of alternative methods. Substances with cytotoxic, anti-neoplastic, and enzyme-inhibiting properties, pharmacological products, and histological staining substances are included, so that the book also covers typical problems encountered in biochemical, microbiological, and medical laboratory practice.

The book begins with a very useful introduction which clearly explains the basic philosophy of appropriate reactions for destroying chemicals. Since many of the breakdown reagents used, which are mostly oxidizing or reducing agents, are themselves hazardous substances, and some of the reactions can become dangerously exothermic if not carefully controlled, the authors emphasize that the work must be carried out by people trained in chemistry or chemical engineering, in a properly equipped laboratory. Each article is well set out according to the following scheme: a) explanation of the potential risks, b) chemical principles of both well-known and new conversion methods, c) detailed laboratory procedures for carrying out recommended conversion reactions for large and small quantities and for dealing with spillages, d) instructions and recommendations for analyzing to check the success of the reaction, with limits of detection, e) mutagenicity assays of the end-products, where appropriate, f) suitability of the method for related compounds not specifically covered, g) an extensive bibliography. In addition there are four appendices as follows: a table of recommended solvents for obtaining samples from contaminated surfaces, methods for drying solvents without the use of highly reactive reagents, recommended safe procedures for using potassium permanganate, and recent developments in techniques for dealing with waste materials in biomedical research.

The substances included are listed in the alphabetical index under their systematic names, and also under synonyms, acronyms, and trade names. Dyes and biochemical compounds are also listed under the corresponding alphanumeric codes. One can also search for a compound via its molecular formula or CAS number. For example, under the heading "Halogenated Compounds" one finds a table listing alkyl halides, halogenated carboxylic acids, alcohols, and arenes (35 compounds altogether) with toxicological information supported by literature references. The recommended breakdown reactions are reductive dehalogenation by a Raney-nickel catalyst in alkaline solution, and substitutive dehalogenation in alcoholic NaOH. Tables giving the percentage conversion, as determined by GC analysis, are also provided. With this information it should be relatively easy for a chemist to choose the best method, even for compounds not listed in the book.

The authors work in a laboratory of the US National Cancer Institute, and the book has therefore been written from the standpoint of experience in American research organizations, where an agreed safety concept that meets the detailed requirements and is supported by expert opinion can be put into practice with less formalization and bureaucratic justification than under the rules of the European Union. Consequently the introduction contains only one brief mention of internal regulations. Thus, for example, the frequently appearing phrase "the decontaminated solution is discarded" should not necessarily be taken to mean that the end-product can safely be poured into the drain or the waste bin; instead one should proceed according to the regulations in one's own situation. Within the European Union one needs to set out formal instructions for carrying out the destruction reaction, and the necessary data must be obtained from elsewhere, as in all other procedures in a laboratory.

This professionally written and information-packed book should prove to be very useful in biomedical as well as chemical laboratories. The only qualification is that in the latter case, since the destruction process usually results in a rather large final volume, one would often prefer direct disposal as special waste for incineration. The book should be available as a standard work of reference in every library, and many laboratories should also have a copy to hand, a purpose for which it is well suited, especially in view of its stout binding.

Ligand-Accelerated Catalysis

David J. Berrisford, Carsten Bolm, and K. Barry Sharpless*

The search for new metal-catalyzed asymmetric reactions has provided some fascinating insights into the effects imposed on the metal catalysts by chiral ligands. A practical consequence is the discovery of ligand-accelerated catalysis (LAC). Thus, an existing catalyzed process is improved by the addition of a specific ligand, which leads to a faster, "ligand-accelerated" reaction. Both homogeneous and heterogeneous catalysts are known to exhibit this behavior. The concept is especially valuable in reactions catalyzed by early transition metals, where dynamic ligand exchange processes require an efficient in situ self-selection of a highly reactive catalyst from a variety of thermodynamically dictated assemblies. Results of detailed mechanistic studies will be presented, and the significance of LAC phenomena in transformations catalyzed by early and late transition metals will be discussed.

Keywords: asymmetric syntheses · catalysis · dihydroxylations · epoxidations · titanium compounds

1. Introduction

More than a decade has passed since the discovery of the titanium-catalyzed asymmetric epoxidation (AE) of allylic alcohols.[1] The efforts to understand and develop this process have led to mechanistic insights,[2] many of which have extended its synthetic utility.[3] Discovery of the AE demonstrated that an abiotic catalyst could overcome the limitations on substrate that are often characteristic of the exquisite selectivity of enzymes (the lock-and-key phenomenon). More recently, another catalyst system has captured our imagination. The osmium tetraoxide catalyzed asymmetric dihydroxylation[4, 5] (AD) of olefins has, at first sight, little in common with asymmetric epoxidation save the obvious modus operandi—enantiofacially selective addition of heteroatoms to prochiral olefins. However, one factor irrevocably links the AE and the AD—they are both manifestations of, and owe their success to, ligand-accelerated catalysis (LAC).

The purpose of this review is to discuss these and other significant examples in which ligand-acceleration effects are essential for a catalyzed reaction to occur in a rapid and highly enantioselective manner. A simple picture of the LAC phenomenon is presented in Section 2.

2. General Concept

In ligand-accelerated catalysis the addition of a ligand increases the reaction rate of an already existing catalytic transformation (Scheme 1). Both the ligand-accelerated and the basic catalytic process operate simultaneously and in competition with each other.

$$A + B \xrightarrow[k_0]{\text{catalyst}} \text{product}^* \xleftarrow[k_1]{\text{catalyst / ligand}^*} A + B$$

Scheme 1. Ligand acceleration. * = optically active.

Of course, the nature of the ligands bound to a metal center or complex almost always affects the selectivities and rates of the organic transformations catalyzed by such a species. When a ligand is bound, the rate of product formation can either be slowed down ($v_{ML} < v_M$, where v_{ML} is the overall rate of product formation in the presence of the ligand, and v_M is the rate of the reference reaction in the absence of the ligand in question), remain the same ($v_{ML} = v_M$), or be increased ($v_{ML} > v_M$). The latter, the accelerated process, offers a powerful approach to increasing reaction efficiency.[6]

The simplest definition of ligand acceleration is given in Equation (1a). The rate comparison should be performed for reactions giving a product common to the reference reaction and the ligand-accelerated version. Ligand deceleration then can obviously be defined by Equation (1b).

$$v_{ML}/v_M > 1 \quad (1a)$$

$$v_{ML}/v_M < 1 \quad (1b)$$

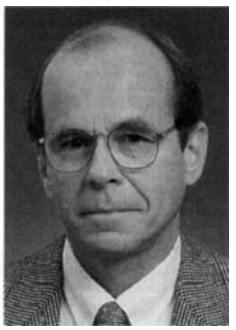
In processes with rapidly exchanging ligands both the relative microscopic rate constants (k_0 and k_1) and the magnitude of the catalyst/ligand binding constant (expressed by K_{eq}) are important to the overall ligand-acceleration effect (LAE). In terms of these quantities (and assuming no change in the rate law), the LAE can be defined by Equation (2). Particularly attractive pos-

$$k_1 K_{eq}[\text{ligand}]/k_0 > 1 \quad (2)$$

sibilities are offered, when the accelerating ligand also affects the stereochemical outcome.[7] Thus, use of chiral ligands[8] generates asymmetric catalysts.[9] If the reaction rate is increased upon ligand binding, the stereoselective pathway can dominate over the nonselective one. Although a mixture of several different reactive species—selective and nonselective ones—are present in solution, enantioselectivity can be achieved. Even with a relatively modest acceleration effect, useful levels of selectivity may be reached. In general, we regard a ligand-accelerated pathway to be potentially viable for asymmetric synthesis when the value of the expression in Equation 2 is greater than or equal to 20. The ligand-derived process is then responsible for 95% or more of the conversion (thus producing $\geq 95\%$ *ee* in ideal cases for which the ligand provides perfect enantioselection).

For the majority of asymmetric processes, however, no significant reactivity enhancement is observed; that is, $v_{ML} \leq v_M$. The creation of an effective chiral environment often results in extra steric crowding around the binding/catalytic site, which leads to rate *deceleration*. Useful levels of asymmetric induction then require high ligand concentrations—a situation not conducive to efficient catalysis.

Significant selectivity in organic transformations can only be achieved in reactions that proceed through highly organized transition states. In principle, the creation of a single reactive species (reactant or catalyst) is desirable to avoid participation of intermediates that react with different selectivity.[10] In many organometallic reactions this goal is accomplished by tight metal-to-ligand binding. For example, in the most widely studied asymmetric reaction, the metal-catalyzed hydrogenation of olefins, bidentate phosphane ligands possessing high binding constants for the transition metal complexes provide the asymmetric bias.[8–11] Such ligands do not dissociate under the reaction conditions, which ensures the structural integrity of the asymmetric environment during the catalysis.



In reactions with early transition metals, however, a variety of metal complexes often exist in solution.[12] These molecular assemblies form spontaneously, and the composition of the mixtures depends only on thermodynamic factors. Dynamic ligand exchange processes result in complex solution equilibria. Unraveling of the mechanism of the AE has revealed that even though the coordination chemistry of early transition metal complexes is capricious, an appropriate conjunction of metal, ligand, and correct stoichiometry may, even in such complex systems, lead to the discovery of new catalysts for efficient asymmetric reactions.[13] The goal of channeling the catalysis

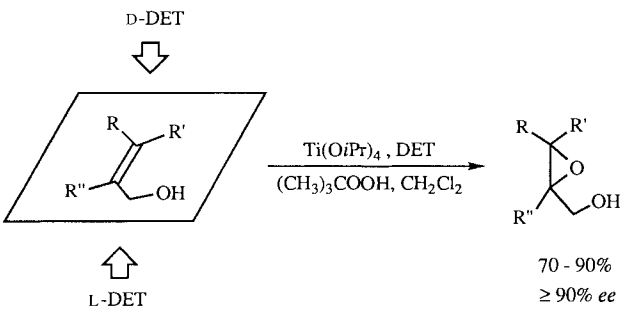
C. Bolm

K. B. Sharpless

David J. Berrisford studied for his PhD (1990) at the University of Sheffield (UK) under the supervision of Dr. J. F. Stoddart, working on chiral lithium amides. He then took up a SERC–NATO Postdoctoral Fellowship with Prof. K. B. Sharpless, then at Massachusetts Institute of Technology, Boston (USA). After returning to the UK, he joined the research group of Dr. I. Paterson in Cambridge (1992–1993). In January 1994 he was appointed lecturer in Chemistry at the Institute of Science and Technology of the University of Manchester and continues research into asymmetric catalysis with metals (conjugate addition, chiral Lewis acids) and bifunctional organic systems.

Carsten Bolm, born in 1960, studied chemistry in Braunschweig (Germany) and at the University of Wisconsin, Madison (USA). He completed his doctorate with Prof. M. T. Reetz in Marburg (Germany) on chiral catalysts for enantioselective C–C coupling. After a postdoctoral stay with Prof. K. B. Sharpless at the Massachusetts Institute of Technology, Boston (USA), he worked with Prof. B. Giese in Basel (Switzerland), obtaining his habilitation on enantioselective catalysis with chiral ligand–metal complexes. Since 1993 he has been Professor of Organic Chemistry at the University of Marburg (Germany). His awards include the Heinz-Maier-Leibnitz prize, the ADUC-Jahrespreis for habilitands, and the annual prize for Chemistry of the Akademie der Wissenschaften zu Göttingen.

K. Barry Sharpless, born in 1941, obtained his doctorate at Stanford University (USA) with Prof. E. E. Tamelen. After postdoctoral years at Stanford with Prof. J. P. Collman and at Harvard University with Prof. K. Bloch, he joined the faculty at the Massachusetts Institute of Technology, Boston (USA). In 1990 he moved to the Scripps Research Institute, La Jolla, CA (USA). Finding new metal-catalyzed transformations of use in organic synthesis is the main goal of his research.

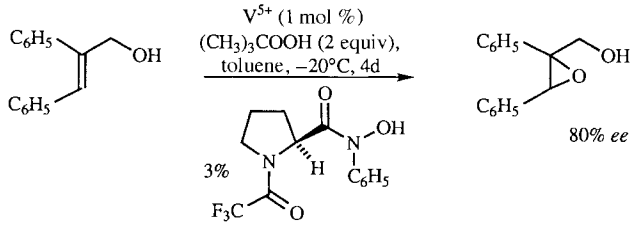


through one particular complex is usually achieved by an overwhelming *kinetic activity* favoring that one complex over the many other complexes which assemble in solution.[14] *For ligand-accelerated processes with early transition metal complexes, this in situ selection* of a highly reactive (and selective) metallic complex from a variety of thermodynamically dictated assemblies *is a crucial requirement.*

Our understanding of LAC phenomena has required detailed mechanistic studies. In the following paragraphs significant results will be presented, focusing in particular on ligand-acceleration effects in early and late transition metal-catalyzed asymmetric reactions.

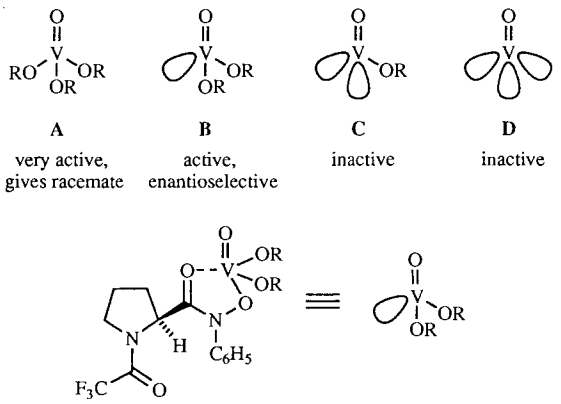
3. Ligand-Acceleration in Early Transition Metal Catalysis

3.1 Asymmetric Oxidations



The discovery of titanium-catalyzed asymmetric epoxidation was, in hindsight, dependent on ligand acceleration. A remarkable consequence of the coordination chemistry[12, 15] of early transition metals is the extreme sensitivity of epoxidation catalysts to varying combinations of ligand and metal. The unsuccessful experiments prior to the discovery of the titanium/tartrate AE[3, 16] (Scheme 2) did not foresee, or allow for, either the complexity surrounding the coordination chemistry of early transition metals or the phenomenon of LAC.

Scheme 2. Catalytic asymmetric epoxidation (AE) of allylic alcohols with D-(−)- and L-(+)-diethyltartrate (D- and L-DET).



Of the twenty-five metals that were eventually found to catalyze the epoxidation of allylic alcohols by *tert*-butylhydroperoxide (TBHP), catalysis by all but one is either stopped or strongly inhibited by adding tartrate.[17] With tartrate esters as ligands, vanadium and molybdenum alkoxides[1d, 18, 19] are the runner-up catalysts, but they fall far behind titanium alkoxides in both rate and enantioselectivity.

To set the stage for discussing LAC reactions, it is instructive to begin with the catalytic asymmetric epoxidations effected by chiral vanadium hydroxamate complexes reported in 1977[1d, 18, 19] (Scheme 3). The significant deactivation of the catalyst upon binding of the chiral ligand to the metal (that is, ligand deceleration), along with the occurrence of dynamic ligand exchange processes, made it impossible to develop useful catalysts in this system.

Scheme 3. Asymmetric epoxidation with a chiral hydroxamatovanadium catalyst.

Whereas the vanadium-catalyzed reaction in the absence of the hydroxamic acid ligand is over in less than one day, the enantioselective reaction under the optimized conditions requires four days. As shown in Scheme 4, progressive replacement of the three alkoxide groups (-OR in **A**) by the chiral bidentate ligand first reduces and then destroys the activity of the complexes so produced. Exchange of more than one alkoxide group leads to inactive complexes, because the mechanism for these metal-catalyzed epoxidations of allylic alcohols requires that at least two such groups be present and in adjacent positions.[2]

Scheme 4. Activity of vanadium alkoxide complexes in epoxidations.

Ligand exchange in vanadium(v) alkoxides is rapid.[12] Even supposing that complex **B** (Scheme 4) represents the major species in solution, it is still in equilibrium with complexes **A** and **C**. While **C** is inactive, racemate-producing complex **A** is a more active species than **B**. To avoid the racemic pathway (with complex **A**), one must maintain all the vanadium in the inactive forms (complexes **C** and **D**) and depend on the occasional disproportionation of **C** into **B** and **D** to generate some of the desired enantioselective catalyst (**B**). Hence, an excess of hydroxamic acid is necessary. The cost of completely suppressing the presence of catalyst **A** is to have essentially all the vanadium bound within the inactive complexes. Consequently, with rising ligand concentration the enantiomeric excess increases to a plateau, whereas the reaction rate decreases steadily (Fig. 1).

In the vanadium case, dynamic ligand exchange generates a mixture of vanadium–ligand species in which only two complexes are significantly active. In general, however, all complexes formed in solution have to be considered as potential catalysts, even though they may only exist in minor quantities. Given this fact, it is clear that LAC offers an appealing, and perhaps a

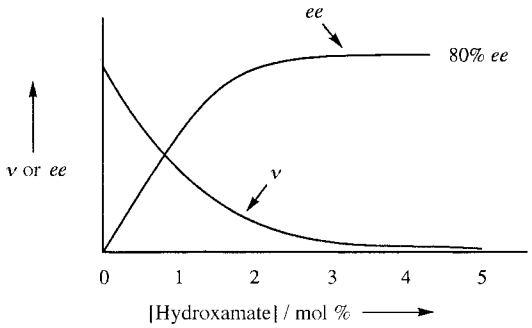


Fig. 1. Asymmetric epoxidation with chiral vanadium hydroxamate catalysts: the dependence of the rate v and enantioselectivity *ee* [%] on ligand concentration. Mol% of ligand corresponds to number of equivalents, since 1 mol% of vanadium catalyst was used.

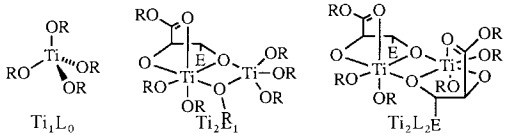
unique, means for simultaneously achieving both high rates and enantioselectivities.



In the asymmetric epoxidation catalyzed by titanium complexes, the ability of titanium(IV) alkoxides to exchange ligands rapidly makes the reaction mixture difficult to characterize. Exchange of bound monoalkoxide ligands (including allylic alkoxide, "spectator" alkoxides such as isopropoxide, epoxy alkoxide, and alkylhydroperoxide) between metals via oligomeric intermediates and with free alcohols in solution is rapid in most cases. Therefore, a mixture of complexes involving various alkoxides is expected to be present, subject only to thermodynamic factors. In equimolar mixtures of titanium tetraalkoxides and dialkyltartrates, more than one complex may be present, and individual oligomeric complexes may have nonequivalent amounts of metal and tartrate ligand (Table 1). Many of these are potential epoxidation catalysts, each of which would be expected to operate with a different profile with respect to rate, enantioselectivity, and facial selectivity.

Table 1. Titanium/tartrate species in solution (Ti = titanium, L = tartrate; species are in boldface if there is evidence for their existence from either NMR spectroscopy, mass spectrometry, or X-ray diffraction).

	L_0	L_1	L_2	L_3	L_4	$L_5 \rightarrow L_n$

Studies on the solution-phase structures of titanium/tartrate mixtures indicate that one major species of 1:1 stoichiometry is present in the reaction mixture along with at least two minor components.[2] Kinetic experiments using different ratios of $[Ti(OiPr)_4]$ to (+)-diisopropyltartrate [(+)-DIPT] revealed that the major species (a dimeric complex) is the catalyst that dominates the epoxidation activity. One minor component identified as a 2:1 Ti:tartrate species, as well as other oligomeric species with more tartrate ligands than titanium atoms, proved to be sluggish epoxidation catalysts. Thus, a comparison of the epoxidation rates of different titanium alkoxides (Table 2)

Table 2. Estimated fractions of the three main epoxidation catalysts present in a 1:1 mixture of $[Ti(OiPr)_4]$ and DIPT (R = *i*Pr, E = CO_2iPr), their approximate relative epoxidation rates, and the enantioselectivity of the epoxidation of (*E*)-2-hexen-1-ol in CH_2Cl_2.

	Ti_1L_0	Ti_2L_1	Ti_2L_2E
fraction in solution[%]	ca. 10	ca. 10	ca. 80
relative epoxidation rate	1.4	1.0	3.6
enantioselectivity	none	low	high

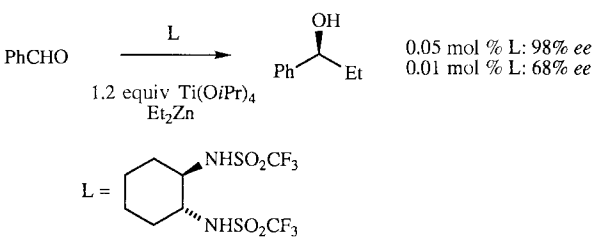
showed that the reaction rate with a mixture of $[Ti(OiPr)_4]$ and 50 mol% tartrate (forming the $[Ti_2(DIPT)(OiPr)_6]$ complex as the major species) was significantly *lower* than that of free $[Ti(OiPr)_4]$ alone—an example of ligand deceleration. In contrast, substantial *rate acceleration* was observed for the 1:1 $[Ti(OiPr)_4]$:tartrate ratio known to favor formation of the most active dimeric complex, $[Ti(DIPT)(OiPr)_2]_2$.

The kinetic data presented in Table 2 only represent the lower limits for the rate acceleration, since the rate laws for epoxidation of the competing species are different. Taking into account the number of exchangeable ligand sites per metal center, the $[Ti_2L_2]$ complex is approximately ten times more active than $[Ti(OiPr)_4]$.[2b] In addition, the standard AE recipe calls for a 20% excess of tartrate (that is, Ti:L = 1:1.2) which shifts all the equilibria involving the complexes in Table 1, with the consequence that the unwanted epoxidation catalysts $[TiL_0]$ and $[Ti_2L_1]$ are elimininated.

The use of a 2:1 ratio of $[Ti(OR)_4]$ to tartrate under otherwise standard stoichiometric epoxidation conditions results in epoxidation of the "predicted" olefinic face in reduced enantiomeric excess. For example, a 2:1 ratio of $[Ti(OiPr)_4]$ to (*R*,*R*)-diethyltartrate yields the (2*S*)-epoxy alcohol of (*E*)-α-phenylcinnamyl alcohol in 80% *ee*, compared to more than 98% *ee* for a 1.0:1.2 ratio of reagents.[2a] We have also found that the addition of electron-withdrawing monodentate additives (such as *p*-nitrophenol or hexafluoroisopropanol) to this 2:1 Ti:tartrate system results in a reversal of enantioselectivity in epoxidation of allylic alcohols; for example, in the presence of *p*-nitrophenol, (*E*)-α-phenylcinnamyl alcohol gives the (2*R*)-epoxy alcohol in 80–85% *ee*. Thus, the potential exists for many manifolds of reactivity in the titanium/tartrate system.

We have since found, in experiments that involved pairing approximately 50 tartrate analogues with titanium and other neighboring transition metal alkoxide epoxidation catalysts,[17] that tartrate and titanium are perfectly matched. Slight deviations in ligand structure and/or a change in the metal catalyst severely reduce the rate and/or enantioselectivity.[3] Ligand deceleration of catalysis seems to be the dominant phenomenon. Fortunately, in the titanium/tartrate-catalyzed epoxidation of allylic alcohols the major species present in solution is not only the most reactive but probably also the most enantioselective.

Titanium/tartrate mixtures different from 1:1 stoichiometry have also been found to mediate other oxidation reactions. For example, catalysts for the chlorohydroxylation of allylic alcohols[20] and the kinetic resolution of β-amino alcohols[21] have



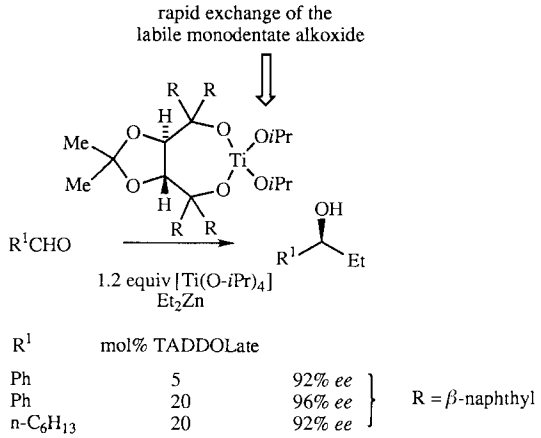
been developed that utilize a 2:1 Ti:tartrate formulation. The former reaction provides chlorohydrin derivatives by opening of the intermediate epoxides with enantiofacial selection opposite to that of the "parent" AE system.

The in situ selfselection of a highly reactive and enantioselective catalyst from a variety of titanium-containing species is also important in sulfide oxidations. Kagan et al. discovered a water-modified titanium reagent consisting of [Ti(O*i*Pr)$_4$], diethyltartrate (DET), and water in a 1:2:1 ratio.[22] With TBHP as oxidant, optically active sulfoxides with high enantiomeric excesses were obtained from sulfides by asymmetric oxidation. The titanium-mediated pathway is almost 200 times faster than the uncatalyzed oxidation with TBHP. Use of cumene hydroperoxide allowed the development of a catalytic process.[23] Catalyst loading can be reduced to 20 mol% while retaining good enantioselectivity. In the absence of water a larger excess of DET with respect to [Ti(O*i*Pr)$_4$] has a beneficial effect on enantioselectivity.[24] Uemura et al. studied a similar sulfide oxidation system prepared from [Ti(O*i*Pr)$_4$] and binaphthol (BINOL).[25] Again, added water is essential for high enantioselectivity. With 2.5 mol% of the titanium complex, aqueous TBHP as oxidant, and an excess of water, about 50% *ee* was achieved in the oxidation of aryl methyl sulfides to the corresponding sulfoxides. Titanium-catalyzed kinetic resolution following the asymmetric sulfide oxidation provides chiral sulfoxides with over 90% enantiomeric excess.

3.2 Asymmetric Nucleophilic Additions

The significant effort devoted over the years to achieving asymmetric nucleophilic additions to carbonyls has yielded some spectacular successes.[26] Ligand acceleration also plays an important role in these reactions. Again titanium chemistry provides excellent examples.[27–29]

Yoshioka, Ohno et al. have demonstrated the utility of Ti-mediated organozinc additions to aldehydes (Scheme 5).[28] Here one sees an extraordinary effect of a chelating, and relative to the other ligands present within the mixture, highly electron-withdrawing ligand coordinated to the titanium. In favorable cases, very small quantities of the chiral ligand still afford high *ee*'s (Scheme 5). For example, the alkyl transfer from diethylzinc to benzaldehyde is effected by 1.2 equivalents of [Ti(O*i*Pr)$_4$] and 0.05 mol% of the chiral ligand (Ti:L = 2400:1) to give the addition product in 98% *ee*. Reducing the catalyst loading still further (0.01 mol%; Ti:L = 12000:1) has a significant effect on the *ee* which, for benzaldehyde, decreases to 68%.[28] However, even this case is remarkable in that a preequilibrium Ti:L ratio

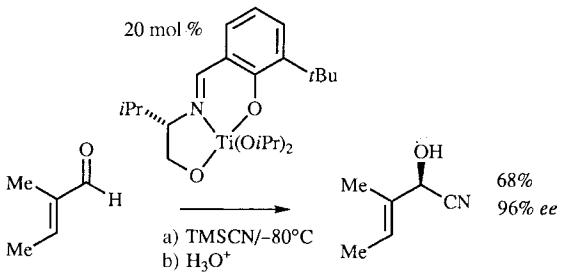


Scheme 5. Titanium-catalyzed asymmetric addition of dialkylzinc compounds to aldehydes.

of 12000 still provides two out of every three product molecules from the asymmetric pathway! This reaction dramatically illustrates the virtues of ligand-accelerated catalysis; a very practical process results when only a trace of the chiral ligand is used.

A significant recent extension of this chemistry is the observation that a variety of functionalized organometallics[30] may also be employed to provide access to a broad range of chiral synthons.[31]

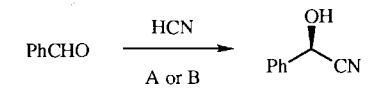
Ligand acceleration in titanium-catalyzed processes is not limited to the straightforward (but valuable!) effects of Lewis acidity. The α,α,α′,α′-tetraaryl-1,3-dioxolane-4,5-dimethanol (TADDOL) ligands[26, 32] pioneered by Seebach[29] form a class of titanium complexes (Ti–TADDOLates) that catalyze asymmetric addition of organozincs to aldehydes (Scheme 6). Comprehensive studies indicate that the highly hindered TADDOLate complexes are more active than [Ti(O*i*Pr)$_4$]. Such activity is necessary as [Ti(O*i*Pr)$_4$] is present in excess (greater than one equivalent). The steric hindrance of the chiral complex ensures that oligomerization of the catalyst is minimized.[33] In turn, this effect allows rapid exchange of the monodentate ligands on the active, monomeric complex.[29d] The reactivity *increases* in parallel with the steric demand of the anterior part of the TADDOL ligands (R = Me < R = Ph < R = β-naphthyl; Scheme 6).[33]



Scheme 6. Ti-TADDOLate catalyzed additions [29] of organozinc compounds to aldehydes.

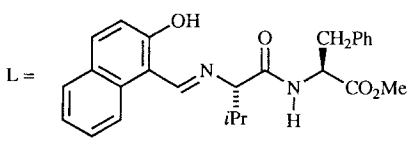
Oligomerization of [Ti(OR)$_4$] causes a marked decrease in the catalytic efficiency for the racemic pathway.[34] This large difference in activity of the chiral and achiral complexes allows efficient asymmetric induction at low catalyst loading. For example, with only 5 mol% of TADDOLate (R = β-naphthyl) the *ee* in the diethylzinc addition to benzaldehyde decreases by just 4% from the ceiling value at 20 mol% catalyst loading (Scheme 6). The ligand-accelerated asymmetric pathway is around 23 times faster than the racemic route, even though the ratio of chiral titanium complex to free [Ti(O*i*Pr)$_4$] is 1:24.

Allylation of aldehydes is also catalyzed by titanates.[35–38] Enantioselective catalysis in the presence of BINOL has recently been achieved by three independent groups. It is interesting to note that there appears to be a very specific structural requirement for the ligand. An Italian group reports[35] that [TiCl$_2$(O*i*Pr)$_2$] is less active than [TiCl$_2$(binol)], a result which



could be explained by the relative acidities[32, 39] of the ligands. An excess of $[TiCl_2(OiPr)_2]$ relative to binol decreases the enantioselectivity.[35, 36c] In a cleaner demonstration of LAC, $[Ti(OiPr)_4]$ is inactive by itself but allylation using allylstannanes is very selectively promoted by $[Ti(OR)_2(binol)]$.[36] Other ligands with comparable acidity, like tartrate esters, or higher acidity than to binol, like the bistriflamide of *trans*-1,2-diaminocyclohexane, are ineffective.[40, 41] Mikami has also utilized $[TiCl_2(binol)]$ to promote asymmetric ene reactions,[39, 42] aldol reactions,[43] and cycloadditions.[44] As with the allylation chemistry promoted by this Lewis acid, coordination of the binol ligand appears to enhance the reactivity relative to $[TiCl_2(OiPr)_2]$.[39e, 41]

Dynamic ligand exchange behavior also gives rise to profound effects in other transformations involving titanium alkoxides. Trimethylsilylcyanation and hydrocyanation of aldehydes can be catalyzed by a number of chiral titanium-based Lewis acids.[45] Recently Oguni et al. have found a very selective process (Scheme 7) using an amino alcohol derived Schiff base ligand and and $[Ti(OiPr)_4]$.[46] The catalyst is formed in situ from titanium/ligand mixtures, and the cyanation is accelerated in the presence of the chiral ligand when compared to the reference $[Ti(OiPr)_4]$ catalyzed reaction. This acceleration makes the asymmetric reaction viable at low catalyst loadings. Similar ligand-acceleration effects were noted in the asymmetric addition of TMSCN to epoxides.[47]



Scheme 7. Titanium-catalyzed trimethylsilylcyanation of aldehydes.

A related series of ligands (Scheme 8) was investigated by Inoue et. al.,[48] who found that the rate of hydrocyanation catalyzed by Ti and Zr alkoxides was enhanced by the presence of amide groups on the Schiff base–peptide ligands. This observation led to a development of an asymmetric process[49] that retains the ligand-acceleration effect, as demonstrated by the increased yield in the presence of the ligand (Scheme 8).

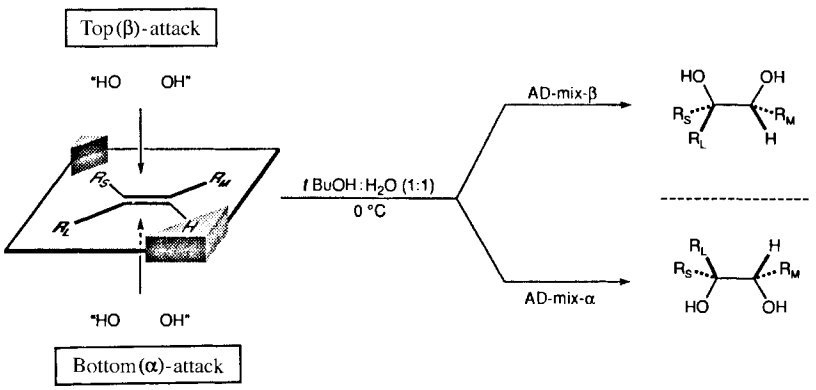
B) –20°C/10 mol % $[Ti(OiPr)_4/L]$ 94%, 78% *ee*

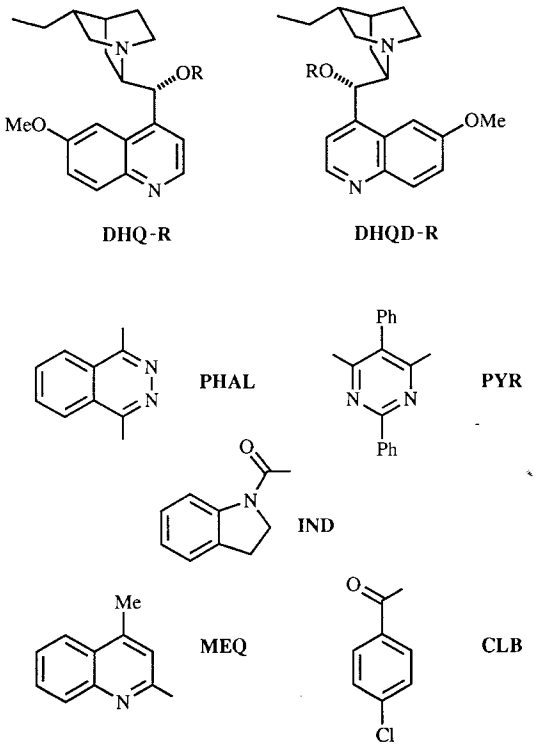
Scheme 8. Titanium-catalyzed hydrocyanation of aldehydes [49b].



In this review on ligand acceleration in nucleophilic addition reactions only a few contributions have been highlighted, and our discussion is based on published information that refers explicitly to rate enhancements conferred by the chiral ligand. Undoubtedly, ligand-acceleration effects will be revealed in many more asymmetric transformations involving early transition metals. A detailed knowledge of mechanism—often unavailable—is necessary for the understanding and rational design of new ligand-accelerated processes.

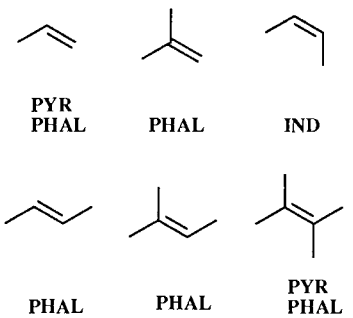
4. Ligand-Acceleration in Late Transition Metal Catalysis

4.1 Asymmetric Oxidations



The discovery[5] of the catalytic asymmetric dihydroxylation of olefins (AD) (Scheme 9) has been equally instructive regarding ligand-acceleration effects. Again, ligand acceleration is central to the efficiency and selectivity of this catalytic process.

Historically, the first documented example of a ligand-accelerated reaction emerged from the pioneering study[50] by Criegee. This investigation demonstrated that the addition of pyridine led to a marked increase in the rate of formation of cyclic osmate esters from alkenes and OsO_4. Criegee's ligand-acceleration effect was the direct inspiration for the discovery of the stoichiometric version of the AD.[4] The AD in its present form[51–53] is the result of many incremental improvements, since the catalytic version of the reaction was first uncovered.[5a] The synthetic utility[53] of the AD is now comparable with, or perhaps surpasses that of the titanium-catalyzed asymmetric epoxidation.



Scheme 9. Asymmetric catalytic dihydroxylation (AD) of olefins: the diagram allows prediction of the face selectivity (R_L, R_M, and R_S are respectively, the large, medium, and small olefinic substituents).

By judicious selection of the alkaloid ligand (Scheme 10), enantioselectivities of greater than 95% are achievable for members of five out of the six olefin classes (Scheme 11). Highly enantioselective dihydroxylation of generic *cis*-di- and tetrasubstituted olefins remains elusive, however. Modification of the cinchona alkaloid ligand has led to remarkable levels of enan-

Scheme 10. Ligand structures and their abbreviations. The ligands consist of one or two alkaloid units and a mono- or divalent group R. DHQ-R = dihydroquinine (R = H), DHQD-R = dihydroquinidine (R = H). R: PHAL = 1,4-phthalazinediyl, PYR = 2,5-diphenylpyrimidinediyl, IND = 1-indolinyl, MEQ = 4-methyl-2-quinolinyl, CLB = 4-chlorobenzoyl). See also ref. [53].

Scheme 11. Optimum ligand recommendations (only the R group is given, see Scheme 10) for the six olefin classes.

tioselectivity, undreamed of at the time of the original discovery,[4, 5] and has also helped delineate other profound effects that the ligands have on the reaction.

A feature common to both the catalytic AD and the parent stoichiometric process[4] is the facilitation of the osmylation step by the nitrogen donor ligand—the Criegee effect. Rate accelerations are always observed in the presence of the alkaloid.[55] For example, the second order rate constant k_0 for formation of the osmate ester from 2-vinylnaphthalene at 25 °C in *tert*-butanol in the *absence* of ligand is only 2.41 L mol^{-1} min^{-1}.[55a] In the presence of (DHQD)$_2$PHAL the reaction becomes extremly rapid, and a saturation rate constant (k_c) of 35600 L mol^{-1} min^{-1} has been measured for the dihydroxylation of 2-vinylnaphthalene with OsO_4.[55a] In the catalytic version the turnover-limiting step is often hydrolysis of the intermediate osmate ester, not the ligand-accelerated oxidative process. Thus, in the case of 2-vinylnaphthalene in the homogeneous acetone/water system with *N*-methylmorpholine-*N*-oxide (NMO) and (DHQD)$_2$PHAL a turnover number of 3000 min^{-1} at 25 °C was determined.[55c] This turnover number would be much higher if the hydrolysis step were not rate-limiting.

It is instructive to explore the rate accelerations induced by the ligand on the osmylation step in isolation from the effects of turnover. We have evaluated a series of ceiling rate constants (k_c) for the ligand-accelerated reaction of OsO_4 with various olefins under pseudo first-order conditions.[55a] At this high concentration of ligand all of the reaction is funneled through the ligand-mediated pathway. The ratio of rate constants $k_c:k_0$ (where k_0 is the background rate constant in the absence of the ligand) is a measure of the ligand-acceleration effect for the osmylation step (Table 3). These figures confirm that there is marked acceleration (up to 10^4) of the reaction in the presence of the ligand. The data also reveal that the rate accelerations are significantly greater with the alkaloid derivatives than with quinuclidine; that is, the rate accelerations are not directly related to the ground state binding energy between the ligand and OsO_4, a feature that we shall return to. Furthermore, the rate accelerations are dependent on the substrate; for example, 2-vinylnaphthalene reacts 19 times faster under these conditions (PHAL ligand, 25 °C, *t*BuOH) than 1-decene. However, the rates of osmylation of these two olefins are virtually identical when quinuclidine is used as the ligand (Table 3). In general, aromatic olefins are more sensitive to the structure of the ligand, but even 1-decene shows substantial rate accelerations specifically with the alkaloid ligands. These rate ratios amply demonstrate the unique effectiveness of the alkaloid ligand's structure in facilitating the osmylation step of the AD.

Table 3. Ratio of the rate constants k_c/k_0 in *t*BuOH at 25 °C for the reaction of OsO_4 with olefins [55a] in the presence of various ligands. k_c = rate as ligand concentration $\rightarrow \infty$, k_0 = rate with no ligand (see Fig. 2).

Ligand			
(DHQD)$_2$PHAL	14771	4182	770	341
DHQD-CLB	791	622	238	139
quinuclidine	61	75	55	–

Clearly, the rate enhancement [Eq. (2)] will depend on the ligand concentration and the OsO_4–ligand binding constant (K_{eq}). The K_{eq} for quinuclidine[55a, 56] is 2630 L mol^{-1} (*t*BuOH, 25 °C), a value which should be compared with that for the (DHQD)$_2$PHAL ligand of 27.7 L mol^{-1} (*t*BuOH, 25 °C). However, there is no correlation between the binding constant of a particular ligand and the observed rates of the osmylation reaction. The ratio of binding constants for quinuclidine:(DHQD)$_2$PHAL is approximately 95:1. However, the (DHQD)$_2$PHAL promoted reaction occurs between about 240 (2-vinylnaphthalene) and about 14 (1-decene) times *faster* than the reaction in the presence of quinuclidine (Table 3). Under the standard (potassium hexacyanoferrate(III)) catalytic AD conditions, all olefins exhibit rates greater than or equal to those in the absence of the ligand. This is because the ligand accelerates the addition step and does not retard the hydrolysis step.[57] For those olefins (for example, terminal olefins) producing osmate esters that are rapidly hydrolyzed, the rate acceleration in the addition step results in increased rates of catalysis. However, for

the more substituted olefins, osmate ester hydrolysis is often slow enough to partially or completely obscure the acceleration of the rate by the ligand in the addition step. As already mentioned for 2-vinylnaphthalene, even a terminal olefin can reach the turnover-limiting hydrolysis barrier if the ligand concentration is raised above the low levels used in the standard AD procedures. At higher ligand concentrations, one climbs the saturation-rate curve, and for "good" substrates like 2-vinylnaphthalene, the ligand-accelerated addition step soon outpaces even a fairly rapid hydrolysis step, since the latter is largely unaffected by the higher ligand concentration. This analysis offers a clear objective for improving the AD process: for many substrates, the catalytic efficiency will be increased if yet better ways to increase the rate of osmate ester hydrolysis can be found. One key discovery has already been made in this context:[51a] The hydrolysis of the Os^{VI}-glycolate product can be significantly accelerated by $MeSO_2NH_2$. Thus, for some substrates the reaction time is as much as 50 times shorter in the presence of this additive.

In a catalytic asymmetric process, rate and enantioselectivity are the important criteria for synthetic chemists. In the AD the enantiomeric excess approaches its maximum value[5b] at much lower alkaloid concentrations than the onset of rate saturation. In Figure 2 data for the asymmetric dihydroxylation of (*E*)-stilbene under the original conditions (DHQD-CLB/NMO) are depicted. Similar results have been obtained with the $(DHQD)_2PHAL$ ligand giving the corresponding diol with much higher enantiomeric excess.

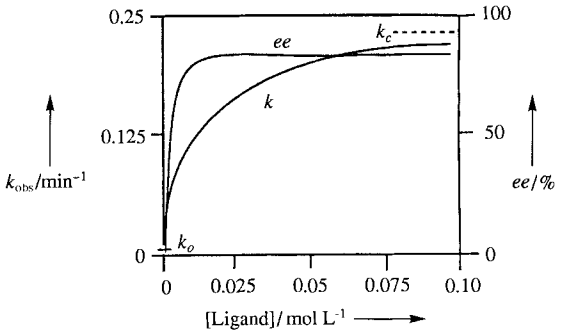


Fig. 2. Plot of concentration of the DHQD-CLB ligand against observed rate constant k_{obs} and against *ee* [%] for the AD of (*E*)-stilbene under original conditions (with NMO) [5b].

A consequence of this particular relationship between *ee*, rate, and ligand concentration is that extremely low levels of ligand can be employed while retaining optimal enantioselectivity. For terminal, disubstituted, and trisubstituted olefinic substrates, a standard AD protocol[58] calls for 0.2–0.4 mol% of osmium and 1 mol% of ligand (PHAL or PYR). Moreover, in the AD of stilbene[51a] [$(DHQD)_2PHAL$, 0 °C], the amount of ligand can be reduced 100-fold to 0.01 mol% when 0.2 mol% of osmium is used. Under these conditions there is only a slight reduction in enantioselectivity from over 99% (1 mol% ligand) to 96% (0.01 mol% ligand). This outcome translates to a ratio of rates for the enantioselective to the racemic reaction ($R_{Os\cdot L}:R_{Os}$) of 24:1 (Equation 1). Given the osmium-to-ligand ratio of 20:1 in this 0.01 mol% ligand experiment, the approximate ratio of the rate constants $k_1:k_0$ must be 480:1. Expressed in a different way, in a mixture of 10000 molecules of stilbene, 20 molecules of OsO_4 and *1 molecule* of chiral ligand, only 400 stilbene molecules are dihydroxylated by unbound osmium tetraoxide. The remaining 9600 stilbene molecules are enantioselectively oxidized through the OsO_4/ligand-assisted process.

The present ligand recommendations[51, 53] have arisen through an extended process of screening experiments. The presence of oxygenation at C-9 of the alkaloid and the nature of the substituent on the oxygen are of paramount importance in determining the enantioselectivity and the reaction rate. An extended aromatic moiety, provided by the C-9 ether substituents of the PHAL and PYR ligands, is a crucial structural feature. Other structure–activity relationships are more subtle,[59] and yet more are manifest[55a] in the binding of the ligand to the osmium. Our recent kinetic studies[55a] indicate that transition-state stabilization is an important factor in determining the rate and enantioselectivity of the AD. Given the differential rate effects between substrates (Table 3), especially the rapidity of the reaction with aromatic olefins, we believe that the contribution[60] of stabilizing, attractive[61–63] transition-state stacking interactions and solvophobic effects[64] are significant. Although of lower magnitude, the rate enhancements observed with alkyl-substituted olefins indicate that similar effects[64, 65] are active for these substrates too. The alkaloid ligands always outpace quinuclidine (Table 3), presumably because of the large aromatic moieties specific to the alkaloids. In particular, the PHAL ligand exhibits some unique effects, which we ascribe[55] to the presence of a "binding pocket", created by the phthalazine spacer and the methoxyquinoline group of the bystander alkaloid moiety. In the year following the centenary of Emil Fischer's lock-and-key analogy, it is worth noting that the AD responds to subtle variations in the substrate's shape, particularly when a ligand possessing a binding pocket is used.[53, 66]

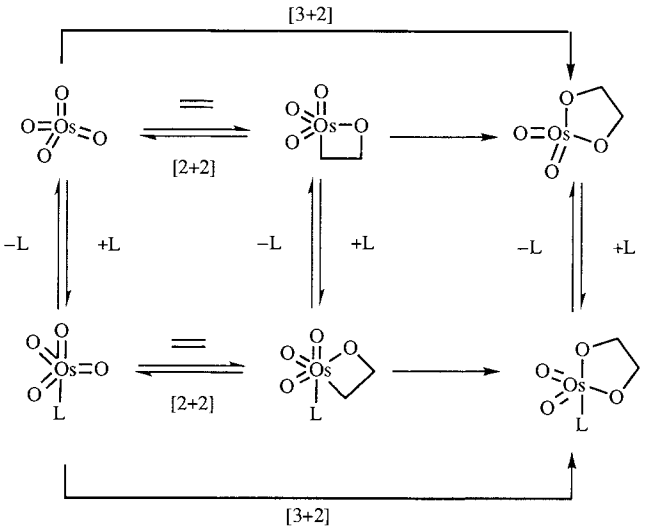
Attractive transition-state interactions should manifest themselves in both the rate and enantioselectivity of the process. Indeed, an intriguing relationship exists between the enantioselectivities and the ceiling rate constants (k_c) for the osmylation. The measurements of k_c were correlated with the *ee* values in a series of experiments conducted with a range of ligands (Table 4). In-

Table 4. Comparison of enantioselectivity and ceiling rate constants k_c (measured at 0 °C) for various olefin/ligand combinations [55].

Ligand	$C_8H_{17}CH=CH_2$		$PhCH=CH_2$	
	ee[%]	k_c[L mol^{-1} min^{-1}]	*ee*[%]	k_c[L mol^{-1} min^{-1}]
DHQD-CLB	45[a]	331	74	1089
DHQD-MEQ	65	335	87	1210
$(DHQD)_2PHAL$	84	1065	97	7320

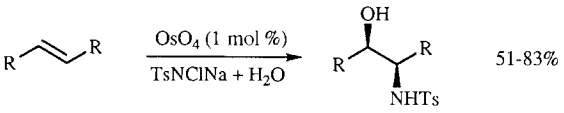
[a] The AD reaction was carried out at room temperature.

creases in k_c and the enantioselectivity in the AD of, for example, 1-decene and styrene, occur in concert. These concurrent trends provide additional support for the proposed attractive transition-state interactions.



In summary, a balance must be struck in the binding ability of the ligand. The ligand must mediate the asymmetry-inducing step but must also allow efficient turnover to occur. This is where the many bidentate chiral amine ligands recently intro-

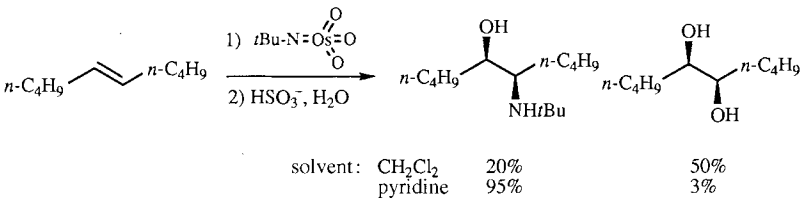
duced for asymmetric dihydroxylation fail.[54] They yield stable octahedral osmate ester complexes, and catalytic turnover is blocked. Ligand acceleration of the osmylation step by monodentate amines offers the unique opportunity for effective catalysis to be realized. By definition, ligand-accelerated reactions are less prone to the deleterious rate reductions usually encountered when architecturally complex ligands are used. In fact, in the AD the more complex ligands actually enhance the reactivity!



The origin of the acceleration effect is irrevocably linked with the remaining uncertainties about the mechanism of the osmylation step (Scheme 12). Kinetic studies[55, 67] on the AD do not prescribe whether a [3+2][68] or a [2+2][69] pathway is involved. Nonetheless, temperature effects,[70] Gable's strong evidence for an intermediate in the extrusion of olefins from rhenium glycolates,[71] and theoretical studies[55, 72] encourage us in our preference for the metallaoxetane [2+2] pathway.

Given the often near perfect enantioselection of the AD, the enforced proximity of the ligand and olefin in the [2 + 2] mechanism is a powerful argument in favor of that pathway. The significant rate accelerations documented here may be attributed to either a) the formation of an osmium tetraoxide–alkaloid complex which is more reactive[68] than unbound osmium tetraoxide, or b) the trapping of a transitory[73] metallaoxetane[74] by the alkaloid ligand and subsequent oxygen insertion into the metal–carbon bond.[75] We believe that our evidence[70] for a process with at least two enantioselectivity-determining steps (weighted differentially according to temperature) lends credence to the latter rationale.

A close relative of the dihydroxylation reaction is the vicinal oxyamination[76] of olefins (Scheme 13). It seems likely that the mechanisms, and therefore also the ligand-acceleration effects, operating in both processes are intimately linked. Oxyamination can be performed either using stoichiometric quantities of trioxo(*tert*-butylimido)osmium[77] or catalytic amounts of osmium



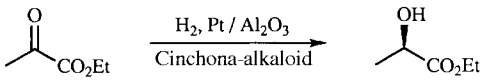
Scheme 12. Plausible mechanistic pathways for the AD of olefins (shown for ethylene).

Scheme 13. Catalytic oxyamination of olefins [78].

tetraoxide in the presence of Chloramine-T or argentochlorocarbamates.[78]

Investigation of the stoichiometric reactions with trioxo(*tert*-butylimido)osmium revealed[76] remarkable effects upon addition of a ligand (Scheme 14). In the absence of pyridine or quinuclidine, a major competing pathway is the formation of *cis* diols. In a noncoordinating solvent, reaction[76] of trioxo(*tert*-butylimido)osmium with (*E*)-5-decene affords a 5:2 ratio of diol:amino alcohol. When pyridine is the solvent, the ratio swings dramatically to 3:95 in favor of the amino alcohol. The ligand completely alters the reaction path, enhancing the

Scheme 14. Effect of the ligand on stoichiometric oxyamination of (*E*)-5-decene [76].



formation of amino alcohol. In addition, the overall reaction rate is increased.

Unlike the asymmetric dihydroxylation (AD), asymmetric oxyamination (AOA) is virtually unexplored,[79] but up to 92% *ee* has been achieved[80, 81] in a stoichiometric reaction of trioxo(*tert*-butylimido)osmium with stilbene in the presence of DHQD-CLB at ambient temperature. The catalytic process with an argentochlorocarbamate[80] gives a 63% *ee* with stilbene. However, turnover in these catalytic asymmetric oxyaminations is very slow, and unless it can be improved they will not be of interest in organic synthesis.

4.2 Asymmetric Hydrogenations

Ligand-accelerated processes require the in situ selection of a catalyst from many possible interconverting structures. When ligands are strongly bound to the metal, in situ selection becomes irrelevant. This is the case in catalyzed homogeneous hydrogenations[11] when bidentate phosphane ligands[8, 9] are used. They have uniformly high binding constants for the transition metal. Hence it is impossible for ligand-acceleration to be involved, and the concept of LAC is not applicable. However, a striking example of ligand-accelerated catalysis has been discovered in an important *heterogeneous* hydrogenation process.

Blaser and co-workers at Ciba-Geigy developed a remarkably effective process for the enantioselective hydrogenation of α-ketoesters (Scheme 15).[82–85] This reaction had first been described by Orito et al.[82] who investigated the use of cinchona-modified heterogeneous platinum catalysts for asymmetric reductions. Reactivity and enantioselectivity are strongly de-

Scheme 15. Heterogeneous asymmetric hydrogenation.

pendent on catalyst pretreatment and on the presence of various additives in the reaction mixture.

Catalysts modified with cinchona alkaloids were up to 100 times more active than ligand-free catalysts used as the reference.[83b] Only small amounts of cinchonidine were needed to give optimal enantioselectivity. As in the asymmetric dihydroxylation, higher alkaloid concentrations were required to obtain rate saturation (Fig. 3).

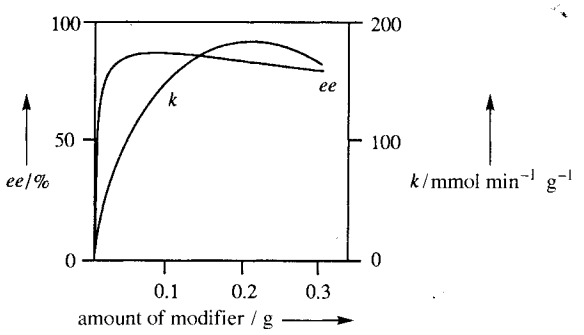


Fig. 3. Heterogeneous asymmetric hydrogenation: dependence of enantiomeric excess *ee* [%] and rate *k* [mmol min^{-1} g^{-1}] on concentration of the alkaloid modifier [g] [83b].

No correlation was found between enantioselectivity and total or metal surface area.[83b] Although the rate acceleration tends to depend on the basicity of the additive,[84] the cinchona alkaloids show a stronger effect than additives of comparable pK_a. A kinetic model describing the effect of the alkaloid modifier on *ee* and reaction rate was developed.[83a, 85] Analysis of the model predicts the linear relationship between the enantiomeric excess and the reciprocal of the rate that was indeed observed. Reversible adsorption of the alkaloid on the metal surface is thought to promote an interaction with the prochiral α-ketoesters leading to enantioselection and enhanced activity of the modified metal centers or active sites. Apparently, alkaloids do *not* block unselective catalyst sites (a negative effect) as proposed for modifiers in related heterogeneous hydrogenation catalysts containing nickel tartrate.[86] Stereoselectivity and enhanced catalytic activity may result from well-defined interactions between the platinum surface and individual cinchona molecules[85] or, as suggested by Thomas,[87] from a highly ordered, well-spaced array of modifier molecules in the sorbed layer. For higher alkaloid concentrations the observed effects were rationalized by invoking two- and three-site models.[85, 88, 89]

5. Summary and Outlook

Given the enormous variety offered by the periodic table and especially the dominance of metallic elements along with their special ability to enhance reactivity, metal-catalyzed reactions would seem to be pivotal in the development of viable synthetic strategies. The powerful phenomenon of ligand-accelerated catalysis offers great promise. No doubt serendipity will play a significant role in further discoveries, since predictions regarding catalysis are often wrong. We recall with humility the unproductive foray into the synthesis and application of tridentate chiral ligands for vanadium-catalyzed asymmetric epoxidation.[1c] This, of course, was prior to our realization that this approach is irrelevant for the reasons outlined in this article. The appeal of ligand-accelerated catalysis, albeit extremely rare and difficult to find, is the arresting efficiency it can possess. Not to be overlooked is the often unique window on fundamental aspects of mechanism that is afforded by the discovery of a ligand-accelerated variant of a reaction. We look forward to the new selective catalysts, still lying undiscovered, that all of us will be able to share.

We are especially grateful to the colleagues and friends who gave us excellent advice and help during writing of this review. We particulary thank Professors M. G. Finn (Charlottesville), R. W. Hoffmann (Marburg), E. N. Jacobsen (Cambridge), and Drs. P.-O. Norrby (Copenhagen), S. Loren (La Jolla), P. T. Ho (La Jolla), H. Kolb (Basel), and H.-U Blaser (Basel) for their suggestions, comments and helpful discussions. K.B.S. thanks the National Institutes of Health (GM-28384), the National Science Foundation (CHE-9296055), and the W. M. Keck Foundation for financial support. D.J.B. and C.B. thank SERC-NATO and the Fonds der Chemischen Industrie, respectively, for funding and fellowships.

[6] The activation of a stoichiometric reagent by a ligand is considered as "ligand acceleration". To be a *ligand-accelerated catalysis* (LAC) a catalytically active species (other than the ligand) must be present.

For a review of functionalized organozinc reagents, see g) P. Knochel, R. D. Singer, *Chem. Rev.* **1993**, *93*, 2117. Functionalized organozincs have been used in the amino alcohol catalyzed reaction: h) W. Oppolzer, R. N. Radinov, *Tetrahedron Lett.* **1991**, *32*, 5777; i) *Helv. Chim. Acta* **1992**, *75*, 170; j) *J. Am. Chem. Soc.* **1993**, *115*, 1593.
[31] The normal catalyst loadings are 8 mol% for the additions of the functionalized organozinc complexes [30a–g].
[32] a) N. Iwasawa, Y. Hayashi, H. Sakurai, K. Narasaka, *Chem. Lett.* **1989**, 1581; b) K. Narasaka, K. Hayashi, Y. Hayashi, *Tetrahedron* **1994**, *50*, 4507, and references therein.
[33] β-Naphthyl appears optimal; α-naphthyl is too hindered, and both the rate and *ee* suffer [29]. A similar effect was reported by Oguni in the enantioselective opening of *meso* epoxides by Me_3SiN_3 catalyzed by titanium/tartrate mixtures. The complex derived from di-*tert*-butyltartrate ester effected enantioselective catalysis, whereas the catalyst prepared with the diisopropyl ester was only effective under stoichiometric conditions: M. Hayashi, K. Kohmura, N. Oguni, *Synlett* **1991**, 774.
[34] Use of a more hindered alkoxide, for example $[Ti(OtBu)_4]$, in stoichiometic quantities disrupts the relative rates of exchange between chiral and achiral complexes and has a deleterious effect on *ee*. Related effects have been noted in the kinetic resolution of allylic alcohols by titanium alkoxide/tartrate mixtures: B. H. McKee, T. H. Kalantar, K. B. Sharpless, *J. Org. Chem.* **1991**, *56*, 6966.

[56] K_{eq}(quinuclidine) = 80000 L mol^{-1} (toluene): H. C. Kolb, K. B. Sharpless, The Scripps Research Institute, unpublished results. Binding constants for the alkaloids DHQ and DHQD are greater in toluene than in *t*BuOH. The stoichiometric osmylations with bidentate chiral amines [54] are generally run at low temperature in toluene.
[57] a) The effect of tertiary amine ligands on the catalytic turnover in the original AD process with NMO as the oxidant in a homogeneous acetone/water system is quite different from that seen in the new two-phase AD process with potassium hexacyanoferrate(III) as the oxidant. In the NMO system, quinuclidine strongly inhibits the catalysis at concentrations above 0.01 M [5a], and even the

alkaloid ligands DHQ and DHQD begin to show inhibition at concentrations greater than 0.5 M [5b]. These effects are probably due to "second-cycle problems" [5b, 57b], which will not be discussed here since they are absent in the now favored potassium hexacyanoferrate(III)-based AD system. b) Y. Ogino, H. Chen, H.-L. Kwong, K. B. Sharpless, *Tetrahedron Lett.* **1991**, *32*, 3965.

[58] The commercial AD mixes use 0.4 mol% OsO_4 to ensure reproducible results. With slower reacting olefins the OsO_4 loading should be increased to 1 mol%.

[59] For example, the presence of the methoxy group on the quinoline ring (the difference between the quinine and cinchonine series) imparts an approximately twofold rate increase (k_c) for 2-vinylnaphthalene [55a].

[60] For a similar earlier proposal, see B. B. Lohray, V. Bhushan, *Tetrahedron Lett.* **1992**, *33*, 5113.

[62] Stacking interactions have been invoked as stereocontrolling elements in asymmetric Diels–Alder reactions: a) J. M. Hawkins, S. Loren, *J. Am. Chem. Soc.* **1991**, *113*, 7794; b) J. M. Hawkins, S. Loren, M. Nambu, *ibid.* **1994**, *116*, 1657; c) E. J. Corey, T.-P. Loh, T. D. Roper, M. D. Azimioara, M. C. Noe, *ibid.* **1992**, *114*, 8290; d) D. A. Evans, K. T. Chapman, D. T. Hung, A. T. Kawaguchi, *Angew. Chem.* **1987**, *99*, 1197; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1184; e) J. A. Tucker, K. N. Houk, B. M. Trost, *J. Am. Chem. Soc.* **1990**, *112*, 5465. Stacking interactions have also been invoked to rationalize the regioselectivity in asymmetric hydroformylation: f) L. A. Castenguay, A. K. Rappé, C. J. Casewit, *J. Am. Chem. Soc.* **1991**, *113*, 7177.

[63] For recent examples in which attractive van der Waals interactions play an important role, see: a) T. Harada, I. Wada, J. J. Uchimura, A. Inoue, S. Tanake, A. Oku, *Tetrahedron Lett.* **1991**, *32*, 1219; b) T. Harada, A. Oku, *Synlett* **1994**, 95; c) U. Berg, I. Pettersson, *J. Org. Chem.* **1987**, *52*, 5177.

[64] For leading references on stacking interactions, see: a) D. B. Smithrud, F. Diederich, *J. Am. Chem. Soc.* **1990**, *112*, 339; b) W. L. Jorgensen, D. L. Severance, *ibid.* **1990**, *112*, 4768; c) F. Cozzi, M. Cinquini, R. Annuziata, J. S. Siegel, *ibid.* **1993**, *115*, 5330; d) C. A. Hunter, *Chem. Soc. Rev.* **1994**, *23*, 101; e) G. Liang, R. Tribolet, H. Sigel, *Inorg. Chem.* **1988**, *27*, 2877; for π-dicarbonyl interactions, see: f) J. K. Whitesell, J. N. Younathon, J. R. Hurst, M. A. Fox, *J. Org. Chem.* **1985**, *50*, 5499.

[65] The attractive interactions are also manifest in the application of the device (Scheme 9) that aids prediction of the AD face selectivity. Predictions for 1,1-disubstituted olefins can seem ambiguous because one must know which of the substituents prefers to occupy the attractive SW quadrant [53]. The order of occupancy is aryl > alkyl > Me ≈ CH_2OR: cf. K. J. Hale, S. Manaviazar, S. A. Peak, *Tetrahedron Lett.* **1994**, *35*, 425.

On the Synthesis of the FeMo Cofactor of Nitrogenase: Gene-Controlled in Nature versus Laboratory-Produced by Man

Achim Müller* and Eugen Krahn

One of the primary challenges of chemistry is the controlled synthesis of compounds with tailor-made structures and properties. Natural products serve as inspiration in this quest, ranging from biocatalysts with optimal selectivity and activity to "inorganic materials" with exceptional properties, whose generation can be described by the term biomineralization. It is of fundamental importance to comprehend the courses of events at the interface between gene expression and the subsequent processes of epigenesis that are no longer under gene control. Chemistry has been able to achieve many goals; however, in the area of controlled syntheses of highly complex, tailor-made metal clusters, there is a lack of fundamental theories and principles. This is especially true for the fascinating metal–sulfur cluster of nitrogenase, which, in this enzyme, functions as the active center for the N_2 reduction and, so far, has eluded all attempts to be synthesized in the laboratory. To understand the biosynthesis of this cluster, information from genetics *and* chemistry must be combined.

Keywords: bioinorganic chemistry · biosynthesis · iron–molybdenum cofactor · iron–sulfur cluster · nitrogenases · nitrogen fixation

The fixation of nitrogen from the air will be one of the great discoveries, which are awaiting the ingenuity of chemists.
Sir William Crookes, 1898[**]

1. Introduction

In spite of innumerable attempts, it has not yet been possible to synthesize the iron–molybdenum cofactor (FeMo cofactor) that is central to the bacterial fixation of nitrogen by the nitrogenase enzyme system. This synthesis would be a groundbreaking contribution to the efforts made to adapt the "natural Haber–Bosch process", that is, the action of biological nitrogen fixation, which, together with photosynthesis, is the most important natural process for food production. The desire to gain a deeper understanding of this fundamental metabolic process stems from the dream to improve the extremely energy-intensive industrial procedure. In contrast, however, it is virtually impossible to prevent the formation of chemically similar clusters, particularly those with an $[Fe_4S_4]^{2+}$ core, once the basic constituents are present. What is the reason for this apparent contradiction? Exciting results from genetic investigations, which, in chemical circles, have not received as much attention as those obtained from crystallographic studies, have begun to yield an emerging picture of how nature proceeds with the synthesis of this cluster. The analysis of the results of genetic studies, however, could be of prime importance for the successful synthesis "in the test-tube", as they yield hints regarding the special conditions employed for the stepwise synthesis: the in vivo synthesis of the FeMo cofactor of the nitrogenase enzyme system is so far the only biosynthesis of an inorganic cluster known to proceed by enzymatically catalyzed intermediate steps.

The numerous attempts to synthesize chemically the FeMo cofactor were hampered for a long time by the fact that only the approximate composition, and not the exact structure of this cluster was known.[1] In this context, the limits of current chemical understanding became apparent, as it proved to be impossible to determine the structure of this cluster, which is relatively small from the standpoint of a chemist, despite the application of all modern chemical knowledge, especially in combination with the availability of virtually all imaginable spectroscopic data.

Then a report came that spread like wildfire among scientists—and even appeared in the daily newspapers: based on X-ray crystal structure analyses, it was possible to successfully model the spatial structure of both components of nitrogenase, including the almost legendary cluster centers. This structural analysis also made known the exact position and the protein environment of the clusters in the MoFe protein (Fig. 1).[2] The so-called Kim model of the FeMo cofactor showed—much to the disappointment of chemists—that none of the previous models exhibited the determined structure; however, a fascinating chemistry was developed, stimulated by the endeavor to obtain the FeMo cofactor synthetically (see below). The struc-

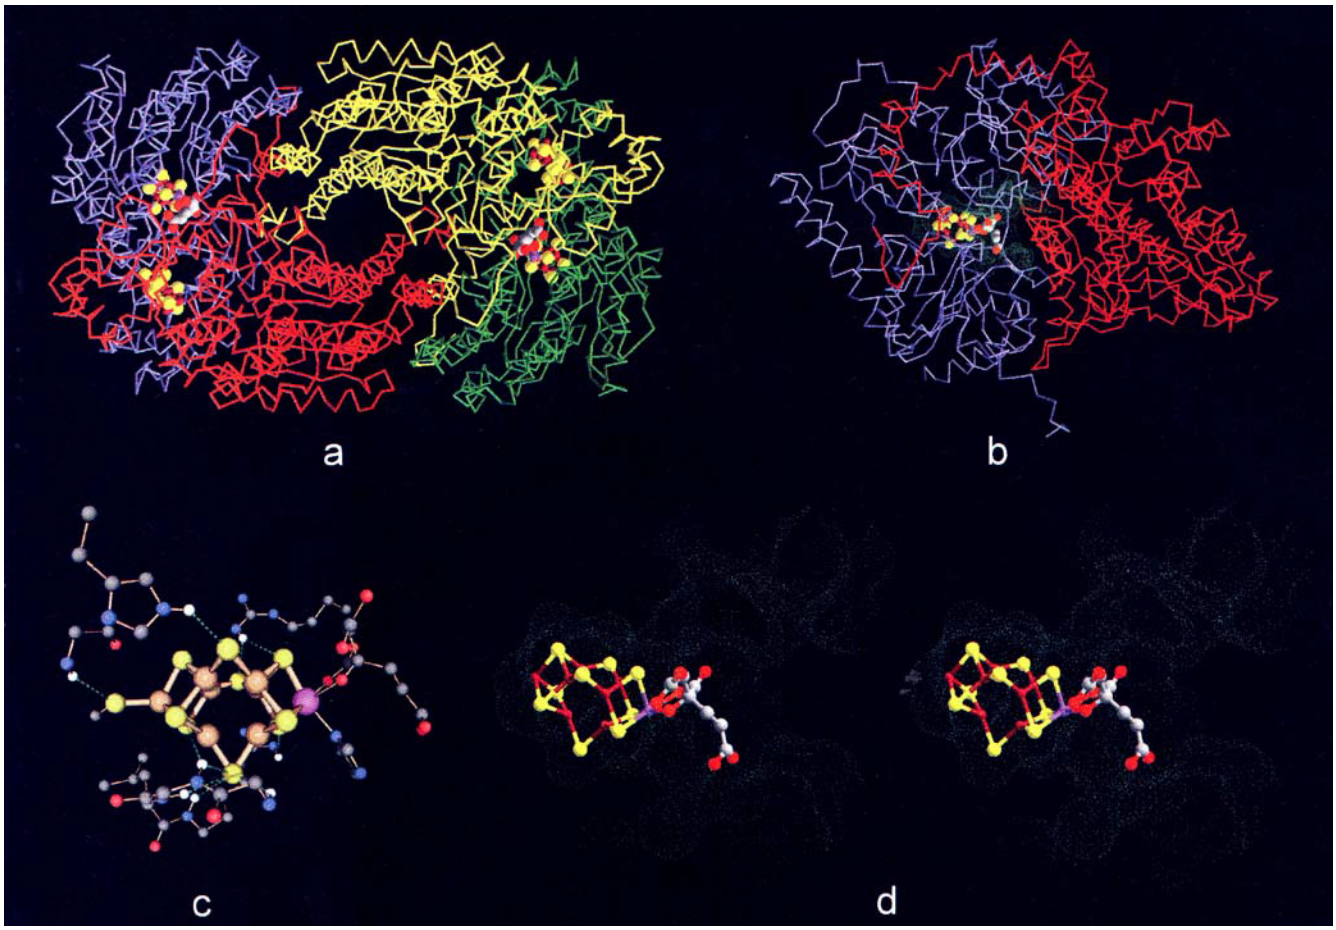

Fig. 1. a) Protein chains (only α-carbon atoms are shown) and cluster centers of the MoFe protein (α-subunits: blue and green; β-subunits: yellow and red). b) Protein chains (only α-carbon atoms) of one α and one β-subunit, including the FeMo cofactor and its protein environment within the α-subunit (represented as a segment of the water-accessible surface (see text) of the α-subunit). c) Structure of the FeMo cofactor including amino acid side chains from its protein environment, which are coordinatively bound or form hydrogen bonds to it (hydrogen bonds: green, dashed lines; Fe: brown, S: yellow, Mo: violet, C: gray, O: red, N: blue). d) Stereoscopic view of the FeMo cofactor and the water-accessible surface of its protein environment.

ture of the cofactor (Fig. 1c, d) formally consists of an Fe_4S_3 and a $MoFe_3S_3$ cubane fragment, which are linked by three (inorganic) sulfide ligands. The composition $MoFe_7S_9$/homocitrate and its unusual structure—particularly the six Fe centers that are in a nearly trigonal environment and, hence, are coordinatively unsaturated—make the FeMo cofactor the largest and most complex metal cluster in the biosphere that is known to exist in enzymes.

In spite of the above-mentioned detailed structural information, many essential features of the nitrogenase enzyme system are

Achim Müller, born in 1938 in Detmold, studied chemistry and physics at the University of Göttingen and received his Ph. D. (1965) and his Habilitation (1967) there under the supervision of O. Glemser. He is now Professor of Inorganic Chemistry at the University of Bielefeld. He is a member of several scientific academies, including the Deutsche Akademie für Naturforscher (Leopoldina) and the Polish Academy of Sciences. His research interests range from problems of molecular physics (theory of mass influence on molecular constants), vibrational spectroscopy (matrix isolation spectroscopy, band contour analysis, resonance Raman effect, metal isotope effects), bioinorganic chemistry (model compounds and biological nitrogen fixation by free-living organisms), and molecular metal chalcogenide complexes and clusters (synthesis, geochemical relevance, electronic and molecular structure, topological and supermolecular aspects, and use in heterogeneous catalysis) to aspects of natural philosophy. He has published, besides numerous original papers, more than 30 reviews in these areas and is coeditor of eight books.

not yet understood.[8] Only very little is known about the mechanism of the catalysis. Even the question of the binding sites of the various substrates remains unanswered, as well as the one concerning the structure of reaction intermediates. In addition to the mechanistic aspects, the following are of interest:

- How does the biosynthesis of the cluster occur, that is, where are the elements that constitute the FeMo cofactor (Fe^{n+}, Mo^{n+}, S^{2-}, and homocitrate) introduced into the biosynthetic pathway? Are there any preassembled units involved and which intermediates occur?
- How does nature stabilize the structure of the FeMo cofactor—especially with regard to the six coordinatively unsaturated Fe centers—and the possible intermediates in the biosynthesis? Is an in vitro synthesis fundamentally impossible or has it only not yet been achieved? Which new concepts are required to mimic nature in this context?

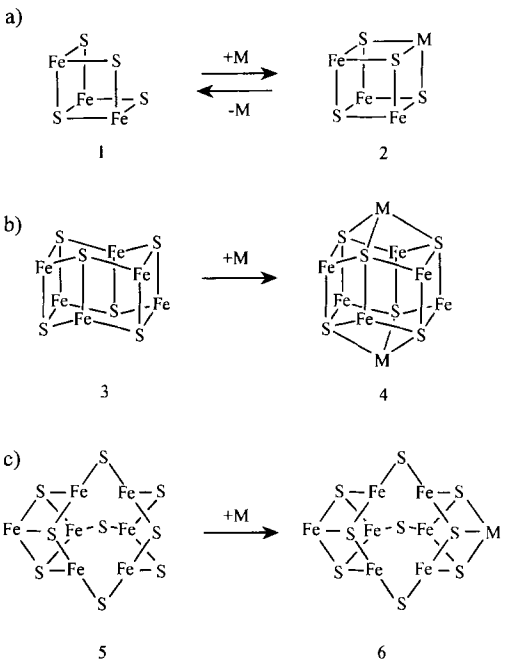
The answers to these questions are also of a more general relevance, as they will certainly be able to provide contributions towards the understanding of the in vivo formation of metal clusters that occur in the active center of other enzymes. There are very few details known about the biosynthesis of a number of different binary FeS clusters with the compositions $\{Fe_2S_2\}$, $\{Fe_3S_4\}$, $\{Fe_4S_4\}$,[9] and $\{Fe_6S_6\}$.[10, 11] The same is true for the Mn_xO_y cluster of photosystem II.[12]

2. Why Is the Cluster Synthesis of the FeMo Cofactor In Vitro so Difficult?

The one-pot synthesis of MoFeS clusters, especially those containing only one Mo atom is a non-trivial problem. The difficulties most encountered are as follows:

- maintaining the desired oxidation states—in particular for the molybdenum centers—in the presence of redox-active ligands such as S^{2-};[13]
- controlling the configuration, for example during the formation of a *fac*-environment around the Mo center;
- avoiding the formation of polynuclear Mo species, a tendency favored by the inclination of the S^{2-} and O^{2-} ligands to form bridges and of molybdenum in low oxidation states to form metal–metal bonds;
- generating specific low coordination numbers at the metal and sulfur centers;
- bypassing the formation of cubane-type systems if non-cubane structures—like the FeMo cofactor—are desired.

The most stable FeS clusters are those of the type Fe_4S_4. Bridged cubane systems, are also accessible (compare for example the synthesis of $[(Fe_4S_4Cl_3)_2S]^{4-}$[14]). The first reported MoFeS species that were synthesized as model compounds for the active center of the MoFe protein were prepared by "strict self-assembly" (SSA), given the appropriate reaction conditions. These compounds are mostly heteroatom analogues or derivatives of the more readily accessible binary FeS clusters mentioned above. The resulting compounds are, for instance, of the double-cubane type $[(MoFe_3S_4)_2(SR)_3]$.[15] It took several years of intensive work from the first synthesis of a double-cubane type species to the successful preparation of the corresponding monocubane type species—containing only one $MoFe_3S_4$ center—by solvent-induced cleavage of a double-cubane system.[16] This long delay stemmed primarily from the difficulties mentioned above, particularly from the strong tendency of the Mo centers to form metal–metal bonds. In addition to the Fe_4S_4 core, Fe_2S_2, Fe_3S_4, and (probably) Fe_6S_6 centers, all of which are known from iron–sulfur chemistry, can be found within metalloenzymes. Due to the comparatively lower formation tendency of these clusters, their syntheses require that specific conditions are maintained.[17] A reaction type that seems to be important for considerations on the course of the FeMo cofactor biosynthesis is the interconversion (Fig. 2a) of the cluster types Fe_4S_4, Fe_3S_4, and MFe_3S_4, which has been successfully performed in vitro in metalloproteins and with model compounds.[18] During capping-type reactions, additional metal centers are coordinated to or removed from suitably oriented metal–sulfur fragments. The $Fe_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3$ fragment **1** (Fig. 2a) acts hereby formally as tridentate η^3-ligand.[19] Compounds of the prismane type, that is, those with a central $[Fe_6S_6]^{n+}$ unit (**3** Fig. 2b; compare also the analogous heteroprismane cluster anion $[MoFe_5S_6L_6]^{n-}$)[14] presumably also represent an intermediate during the reaction leading to compounds with the unit $[Fe_8S_6]^{4+}$ (**4**, Fig. 2b; M = Fe).[20] During this reaction, capping of the Fe_3S_3 faces occurs, which act—in analogy to the Fe_3S_4 fragment—as η^3-ligands, but with a $(\mu_3\text{-}S)_3$ arrangement. The capping of an $L_6Fe_6S_6$ structure with a $MoL_3(solv)_3$ fragment yields clusters of the type $[(MoL_3)_mFe_6S_6L_6']^{n-}$ (m = 1, 2) (**4**, Fig. 2b; M = Mo).[14]



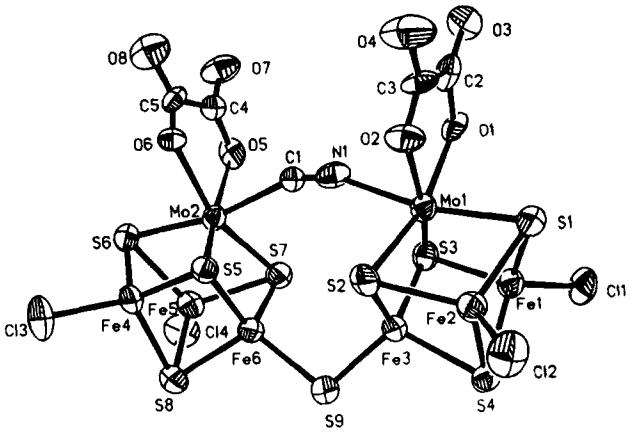


Fig. 2. Schematic representation of the transformation of cluster centers by complexation of metal ions by sulfur-containing cluster fragments. a) An Fe_3S_4 unit (**1**) binds a metal cation M using the three μ_2-sulfur centers, thereby forming a MFe_3S_4 cluster core (**2**). b) Capping of the Fe_6S_6 cluster **3**. c) A possible terminal reaction step within the nifEN protein during the biosynthesis of the FeMo cofactor: capping the Fe_7S_9 fragment **5** analogous to a) leads to the FeMo cofactor cluster core structure MFe_7S_9 **6** (M = Mo). A preceding formation of **5** from **6** (M = Fe) is also possible, as the cofactor pocket of the MoFe protein—and, therefore presumably in the nifEN protein as well—leaves only one of the two "ends" of the cluster unprotected (see Fig. 1b, d).

The driving force for the capping reaction can be found in the tendency to increase the coordination number of the sulfide ligands, corresponding to the sequence μ_2-S to μ_3-S or μ_3-S to μ_4-S, respectively. This tendency increases significantly with a decreasing oxidation state of the cluster, expressed, for instance, by the ratio of Fe^{II} to Fe^{III} centers which can be seen from the following series of core cluster units:[21]

$$[Fe_2^{III}(\mu_2\text{-}S)_2]^{2+} / [Fe_2^{II}Fe_2^{III}(\mu_3\text{-}S)_4]^{2+} / [Fe_8^{II}(\mu_4\text{-}S)_6]^{4+}$$

This indicates that the μ_2-sulfur centers of the FeMo cofactor are more readily formed in a relatively highly oxidized cluster intermediate.

Meanwhile, compounds with bridged, cubane-type $MoFe_3S_4$ units without significant Mo–Mo interactions are accessible by multistep syntheses. The cluster anion $[\{(MoFe_3S_4Cl_2)(C_2O_4)\}_2(\mu_2\text{-}S)(\mu_2\text{-}CN)]^{5-}$ (Fig. 3 top) is a relevant example. The synthesis of analogous compounds containing one $MoFe_3S_4$ and one Fe_4S_4 unit, has, however, so far not been achieved.

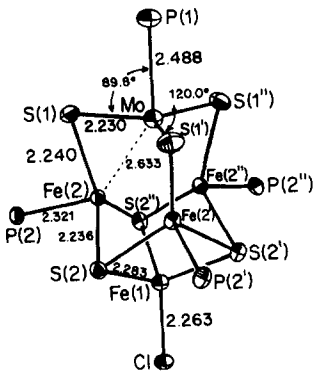

Fig. 3. Top: ORTEP representation of the cluster anion $[\{(MoFe_3S_4Cl_2)(C_2O_4)\}_2(\mu_2\text{-}S)(\mu_2\text{-}CN)]^{5}$ (see K. D. Demadis, D. Coucouvanis, *Inorg. Chem.* **1995**, *34*, 436–448). Bottom: Structure of the cluster $[MoFe_4S_6(PEt_3)_4Cl]$ [22a]. The distances are given in Å; the Mo···Fe(1) distance is 4.343 Å.

A recently published compound, namely the cluster $[MoFe_4S_6(PEt_3)_4Cl]$ (Fig. 3 bottom),[22] obtained by strict self-assembly in a nonpolar solvent, is notable in this context, as the $Fe_4(\mu_3\text{-}S)_3(\mu_2\text{-}S)_3$ fragment in this molecule represents the largest partial structure of the Kim model obtained so far. The Fe_4S_3 unit, which has an inverted Fe_3S_4 core structure, has until now only been known to exist in the anion of the black Roussin salt and some of its derivatives.[23] The $(\mu_2\text{-}S)_3$ arrangement in the $MoFe_4S_6$ cluster is, however, probably determined and stabilized by a $(PEt_3)MoS_3$ fragment, as the side product is an Fe_6S_6-type prismane cluster instead of a compound with an $(Fe_4S_3)(\mu_2\text{-}S)_3(Fe_4S_3)$ core (**6**, Fig. 2c; M = Fe). In contrast to the trigonal coordinated Fe centers in the FeMo cofactor, the four Fe atoms of this compound are coordinatively saturated by the PEt_3 groups acting as fourth ligands. The results summarized above give an outline of the closest approximations to nature achieved by inorganic model systems so far.

In view of these results, a key to the biosynthesis of the FeMo cofactor must lie in the linking of preorganized fragments according to the principles laid out below, as the FeMo cofactor is obviously not formed by a single strict self-assembly process. Therefore, a chemical synthesis should apply a basic principle of nature, namely to create small building blocks that contain within them the relevant information for the (later) formation of the complex structure.[24] For instance, an $[OMoS_3]^{2-}$ unit—as a fragment of a distorted cube—in the presence of soft metal centers leads to the formation of cubane structures, such as $[(CuCl)_3(OMoS_3)]^{2-}$ (Fig. 4).[25] The anion $[OMoS_3]^{2-}$ represents half a cube, with the oxygen ligand exhibiting less affinity towards Cu^+ than the sulfur ligands. The information contained in the $[OMoS_3]^{2-}$ fragment that is necessary for the generation of the target structure is read by the coordination algorithm of the copper atoms.[24] An example for the guidance of a further linkage of such cubane fragments is the formation of the prismane-shaped compound $[(OMoS_3)_2(CuPPh_3)_4]$ from two equal precursors, namely $OMoS_3(CuPPh_3)(Cu(PPh_3)_2)$ units (Fig. 5). After the PPh_3 moiety, one of the archetypal protecting groups for cluster fragments, is cleaved off in solution, the "dimerization" to form the target compound takes place.[25]

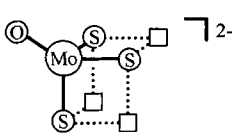

Fig. 4. Schematic representation of the cubane-like cluster anion $[(CuCl)_3(OMoS_3)]^{2-}$. Each square represents one CuCl moiety.

The contribution of inorganic chemistry can be summarized as follows: even though the hunt for the FeMo cofactor has so far been in vain, the hunting party has brought forth a fascinating multitude of compounds.[14, 18]

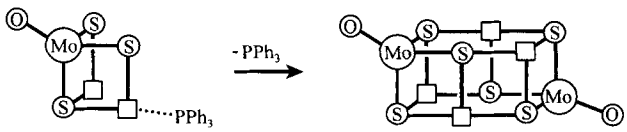

Fig. 5. Schematic representation of the formation of the prismane-shaped compound $[(OMoS_3)_2(CuPPh_3)_4]$ by the "dimerization" of two $[OMoS_3(CuPPh_3)(Cu(PPh_3)_2)]$ units. Each square represents one $CuPPh_3$ moiety.

3. How Does Nature Control the Biosynthesis of the FeMo Cofactor?

Nature is to be considered as a system of steps, each of which is necessarily born out of the previous one.

G. W. F. Hegel

3.1. Functions of the Participating Gene Products

Nearly unnoticed by chemists, geneticists have accumulated a lot of material describing the molecular tools that achieve the assembly of the FeMo cofactor in nitrogen-fixing microorgan-

isms. Bacteria require more than twenty genes for the process of nitrogen fixation. The biochemical characterization of mutants, in which these so-called *nif* genes[26] were selectively inactivated, has led to evidence that at least six gene products (*nif* genes E, N, Q, V, B, and H) participate in the biosynthesis of the FeMo cofactor.[27, 28] This indicates that essential aspects of the synthesis of the inorganic cofactor are genetically controlled. The central question is: how do gene products, that is, proteins, prepare and clear the pathway through the cell for the elements that make up the FeMo cofactor, namely Fe, S, and Mo?

Two genes, *nifE* and *nifN*, show a clear homology (similarities in their sequences) to *nifD* and *nifK*, which are the structural genes that code for the protein chains of the MoFe protein. Accordingly, the gene products of *nifE* and *nifN* also form a tetrameric protein.[29] In addition, bacterial strains containing inactive forms of these genes produce a cofactor-free apo-MoFe protein. This protein can be activated by the addition of the previously isolated FeMo cofactor in the so-called reconstitution test.[30] These results support the conclusion that the nifEN protein forms a template for a crucial step of the FeMo cofactor biosynthesis. In addition, it is assumed that the Fe protein binds also to the nifEN protein and provides electrons for reductive steps.[29]

A decisive hint for the function of the nifB protein within the iron processing system came from the observation that the *nifB* gene is essential for the two alternative nitrogenase systems as well.[31, 32] This is in contrast to the other above-mentioned genes, which are unique for all three systems. The group of P. Ludden succeeded in making a further breakthrough by the recent isolation of the cofactor of the nifB protein (nifB cofactor), which is the only intermediate of the FeMo cofactor biosynthesis known so far.[33] This group at the University of Wisconsin in Madison has been working for some time on an in vitro system for the FeMo cofactor biosynthesis.[34] The initial basis was cell-free extracts of two bacterial strains, deficient in *nifB* and *nifEN*, respectively. While both strains can only form cofactor-free apo-MoFe protein, a combination of the two extracts yields the complete machinery for the cofactor synthesis. Using this system, it proved possible, about six years ago, to integrate into the MoFe protein modified forms of the cofactor, in which homocitrate[2] was replaced by similar organic species. This system has been used as an "activity test" for the enrichment and purification of the nifB and nifEN proteins. The crucial aspect is that nifB cofactor, which, according to current knowledge, is an FeS cluster, can replace the nifB protein in the in vitro system.[33]

In addition, the characterization of the nifS protein[35] has apparently yielded the synthetic equivalent for the inorganic sulfide ligands, which cannot be present in the cell in an unbound state owing to their toxicity. This enzyme activates the cysteine sulfur for biosynthesis by the formation of a protein-bound persulfide moiety. The proposed mechanism is of general relevance for the biosynthesis of FeS clusters.[35]

The element molybdenum is taken up by the cells in the form of $[MoO_4]^{2-}$ or $[MoO_3(OH)]^-$ ions. Therefore, the Mo processing must contain the following steps: 1) a change of the ligand environment (to soft S ligands and homocitrate), 2) an increase in the coordination number from 4 to 6, and 3) a reduction of the Mo center (the oxidation state in the FeMo cofactor appears to be IV).[36]

The participation of the nifQ protein in the Mo processing is illuminated by the following results: the inactivation of this gene has no influence on the activity of the alternative (Mo-independent) nitrogenase systems[31] and does not manifest itself phenotypically in the presence of high concentrations of $[MoO_4]^{2-}$ ions or cysteine in the environment of the organisms. In addition, experiments with $[^{99}MoO_4]^{2-}$ and tritium-labeled homocitrate show that molybdenum atoms and homocitrate enter the pathway of the FeMo cofactor synthesis relatively early.[27]

In vivo measurements using ^{99}Mo TDPAC spectroscopy (TDPAC = *t*ime *d*ifferential *p*erturbed *a*ngular *c*orrelation), allow the gathering of information about the Mo processing. This method is based on the determination of the interaction of the nuclear quadrupole moment and the electric field gradient caused by the electron shell, that is, the obtained frequency data are basically comparable to those of nuclear quadrupole resonance spectroscopy. The results mean that, in principle, information about the nature of intermediate Mo species can be gained. We performed measurements on mutant strains, in which the FeMo cofactor biosynthesis had been interrupted at different stages by the inactivation of one or several of the involved genes. We have so far been able to detect the completed MoFe protein and a Mo storage protein.[37]

3.2. The Assembly of the Fragments

The results from genetic studies clearly indicate that the FeMo cofactor biosynthesis is a multistep process. Obviously, this information cannot be directly derived from the structural model of the cluster itself. The nifEN protein apparently acts as the site of the completion of the FeMo cofactor. An "FeS" fragment (nifB cofactor) is taken up and subsequently fused with a molybdenum-containing fragment (Fig. 6), yielding the

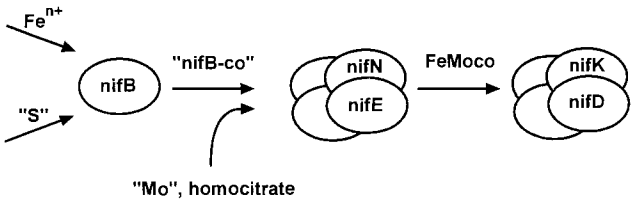

Fig. 6. Simplified schematic representation of the introduction of the "ingredients" Fe^{n+}, "S", "Mo", and homocitrate into the biosynthetic pathway of the FeMo cofactor. NifX denotes the gene product (protein or protein subunit) of the *nifX* gene, co the cofactor.

complete FeMo cofactor. Further conclusions regarding the function of the nifEN protein are made possible by a comparison of the amino acid sequences of the MoFe and the nifEN protein together with a subsequent correlation of the "observed" particularities with the function of amino acids derived from their spatial arrangement within the Kim/Rees structure of the MoFe protein.[38]

The information presented so far leads to two possible scenarios for the course of the FeMo cofactor biosynthesis.

1) The linking of an "Fe_4" fragment with a "$MoFe_3$" cluster fragment occurs within the nifEN protein. (The formation of such a $MoFe_n$ fragment could proceed with the participation of

a MoS precursor, which could—in analogy to the above-mentioned $OMoS_3$ fragment—determine the environment of one of the corners of the cluster.[39]

2) The nifB cofactor forms the entire iron–sulfur part of the FeMo cofactor (**5**, Fig. 2), and the capping of the η^3-S arrangement (analogous to the $Fe_3S_4 \rightarrow MFe_3S_4$ conversion, **1** → **2**, Fig. 2) with a Mo-homocitrate moiety within the nifEN protein occurs as the terminal step in the FeMo cofactor synthesis (**5** → **6**, Fig. 2). The molecular recognition of molybdate in the cell is done by homocitrate, thereby forming a complex of the type MoO_n/homocitrate. This complex is then captured and positioned by the nifEN protein.[41] The subsequent in situ reduction of molybdenum(VI) increases the basicity of the metal center, which in turn facilitates the protonation of terminal oxygen ligands, thereby increasing the lability of the ligand sphere. In addition, the reduction of the molybdenum center increases its affinity for "soft" sulfur ligands, which facilitates the capping of the Fe_7S_9 fragment. The generation of such a fragment within the nifB protein would require that the fragment is stabilized in a relatively highly oxidized state in order to form the μ_2-sulfur centers. (The reduction steps necessary for the capping reaction could occur in the nifEN protein, with the participation of the Fe protein.)

3.3. How Does the Completed FeMo Cofactor Get Incorporated into the MoFe Protein?

The question now arises, how does the cofactor, after its synthesis in the nifEN protein, get into the apo-MoFe protein, and how is the higher affinity achieved that the target protein must possess compared to the synthesis template? The fact that the apo-MoFe protein can be reconstituted with isolated FeMo cofactor in the presence of the Fe protein[36] indicates that during the transition, the FeMo cofactor is present in the cytosole of the cell in a more or less "free" state—that is, not bound by proteins. Additionally, we were able to demonstrate that newly synthesized FeMo cofactor is taken up in vivo by the apo-"MoFe" protein of a previously expressed alternative nitrogenase system[42] (cf. in particular Fig. 5 in ref. [43]). This requires at least a certain kinetic stability of the cluster outside the protein environment. (The slightly different ESR spectrum indicates that the FeMo cofactor is present outside the protein in a marginally modified form.[36])

A number of further proteins play a role in the "relocation" of the FeMo cofactor. For example, the Fe protein has a so far unknown function during the insertion of the FeMo cofactor into the apo-MoFe protein. The apo-MoFe protein is also associated with a helper protein (nifY), which assumably stabilizes a conformation that facilitates the uptake of the cofactor.[28] For this uptake, an insertion channel must be opened up, as, surprisingly, the structure of the MoFe protein determined by Rees et al. does not show any permanently present openings for a possible cofactor insertion.[5]

In order to study this problem in more detail, we calculated with a molecular modeling program,[45] based on the structural data of the MoFe protein obtained by D. C. Rees et al., the water-accessible surface[46] of the α-subunit (Fig. 1b, d). One can clearly discern a hollow which "houses" the cofactor. This cavity exhibits an opening, which, in the MoFe protein, is completely closed off by the β-subunit in a lidlike manner (Fig. 1b). An insertion of the cofactor through this channel would require an at least partial dissociation of the α-subunit.[38] Potential deviations of the protein structure in solution from that of the crystallographically determined structure are of fundamental interest. Therefore we are investigating solutions of the MoFe protein with dynamic light scattering techniques. Preliminary results indicate that the hydrodynamic volume of the MoFe protein is slightly larger than that implied by the structure in the crystal lattice. (The experimentally determined diffusion coefficient is about 10–15% higher than the one obtained by hydrodynamic calculations based on the crystallographic data.) The sequence comparison has yielded new clues that the extent of the interactions between the α and β-subunits is smaller in the nifEN protein than in the MoFe protein. Hence, the insertion channel is more readily opened up in the nifEN protein.[47] In this context, it is also important that in the nifEN protein, there is an asparagine residue at the corresponding site where the MoFe protein possesses a histidine residue that coordinates the molybdenum atom.[29] This certainly leads to a destabilized binding of the cofactor compared to the MoFe protein. An amide nitrogen is much less basic than an imidazole nitrogen atom, and thus is a much weaker ligand. These results have therefore yielded reasonable indications about the manner in which the completed cofactor can "escape" from its nifEN synthesis template and how, once integrated into the MoFe protein, it is firmly held in place at its final position.

4. Perspectives: What Can Chemists Learn from Nature?

The completed structure was nowhere preexistent as such. Its design plan, however, did already exist in its basic components.

J. Monod

The formation of larger "cluster" aggregates, like the FeO core of ferritin, shows, in addition to a nucleation process, evidence of a growth phase dominated by self-assembly processes.[48] In contrast, the *stepwise* synthesis of the FeMo cofactor appears to be controlled to a large extent by protein templates. This can be compared with some of the template-directed syntheses in inorganic host–guest chemistry.[49] The active centers of the template proteins carry the secret discussed herein: *the blueprint for the synthesis of the FeMo cofactor is written in the language of proteins.* Proteins can solve many of the problems that chemists have a difficult time tackling. The control of the redox processes is performed in the example discussed herein in part by the enzymatic control over the sulfide ligands, that is, by the nifS protein. The formation of polynuclear Mo species of the double-cubane or prismane types—clearly favored in in vitro reactions—is inhibited by the provision of well-defined cavities, specific interactions, such as hydrogen bonds, as well as by charge compensation. In this manner, the type of linkage formed between the fragments is controlled and shielding from "destructive" molecules (e.g., nucleophiles) is achieved.

The FeMo cofactor structure is stabilized within special cavities of the proteins. Hydrogen bonds, especially those to the less stable μ_2-sulfur ligands (Fig. 1c), play a decisive role.

In this context it becomes clear why no template proteins have been found for the synthesis of Fe_4S_4 protein centers, which are ubiquitous in the biosphere. These species have such a strong tendency of formation by self-assembly processes that they are formed directly within enzyme pockets that contain a preformed set of ligands.[50] This is probably also true for Fe_2S_2 centers, which are somewhat less thermodynamically favored.[51] $\{Fe_4S_4\}^{2+}$ clusters can be found in the phylogenetically oldest organisms, for example, the N_2-fixing chlostridia, a fact that appears plausible also because of the relatively high Fe^{2+} content of this compound type. These clusters could have readily formed in the reducing atmosphere of the early earth from Fe^{2+} and S^{2-} ions in the presence of an electron acceptor, which could have been traces(!) of O_2—stemming maybe from the radiolysis of H_2O.[52]

A final word on the central question: how would a tailor-made "synthetic" host have to look to function as the template for an in vitro synthesis of the FeMo cofactor? Such a host would certainly have to reflect the threefold symmetry of the cofactor and contain a cavity that is suitable with respect to shape, size, and hydrophobicity. Additionally, the host should—in a truly biomimetic approach—contain a thiolate function as a ligand for the *exo*-iron atom, hydrogen-bond-forming centers to stabilize the μ_2-S^{2-} ligands, as well as (basic) groups to compensate the negative charge of the potential guest. Such a "synthetic" host could of course also be used for the complexation of the isolated FeMo cofactor. Another interesting case would be to preprogram a "molecular receptor"[24, 49] which is not preorganized and formed under the auspices of the FeMo cofactor by self-organization from several building blocks, following a given algorithm. The fact that even a cluster synthesis and the concomitant formation of an envelope from several fragments is possible as an interdependent and synergistic overall process is demonstrated by the synthesis of the polyoxo anion $[V_{34}O_{82}]^{10-}$. This anion contains at its center a cubane-like $[V_4O_4O'_4]$ cluster which serves as template for the formation of its host structure. The formation of this core cluster itself, however, is not independent of the assembly of the "outer shell".[53]

The long-range goal of this concept, of course, is to achieve the in vitro synthesis of the FeMo cofactor using a host–guest complex—perhaps even in the sense of a not completely preexisting host structure like in the $[V_{34}O_{82}]^{10-}$ case—and thereby to enable the reduction of N_2 "in the test-tube". In that case, chemistry would have once again—after the development of the Haber–Bosch process—acted in accordance with the statement of Sir William Crookes, but this time in cooperation with other scientific disciplines, especially by incorporating results from genetics.

We wish to thank Priv.-Doz. Dr. Werner Klipp, Bielefeld, for the fruitful cooperation in the context of a project of the Forschergruppe: "Biosynthese, Struktur und Wirkungsweise einiger der am N-Stoffwechsel beteiligten Enzyme mit besonderem Bezug zur N_2-Fixierung und Photosynthese" which was funded by the Deutsche Forschungsgemeinschaft. We also thank Prof. Dr. D. C. Rees, Los Angeles, for providing crystallographic data. This project was funded by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

[2] The nitrogenase enzyme system consists of two components: The Fe protein is a γ_2-dimer with a molecular mass of about 60000 Da, and, in an ATP-dependent reaction, transfers electrons to the MoFe protein, which is the site of the nitrogen reduction. The MoFe protein is an $\alpha_2\beta_2$ tetramer and has a molecular mass of about 240000 Da. The FeMo cofactor is situated in the α-subunit and covalently linked to the protein by two amino acid side chains (a cysteine and a histidine residue). In addition, several hydrogen bonds exist between the protein and various sulfur ligands of the cofactor. The molybdenum atom is coordinated in a bidentate fashion by the hydroxyl and a carboxyl group of a homocitrate anion (Fig. 1c, d). The MoFe protein contains, in addition to the FeMo cofactor, also another type of metal–sulfur aggregate (P clusters) (Fig. 1a). For these clusters, two structural models are currently under consideration: 1) two Fe_4S_4 cubanes linked through an S–S bond involving one S atom from each unit [3–5] or 2) two Fe_4S_3 fragments that are linked by a hexacoordinated sulfur atom [6,7]. The two P clusters form bridges between the α and β-subunits; they are linked by three cysteine residues to each subunit. One of these three cysteine sulfur atoms links the two halves of the cluster, the other two function as terminal ligands for the "outer" Fe atoms of the cluster [3–7].

[26] A number of these *nif* genes (*nif*: *n*itrogen *f*ixation) have been sequenced, which allows the determination of the amino acid sequences of the corresponding gene products. The structural genes for the α and β-protein chains of the MoFe protein are termed *nifD* and *nifK*, the γ-subunit of the Fe protein is encoded by *nifH* (cf. D. R. Dean, M. R. Jacobsen in *Biological Nitrogen Fixation* (Eds.: G. Stacey, R. H. Burris, H. J. Evans), Chapman and Hall, New York, **1992**; J. Erfkamp, A. Müller, *Chem. Unserer Zeit* **1990**, *6*, 267–279, and references therein). The product of the *nifV* gene catalyzes the synthesis of the homocitrate ligand (reviewed in [27]). The use of genetics enables the comprehension of numerous aspects of biological nitrogen fixation. This includes, apart from the cluster synthesis, also the regulation of the *nif* gene expression by ammonium ions and other nitrogen-containing compounds, as well as by molyb-

date ions and O_2. The transfer of *nif* genes to plants is obviously of general interest.

Int. Ed. Engl.* **1987**, *26*, 110–126. In principle, scanning tunneling microscopy (STM) can be used in addition to TDPAC spectroscopy to study mutants with defects in genes coding for gene products, which are involved in the Mo processing. So far we could visualize the gross metal cluster organization in the MoFe protein using this technique (E. Diemann, A. Branding, A. Müller, *Naturwissenschaften.* **1992**, *79*, 267).

[38] A. Müller, E. Krahn, U. Gollan, W. Suer, K. Schneider, unpublished results.

[39] In connection with the outlined problem of the synthesis of a $MoFe_3S_4$ fragment, a comparison of the amino acid sequences of the so far known nifEN and MoFe proteins (of different N_2-fixing organisms) yields a further notable characteristic: All nifEN proteins exhibit, compared to the MoFe protein, homogeneous deviations in the region corresponding to the P cluster bonding site in the MoFe protein. Of the corresponding cysteine residues, which bind the P cluster in the MoFe protein [2], the two terminal cysteine residues in the β-subunit are missing. The remaining ones form a complete set of ligands for an Fe_4S_4 cluster, or even its synthesis. The 3:1 differentiation among the iron centers [18,40] (3 α-cys, 1 β-cys) could also enable a conversion like $Fe_4S_4 \rightarrow Fe_3S_4 \rightarrow MoFe_3S_4$ in this particular environment [38].

[41] In the MoFe protein, a glutamine residue interacts with one of the carboxyl groups of homocitrate [3]. The corresponding site in the nifEN protein is occupied by a lysine residue [29]. This leads—compared to the MoFe protein—to an additional electrostatic interaction, which could be involved in the capture and the alignment of the homocitrate ion (or a Mo-homocitrate intermediate) [38]. Homocitrate is negatively charged under physiological conditions.

[42] We have been able to demonstrate that the addition of molybdate ions to a growing bacterial culture, which has already expressed the alternative "FeFe" nitrogenase, leads to the formation of a "hybrid" enzyme. This was shown to consist of the "alternative" apo-protein, which has incorporated the "conventional" cofactor (FeMo cofactor), instead of the FeFe cofactor, by spectroscopic and catalytic characterization. The addition of $[MoO_4]^{2-}$ stimulates the biosynthesis of the FeMo cofactor on the one hand; on the other hand, the presence of molybdate ions also induces the expression of protein components for the conventional nitrogenase system. In order to prevent the formation of the MoFe protein, mutants were employed in which the genes coding for the structural proteins of the conventional system had been deactivated [43]. These results [43,44] indicate that the alternative cofactors [31]—for which, compared to the FeMo cofactor, there is much less structural information available—are structurally very similar to the FeMo cofactor.

[47] The α-β arrangement of the MoFe protein is stabilized by seven salt bridges (ionic interactions between charged amino acid residues). In addition, the N-terminal of the β-subunit is "wrapped" around the α-subunit (Fig. 1b) [3]. A comparison of the sequences of *nifDK* and *nifEN* (from *azotobacter vinelandii*) shows that the first 52 amino acids in the *nifN*-coded β-subunit are missing [29]. The β-branch of the MoFe protein, which is missing at the corresponding site in the nifEN protein, carries three of these salt bridge forming residues. Two additional (of the seven) salt bridges appear to be absent in the nifEN protein [38]. The changes in the region that corresponds to the P cluster binding site in the MoFe protein [39] can also contribute to the destabilization of the α-β complex in the nifEN protein.

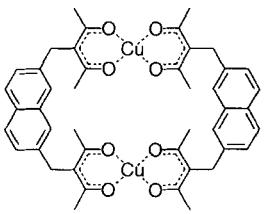
Self-Assembly of Molecular-Sized Boxes

C. A. Hunter*

Molecular recognition of guests by synthetic hosts is a rapidly developing field, and many of the basic principles that govern the efficiency and selectivity of intermolecular complexation have been elucidated.[1] The following requirements have emerged for the design of an effective receptor for a particular target molecule:

1. The host should be polymacrocyclic and contain a large cavity in which the number of interactions with the bound guest can be maximized.



2. The van der Waals surfaces and electrostatic potential surfaces of the host and guest should be complementary.

3. The host should be relatively rigid so that the loss of conformational entropy on binding a guest is minimized.

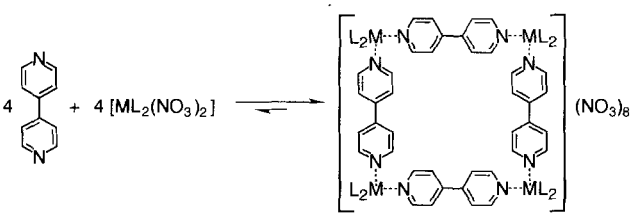
While these principles are clear, the realization of rigid polymacrocyclic structures is a difficult synthetic challenge. The use of high-dilution conditions is one way to encourage macrocyclization and reduce polymer formation, but yields can be low, and chromatographic separation of mixtures of linear and cyclic oligomers with similar properties can be difficult. Template-directed synthesis has proved to be a very successful method for generating macrocycles.[2] Since it works well when the interactions between the template and the acyclic precursor are strong, its use has been restricted to metal ion/ligand interactions and the construction of hosts for ionic or coordinating guests. Templating is not a viable approach for the construction of macrocyclic hosts for neutral organic guests where the individual interactions between the template and the acyclic precursor are orders of magnitude weaker.

Thus new techniques are needed for the construction of polymacrocyclic structures. Over the last few years, self-assembly has emerged as a very promising approach to the generation of compounds with large molecular-sized cavities. Self-assembled complexes are discrete, structurally well-defined species composed of at least two molecular units connected by noncovalent interactions.[3] The use of noncovalent interactions to generate macrocyclic structures is particularly attractive since the cyclization is under thermodynamic control. Provided that the design of the components is sufficiently accurate, entropically unfavorable polymerization is avoided. Moreover, the self-assembly process should become increasingly favorable as the complexity of the structure increases from simple macrocyclic to polymacrocyclic architectures. There are obvious parallels in nature where large three-dimensional cavities are almost always generated by the self-assembly of many proteins, for example in the coats of viruses.

The first self-assembled macrocyclic host (**1**) was reported in 1986 by Maverick et al.[4] This work showed how coordination chemistry could be used to generate cyclic structures in good yield by simply mixing the appropriate components in solution. **1** also functioned as a host: it selectively complexed 1,4-diazabicyclo[2.2.2]octane in chloroform ($K = 220\ M^{-1}$).

1

An appealing design for a host molecule is a regular box shape—construction in three dimensions is conceptually simpler if we use three orthogonal axes, in other words, if we use right angles in our building blocks. An attractive feature of inorganic complexes is that they afford a range of 90° linkages for the construction of macrocyclic boxes. The square-planar geometry of platinum(II) and palladium(II) complexes makes them ideal building blocks, and in 1990, Fujita et al. first demonstrated the utility of palladium(II) in the self-assembly of a large macrocyclic cavity (Fig. 1).[5] The thermodynamic cyclization resulted in a quantitative yield of the macrocycle, which also formed a stable 1:1 complex ($K = 750\ M^{-1}$) with 1,3,5-trimethoxybenzene in water.



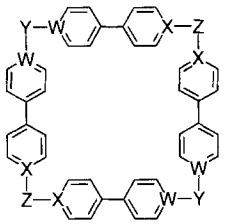


Fig. 1. Fujita and Ogura's box forms in quantitative yield on mixing the components [5]. M = Pd^{II}, L_2 = ethylenediamine.

Stang and others have recently produced several variations on this basic idea (**2** and **3**).[6] These structures are obtained in high yields by simply mixing the components. Interestingly, covalent analogues of these macrocycles are known (**4** and **5**).[7] These require multistep syntheses concluding with a low-yielding macrocyclization reaction which produces large quantities of acyclic oligomers. The similarity between these self-assembled

macrocycles and Stoddart's "big blue box" (**5**) suggests that they will have a bright and colorful future in supramolecular chemistry.

Fujita and Ogura have now extended this work to the construction of a three-dimensional cavity (Fig. 2).[8] This self-assembly process is significantly less efficient than that in Figure 1 because the ligands are more flexible; less than 60% of the molecules exist as the macrobicyclic complex which is in equilibrium with other oligomers. However, addition of a complementary guest such as sodium 4-methoxyphenylacetate shifts the equilibrium dramatically such that only the cage complex can be detected. Guests that are too large to fit inside the cage can still bind but shift the equilibrium in the opposite direction, in favor of open oligomers.

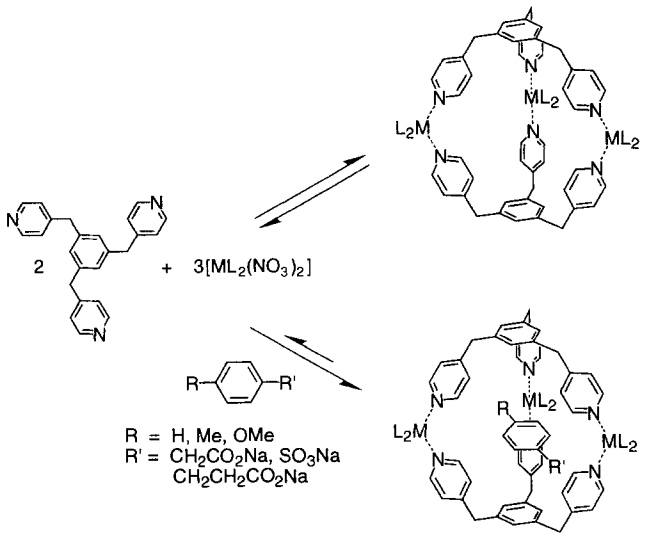

Fig. 2. This macrobicyclic structure does not assemble efficiently unless a complementary guest is added to the mixture [8]. M = Pd^{II}, L_2 = ethylenediamine.

Three-dimensional macrobicyclic assemblies have also been described by Baxter et al. and by Saalfrank et al. The Lehn group used the coordination of copper(I) by 2,2'-bipyridyl derivatives to generate a large cylindrical box (Fig. 3a).[9] In total, five ligands are complexed by six metal centers in this singularly impressive example of the power of self-assembly to generate polymacrocyclic architectures. Saalfrank et al. have developed the coordination chemistry of iron with malonic acid derivatives to produce tetrahedral tetranuclear complexes which enclose cavities of variable dimensions (Fig. 3b).[10] The smallest structure encapsulates cations such as ammonium. Both of these systems use bifunctional chelating ligands rather than pyridyl ligands: the cylinder in Figure 3a is generated by a distorted tetrahedral metal center and the tetrahedron in Figure 3b is generated by an octahedral metal center.

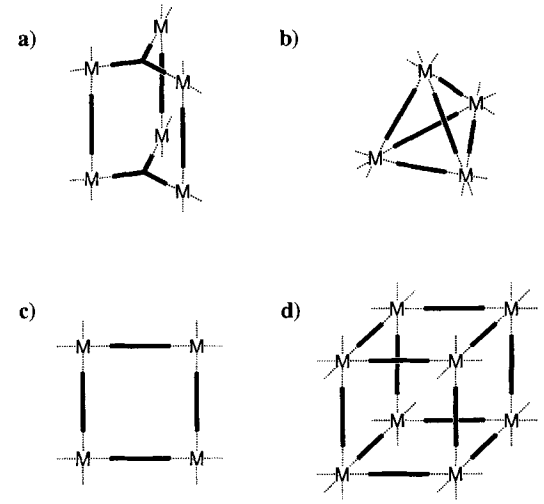

Fig. 3. Schematic representations of cavities assembled on metal centers. a) Lehn's cylindrical box based on copper(I) and coordination of 2,2'-bipyridine [9]. b) Saalfrank's tetrahedral iron–malonate assembly [10]. c) Fujita and Ogura's square box, which could be extended into a cube (d) by using an octahedral metal center [5].

In principle, such three-dimensional assemblies should be more stable than simple macrocycles since the number of interactions per component is larger. It remains to be seen whether the two-dimensional self-assembly of square boxes based on pyridyl ligands and square-planar metal centers can be extended into three-dimensional cubic structures by the use of octahedral metal centers (Fig. 3c and d).

Self-assembly of macrocyclic hosts is not restricted to metal complexes, and macrocyclic hosts have been reported in which hydrogen bonding alone controls the assembly process.[11] The most striking example is Rebek's "tennis ball".[11c] Two self-complementary molecules form a three-dimensional spherical cavity, which complexes small nonpolar guests such as methane in organic solvents.

Self-assembly appears to be an extremely promising method for the construction of polymacrocyclic structures and will facilitate the construction of large cavities for use in molecular recognition. An interesting feature of these systems is that assembly of the host structure may itself be coupled with guest recognition such that the host only exists in the presence of the guest. The structures generated to date all have a high degree of symmetry, which may limit the range of substrates that can be recognized, but strategies for avoiding symmetry have yet to be explored.

Does the Death Knell Toll for the Metallic Bond?**

J. Christian Schön*

"There is an appointed time for everything under the heavens—a time to be born, and a time to die." Judging from two recent publications,[1, 2] the latter fate awaits the concept of the metallic bond. Based on two somewhat different trains of thought, the authors conclude that the metallic bond is a disposable quantity in descriptions of bonding in solids, and should be subsumed into the supposedly better established concepts of the covalent and ionic bond.

Analyzing their arguments in more detail, we notice that Allen et al.[1] base their conclusion on an attempt to quantify the so-called van Arkel–Ketelaar triangle.[3, 4] They suggest that a configuration energy (CE) should be defined as an average "valence shell energy", in other words, the average energy needed to remove a single valence electron. Here, it is assumed that the remaining valence electrons remain in their original states during this "ionization" process. Thus, according to Koopman's theorem, these valence shell energies correspond to the one-particle energies in the Hartree–Fock approximation.[5][***] For a compound composed of A and B, Allen et al. then identify CE_A and CE_B with the diagonal elements of the interaction matrix within the approximation of the extended Hückel theory (EHT).[1, 2] Using a common approximation for the off-diagonal matrix elements,[6] $H_{ij} = 1/2(H_i + H_j)$, they find that $H_{AB} = (CE_A + CE_B)/2$ holds. Since the off-diagonal matrix elements explain (within the context of the EHT, at least) the Peierls distortion,[7, 8] which accompanies the change from "metallic" to "covalent" band structures, Allen et al. conclude that $(CE_A + CE_B)/2$ is a natural coordinate along the metallic → covalent edge of the van Arkel–Ketelaar triangle.

The second coordinate in the description of the triangle would have to reflect the degree of ionicity in the bonds. Here, Allen et al.[9] refer to the classical concept of the difference in electronegativities for the characterization of the polarity of the bond. Within their model, this concept is most easily implemented by employing the difference in configuration energies, $(CE_A - CE_B)/2$.[*] From these considerations it follows that the three traditional bonding concepts should be expressed in a natural way through the two "coordinates" derived from the configuration energy.[**]

At the same time, Anderson, Burdett, and Czech[2] (= ABC) have addressed the issue that certain materials should not necessarily be described in terms of typical metallic bonding, although they show macroscopic metallic behavior. Examples are doped molecular crystals and ionic systems, for instance fullerenes and compounds related to the high-temperature superconductors, respectively. The band structures of such "metals" can be determined within the tight-binding (TB) approach,[5, 11] and it is not necessary to invoke the metallic bond with its somewhat vague concept of delocalized vs. localized electrons to explain the metallike behavior. Thus, ABC suggest that one should reevaluate the concept of metallic bonding in light of the current understanding of theoretical models of the bonding in solids. They point out that most of the properties associated with metallic behavior are related to the position of the Fermi surface in the band approximation[11] for the theoretical analysis of the

[**] I would like to thank Prof. Dr. M. Jansen, Bonn, for many valuable comments and discussions.

[***] The interpretation of the one-particle energies is subtle: the total energy of the solid is not the sum of all one-particle energies, since we are dealing with an interacting system. In particular, a one-particle energy is in general *not* identical with the standard ionization energy.

[*] Based on these considerations, Allen draws the conclusion that CE should be used as a general characteristic quantity for the chemical behavior of an atom on the same level as its position in the periodic table.

[**] For an alternative approach to go beyond the van Arkel–Ketelaar triangle by applying quantum mechanical concepts, see the work by Urland [10].

electronic degrees of freedom in the solid. In metals, the bands are filled only partly, and thus no energy gap exists for the promotion of a (quasi-)electron into a conducting state. With statistical mechanics it can be shown that this lack of a gap explains many of the characteristic properties of a metal.[12]

It is known[5, 11] that within the context of the one-electron band approximation the eigenfunctions of the corresponding one-particle Hamiltonian for a periodic lattice are Bloch functions of the form $\Psi_n(\vec{k};\vec{r}) = \exp(i\vec{k}\vec{r})\,u_n(\vec{k};\vec{r})$. The function u_n reflects the periodicity of the crystal lattice, such that $u_n(\vec{k};\vec{r}) = u_n(\vec{k};\vec{r}+\vec{R}_i)$, where $\vec{R}_i$ is any translation vector of the lattice. Since these Bloch functions are obviously "delocalized", any description of the electronic degrees of freedom of the crystal relying on this approximation refers to delocalized (quasi)-particles. On the other hand, it is always possible to choose any complete orthogonal basis of functions, including rather localized bases, and express the Bloch functions in this basis. One should notice here that nothing has been said about the actual method used to calculate the band structure. The reason is that plane-wave expansions (NFE, OPW, etc.),[5, 11] expansions using atomic/molecular orbitals including ionization states (TB, LCAO, etc.),[5, 11] and also the "cell-methods" (APW, KKR, etc.)[5, 11] are in principle applicable to all band structures and all types of chemical bonding.[5] Only the ease of computation for a given system and property favors one method over the others.

Next, ABC point out that because of the high degree of degeneracy a Fermi surface is subject to instabilities, which in a partly filled band can lead to the opening of an energy gap in the density of states.[8] Slight distortions of the arrangement of the ion cores away from a high-symmetry configuration can remove this degeneracy (= Peierls distortion in analogy to the Jahn–Teller effect,[8] its strength should be related to the electron-phonon interaction). Similar effects can be produced by a modulation of the electron distribution, in other words, charge density waves.[8] This removal of the degeneracy can result in the opening of an energy gap at the Fermi surface. This would be of importance in a metal, since the band gap would cause a change to an insulator/semiconductor. Whether this actually occurs depends on whether the ground state energy of the symmetric (undistorted) structure lies above or below that of the distorted structure, a fact that can be influenced, for instance, by the application of external pressure.[13] As was pointed out earlier, within the EHT one can estimate the relative stability of the Peierls distortion in compounds by considering the off-diagonal elements. Thus the considerations of ABC lead to the same classification of the metallic → covalent bond transition as those of Allen et al.,[1] who started from the calculation of the configuration energy.

Finally, ABC suggest that one might define the metallic bond to apply to those systems within the one-electron approximation for which the interpretation of Wannier functions[5] as single-electron wave functions is inappropriate. Since the (relatively localized) Wannier functions are not eigenfunctions of the one-particle Hamiltonian (in contrast to the Bloch functions, which can be transformed into Wannier functions by a type of Fourier transform), their Slater determinant may be interpreted as a many-electron state only if all the Bloch states within a band are filled and present in the determinant. Recalling that metals are essentially defined by the property of having a partly filled energy band, one can conclude that metallic bonds are just bonds in metals; no special attributes belong to the metallic bond itself.

Adding to this their analysis of the transition from metallic to covalent bonds, ABC draw the conclusion that the traditional concept of a metallic bond as such, as an individual type essentially different from other bonds, is no longer necessary. It might even be disadvantageous to maintain this concept, since it hides the more fundamental aspects of the bonding situation as reflected in the (calculated) band structures.

Now, while the arguments of Allen and ABC against the metallic bond as an entity completely separate and distinct from other types of bonds are very interesting, one should not overlook that the concept of metallic bonding is first and foremost a qualitative one based on the prominence of certain features of the wave function(s) describing a solid. In this sense, the metallic bond is not different from other types of bonds that stress other properties of the wave function. They all serve the same purpose of allowing a first qualitative characterization of a solid and its behavior. Similarly, as pointed out above, in the context of quantum mechanical band structure calculations, covalent or ionic bonds are no more special than metallic ones (and neither are the use of localized or delocalized bases for the expansion of the Hamiltonian). Thus, the arguments of both ABC and Allen et al. carried to their final conclusion actually imply that not only the concept of the metallic bond should vanish, but so should all the traditional concepts of bonds in solids!

Has a major change of paradigm thus occurred in solid-state chemistry? Not really. The seemingly radical conclusion we have just reached should come as no surprise, since it is known that any solid is composed of strongly interacting particles, namely ion cores and electrons. Thus any more detailed understanding of its properties will always involve studying the collective behavior of its constituents, which implies that local concepts like bonds will only be of limited value.[*] However, the necessity of having to solve the full quantum mechanical problem first is a certain disadvantage over more simple classification procedures, although it seems quite likely that with the increasing availability of powerful computers and sophisticated algorithms the concepts of metallic or ionic bonds will become more quantitative.[**]

As a consequence, the boundaries between bonding regimes will become less sharp than a more qualitative heuristic picture of bonds in solids usually implies. Nevertheless, the extreme cases of the ideal covalent, ionic, or metallic bond will retain their usefulness, as long as one is always aware of their limitations. Thus, we expect the different concepts of bonds in solids, including the metallic one, to keep their place in the tool box of the solid-state scientist. The time has not yet come for the metallic bond to pass into oblivion.

[*] Compare, however, the fruitful concept of quasi-particles introduced by Landau [5].

[**] Such a direct classification method has been recently proposed by Silvi and Savin [14]. They suggest employing the electron localization function(s) (ELF) [15, 16] for a more rigorous definition of quantities like ionicity or metallicity of a compound. Clearly, their procedure points the way towards a quantum mechanical classification of the types of bonds prevalent in a given chemical compound, thus providing us with definitions that would allow us to speak with confidence about the metallic, covalent, and/or ionic character of bonds.

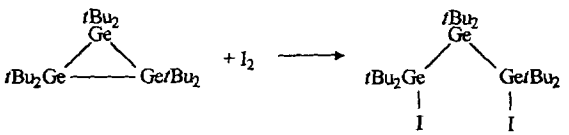
Reactions of Hexa-*tert*-butylcyclotrigermane: Isolation of an Enantiomerically Pure 1,3-Diiodotrigermane**

Manfred Weidenbruch,* Annette Hagedorn, Karl Peters, and Hans Georg von Schnering



The hexaarylcyclotrigermanes **1**, which have been known since 1982, can be photochemically and thermally converted to tetraaryldigermenes (tetraaryldigermaethenes) **2**.[1] These, in turn, undergo a large variety of addition and cycloaddition reactions,[7] for example with chalcogens,[2-6] alkynes,[4, 6] and azides.[4, 6]

1 **2**

R = 2,6-$Et_2C_6H_3$, 2,6-$iPr_2C_6H_3$ etc.

Hexa-*tert*-butylcyclotrigermane **3**,[8] the only known hexaalkylcyclotrigermane[1] to date, behaves rather differently, reacting with the heavier chalcogens by cleavage of just one Ge–Ge bond to give the ring-expanded thia-, selena-,[9] and telluratrigermetanes.[10] We have now found that the reaction with iodine also occurs with the cleavage of one Ge–Ge bond and results in the formation of the strained open-chain hexa-*tert*-butyl-1,3-diiodotrigermane **4**.

3 **4**

According to the crystal structure analysis,[11] **4** assumes the *gauche-trans* conformation. The Ge–Ge bonds are of different lengths (266.0 and 262.2 pm) and considerably stretched in comparison to the normal bond length of 244 pm.[17] This length is only exceeded by the Ge–Ge bond in hexa-*tert*-butyldigermane (d = 271.0 pm).[8] Trigermane **4** is thus analogous to the structurally related hexa-*tert*-butyl-1,3-diiodotrisilane,[12] which also contains extended Si–Si bonds of different lengths.

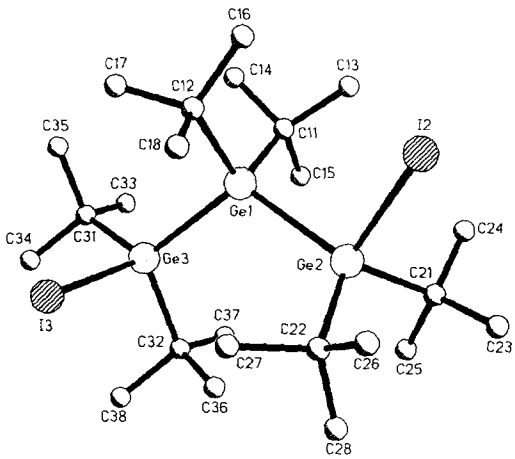
Whereas the Si analogue of **4** crystallizes as a racemate,[12] **4** forms a conglomerate of enantiomerically pure crystals on slow cooling to −25 °C. The absolute configuration of the single crystal that was selected and investigated was determined by the anomalous scattering of X-rays and is shown in Figure 1.



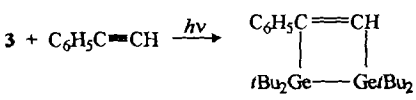


Fig. 1. Molecular structure of *P*-**4** in the crystal (H atoms not shown). Selected bond lengths [pm] and angles [°]: Ge1-Ge2 266.0(1), Ge1-Ge3 262.2(1), Ge2-I2 261.0(1), Ge3-I3 260.5(1); Ge2-Ge1-Ge3 115.4(1).

Although several hundred conglomerates have been described since their initial discovery by Pasteur,[13] the enantiomers isolated from these almost all owe their chirality to the presence of stereogenic centers.[14] In contrast, the chirality in **4** is based on a helical arrangement of the germanium and iodine atoms, in which the conformers form either a right-handed or a left-handed helix. This is the first case known to us in which a simple molecular compound made from heavier elements of Group 14 (fourth main group) undergoes spontaneous enantiomeric resolution on crystallizing. Intermolecular contacts that could be significant for the formation of the conglomerate are not observed, since the I···I and I···Ge distances of >450 pm are too long for bonding interactions.

Further proof of the presence of a conglomerate is provided by the melting points of **4**; the melting point of the racemate is 21 K lower than that of the pure enantiomers. In solution, **4** may have a symmetrical structure with unhindered rotation around the Ge–Ge bonds, as the very simple ^1H and ^{13}C NMR spectra do not reflect the different Ge–Ge bond lengths nor the different orientations of the *tert*-butyl groups observed in the crystal.

Whereas **3** reacts differently in the absence of light than the cyclotrigermanes **1**, it undergoes photochemically induced bond cleavage to give tetra-*tert*-butyldigermene. This can be trapped,

5

for example, by [2 + 2] cycloaddition with phenylacetylene leading to 1,2-digermacyclobutene **5**, the constitution of which has been confirmed by the X-ray structure analysis (Fig. 2).[11]

This manner of reaction is not self-evident, since the only tetraalkyldigermene $R_2Ge{=}GeR_2$ ($R = CH(SiMe_3)_2$) known to date, although stable in the crystal, reacts in solution exclusively as singlet germylene (germanediyl).[15]

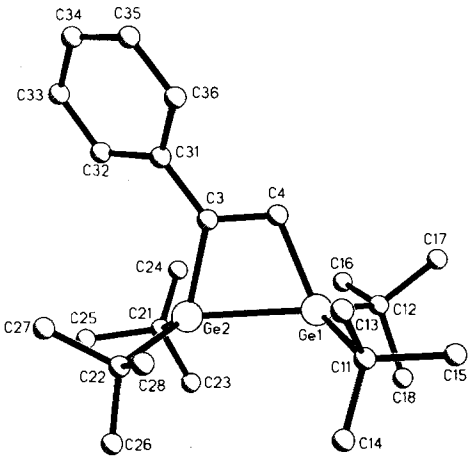

Fig. 2. Molecular structure of **5** in the crystal (H atoms not shown). Selected bond lengths [pm] and angles [°]: Ge1-Ge2 253.1(6); Ge1-Ge2-C3 73.0(3), Ge2-C3-C4 107.0(6), C3-C4-Ge1 107.8(6), C4-Ge1-Ge2 72.2(3).

Experimental Procedure

4: A solution of **3** (100 mg, 0.18 mmol) in *n*-hexane (50 mL) was cooled to −78 °C and a solution of iodine (46 mg, 0.18 mmol) in *n*-hexane (30 mL) added dropwise. The mixture was allowed to warm to room temperature and solvent removed under reduced pressure to give 30 mL of solution. After cooling to −25 °C, colorless needles of **4** (120 mg, 83% yield) were obtained. M.p. (enantiomers) 122 °C, m.p. (racemate) 101 °C. ^{1}H NMR (300 MHz, C_6D_6): $\delta = 1.44$ (s, 36H, 1.57 (s, 18H); ^{13}C NMR (75.44 MHz, $CDCl_3$): $\delta = 33.13$ (C_p), 34.46 (C_q), 37.02 (C_q), 37.34 (C_q); MS (CI, isobutane): *m/z* (%): 687 (54, $M^+ - I$). Correct C, H, I elemental analyses.

5: A solution of **3** (150 mg, 0.27 mmol) and phenylacetylene (73 mg, 0.71 mmol) in *n*-hexane (70 mL) was irradiated at −25 °C with a high-pressure mercury lamp (Heraeus TQ150) until **3** was no longer detectable by TLC (about 4 h). After exchanging *n*-hexane with toluene and cooling to −25 °C, yellow crystals of **5** (36 mg, 27%) were obtained. M.p. 96 °C. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.30$ (s, 18), 1.33 (s, 18H), 7.27 (m, 5H), 7.82 (s, 1H); ^{13}C NMR (75.44 MHz, $CDCl_3$): $\delta = 29.99$ (C_q), 30.07 (C_q), 32.18 (C_p), 32.25 (C_p), 126.78, 126.99, 128.16, 142.46, 152.29, 173.43; MS (CI, isobutane): *m/z* (%): 476 (28, $M^+ - t$Bu). Correct C, H elemental analyses.

[**] Electrochemistry of Oxygenation Catalysts, Part 5. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. B. S. would like to thank the Deutsche Forschungsgemeinschaft for a Heisenberg fellowship. Part **4**: [1].

Scheme 1. Ladder scheme with electron transfer and ligand exchange reactions of [Co(salen)]; for the nomenclature of the equilibrium constants see [8].

substrate molecules (L^2). We also present the equilibrium constants determined by electrochemistry and by NMR spectroscopy for the binding of anilines **3** to $[Co^{III}(salen)]^+$ in dimethylformamide (dmf), a solvent commonly used for oxygenation reactions. The kinetics and thermodynamics of the binding of these substrates to the catalyst may play an important role in the oxygen transfer reaction.

3

a	R=N(CH$_3$)$_2$	**e**	R=Cl
b	R=OCH$_3$	**f**	R=Br
c	R=CH$_3$	**g**	R=CF$_3$
d	R=H	**h**	R=NO$_2$

In dmf the Co^{III} complex, present as $[Co^{III}(salen)(dmf)_2]^+$, is reduced in a quasi-reversible one-electron transfer (formal potential $E^0 = -0.450 \pm 0.007$ V, cyclic voltammogram[7] in Fig. 1a, curve 1). If 4-methoxyaniline (**3b**) is added (Fig. 1a, curve 2, and Fig. 1b) a further reduction peak appears ($E_p \approx -0.7$ V). The intensity of the original peak ($E_p \approx -0.5$ V) is greatly decreased already for a deficit of aniline compared to the complex (Fig. 1a, curve 2), and with a tenfold excess (Fig. 1b, curve 1) this peak disappears. At the same time a new reduction peak at $E_p \approx -1.0$ V appears, which, with a 30-fold excess of aniline, dominates the voltammogram (Fig. 1b, curve 2). In these voltammograms, the oxidation peak remains virtually unchanged.

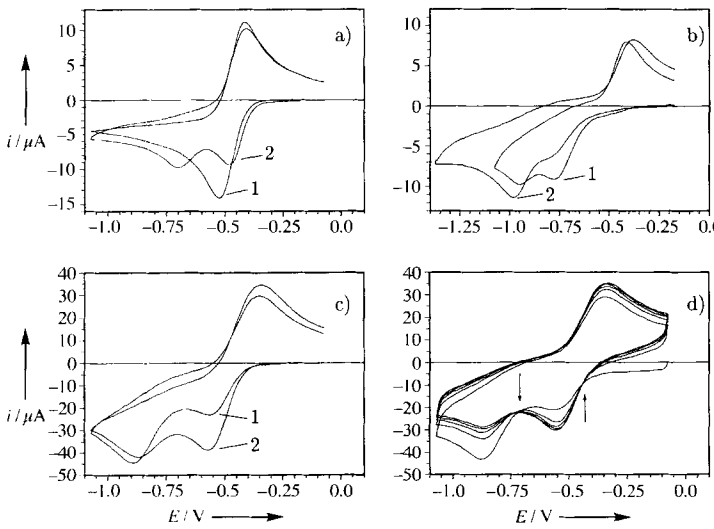

Fig. 1. Cyclic voltammograms of **2**-ClO_4 in dmf. a) Before (curve 1) and after addition of **3b** ($c = 0.24$ mM) (curve 2): c(complex) = 0.45 mM, $v = 0.5$ Vs^{-1}. b) After addition of **3b** [curve 1: $c = 5.02$ mM; curve 2: $c = 15.02$ mM]; c(complex) = 0.45 mM, $v = 0.5$ Vs^{-1}). c) After addition of **3b** [curve 1, c(complex) = 0.75 mM] and **3c**, respectively [curve 2, c(complex) = 0.79 mM]; c(aniline) = 0.75 mM, v = 5.1 Vs^{-1}. d) Current/potential curve with isopotential points (arrows), c(**3b**) = 0.39 mM, c(complex) = 0.73 mM, $v = 5.1$ Vs^{-1}, multicycle experiment.

This behavior is consistent with the presence of a ladder scheme for the exchange of dmf by **3b** [Scheme 1 (L^1 = dmf, L^2 = **3b**)]. As the concentration of **3b** increases, the equilibria on the right-hand side of Scheme 1 shift from top to bottom; starting from $[Co^{III}(salen)(dmf)_2]^+$, a mixed complex $[Co^{III}(salen)(dmf)(\mathbf{3b})]^+$ (reduction at -0.7 V), and then a bis(aniline) species $[Co^{III}(salen)(\mathbf{3b})_2]^+$ (reduction at -1.0 V) are observed. As in the case of the solvent system dmf/pyridine[1] the exchange reactions for the Co^{II} complexes are fast and their equilibria are shifted less to the side of complexes containing L^2. Therefore, because of the large excess of dmf compared to **3b** we find only *one* oxidation peak, which corresponds to the electron transfer $[Co^{II}(salen)(dmf)_2] - e^- \rightarrow [Co^{III}(salen)(dmf)_2]^+$. As in the case of dmf/pyridine, isopotential points are observed here (Fig. 1d). Thus reactions apart from those constituting the ladder scheme can be excluded.[1] Experiments with a number of substituted anilines resulted in analogous cyclic voltammograms. However, it can be seen from Figure 1c that for example 4-methylaniline (**3c**) (curve 2) under almost identical concentration conditions is less strongly bound than **3b** (curve 1).

The ratios of the reduction peak currents in the cyclic voltammograms are independent of the experimental time scale when the sweep rates are larger than $v = 2.0$ Vs^{-1}. Here, the rate of the reactions in the Co^{III} oxidation state is already so small compared to v that the peak currents are measures of the equilibrium concentrations of the individual species. The concentration of free aniline can be determined from its oxidation peak current at more positive potentials (not shown in the cyclic voltammograms in Fig. 1). These concentrations were used to determine the equilibrium constants according to Equation (a)

$$K^{III}_{dmf/dmf,\,3} = \frac{c([Co^{III}(salen)(dmf)(\mathbf{3})]^+) \cdot c(dmf)}{c([Co^{III}(salen)(dmf)_2]^+) \cdot c(\mathbf{3})} \qquad (a)$$

(Table 1)[8] [c(dmf) = 13.0 M]. Nearly all the investigated anilines are capable of displacing dmf from the complex. However, in the case of R = CF_3 (**3g**) the bonding is weak, and for R = NO_2 (**3h**) complexation cannot yet be detected even with an

Table 1. Equilibrium constants for the exchange of axially bound dmf on **2** by anilines **3a**-**3g**.

Aniline	$K^{III}_{dmf/dmf,\,3}$ [a]	$K^{III}_{dmf/dmf,\,3}$ [b]	$K^{III}_{3/dmf,\,3}$ [b]
3a	$2.7 \pm 0.2 \times 10^5$

excess of **3h/2** of roughly 100. Values for the equilibrium constants for the exchange of the second dmf molecule by **3** cannot be obtained from the cyclic voltammograms because several currents are superimposed.

The exchange of the solvent molecules by anilines was also investigated by ^{1}H NMR spectroscopy for three examples (**3b**, **3c**, **3f**).[9] Four species may be present simultaneously in solution: $[Co^{III}(salen)([D_7]dmf)_2]^+$, $[Co^{III}(salen)([D_7]dmf)(\mathbf{3})]^+$, $[Co^{III}(salen)(\mathbf{3})_2]^+$ and free **3**. By recording spectra of solutions of the components **2** and **3** (each separately in $[D_7]$dmf) as well as of solutions with various concentration ratios between **2** and **3**, all the ^{1}H NMR signals can be assigned to the respective species.

Figure 2 shows the changes in the ^{1}H NMR spectra in the regions of the N=CH protons (Figs. 2a–c) and the protons of

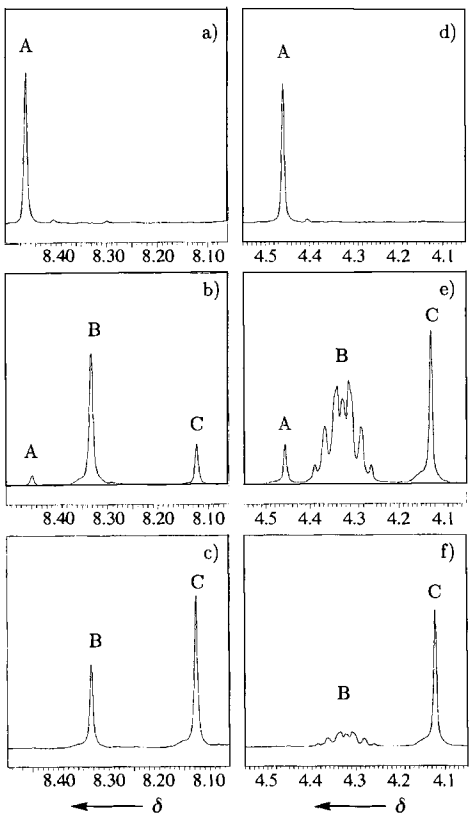

Fig. 2. Parts of the ^{1}H NMR spectra of **2**-ClO_4 in $[D_7]$dmf. a) and d) Without added **3b**; b) and e) concentration ratio **2**:**3b** = 1:1.18; c) and f) concentration ratio **2**:**3b** = 1:1.81.

the ethylene bridge (Figs. 2d–f) in the salen ligands with different concentrations of **3b**. Initially, the azomethine protons give rise to only one signal (δ(A) = 8.45, bis($[D_7]$dmf) complex), while at higher concentrations of **3b** several singlets are observed. The intensity of signal B (δ = 8.33, mixed complex) increases and then decreases, whilst signal C (δ = 8.13, $[Co^{III}(salen)(\mathbf{3b})_2]^+$) becomes more intense with increasing aniline concentration. The signals of the H atoms of the ethylene bridge behave analogously. In the spectrum of the mixed complex, in contrast to the other species, however, there is a multiplet (AA'BB' system). Similar multiplets were observed for Co^{III} Schiff base complexes substituted with two different axial ligands.[10, 11] We explain this coupling pattern in $[Co^{III}(salen)(dmf)(\mathbf{3})]^+$ by a nonplanar, flexible conformation of the N-CH_2-CH_2-N bridge in the salen ligand. We obtained analogous spectra for **3c** and **3f**.

The integration of the signals in the ^{1}H NMR spectra and the total weighted amounts of **2**-ClO_4 and **3** were used to determine the amounts of the equilibrium partners present, and from those the equilibrium constants (Table 1). The values obtained for $K^{III}_{dmf/dmf,3}$ are in very good agreement with those determined electrochemically. In addition, we succeeded in evaluating $K^{III}_{3/dmf,3}$, the equilibrium constant for the exchange of the second solvent molecule by **3**. The values for $K^{III}_{3/dmf,3}$ are smaller than the values of $K^{III}_{dmf/dmf,3}$ by several orders of magnitude (see Table 1) due to statistical[12] and electronical reasons.

The equilibrium constants $K^{III}_{dmf/dmf,3}$ determined electrochemically correlate linearly with the σ_p substituent constants:[13] $K^{III}_{dmf/dmf,3} = 3.64 - 3.28\,\sigma_p$ (r = 0.984). The σ_p^- and the σ_p^0 series give—in contrast to σ_p^+—only slightly inferior correlations. The more electron-rich the aniline, the more sucessfully it can displace dmf from the $Co^{III}(dmf)_2$ complex. However, the effect is not completely parallel to the basicity of the anilines which, at least in water, is best represented by the σ_p^- constants.[14]

Therefore, we have succeeded in characterizing the thermodynamics of the interaction of $[Co^{III}(salen)]^+$ **2** with anilines **3** by two methods and have obtained concurrent results. The displacement of dmf by **3**, as given by the equilibrium constants found here, is part of the ladder scheme which is decisive for the redox reactions of [Co(salen)] **1** in dmf in the presence of anilines. The exchange of ligands considerably shifts the redox potentials of the complexes. Although at least the electrochemical experiments were conducted with exclusion of oxygen, the results are also fundamental for the comprehension of oxygenation reactions with Co Schiff base catalysts. Redox reactions at the Co center are part of the oxygenation.[15] Basic axial ligands favor the complexation of oxygen thermodynamically.[4, 16] Furthermore, axially bound bases increase the rate of the O_2 uptake by Co–tetrahydrosalen complexes with simultaneous dehydrogenation.[17] Finally, the ease with which the anilines coordinate to $[Co^{III}(salen)]^+$ **2** in dmf is parallel to the ease and yield of their preparative oxygenation.[18] Thus the reaction steps characterized here must be a central part of the oxygenation mechanism.

$(Nb,Ta)_9(S,Te)_5$, a Metal-Rich Chalcogenide with a Microporous Metal Substructure**

Thomas Degen and Bernd Harbrecht*

Niobium and tantalum form several metal-rich chalcogenides of complex structure. Compounds such as $Nb_{21}S_8$,[1] Nb_5Se_4,[2] or Ta_6S[3] have been known for many years; others such as Ta_6S (triclinic),[4] Ta_3S_2,[5] Ta_2Se,[6] $Nb_{4.7}Te_5$,[7] Ta_2Te_3,[8] and Ta_6Te_5[9] have been characterized very recently. A striking feature of these compounds is the structural heterogeneity which, as a matter of fact, is not only due to variation in composition. The pronounced variety is also based on the fact that the structures of the sulfides, selenides, and tellurides differ significantly, as do the structures of the niobium- and tantalum-rich chalcogenides. Thus, compounds with the same number of valence electrons, for example Ta_2S,[10] Ta_2Se,[6] and Nb_2Se,[11] form unique structures. Whereas the metal partial structure of the sulfide comprises interpenetrating and interconnecting Ta_{13} icosahedra, the structures of the selenides contain fragments of the metal bcc structure. Such bcc fragments extend in three dimensions in Nb_2Se, but are confined to two dimensions in Ta_2Se.

The structural diversification caused by both components, metal and chalcogen, evidently holds a remarkable potential for syntheses: Structurally modified phases such as $Ta_{6-x}V_xS$,[12] $AuTa_5S$,[13] or $Ta_2S_{1-x}Se_x$[14] are accessible by partial substitution at the metal or chalcogen atom sites in phases of known stoichiometry. Moreover, ternary phases of new compositions and structural types such as $Au_xTa_{15-x}S_2$,[13] $Ta_n(S,Se)_4$ ($n = 9$, 10),[14b] and $(Nb,Ta)_nS_4$ ($n = 10-12$)[15] have been characterized. In some cases such phases exhibit only small, islandlike homogeneity ranges in the three-component systems. Here we report a new phase[16] existing in the quaternary system Nb-Ta-S-Te. It is formed by reduction of a mixture of niobium dichalcogenides by the elemental metals in sealed tantalum ampoules (1870 K to 1470 K, 12 h). The phase occurred in form of a black wad containing a few needles, up to 50 μm thick. EDX analyses proved that the needlelike crystals and the fibrous product of a batch do not noticeably differ in composition. Phases of different batches had nearly constant ratios n_S/n_{Te} (about 2) even when starting mixtures containing equimolar amounts of dichalcogenides were used. In contrast, the metal ratios n_{Nb}/n_{Ta} could vary significantly: examples so far varied from about 1 to 3.

The structure[17] (Fig. 1) contains—like numerous structures of niobium-rich chalcogenides and pnictides—fragments of the bcc arrangement of the element (see Fig. 2). A striking new feature is that those complex columnar bcc fragments (Fig. 1, bottom) are connected through extended metal-metal bonding regions—indicated by numerous M–M distances in the range of 283–342 pm—to a remarkable microporous metal partial structure. The remaining valences on the inner surfaces of the pores are saturated by chalcogen atoms. In accord with their surface-covering function, these chalcogen atoms are coordinated on one side by four, five, or six metal atoms. The chalcogen atoms themselves enclose channels that in principal could serve as hosts for small metal atoms.

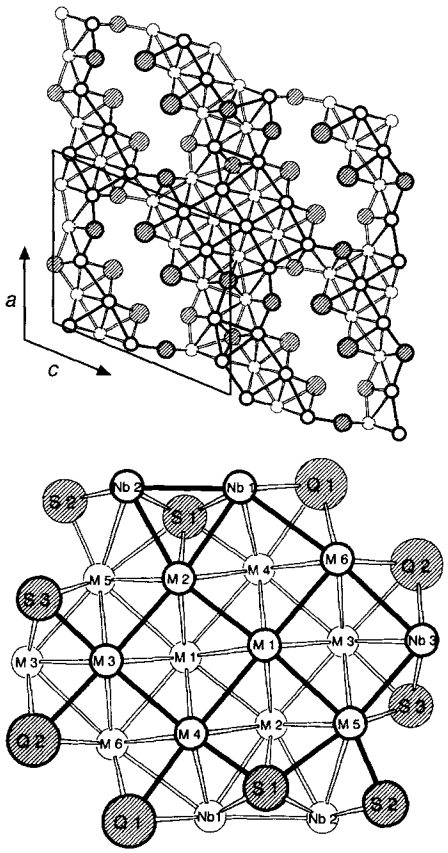

Fig. 1. Section of the structure of $(Nb,Ta)_9(S,Te)_5$ shown as a projection along *b*. Top: Four unit cells. Bottom: Double asymmetric unit. All atoms are in mirror planes perpendicular to *b* at $y = 1/4$ and 3/4 modulo 1; atoms from neighboring layers are symmetry-related by 2_1 screw axes; different depths are indicated by outlines of different thickness for the circles; for occupation factors of the positions M1–M6 and Q1, Q2 with mixed occupation, see text.

The seemingly arbitrary coordination figures of the chalcogenides are based on a common construction principle: They are fragments of a tetrakaidecahedron, a regular body with 14 planes, built up of nine metal atoms located at the vertices of a tricapped trigonal prism. In accordance with the topological concept that was developed for the boranes,[18] the coordination figure about S3 (see Fig. 1, bottom) with the coordination number six (average distance: 254.5 pm) is a *hypho* fragment. The polyhedra that cover the five-coordinate positions with mixed occupation represented by the symbols for chalcogens Q1 (80(1)% Te, 20% S, 291.1 pm) and Q2 (74(1)% Te, 26% S, 289.3 pm) correspond to

a sub-*hypho* fragment. S2 is only fourfold coordinated (249.2 pm). S1 has a special function playing a decisive role in the aggregation of the bcc fragments. The nine surrounding metal atoms (262.1 pm) form a *closo*-cluster which is otherwise found only in the most metal-rich sulfides, for example $Au_xTa_{15-x}S_2$ (265.6 pm).[13] As expected, the average distances correlate with the coordination numbers of the chalcogen atoms and for a given coordination geometry, reflect slight differences in S/Te occupations. Neighboring chalcogen atoms (shortest distances: 339.8 pm (S2–S3), 341.6 pm (*b* lattice constant)) are in van der Waals contact.

The analysis of electron density leads to two (out of five) chalcogen positions with mixed occupation (Q1, Q2) if we assume that all 14 distinct positions are fully occupied. At the metal sites, six (M1–M6) out of nine are statistically occupied. Nevertheless the specific distribution of the metal atoms is more likely driven by a minimization of enthalpy than by maximization of entropy. Like in the case of the mixed sulfides $(Nb,Ta)_nS_4$,[5] tantalum preferably accumulates at the central positions of the bcc fragments, in accordance with its cohesive energy that is higher than that of niobium. M1 at the center, most enriched with tantalum (67.4(9)%), is surrounded primarily by metal atoms only (six plus eight). The chemically similar atoms M2 (50.5(9)%), M3 (49.1(9)%), and M4 (48.7(9)%) each have two chalcogen atoms in the 14-fold coordination. Considerably less tantalum is found at M5 (24.3(9)%) and M6 (9.6(9)%). At these sites, 4 out of 14 and 13 neighbors, respectively, are chalcogen atoms. Nb1 and Nb3 occupy peripheral positions of the bcc fragments. They are, like Nb2, primarily coordinated by five chalcogen atoms.

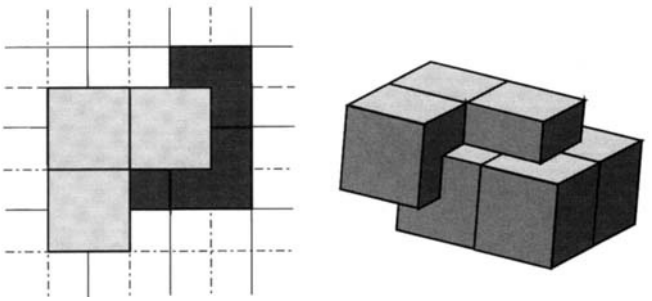

Fig. 2. Schematic representation of the columnar bcc fragments of $(Nb,Ta)_9(S,Te)_5$ as sections of 4^4 nets (left) and interpenetrating cubes (right).

Because of the larger number of Nb–Q contacts, such a partitioning pattern is also favored if the affinity of chalcogen is larger toward niobium than toward tantalum. This sequence in the affinities is also indicated by the higher decomposition pressure above Ta_2S/Ta_6S than above $Nb_{21}S_8/Nb_{14}S_5$ at a given high temperature.[19] Extended Hückel calculations, however, point to stronger Ta–S interactions than Nb–S interactions.[20] If these calculations were correct and if the M–Q interactions were the deciding factor for the occupation, tantalum should accumulate at the periphery of the fragments. All results known so far reject this distribution (see also ref. [15]). The partition of the metal atoms is obviously dominated by the differences between the cohesive energies of the metals.

The compound $(Nb,Ta)_9(S,Te)_5$ gives rise to the idea that phases with more marked, perhaps even zeolite-like, porosity may be hidden in the metal-rich regions of multicomponent chalcogen-containing systems. We think it is worthwhile to track down such phases.

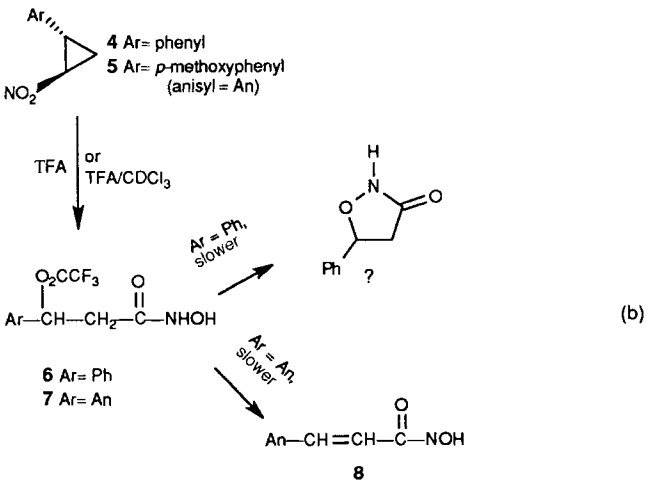
Formation of Nitronic Acids by Ring Opening of Nitrocyclopropanes by a Concerted, Acid-Catalyzed Mechanism**

Weiguo Cao, Ihsan Erden,* and James R. Keeffe*

Tautomerism of aldehydes, ketones, and nitroalkanes has played a central role in the development of our ideas about acid- and base-catalyzed reactions. Unlike the interconversion of keto and enol isomers, the nitroalkane–nitronic acid prototropy is not acid-catalyzed;[1] this is presumably a consequence of the very poor basicity of the nitro group coupled with its ability to permit C–H cleavage by bases as weak as water itself.[2]



Recently we reported on the formation of nitronic acids from nitroalkanes **1**–**3** under acid catalysis.[3] In these reactions [Eq. (a)] the departing electrofuge is not a proton, but the highly

(a)

stable tropylium cation (Tr^+), which can depart from the protonated nitroalkane in a unimolecular fashion (no base needed).

In this communication we show that relief of ring strain is a powerful factor which also enables acid-catalyzed cleavage of a C–C bond in nitroalkanes. Compounds **4** and **5** undergo ready ring opening at or below room temperature in CF_3CO_2H (TFA), or (more slowly) in 4 M TFA in $CDCl_3$,[4] to give the products shown in Equation (b).

(b)

Compounds **6**–**8** were synthesized independently and subjected to the reaction conditions. The ^1H NMR spectra of these synthesized compounds were identical to the spectra of the reaction solution corresponding to Equation (b) and also indicated the slower formation of secondary products from **6** and **7**.[5] The spectra for reactions in deuterated and non-deuterated TFA were identical. Even after the starting material had disappeared, there was no evidence of deuterium incorporation, as would be found if protonation of the cyclopropane ring had occurred.[6] Hydroxamic acids are, in fact, the products expected from the generation of nitronic acids, $RCH{=}NO_2H$, in strongly acidic media.[1, 3, 7]

Compound **5** reacts with TFA much more rapidly than **4** does. The reaction of **4** in TFA and in 4 M TFA in $CDCl_3$ showed excellent first-order kinetics.[8] The rate constants for the reaction of compounds **1**–**5** are listed in Table 1. Although it was

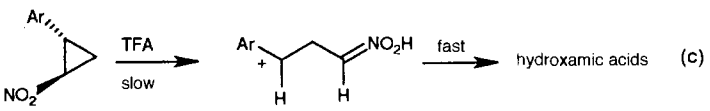


Table 1. Rate constants k for acid-catalyzed cleavage of tropylnitroalkanes **1**–**3** and 1-nitro-2-arylcyclopropanes **4** and **5** in CF_3CO_2H.

Compound	$k \times 10^3$ [s^{-1}] TFA	T [°C]	$k \times 10^3$ [s^{-1}] 4 M TFA/$CDCl_3$	T [°C]
1	0.0335 [a]	25	–	–
2	0.590 [a]	25	–	–
3	11.8 [a]	25	–	–
4	1.08, 0.51 [b]	18–20	0.0117	18–20
5	–	18–20	>23	18–20

[a] Ref. [3]. [b] In [D]TFA corrected for contribution from 2 mol% TFA.

not possible with our NMR method to determine accurately the rate of reaction of **5**, we could obtain a lower limit in the TFA/$CDCl_3$ medium. The rate constant of **5** is more than 2000 times greater than that of **4**, which allows an estimate of the reaction constant, $-\rho^+ \geq 4$. ρ values of this magnitude are common for reactions leading to carbocation-like transition states from tetracoordinate precursors.[9]

A solvent kinetic hydrogen isotope effect $k_{TFA}/k_{[D]TFA}$ of 2.1 ± 0.1 was determined for the reaction of **4**. Based on this result and the large *para*-substituent effect, we propose that protonation of the nitro group and cleavage of the C1–C2 bond are *concerted* [Eq. (c)]. As in aqueous solutions, preequilibrium

(c)

protonation followed by a rate-controlling step, is revealed in TFA by an inverse solvent kinetic isotope effect.[10] To the best of our knowledge no other examples of protonation at a heteroatom concomitant with C–C bond cleavage have been demonstrated. We suggest that relief of ring strain enabled by incipient protonation is the causal factor.

Experimentally observed primary kinetic isotope effects for proton transfer between heteroatoms are not common, but have been reported by several groups.[11] Maxima in k_H/k_D ranging from roughly 2.5 to 4.3 have been found; such maxima appear to require a close match of the pK_a values of the proton donor and acceptor. The magnitude of the effect drops off rapidly as ΔpK_a deviates from the optimum. These smaller values signify either a variable isotope effect on the proton transfer step itself and/or partial rate control by preceeding or succeeding steps: encounter and association of reactants, or separation of the

conjugate acid/conjugate base pair. At first glance it does not appear that the pK_a values can be similar in the present case. A protonated nitroalkane should be much more acidic than TFA. We postulate that nitrocyclopropanes, especially if activated by donors at C2, are effectively more basic than expected owing to electron release from the C1–C2 bond. Since this mode of release opens the ring, protonation produces a nitronic acid rather than a protonated nitroalkane. The transition state might be further stabilized by interaction at C2 with the solvent. In another scenario the transferred proton is not part of the reaction coordinate but always lies in a stable potential well.[12] A hydrogen-bonded TFA–nitrocyclopropane complex first forms, then the C1–C2 bond starts to break. During the bond cleavage the NO_2 oxygen atoms become more basic until the pK_a values of the donor and acceptor nearly match. The proton then moves to the NO_2 group in an altered hydrogen-bonded complex. The isotope effect arises as a consequence of a reduced zero-point energy difference for the hydrogen bond in the transition state relative to that in the initial TFA–nitrocyclopropane complex.[13]

Semiempirical MO calculations (AM1[14] and PM3[15]) support the possibility of a concerted ring opening for **4** and **5**. Although conjugate acids $\mathbf{4H^+}$ and $\mathbf{5H^+}$ are found to be stable, transition states for the succeeding reaction are only 2.5–3.9 kcal mol^{-1} higher in energy. By contrast cleavage of protonated tropylnitroalkanes $\mathbf{1H^+}$–$\mathbf{3H^+}$ is calculated to require another 12 kcal mol^{-1} of activation.

Finally, we wish to quantify the effect of ring strain in these C–C heterolyses. Despite the enormous difference in stability between tropylium ion ($pK_R^+ = 4.7$)[16] and $PhCHR^+$ (estimated $pK_R^+ = -15.3$),[9] compounds **2** and **4** react with TFA at similar rates to yield monoalkylnitronic acids $RCH{=}NO_2H$ (Table 1). The ΔpK_R^+ of approximately 20 units corresponds to 27 kcal mol^{-1} at room temperature, which is also the strain energy of a cyclopropane ring.[17] The two compounds present an interesting case in which the development of carbocation character at the transition state, a factor favoring the reaction of **2**, is almost exactly balanced by relief of ring strain favoring **4**!

A Li_2Ti_2-Substituted Acetylene Formed from Ethylene by Reaction with (*meso*-Octaethylporphyrinogen)titanium**

Stefania De Angelis, Euro Solari, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

The chemistry of metal carbides is dramatically expanding in a number of directions.[1] These compounds include those in which linear carbon chains bridge different organometallic building blocks.[2] In particular, complexes with a C_2 bridge, which can be obtained readily from acetylene,[3] are a rapidly developing class of compounds.[4] We report here the one-step synthesis of a complex with C_2 bridge directly from ethylene. The "naked" C_2 unit is confined in a square-planar array of two titanium and two lithium cations supported by two *meso*-octaethylporphyrinogen tetraanions ($Et_8N_4^{4-}$).[5] The starting material $[Et_8N_4Ti(thf)_2]$ **1** was obtained by the established procedure[5] according to Equation (a) and its structure shown in Figure 1.[6]

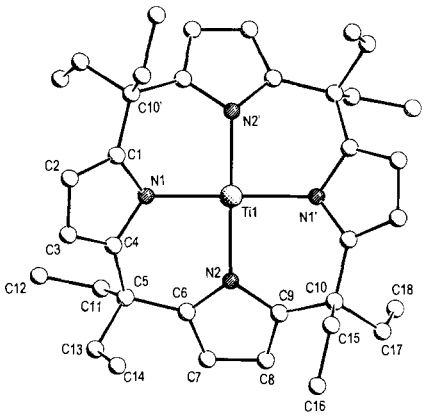

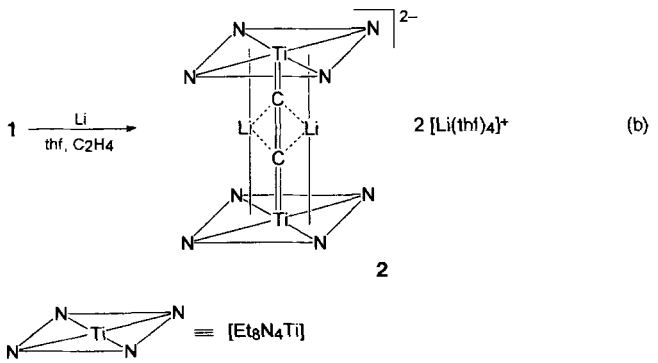

Fig. 1. Crystal structure of complex **1** (SCHAKAL). Selected bond lengths [Å] (O1 and O2 are the oxygen atoms on the axial thf ligands on Ti1 which are not shown): Ti1-O1 2.113(3), Ti1-O2 2.091(3), Ti1-N1 2.036(2), Ti1-N2 2.034(2). Selected bond angles [°]: N1-Ti1-N2 89.9(1), O1-Ti1-O2 180.0(1), N2-Ti1-N2' 178.6(11), N1-Ti1-N2' 90.1(8), N1-Ti1-N1' 178.6(11). Primed atoms derived by a transformation of 0.5 $- x, y, -z$.

The complex possesses a crystallographically imposed C_2 axis passing through the titanium cation and the oxygen atoms of the two thf molecules. The η^1-η^1-η^1-η^1-bound porphyrinogen[5g] has a saddle-shaped conformation; the pyrrole rings are tilted up and down alternately relative to the N_4 core, forming dihedral angles of 149.5(1)° and 149.8(1)° for N1,C1–C4 and N2,C6–C9, respectively. The Ti–N bond lengths are in the lower end of the range found for Ti^{IV}–N bonds in such compounds.[5]

Reduction of **1** in thf under a C_2H_4 atmosphere with an excess of Li metal at room temperature led to the formation of red crystals of **2** [Eq. (b)]. This reaction may have promise as a

general route to metal carbides or μ-hydrocarbon complexes directly from the corresponding hydrocarbon skeleton. Complex **2** is a paramagnetic species with $\mu_{eff} = 1.80\ \mu_B$ per titanium center at 290 K. The lithium cations are sandwiched between two $[Et_8N_4Ti]$ moieties (A and B; the values referring to the B moiety are given in square brackets) in which the titanium centers are bound through σ bonds to all the pyrrolyl rings (Fig. 2).[8] This arrangement creates a square-planar Li_2Ti_2[9] array about the C_2 unit. The titanium centers lie out of the N_4 mean plane by 0.585(2) Å [0.563(2) Å]. The two N_4 planes are parallel (dihedral angle 0.8(2)°) and rotated with respect to each other by 18.5(2)°. The Ti1A-C37-C38-Ti1B vector is perpendicular to the N_4 planes, and the dihedral angle it forms with the normal to the N_4 plane is 1.0(2)° [1.3(1)°]. The Ti–N distances within the porphyrinogen complex are significantly longer (Ti–N_{av} 2.120(5) Å) that those in **1** (2.033(2) Å) for the same

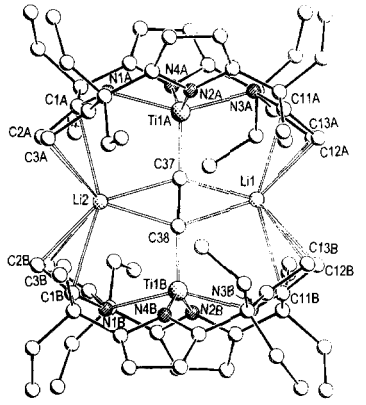

Fig. 2. Crystal stucture of the anion in complex **2** (SCHAKAL). Disorder omitted for clarity. Bond lengths [Å] for the A [B] unit: Ti1A-C37 1.809(9), Ti1B-C38 1.757(7), Li1-C37 2.221(25), Li1-C38 2.292(25), Li2-C37 2.304(25), Li2-C38 2.266(24), C37-C38 1.301(11), Ti1-N1 2.113(9) [2.115(10)], Ti1-N2 2.127(11) [2.133(10)], Ti1-N3 2.115(9) [2.140(10)], Ti1-N4 362.122(11) [2.091(12)]. Bond angles [°]: Ti1A-C37-C38 178.7(9), Ti1B-C38-C37 178.7(8).

bonding mode of the ligand. The lithium cations are bound η^3-fashion to both porphyrinogen moieties[5] (assuming that interactions for distances greater than 2.8 Å can be disregarded).[10] The major feature in the structure is the Ti-C-C-Ti skeleton, which is linear within experimental error. The Ti–C bonds (1.809(9) and 1.757(7) Å) are much shorter than those in the Ti–C≡C–R fragments in both **3**[11] [Ti–C, 2.056(11) Å] and **4**[12] [Ti–C 2.051(2) Å]. Consequently the C–C bond length

$[\{Cp_2Ti-C\equiv C-SiMe_3\}_2]$ **3**

$[Cp_2(Me_3P)Ti-C\equiv C-Ti(PMe_3)Cp_2]$ **4**

[C37–C38 1.301(11) Å] is significantly longer than in complexes **3** [1.253(15) Å][11] and **4** [1.253(2) Å][12] and in many other complexes with bridging acetylide ligands. The bond lengths we determined are much closer to those expected for a sequence of double bonds.[4] Curiously, the magnetic moment of **2** is much better accounted for by a bridging acetylide. We should emphasize that this sort of bridging C_2 unit is unprecedented in metal complexes of macrocycles, although related C_1 bridges in porphyrin[13a] and phthalocyanine complexes[13b] are known.

The formation of **2** can be interpreted as a consequence of both the very electron-rich nature of the titanium under the reducing conditions employed and the coordination environment, since the bifunctional porphyrinogens can bind the lithium cation at their periphery.[5] Both of these factors are believed to contribute to the stabilization of the C_2 unit. The extension of such synthetic methods to complexes with bridging hydrocarbon species and explorations of the chemistry of the C_2 moiety is in progress.

Experimental Procedure

1: $[TiCl_4(thf)_2]$ (8.90 g, 26.8 mmol) and $[Et_8N_4Li_4(thf)_2]$ [6] (22.88 g, 2.68 mmol) were added to toluene (350 mL). The resulting dark green-black solution was stirred at room temperature for 1 d, then LiCl was removed by filtration. After evaporation of the solvent and trituration of the residue with pentane (120 mL) a dark green solid was filtered off and dried in vacuo (12.0 g, 62%). Recrystallization from benzene gave crystals suitable for X-ray analysis. Anal. calcd for $C_{44}H_{64}N_4O_2Ti$: C 72.50, H 8.85, N 7.69; found: C 72.69, H 8.93, N 7.89; ^1H NMR (C_6D_6, 25 °C): δ = 5.98 (s, 8H, C_4H_2N), 3.40 (m, 8H, thf), 1.93 (q, 16H, CH_2), 1.18 (m, 8H, thf), 0.90 (t, 24H, CH_3).

2: Lithium sand (0.100 g, 14.0 mmol) was added to a solution of **1** (2.40 g, 3.30 mmol) in thf (100 mL) under ethylene, and the mixture was stirred at room temperature for 3 d. After removal of excess lithium from the dark red solution, the solvent was evaporated and the residue triturated with *n*-hexane (30 mL) and collected (1.3 g, 44%). Recrystallization of the powder from thf/*n*-hexane gave crystals suitable for X-ray analysis. Anal. calcd for $C_{53}H_{80}Li_2N_4O_4Ti$: C 70.78, H 8.97, N 6.23; found: C 70.33, H 9.50, N 6.48.

Electrochemistry and Ab Initio Study of the Dimetallofullerene $La_2@C_{80}$**

Toshiyasu Suzuki,* Yusei Maruyama, Tatsuhisa Kato, Koichi Kikuchi, Yasuhiko Nakao, Yohji Achiba, Kaoru Kobayashi, and Shigeru Nagase*

Metallofullerenes are fullerene derivatives that contain some metals inside their cages.[1] Although their structures, including the cage structures and the positions of the metals, have not yet been determined, the recent development of methods for purifying metallofullerenes allows more advanced studies of these new molecules.[2–10] Theoretical calculations suggest that their electronic structures are significantly changed by electron transfer from highly electropositive metals to the electronegative carbon cages.[11, 12] Very recently, we reported that $La@C_{82}$ and $Y@C_{82}$ showed almost identical electrochemical properties,[6, 7] in accord with the ab initio calculations.[12e] It is interesting to see how redox properties of the metallofullerene change when *two* lanthanide atoms are present in the cage. Encapsulating two lanthanide atoms is expected to result in an increase in total charge transfer from the two metals to the cage and in the interaction between the two metals. Since the first detection of $La_2@C_{80}$ by mass spectrometry in 1991,[13] there has been little information about the electronic structure. Unlike $La@C_{82}$, $La_2@C_{80}$ is EPR-silent. We report here the electrochemistry of $La_2@C_{80}$, which significantly differs from those of empty fullerenes and monometallofullerenes, and the ab initio study of $La_2@C_{80}$ at the HF level.

$La_2@C_{80}$ was obtained as a by-product in the synthesis of $La@C_{82}$ and isolated in pure form by HPLC.[14] The cyclic voltammogram (CV) of $La_2@C_{80}$ in 1,2-dichlorobenzene shows two reversible oxidations and two reversible reductions (Fig. 1 and Table 1). The differential pulse voltammogram (DPV) displays four well-defined peaks with the same current intensities as well as an additional ill-defined peak at -2.13 V (Fig. 1).

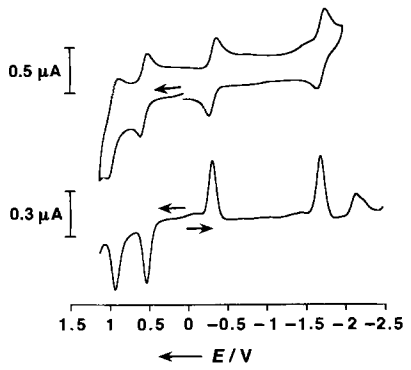

Fig. 1. CV (top) and DPV (bottom) of $La_2@C_{80}$ at 20 mVs^{-1} in 1,2-dichlorobenzene containing 0.1 M nBu_4NPF_6.

When the CV scan is continued beyond this potential, the second reduction also becomes irreversible. The first reduction potential of $La_2@C_{80}$ is anodically shifted relative to those of $La@C_{82}$-A[6] and -B[8] (major and minor isomers, respectively), suggesting that the dimetallofullerene is a stronger electron acceptor than the monometallofullerenes (Table 1). The first oxidation potential of $La_2@C_{80}$ is much more anodic than those of $La@C_{82}$-A and -B, implying that $La_2@C_{80}$ is a weaker electron donor than the $La@C_{82}$ isomers.[15] Also, $La_2@C_{80}$ has a remarkably narrow HOMO–LUMO gap compared to the empty fullerenes such as C_{60}[16] and C_{76}[17] ($E_{ox}1-E_{red}1$: $La_2@C_{80}$, 0.87; C_{60}, 2.33; C_{76}, 1.75 V).

Table 1. Redox potentials of metallofullerenes and empty fullerenes[a].

Compound	$E_{ox}2$	$E_{ox}1$	$E_{red}1$	$E_{red}2$	$E_{red}3$	$E_{red}4$

[a] Half-cell potentials unless otherwise stated. Values are in volts relative to ferrocene/ferrocenium couple. [b] Irreversible. Values were obtained by DPV. [c] Two-electron process.

To understand the redox behavior of $La_2@C_{80}$, we carried out ab initio theoretical calculations.[18] Among the seven C_{80} isomers that obey the isolated-pentagon rule,[19] we chose the most symmetrical cage structure, I_h-C_{80}, which was first proposed by Whetten et al.[15] As shown in Figure 2, the La_2 dimer is placed inside the I_h-C_{80} cage along the C_2 axis that passes through the centers of two six-membered rings. This endohedral structure has D_{2h} symmetry. The Hückel molecular orbital calculations suggest that I_h-C_{80} has fourfold degenerate HOMOs occupied by two electrons and fourfold degenerate LUMOs.[20] In Figure 3, two electrons are added to the a_g orbital for convenience. In the ab initio calculations, the energy level of the a_g orbital becomes lower than those of the other three orbitals (b_{1g}, b_{2g}, and b_{3g}).[21] Upon endohedral doping, the HOMOs are fully occupied by six electrons from La_2 and stabilized at a La–La distance of 3.45 Å. Because the LUMO levels of C_{80} are not significantly affected by endohedral doping, the low-lying empty $6s\sigma_g$ orbital of La_2 becomes the LUMO of $La_2@C_{80}$. Interestingly, this is not the case for $La@C_{82}$, in which the energy levels of the empty 5d and 6s atomic orbitals are higher than those of the unoccupied orbitals derived from the C_{82}.[12a] Upon electroreduction of $La_2@C_{80}$, the first electron goes to the LUMO (a_g) which is mostly localized on La_2. This process is favored, and the a_g orbital is lowered from −2.6 to −4.4 eV. The first reduction potential observed is very positive because the energy level of the LUMO is relatively low. The second electron goes to the same orbital (a_g), and not to b_{2u} or b_{3u}. This process costs much energy because of the unfavorable electrostatic repulsion between the two electrons on the LUMO.[22] Unlike electroreduction, the oxidation processes would take place on the C_{80} cage. The electron–electron repulsion is expected to be larger on the relatively small La_2 orbitals than on the delocalized fullerene orbitals. This may explain why the potential difference between the two reductions is much larger than that between the two oxidations (1.40 and 0.39 V, respectively).

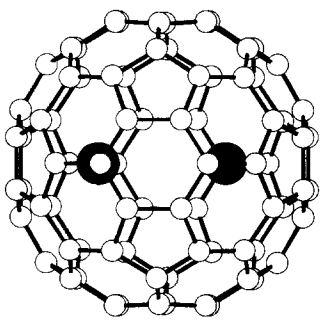

Fig. 2. View of $La_2@C_{80}$ with the I_h-C_{80} cage.

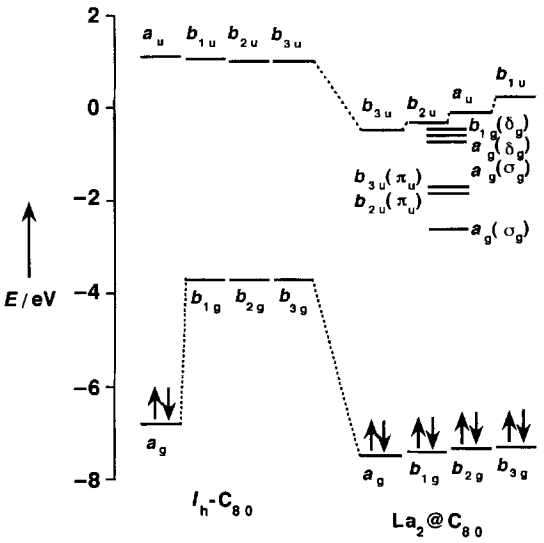

Fig. 3. The orbital energy levels [eV] of I_h-C_{80} and $La_2@C_{80}$ at the HF level..

In summary, in the first electrochemical study of the pure dimetallofullerene we have shown that $La_2@C_{80}$ is a stronger electron acceptor than monometallofullerenes such as $La@C_{82}$-A and -B and has a remarkably narrow HOMO–LUMO gap compared to empty fullerenes. The theoretical calculations predict that upon electroreduction, at least the first two electrons go to the lanthanum atoms, not to the C_{80} cage. Because only small amounts of the materials are available, electrochemistry is a quite useful method for characterizing metallofullerenes, especially, the EPR-silent ones.

Experimental Procedure

Cyclic (CV) and differential pulse voltammograms (DPV) were recorded on a BAS-B/W electrochemical analyzer. A three-electrode configuration was used throughout. All measurements were performed at ambient temperature under an argon atmosphere in 0.1 M 1,2-dichlorobenzene solution of nBu_4NPF_6. The concentration of $La_2@C_{80}$ was 10^{-4} M. IR compensation was employed throughout. A platinum working electrode (1 mm diameter) was polished with 0.05 μm alumina before measurements. A platinum wire was used as the counter electrode. The reference electrode was a Ag/0.01 M $AgNO_3$ electrode filled with 0.1 M nBu_4NClO_4 in CH_3CN. All potentials are referenced to the ferrocene/ferrocenium couple (Fc/Fc^+) as the

internal standard. CV: scan rate, 20 mVs^{-1}. DPV: pulse amplitude, 50 mV; pulse width, 50 ms; pulse period, 200 ms; scan rate, 20 mVs^{-1}.

[21] Because we keep the I_h symmetry of the C_{80} cage during our calculations, this is not due to the Jahn–Teller distortion.
[22] In this case, the a_g orbital is raised from −4.4 to −0.1 eV.

Assembly and Crystal Structure of a Photoactive Array of Five Porphyrins**

Sally Anderson,* Harry L. Anderson, Alan Bashall, Mary McPartlin,* and Jeremy K. M. Sanders*

The investigation of conformationally homogeneous porphyrin assemblies is essential for the better understanding of energy and electron transfer in natural photosynthetic reaction centers.[1] This area of research has been stimulated by the characterization of natural photosynthetic reaction centers by Deisenhofer, Huber, and Michel,[2] and by the theoretical work of Marcus.[3] Structures containing many porphyrin chromophores are of particular interest as models for light-harvesting antennae; only a few antennae models containing more than three porphyrin units have been studied,[4] and all of these structures are rather flexible, which hampers understanding of their photophysical properties. The structure of the five-porphyrin complex presented in this communication is exceptionally well defined; its conformation in solution, deduced by NMR, is essentially identical to that in the solid state, as determined by single-crystal X-ray diffraction. It should be straightforward to vary the structure of this complex systematically, because the central porphyrin is inserted in the last step with strong but reversible noncovalent binding interactions.

Corey–Pauling–Koltun (CPK) models of the cyclic zinc porphyrin tetramer[5] Zn_4-**1** indicate that it is rather flexible, and NMR spectroscopy confirms that the molecule exists in several conformations, which interchange slowly on the chemical shift time scale.[5c, 6] One possible conformer is shown schematically in Figure 1. When *meso*-tetra(4-pyridyl)porphyrin H_2-Py_4P is added to a solution of cyclic tetramer Zn_4-**1**, a strong 1:1 complex forms, which is in slow exchange with excess of either component on the ^{1}H NMR chemical shift time scale and runs on a silica column as a single band. The H_2-Py_4P ligand locks the tetramer in a single symmetrical conformation: the signals of the ester methyl (Me_a) and ring methyl (Me_b) groups each give rise to two singlets of equal intensity separated by $\Delta\delta = 0.28$ and 0.05, respectively, which rules out the D_{4h} conformation shown schematically in Figure 1. Similar splittings are also observed in the ^{13}C NMR spectrum. Molecular mechanics calculations and CPK models indicate that the

[**] This work was supported by the Science and Engineering Research Council (UK), Rhône Poulenc Rorer, Magdalene College Cambridge, and Trinity College Cambridge. We are grateful to Prof. F. Diederich (ETH Zürich, Switzerland) for generously providing facilities for fluorescence measurements.

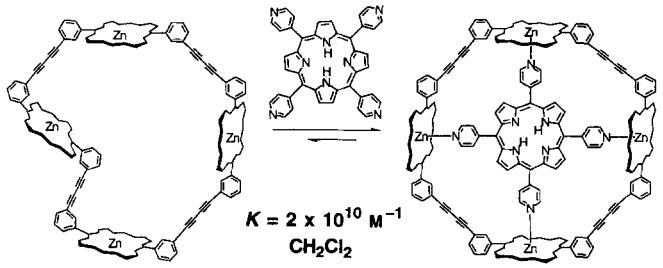

Fig. 1. One possible conformer of cyclic tetramer Zn_4-**1**, and the complex formed with H_2-Py_4P.

complex H_2-$Py_4P \cdot Zn_4$-**1** prefers to adopt a tub-shaped geometry reminiscent of cyclooctatetraene (Fig. 2). This D_{2d} symmetry is consistent with the ^1H and ^{13}C NMR spectra.[7] Split signals result from the two pyrrole environments shown in Figure 2.

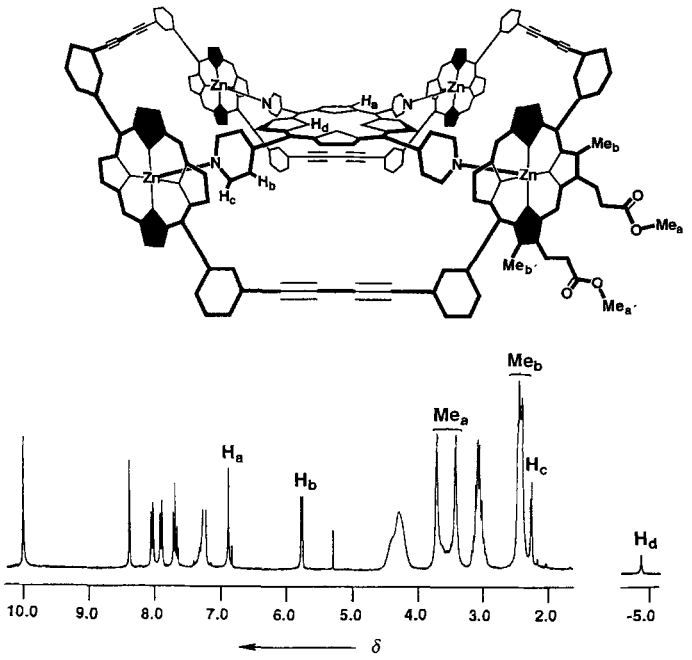

Fig. 2. Idealized structure and ^1H NMR spectrum of the H_2-$Py_4P \cdot Zn_4$-**1** complex. Most functional groups have been omitted for clarity. Axial pyrrole units are shaded black and equatorial units unshaded.

The H_c and H_b pyridine protons of H_2-Py_4P appear in the complex as sharp doublets at $\delta = 2.26$ and 5.77, respectively. The H_c protons are shifted upfield by $\Delta\delta = 6.81$ and the H_b protons by $\Delta\delta = 2.41$ on complexation to the cyclic tetramer. The magnitude of these upfield shifts, when compared with those in other pyridine–zinc porphyrin complexes,[8] shows that all four porphyrins of Zn_4-**1** must be bound simultaneously. The N–H signal of the ligand is shifted upfield by $\Delta\delta = 2.9$ to $\delta = -4.8$, as would be expected from the additive effect of four porphyrin ring currents perpendicular to the ligand plane and in close proximity.

The symmetry of the tetrazinc complex H_2-$Py_4P \cdot Zn_4$-**1** in the solid state is consistent with that observed in solution. X-ray structure analysis[9] of a well-formed, but very poorly diffracting crystal established the structure shown in Figure 3 with exact crystallographic S_4, and idealized D_{2d} symmetry. The four zinc porphyrin rings are orthogonal to the central H_2-Py_4P porphyrin unit (dihedral angle between N_4 planes 91.2°) and highly bowed. The bonds from the central porphyrin pyridyl nitrogen atoms to the surrounding zinc atoms, responsible for the conformational homogeneity of the tetramer, are equal by symmetry, with a Zn–N length of 2.20(2) Å. The N_4 donor set is planar to within 0.06 Å; the zinc atom lies 0.29 Å out of the plane towards the pyridyl group.

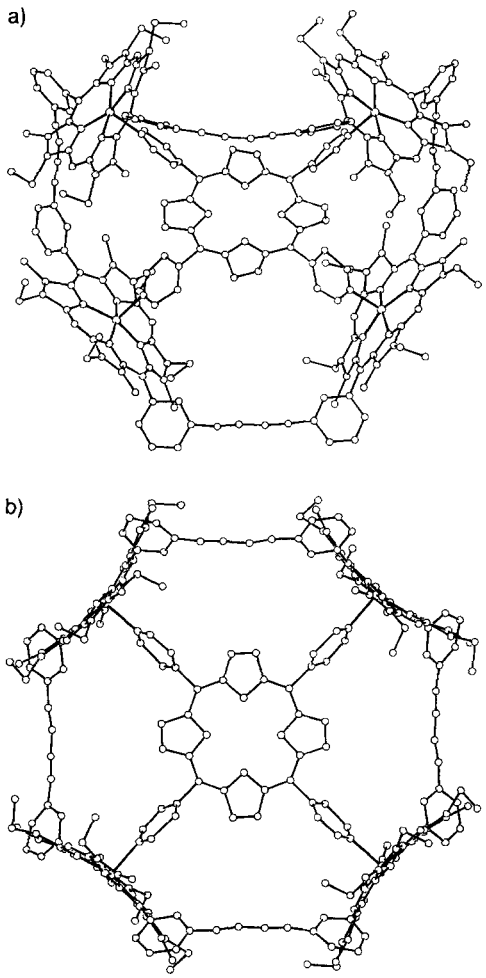

Fig. 3. Crystal structure of the tetrameric zinc porphyrin complex H_2-$Py_4P \cdot Zn_4$-**1**. a) Side view. b) A view perpendicular to the central porphyrin plane showing the crystallographic S_4 symmetry and the orthogonal orientation of the four peripheral zinc porphyrins of the Zn_4-**1** unit.

In the solid state the tetramer molecules form infinite stacks, parallel to the *c* axis, and each alternate molecule is rotated relative to its neighbors along this axis as shown in Figure 4a. Large channels parallel to the *a* and *b* axes (shown in cross section in Fig. 4a) lie between adjacent molecules. The stacks do not adopt a close-packed arrangement, but pack to leave large, square channels running the length of the crystal (Fig. 4b) in the *c* direction. Apparently, π–π interactions between porphyrins from adjacent stacks determine this arrangement; the minimum interporphyrin distance is 3.66 Å and the offset between the porphyrin centers 4.49 Å. Extended regions of electron density are consistent with occupation of the three sets of mutually perpendicular channels by randomly oriented solvent molecules. Similar large channels running the length of the crystal, and accommodating a large number of solvent molecules, were also found in a related trinuclear zinc porphyrin,[10] and both structures are reminiscent of the "porphyrin sponges" reported for tetraarylporphyrins.[11]

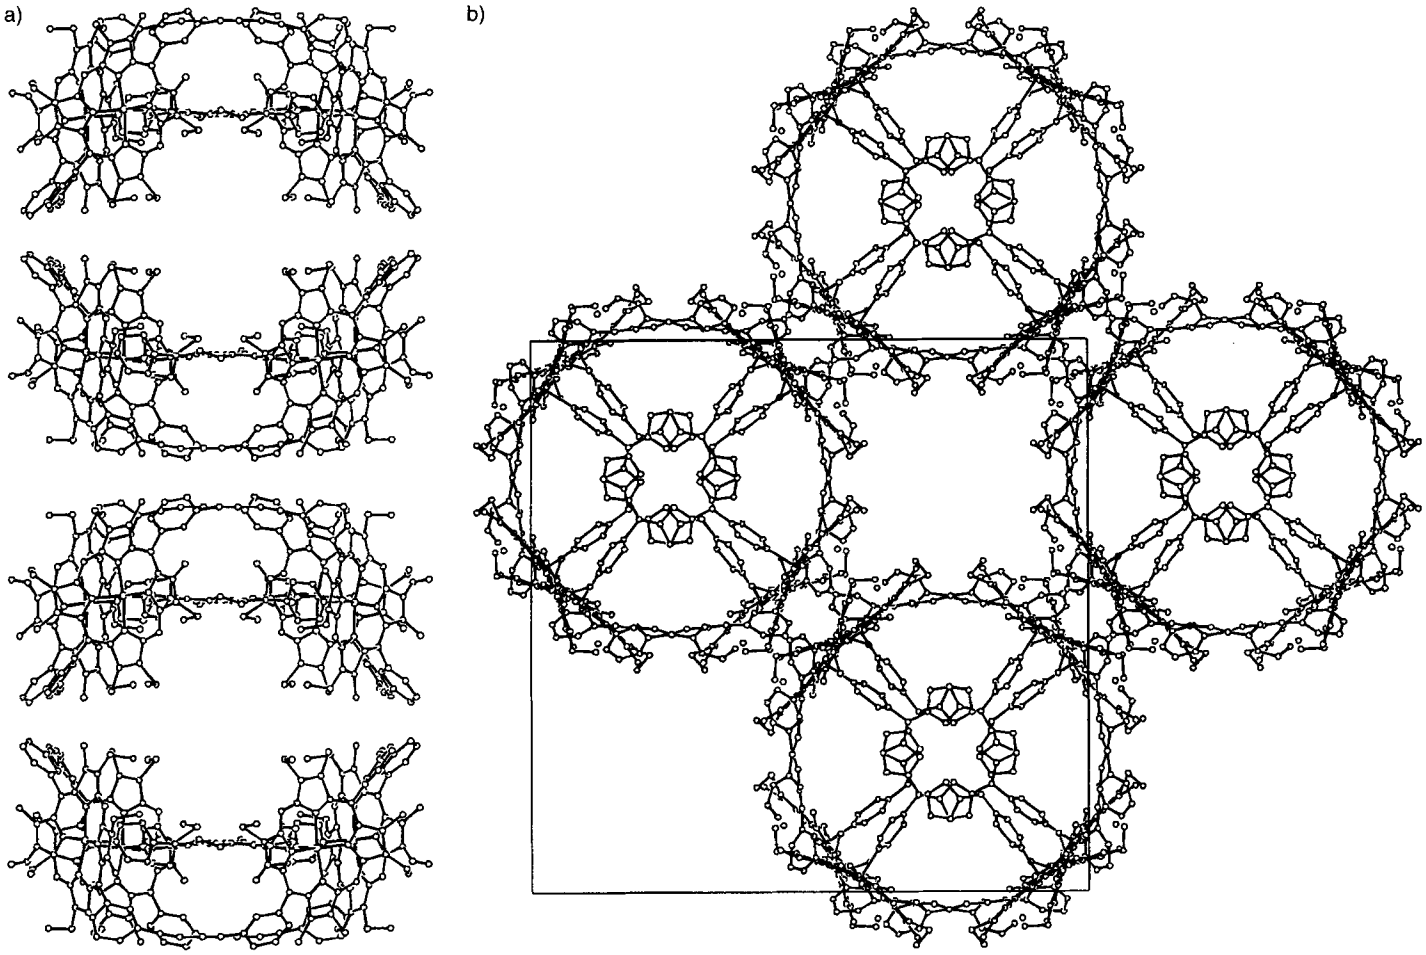

Fig. 4. a) The stacks of H_2-$Py_4P \cdot Zn_4$-**1** molecules parallel to the *c* axis, showing a cross section of the channels running parallel to the *b* axis (identical channels parallel to the *a* axis are generated by symmetry). b) A view down the stacks of H_2-$Py_4P \cdot Zn_4$-**1** showing the square cross section of the large channels that run parallel to the *c* axis.

The association constant between Zn_4-**1** and H_2-Py_4P was found to be $2 \pm 1 \times 10^{10}\,M^{-1}$ at 30 °C in dichloromethane by using UV/visible spectroscopy (Fig. 5).[12] Although this is a very strong binding constant, it is much lower than would be expected by extrapolation from the binding constants of the cyclic dimer for 4,4′-bipyridyl ($6 \times 10^{8}\,M^{-1}$) and the cyclic trimer for tris(4-pyridyl)triazine ($1 \times 10^{9}\,M^{-1}$).[8] Presumably the entropy and enthalpy associated with locking the conformation of the cyclic tetramer into a tub geometry are unfavorable.

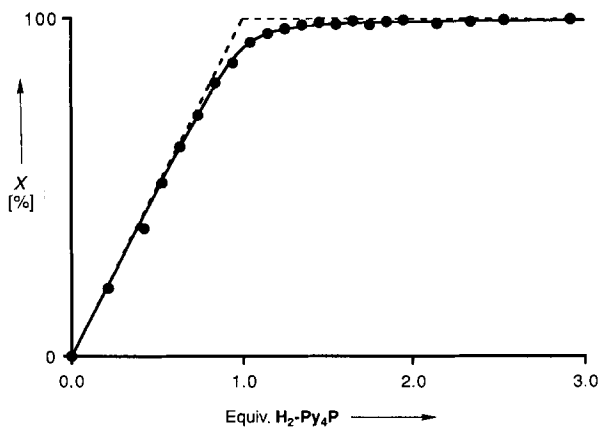

Fig. 5. Binding curve for cyclic tetramer binding to H_2-Py_4P. Experimental points on the calculated curve for $K = 2 \times 10^{10}\,M^{-1}$. Dashed curve shows strong-binding limit. X = fraction of bound H_2-Py_4P.

The absorption spectrum of the H_2-$Py_4P \cdot Zn_4$-**1** complex is essentially the sum of the absorption spectra of the two component parts. However, the fluorescence emission spectrum of the complex is around 1000 times less intense than that of either component; even the residual fluorescence of the 1:1 mixture can mainly be accounted for by traces of the dissociated components (Fig. 6). Similar fluorescence quenching is observed in the Zn-$Py_4P \cdot Zn_4$-**1** complex, where the central tetrapyridylporphyrin has been metalated with zinc. This behavior is much more dramatic than that observed in Lindsey's five-porphyrin array, where the fluorescence of only the peripheral zinc porphyrins was quenched.[4d] A possible explanation for the fluorescence quenching in our system is that photoinduced electron transfer occurs, as in natural photosynthetic reaction centers, followed by nonradiative decay of the charge-separated state.

This is one of the most conformationally homogeneous and well-characterized mimics of the photosynthetic reaction center, and it is also one of the most versatile. Reversible interactions leading to noncovalent bonds are often thought of as more flexible than covalent bonds, but this system demonstrates that many cooperative weak interactions can yield a well-defined supramolecular object. It should be possible to insert a range of tetrapyridylporphyrin ligands into the cyclic tetramer to give a variety of models for photosynthetic reaction centers with iden-

tical geometries but different electronic properties; this will provide a valuable tool for analyzing the photophysics of such systems.

Experimental Procedure

Binding studies: A solution of H_2-Py_4P (1.0 μM in CH_2Cl_2, also containing 6.0 nM Zn_4-**1**) was titrated into a solution of Zn_4-**1** (6.0 nM in CH_2Cl_2) in a 10 mm quartz cuvette kept at 30 C. The absorptions at 412 and 427 nm were recorded; the absorption at 412 nm was subtracted from the absorption at 427 nm to remove errors due to the slow drift in the baseline. The results were reproduced twice. A Perkin Elmer Lambda 2 spectrophotometer was used, which can reliably record absorption changes of 1×10^{-4}.

Fluorescence measurements: All spectra were recorded on a Spex 1680 0.22-m Double Spectrometer in emission mode exciting at 411 nm at 1 μM concentration in argon-saturated dichloromethane.

[9] Crystal data for H_2-$Py_4P \cdot Zn_4$-**1** $\cdot 5C_6H_{12} \cdot 3CHCl_3$, $C_{207}H_{289}Cl_9N_{24}O_{32}Zn_4$, $M_r = 5287.26$, tetragonal, space group $P4/nnc$ (No. 126), $a = 35.860(8)$, $c = 29.244(6)$ Å, $Z = 4$, $V = 37606.02$ Å^3, $\rho_{calcd} = 0.934$ g cm^{-3}, $F(000) = 11072$, $\mu(Mo_{K\alpha}) = 0.37$ mm^{-1}. Crystals of H_2-$Py_4P \cdot Zn_4$-**1** were very fragile and rapidly lost solvent in air, so data were collected for a crystal sealed with mother liquor in a Lindemann tube. 16183 (7562 unique) data were collected in the θ range of 3–19° using a Phillips PW 1100 diffractometer with ω–2θ scans. The structure was solved with difficulty by direct methods [SHELXS-86]; the center of the molecule lies on a site of S_4 symmetry, and the main skeleton of the structure was only slowly revealed during many subsequent difference-Fourier syntheses. Only the first two carbon atoms of each methyl propanoate side chain (that is, the two carbon atoms closest to the zinc porphyrins) were located, and there was an unresolved region of extended electron density near to the terminal atom of each two atom chain. The presence of approximately three chloroform and five cyclohexane molecules per tetramer was indicated by analysis of the ^1H NMR spectrum of crystals of H_2-$Py_4P \cdot Zn_4$-**1** in CD_2Cl_2 (that is, 103.5 e per asymmetric unit). No recognizable solvent molecules could be identified, but many regions of extended electron density were located in the channels running parallel to the three cell axes. The highest residual maxima were included in the refinement as carbon atoms with their population parameters adjusted to correspond to the expected total-solvent and side-chain electron density. The structure was refined on F^2 [SHELXL-93] using all 7562 independent refelections. Due to the paucity of data, geometrical restraints were applied to chemically equivalent bonds and to make the phenyl and pyridyl groups planar. $wR_2 = [\sum w(F_o^2 - F_c^2)/\sum F_o^2]^{1/2} = 0.471$, $R_1 = \sum ||F_o| - |F_c|| / \sum F_o = 0.167$ [for 1202 refections with $F_o^2 > 2\sigma(F_o^2)$], goodness of fit on $F^2 = 0.893$ on 532 parameters. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK) on quoting the full journal citation.

[12] Both host and guest absorb in the same region of the UV spectrum. This does not hinder the measurement of binding constants since the extinction coefficients for the absorbing ligand are known, but rather allows an internal check on the ligand concentration.

Electronic Energy Transfer Across Ethynyl-Bridged Ru^{II}/Os^{II} Terpyridyl Complexes**

Vincent Grosshenny, Anthony Harriman,* and Raymond Ziessel*

Current interest in the design of materials for applications in molecular electronics has focused, in part, on the identification of molecules having spatially remote, redox-active subunits in good electronic communication.[1, 2] In turn, this requires the synthesis of multicomponent molecular systems with highly restricted conformational mobility and well-defined and logically placed structural subunits. For the construction of linear molecules with extended bridges separating terminal redox-active subunits, it is appropriate to consider alkenes,[3] alkynes,[4-6] and polyphenyls[7] as potential spacer moieties. Such bridging units facilitate long-range electronic coupling between terminal subunits and, at least with alkynes and polyphenyls, do not pose problems with stereoisomerism. Indeed, compounds have been described recently in which alkenes[8] and polyphenyls[7] promote through-bond photoinduced energy or electron transfer over considerable distances (i.e. 20 Å).

It has also been proposed that alkynes can be used as effective bridges for electron donor/acceptor systems[9] and for the fabrication of novel chromophoric materials.[10] The incorporation of alkynes is also a simple strategy for enhancing the triplet lifetime of metal bis(terpy) complexes (terpy = 2,2′:6′,2″-terpyridine) and, in the case of bis(terpy)ruthenium(II) **1**, converting a poor photosensitizer into a much more effective one.[10] Here, we report that alkyne bridges allow for rapid intramolecular triplet energy transfer from a bis(terpy)ruthenium(II) to a bis(terpy)osmium(II) unit at both 295 and 77 K, as reported previously for the molecular systems with spacers formed from one or two phenyl rings,[7] from a single 1,4-bis(ethynyl)bicyclo-[2.2.2]octane unit,[11a] or from a 1,4-bis(ethenyl)bicyclo[2.2.2]-octane unit.[11b]

The PF_6^- salts of the ethynyl-bridged monoruthenium(II) complexes **3** and **4** (Fig. 1) were synthesized by reacting alkyne-linked terpy ligands with $[Ru^{II}(terpy)(dmso)Cl_2]$ (dmso = dimethyl sulfoxide) and anion exchange with NH_4PF_6 as described previously.[5, 12] The PF_6^- salts of the heterodinuclear Ru^{II}/Os^{II} compounds **5** and **6** were prepared by reaction of $[Os(terpy)(O)_2(OH)](NO_3)\cdot 2H_2O$ with complexes **3** and **4** in THF/H_2O with hydrazine hydrate as a reducing agent.[13] The compounds were purified by chromatography on alumina followed by recrystallization from CH_2Cl_2/hexane (53% yield for **5**-PF_6 and 23% yield for **6**-PF_6). All new compounds were characterized by UV/Vis, emission, and FT-IR spectroscopy, FAB mass spectrometry, and elemental analysis.

Absorption spectra recorded for **5** and **6** in acetonitrile solution retain the essential characteristics of the corresponding molecular components (i.e., **2** + **3** and **2** + **4**, respectively), although there is considerable overlap of absorption transitions associated with the individual subunits in the 400–500 nm region. Excitation at 600 nm, where bis(terpy)Os^{II} is the dominant if not sole chromophore, results in luminescence centered around 750 nm, which is characteristic of the bis(terpy)Os^{II} chromophore.[14] The luminescence quantum yields Φ_L and lifetimes τ_L recorded in acetonitrile solution at 295 K and in an ethanol glass at 77 K are comparable to those recorded for bis-(terpy)Os^{II} **2** under identical conditions (Table 1). Slight variations in these parameters and in the luminescence maxima λ_{em} can be attributed to the ethynyl substituents in compounds **5**

and **6**, as described previously for the corresponding Ru^{II} analogues.[10] Both the energy and the lifetime of the triplet state decrease with increasing number of ethynyl units. Furthermore, relative to related bis(terpy)Os^{II} complexes of comparable triplet energy[2] the compounds reported here exhibit a small but significant enhancement in triplet lifetime at both 295 and 77 K.[15] Such findings appear to be entirely in accord with selective population of the substituted terpyridine ligand and subsequent delocalization of the electron over an extended π^* orbital following excitation at 600 nm.[10, 16]

Upon excitation of **5** and **6** in acetonitrile solution at 295 K or in an ethanol glass at 77 K with light at 440 nm it was very difficult to detect luminescence characteristic of the bis(terpy)Ru^{II} unit. At this excitation wavelength the bis(terpy)Ru^{II} unit absorbs roughly 60% of the incident photons, as judged from studies made with the reference compounds. Comparison with the corresponding mononuclear bis(terpy)Ru^{II} complexes, **3** and **4**, indicates that for these units in **5** and **6** Φ_L is less than 0.0001 (Table 1). On the basis of highly sensitive single-photon counting studies it was concluded that the luminescent lifetimes of the bis(terpy)Ru^{II} units in **5** and **6** are approximately 10^4 times shorter than those observed for the corresponding mononuclear complexes **3** and **4** (Table 1). Triplet lifetimes were also determined by transient absorption spectroscopy following excitation of **5** and **6** in acetonitrile solution at 295 K with a 1-ps laser pulse at 295 nm and monitoring recovery of the ground state at 450 nm (Table 1). It can be seen that the triplet lifetimes measured by the two techniques are quite similar (Table 1), although, because of the temporal resolution of these instruments, we consider those recorded by transient absorption spectroscopy to be the more reliable values.

In marked contrast, emission from the bis(terpy)Os^{II} units in **5** and **6** was clearly apparent following excitation of the bis(terpy)Ru^{II} unit at 440 nm. By comparison to the appropriate reference compounds, it appears that triplet energy transfer from bis(terpy)Ru^{II} to the appended bis(terpy)Os^{II} unit is quantitative for the two compounds at both 295 and 77 K. Photophysical properties measured for the bis(terpy)Os^{II} units are insensitive to the excitation wavelength, while the corrected excitation spectra were found to be in good agreement with the absorption spectral profiles recorded across the visible region. The spectroscopic triplet energy gaps ΔE measured in solution and in ethanol glass are consistent with the proposed triplet energy transfer (Table 2).

Efficient intramolecular triplet energy transfer across binuclear metal complexes has been observed in many other cases,[2, 11, 17] although kinetic data for short separations are scarce. We determined rate constants[18] for triplet energy transfer across one and two ethynyl bonds from the transient absorption and time-resolved luminescence studies at 295 and 77 K (Table 2). For both **5** and **6** there is a moderate (i.e., 50-fold) decrease in rate at the lower temperature, while at both temperatures the rate of energy transfer is slightly faster for **5** than for **6**. The magnitude of the decrease in the rate of energy transfer upon insertion of the second ethynyl bond, in fact, is surprisingly small, even when compared to the rates obtained for complexes with alkene[19] and phenyl[20] spacer groups. Such findings might be used to argue that polyalkynes are especially effective at promoting long-range electronic coupling between remote subunits.

It is instructive to consider the mechanism by which intramolecular triplet energy transfer occurs in these compounds. Studies with closely related binuclear systems have provided support for a through-bond electron exchange (i.e., Dexter-type) mechanism.[2, 11] A schematic description of the overall process is shown in Figure 2. In our case, the 50-fold decrease in rate of triplet energy transfer observed upon changing from

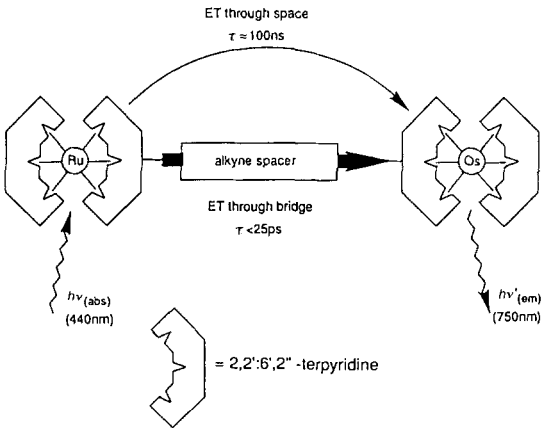

Fig. 2. Representation of energy transfer across one ($k = 7.1 \times 10^{10}\ s^{-1}$) and two ($k = 5 \times 10^{10}\ s^{-1}$) alkyne groups at room temperature. The rate of energy transfer through space ($k = 1 \times 10^{7}\ s^{-1}$) is calculated from the Förster expression for a single ethynyl spacer.

fluid solution to a frozen glass appears to be more consistent with a Dexter mechanism than with dipole–dipole (i.e., Förster-type) transfer.[21] Furthermore, the small decrease in rate observed for **6** relative to that of **5** corresponds roughly to an R^{-2} dependence rather than the R^{-6} dependence (where R is the metal–metal distance in the binuclear complexes) that is required for transfer by means of the Förster mechanism.[22] The rate constants for triplet energy transfer occurring by the Förster mechanism (k_F) can be estimated by Equation (a). Here Φ_L and τ_L refer to the photophysical properties of the appropri-

$$k_F = 8.8 \times 10^{-25} \Phi_L J_F K^2 / n^4 \tau_L R^6 \quad \text{(a)}$$

ate mononuclear bis(terpy)Ru^{II} complex, n is the refractive index of the solvent, J_F is the spectroscopic overlap integral ($J_F = 1 \times 10^{-13}\ cm^6\ mol^{-1}$), and K is the orientation factor ($K^2 = 0.67$). At 77 K the calculated k_F values are $1.2 \times 10^7\ s^{-1}$ and $4.4 \times 10^6\ s^{-1}$ for complexes **5** and **6**, respectively. Even allowing for errors in the measured values, it is clear that dipole–dipole transfer cannot account for the observed rates of triplet energy transfer.

The rate constant for Dexter-type triplet energy transfer (k_D) is expressed by Equations (b) and (c), where V is the electronic

$$k_D = (2V^2/h)(\pi^3/\lambda k_B T)^{1/2} \exp[-\Delta G^{\ddagger}/k_B T] \quad \text{(b)}$$

$$\Delta G^{\ddagger} = [(\lambda - \Delta E)^2/4\lambda] \quad \text{(c)}$$

matrix coupling element, λ is the reorganization energy accompanying energy transfer, and ΔE is the difference in energy between donor and acceptor. Values for ΔE can be estimated from the luminescence spectra (Table 2), while λ has been estimated to be 0.15 eV from the relevant Stokes' shift.[23] Based on these values and the assumption that triplet energy transfer does indeed occur exclusively by an electron exchange mechanism, the magnitude of V is estimated to be about $7\ cm^{-1}$ at room temperature. The rate of energy transfer is expected to decrease exponentially with increasing metal–metal distance (R), as described by Equation (d).[24] As such, the decreased rate of energy

$$k_D = A \exp[-\beta R] \quad \text{(d)}$$

transfer for **6** relative to **5** corresponds to an attenuation factor β of $0.17 \pm 0.04\ Å^{-1}$. Comparison of this derived parameter to the

5	295	0.13	7.1 [c]
	77	0.25	0.14 [d]
6	295	0.11	5.0 [c]
	77	0.26	0.09 [d]

[a] ΔE = triplet energy gap, ±15%; k = rate constant for triplet energy transfer. [b] Calculated by using **3** and **4** to estimate the triplet energy of bis(terpy)Ru^{II}units. [c] From transient absorption spectroscopy, ±20%. [d] From time-resolved luminescence spectroscopy, ±10%.

corresponding values obtained for electron transfer through alkenes ($\beta = 0.06$ Å^{-1}),[8] aromatic hydrocarbons ($\beta = 0.4$ Å^{-1}),[25] proline groups ($\beta = 0.7$ Å^{-1}),[26] fused alkanes ($\beta = 0.6-1.0$ Å^{-1}),[27] DNA ($\beta = 0.9$ Å^{-1}),[28] and proteins ($\beta = 1.7$ Å^{-1})[29] confirms the high efficacy of electronic coupling along alkyne spacers. It is important to realize, however, that the rate of intramolecular (through-bond!) triplet energy transfer observed for **6** at 295 K ($k = 5 \times 10^{10}$ s^{-1}) is less than that reported[2, 7] for the corresponding binuclear system with a biphenyl spacer ($k > 5 \times 10^{10}$ s^{-1}), even though the metal–metal distance in **6** is 3.5 Å less and correspondingly the β value is smaller. This suggests that electronic coupling between terpyridine and alkyne groups, but not between adjacent alkynes, is relatively ineffective, probably due to symmetry restrictions.

Experimental Procedure

Preparation of **5**-PF_6 and **6**-PF_6: To a stirred solution of compounds **3** and **4** (30 mg, 0.027 mmol) in THF/H_2O (1/1, 20 mL) was added dropwise a solution of [Os(terpy)$(O)_2$(OH)]$(NO_3)\cdot 2H_2O$ [13] (18 mg, 0.033 mol) in H_2O (5 mL). After the reaction mixture was heated at 45 °C for 15 min. three drops of hydrazine hydrate were added. Complexation was evidenced by development of a deep brown color. The reaction mixture was allowed to stand for ca. 12 h before an aqueous solution (10 mL) of NH_4PF_6 (22 mg, 0.135 mmol) was added, resulting in the precipitation of the crude product. The salts were purified by chromatography (alumina standard, 1–6% CH_3OH/CH_2Cl_2, $R_f = 0.57$ for **5**-PF_6 and $R_f = 0.52$ for **6**-PF_6 in CH_2Cl_2/CH_3OH 9/1). The resulting red-brown salts were recrystallized from CH_2Cl_2/hexane.

5: 57% yield; UV/Vis (CH_3CN): λ_{max} (ε) = 266 (63800), 302 (67300), 476 (18300), 536 nm (sh, 7200); FT-IR (KBr pellets): $\tilde{\nu} = 2070$ (C≡C), 1638, 1450, 1385, 1262, 1087, 1048, 844 cm^{-1}; FAB-MS (*meta*-nitrobenzylalcohol as matrix): *m/z* 1536/1538 [$M^+ - 2PF_6$], 1391/1393 [$M^+ - 3PF_6$], 1246/1248 [$M^+ - 4PF_6$]; anal. calcd. for $C_{62}H_{42}N_{12}P_4F_{24}RuOs$ (M_r = 1826.233): C 40.78, H 2.32, N 9.20; found C 40.50, H 2.09, N 8.93.

6: 23% yield; UV/Vis (CH_3CN): λ_{max} (ε) = 266 (118600), 301 (94400), 478 (24600), 539 nm (sh, 11500); FT-IR (KBr pellets): $\tilde{n} = 2081$ (C≡C), 1604, 1450, 1386, 1262, 1089, 1048, 844 cm^{-1}; FAB-MS (*meta*-nitrobenzylalcohol as matrix): *m/z* 1560/1562 [$M^+ - 2PF_6$], 1415/1417 [$M^+ - 3PF_6$], 1270/1272 [$M^+ - 4PF_6$]; anal. calcd. for $C_{64}H_{42}N_{12}P_4F_{24}RuOs$ (M_r = 1850.255): C 41.55, H 2.29, N 9.08; found C 41.37, H 2.03, N 8.96.

Methods: Luminescence lifetimes were measured by time-correlated, single-photon counting methods after excitation with a synchronously pumped, cavity-dumped dye laser. Rhodamine 6G (for excitation at 600 nm) and frequency-doubled Styryl-9 (for excitation at 440 nm) dye lasers were used. After application of global analysis techniques to the deconvoluted decay profiles, the temporal resolution of this instrument was around 15 ps. Transient absorption studies were made with a frequency-doubled, mode-locked Nd:YAG laser (pulse width 30 ps, Raman shifted to 598 nm, 2 mJ per pulse) or a frequency-doubled Rhodamine 6G dual-jet dye laser (pulse width 1 ps, 295 nm, 450 μJ per pulse). Kinetic measurements were made by following the recovery of the ground-state absorption band at 450 nm (bis(terpy)Ru^{II}) or 650 nm (bis(terpy)Os^{II}).

[20] J. P. Collin, P. Lainé, J. P. Launay, J. P. Sauvage, A. Sour, *J. Chem. Soc. Chem. Commun.* **1993**, 434.
[21] The primary reason for expecting a slower rate of Förster-type energy transfer at 77 K compared to 295 K is due to the increase in refractive index when a solution is frozen. Inserting appropriate values into the Förster expression indicates that the rate will decrease by a factor of ca. 5 on changing from solution to glass, provided there is no change in orientation.
[22] Based on metal–metal distances of 13.8 and 16.2 Å from CPK models of **5** and **6**, respectively, the average decrease in rate with increasing separation corresponds to an $R^{-2.2}$ dependence.

First Isolation of an Enol of a Carboxylic Acid by Complexation to an (Ethane-1,2-diamine)-platinum(II) Fragment**

Markus Galanski, Bernhard Klaus Keppler,* and Bernhard Nuber

Enol isomers of simple aldehydes and ketones have been known for a long time,[1] but very little is known about the enols of other carbonyl compounds such as carboxylic acids and carbonic acid esters. On account of the high thermodynamic instability with respect to the carboxylic acid isomer it has so far not been possible to isolate a geminal enediol or its metal derivative. Only a few enols of carboxylic acids in solution are known. These include the two sterically hindered derivatives of enolizated acetic acid,[2] 2,2-bis(pentamethylphenyl)ethane-1,1-diol and 2,2-bis(mesityl)ethane-1,1-diol, the enol of amygdalic acid,[3] fulvene-6,6-diol,[4] the enol of α-cyano-α-phenylacetic acid,[5] and the enols of various indene carboxylic acids.[6] The synthesis of geminal enediols in all cases was carried out by hydration of the corresponding ketenes. Dilithium and organomagnesium derivatives of 1,1-enediols so far have only been prepared in solution as reactive intermediates and reacted in situ.

The synthesis of osteotropic (bone-seeking) analogues[7] of *cis*-diamminedichloroplatinum(II), cisplatin,[8] one of the most successful drugs in the treatment of malignant tumors, led to not only ethane-1,2-diamine[(bis(phosphonatomethyl)amino)acetato(2−)-O^1,N^1]platinum(II) (**4**) (Scheme 1) but also to the enol tautomer **4a** (see Fig. 1).[9] Thus a geminal enediol derivative

Scheme 1. Synthesis of **4** as well as enol and keto isomers of the complexed α-amino carboxylic acid and the possible zwitterions **4a** and **4b** of the enol isomer.

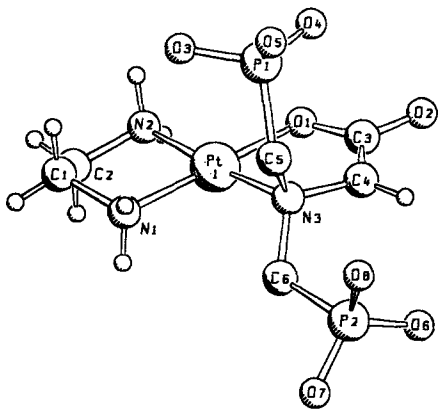

Fig. 1. Molecular structure of **4a** in the crystal. Selected distances [pm] and angles [°]: Pt1–N1 203.1(12), Pt1–N2 205.0(13), Pt1–N3 205.9(12), Pt1–O1 198.9(10), O1–C3 129.9(19), O2–C3 127.8(20), C3–C4 138.6(22), P1–O3 154.0(10), P1–O4 146.8(12), P1–O5 152.1(12), P2–O6 150.1(12), P2–O7 150.1(13), P2–O8 151.6(12); N1-Pt1-N2 84.0(5), N1-Pt1-N3 98.2(5), N2-Pt1-O1 93.7(5), N3-Pt1-O1 84.2(4), O3-P1-O4 114.4(6), O3-P1-O5 105.3(6), O4-P1-O5 113.3(6), O6-P2-O7 113.8(7), O6-P2-O8 110.5(6), O7-P2-O8 112.4(7); O1-C3-C4-N3 8.54, Pt1-O1-C3-C4 0.24.

of a carboxylic acid was isolated for the first time in the solid state.

Activation of the dichloro complex **1** with silver nitrate gives the aqua complex **2**, which is treated in situ with *N*,*N*-bis(phosphonomethyl)aminoacetic acid (BPMAA) (**3**) (Scheme 1) to give **4**. Complex **4** is precipitated with acetone as a white solid. In the recrystallization from water (pH = 1), a colorless clear crystal was obtained after four weeks. In addition to the crystal structure analysis, an IR spectrum was recorded with a fragment of the crystal.

Since we determined the crystal structure of the keto isomer[7, 10] *cis*-diammine[(bis(phosphonatomethyl)amino)acetato(2−)-O^1,N^1]platinum(II) (**5**) (see Fig. 2) previously, the complexation of **3** to the *cis*-diam(m)ineplatinum(II) fragments thus makes it possible to directly compare the structures of the two isomers of the keto–enol equilibrium of a carboxylic acid.

As expected, the ligands are arranged in a square-planar fashion about the platinum centers; sum of angles: 360.1° for **4a** and 360° for **5**. The N1-Pt1-N2, N1-Pt1-N3, and O1-Pt1-N3 angles (84.0(5)–98.2(5)°) deviate markedly from the ideal value of 90°. The Pt–N (203.1(12)–208.0(7) pm) and Pt–O bond lengths (198.9(10)–201.5(5) pm) lie in the usual range. As expected, the sum of angles in the Pt1-N1-C1-C2-N2 five-membered ring of **4a** (513.7°), differs markedly from the sum of angles in a planar five-membered ring (540°). Values between 13.4 and 56.3° were

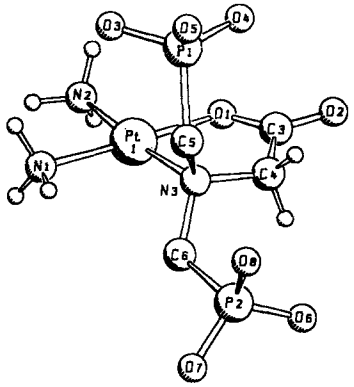

Fig. 2. Molecular structure of **5** in the crystal. Selected distances [pm] and angles [°]: Pt1–N1 205.4(7), Pt1 N2 204.3 (8), Pt1–N3 208.0(7), Pt1–O1 201.5(5), O1–C3 129.9(10), O2–C3 121.5(10), C3–C4 150.1(13), P1–O3 155.1(6), P1–O4 150.9(6), P1–O5 153.9(7), P2–O6 153.9(9), P2–O7 154.1(7), P2–O8 152.0(6); N1-Pt1-N2 88.7(3), N1-Pt1-N3 97.1(3), N2-Pt1-O1 89.0(3), N3-Pt1-O1 85.2(2), O3-P1-O4 113.6(4), O3-P1-O5 106.8(3), O4-P1-O5 113.4(3), O6-P2-O7 112.0(4), O6-P2-O8 110.1(3), O7-P2-O8 113.1(4); O1-C3-C4-N3 16.45, N3-Pt1-O1-C3 1.69.

determined for the dihedral angles. The sum of angles in the Pt1-O1-C3-C4-N3 five-membered ring of **4a** is 538.7° with dihedral angles of 0.2–11.9°; that in the five-membered ring of **5** is 538.1° with dihedral angles of 1.7–16.5°.

The unexpectedly short C3–C4 bond length of **4a** (138.6(22) pm) corresponds to a double bond. In contrast, the length of the C3–C4 bond of **5** (150.1(13) pm) reveals the presence of a single bond. In the case of a double bond, the ideal dihedral angle is expected to be 0°; however, in the crystal structure of **4a**, it is 8.5°, that is the bond is slightly twisted. This can be attributed to the complexation to the platinum through the N3 nitrogen if the fact that Pt1, O1, C3, and C4 are in a coplanar arrangement (dihedral angles 0.2°!) is taken into account. The difference to the O1-C3-C4-N3 dihedral angle of **5** at the C3–C4 single bond (16.5°) is very marked; in this case, the atoms N3, Pt1, O1, and C3 lie almost in a single plane (dihedral angle 1.7°).

The presence of the enol isomer **4a** is confirmed by the comparison of the IR spectra of **4** and **4a**. Complex **4** shows a strong carbonyl band at 1655 cm^{-1}, while **4a** shows two sharp bands at 1633 and 1603 cm^{-1}. The band at 1633 cm^{-1} is assigned to the stretching vibration of the enolic double bond,[2] the absorption at 1603 cm^{-1} to the N–H deformation vibration.

A direct statement as to whether the zwitterion **4a** or **4b** (Fig. 1) is present in the crystal cannot be made on the basis of structure analysis. A comparison of the bond lengths and bond angles of the two phosphonic acid groups with the data of phosphonic acid (P–O 154 pm, P=O 147 pm; O–P=O 113° and 116°, O-P-O 102°) and that of a bis(diethylphosphonate) derivative (P–O 154 and 153 pm, P=O 144 pm; O–P=O 116°, O-P-O 101 and 102°) suggests structure **4a**. The crystal structure data of **4a** shows that for charge equalization with respect to platinum, the phosphonic acid group P2 is singly deprotonated.

Experimental Procedure

All reactions were carried out in distilled water and in the absence of light.

4: To a suspension of **1** (946 mg, 2.90 mmol) in water (40 mL) was added silver nitrate (937 mg, 5.52 mmol), and the mixture was stirred for one day at room temperature. The silver chloride formed was removed by filtration, and the volume of the remaining yellow solution was reduced to 10 mL. Thereafter **3** (750 mg, 2.85 mmol) was added, and the solution was stirred for one hour at 50 °C and subsequently for one day at room temperature. Complex **4** was precipitated with acetone, filtered, and dried under high vacuum. Yield: 77.3% (based on the amount of silver nitrate used). If **4** is contaminated with free ligand, it can be purifed by recrystallization from water.

4: ^1H NMR (D_2O, 25 °C, 200 MHz): δ = 2.42 (m, 4H, N–CH_2CH_2–N), 3.1–3.6 (m, 4H, 2 CH_2–P), 4.04 (s, 2H, CH_2–COO), 5.0–6.0 (2 broad signals, 2 NH_2); ^{13}C NMR (D_2O, 25 °C, 50 MHz, [D_6]acetone): δ = 47.1, 47.8, 61.7 (d, ^1J(C,P) = 149 Hz, 2C), 66.2, 184.5; ^{31}P NMR (D_2O, 25 °C, 81 MHz, 85% H_3PO_4): δ = 11.73; IR (KBr): $\tilde{\nu}$ = 1655 cm^{-1} (C=O); correct C,H,N analysis.

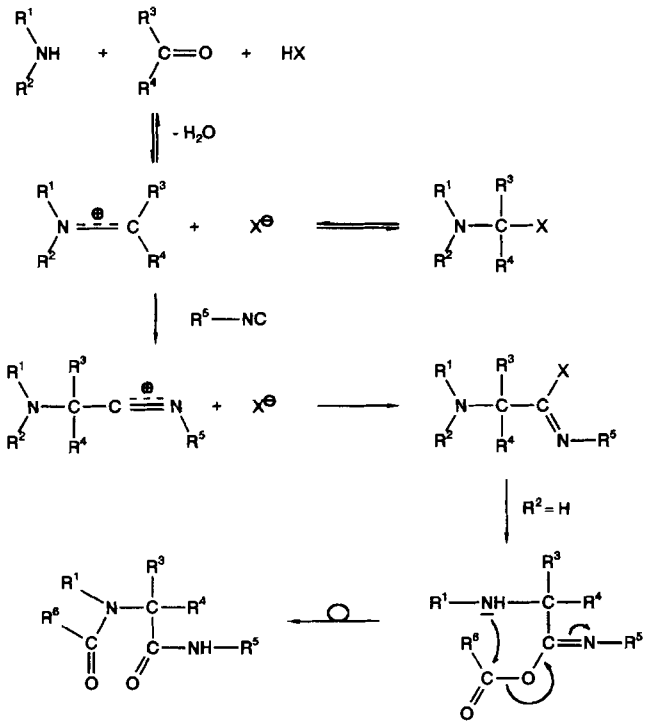
Stereoselective Syntheses of Peptide Derivatives with 2-Acetamido-3,4,6-tri-*O*-acetyl-1-amino-2-deoxy-β-D-glucopyranose by Four-Component Condensation

Stefan Lehnhoff, Matthias Goebel, Rosa Maria Karl, Roland Klösel, and Ivar Ugi*

Dedicated to Professor Miklos Bodanszky

Syntheses that feature the simultaneous reaction of several reactants in a one-pot procedure are called multicomponent reactions (MCRs). In 1850 A. Strecker[1] discovered a reaction, subsequently named after him, which in our nomenclature is formulated as S-3CR, and in which ammonia, carbonyl compounds, and hydrogen cyanide react to form α-aminoalkyl cyanides that can be hydrolyzed to the corresponding amino acids. Since 1934 α-amino acids have been obtained by the Bucherer–Bergs reaction (BB-4CR),[2] one of the very first 4CRs.



Hellmann and Opitz[3] recognized that many 3CRs are of the same basic type of reaction, namely an α-aminoalkylation of nucleophiles (HO-3CR). In 1921 Passerini[4] discovered that carboxylic acids, isocyanides, and carbonyl compounds form α-imino esters, which rearrange irreversibly thereafter. Other acids, such as HN_3 undergo analogous reactions.[5]

Although isocyanides have been available since 1867,[6] this P-3CR was their only significant application in organic syntheses until 1958 when their preparation was notably simplified

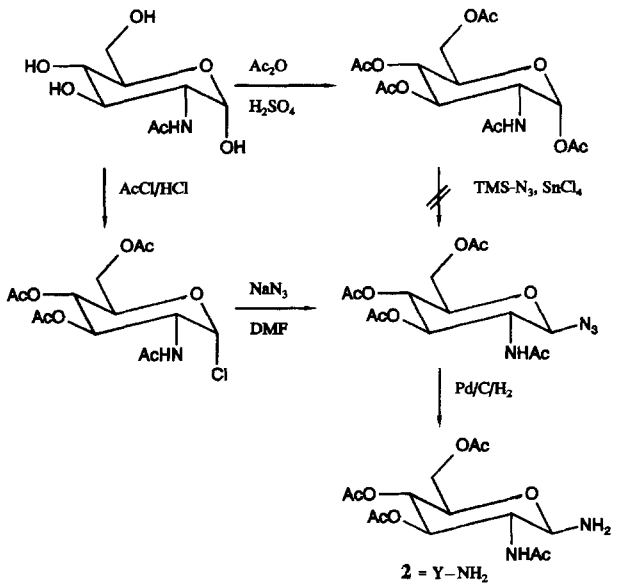
(dehydratation of *N*-formyl amides).[7, 8] The four-component condensation U-4CR was discovered in 1959, and most variants of this reaction followed within a few weeks (HX = H_2O, $H_2S_2O_3$, H_2Se, HN_3, HNCO, HNCS, RCO_2H).[9–11] The U-4CR is by far the most versatile of all multicomponent reactions. It is not only the starting point of all higher MCRs such as the AU-7CR[12] but also an ideal system for stereoselective reaction planning such as that necessary for the preparation of peptide derivatives. This point was made by M. Bodanszky and A. Ondetti in 1966.[13] Preparatively, the most important kind of U-4CR is the reaction with carboxylic acids[8, 11] (Scheme 1). Thereby, for instance, β-lactam antibiotics, α-amino acids, peptide derivatives, and various other types of compounds became available.[11, 14]

Scheme 1. U-4CR with X = R^6COO.

In the meantime, the rather complex reaction mechanisms have been described well by mathematical models,[15] resulting in the successful development of stereoselective U-4CRs by using α-aminoalkylferrocenes as chiral templates.[16] These chiral auxiliaries prepared by the Herrmann reaction (He-3CR) could be cleaved from the peptide formed in the U-4CR under mild conditions and recycled as well.[17] Besides *de* values that were not completely satisfactory, the disadvantages of this procedure are relatively low yields and limited stability of the ferrocene derivatives.

During the last decade many methods of syntheses of α-amino acids and their derivatives have been developed, but all these procedures are multistep syntheses consisting of, in some cases, up to ten steps.[18] Kunz et al. used 1-amino-2,3,4,6-tetra-*O*-pivaloyl-β-D-galactopyranose (**1**) as a chiral template in the U-4CR to form N-formylated derivatives of α-D-amino acids from various aldehydes with *tert*-butyl isocyanide and formic acid. Acidolysis at high temperatures followed by amide cleavage gave α-D-amino acids in more than 90% *ee*[19, 20] (Scheme 2). Other acids besides formic acid have not been used, since only

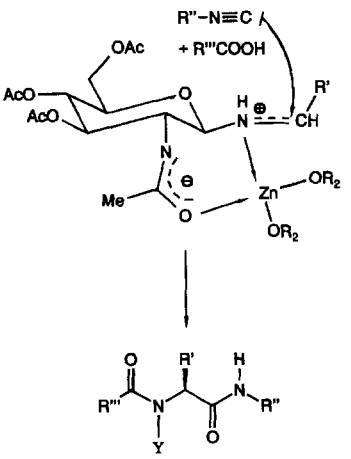


Scheme 2. Stereoselective synthesis of α-amino acids with 1-galactopyranosyl amines by Kunz et al.; R^2 = *t*Bu.

the N-formyl derivatives are cleavable by this rather drastic method. Therefore, peptides were not accessible.

These results motivated us to employ *O*-alkylated 1-aminopyranoses in a similar way, and in this case several peptide derivatives could be synthesized, since the glycosidic template could be removed by mild acidolysis with various, often sulfur-containing, nucleophiles.[21] The stereoselectivity reached was at a level similar to that obtained by Kunz et al.; however, the yields of these fragmentations were mostly low and the uniformity of the products often dissatisfying.

A major improvement was achieved by the use of the acetylated aminoglucopyranose **2**.[22] This compound is easy to prepare from readily available "*N*-acetyl glucosamine" in three simple steps[23, 24] (Scheme 3). The imine obtained from an aldehyde and the amine **2** forms a rigid complex with zinc chloride, which,



Scheme 3. Synthesis of the acetylated 1-aminoglucopyranose **2**. TMS = trimethylsilyl.

together with a clearly favored *trans* configuration of the imine, results in restricting the nucleophilic attack of the isocyanide to the back side at sufficiently low temperatures (Scheme 4). The diastereoisomeric excesses achieved thereby are above 99% in most cases, as a matter of fact, the second diastereoisomer could not be found. Small amounts of the second diastereoisomer were detected only for the smallest aldehydes, namely acetaldehyde and propionic aldehyde, (*de* = 89 and 94%, respectively, Table 1).

While the stereochemical inductivity of the templates used by Kunz et al. relied heavily on type and steric position of the chosen acyl groups on the pyranosyl system, these factors had no influence when using template **2**. Therefore, simple acetyl groups and the inexpensive glucopyranose system could be used. Significantly, there is no stereoselectivity, when **2** is used without the zinc catalyst, which also catalyses the formation of

Scheme 4. Mechanism of the stereoselective U-4CR with the amine **2**. R = Et, Y = sugar group (see Scheme 3).

Table 1. Selection of condensation products that were obtained with the amine **2** according to the reaction given in Scheme 2; in the formulas the newly formed stereocenters (all D configurated) are labeled with an asterisk; the amino acid derivatives used were all L configurated.

the imine. Other metal salts, like $MgBr_2$, show similar effects, but none as convincingly as zinc chloride dietherate. Typical yields are in the range of 80% (Table 1) with best yields obtained at $-40\,^{\circ}C$ in most cases, while optimal stereoselectivity was always achieved at $-75\,^{\circ}C$. Much lower optical and chemical yields are obtained at temperatures above $0\,^{\circ}C$.

Possible acid components are all soluble acids that are not too strongly acidic. For example, trifluoroacetic acid already leads to a rather uncertain mixture of by-products, while excellent results were obtained with formic acid. Aromatic or heteroaromatic aldehydes do not form stable imino chelates, which differs from our experiences concerning alkylated 1-amino pyranoses. Isocyanides have to be sufficiently nucleophilic, otherwise reaction times will be very long. Tests with (*para*-toluenesulfonyl)methyl isocyanide, for instance, gave yields of less than 10% after 10 days reaction time. THF and methanol are suitable solvents for these reactions, whereas halogen-containing solvents strongly favor the P-3CR, making them as unsuitable as nonpolar solvents (amine will not dissolve!) or solvents that show a high viscosity at the temperatures employed. At $-75\,^{\circ}C$, reaction times including the time for the precondensation of the imine are roughly six days. Other limitations were not found. All compounds in Table 1 were made by this simple one-pot procedure without special adaptations. Syntheses of longer peptide structures are currently under investigation as are preparations of cyclopeptides. We are also developing a template for the preparation of the analogous L derivatives. An important feature of the amine **2** is its ability to form dihydrooxazoles, which should make cleaving the chiral template easier. We have already been able to realize an acidolytic and a reductive fragmentation process. However, since yields and overall reproductivity have yet to be optimized, this work will be reported at a later date. One aspect herein, is the possible variation of the amide group at C2 of **2** in order to get better fragmentation and also to improve the diastereoselectivity at higher temperatures.

Experimental Procedure

General procedure for the stereoselective U-4CR: To the amine **2** (10 mmol) and the chosen aldehyde (10 mmol), dissolved in THF or methanol (90 mL) at the chosen temperature (standard value is $-75\,^{\circ}C$), molecular sieves (4 Å) (2.5 g) and catalyst ($ZnCl_2$ in Et_2O) (11 mmol) were added under an argon atmosphere. This mixture was stirred for several hours until complete formation of the imine. Then the isocyanide (10.4 mmol), dissolved in precooled solvent (5 mL), and subsequently the acid component (10.4 mmol), dissolved or suspended in precooled solvent (5 mL), were added. The mixture was stirred at a constant temperature until no amine was detectable by TLC. The reaction mixture was then filtered swiftly through a layer of celite (1 cm) and this was additionally washed with dichloromethane (20 mL). Under vigorous stirring a mixture of saturated aqueous sodium hydrogen carbonate solution (15 mL) and methanol (65 mL) was poured into the reaction mixture. After five minutes of additional stirring, the resulting suspension was filtered and the solvent removed. The sometimes oily, often foamy residue was taken up in dichloromethane (100 mL) and the remaining isocyanide was removed by extraction with aqueous tartaric acid (for *tert*-butyl isocyanide) or by treatment with acetic acid (for involatile isocyanides). This was followed by extraction with water, saturated sodium hydrogen carbonate, and water again (each 250 mL). The mixture was then dried over sodium sulfate and the solvent evaporated. In most cases, after several hours at high vacuum a crystalline foam was obtained, which was often found to be already analytically pure. Otherwise it was purified by recrystallization and/or chromatography.

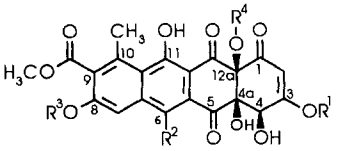
Novel Genetically Engineered Tetracenomycins**

Heinrich Decker, Sabine Haag, Györgyi Udvarnoki, and Jürgen Rohr*



Chemically untreatable diseases as well as increasing numbers of bacteria,[1] viruses, parasites, and cancer cells resistant to chemotherapy demand innovative concepts to find new molecules, which might serve as lead structures for pharmaceutically useful drugs. Natural products have proven to be a primary basis for novel bioactive molecules. Since the pioneering experiments of Hopwood et al. in 1985, genetically engineered hybrid microorganisms[2] with modified genes have also been discussed as a possible source of new natural products.[3] Even though this method has been highlighted as a major step forward in biotechnology,[3c] there are no other examples of genetically engineered hybrid compounds except for some macrolide derivatives.[4] Re-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We also thank Dipl.-Chem. R. Machinek for the H,H-NOESY NMR spectrum, and Dr. J. Metzger (Universität Tübingen) for the electron spray, and Dr. G. Remberg (Universität Göttingen) for all other mass spectra.

cently, however, Khosla et al. have proven the general concept to be prosperous, since the interspecies exchange of polyketide synthase genes of different producers of multicyclic aromatic polyketides resulted in the production of several new metabolites.[5] Consequently, more and various types of hybrid products should be expected in the future. Polyketides occur in most organisms (bacteria, fungi, plants) and are an extremely rich family of bioactive molecules (antibiotics, antitumor agents, immunosuppressants, etc.). The biosynthetic pathways of many polyketides have been elucidated and the analysis of the genetics of polyketide production is under intense investigation.[2b] Therefore, this group of natural products seems to be the most promising one to be approached by genetic engineering for the production of novel hybrid compounds,[2c] as the current examples show.[3–5] Our strategy in this context was to combine genes of two well-studied producers of related types of multicyclic, aromatic polyketides in order to enhance the chance for detection of novel hybrid products. The first results of our studies are three novel tetracenomycins isolated from two hybrid strains, which were made by transferring the tetracenomycin biosynthesis genes from *Streptomyces glaucescens* GLA. O[6] and elloramycin biosynthesis genes from *Streptomyces olivaceus* Tü 2353,[6] into the urdamycin-producer *Streptomyces fradiae* Tü 2717.[7]

The tetracenomycins (tetracenomycin C **1**) and the related elloramycins[6] (elloramycin A **2**) as well as the urdamycins[7] (urdamycin A **3**) are examples of biosynthetically well-studied polyketide antibiotics. In addition, since the elloramycins and urdamycins are glycosylated during the biosynthesis, the producing strains contain, besides the biosynthetic genes coding for the polyketide synthase, the genes necessary for the biosynthesis of the special carbohydrate moieties as well as for the glycosylation of the polyketide-derived aglycon moieties. Thus, from a combination of the biosynthetic genes of both parent *Streptomyces* species, one could expect as possible hybrid products not only those derived from a hybrid polyketide synthase, but also those that result from intercombining the polyketide biosynthesis with the post-polyketide biosynthesis apparatus of the other parent, for instance the enzymes of the carbohydrate biosynthesis, including the glycosyl transferase activities. Biosynthetic enzymes for middle or late biosynthetic steps, for example methyltransferases and oxygenases, may be expected also to contribute by acting on the other strains intermediates or end products. The success of this approach depends mainly on the substrate specificity of the enzymes involved in the biosynthesis of the different polyketide compounds. To inspect this general possibility, we introduced the entire tetracenomycin (*tcm*) gene cluster (pWHM3 with a 12.5 kb DNA insert = pWHM1026[8a]) and part of the elloramycin (*elm*) gene cluster (pKC505[8b] with a 25 kb DNA insert = 16F4[8c]) into the urdamycin producer *Streptomyces fradiae* Tü 2717 by transformation.[8c] Most of the metabolites in the fermentation broth of the two hybrid strains were recognized as tetracenomycin-, elloramycin-, or urdamycin-related natural products through their UV spectra (HPLC/diode array detector).[9a] Three of the compounds did not match with any known products and their subsequent isolation and structure elucidation revealed the presence of novel tetracenomycin derivatives, namely 6-hydroxytetracenomycin C (**4**) from *Streptomyces fradiae* Tü2717(pWHM1026), and 3,8-didemethyltetracenomycin C (**5**) and 8-β-D-olivosyl-8-demethyltetracenomycin C (**6**) from *Streptomyces fradiae* Tü2717(16F4). The structures could be determined from the analyses of the NMR (Tables 1 and 2) and mass spectra by comparison with that of tetracenomycin C (**1**). The characteristic NMR features of **4** are the missing 6-H signal (Table 1) and the additional chelated OH group ($\delta = 12.68$; Table 2) in the ^{1}H NMR spectrum, and the quarternary C-6 in the ^{13}C NMR spectrum (attached proton test (APT); Table 1). The molecular formula $C_{23}H_{20}O_{12}$ (488.4) follows from the electron spray (ES) MS (*m/z* 556.5 (100%)

$[M + 3\,Na]$) as well as from the highly resolved molecular peak of the EI-MS (488.0954). The molecular formula $C_{21}H_{15}O_{11}$ (443.3) and structure of **5** were derived from the ES-MS (*m/z* 466.5 (100%) $[M + Na]$) and the NMR spectra, containing only one OCH_3 group and the additional keto group at $\delta = 187.0$. The position of the remaining OCH_3 group at C-9 could be deduced from its chemical shift in the NMR spectra (Tables 1 and 2) in comparison with that of the corresponding group in **1**. The compound is obtained after workup (pH 7) as the sodium salt of the anion and has the 1,3-diketo structure, in which one of the acidic 2-H atoms is removed. The compound resembles 3-demethylelloramycinone, a hydrolysis derivative of **2**.[6a] The NMR spectra of the third novel compound **6** show the structural elements of the 8-demethyltetracenomycin C aglycon plus one D-olivose moiety. Its molecular formula $C_{28}H_{28}O_{14}$ (588.5) could be deduced from negative ion FAB-MS (*m/z* 587 (100%) $[M-H^-]$). The assignment of the position of the sugar moiety was complicated, since no helpful $^3J_{C-H}$ coupling could be detected in the HMBC or COLOC spectrum. Although a significant upfield shift of C-4a in **6** (in comparison with the chemical shifts of this carbon in **1**, **4** and **5**, Table 1) seems to indicate a variation of the molecule in this region, it could be unambigously concluded that 8-O is the linkage position of the sugar moiety. This was deduced from the ^{1}H NMR spectrum (all other OH groups are free, see Table 2), the UV data (the UV spectrum of the compound at pH > 7 does not show the typical absorption at 315 nm, caused from the 8-OH group, which is, for example, observed in elloramycinone[6d]), and finally from the H,H-NOESY NMR spectrum, in which a significant NOE effect is observed inter alia between 1′-H and 7-H. The β-glycosidic linkage follows from the coupling pattern of the 1′ and 2′-H_a signals in the ^{1}H NMR spectrum, the absolute stereochemistry of the sugar moiety from the $[\alpha]_D$ value of its liberated α-methylglycoside (+133, $c = 0.08$, EtOH, 21 °C).[9b]

We demonstrated the co-production of tetracenomycin C (**1**) and its biosynthetic intermediate 8-demethyltetracenomycin C (**7**) in the urdamycin-producer *Streptomyces fradiae* Tü 2717 (pWHM1026) and *S. fradiae* Tü2717(16F4), respectively. Furthermore three novel compounds were produced by the hybrid strains, namely a minor product **5**, and two major products **4** and **6** (production ca. 10 mg L^{-1}). 8-demethyltetracenomycin C (**7**) has previously been isolated by Yue et al.[10a] from a mutant of *Streptomyces glaucescens* impaired in the 8-*O*-methylation step. The plasmid conferring tetracenomycin C (pWHM1026) production is well-characterized and all *tcm* genes on this plasmid have been sequenced and analyzed.[10b] Since there is no indication for an enzyme in the *tcm* cluster catalyzing the 6-hydroxylation of **1**, this activity has to arise from an enzyme present in *Streptomyces fradiae*. Therefore, **4** could be formed by one of the oxygenases of urdamycin biosynthesis through which oxygens in the 12 and the 12b positions are introduced[11] at carbons 4 and 6, respectively, of its initial decaketide. The 6-position of the tetracenomycins corresponds to the carbon 6 of its initial decaketide precursor (Scheme 1). 6-hydroxytetracenomycin (**4**) is the **1**-analog of elloramycin F (6-hydroxyelloramycin A), known as a minor side product (production 0.01 mg L^{-1}) of the elloramycin-producer *S. olivaceus*.[12]

Scheme 1. Decaketide precursors of **4** and **3**.

The plasmid carrying some of the elloramycin biosynthetic genes (16F4)[8c] is less well characterized than pWHM1026. It confers resistance to elloramycin (**2**) and tetracenomycin C (**1**), and introduction of 16F4 into *Streptomyces fradiae* Tü 2717 or *Streptomyces lividans* TK24 by transformation results in the production of 8-demethyltetracenomycin C (**7**).[8c] In addition, *Streptomyces fradiae*(16F4) produced 3,8-didemethyltetracenomycin C (**5**) and 8-β-D-olivosyl-8-demethyltetracenomycin C (**6**). Compound **5**, a minor side product (1 mg L^{-1}), seems to be the result of an incomplete aglycon biosynthesis in which 3-*O*-methylation did not occur. The occurrence of compound **5** can be considered an indicator that the methylation sequence for the biosynthesis of **1**, as outlined by Hutchinson et al.,[6c, 10a] can be curtailed in some instances. In contrast, **6** is a true hybrid molecule, because the 2,6-dideoxy sugar olivose is normally only produced for urdamycin biosynthesis; it occurs twice in urdamycin A (**3**). Elloramycin (**2**) bears a permethylated L-rhamnose moiety, also linked at 8-O. The genes for the biosynthesis of the permethylated L-rhamnose moiety are not present on 16F4.[8c] Thus, the hybrid strain *Streptomyces fradiae*(16F4) must use glycosyl transferase activity to link the dideoxy sugar β-D-olivose and the elloramycin polyketide backbone resulting in the hybrid product **6** (Scheme 2). We cannot exclude the possibility that there is a glycosyl transferase present on 16F4; therefore this reaction may either be catalyzed by an enzyme present on 16F4 or by an enzyme of the urdamycin producer. That **6** can only be obtained through transferring the genes into *Streptomyces fradiae* and not by simple microbial transformation[13]

6

Scheme 2. PKS = Polyketide synthase; "DSS" = "deoxy sugar synthase", that is, genes necessary for the biosynthesis of the deoxysugar olivose from glucose; GT = glycosyl transferase; Enz = enzyme.

was shown by a control experiment: Feeding of **7** to a growing culture of the urdamycin-producing wild-type strain did not yield any olivosyltetracenomycin (**6**). This indicates that the glycosyltransferase from the urdamycin producer either does not work on **7** but on a different biosynthetic intermediate, or that there is an unidentified glycosyl transferase present on 16F4 that catalyzes the linkage of the sugar moiety.[14]

Our initial experiments indicate that co-expression of two different polyketide pathways in one hybrid strain is a promising tool to create new natural products in reasonable yields (10 mg L^{-1}). We have not yet detected any novel urdamycin derivatives or novel types of polyketides derived from the activity of a hybrid polyketide synthase.[5] Therefore, the expression of engineered hybrid polyketide synthases in a heterologous host as demonstrated by Khosla et al.[5] should be done to obtain further hybrid compounds.

Experimental Procedure

Bacterial strains and plasmids: *S. fradiae* Tü 2717 was transformed with 16F4 and pWMH1026 by protoplast fusion and protoplasts were regenerated on R2YE agar plates [15]. Plasmid pWHM1026 carrying the entire *tcm* cluster was described previously [8a]. 16F4 consists of the cosmid vector pKC505 [8b] that contains a 25 kb DNA fragment isolated from the elloramycin-producer *S. olivaceus* Tü 2353 [8c]. This plasmid contains all the genes necessary for the production of **7** [8c].

Cultivation of the recombinant strains: *S. fradiae* Tü2717(16F4) and *S. fradiae* Tü2717(pWHM1026) were grown for 96 h in a production medium (2% soybean meal, 2% glucose, pH 7.2 [7]) with 25 μg mL^{-1} apramycin and 10 μg mL^{-1} thiostrepton, respectively.

Isolation of the novel products: The culture was extracted twice with ethyl acetate at pH 7 and evaporated to dryness. The ethyl acetate residue was disolved in CH_2Cl_2 and further purified on silica gel saturated with oxalic acid (silica gel SI 60, Merck, Germany). The silica gel column was washed with CH_2Cl_2 and the compounds were eluted with CH_2Cl_2/MeOH (95:5, 9:1, and 8:2). Fractions containing different urdamycin and tetracenomycin metabolites were pooled, evaporated to dryness, and further purified on Sephadex LH 20 (MeOH). The final purification was performed by HPLC (preparative column, Nucleosil 100 C-18, particle size 10 μm), elution with water/MeOH (gradient 40% to 100% MeOH in 15 min).

Instruments: All NMR spectra were recorded on a Varian VXR 500 spectrometer at a field strength of 11.7 Tesla, except the HMBC spectra and the NOESY spectrum which were recorded on a Bruker AMX 300 at a field strength of 7.1 Tesla. Details see Tables 1 and 2. All mass spectra (except ES- MS, see below) were obtained on a Finnigan MAT 95 spectrometer, for the FAB-MS 3-nitrobenzyl alcohol was used as the matrix. The electron spray mass spectra (ES-MS) were recorded on a API III Taga 6000 E equipped with an ion spray source (Sciex, Thornhill, Canada).

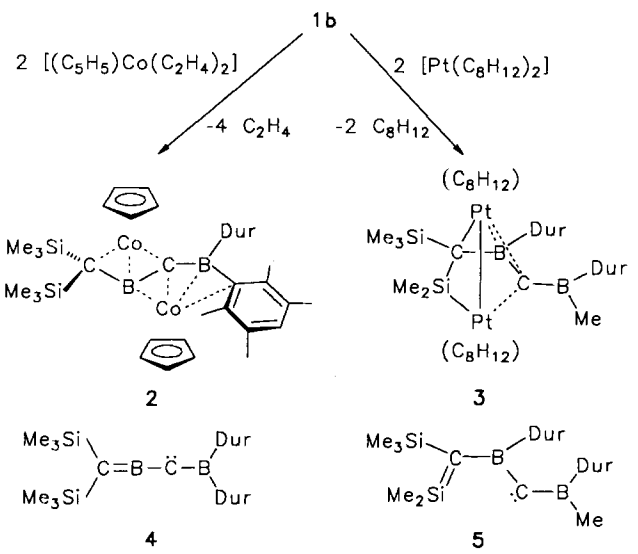
Dicobalt and Diplatinum Complexes of Diborylcarbenes**

Anuradha Gunale, Hans Pritzkow, Walter Siebert,* Dirk Steiner, and Armin Berndt*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday



The nonclassical structure **1** of boriranylideneboranes[1] (the classical formulation is **1***[2]) was predicted by Schleyer[3] and others[4] years before proof was provided by an X-ray structure determination of **1a**.[5] Among the versatile reactions of **1b**, **c**[6] several occur with cleavage of bonds in the three-membered ring and migration of substituents.

1* 1

a: R^1 = 2,3,5,6-tetramethylphenyl (Dur), R^2 = $GeMe_3$
b: R^1 = Dur, R^2 = $SiMe_3$
c: R^1 = 2,4,6-trimethylphenyl (Mes), R^2 = $SiMe_3$

Here we show that **1b** reacts with $[Co(C_5H_5)(C_2H_4)_2]$ and $[Pt(C_8H_{12})_2]$ to yield **2** and **3**. During the formation of **2** a duryl group migrates from one boron to the other; in the case of **3** a methyl group migrates from silicon to boron. They can be viewed as the first examples of complex-stabilized diborylcarbenes **4** and **5**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie.

Two equivalents of $[Co(C_5H_5)(C_2H_4)_2]$[7] react with **1b** in hexane with evolution of ethene. Chromatographic workup gives a dark green diamagnetic compound in 46% yield; its mass spectrum is in agreement with the formula $[(CpCo)_2C_2B_2(SiMe_3)_2Dur_2]$. In the ^1H NMR spectrum two singlets for the CpCo moieties, two singlets of the $Si(CH_3)_3$ groups, and eight signals for the methyl groups of the duryl substituents indicate an unsymmetrical complex. Its unusual constitution was determined by an X-ray structure analysis (Fig. 1).[8]

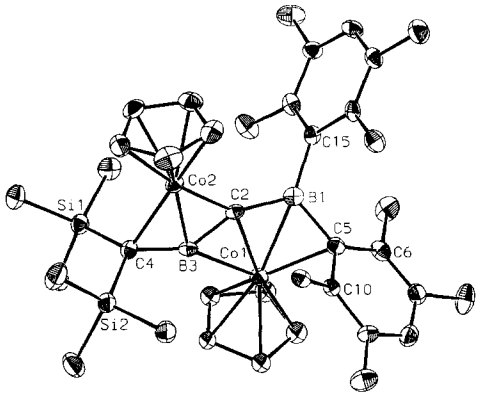

Fig. 1. Structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Co1-B1 2.276(6), Co1-C2 2.009(6), Co1-B3 2.081(8), Co1-C5 2.180(7), Co1-C10 2.554(9), Co1-C6 3.06, Co2-C2 1.887(6), Co2-B3 1.973(7), Co2-C4 2.114(6), B1-C2 1.522(10), C2-B3 1.474(9), B3-C4 1.483(10), B1-C5 1.601(10); B1-C2-B3 150.3(6), C2-B3-C4 138.0(6).

The C-B-C part of the C-B-C-B chain in **2** is *trihapto*-coordinated to a CpCo moiety. The distances between the atoms Co2, C4, and B3 show structural similarity to the CpCo(CO) complex of an aminomethyleneborane.[10] The second CpCo fragment is bonded *tetrahapto* to the other side of the ligand through the B-C-B atoms as well as one duryl substituent (to C5 and weakly to C10; see also the temperature-dependent ^{13}C NMR shifts). The dinuclear complex with a bridging B–C group has short Co1–C2 and Co2–C2 distances, which may be compared with the length of a C=Co bond [1.881(6) Å] of a cyclopentadienylidene cobalt complex.[11] The Co–B distances fall within normal bonding ranges,[12, 13] although Co1–B1 [2.276(8) Å] is somewhat long.

The ^{13}C NMR chemical shifts of one duryl ring [δ = 146.3 (*i*-C), 132.9, 133.4, 135.5, 136.0 (*o*- and *m*-C), 130.9 (*p*-C)] are essentially temperature-independent ($\Delta\delta$ = 0.1 to 0.3). In contrast, the second duryl ring shows signals that are clearly shifted to higher and lower field (to δ = 97.2 and δ = 155.6). These signals are of varying broadness and are temperature-dependent ($\Delta\delta$ = 1.6–10.5, Table 1).

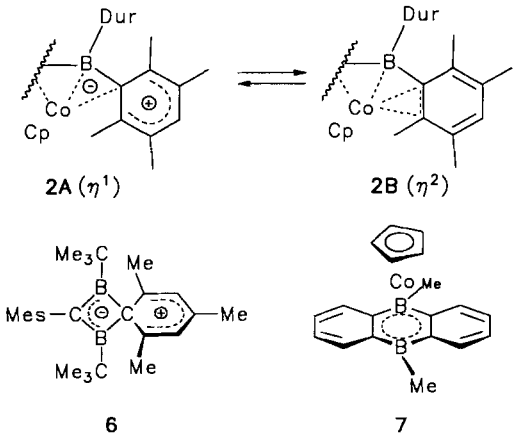

Table 1. ^{13}C NMR chemical shifts [δ] of selected C atoms in **2** at various temperatures.

T [K]	193	233	273	298	$\Delta\delta$ (298–193)
CSi_2	29.1	28.9	27.2	[a]	
i-C	97.2	97.9	100.9	105.5	+8.3
o-C	120.9	124.2	128.0	131.4	+10.5
m-C	131.4	131.5	130.8	129.8	−1.6
p-C	134.4	134.9	136.0	137.4	+3.0
m'-C	141.2	140.4	139.3	138.0	−3.2
o'-C	151.9	152.7	154.1	155.6	+3.7
CB_2	196.5	194.5	189.9	[a]	

[a] Not observed.

This finding can be explained as a dynamic equilibrium in solution between the complex **2A** with η^1 interaction and the valence isomer complex **2B** with η^2 interaction. It is expected that the Co1-bound C atom of the coordinated duryl ring in **2B** (η^2) has a similar chemical shift as in complex **7** [δ = 103 (*i*-C), 128.3 (*o*-C), 137.2 (*m*-C)[14]]. Compound **2A**, however, should be similar to **6** [δ = 113.4 (*i*-C), 160.4 (*o*-C), 129.3 (*m*-C), 146.1 (*p*-C)[15]]. The weighted averaging has an especially strong effect on the chemical shifts of the *i*-C and *o*-C atoms of the duryl ring in **2**. Similar equilibria $\eta^1 \rightleftarrows \eta^2$ have been postulated for Re–aryl complexes.[16]

The atoms of the C4-B3-C2-B1 chain and the two Co atoms lie in a plane. The plane through Si1-C4-Si2 is perpendicular to this plane and that through C5-B1-C15 forms an angle of approximately 30° to it. The C2 carbon atom is planar-coordinated (sum of angles = 359.9°) by four electron-poor centers.[17] Its ^{13}C NMR resonance at 194.5 shows that it is notably deshielded. Similar deshielding of carbene-C atoms appears in other dinuclear carbene complexes.[18] The C-B-C-B chain is bent (C4-B3-C2 = 138.0° and B3-C2-B1 = 150.3°). The bonds C4–B3 and B3–C2 are quite short [1.483(10) and 1.474(9) Å, respectively] and are in the range of coordinated B=C bonds.[10] The C2–B1 bond [1.522(10) Å] is a bit shorter than a B–C single bond (1.55–1.60 Å). Both Co centers in the μ_2,η^3,η^4-dinuclear complex **2** have a closed-shell configuration. The 14 VE fragment CpCo of Co2 interacts with the atoms C4–B3 (C=B as 2e donor) and with μ-C2, which as a carbene carbon atom forms a 3c–2e Co2-C2-Co1 bond. Co1 completes its 18 VE configuration through this 3c–2e bonding and the interaction with the duryl group.

The addition of one equivalent of [Pt(η^4-C_8H_{12})$_2$] to **1b** in toluene at room temperature led unexpectedly to the diplatinum compound **3**. An optimized synthesis of red-orange crystalline **3** occurs in 63% yield. An analysis of its ^{1}H NMR spectrum demonstrates the migration of a methyl group from silicon to boron. The two ^{11}B NMR signals (δ = 41 and 65) indicate that the interaction of platinum with one boron atom is strong while that with the other is weak. This is confirmed by the X-ray structure (Fig. 2).[8] The complex is best described as a five-membered ring (made up of Si1, Pt2, C2, B3, and C4) which is *tetrahapto*-bonded to Pt1. Unusual is the *dihapto*-complexation of the C_8H_{12} ligand to Pt2.

In contrast to the *anti* arrangement of the CpCo moieties in **2**, the platinum atoms in **3** are adjacent. Although the Pt–Pt distance of 2.864(2) Å is slightly longer than normal for a Pt–Pt bond (2.6–2.8 Å), it is considered a real interaction. The platinum atoms are bridged by the carbene carbon atom. Similar structural features have been reported for di- and triplatinum complexes.[19] The Pt1 atom can be assigned an 18 VE configuration (C_8H_{12} as a η^4-ligand, σ-bonds to C4 and Pt2, and a 3c–2e bond Pt1-C2-Pt2).[20] On this basis Pt2 formally has a 16 VE configuration, since it is only *dihapto*-coordinated to its C_8H_{12} ligand.

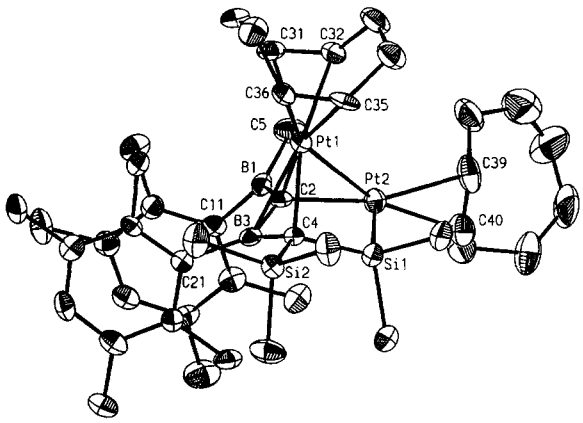

Fig. 2. Structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: Pt1-C2 2.118(10), Pt1-B3 2.409(12), Pt1-C4 2.166(10), Pt1-Pt2 2.864(2), Pt2-C2 2.084(10), Pt2-Si1 2.304(4), B1-C2 1.58(2), C2-B3 1.53(2), B3-C4 1.56(2); C2-B3-C4 107.4(9), B3-C4-Si1 105.3(7), C4-Si1-Pt2 102.9(4), Si1-Pt2-C2 81.2(3), Pt2-C2-B3 122.5(8).

Our results show that though the complexes **2** and **3** are structurally very different, the formation of both involves cleavage of the C–C bond in **1b** as well as migration of a substituent (either Dur or Me) to a boron atom.

Experimental Procedure

2: A mixture of **1b** (0.310 g, 0.68 mmol) and [Co(C_5H_5)(C_2H_4)$_2$] (0.380 g, 2.1 mmol) in 15 mL hexane was stirred for 3 h. Chromatographic workup of the brown solution on Al_2O_3 with hexane provided an orange fraction (excess [Co(C_5H_5)(C_2H_4)$_2$]) and dark green **2**; 230 mg (46%), m.p. 183 °C (from hexane). ^{1}H NMR (500 MHz, [D$_8$]THF, −40 °C): δ = 0.21, 0.29 (each s, 2 × 9 H; Si(CH_3)$_3$), 0.57, 2.16, 2.20, 2.24, 2.25, 2.30, 2.32, 2.39 (each s, 8 × 3 H; *o*- and *m*-CH_3), 4.07, 4.18 (each s, 2 × 5 H, C_5H_5), 7.00, 7.12 (each s, 2 × 1 H, *p*-H). ^{13}C NMR (125 MHz, [D$_8$]THF, −40 °C): δ = 5.4, 5.6 (2 q, Si(CH_3)$_3$), 20.0, 20.1, 20.6, 20.7, 20.9, 21.2, 22.4, 29.3 (8 q, *o*- and *m*-CH_3), 28.9 (br. s, CSi_2), 80.1, 83.8 (2 d, C_5H_5), 97.9 (br. s, *i*-C(B-Dur-Co)), 124.2 (br), 131.5, 132.9, 133.4, 135.5, 136.0, 140.4, 152.7 (7 s, *o*- and *m*-C), 130.9, 134.9 (2 d, *p*-C), 146.5 (br. s, *i*-C(B)), 194.5 (br. s, CB_2). ^{11}B NMR (96 MHz, [D$_8$]THF, 25 °C): δ = 41; EI-MS: *m*/*z* (%) = 706 ([*M*$^+$], 39), 632 ([*M*$^+$ − Si(CH_3)$_3$ − H], 5), 582 ([*M*$^+$ − Co(C_5H_5)], 100), 567 ([*M*$^+$ − Co(C_5H_5) − CH_3], 3), 517 ([*M*$^+$ − Co(C_5H_5)$_2$], 9).

3: A solution of **1b** (0.225 g, 0.49 mmol) in a mixture of hexane (6 mL) and toluene (1 mL) was added at 0 °C to [Pt(η^4-C_8H_{12})$_2$] (0.405 g, 0.98 mmol) and stirred for 3 h at 20 °C. Chromatographic workup on Al_2O_3 with hexane eluent provided a yellow fraction (**1b**) and uncharacterized side products. Elution with hexane/toluene (1:1) provided red-orange **3**, 330 mg (63%), m.p. 165 °C (decomp.). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = −0.12 (s, 9H; Si(CH_3)$_3$), 0.37, 0.48 (2 s, 2 × 3 H, *J*(Pt,H) = 42 Hz; Si(CH_3)$_2$), 0.81 (s, 3 H; BCH_3), 1.56, 1.66, 1.72, 1.75, 2.03, 2.08, 2.28, 2.35 (8 s, 8 × 3 H; CCH_3), 1.95–2.70 (m, br, 16 H; CH_2), 4.05–4.35 (m, br, 2 H; −CH=), 5.10–6.10 (m, br, 6 H; −CH=), 6.41 (s, 2 H; *p*-H). ^{11}B NMR (96 MHz, CD_2Cl_2, 25 °C): δ = 41, 65. ^{13}C NMR (50.3 MHz, CD_2Cl_2): δ = 2.9 (Si(CH_3)$_3$), 5.4, 5.7 (Si(CH_3)$_2$), 18.7, 19.3, 19.4, 19.5, 19.8, 20.9, 21.5, 22.4 (CCH_3), 27.9, 29.0, 29.2, 29.5, 29.6, 30.8, 31.1, 33.2 (CH_2), 80.8, 81.8, 88.2, 89.1, 89.3, 93.5 (Pt-coordinated −CH=), 128.0, 128.5, 129.2, 130.0 (uncoordinated −CH= and *p*-H), 130.9, 131.0, 131.1, 131.2, 131.4, 131.6, 133.8, 134.5 (CCH_3), carbon atoms adjacent to boron were not observed. EI-MS: *m*/*z* (%) = 761 ([*M*$^+$ − Pt(C_8H_{12})], 0.23), 746 ([*M*$^+$ − Pt(C_8H_{12})−CH_3], 0.7), 703 ([*M*$^+$ − Pt(C_8H_{12})−CH_3], 0.7), 703 ([*M*$^+$ − Pt(C_8H_{12})−Si(CH_3)$_2$], 0.2), 653 ([*M*$^+$ − Pt(C_8H_{12})$_2$], 0.9), 476 (**1b**·H_2O^+, 6) 134 ([$C_6(CH_3)_4H_2$]$^+$, 65), 119 ([$C_6(CH_3)_3H_2$]$^+$, 100), 73 ([Si(CH_3)$_3$]$^+$, 99).

Relationship between C(O)–N Twist Angles and ^{17}O NMR Chemical Shifts in a Series of Twisted Amides**

Shinji Yamada*

The structure and spectroscopic properties of twisted amides[1] have received considerable attention not only in organic chemistry but also in biochemistry.[2] The influence of the rotation about the C(O)–N bond on IR,[3] UV,[4] and ^1H,[5] ^{13}C,[6] ^{15}N[7] NMR, and ESCA[8, 9] spectroscopic data has been studied. However, no investigations on the dependence of the ^{17}O NMR chemical shift on the C(O)-N twist angle have been carried out, although it has been recognized that the chemical shift of the ^{17}O NMR signal is more sensitive to structural variation than the shifts of the ^{13}C and ^{15}N NMR signals.[10] Here we describe the relationships between the C(O)–N twist angles[11] and the ^{17}O and ^{13}C NMR chemical shifts of the 3-acyl-1,3-thiazolidine-2-thiones **1a–e** (Scheme 1). Furthermore, the relationship with the amide resonance, which on the basis of calculated electron populations has been challenged recently,[12] is also described.

Scheme 1. Structural formulas of the twisted amides **1a–e** and those of the dimethyl amides **2a–c**.

We previously reported[13] that the C(O)–N bond of 3-pivaloyl-1,3-thiazolidine-2-thione (**1c**) is highly twisted, whereas, that of 3-acetyl-1,3-thiazolidine-2-thione (**1a**) is almost planar; both results were confirmed by X-ray crystallographic analysis. A series of derivatives with different substituents at the C-4 atom and the acyl carbon atom were synthesized to give a variety of twist angles between 0–90°. Amides **1b**, **1d**, and **1e** were newly prepared by the acylation of the corresponding 1,3-thiazolidine-2-thiones with acetyl, pivaloyl, and phenylacetyl chloride, respectively. Table 1 shows the structural parameters of the C(O)–N twist angle τ, and the bond lengths r(C=O) and r(C(O)–N) of **1a–e**. The value of the twist angles τ lies in the range of 10° to 75°. The carbonyl group and the 1,3-thiazolidine-2-thione ring of **1a** and **1e** are coplanar, whereas, those of **1c** and **1d** are nearly orthogonal because of their steric repulsion between the bulky *t*Bu and C=S groups. In amide **1b** the two *gem*-dimethyl groups at the C-4 atom twist the C(O)–N bond to produce a twist angle of 36.5°, which is almost half the value of that of **1c**. An increase in the twist angle lengthens the C(O)–N bond, while the C=O bond lengths remain virtually unchanged. The independence of C=O bond lengths on twist angles has also been observed in bicyclic amides.[7]

Table 1. Selected structure parameters of **1a–e**.

Compd.	τ [°]	r(C(O) – N) [Å]	r(C=O) [Å]	Ref.
1a	20.1	1.413(9)	1.21(1)	[13]
1b	36.5	1.432(3)	1.210(3)	[17]
1c	74.3	1.448(4)	1.196(4)	[13]
1d	65.5	1.466(5)	1.195(5)	[17]
1e	10.2	1.415(6)	1.203(7)	[17]

To examine the relationships of ^{17}O and ^{13}C NMR chemical shifts with twist angles, ^{17}O NMR spectra of the compounds were acquired in natural abundance in CD_3CN (2–3 M solution) at 54.1 MHz at 23 °C; the chemical shifts were referenced to external H_2O. Table 2 shows the ^{17}O NMR chemical shifts[14] for **1a–e** and their partial structures **2a–c**. In order to compensate for the substituent effects around the carbonyl groups the $\Delta\delta(^{17}O)$ values are given as the differences in the ^{17}O chemical shifts of the compounds **1a–e** and the corresponding dimethyl amides **2a–c**. The range of $\Delta\delta(^{17}O)$ values is 100–173 ppm. As shown in Figure 1a, a linear relationship was observed between

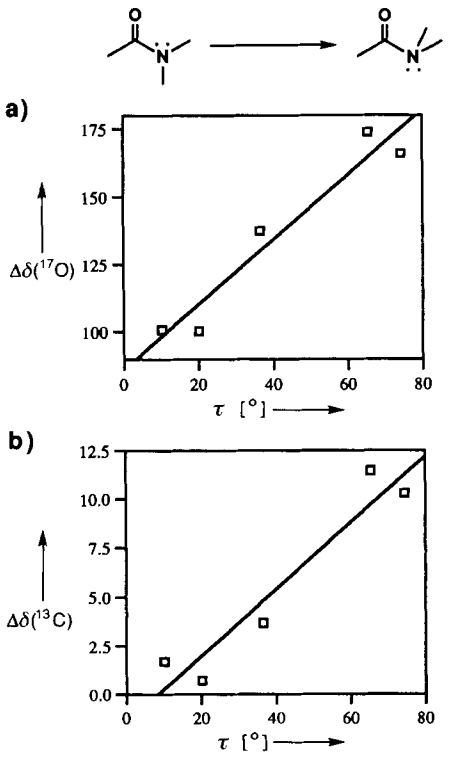
the $\Delta\delta(^{17}O)$ and the τ values; increasing the twist angle causes an increase in the $\Delta\delta(^{17}O)$ value. The influence of the structure of the NC(S)S ring on the chemical shift of the carbonyl groups seems to be very small because the NC(S)S and carbonyl groups are not very close together. Since these amides have similar structures, the influence on the chemical shift arising from structural differences should also be negligible. In general, ^{17}O NMR chemical shifts are thought to be essentially dependent upon the paramagnetic term which is proportional to the charge density. Therefore, the changes in the $\Delta\delta(^{17}O)$ values are largely ascribed to the changes in the charge density of the O atom during C(O)–N bond rotation. The ^{13}C chemical shifts of the carbonyl carbon for **1a–e** and **2a–c**, and their difference $\Delta\delta(^{13}C)$ are listed in Table 3. The plot of the $\Delta\delta(^{13}C)$ against the τ values was also found to be almost linear (Fig. 1b). These relationships can



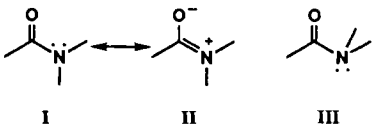


Fig. 1. Plot of the relationship between the $\Delta\delta(^{17}O)$ and the τ values (a) as well as between the $\Delta\delta(^{13}C)$ and the τ values (b).

be explained by the classical amide resonance model (Scheme 2). Thus, for the small twist angle the contribution of the form **II** leads to shielding of the O atom. The rotation of the C(O)–N bond disturbs this contribution, which leads to weakening of the shielding effects. A similar explanation can be adopted for the results observed for the ^{13}C chemical shifts.

I **II** **III**

Scheme 2. Structures of the planar amide **I**, the form **II**, and the twisted amide **III**.

Wiberg and Laidig made a prediction[12] concerning the amide resonance based on a comparison of the C, N, O electron populations in planar **I** and in twisted **III** amides (Scheme 2) calculated with Bader's method.[15] They describe that the electron population of carbon and nitrogen are opposite of what would be expected from the resonance model and that of oxygen is not dependent on the rotation of the C(O)–N bond. In connection with this prediction a number of theoretical studies were undertaken;[16] however, only a few experimental approaches have been carried out.[7, 9] The results described above seem inconsistent with the analysis, because the $\Delta\delta(^{17}O)$ value, which is closely related to the electron population of the O atom, is dependent on the C(O)–N twist angle as shown in Figure 1a. Furthermore, the relationship of $\Delta\delta(^{13}C)$ value with the twist angles in Figure 1b is opposite to that predicted from the reported analysis. However, the relative independence of the C=O bond length on the twist angle compared to the C(O)–N still remains to be explained.

Further investigations of the C(O)–N rotational effect on other spectra and the relation with the amide resonance are currently in progress.

Binding of Boron and Alkali Metal Cations by a Pseudocryptand**

Ernest Graf,* Mir Wais Hosseini,* Romain Ruppert, Nathalie Kyritsakas, André De Cian, Jean Fischer, Christine Estournès, and Francis Taulelle

Since the discovery of cryptands, in particular the [2.2.2] macrobicyclic ligand **3**, some 25 years ago by Dietrich, Lehn, and Sauvage[1] and of the crown ethers by Pedersen[2] an exciting new field of research named supramolecular chemistry has opened to inorganic, organic, and physical chemists.[3–5] Whereas at the outset much attention was focused on the selective binding of spherical monoatomic alkali metal and alkaline-earth metal cations, very rapidly considerable achievements were reported with regard to the recognition of molecular cations.[6] Many aspects of supramolecular chemistry remain to be developed, for example, new materials based on self-assembly may be targeted by using weak interactions.[7]

The early design of cryptands involved the construction of cage molecules capable of binding cationic substrates within their cavities leading to the formation of cryptates. Since the [2.2.2]cryptand **3** is neutral, for the sake of charge neutrality the cationic cryptate complex must be accompanied by a counter anion. In order to overcome the problems associated with the presence of the anion, we designed a cryptand bearing a negative charge within its framework. Inspired by the naturally occurring antibiotics such as boromycin[8] and aplasmomycin,[9] which both bear a borate ester moiety, we synthesized the pseudocryptand **1**.[10] This compound combines the [2.2] macrocyclic core[11] of the [2.2.2]cryptand with two bidentate dianionic catecholate units. A similar concept was previously reported for podands and coronands bearing two catechol units linked by polyethyleneglycol chains.[12] Compounds bearing the [2.2] macrocycle and two bipyridine moieties are known and their ability to bind both transition and alkaline metal cations has been described.[13] Triaza and tetraaza macrocycles bearing three and four pendant catecholate units, respectively,[14] as well as macrobicyclic tris-catecholate ligands that serve as siderophore analogues have also been reported.[15]

Compound **1** may also be regarded as a binucleating ligand capable of binding two cations. Indeed, the binding of a main group element such as boron by **1** would lead to the negatively charged pseudocryptand **2**, a complex of the Böeseken type[16] found in boromycin[8] and in aplasmomycin.[9] In turn, this complex should bind an alkali metal cation, affording the neutral cryptate [$M^+ \cdot$ **2**]. Although the design and synthesis of binuclear complexes have been extensively studied over the past twenty years,[17] only recently has considerable effort been invested in the synthesis of heterobinuclear complexes bearing both a hard alkali or alkaline-earth metal cation and a soft transition metal cation.[18]

Treatment of **1**[10] in EtOH with one equivalent of $B(OH)_3$ and one equivalent of MOH in H_2O at room temperature led exclusively to the formation of the [$M^+ \cdot$ **2**] complex. A single recrystallization of the raw material afforded the pure [$M^+ \cdot$ **2**] complex (M = Li, Na, K, Rb, Cs, NH_4).

The binding ability of **2** towards alkali metal cations was studied in solution by NMR spectroscopy in $CDCl_3$ and in CD_3OD. In $CDCl_3$, the ^1H NMR spectrum of the parent compound **1** in the region $\delta = 2$–4.5 showed two triplets at $\delta = 2.82$ and 3.69 for CH_2N and NCH_2CH_2O, respectively, and two singlets at $\delta = 3.61$ and 3.81 for OCH_2CH_2O and the benzylic CH_2N protons, respectively (Fig. 1a). The coordination of boron in **1**, caused dramatic changes in the ^1H NMR spectrum. In particular, the benzylic CH_2N protons in **2** give rise to an AB quartet. Furthermore, the chemical shift values in the ^1H NMR spectrum appear to be strongly dependent on the nature of the cation complexed in the cavity. This was especially true for the benzylic CH_2 protons for which the observed chemical shift difference ($\delta_A - \delta_B$) varied from about 375 Hz for Na^+ to about 554 Hz for K^+ (Fig. 1). For the complex [$K^+ \cdot$ **2**] all ^1H and ^{13}C signals were assigned based on a ^1H–^{13}C correlation experiment. For the other complexes the same assignment was assumed to be correct. Since the positions of the ^1H signals for the [$M^+ \cdot$ **2**] complexes appeared to be cation-dependent, the selectivity and stability were studied by ^1H NMR spectroscopy. The stability of [$M^+ \cdot$ **2**] complexes (M = Na^+, K^+, Cs^+) was investigated by competition experiments with [2.2.2]cryptand **3** in CD_3OD. Addition of less than one equivalent of **3** to a solution of [$Na^+ \cdot$ **2**] caused partial decomplexation of the Na^+ ion leading to a mixture of [$Na^+ \cdot$ **2**] and [$Na^+ \cdot$ **3**] complexes. [**] This work was supported by the CNRS and by the Institut Universitaire de France. The first publication about [2.2.2]cryptands by B. Dietrich, J.-M. Lehn, and J.-P. Sauvage appeared in 1969 (ref. [1]); this work is dedicated to them.

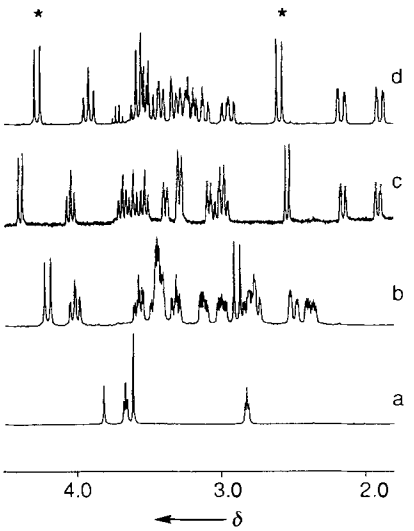

Fig. 1. Selected regions ($\delta = 1.8-4.5$) in the ^{1}H NMR spectra ($CDCl_3$): a) free ligand **1**, b) $[Na^+ \cdot \mathbf{2}]$, c) $[K^+ \cdot \mathbf{2}]$, and d) $[Cs^+ \cdot \mathbf{2}]$. The quartet in Fig. 1d at $\delta = 3.72$ is attributed to residual EtOH. The quartet of AB benzylic protons are indicated with an *.

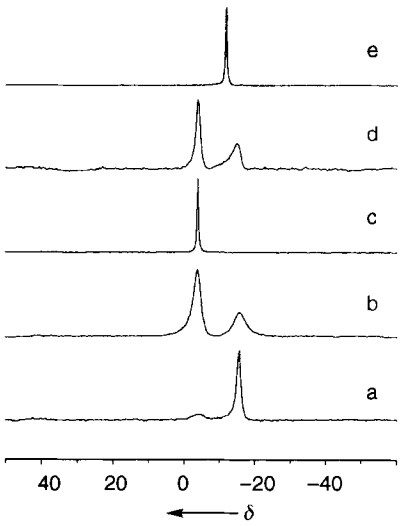

Fig. 2. ^{23}Na NMR spectra (105 MHz, CD_3OD, 25 °C). a) $[Na^+ \cdot \mathbf{2}]$, b) $[Na^+ \cdot \mathbf{2}] + 1$ equiv NaI, c) $[Na^+ \cdot \mathbf{2}] + 1$ equiv KI, d) $[Na^+ \cdot \mathbf{2}] + 1$ equiv CsBr, e) $[Na^+ \cdot \mathbf{2}] + 1$ equiv **3**. 5 M NaCl in D_2O was used as external reference.

removal of Na^+ from **2** was attained by addition of more than one equivalent of **3**, indicating that the $[Na^+ \cdot \mathbf{2}]$ complex was less stable than the $[Na^+ \cdot \mathbf{3}]$ complex. On the other hand, addition of up to 100 equivalents of **3** to the $[K^+ \cdot \mathbf{2}]$ complex did not lead to the removal of the K^+ ion from **2**, indicating that the $[K^+ \cdot \mathbf{2}]$ complex was at least two orders of magnitude more stable than the $[K^+ \cdot \mathbf{3}]$ complex. In other words, since the binding constant K_s for the $[K^+ \cdot \mathbf{3}]$ complex in methanol was initially estimated to be greater than 10^7 L mol^{-1},[19] and subsequently determined to be $10^{10.49}$ in methanol in the presence of 0.5 M NEt_4ClO_4,[20] for the $[K^+ \cdot \mathbf{2}]$ complex this K_s value should be greater than $10^{12.5}$ L mol^{-1}. However, owing to the high stability of the $[K^+ \cdot \mathbf{2}]$ complex we have so far been unable to determine its binding constant accurately using conventional methods. The selectivity of **2** towards Na^+, K^+, and Cs^+ ions was likewise investigated by competition experiments in CD_3OD. Whereas addition of less than one equivalent of KI to the $[Na^+ \cdot \mathbf{2}]$ complex led to a mixture of both $[Na^+ \cdot \mathbf{2}]$ and $[K^+ \cdot \mathbf{2}]$ complexes, upon addition of one equivalent of KI, only the characteristic ^{1}H NMR pattern of the $[K^+ \cdot \mathbf{2}]$ complex was observed. These findings indicated a stronger binding of K^+ than Na^+ by **2**. Further confirmation of this was obtained from the following experiment. Addition of up to 10^3 equivalents of NaI to the $[K^+ \cdot \mathbf{2}]$ complexes led to no changes in the ^{1}H NMR spectrum, indicating that the selectivity factor between Na^+ and K^+ lay in the favor of the latter by at least a factor of 10^3. For comparison, a selectivity factor of about 300:1 for K^+/Na^+ was reported in methanol for the cryptand [2.2.2] (**3**).[20] Analogous competition experiments between Cs^+ and K^+ revealed that **2** binds K^+ more strongly than Cs^+ with a selectivity factor greater than 10^2.

The binding ability of **2** towards alkali metal cations was also studied by ^{23}Na NMR spectroscopy (Fig. 2). In CD_3OD, the $[Na^+ \cdot \mathbf{2}]$ complex gave a major signal at $\delta = -15.7$ with a line width of 113 Hz; and a minor signal at $\delta = -4.1$ is attributed to some sodium contamination (5 M NaCl in D_2O was used as external reference) (Fig. 2a). For NaI under the same conditions values of $\delta = -3.91$ and line width = 16.1 Hz were observed. For the $[Na^+ \cdot \mathbf{3}]$ cryptate the ^{23}Na NMR signal occurs at $\delta = -11.4$ and the line width $\Delta\nu$ is 29 Hz in CD_3OD/D_2O: 95/5.[21] Since **2** is considerably less symmetrical than **3**, the increase in the line width values from 29 Hz for the $[Na^+ \cdot \mathbf{3}]$ complex to 113 Hz for the $[Na^+ \cdot \mathbf{2}]$ complex may be expected because of the nuclear quadrupolar moment of ^{23}Na ($I = 3/2$). Upon addition of one equivalent of NaI (Fig. 2b) to the solution containing the $[Na^+ \cdot \mathbf{2}]$ complex, two signals were observed at $\delta = -15.4$ and -3.7 with line widths of 238 and 192 Hz, respectively; this indicates a slow exchange process between the free and the complexed Na^+ at 25 °C ($T_c = 55$ °C, $k_c = 2.7 \times 10^3$ s^{-1}, $\Delta G^+ = 15.5$ kcal mol^{-1}). The addition of one equivalent of KI to this solution restored the signal at $\delta = -3.9$ with a line width of 18.9 Hz corresponding to free Na^+ ions (Fig. 2c). This thus confirmed the results of the ^{1}H NMR investigations namely that the K^+ ion was more strongly complexed by **2** than the Na^+ ion. Furthermore, addition of one equivalent of CsBr to a solution of the $[Na^+ \cdot \mathbf{2}]$ complex gave two signals at $\delta = -15.5$ and -4.0, which are assigned to the free and complexed sodium, indicating that the affinity of **2** for Na^+ and Cs^+ was in the same range (Fig. 2d). Finally, addition of the [2.2.2]cryptand **3** to a solution of the $[Na^+ \cdot \mathbf{2}]$ complex led to a single signal at $\delta = -11.8$ with a line width of 21.3 Hz. This signal corresponds to the $[Na^+ \cdot \mathbf{3}]$ complex, confirming the results of the ^{1}H NMR studies according to which **3** showed a higher affinity for the Na^+ ion than **2** (Fig. 2e).

Although X-ray data were collected for the $[M^+ \cdot \mathbf{2}]$ complexes with $M = K^+$, Cs^+, and NH_4^+, only the crystal structure of $[K^+ \cdot \mathbf{2}]$ is reported here.[22] The X-ray crystal structure analysis of the racemic potassium complex (Fig. 3) showed that K^+ is

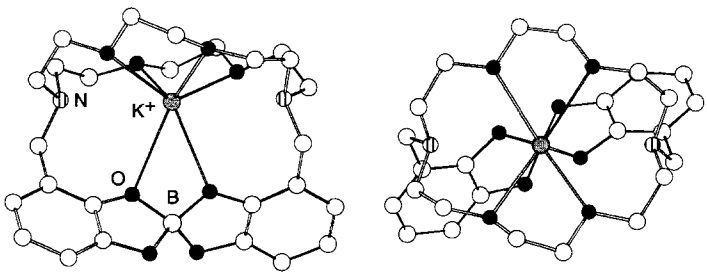

Fig. 3. X-ray structure of the $[K^+ \cdot \mathbf{2}]$ complex. The enantiomer shown is arbitrary. Side view (left) and view along the boron–potassium axis (right). Selected bond lengths [Å] and angles [°] (average values given): K-O 2.82, K-N 3.15, B-O 1.48; O-B-O 105.0 and 109.9, N-K-N 179.

located within the cavity formed by the negatively charged cryptand **2**. The coordination geometry around the boron atom is indeed tetrahedral with two sets of O-B-O angles of about 105 and 109.9°, and an average B–O distance of about 1.48 Å. As expected, because of the tetrahedral coordination around the boron atom, *R* and *S* isomers are present in the unit cell. The lone pairs of the two nitrogen atoms are oriented towards the interior of the cavity (*in,in* conformation) and the K^+ ion is located at position that is almost equidistant from the two bridgehead nitrogen atoms (N–K distance ca. 3.15 Å); the N-K-N angle is 179°. Among the eight oxygen atoms present in **2**, only six of them, namely the four oxygen atoms of the ether junctions and two borate oxygen atoms, are localized within a bonding distance of K^+ (average distance of ca. 2.82 Å). The coordination polyhedron of the K^+ ion in the [K^+ · **2**] complex, in which the K^+ ion is surrounded by six oxygen and two nitrogen atoms at distances of 2.82–3.15 Å, is irregular. The average K–O distance of about 2.82 Å is considerably shorter than the average K–N distance of about 3.15 Å. In contrast the K^+ ion in [K^+ · **3**] is located almost in the center of the cage with average K–O and K–N distances of about 2.78 Å and 2.87 Å, respectively.[23]

In conclusion, we have demonstrated that the pseudocryptand **1** participates in a cascade-type complexation process. Indeed, binding of the boron atom by both catecholate moieties in **1** leads to the borate ester **2**, thus creating a preorganized cavity bearing one negative charge. Compound **2** acts as a cryptand and binds an alkali metal cation, leading to a neutral [M^+ · **2**] complex. To our knowledge, both the estimated binding constant of about $10^{12.5}$ mol L^{-1} for the potassium complex in methanol and the selectivity factor of the ligand **2** for K^+ over Na^+ and Cs^+ cations of more than 10^3 and 10^2, respectively, are the highest values obtained to date for artificial K^+ receptors.

Synthesis and Characterization of the First Mixed Alkali Metal Enolate Containing Amine Ligands: A Novel "Open-Stack" Structure and Its Implications for Aldol Addition**

Kenneth W. Henderson, Paul G. Williard,* and Peter R. Bernstein

During the past two decades there has been an increasing awareness of the role that aggregation plays in the reactions of lithium enolates.[1] This focus has been created by interest in the aldol reaction and in particular in the possibility of forming chiral materials from simple ketones [Eq. (a)].[2] The synthetic

(a)

utility of this carbon–carbon bond-forming reaction has proved itself in numerous natural product syntheses, leading to an evolution in its methodology. Generally, lithium amides such as lithium diisopropylamide (LDA) or lithium hexamethyldisi-

lazide (LHMDS) are used as strong bases to perform the deprotonation reaction, producing the corresponding amine and lithium enolate.

Much of the attention on enantioselective aldol syntheses has concentrated on the use of chiral amide bases and amines as chiral catalysts.[1-3] Of fundamental importance is the role the chiral moiety plays in the reaction. Despite this, no direct structural evidence has been reported for an enolate bonded to its reprotonated secondary amine. Seebach et al.[4] have studied in detail the interaction of lithium enolates with the chelating secondary amine *N,N,N'N'*-trimethylethylenediamine (triMEDA). This revealed an interaction between the enolate moiety and the hydrogen of the N–H bond. Typically, however, external donor bases such as THF or *N,N,N',N'*-tetramethylethylenediamine (TMEDA) have been used to mimic the action of the chiral moiety.

Only a handful of enolates of the heavier alkali metals have been structurally characterized, which is surprising considering these species offer different selectivities to their lithium counterparts.[5] To our knowledge no studies, either synthetic or theoretical, have been performed for simple mixed-cation enolate systems.[6] This contrasts to the growing documentation on mixed-anion systems.[7] We now outline the characterization of the first mixed alkali metal enolate, which furthermore contains a secondary amine formed by protonation of the amide base as donor ligand.

Specific categories of mixed alkali metal systems, such as superbases,[8] amides,[9] and imides,[10] have recently received an increasing degree of attention because their reactivity and structures are different from that of their homometallic analogs. We were interested in obtaining structural details of mixed alkali metal enolate complexes. Reaction of sodium diisopropylamide (NDA) and LDA with 3,3-dimethyl-2-butanone (pinacolone) yields crystals of $[Li_2Na_4\{OC(=CH_2)tBu\}_6 \cdot (iPr_2NH)_2]$ (**1**) [Eq. (b)].

$$4\,iPr_2NNa + 4\,iPr_2NLi \xrightarrow{8\,tBuCOMe} \mathbf{1} + 6\,iPr_2NH + 2\,[LiOC(=CH_2)tBu] \quad \text{(b)}$$

A single-crystal X-ray structural analysis of **1** revealed a triple-layered stack of one NaONaO ring dimer sandwiched between two LiONaO dinuclear rings (Fig. 1).[11] Stack structures, either tetrameric (cubane) or hexameric (consisting of two stacked trimers), have been found for a number of alkali metal compounds, including imides ($R_2C{=}N^-$), alkynyls ($RC{\equiv}C^-$), alkoxy/aryloxy (RO^-), and enolates $[RC(=CR_2)O^-]$.[12] The triple-layered stack unit found for **1** is rather unusual, and only two such structures have been reported,[10] namely the bimetallic imides **2** and **3**, which interestingly also contain both sodium and lithium. Higher oligomeric stacks have been found for lithium alkynides[13] and also for sodium amides.[14]

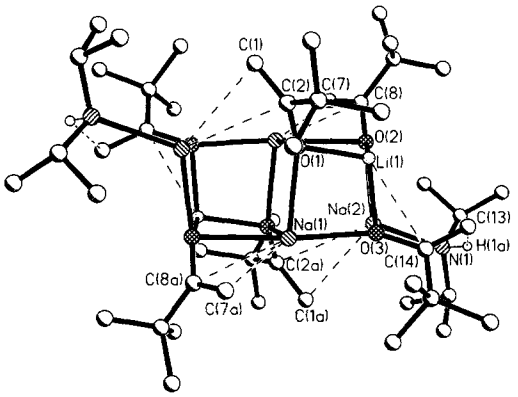

Fig. 1. Molecular structure of **1** (hydrogen atoms, except H(1a), omitted for clarity). Key bond lengths [Å] and angles [°] not in text: Na(1)-O(1) 2.366(7), Na(1)-O(1a) 2.418(7), Na(2)-O(2) 2.288(7), Li(1)-O(2) 1.87(2), Li(1)-O(3), 1.93(2); O(1)-Li(1)-O(2) 108.7(7), O(1)-Li(1)-O(3) 102.7(7), O(3)-Na(1)-O(1a) 95.8(2), O(1a)-Na(1)-O(2a) 80.3(2), O(2)-Na(2)-O(1a) 84.5(2), O(3)-Na(2)-O(1a) 81.6(2), Li(1)-O(1)-Na(1) 83.8(5), Li(1)-O(1)-Na(1a) 83.5(5), Li(1)-O(2)-Na(1a) 85.3(5), Na(2)-O(2)-Na(1a) 97.2(2), Li(1)-O(3)-Na(1) 88.1(5), Na(1)-O(3)-Na(2) 99.3(3).

$[Li_4Na_2\{N{=}C(NMe_2)_2\}_6]$ **2**

$[Li_{4-x}Na_{2+x}\{N{=}C(Ph)tBu\}_6]$ **3**

A clear difference between **1** and the imides **2** and **3** is the ratio of metals present. Both **2** and **3** are lithium rich (4 Li:2 Na), while **1** is sodium rich (2 Li:4 Na). The stoichiometry of metal atoms in **1** deviates from the 1:1 ratio of reactants used. Similar situations have been found to arise commonly for mixed-metal systems containing alkali metals, where the stability of the structural arrangement determines which products are isolable.[15] Even when the mixture of starting materials contains more lithium (2 LDA:1 NDA), only **1** was isolated. This implies that a soluble lithium enolate species is present in solution; lithium pinacolate is known to be highly soluble in hydrocarbons.[16]

Also unique to **1** is its structural form, in which two edges of the face-sharing cubes are absent. The distance between Na(2)–O(1a) and Na(2a)–O(1), that is, the "open" edges, is 2.875 Å. This contrasts sharply with the lengths of the shorter closed edges Na(1)–O(3) and Na(1)–O(2a) of 2.242 Å and 2.420 Å, respectively (and Li(1)–O(1) at 1.96 Å). Short contacts are apparent between the $H_2C{=}C$ units of the central NaONaO enolate ring and the terminal sodium atoms (Na(2)–C(1a) 2.778 Å; Na(2)–C(2a) 2.873 Å). Even shorter contacts are observed between the central sodium atoms and the π bond of the outer enolate residues (Na(1)–C(8a) 2.702 Å; Na(1)–C(7a) 2.716 Å). Similarly Li(1)–C(14) is short (2.74 Å), but Li(1)–C(13) is longer than 3 Å. This feature also manifests itself on comparison of the bond angles. The angles of the central dimeric ring are not unusual (93.7° at sodium and 86.3° at oxygen), whereas the outer rings are very distorted from square (106.8° at lithium, 81.4° at sodium, 88.0° at O2, and 83.8° at O3). Each closed side of the stack is more linear (O(3)-Na(1)-O(2a) 174.6°) than the sides with an "open" edge (Li(1)-O(1)-Na(2a) is 162.6°).

Several factors may combine to give the framework of **1**. The disparity in size between the lithium and sodium atoms causes significant distortion of the structure.[9, 10] Interactions between the π bonds of the enolates and the metals amplifies the distortion, resulting in two "open" edges of the stack. An "open-stack" arrangement has not been noted for any prior alkali metal complexes in the solid state, although Jackman et al. suggested such structures as intermediates in transesterification reactions.[17] Also of note is the mixed-cation imide **4** that can be described as a "broken-cube".[18] A number of "open-dimers" have been proposed both as solution aggregates and as important reaction intermediates.[19] Structures such as **1** can be considered close cousins to open dimers.

$[\{Sb_2Li_2\{N(C_6H_{11})\}_4\}_2]$ **4**

The final component of **1** is a coordinated diisopropylamine at each of the outer sodium atoms; the Na(2)–N(1) bond length

is 2.558 Å. Previously, tertiary or secondary amines were added as cosolvents to alkali metal enolates in order to study the interaction of the free base with the salt.[1-4] Compound **1** represents a new and important stage after full enolization has taken place: the enolate is immediately solvated by free amine. Although much attention has been paid to using amides as chiral additives in the aldol reaction, the role the base plays has not yet been fully defined. We now have direct evidence that the free base can form a coordination complex with the metal enolate. This implies that the amine, and not only the metalated amide, may influence the regioselectivities of an incoming reactant in the formation of chiral materials. Such a suggestion is supported by synthetic results, which show a correlation between enantioselectivity and stoichiometry of the chiral amine.[3] Each amino hydrogen is directed towards a terminal carbon atom of an enolate residue (C(13)–H(1a) 3.006 Å), but does not lie on the N(1)–C(13) vector (N(1)–C(13) 3.646 Å). This is reminiscent of the geometry involved in the enolization reaction.[4]

In conclusion, we have reported the synthesis and structure of the first mixed alkali metal enolate. It adopts a unique "open-stack" arrangement in the crystal and contains a secondary amine formed during protonation as ligand. The triple-stack motif is unprecedented for alkali metal enolates. Such structures should now be considered when conducting theoretical or NMR studies of the aldol reaction.

Experimental Procedure

A vigorously stirred mixture of *n*-butyllithium (1 mmol) and *n*-butylsodium (1 mmol) in 2 mL of pentane, under a protective nitrogen blanket, was treated at 0 °C with diisopropylamine (2.2 mmol). After warming to 20 °C, the mixture was placed in an ultrasound bath for 5 minutes. The homogeneous suspension was cooled to 0 °C and pinacolone (2.2 mmol) added over a 5 minute period. The now near clear solution was filtered through a glass frit and the clear colorless filtrate kept at 0 °C. Colorless cubic crystals of X-ray diffraction quality of **1** were deposited after 12 hours. Yield of first crop of crystals (based on *n*BuNa) 22%; m.p. 207–210 °C; ^{1}H NMR (400 MHz, C_6D_6, 300 K): 0.25 (br.s., 2H; NH), 0.94 (d, 24H; $(CH_3)_2CH$), 1.20 (s, 54H; $(CH_3)_3C$), 2.74 (oct, 4H; $(CH_3)_2CH$), 3.43 (br.s., 6H; $C=CH_2$), 3.77 (br.s., 6H; $C=CH_2$).

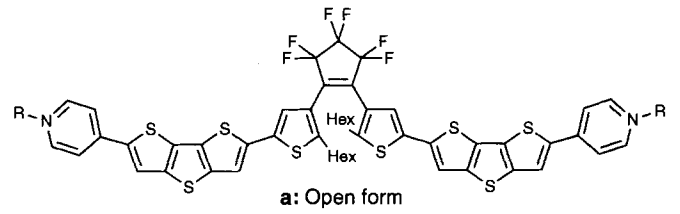
Photonic Molecular Devices: Reversibly Photoswitchable Fluorophores for Nondestructive Readout for Optical Memory**

Gerasimos M. Tsivgoulis and Jean-Marie Lehn*

Systems that allow the reversible modulation of a given electronic property like conjugation by an external trigger such as light constitute basic components for the development of molecular and supramolecular devices.[1] This is the case for organic photochromic compounds,[2-10] some of which exhibit remarkable properties for use in optical memory media,[2-4] for example low fatigue and/or very good thermal stability. However, photochromic materials must fulfill many criteria for practical applications in optical information storage systems.[2] A major problem arises from readout unstability. Some possible solutions have been proposed,[3, 5, 8, 10] but the development of a nondestructive readout method remains a challenging problem.[2, 3]



Diarylethenes, notably bis(thien-3-yl) systems, display excellent photochromic properties[6-8] and can be reversibly inter-

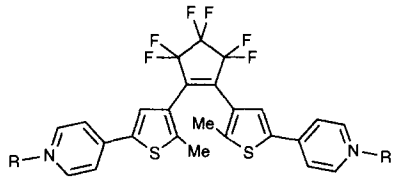
converted between a nonplanar, colorless, open form and a planar, colored, closed form in which extended conjugation over the whole molecule is possible.[7] Thus, properties depending on changes in the π system (electrical, optical) as well as structural changes (solubility, chirality, recognition) may be strongly altered by the form of the system.

We have designed and synthesized (as delineated in Scheme 1[11]) two photoswitching units **1** and **2**, in which extensive conjugation between two condensed dithieno(thiophene)



>600 nm ⇌ 330-365 nm

units is possible, in order to: a) extend the concept of a switchable molecular wire,[7] b) introduce new absorption bands and study their behavior with regards to the "switch" action, and c) bathochromically shift the UV/Vis absorbance bands relative to those of related systems. We report here the optical properties of the novel unit **2** which meets many of the criteria for practical applications of organic photochromic compounds, notably thermal stability, fatigue resistance, sensitivity to diode laser wavelength, close to quantitative reversible interconversion, and in particular nondestructive readout capability.

The photochemical interconversion properties of compound **2** were studied by irradiating methanolic solutions (1×10^{-5} M and 2×10^{-6} M in a 1×1 cm quartz cell) under a variety of conditions. The UV/Vis spectra of the open **2a** and closed **2b** forms are shown in Figure 1. Irradiation of the main band of the open form **2a** ($\lambda_{max} = 459$ nm, $\varepsilon = 92800\ M^{-1}cm^{-1}$) at 400–500 nm through a window filter[12] gave no change, whereas in related compounds,[7, 8] as well as in the parent compound **1**, irradiation of the main bands of the open forms gave the closed forms in nearly quantitative yields. The main band of the open form **1a** is so active that very fast, quantitative conversion to the closed form **1b** occurs simply on exposure to daylight. Conversion of **2a** to the closed form **2b** (in 92% yield) can be achieved only by irradiation at wavelengths less than 400 nm; backconversion occurs (>98%) on irradiation of **2b** at $\lambda > 600$ nm[13] for roughly 30 min. Under the conditions used, irradiation times of about 10 min were sufficient to give conversions of 70–75% in both directions. The ring closure was not quantitative but reached around 92% conversion. To confirm that this reaction corresponds to a photostationary equilibrium, solutions of the closed form **2b** were irradiated at 365 nm, giving **2a** exponentially with a maximum conversion of around 8%.

The closed form **2b** presents an intense ($\varepsilon = 41000\ M^{-1}cm^{-1}$ in MeOH and $\varepsilon = 43300\ M^{-1}cm^{-1}$ in CH_3CN) broad absorption band at $\lambda_{max} = 704$ nm, which is red-shifted by roughly 45 nm and is about 2.7 times more intense than the corresponding band[7] of compound **12** ($\lambda_{max} = 662$ nm, $\varepsilon = 16000\ M^{-1}cm^{-1}$ in CH_3CN). Minimal solvatochromism is observed; in MeOH,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1010-1120 $ 10.00+.25/0

CH_3CN, and DMSO, $\lambda_{max} = 704$, 707, and 724 nm, respectively. This sensitivity in the 650–830 nm region is of much interest for practical applications.[2]

The absorption spectrum of **2a** presents at least three bands ($20000 < \varepsilon < 26000$) in the region between 210 and 400 nm (Fig. 1). To find out which band is active in the closing process, **2a** was irradiated with light of different wavelengths between 250 and 400 nm (using the monochromator of the fluorimeter). We found that only the band at $\lambda_{max} = 329$ nm led to conversion to **2b**. Similar results were obtained by irradiating samples of **2a** with three UV lamps of equal power (6 W) at 365, 312, and 254 nm (Table 1).

Table 1. Conversion of the open form **2a** to the closed form **2b** by irradiation in methanol for 1, 2, 4, and 6 min at different wavelengths λ.

	Conversion of **2a** to **2b** [%]			
	1 min	2 min	4 min	6 min
365 nm	9.5	19.0	36.5	50.0
312 nm	8.0	17.0	32.5	44.5
254 nm	3.0	6.5	12.0	18.0

The thermal stability of **2a** and **2b** was investigated by storing methanolic solutions of both in the dark a) at room temperature for more than 15 days and b) at 60 °C for five hours. In both cases no change was observed in the UV/Vis spectra. Also, no decomposition was detected when compound **2a** was exposed to daylight in air for two to three days. Nevertheless, irradiation experiments were always conducted under an inert atmosphere (N_2). Under these conditions, ten photocycles[14] did not cause any change in the UV/Vis spectra.

It was mentioned above that the strong band of **2a** at 459 nm was found to be inactive. In the same region the closed form **2b** also displays a weakly active band only 19% lower in intensity and at nearly the same wavelength ($\lambda_{max} = 454$ nm). These two bands may be assigned to the [pyridyl–dithieno(thiophene)–thiophene] units, as indicated by comparison of the spectra of **2a** and **2b** with that of the isolated unit. However, because of the small difference between their absorption coefficients, these bands are of little interest for nondestructive readout capability. Therefore, attempts were made to find other properties related to these bands.

The open form **2a** was found to present a strong emission at 589 nm when excited in the 400–500 nm region (Fig. 2). In contrast, the closed form **2b** displays only a weak fluorescence (less than 3% of the intensity of **2a**) that seems to be due, at least in part, to contamination from the open form.[15, 16] It is not possible at present to determine which structural and/or conjugation effects are responsible for this dramatic change in fluorescence.

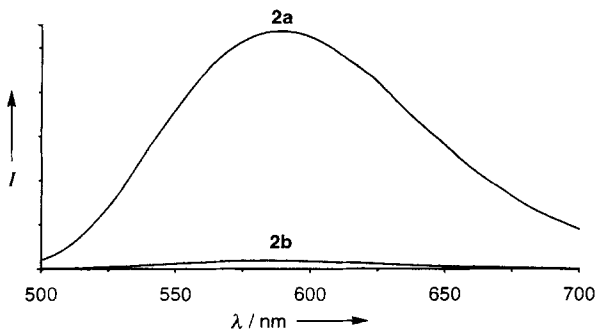

Fig. 2. Emission spectra of forms **2a** and **2b** (2×10^{-6} M in methanol; excitation at 459 nm).

Of special interest is the fact that the absorption bands of both **2a** and **2b**, which by excitation give a fluorescence discrimination, are photochemically almost inactive, while two other absorption bands can be used to interconvert the open and closed forms. Ideally, the bands in the 400–500 nm region must be completely inactive to irradiation for achieving a nondestructive readout capability. As already mentioned, the band of the open form at 459 nm is inactive, while the analogous band of the closed form ($\lambda_{max} = 454$ nm) appears to have low activity when irradiated at 400–500 nm with a 300 W tungsten lamp; a slow conversion of less than 10% per hour is observed. In order to evaluate the fluorescence properties of compounds **2** irradiations were performed with a narrow range of excitation wavelengths. The results (Table 2) show that indeed the "switch position" remains almost unaffected (less than 1%) after 1 h excitation at 459 nm (1 nm excitation width); a broader excitation range (2.5 nm width) gave only a very slow change.

Table 2. Interconversion between the open (**2a**) and closed form (**2b**) in MeOH under different conditions.

λ (conditions)	Conversion after 30 min radiation [%]	
	2a → **2b**	**2b** → **2a**
> 610 nm (cutoff filter) [13]	0	> 98
365 nm (UV lamp)	ca. 92 (max.)	ca. 8
400–500 nm (window filter) [12]	< 0.5	ca. 5
459 nm (2.5 nm width)	< 0.5	2
459 nm (1.0 nm width)	–	< 0.5

In conclusion, the photochromic unit **2** acts as an optical switch presenting a light-triggered fluorescence by excitation of absorption bands that have almost no effect on the switch process. Since excitation at 459 nm leaves the fluorescent open form **2a** unchanged and affects the nonfluorescent closed form **2b** only very little (1% after 1 h) the interconversion between **2a** and **2b** may be used for writing and erasing, while reading can be performed on either form by means of the fluorescent/nonfluorescent contrast. A very large number of fluorescence readings can in principle[17] be performed on **2a** before any significant change takes place. The combination of these properties can offer a promising route towards nondestructive readout capability in optical memory media.

[11] Details regarding the syntheses as well as spectroscopic and electrochemical properties of compounds **1** and **2** will be published in a forthcoming paper. All new compounds were characterized by spectroscopy and microanalysis; compounds **1a**, **b** gave correct microanalyses and FAB mass spectra; for **2a**, **b** only the FAB mass spectra were obtained. The synthesis of the dithieno(thiophene) **8** was described: F. de Jong, M. J. Janssen, *J. Org. Chem.* **1971**, *36*, 1645. Compound **1** is soluble in many common organic solvents like $CHCl_3$, CH_2Cl_2, acetone, THF, and higher alcohols, and is even slightly soluble in hexane. On the other hand, compound **2** carrying two positive charges, is insoluble in solvents of low or medium polarity like hexane, $CHCl_3$, CH_2Cl_2, and acetone, but soluble in solvents of high polarity like CH_3CN, DMSO, DMF, and MeOH.
[12] Characteristics of the window filter: 425–475 nm, transmittance = 68%; $\lambda < 400$ nm and $\lambda > 500$ nm, transmittance < 3%.
[13] Characteristics of the cutoff filter: $\lambda > 620$ nm, transmittance = 83%; $\lambda < 585$ nm, transmittance < 1%.
[14] Conversion to the closed form was limited to 70–75% (10 min irradiation) during these photocycles, while the opening was carried to completion (ca. 30 min irradiation) to check for any change in the spectra. In contrast to experiments in methanol, irradiation of **2a** in aprotic solvents like DMSO or CH_3CN at wavelengths less than 400 nm resulted in partial decomposition.
[15] The only possibility of obtaining pure **2b** is by synthesis from **1b** because the photochemical ring closure of **2a** reaches a maximum of 92% conversion. Contamination by the open form is also indicated by the similar λ_{max} and shape of the emission bands of the two forms.
[16] As in the case of **2**, solutions of the open form **1a** in *n*-pentanol present strong emission bands (at 465 and 444 nm; excitation at 395 nm), whereas the closed form **1b** is only weakly (ca. 1%) luminescent.
[17] Supposing that irradiation for 1 s is necessary for a fluorescence reading (actually this can be much shorter), then over 10^4 readings of the weakly photoactive closed form **2b** can be performed with less than 10% backreaction to the open form.

Synthesis, Structure, and Properties of Dinuclear and Trinuclear Rack-Type Ru^{II} Complexes**

Garry S. Hanan, Claudia R. Arana, Jean-Marie Lehn,* and Dieter Fenske

The design of organic and inorganic programmed systems that self-assemble into well-defined architectures is a major current research theme in supramolecular chemistry.[1, 2] Ligands containing suitable binding sites in a correct arrangement may be read by metal ions following the algorithm defined by their coordination geometry, thus spontaneously generating as output the desired inorganic architecture. In the area of self-assembled inorganic complexes our work has been concerned with several types of systems: double-[3, 4] and triple-helical[5] complexes, helicates, based on tetrahedral and octahedral metal centers, respectively, multicomponent cylindrical cage complexes,[6] and grid-type arrays of metal ions.[7]

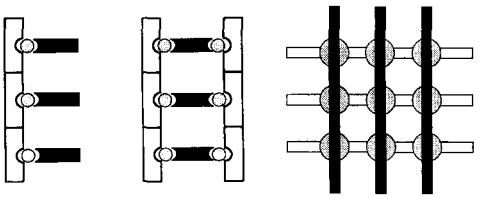
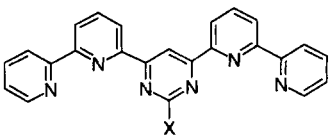
The latter grid structure belongs to a broad class of ordered inorganic architectures comprising, in sequence of increasing complexity, two-dimensional geometries that may be termed racks [*n*]R, ladders [2*n*]L, and grids [*m* × *n*]G (Fig. 1), where [*n*], [2*n*], and [*m* × *n*] specify the number of metal atoms in the R, L, and G structures, and *n* (for a square grid) represents their rank. Extension into three-dimensional structures is conceivable.





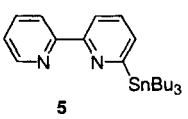


Fig. 1. Inorganic architectures of rack (left), ladder (center), and grid type (right).

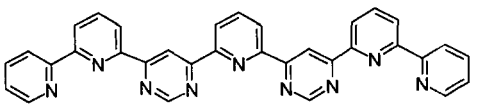
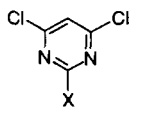
Such inorganic architectures may be assembled from either tetrahedral metal ions and bidentate ligands such as 2,2′-bipyridyl (bpy) or from octahedral metal ions and tridentate ligands such as 2,2′:6′,2″-terpyridyl (tpy). In addition to serving as centers for ligand binding and positioning, the metal ions also introduce electrochemical, photochemical, and reactivity properties, thus conferring functionality to the final architectures for development towards inorganic molecular devices.[1, 8]



We now report the synthesis of the linear ligands **1** and **2**, which contain two and three binding sites, respectively, of tpy



1a X = H
b X = 9-anthryl =

b X = 9-anthryl

[3]R; **4**

type, and the formation of the corresponding rack complexes [2]R **3** and [3]R **4** by coordination of these ligands to $Ru(tpy)^{2+}$ centers.

The synthesis[9] of the bis(bipyridyl)pyrimidines **1a, b** involved the Pd^{II}-catalyzed cross-coupling[10] of 6-tributylstannyl-2,2′-bipyridine (**5**)[11] with the 2-substituted 4,6-dichloropyrimidines **6a, b**[12] in DMF. After column chromatography (alumina, CH_2Cl_2; R_F: **1a** 0.06, **1b** 0.48) **1a** was obtained as a white solid in 49% yield (m.p. 233–235 °C) and **1b** as a yellow solid in 65% yield (m.p. 270–272 °C). Bis(bipyridylpyrimidyl)pyridine **2** was prepared as described elsewhere.[13] The reaction of **1a** with 2.5 equivalents of $[Ru(tpy)Cl_3]$[14] in refluxing ethanol/water (1:1) proceeded smoothly giving a deep green solution, from which the green dinuclear complex $[\{Ru(tpy)\}_2(\mathbf{1a})][PF_6]_4$ **3a** precipitated upon addition of excess NH_4PF_6. The complex was chromatographed on neutral alumina eluting with 2:1 acetonitrile/toluene, and the green fraction was collected and recrystallized from acetonitrile/diethyl ether affording the pure complex **3a** in 72% yield. The complexes $[\{Ru(tpy)\}_2(\mathbf{1b})][PF_6]_4$ **3b** and $[\{Ru(tpy)\}_3(\mathbf{2})][PF_6]_6$ **4** were synthesized in an analogous fashion from refluxing ethylene glycol in the presence of *N*-ethylmorpholine. The products were purified by precipitation out of acetone solution by addition of diethyl ether followed by recrystallization from acetonitrile/toluene, affording the green complexes **3b** and **4** in 51% and 58% yield, respectively.

In the crystal structure of complex **3b**[15] (Fig. 2), the azaheterocyclic backbone of ligand **1b** is slightly distorted from planarity; the anthryl moiety is orthogonal to this main plane.

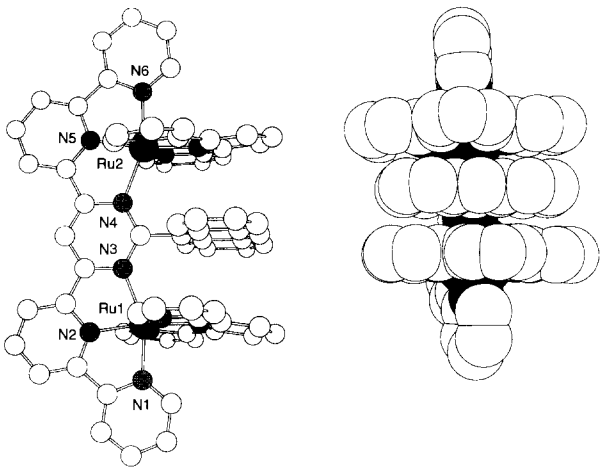

Fig. 2. Left: Ball-and-stick representation of the molecular structure of **3b** with numbered nitrogen and ruthenium sites; the hydrogen atoms, and labels for the carbon and tpy nitrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1-N1 2.067(4), Ru1-N2 2.001(5), Ru1-N3 2.151(4), Ru2-N4 2.148(4), Ru2-N5 1.980(5), Ru2-N6 2.064(4); N1-Ru1-N2 78.9(2), N1-Ru1-N3 156.7(2), N2-Ru1-N3 77.8(2), N4-Ru2-N5 78.3(2), N4-Ru2-N6 157.8(2), N5-Ru2-N6 79.5(2). Right: Space-filling model of **3b** showing van der Waals contact distances.

The ruthenium cations display octahedral coordination to three nitrogen atoms in each of the two tridentate sites of the bridging ligand and to the three nitrogen atoms of the ancillary tpy ligands. The Ru–N bond lengths are comparable with those observed in other ruthenium complexes with azaheterocyclic ligands,[16] although the Ru–N(pyrimidine) bond lengths are slightly longer in **3b**.[17] The ruthenium centers are separated by 6.404 Å, and the carbon atom (C_2) of the pyrimidine unit almost lies on the axis joining the two metal atoms (Ru1-C_2-Ru2 = 174.9°).

As observed in many metal–tpy complexes,[18] the terminal pyridine rings of both tridentate ligands in **3b** as well as those of the ancillary tpys are pulled in toward the metal atoms. The N3-Ru1-N (N atom of the middle pyridine ring in tpy) angle (110.0°) is larger than those in similar complexes,[19, 20] presumably due to the longer Ru–N(pyrimidine) bond and steric interactions between the anthryl moiety and the ancillary tpys, which are stacked at van der Waals contact distances of 3.24 to 3.40 Å.[21] A similar structure persists in solution; ROESY experiments show NOE interactions between the anthracene and tpy hydrogen atoms and inter-ring interactions along the backbone of ligand **1b** in complex **3b**. Until the crystal structure of the trinuclear complex formed by **2** can be determined, its structure may be extrapolated from that of the dinuclear complex **3b**. The schematic representation of **4** is in accord with its ^1H and ^{13}C NMR and mass spectra as well as with its electrochemical behavior.

The degree of metal–metal interaction in polynuclear complexes is highly dependent on the nature of the bridging ligands[22] and of the ancillary ligands.[23] The new complexes **3** and **4** are redox active (Table 1). In cyclic voltammetric studies

Table 1. Electrochemical data for complexes **3a**, **3b**, and **4** [a].

Complex	$E^{\circ\prime}$ (Ox) [V vs SCE]	$\Delta E^{\circ\prime}$ (Ox) [mV]	$E^{\circ\prime}$ (Red) [V vs SCE]

			−0.56 [60]
	+1.47 [70] [d]		−1.08 [60]
4	+1.88 [70]		−1.28 [60]
			−1.38 [b]
			−1.62 [c] [d]

[a] Recorded in acetonitrile solution; scan rate 100 mVs^{-1}; 0.1 M $TBAPF_6$. [b] Stripping peak. [c] Irreversible peak. [d] Two-electron process.

solutions of **3a** in acetonitrile undergo reversible oxidations of the Ru centers at +1.41 and +1.57 V (vs. SCE). Two ligand-based reductions at −0.43 and −1.03 V are ascribed to the sequential reductions of the bridging pyrimidine group. Reduction of the tpy ligands at −1.50 and −1.59 V leads to the adsorption of the formally neutral complex on the electrode surface, as shown by the sharp stripping peak observed at −1.40 V. The redox behavior of **3b** is similar to that observed for **3a** (Table 1), indicating that the presence of the 9-anthryl group does not significantly affect the electrochemical properties. The comproportionation constants for **3a** and **3b**, $K_c = 510$ and 750, respectively, are slightly higher than that of a dimetallic Ru complex incorporating bipyrimidine as the bridging ligand and bpy groups as ancillary ligands ($K_c = 110$).[24]

The cyclic voltammogram of the trimetallic complex **4** exhibits a two-electron oxidation at +1.47 V and a one-electron oxidation at +1.88 V, which are attributed to the terminal Ru sites and the central Ru site, respectively. Since the latter is located between two doubly charged centers, it is expected to be more difficult to oxidize. At negative potentials four one-electron processes are observed between −0.33 and −1.28 V, which are ascribed to sequential reduction of the two bridging pyrim-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1010-1123 $ 10.00+.25/0

idine groups. The large wave at -1.62 V (irreversible) corresponds to adsorption of the formally neutral complex and is ascribed to the reduction of the ancillary tpys. The three Ru^{II} complexes **3a**, **3b**, and **4** have an unusual green color that may be related to both the nature of the ligand and the interaction between the metal sites.[25]

The present results demonstrate the generation of ordered rack-type metal complexes displaying rigid linear arrangements of the metal centers which may communicate through the bridging groups. Extension of these racks, modification of the bridging units (for instance replacing N by C^- sites), and generation of extended arrays of homo- and heterometallic centers will provide a range of novel linear and rigid electroactive and photoactive coordination architectures suitable for incorporation as components of inorganic supramolecular devices.

Synthesis of a Stable Arenesulfenic Acid Bearing a Bowl-Shaped Macrobicyclic Cyclophane Skeleton**

Kei Goto, Norihiro Tokitoh, and Renji Okazaki*

While there have been a great number of reports on functionalized macrocycles that utilize their cavities as a complexing site, far fewer studies have been carried out on the use of those well-defined microenvironments as a reaction field for a functionality fixed on its inside.[1] If a functional group is embedded in a large, shallow molecular bowl with a rigid framework (Fig. 1), the

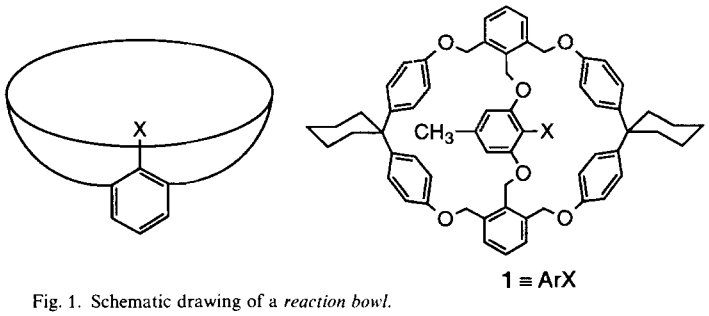

Fig. 1. Schematic drawing of a *reaction bowl*.

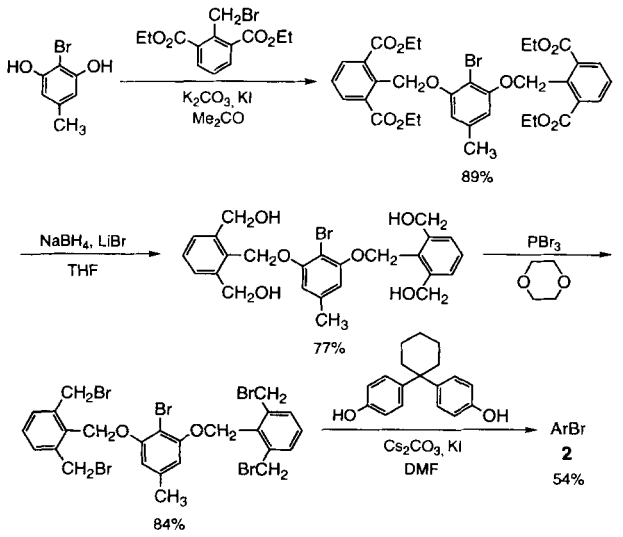
cavity will serve as a reaction field with unique and unprecedented properties. Such a molecule, which we refer to as a *reaction bowl*, is expected to inhibit the approach of functional groups on molecules of the same type, while not preventing different molecules from reacting with it. Thus, for example when a chemical species, which normally dimerizes readily and is therefore unstable, is introduced into the concave environment, it could be stabilized kinetically by the bowl-shaped framework without diminution of its intrinsic reactivity toward other molecules.



In this paper, we report the synthesis of the first kinetically stabilized arenesulfenic acid, for which we have taken advantage of a novel molecular bowl based on a macrobicyclic cyclophane skeleton. In spite of the well-known importance of sulfenic acids in organosulfur chemistry,[2–4] they have proved difficult to synthesize due to the ready self-condensation and most of the sulfenic acids isolated to date have been stabilized by their electronic properties and intramolecular hydrogen bonding,[4] which inevitably perturb the properties of the SOH group. However, a reaction bowl environment would enable us to stabilize such species without perturbing their properties and intrinsic reactivities. While two alkanesulfenic acids have been isolated by kinetic stabilization,[5] no stable arenesulfenic acid has been obtainable even with extremely bulky substituents such as 2,4,6-tri-*tert*-butylphenyl or 2,4,6-triisopropylphenyl groups.[6]

In order to embody the concept mentioned above, we designed the novel bicyclic cyclophane **1** (Fig. 1) based on an aryl benzyl ether framework,[7, 8] which we were able to synthesize readily as the bromide **2** (Scheme 1). The structure of **2** was determined by X-ray crystallography (Fig. 2).[9] The figure clearly shows that **2** is a shallow bowl-shaped molecule; its diameter is about 13 Å.

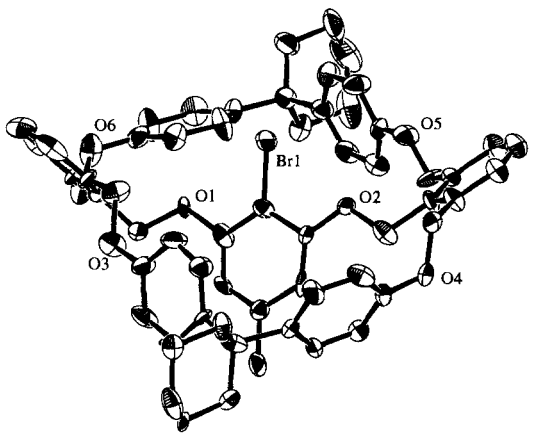
Scheme 1. Synthesis of the bromide **2**.



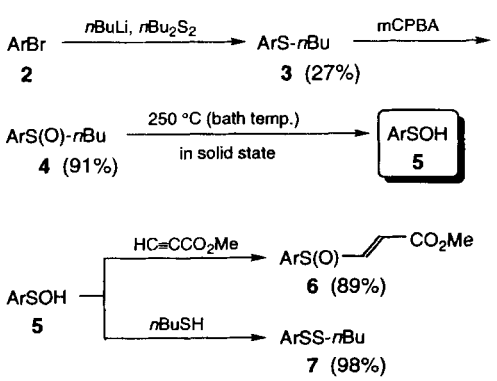


Fig. 2. ORTEP drawing of the structure of **2** with thermal ellipsoid plot (40% probability).

Lithiation of **2** with butyllithium followed by quenching with dibutyl disulfide afforded the butyl sulfide **3**, which was readily oxidized by mCPBA (mCPBA = *meta*-chloroperbenzoic acid) to give the sulfoxide **4** (Scheme 2). Its solid-state pyrolysis gave the sulfenic acid **5** as a crystalline solid (90% based on conversion of **4**). The ^{1}H NMR ($CDCl_3$) spectrum showed the signal of the hydroxyl proton at $\delta = 3.26$ (readily exchangeable with D_2O), which is very close to the reported values for the alkanesulfenic

Scheme 2. Synthesis and reactions of the sulfenic acid **5**.

acids isolated by kinetic stabilization.[10] In the IR spectrum (CH_2Cl_2) the OH stretching bands were observed at 3685 (m), 3600 (w), and 3494 (m) cm^{-1}. These spectral data are fully consistent with the formulation of **5** as a sulfenic acid. The reaction of **5** with methyl propiolate afforded the corresponding vinyl sulfoxide **6** in 89% yield (Scheme 2), which lent further confirmation to the structure of **5**. Unfortunately we have thus far been unable to obtain a crystal of **5** suitable for an X-ray study.

The sulfenic acid **5** is stable at room temperature in air for several weeks. Upon heating at 80 °C for 12 h in [D_8]toluene **5** underwent only slight decomposition, indicating its remarkable thermal stability. While the IR absorption at 3685 cm^{-1} is unambiguously assigned to a free hydroxyl group, the band at 3494 cm^{-1} suggests the intramolecular hydrogen bonding between the OH group and the oxygen atoms at the *ortho*-positions.[11] It is not likely, however, that this hydrogen bonding is responsible for the high stability of **5**, since it has been reported that hydrogen bonding with such an ether functionality alone cannot render a sulfenic acid stable enough to be isolated.[4] Thus, the noticeable stability of **5** is most reasonably explained in terms of the steric inhibition of the self-condensation by the bicyclic cyclophane skeleton, where the brim of the bowl surrounds the SOH group from all sides. Therefore, **5** can be regarded as the first kinetically stabilized arenesulfenic acid.

Oxidation of thiols to disulfides is one of the most important reactions of thiols from a biological point of view.[12] It is assumed that sulfenic acids are transient intermediates in the reaction, but the evidence is circumstantial.[13–15] The reaction of the sulfenic acid **5** with a large excess of 1-butanethiol afforded the disulfide **7** as a single product almost quantitatively (Scheme 2). This is the first conclusive demonstration of disulfide formation from the reaction of a sulfenic acid with a thiol. At the same time this result validates the concept of the reaction bowl, namely that a functional group in its inside is stabilized, yet capable of undergoing an intermolecular reaction with an appropriate molecule.

The stabilization of a sulfenic acid realized in the present study is reminiscent of the formation of stable sulfenic acid intermediates from cysteine in the active sites of some enzymes,[3] where the structural features of the environment around the SOH group are believed to prevent its self-condensation. An exploration of the wider application of this new concept is currently in progress.

Experimental Procedure

Fine powders of **4** (28.7 mg, 0.029 mmol) were loaded into a glass tube of 1 mm diameter and 80 mm long, and the tube was sealed in vacuo and soaked in an oil bath heated at 250 °C for 5 s. About one third of the sulfoxide **4** reacted and the sulfenic acid **5** was obtained in more than 90% yield (by ^{1}H NMR). Compound **5** was isolated by preparative TLC (silica gel/dichloromethane) as a crystalline solid (27%) in addition to recovered **4** (70%). **5**: colorless crystals, m.p. 174 °C (decomp.); ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 1.50$ (br. s, 4H), 1.54 (br. s, 8H), 2.14 (br. s, 8H), 2.28 (s, 3H), 3.26 (s, 1H; OH), 5.10 (s, 4H), 5.20 (s, 8H), 6.40 (s, 2H), 6.77–6.80 (m, 8H), 6.94–6.97 (m, 8H), 7.42–7.46 (m, 2H), 7.55–7.57 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 22.1$ (q), 23.0 (t; cyclohexyl), 26.5 (t; cyclohexyl), 36.6 (t; cyclohexyl), 37.4 (t; cyclohexyl), 45.7 (s), 63.9 (t), 68.9 (t), 107.8 (d), 115.0 (d), 116.2 (s; *ipso* to SOH), 128.3 (d), 129.0 (d), 129.6 (d), 131.6 (s), 138.1 (s), 141.2 (s), 141.7 (s), 156.6 (s), 156.9 (s); IR (CH_2Cl_2): $\tilde{\nu}$(OH) = 3685 (m), 3600 (w), 3494 (m) cm^{-1}.

Synthesis, Structure, and Decay of In_4Br_7**

Richard Dronskowski*

In the In/Br binary system, the phases InBr, In_5Br_7 ($\equiv InBr_{1.4}$), In_2Br_3 ($\equiv InBr_{1.5}$), $InBr_2$, and $InBr_3$ have been recently characterized by crystallographic structure determination.[1] The reduced binary indium bromides in particular are of interest to theoretical chemistry because of their relatively low chemical stability (e.g. toward air and moisture), their weak In^+-Br^- bonds, and their slight electrophilic tendency.[2]

More than 30 years ago, two independent thermoanalytical investigations had suggested the existence of an additional phase, In_4Br_7 ($\equiv InBr_{1.75}$).[3] Due to the unusual sensitivity of In_4Br_7, the first structure determination of In_4Br_7 has only now been accomplished. In_4Br_7 shows not only the typical sensitivity to air and moisture for a reduced indium bromide, but also exhibits the signs of decay due to the influence of light[4] and mechanical stress.

In_4Br_7 can be prepared quantitatively by synproportionation of a stoichiometric melt of $InBr_3$ and metallic indium, followed by slow cooling (2 °C h^{-1}) to room temperature. The nearly colorless product exhibits a slight, pale greenish-yellow tint. In the temperature gradient of 120/210 °C, single crystals appear within two months; however, these crystals tend to macroscopically grow together, thus making isolation of individual single crystals difficult due to the sensitivity of the compound to physical manipulation (see above). Nevertheless, the intensity data of an imperfectly shaped crystal (taken without exposing it to light) allowed the solution of the structure by direct methods. The following structural description is based on a Rietveld refinement of powdery, pure In_4Br_7.[5] Such a refinement is insensitive to absorption errors and problems of twinning.
