Organic Chemistry on Solid Supports**

Jörg S. Früchtel and Günther Jung*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Until recently, repetitive solid-phase synthesis procedures were used predominantly for the preparation of oligomers such as peptides, oligosaccharides, peptoids, oligocarbamates, peptide vinylogues, oligomers of pyrrolin-4-one, peptide phosphates, and peptide nucleic acids. However, the oligomers thus produced have a limited range of possible backbone structures due to the restricted number of building blocks and synthetic techniques available. Biologically active compounds of this type are generally not suitable as therapeutic agents but can serve as lead structures for optimization. "Combinatorial organic synthesis" has been developed with the aim of obtaining low molecular weight compounds by pathways other than those of oligomer synthesis. This concept was first described in 1971 by Ugi.[56f, g, 59c] Combinatorial synthesis offers new strategies for preparing diverse molecules, which can then be screened to provide lead structures. Combinatorial chemistry is compatible with both solution-phase and solid-phase synthesis. Moreover, this approach is conducive to automation, as proven by recent successes in the synthesis of peptide libraries. These developments have led to a renaissance in solid-phase organic synthesis (SPOS), which has been in use since the 1970s. Fully automated combinatorial chemistry relies not only on the testing and optimization of known chemical reactions on solid supports, but also on the development of highly efficient techniques for simultaneous multiple syntheses. Almost all of the standard reactions in organic chemistry can be carried out using suitable supports, anchors, and protecting groups with all the advantages of solid-phase synthesis, which until now have been exploited only sporadically by synthetic organic chemists. Among the reported organic reactions developed on solid supports are Diels–Alder reactions, 1,3-dipolar cycloadditions, Wittig and Wittig–Horner reactions, Michael additions, oxidations, reductions, and Pd-catalyzed C–C bond formation. In this article we present a comprehensive review of the previously published solid-phase syntheses of nonpeptidic organic compounds.

Keywords: combinatorial chemistry · compound libraries · oligomer synthesis · solid-phase synthesis

1. Introduction

More than three decades ago, Merrifield[1] introduced the concept of solid-phase peptide synthesis. Since then, automated solid-phase syntheses of polypeptides,[2, 3] oligonucleotides,[4] and oligosaccharides[5] have been carried out with increasing regularity. The introduction of synthesis robots for the simultaneous multiple synthesis of peptides[3b, 6] was the logical continuation, and more recently the systematic synthesis of peptide libraries was developed.[7]

Compared with classical synthesis in solution, the solid-phase synthesis of modified peptides, for example lipopeptides such as tripalmitoyl-(*S*)-glycerylcysteine peptides,[8] glycopeptides,[9] and cyclosporin,[10] is simpler and can also be carried out more rapidly. Even for less complicated peptides, several weeks are often required for the classical multistep synthesis in solution including isolation and purification. Synthesis of biopolymers on solid supports has simplified these procedures considerably by obviating the need for elaborate separation steps; however, its prerequisite is a quantitative yield in every step.

[**] The following abbreviations are used in this article: 9-BBN: 9-borabicyclo[3.3.1]nonane; Ac_2O: acetic anhydride; Bn: benzyl; Bpoc: biphenylpropyloxycarbonyl; Bu: butyl; CPG: controlled-pore glass; dba: dibenzylidene acetone; DBU: diazobicyclo[5.4.0]undec-7-ene; DCC: dicyclohexylcarbodiimide; DEAD: diethyl azodicarboxylate; DIAD: diisopropyl azodicarboxylate; DIBAL-H: diisobutylaluminium hydride; DIC: diisopropylcarbodiimide; dipamp: 1,2-ethanediylbis[(2-methoxyphenyl)phenylphosphane]; DIPEA: diisopropylethylamine; DMAP: dimethylaminopyridine; Dmt: dimethoxytrityl; DVB: divinylbenzene, EDC: *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide; HATU: azabenzotriazol-1-yl-*N*,*N*,*N'*,*N'*-tetramethyluronium hexafluorophosphate; HBTU: *O*-benzotriazol-1-yl-*N*,*N*,*N'*,*N'* tetramethyluronium hexafluorophosphate; HMPB: 4-(4-hydroxymethyl 3-methoxy)-phenoxybutyric acid; HOBT: hydroxybenzotriazole; LDA: lithium diisopropylamide; MBHA: methylbenzhydryl; MCPBA: *m*-chloroperbenzoic acid; nbd: norbornadiene, NMP: *N*-methylpyrrolidinone; NPEOC: *p*-nitrophenylethoxycarbonyl; PEG: polyethylene glycol; Pfp: pentafluorophenyl; ph-capp: 1-phenylcarbamoyl-4-diphenylphosphino-2-diphenylphosphinomethylpyrrolidine; phth: phthaloyl; PNA: peptide nucleic acid; PPTS: pyridinium (toluene-4-sulfonate); PS: polystyrene; PTH: phenylthiohydantoin; $Py \cdot SO_3$: pyridine–SO_3 complex; SCAL: safety catch amide linker; TFA: trifluoroacetic acid; TG: TentaGel; TMAD: *N*,*N*,*N'*,*N'*-tetramethylazocarboxamide; TMSCl: trimethylsilyl chloride; TOF: time-of-flight; Tol, tol: tolyl; Trt: trityl.

Among the simple peptide derivatives, several peptide alcohols show interesting biological activity,[11] and some of them have already undergone clinical trials (e.g. DAGO,[12] Sandostatine[13]). The peptide aldehydes, which are obtained from alcohols, may be protease inhibitors.[14] Such peptide alcohols and N-protected amino acid alcohols have been synthesized only in solution so far.[15] However, the methods proposed by Swistok et al.[16] and Neugebauer et al.[17] may also be applied to the solid-phase synthesis of C-terminal peptide alcohols. It has been demonstrated with increasing frequency that complicated peptidomimetics and biologically active peptides can also be prepared on solid supports.

Until recently, the solid-phase synthesis of nonpeptidic compounds, generally nonpolymeric substances, received less attention. However, the synthesis of DIVERSOMER™ libraries by Hobbs DeWitt et al.[18] and other examples of combinatorial organic synthesis[56] (cf. Section 2.3) has led to a renaissance in organic synthesis on solid supports. Reactions on polymer supports will be especially significant in future for the fast, simultaneous, and multiple synthesis of many new compounds required in the search for lead structures and their optimization for preparation of novel pharmaceuticals.

In this article we make a distinction between Solid-Phase Peptide Synthesis (SPPS) and other types of Solid-Phase Organic Synthesis (SPOS). We will primarily emphasize the methods used to carry out classical organic synthesis on solid supports, which bear little resemblance to peptide, oligonucleotide, and polysaccharide chemistry. In choosing the reactions discussed, we gave special consideration to their applicability for the multiple synthesis of "chemical libraries" and oligomer libraries. We also wish to point out that reactions on polymeric supports are not limited to the coupling and protecting group cleavage reactions in biopolymer synthesis, but have also been applied for some time to other organic reactions.

The solid support based reactions described in this article are of fundamental significance to combinatorial chemistry, the approach in which the pharmaceutical industry is currently investing for the efficient development of new lead structures. Combinatorial chemistry will be dominated by solid-phase synthesis, since reactions on polymer supports are more amenable to multiple and automated syntheses. A review on the combinatorial organic synthesis of small molecules will soon appear in this journal.[161]

2. Organic Synthesis on Solid Supports and Analysis

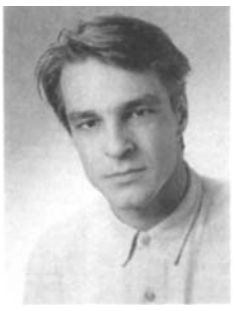
2.1. Advantages of Solid-Phase Synthesis for Procedures and Product Workup

In discussions of syntheses on polymer supports one must differentiate between polymer-bound reagents and polymeric protecting groups. Reactions with polymer-bound reagents are one-step reactions in which the dissolved substrate is allowed to react with chemical reagents, mostly catalysts or enzymes, that are bound to solid supports (Scheme 1). Many support-bound reagents have been developed[19] for conducting a variety of chemical reactions on supports. Solid supports have been used, for example, for immobilizing triarylphosphanes,[20] hydrogenation catalysts, oxidizing and reducing agents, and chiral auxiliaries and catalysts.[21] A number of these polymer-bound reagents are commercially available; they simplify the performance of reactions and especially the workup of reaction mixtures. Until now, most organic chemists have apparently not recognized the advantages of the support-bound reagents and the opportunities offered by solid-phase synthesis.

This review article will not focus on reactions with immobilized reagents, but rather on reactions in which the polymeric support functions as a protecting group for one functional group of the substrate while another site on the substrate is derivatized. These syntheses always consist of several consecutive reaction steps on the solid support, including anchoring of the substrate and cleavage of the reaction product (Scheme 2).

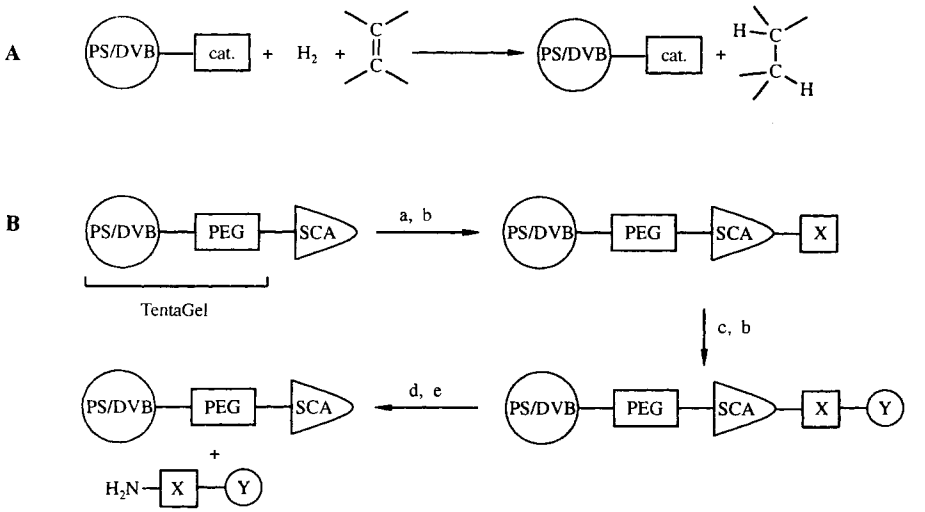
Günther Jung was born in Tübingen (Germany) in 1937 and received his doctorate from the University of Tübingen in 1967. In 1971 he was granted permission to teach organic chemistry and biochemistry. From 1967 to 1968 he was an assistant professor at the University of Houston in Texas (USA). He received the Max Bergmann Medal in 1989 and the Leonidas Zervas Award of the European Peptide Society in 1991. His research interests include the 3D structure elucidation, biological activity, and biosynthesis of peptide antibiotics and siderophores, structure–activity relationships of neuropeptide Y, models for transmembrane channels, multiple peptide synthesis, peptide libraries, B-, T-helper, and T-killer cell epitope mapping, development of synthetic vaccines, and elucidation of sequence motifs of peptides bound to the major histocompatibility complex (MHC). Combinatorial peptide synthesis is one of his main areas of research.

G. Jung

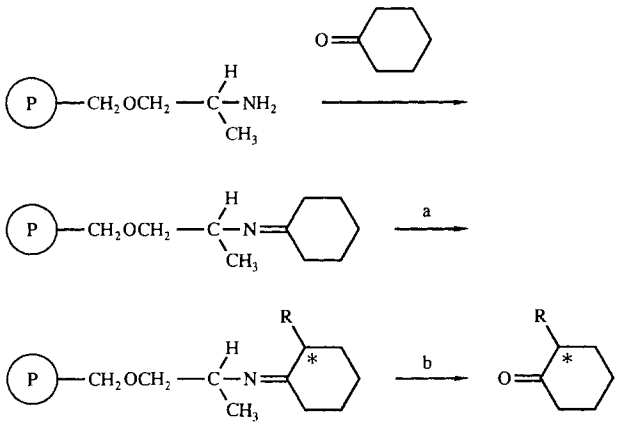


J. S. Früchtel

Jörg S. Früchtel was born in Reutlingen (Germany) in 1967 and studied chemistry at the University of Tübingen from 1987 to 1994. During his studies for the diploma, he started to work in solid-phase combinatory chemistry. He investigated the multiple synthesis of peptoids as analogues of peptide ligands and their binding to MHC class I proteins. In his dissertation, which he started in mid-1994, he has been concentrating on the optimization and development of methods for the combinatorial solid-phase synthesis of small molecules and biopolymer analogues.



Scheme 1. Schematic representation of A) a one-step reaction with a polymer-supported *reagent*, a covalently bound hydrogenation catalyst [19–21]. B) Schematic representation of a reaction with a polymer-supported *substrate* bound by a support–linker–anchor combination. PS/DVB copolymer (Table 1); PEG: polyethylene glycol as the hydrophilic linker between the anchor and support; SCA: Safety Catch Amide (Table 3) anchor for the covalent and reversible binding of the substrate. a) Coupling of compound **X** to the support; b) removal of excess reagents; c) derivatization of X with Y; d) reduction of the anchor; e) cleavage of the final product.



Scheme 2. Example of a multistep synthesis on a solid support (P): Synthesis of chiral 2-alkylcyclohexanone by an enamine reaction according to Stork [21]. a) 1. LDA, 2. RI; b) H^+.

Over three decades, this method has been investigated extensively and optimized for peptide chemistry, especially for carboxyl, amino, thiol, and hydroxyl groups.[22, 23] The following advantages can be expected from this type of solid-phase synthesis.

1) Considerably simplified reaction procedures: Time-consuming purification and isolation steps are eliminated by the covalent binding of the substrate and product to the support. Solutions of reagents in excess are used and the support-bound product is filtered off and washed.
2) Thermodynamic and kinetic influence on the course of the reaction: Higher yields can be obtained by using a large excess of reagents. However, the conditions must also be chosen carefully so that no undesired side reactions such as multisubstitutions take place.
3) Possibility of regenerating the support: The polymeric support can be regenerated and reused for new syntheses if appropriate cleavage conditions and suitable anchor groups are chosen. For industrial syntheses of small molecules involving a few reaction steps, in particular, the support should be chosen such that after cleavage of the product it can be regenerated in a few steps and used again. The price of the support is not an important factor in the multistep synthesis of expensive products. Regenerable supports include chloromethylated PS/DVB resin (Merrifield resin), chlorotrityl-PS/DVB resins, and hydroxymethylated PS/DVB resins (two-step regeneration).
4) Principle of high dilution: Undesired side reactions such as cross-linking and multiple couplings can be suppressed by using supports with low loading (<0.8 mmol g^{-1}) which serve to isolate the reactive sites (see Dieckmann cyclization, Section 3.6).
5) Influencing the stability (thermodynamic, kinetic) of polymer-bound reagents, for example, by making use of the template effect in asymmetric synthesis.
6) Automation: Automated synthesis is a basic requirement for the multiple parallel synthesis of individual products and compound libraries by combinatorial chemistry.

2.2. Supports and Linkers

The correct choice of supports and the bound anchor groups (Scheme 1) is of utmost importance for the success of organic synthesis on solid supports. At present, the choice of available linkers still limits the reaction sequences possible on supports, since these are mostly optimized for biopolymer synthesis.

For reactions in solution extreme conditions are often required for satisfactory results. Synthesis at higher temperatures, the use of reactive substrates, and reactions under inert gas are the rule here and not the exception. When solid-phase syntheses are planned, these factors must be taken into account in the choice of the support and suitable linkers.

So far, no special supports and only a few anchors have been developed for solid-phase organic synthesis. However, the supports developed for peptide chemistry can also be used for numerous organic syntheses (Table 1). The planned reaction sequence ultimately determines what kind of support can be used.

Therefore, the choice of anchors is one of the most decisive factors for the success of a series of reaction steps. Similar to the requirements for peptide chemistry, the anchor and any other necessary protecting groups must be stable to all of the reagents used in the synthesis (orthogonality principle). But it should be possible to remove these groups under mild conditions without damaging the final products.

The anchors developed for peptide chemistry are generally stable to either bases or weak acids, but for the most part they are suitable only for the immobilization of carboxylic acids.[3c]

Table 1. Selected supports (solid phases) used in organic synthesis.

Solid support	Remarks	Ref.
PS/DVB copolymer (1–5% cross-linking)	good swelling properties; swells up to five times its dry volume; at low levels of cross-linking (1%) only limited thermal stability (105–130 °C, dependent on solvent)	[24, 25]
hexamethylenediamine-polyacryl resins and related polymers	polar resins; good swelling properties in H_2O and DMF; do not swell in CH_2Cl_2	[26, 27]
poly[*N*-{2-(4-hydroxyphenyl)ethyl}]acrylamide (Core Q)	SPPS with high loading	[28]
poly(*N*-acryloylpyrrolidine) resins, PAP- and SPARE-polyamide resins	SPPS with high loading; swell in H_2O, DMF, and CH_2Cl_2	[29]
polyethylene functionalized with acrylic acid	synthesis on pins	[30]
kieselgur/polyamide (Pepsyn K)	pressure stable; used in continuous-flow SPPS; low swelling properties due to inorganic support; shaking results in marked wear of the organic polymer	[31]
polyHipe, PS/polydimethylacrylamide copolymer	continuous-flow SPPS; loading capacity up to 5 mmol g^{-1}; high cross-linking of the PS chains	[32] [33]
CPG	pressure and heat stable; stable toward aggressive reagents; low loading	
PS macrobeads	diameter ≦1 mm; loading 50 nmol per bead; available with three different anchors	[34]
TentaGel, PEG-PS/DVB copolymers	polar; swell in H_2O, MeOH, MeCN, DMF, and CH_2Cl_2; pressure stable; suitable for bioassays on resin	[35]

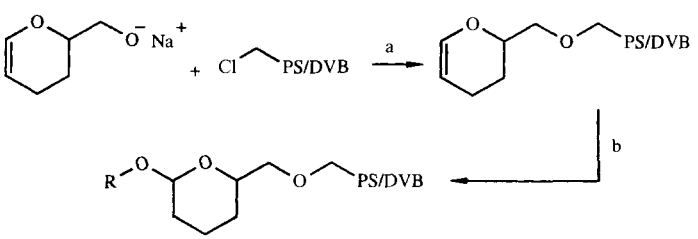
Table 2. Base-stable anchors groups for linking the substrate to the solid phase.

Anchor	Name; reagent for cleavage (acidolysis); application, comments	Ref.
	Wang anchor (R = H); 95% TFA; immobilization of carboxylic acids SASRIN anchor (R = OMe); 1% TFA; immobilization of carboxylic acids	[38, 39]
	trityl chloride anchor (X = H); weak acids (HOAc); immobilization of nucleophiles 2-chlorotrityl chloride anchor (X = Cl); very weak acids, $HOAc/CH_2Cl_2$(1/4); immobilization of nucleophiles	[36]
	PAM anchor; HF, TFMSA; immobilization of carboxylic acids, 100 times more stable than chloromethylated Merrifield resin	[40]
	Rink acid (X = OH); $HOAc/CH_2Cl_2$; immobilization of carboxylic acids Rink amide (X = NH-Fmoc); TFA/CH_2Cl_2; immobilization of carboxylic acids by amide formation	[41]
	BHA anchor; TFMSA; immobilization of carboxylic acids by amide formation	[42]
	Sieber amide; TFA/CH_2Cl_2 (1/99); immobilization of carboxylic acids by amide formation	[43]

One exception is the chlorotrityl-PS/DVB resin[36] (Table 2), which is a suitable support in theory for all nucleophilic substrates (Section 3.1). Unfortunately, the trityl anchoring bond can be cleaved by very weak acids such as acetic acid.

The Safety Catch Amide Linker (SCAL; Table 3) is very stable to acids and bases in its oxidized form, but after reduction with $(EtO)_2P(S)SH$ it can be cleaved with trifluoroacetic acid (TFA). However, the SCAL group can be used to attach only carboxylic acids to the support, and carboxamides are generated upon cleavage. Additional safety catch linkers have already been investigated and reported.[37] A selection of tested, commercially available (only a few) anchors are listed in Tables 2 and 3. For the reversible attachment of special functional groups, known anchors often have to be derivatized and optimized, or when necessary, completely new anchors must be developed. Some of the modified standard anchors with examples of their applications are presented in this article.

In addition to the previously mentioned, versatile trityl and 2-chlorotrityl anchors, other anchor groups have been developed for coupling compounds having other functional groups. Ellman et al.[54] introduced an anchor group for immobilizing alcohols. The sodium salt of this anchor, (6-hydroxymethyl)-3,4-dihydro-2*H*-pyran, is covalently bound to chloromethylated Merrifield resin by a nucleophilic substitution reaction (Scheme 3). The alcohol is coupled to the support by electrophilic addition in the presence of pyridinium toluene-4-sulfonate (PPTS) in dichloromethane (16 h at 80 °C). The resulting tetrahydropyranyl ether, a common protecting group for alcohols, is stable to base but can be cleaved by transetherification or treatment with 95% trifluoroacetic acid.



Scheme 3. Preparation of an anchor used for immobilizing alcohols [54]. The reaction of an alcohol with the anchor generates a tetrahydropyranyl ether; this common alcohol protecting group is base-stable but can be cleaved by acidolysis. a) Dimethylacetamide, room temperature, 16 h; b) 2 equiv PPTS, 5 equiv ROH, 80 °C, 16 h.

Sucholeiki[55] coupled benzyl halides to a photolabile α-sulfanyl-substituted phenyl ketone anchor (Scheme 4). In this approach the 2-methoxy-5-[2-{(2-nitrophenyl)dithio}-1-oxopropyl]phenylacetic acid anchor (NpSSMpact) is protected as a disulfide and coupled to an amino-functionalized resin. The disulfide bond is cleaved by reduction, and then various (substituted) benzyl halides can be coupled to the free thiol group. The

Table 3. Acid-stable anchor groups for linking substrate and support.

Anchor	Cleavage conditions (reagents), mechanism; application; comments	Ref.
	DBU/piperidine, β-elimination; suitable for peptide, oligonucleotide, and oligosaccharide syntheses on aminomethylated solid supports, immobilization of carboxylic acids	[44]
	NaOH, saponification; immobilization of alcohols, amines (irreversible) on hydroxymethylated PS/DVB resins	[45]
	NaOH, β-elimination; immobilization of carboxylic acids on hydroxymethylated PS/DVB resins	[46]
	Bu_4NF; immobilization of carboxylic acids on H_2NCH_2-PS/DVB resins; cumbersome synthesis of the linker	[47]
	Bu_4NF; as in ref. [47]; immobilization of carboxylic acids on aminomethylated PS/DVB resins	[48]
	Hydrazine hydrate, hydrazinolysis; stable in 25% TFA; immobilization of carboxylic acids	[49]
	Pd^0/H_2, catalytic hydrogenation; immobilization of carboxylic acids; HYCRAM supports [c]	[50]
	$(EtO)_2P(S)SH$/TFA, reductive acidolysis; in oxidized form stable toward acids and bases SCAL; immobilization of carboxylic acids	[51]
	photolysis ($h\nu$ = 350 nm, room temperature, 72 h); stable in 50% TFA, labile in hydrazine hydrate; immobilization of carboxylic acids	[52]
	photolysis ($h\nu$ = 350 nm); labile in piperidine/DMF [a], more stable in piperidine/CH_2Cl_2 [b]; immobilization of carboxylic acids	
	photolysis ($h\nu$ = 350 nm, under inert gas; X = Hal, OH, NH_2); immobilization of carboxylic acids	[53]

[a] Up to 3% loss of peptide per Fmoc cleavage. [b] Up to 1% loss per Fmoc cleavage. [c] HYCRAM = hydroxycrotonylaminomethyl.

photochemical cleavage generates disulfides when unsubstituted benzyl halides are used and toluene derivatives when *p*-arylbenzyl halides are employed.

2.3. Multiple, Parallel Syntheses on Solid Supports

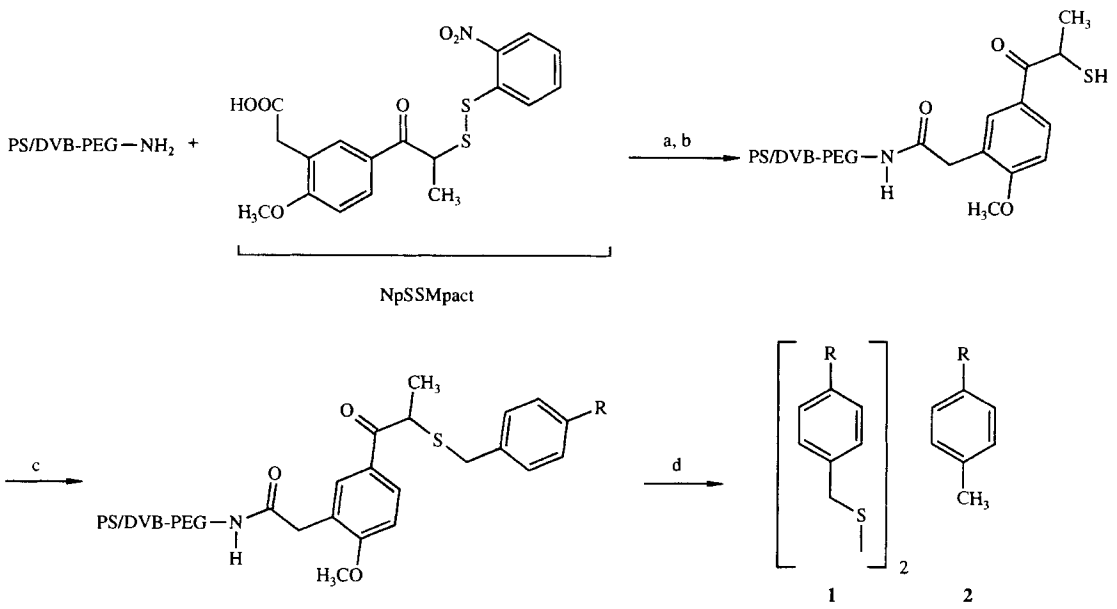
Until a few years ago, new organic compounds were mostly synthesized individually and then tested for their possible biological activity. More recently, the procedures in searching for new lead structures have become tremendously more efficient. Progress in the fields of biotechnology, molecular biology, robotics, and automation have led to the development of new screening assays that can be used to test a series of substances for receptor binding and biological activity in a remarkably short time. As a consequence, the stockpile of new compounds in the pharmaceutical industry requiring testing has been rapidly depleted, and standard methods of synthesis are not efficient enough to supply the demand for new compounds.

In addition to the previously mentioned methods for the automated synthesis of peptides, oligosaccharides, and oligonucleotides, a new method has been developed for the rapid, automated synthesis of a series of oligomeric and nonoligomeric compounds—combinatorial chemistry.[56, 59] Chemists in this area no longer work with three-neck flasks, stirrers, reflux condensers, dropping funnels, and heating mantles. Instead they use the new type of multiple reactors for the parallel and potentially automated simultaneous synthesis of a series of compounds. Reactions on solid supports are especially suitable for this type of synthesis, since the desired products remain bound to the support and can be separated from the excess reagents by filtration (Section 2.1). The starting materials (building blocks) should be versatile, easy to derivatize, and readily accessible. For example, if retrosynthesis leads to a preparative route to a desired product, then multiple procedures can be used to prepare a large series of structurally similar compounds. Generally two strategies are available for this purpose:

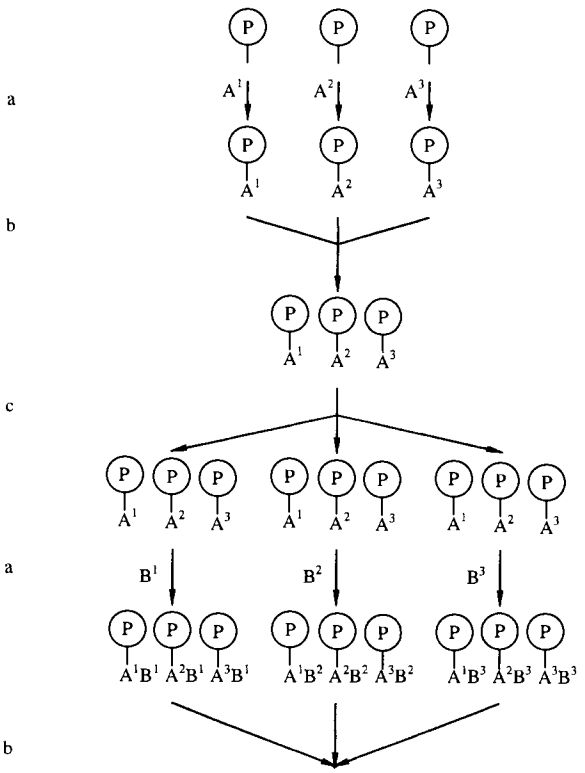
1. The multiple parallel synthesis of *individual compounds*. In this case, only one compound is prepared per reaction vessel (arrays). This method is especially suitable for rapidly optimizing previously identified lead structures.
2. The multiple parallel synthesis of *compound libraries*. Here, many different compounds having a common backbone are synthesized simultaneously in each reaction vessel.

Compound libraries can be prepared with relative ease by "divide, couple, and recombine" techniques[75, 76] (Scheme 5). Portions of the anchor–resin combination are allowed to react separately with the first components (A^1–A^3). After the reaction the resins are thoroughly mixed and then redivided into portions of the same size in order to ensure a random distribution of the components. By subsequent reaction with the building blocks B^1–B^3 one obtains, in this example, nine different compounds after only two reaction steps. Depending on the number of individual building blocks and synthesis steps, thousands of different compounds can be synthesized in each reaction vessel, which can be subjected to screening either as polymer-bound products or as polymer-free libraries.

In the development of methods for combinatorial chemistry, reactions known from solution chemistry must be tested for their suitability for solid-phase synthesis of nonpeptidic and nonoligomeric compounds. In the last decade, in addition to the classical condensation used in peptide synthesis, a representa-



Scheme 4. Preparation of a photochemically cleavable linker for thiols [55]. Toluene derivatives or disulfides are obtained, depending on the reaction conditions. a) DIC, CH_2Cl_2; b) β-sulfanylethanol, DIPEA, DMF; c) a benzyl bromide, DIEA, DMF; d) acetonitrile, $h\nu$ = 350 nm, N_2, 1–5 h. **1** (R = H), **2** (R = aryl).



Scheme 5. Preparation of nine different products on a polymeric support Ⓟ by combinatorial chemistry and the the "divide–couple–recombine" method [75,76]. a) Coupling, b) mixing, c) dividing.

tive series of reaction types (Table 4) have been investigated for their applicability to solid-phase organic synthesis (SPOS).

However, the published solid-phase reactions and anchor–resin combinations do not suffice for the preparation of a truly broad spectrum of compounds. The primary goal of solid-phase organic synthesis must be to extend the range of currently available reactions, regardless of whether these reactions are suitable

Table 4. Examples of reactions that can be carried out on solid supports.

Reaction type	Examples of reactions on the support	Ref.
[2+2]cycloadditions	trapping of butadiene	[103]
[2+3]cycloadditions	synthesis of isoxazolines, furans, modified peptoids	[104,108,147]
acetal formation	immobilization of diols, aldehydes, and ketones	[72,82–85]
aldol condensation	derivatization of aldehydes, synthesis of propanediols	[82–85,136]
benzoin condensation	derivatization of aldehydes	[83,84]
cyclocondensations	benzodiazepines, hydantoins, thiazolidines, β-turn mimetics, porphyrins, phthalocyanines	[115–117,119, 123,125,128,129]
Dieckmann cyclization	cyclization of diesters	[124]
Diels–Alder reaction	derivatization of acrylic acid	[104]
electrophilic addition	addition of alcohols to alkenes	[54]
Grignard reaction	derivatization of aldehydes	[83–85]
Heck reaction	synthesis of disubstituted alkenes	[131]
Henry reaction	synthesis of nitrile oxides in situ (see [2+3]cycloaddition)	[108]
catalytic hydrogenation	synthesis of pheromones and peptides (hydrogenation of alkenes)	[70,71,137]
Michael reaction	synthesis of sulfanyl ketones, bicyclo[2.2.2]octanes	[73,142]
Mitsunobu reaction	synthesis of aryl ethers, peptidyl phosphonates, and thioethers	[78–81]
nucleophilic aromatic substitutions	synthesis of quinolones	[118]
oxidation	synthesis of aldehydes and ketones	[69–71,73,123]
Pausen–Khand cycloaddition	cyclization of norbornadiene with pentynol	[106]
photochemical cyclization	synthesis of helicenes	[127]
reactions with organometallic compounds	derivatization of aldehydes and acyl chlorides	[69–71,72d,89, 90,94]
reduction with complex hydrides and Sn compounds	reduction of carbonyl, carboxylic acids, esters, and nitro groups	[54,70,71,72d, 83,84,89,90,141]
Soai reaction	reduction of carboxyl groups	[81]
Stille reaction	synthesis of biphenyl derivatives	[122,132]
Stork reaction	synthesis of substituted cyclohexanones	[21]
reductive amination	synthesis of quinolones	[118]
Suzuki reaction	synthesis of phenylacetic acid derivatives	[134]
Wittig, Wittig–Horner reaction	reactions of aldehydes; pheromones, sulfanyl ketones	[70–73,83,84]

for the synthesis of single compounds or compound libraries. With this in mind, we will discuss the known solid-phase reactions here without differentiating between "combinatorial" and "noncombinatorial" solid-phase chemistry.

The reproducible, in other words automated, synthesis of compound libraries consisting of oligomers (e.g. peptides, oligonucleotides, and biopolymer analogues) or small molecules (e.g. benzodiazepines) is one challenge; the identification and structural elucidation of biologically active compounds from "combinatorial compound libraries" is another.

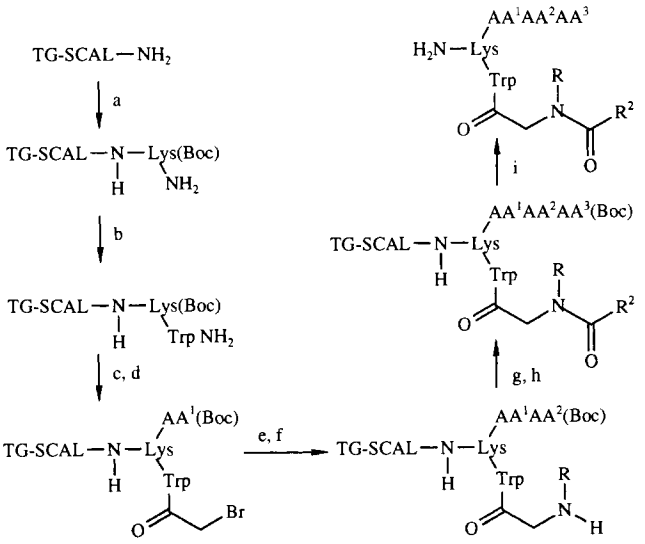
As a result of the new developments in the synthesis of nonpeptide libraries, heavy demands are put on their analysis. Besides the problem of monitoring the solid-phase synthesis mentioned in Section 2.4, common chromatographic methods such as HPLC and TLC are not suitable for the analysis of the liberated, complex substance libraries. The ^{13}C NMR spectrum of a mixture of hundreds or more similar compounds cannot be interpreted completely and, like an IR spectrum, it is only suitable for the analysis of functional groups. In this case, the typical parameters that determine the quality of a synthesis such as purity, yield, exact structure, and stereospecificity can no longer be determined.

Electrospray mass spectrometry (ES-MS), a method recently introduced for the investigation of peptide libraries,[57] furnishes useful information on the identity and purity of a compound library. The coupling of MS with HPLC,[57] or GC and MS-MS[58] allows the analysis of these mixtures; however, even more complex coupled techniques cannot be used to unequivocally characterize more complex mixtures, especially libraries of low molecular weight compounds.

A series of proposals have been made for the identification of active substances in a library, and a few of them will be illustrated here. A complete presentation and discussion of these methods will be found in an article appearing soon in this journal.[161]

A series of reporter systems have been proposed (tags, code molecules)[59] for the identification of compounds after they have been determined to be active lead structures. The aim in this approach is to label individually the components of a library in a parallel synthesis, thus making the identification easier. Kerr et al.[60] and Nicolaiv et al.[61] have used a peptide code for encoding their synthesized compounds. The coding principle is illustrated here with the compound library prepared by Nicolaiev et al. (Scheme 6). A nonpeptide compound library was prepared by acylation of the support with halocarboxylic acids, followed by nucleophilic substitution and subsequent condensation with cyclic carboxylic acids. A standard protocol was used to synthesize the dipeptide Fmoc-Trp-Lys(Boc) on a TentaGel support modified with the SCAL anchor. After removal of the Fmoc group with piperidine, the compound library was assembled on the free amino group of Trp by using the split–couple–recombine technique.[75, 76] In a parallel synthesis, the ε-amino group of the lysine residue was deprotected with TFA and the code sequence was assembled on this site, such that each building block is encoded by an amino acid. The free library can be obtained by reduction of the anchor followed by cleavage with TFA. If an active substance is found by screening, the structure of the compound can be established by sequencing the peptide code.

However, since this method is very time-consuming and requires elaborate instrumentation, it does not seem to be very useful. Further problems could appear by the coding structure itself, since an orthogonal protection strategy is required and the code peptides can participate in the receptor recognition. Finally, the coding can also cause side reactions and lead to false interpretations of the test results.



Scheme 6. Example of the synthesis of a peptide-encoded compound library according to Nicolaev et al. [61]. a) 1. Boc-Lys(Fmoc)-OH, DIC/HOBT, 2. piperidine/DMF (1/1); b) 1. Fmoc-Trp-OH, DIC/HOBT, 2. piperidine/DMF (1/1); c) 1. dividing, 2. bromoacetic acid, DIC; d) 1. TFA, 2. encoding with Boc-protected amino acids (Boc-AA^1), DIC, 3. mixing; e) 1. TFA, 2. dividing, 3. Ohlmeyer et al.[62] encoded their compounds with a chlorophenol binary code that was bound to the resin by a photolabile anchor. In each synthesis step a maximum of 1% of the available anchor positions on each polymer bead were used for the encoding. The remaining binding sites served to link the compound being synthesized. In this way, individual beads, and consequently the compounds synthesized on these beads, are provided with a sort of individual bar code. The code molecules of polymer beads identified by screening were cleaved photolytically from the resin and analyzed by gas chromatography. Due to the extreme sensitivity of this detection method, even the smallest amount of these aryl halide labels can be detected. A variation of this coding was proposed by Baldwin et al.,[140] in which the tag molecules are linked covalently to the resin by carbene insertion. After the synthesis of the compound library the tags are removed by oxidation with ceric ammonium nitrate then silylated, and the code sequence is analyzed by electron capture gas chromatography (EC-GC).

Another completely different method was proposed by Brenner and Lerner.[63] They used a binary code composed of oligonucleotide sequences (DNA-tag) and "read" the code with one of the most sensitive known analytical tools, the polymerase chain reaction (PCR). The DNA-tag of the isolated, active molecule can be amplified with PCR and the code can be decoded by DNA sequencing. Very small amounts of the code molecule can be amplified, identified, and decoded by this approach. However, due to the inherent chemical lability of oligonucleotides, applications of this method are severely limited.

2.4. Analysis and Monitoring of Reactions on Solid Supports

Every step in a multistep synthesis on a solid support yields a resin-bound intermediate whose characterization poses a serious problem. Quantifying the loading (= yield) and determining the structures of the polymer-bound product and possible by-products, which are fairly straightforward in solution-phase syntheses, are very difficult. However, the analysis of resin-bound peptides and peptidomimetics has already reached a high standard even for multiple syntheses. Quantitative determination of coupling yields is possible, for example, by rapid, quantitative UV analysis of the cleavage product formed from the amino acid protecting group Fmoc, by direct sequencing on the support (for individual peptides), and by ES-MS and Edman degradation (for peptides bound to single beads).

By contrast, very few methods have been described for the analysis of compounds on the support during solid-phase organic synthesis, although this is essential information for optimizing successive synthetic steps in combinatorial chemistry. In addition to the standard procedure—1. derivatization, 2. cleavage, 3. purification, and 4. analysis (MS, IR, and/or NMR)—several analytical methods are available for characterizing the polymer-bound compounds and give information on the type and completeness of reactions:

- FT-IR and FT-Raman spectroscopy
- Solid-state and gel-phase ^{13}C NMR spectroscopy[64] as well as ^{1}H and ^{13}C correlation NMR spectroscopy
- High-resolution ^{1}H MAS and MAS-CH correlation in the gel phase[65]
- Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry[66]
- Elemental analysis
- Titration of reactive groups ($-NH_2$, -COOH, ArOH, -SH)
- Gravimetric analysis
- Photometry ($-NH_2$ monitored by photometric Fmoc determination)

Due to the interference of the polymer backbone and low loadings commonly used, conventional IR and NMR spectra are difficult to interpret and are often ambiguous. FT-IR measurements performed under defined conditions furnish qualitative as well as quantitative data. In difference measurements on the free and the loaded support under identical conditions absorption bands can be detected, especially in the fingerprint region, which otherwise are seen only as poorly identifiable shoulders. For example, the absorption band of the H-C-Cl stretching vibration (1250 cm^{-1}) can be used to determine the yield of the coupling of carboxylic acids to a chloromethylated PS-DVB support. By calibrating measurements[72d, 124] on several loaded resins, a calibration curve can be constructed (log(absorption) vs chlorine content) and the completeness of the reaction can be verified.

The developments in the area of solid-state and gel-phase NMR in the last years has led to further suitable methods for monitoring reactions on supports. Gel-phase NMR spectroscopy[64] is a mixture of standard solution-phase and solid-state NMR spectroscopy. For this purpose, a solid sample, for instance PS-DVB resin, is transferred to an ordinary NMR tube and allowed to swell in a suitable solvent (CD_2Cl_2, $CDCl_3$). After the sample is degassed, it can be measured under the conditions typically used for dissolved samples.

The ^{13}C NMR spectra are dominated by the strong resonance signals of the polymeric support, and the weak signals of the polymer-bound substrate are often difficult to see. Due to strong line broadening, one-dimensional ^{1}H NMR spectra cannot be interpreted. High-resolution ^{1}H NMR spectra can be obtained by a combination of MAS (Magic Angle Spinning),[65] a technique normally used in solid-state NMR spectroscopy, and the previously described gel-phase method. As a result line broadening is suppressed effectively, and even with short measuring times the signal-to-noise ratio is improved considerably. However, the proton coupling patterns can be resolved only for support–linker combinations like PS/PEG.

Enger, Langley, and Bradley[66] monitored chemical reactions by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS). In this example, a series of peptides were synthesized on the commercially available acid-labile Rink amide PS/DVB support. After every reaction step, 1–100 polymer beads were removed and placed directly in the sample holder. The synthesized compounds were then cleaved from the polymer by addition of suitable cleaving reagents. The polymer beads and liberated compounds were then embedded in a matrix (e. g. 2,5-dihydroxybenzoic acid) and analyzed by MALDI-TOF-MS. This analytical method was initially applied to compounds attached to the extremely acid-labile Rink amide anchor (Table 2) but has been repeated subsequently with compounds on other acid-labile anchors such as MBHA, trityl, *p*-alkoxybenyl (Wang resin), aminotrityl, and hydroxytrityl.[66b] In addition, the photolabile anchors, which can be cleaved by laser light, have been employed.

Other methods also enable quantitative analysis of polymer-bound compounds. Elemental analysis of resins, in particular, is fraught with difficulties. In general, the inaccuracy and deviation of the results obtained is associated with the low loading of the substrates on the support. Information on the real availability of reactive or functional groups on the resin is also very difficult to obtain by such an analysis. The reproducibility of C, H, N, and halogen determinations is too poor to quantitate small variations. Several independent investigations on $BrCH_2(O)CO$-trityl PS/DVB resins[67] gave values between 0.9–1.8 mmole of Br per gram of resin, with a possible maximum loading of 1.47 mmol g^{-1}. Furthermore, it could be shown that because of frequently occurring side reactions (e.g. cross-linking and multiple coupling of the substrate), the results obtained deviated severely from the actual yields of the cleaved products.[72d]

In spite of the great progress made so far, the analysis of support-bound compounds and compound libraries is not satisfactory. Further attempts must be made to optimize the known methods and to introduce new techniques for the direct monitoring of reactions, for example using electrochemical sensors.

3. Examples of Solid-Phase Syntheses of Small Molecules

A frequent problem in preparative chemistry is the selective protection of one of two identical functional groups in a compound. Typically a mixture of di-, mono-, and unprotected

products is obtained, which must be separated by elaborate procedures. In syntheses in solution this problem is often circumvented noneconomically by using an excess of the difunctional starting material. Consequently, the mono-protected derivative is formed predominantly, but it must be separated from the excess of unreacted starting material.

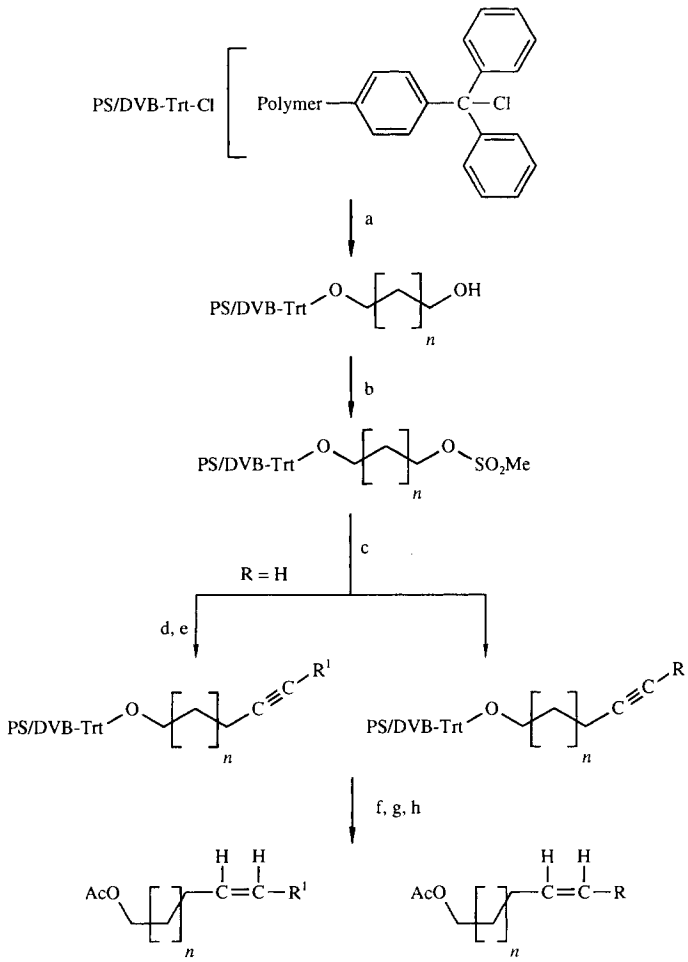
This problem of product isolation does not occur when polymer-bound protecting groups are used, since only one of the functional groups in the substrate is protected by immobilization on the support. Thus, further reactions can be carried out selectively on the unprotected group, and the excess reagents are removed by washing the resin. This reaction is an example of the "fishhook" principle.[68] In particular, the group of Leznoff[69] has worked intensively on the selective blocking of one of many functional groups and the subsequent problems incurred.

3.1. Immobilization and Reactions with Hydroxy Compounds

In extensive studies insect sex attractants were synthesized using polymer-bound symmetrical diols.[70, 71] For this purpose, a series of synthetic procedures were developed, some of which are presented here. A polystyrene (PS) resin heavily cross-linked with 2% divinylbenzene (DVB) served as the support and was functionalized with the acid-labile trityl anchor group. The diols were immobilized on the support by reacting the functionalized resin with a solution of an appropriate alcohol in pyridine (Scheme 7).

Starting with this functionalized resin,[69–71] the solid-phase synthesis of pheromones was achieved by several different procedures. Treatment of the immobilized diol with methanesulfonyl chloride yielded a polymer-bound sulfonate, which was then allowed to react with suitable alkynyllithium compounds to yield a protected alkynol. The compound with R = H can be substituted by deprotonation with butyllithium and subsequent reaction with alkyl halides. However, in contrast to the analogous reaction in solution, a large excess of BuLi must be used for deprotonation on a solid support. Subsequent hydrogenation of the triple bond with H_2/Pd–$CaCO_3$ produces a mixture of *cis* and *trans* alkenes; the stereoselective reduction to *cis* alkenes is possible by using 9-borabicyclo[3.3.1]nonane (9-BBN) or disiamylborane. The resulting alkene is then cleaved and the resin regenerated by hydrolysis with either HCl or acetic acid; the final product can then be esterified by treatment with acetic anhydride in solution.

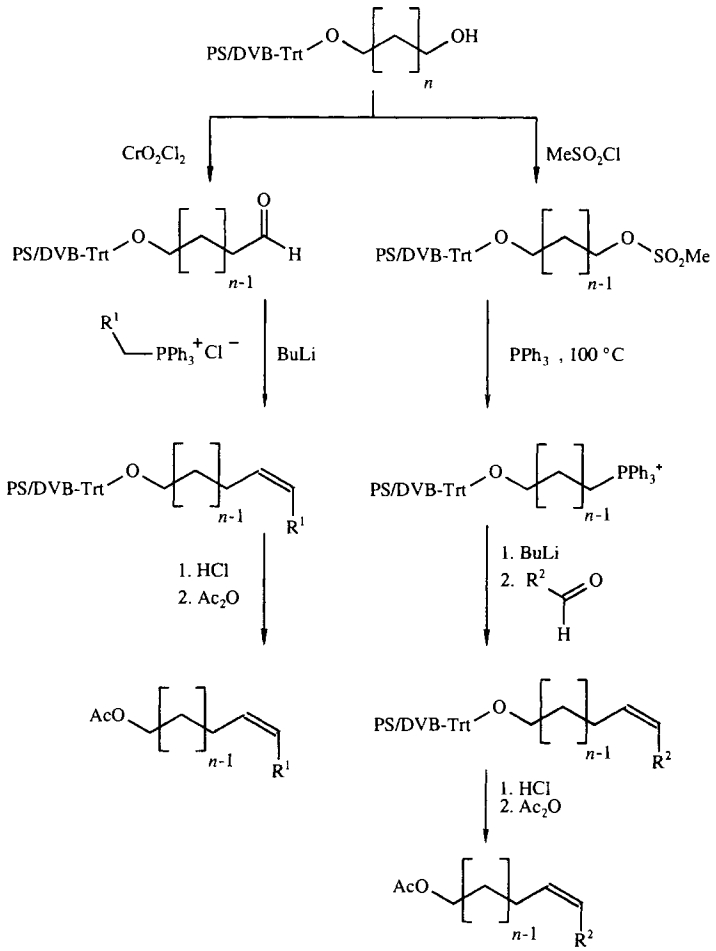
Further variations of the pheromone synthesis have also been investigated using Wittig and "reverse Wittig" reactions.[69–71] Because of the acid-lability of the trityl anchor, basic to neutral conditions are required for the oxidation of the polymer-bound alcohol to the corresponding aldehyde. In addition, precipitation of the oxidizing agent on the resin, either before or during the reaction, must be prevented. Oxidation can be achieved with $CrCl_2O_2$/pyridine/*tert*-butyl alcohol in dichloromethane (Scheme 8 left). The subsequent reaction with an alkyl triphenylphosphonium halide followed by Wittig reaction yields the *cis* alkene with high stereoselectivity (68–91.5%, as determined by HPLC).



Scheme 7. Synthesis of several insect sex attractants linked by trityl anchors to polymer supports can be carried out by the alkyne method as well as by the two-step alkyne method [69–71]. a) Pyridine; b) $MeSO_2Cl$; c) RC≡CLi (R = H, alkyl, aryl), inert gas; d) BuLi; e) R^1Br; f) reduction (e.g. with 9-BBN); g) HCl or acetic acid; h) Ac_2O.

In the reverse Wittig reaction on solid polymers (Scheme 8, right) the phosphonium salt is prepared on the resin starting from polymer-bound alkyl halides or mesylated alcohols. This reaction requires very drastic conditions, since triphenylphosphane does not react with alkyl halides or with mesylated alcohols at room temperature. Preparation of the polymer-bound Wittig reagent is possible only when the resin is heated with molten phosphane at 100 °C for 24 h.

It is not possible to link the less reactive aromatic diols to the trityl resin. If, instead of the trityl anchor, one uses benzoic acid derivatives such as benzoyl chloride[71c] as the anchor, the aromatic diols can be immobilized readily by esterification. However, owing to the base-lability of this aryl ester bond, only reactions in neutral to acidic media are possible. Thus, for example, monomethyl ethers of resorcinol, hydroquinone, and 7-hydroxy-2-naphthol can be obtained by reaction with diazomethane; their monoalkyl ethers are prepared by reaction with potassium *tert*-butoxide and alkyl halides. The yields after cleavage, and based on the maximal loading of the support, ranged from 22 to 74%. These variations were attributed to incomplete alkylation or cleavage reactions. The possibility that both hydroxyl groups are bound simultaneously to the resin has

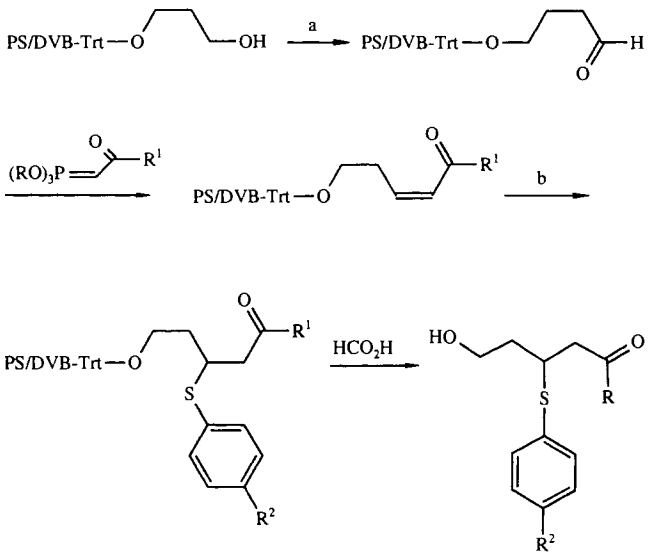


Scheme 8. Preparation of pheromones by Wittig (left) and reverse-Wittig reactions [71, 72] (right) on trityl resin. Because of the sluggish reaction of the mesitylated diol, the resin must be heated with triphenylphosphane at 100 °C. Immobilized halides can also be used as well. R^1, R^2 = alkyl.

also been discussed. But this reaction is not very probable: the best monofunctionalization results have been achieved with hydroquinone, which because of its *para* substitution would be the most suitable diol for cross-linking coupling. Generally, when the experimental results are evaluated, the possibility of a cross-linking reaction involving bifunctional molecules cannot be ruled out.

In addition to the trityl anchor for immobilizing *cis* diols on polymers, Fréchet et al. [72] have investigated the interesting support–anchor combination polystyrene/boric acid. This anchor has several very promising properties: it has moderate to high loading (2–3 mmol g^{-1}), the coupling of the diol as a boronate proceeds simply and with high yield, only *cis* diols are bound, and the resin can be reused without loss of reactivity after the reaction product is cleaved. This anchor has been used for the selective blocking of *cis* hydroxyl groups of carbohydrates. This method has been employed to synthesize desoxysugars on solid supports which otherwise could not have been prepared.

Based on the previous work of Leznoff et al.,[69–71] a recent article has appeared describing a combinatorial method for the simultaneous synthesis of several different β-sulfanyl ketones.[73] In this approach 1,4-butanediol immobilized on a trityl resin is oxidized[74] and subjected to a Wittig–Horner reaction and a Michael addition of an aromatic thiol to afford the resin-bound sulfanyl ketone (Scheme 9), which is cleaved from the resin by acidolysis with formic acid. A series of nine different ketones could be obtained by the divide, couple, and recombine strategy[75, 76] and reactions with three different ylides and three different thiols.

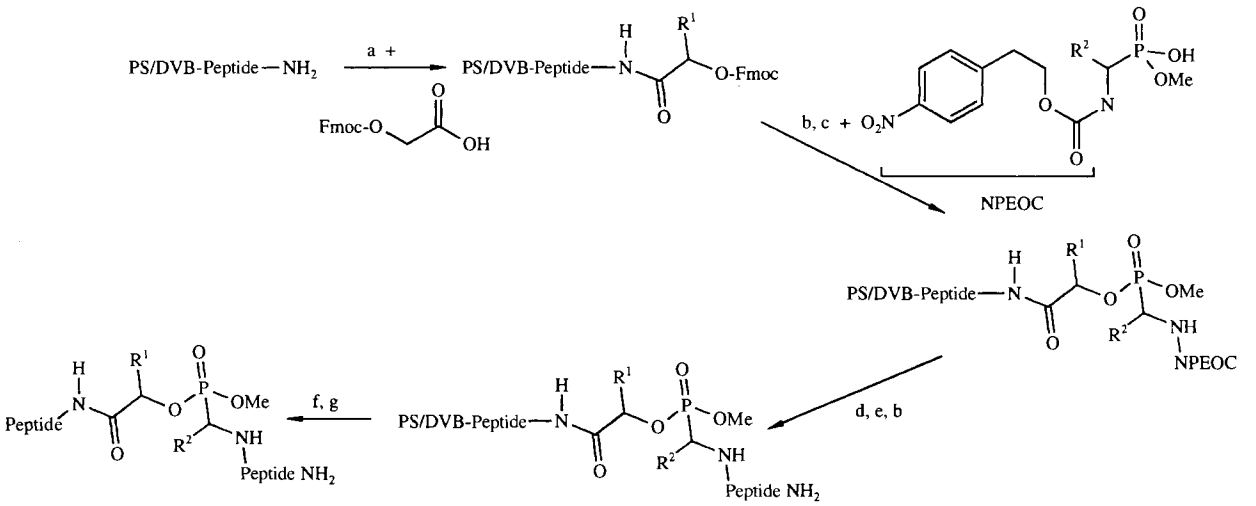


Scheme 9. Synthesis of nine different sulfanyl ketones by a combination of Wittig–Horner reaction and Michael addition [73]. a) Py·SO_3, DMSO, Et_3N, room temperature, 2 h; b) thiophenols, NaOMe (cat.), THF, room temperature, 2 d. R = alkyl, aryl; R^1 = Me, Bu, Ph; R^2 = H, Me, Cl.

3.1.1. Derivatization of Hydroxy Compounds by the Mitsunobu Reaction

The Mitsunobu reaction[77] is an efficient and commonly used organic reaction for the synthesis of esters and aromatic ethers with inversion of configuration. For this reason Richter and Gadek[78] chose this reaction to immobilize *N*-Boc-L-tyrosine methyl ester via its phenolic hydroxyl group on hydroxymethyl-PS/DVB resin. Their aim was to synthesize tail-to-head coupled cyclopeptides. *N*-methylmorpholine was used as the solvent and base for deprotonation of tyrosine, and diethyl azodicarboxylate (DEAD)/triphenylphosphane served as the Mitsunobu reagent. A maximum loading of 0.9 mmole per gram of resin (theoretical maximum loading 1.08 mmol g^{-1}) was obtained.

A modified Mitsunobu reaction was used by Campbell and Bermak[79] to prepare peptide phosphonates from peptides (Scheme 10). As transition state mimetics, peptide phosphonates show inhibitory activity against peptidases, esterases, and metalloproteases. The synthetic method described is compatible with the Fmoc strategy of solid-phase peptide synthesis and enables the unrestricted incorporation of phosphonic acid groups into peptides. An α-*O*-Fmoc-hydroxycarboxylic acid is coupled to the peptide with HOBT/HBTU, and the Fmoc group is then removed with piperidine/*N*-methylpyrrolidinone (NMP). The modified peptide is converted into the peptide phosphonate by reaction with an ethyl α-[*N*-(4-nitrophenylethoxycarbonyl)amino]alkylphosphonate under Mitsunobu



Scheme 10. Preparation of peptide phosphonates by a modified Mitsunobu reaction [79]. a) HBTU, HOBT, DIPEA, NMP; b) piperidine/NMP (3/7); c) $P(4\text{-}ClC_6H_4)_3$, DIAD, DIPEA, THF; d) DBU/NMP (5/95); e) Fmoc-protected amino acids, HBTU, HOBT, DIPEA, NMP; f) thiophenol/triethylamine/dioxane (1/2/2); g) trapping reagent, TFA. R^1 = H, Me, Bn, *i*Bu; R^2 = H, Me, Bn, *i*Pr, *i*Bu.

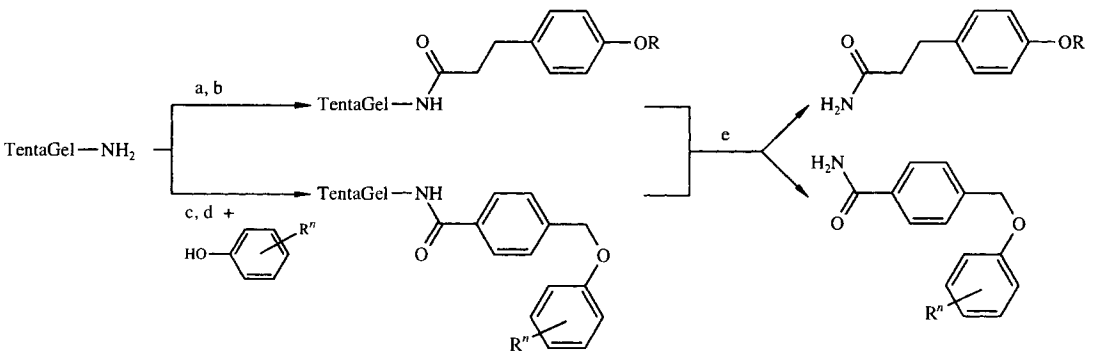
conditions (DEAD, tri(4-chlorophenyl)phosphane, NMP). After cleavage of the 4-nitrophenylethoxycarbonyl (NPEOC) protecting group under basic conditions (DBU/NMP), the peptide synthesis can be continued. This variant of the Mitsunobu reaction afforded couplings yields of >90% with the alkylphosphonic acids tested.

A classical application of the Mitsunobu reaction for the synthesis of phenol ethers was conducted recently by Rano and Chapman[80] with immobilized substrates (Scheme 11). Two model compounds were used to study the coupling of phenols to polymer-bound alcohols, and of alcohols to the resin-bound phenols. The optimal coupling reagents were found to be *N*,*N*′,*N*″,*N*‴-tetramethylazodicarboxamide and tributylphosphane in THF/CH_2Cl_2. A fivefold excess of the coupling reagents and ten equivalents of the phenol (based on the maximum loading of the TentaGel support) were used, and after a reaction time of about 15 min the phenol ethers were obtained in yields of 72–99% with purities of 89–97% as judged by HPLC. Similarly, the reaction of alcohols with the polymer-bound phenols proceeded smoothly. The coupling reagents and the alcohol were used in fivefold excess. Reactions over 45–60 min resulted in yields of phenol ethers of 68–94% with purities of 81–97%.

The first steps for the synthesis of new oligomers, oligosulfones and oligosulfoxides, have been described by Moran et al.[81] The starting materials for these compounds were polymer-bound thioethers, which were prepared in five steps. To follow the reaction course more accurately, the chromophore 2-(4-carboxybenzyloxy)ethanol was coupled to the Rink amide resin and the terminal hydroxyl group was thioacetylated with thioacetic acid under Mitsunobu conditions (PPh_3, DIAD, THF at 0 °C). Reduction of the thioacetate with $NaBH_4$ generated the free thiol. The thiol was alkylated with (*S*)-2-bromopropionic acid and the carboxyl group was subsequently reduced to the alcohol by using a slightly modified Soai reaction.[82] Further synthesis steps could then be carried out on the free hydroxyl group to obtain polymer-bound thioethers, which were oxidized to oligosulfones and oligosulfonates.

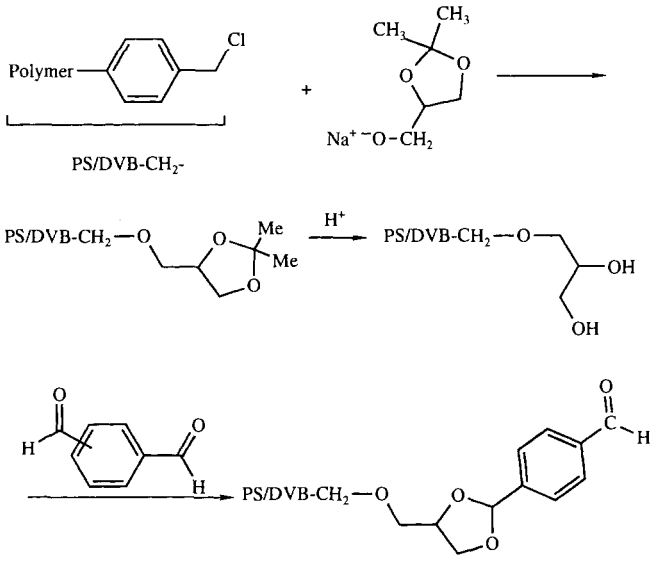
3.2. Immobilization and Derivatization of Aldehydes and Ketones

Immobilization of aldehydes and ketones on polymeric supports is possible by acetalization using resins functionalized with 1,2- or 1,3-diols. The 1,3-dioxolanes and 1,3-dioxanes thus



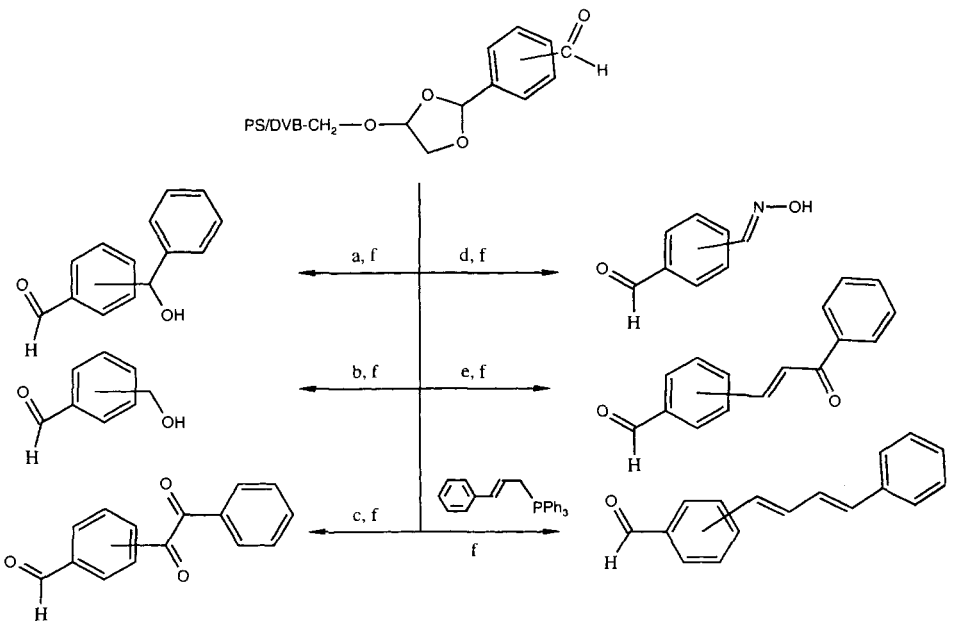
Scheme 11. The classical Mitsunobu reaction for the synthesis of aryl ethers on a polymeric support [80]. a) 3-(4-Hydroxyphenyl)propionic acid, EDC, DMF, 2 h; b) ROH, TMAD, Bu_3P; c) 4-hydroxymethylbenzoic acid, EDC, DMF, 2 h; d) phenol derivatives, TMAD, Bu_3P; e) TFA/H_2O (9/1). R = alkyl, aryl; R″ = H, Ph, OMe, OPh, CN, Br, CHO, CO_2Me.

formed are base-stable but can be cleaved by strong acids. Several of these functionalized polymers have already been prepared by Leznoff et al.[83] (Scheme 12). To prevent cross-linking of the resin, the reaction must be carried out with a large excess of the dicarbonyl compound; the acetal formation is catalyzed by *m*-benzenedisulfonic acid.



Scheme 12. Preparation of a modified chloromethyl-PS/DVB support for immobilizing aldehydes and ketones [83, 84]. Alternatively, diols can be linked to an aldehyde- or ketone-modified support.

Leznoff et al.[83, 84] developed six methods for derivatizing polymer-bound dialdehydes (Scheme 13). Analogous reactions can be carried out with acetalated ketones. As an example, Grignard reactions on these solid supports yield substituted olefins.[84]



Scheme 13. Several organic reactions carried out by using immobilized aromatic aldehydes, for example preparation of oximes, Grignard reaction, selective reduction of carbonyl groups, benzoin condensation, aldol condensation, and Wittig reaction [83, 84]. a) PhMgBr; b) $Na[AlH_2(OCH_2OCH_3)_2]$; c) PhCHO, NaCN; d) NH_2OH; e) acetophenone; f) acidolysis.

Ren et al.[85] synthesized a 1,3-diol-functionalized polystyrene resin by aldol condensation and disproportionation (mixed Cannizzaro reaction) of a butyrylated PS/DVB copolymer with paraformaldehyde in the presence of NaOH. Aldehydes (terephthalaldehyde is particularly well suited) have been immobilized on this resin and treated with hydroxylamine, NaOH, and Grignard and Wittig reagents. The resulting products, *p*-formylbenzaldoxime, *p*-formylbenzyl formate, mono-*p*-formylstilbene, and mono-*p*-formyldiphenyl formate, were obtained in high yields.

3.3. Immobilization and Derivatization of Dicarboxylic Acids and Their Derivatives

Monoester monoamides are typically prepared by the reaction of monoester carboxylic acid chlorides with ammonia.[86, 87] However, synthesis of these acid chlorides generally proceeds with yields of less than 50%.[88] Only in the reactions using anhydrides are yields of up to 70% achieved. Higher yields of monoester monoamides have been obtained by solid-phase synthesis.[89, 90] As long as strongly acidic conditions are not required, both hydroxymethylated PS/DVB resins and *p*-alkoxy resins[91] (Wang resins) can be functionalized with the corresponding dicarboxylic acid chlorides (Schemes 14, 15; Table 5). Subsequently, the polymer-bound monoester monoamides are further derivatized by reaction with amines (Table 5). Based on the resin loading of 0.3–0.56 mmol g^{-1}, yields of 65–98% have been obtained. The resin–substrate bond is cleaved by alkaline saponification using potassium carbonate.

Ketones can be prepared by treating polymer-bound acyl chlorides with phenylcadmium chloride[92] (Scheme 15). The selective reduction of acyl chlorides to primary alcohols is achieved with $NaBH_4$ without cleavage of the ester group;[93] reaction with alkylmanganese iodides[94] converts acyl chlorides into tertiary alcohols. Some of these alcohols may serve as precursors of 4,4-diphenyl-γ-butyrolactones, which have known biological activity against pathogenic viruses.[95]

Similar reactions have been conducted with a specially derivatized sulfonylethanol-PS/DVB resin.[72d] This anchor combination has ester bonds with different reactivities, one of which can be cleaved by β-elimination. The remaining ethenesulfonyl moiety can be regenerated without loss of reactivity and utilized in further syntheses.

Camps et al.[96] and Patschorkin and Kraus[97] succeeded in finding reaction conditions that allow monoalkylation and monoacylation of polymer-bound carboxylic acids. Side reactions that are often observed in solution synthesis, for example the Claisen condensation, were suppressed completely by using low loading (<0.2 mmol g^{-1}).

Table 5. Starting materials for the solid-phase synthesis of monoamides.

Dicarboxylic acid dichloride	Amine
isophthaloyl dichloride	*tert*-butylamine
terephthaloyl dichloride	*tert*-butylamine

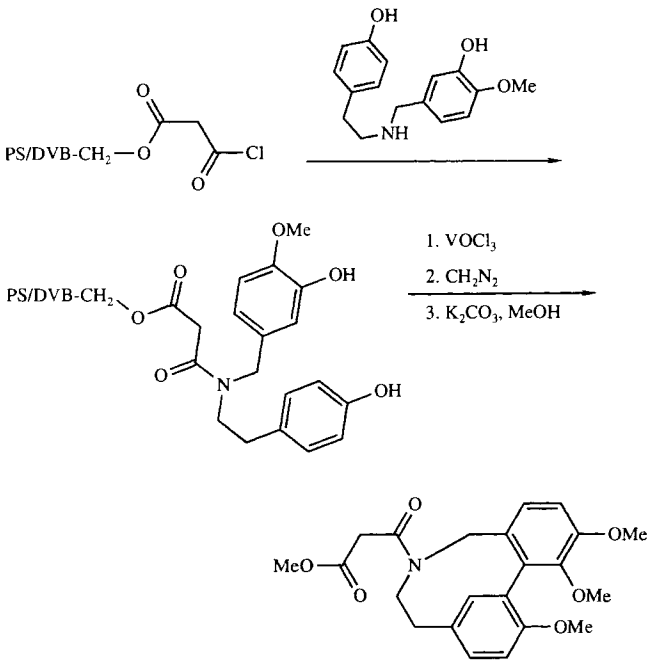
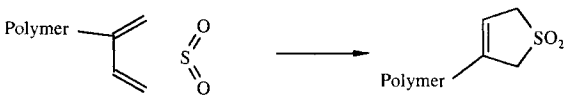


Scheme 15. Oxidative synthesis of a biphenyl derivative on a polymer support [69].

3.4. Ring-Closing Reactions

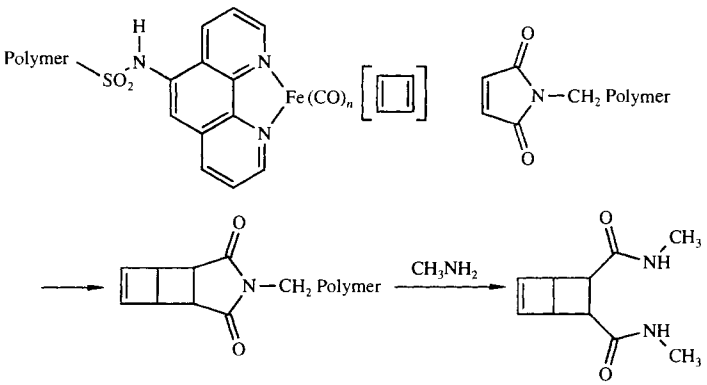
In this section we will not discuss methods for the cyclization of polymer-bound peptides and proteins,[98] but rather we will focus on adaptations of ring-closing reactions that have been used successfully in solution-phase synthesis.

Due to their high regio- and stereoselectivity, pericyclic reactions are often employed in the synthesis of compounds with defined structures.[100] For this reason several groups are engaged with the investigation of solid-phase cyclization reactions. Blazka and Harwood,[101] for instance, prepared a resin-bound Diels–Alder product by reacting a polymer-bound maleimide with a cyclopentadiene. Nieuwstad and co-workers[102] employed a series of polymer-bound dienes for desulfurizing fume gases by cycloaddition with sulfur dioxide (Scheme 16). However, in both cases the synthesized products were not cleaved from the polymer.



Scheme 16. Gas desulfurization through trapping of SO_2 by immobilized butadienes [102].

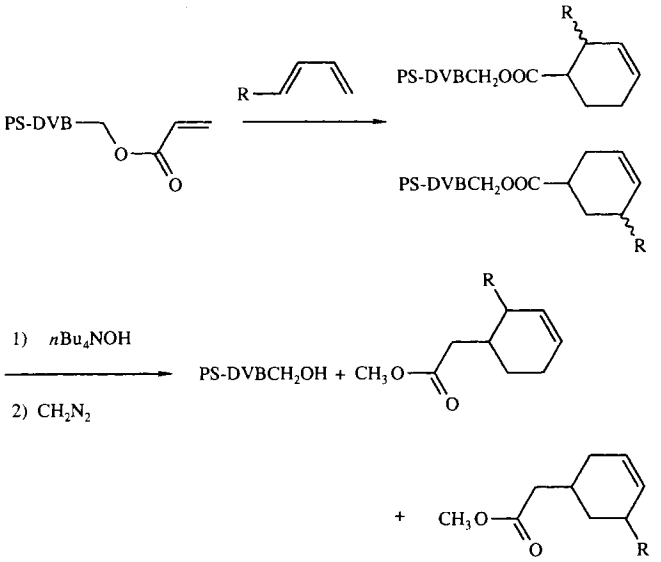
Resin-bound dienes and dienophiles have also been used to trap reactive intermediates[103] (Scheme 17). Trapping reactions with reactive polymers could also be interesting for combinatorial chemistry in solution, for example, to facilitate workup and automation.



Scheme 17. Two different resins were combined to generate an interesting "trap" for reactive intermediates [103]. The trapping reagent maleimide was immobilized on a support (PS/DVB (2%) copolymer). A butadiene precursor was prepared on the second resin, a chlorosulfonated support, by reaction with 5-amino-*o*-phenanthroline and tricarbonyl(cyclobutadienyl)iron. A suspension of these resins was oxidized with metals or pyridin-1-oxide, the resins were separated, and the product, bicyclo[2.2.0]hexenediamide, was obtained.

The research group led by Leznoff[104] investigated the reaction of substituted 1,3-butadienes with polymer-bound dienophiles, in particular immobilized acrylic acid. In the reaction with electron-deficient dienophiles in solution a mixture of 3,4- and 3,5-disubstituted cyclohexanes results, in which the 3,4-disubstituted isomer is the major product.[105] The aim of these investigations was to shift the reaction in favor of the

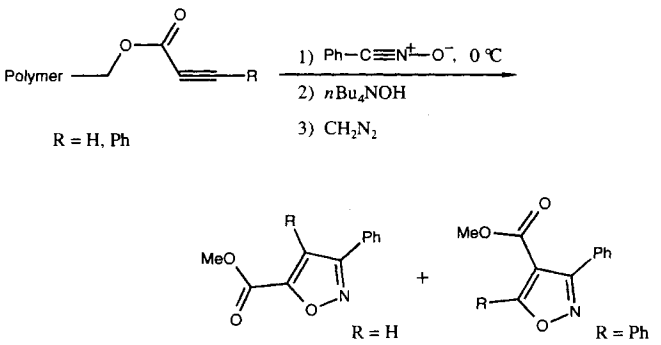
3,5-disubstituted product by taking advantage of the increased steric bulk of the resin-bound dienophile. Acrylic chloride was anchored to a hydroxymethylated PS/DVB resin as described in Section 3.3 and was then allowed to react with a hot solution of (*E*)-1-phenyl-1,3-butadiene in xylene (Scheme 18). The Diels–Alder product was removed from the polymer with base.



Scheme 18. Diels–Alder reaction of a butadiene (e.g. R = Ph) with polymer-bound acrylic acid [104] and cleavage of the cycloaddition product.

In other studies the regio- and stereoselectivity of 1,3-dipolar cycloadditions of nitrile oxides to polymer-bound alkynes was examined[104] (Scheme 19, see also Section 4.1). The reactions of support-bound propionic and phenylpropionic acids with benzonitrile oxide followed by alkaline cleavage and esterification with diazomethane yielded exclusively methyl 3-phenylisoxazole-5-carboxylate and methyl 3,5-diphenylisoxazole-4-carboxylate, respectively.

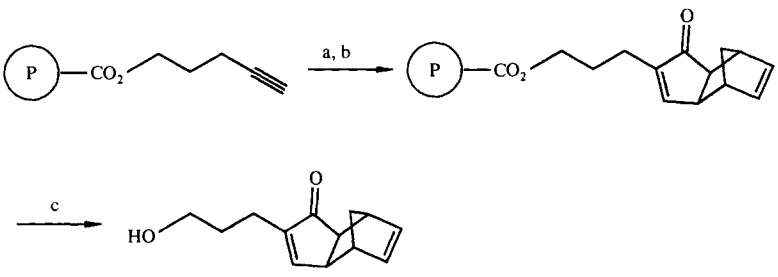
Although Leznoff et al.[104] could not demonstrate conclusively that regioselectivity is influenced by the substrate–support linkage in general, these experiments showed that pericyclic reactions can be carried out successfully on polymer supports. The stereoselectivity may not be affected or at best only minimally, but the yields and purity are considerably improved.



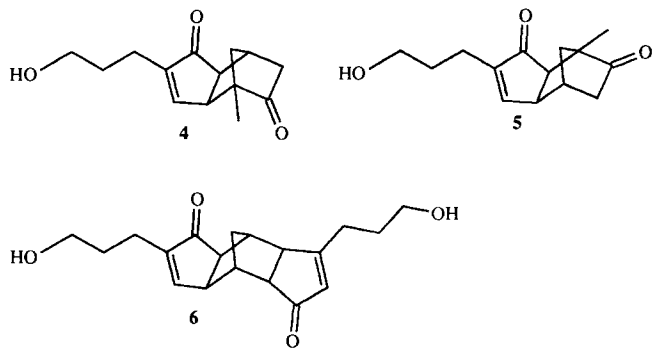
Scheme 19. 1,3-dipolar cycloaddition of nitrile oxides to resin-bound alkynyl carboxylic acids [104].

The findings of Leznoff et al. from the 1980s[104] have served as impetus for more recent studies. Schore and Najdi[106] treated immobilized 4-pentyn-1-ol with excess norbornadiene in a Pauson–Khand cycloaddition[107] and, after hydrolysis, obtained the monocyclic product **3** in 69% yield (26% by solution synthesis; Scheme 20); the bicyclic adduct **6** (20% yield, only traces are found in solution synthesis) could also be isolated when norbornadiene was used in equimolar amounts. An analogously performed reaction with 1-methyl-5-norbornen-2-one furnished a 3:7 mixture of isomers **4** and **5** (total yield 99%; 10% by solution synthesis) (Scheme 21). The formation of **6** can be explained by assuming a cross-linking reaction involving norbornadiene. This has been confirmed in further experiments using 2% cross-linked PS/DVB. It is assumed that the cross-linking reaction is suppressed since the reactive groups of a more highly cross-linked polymer are more isolated. Indeed, formation of **6** could be suppressed under analogous reaction conditions with 2% cross-linked PS/DVB.[106b]

In 1992 Beebe, Schore, and Kurth[108] described the solid-phase synthesis of 2,5-disubstituted tetrahydrofurans by a "tandem" 1,3-dipolar cycloaddition of a support-bound nitrile oxide with 1,5-hexadiene (Scheme 22). Nitrile oxides were produced by reacting nitromethane with polymer-bound aldehydes in a Henry reaction. After protection of the hydroxyl group as a trimethylsilyl ester and dehydrogenation, a cyclization yielded

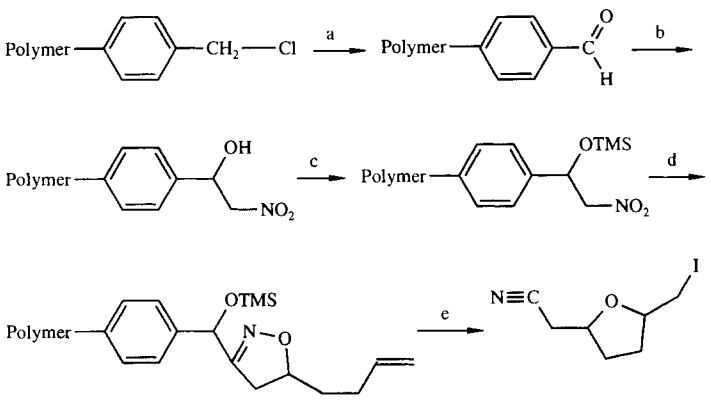


Scheme 20. Dicobalt octacarbonyl mediated Pauson–Khand cycloaddition [106, 107]. a) [Co$_2$(CO)$_8$]; b) norbornadiene, 80–100 °C; c) nBu$_4$NCl, KOH, H$_2$O, 80 °C, 4 h. Ⓟ = polymer.



Scheme 21. Compounds prepared by Pauson–Khand cycloaddition [106, 107].

a resin-bound isoxazoline. The subsequent electrophilic cyclization by addition of iodine monochloride (ICl) afforded 2,5-disubstituted dihydrofurans. The *cis* to *trans* ratio was 1:2.1 (1:1.92 in the solution synthesis) with a total yield of 17% based on a maximum loading of 0.65 mmol g^{-1} (18% yield in solution).

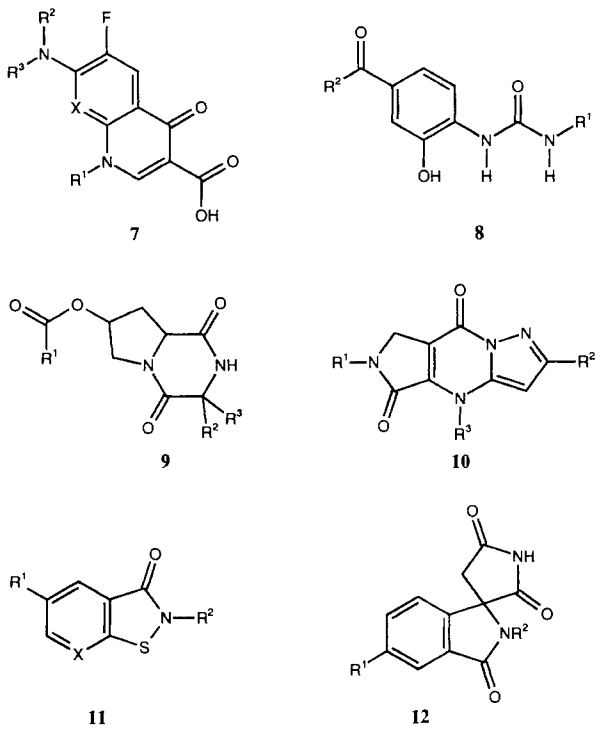


Scheme 22. Tandem 1,3-dipolar cycloaddition for the preparation of substituted tetrahydrofurans [108]. a) DMSO, $NaHCO_3$, 155 °C, 6 h; b) CH_3NO_2, Et_3N, THF, EtOH, 14 h; c) TMSCl, Et_3N; d) PhNCO, Et_2O, PhH, 80 °C, 1,5-dienes; e) ICl, CH_2Cl_2, −78 °C, 1.5 h.

[3 + 2]Cycloaddition reactions have also been carried out to derivatize alkene- and alkyne-substituted peptoids[147] (Section 4.1).

3.5. Synthesis of Heterocyclic Compounds: Benzodiazepines, Hydantoins, and Thiazolidines

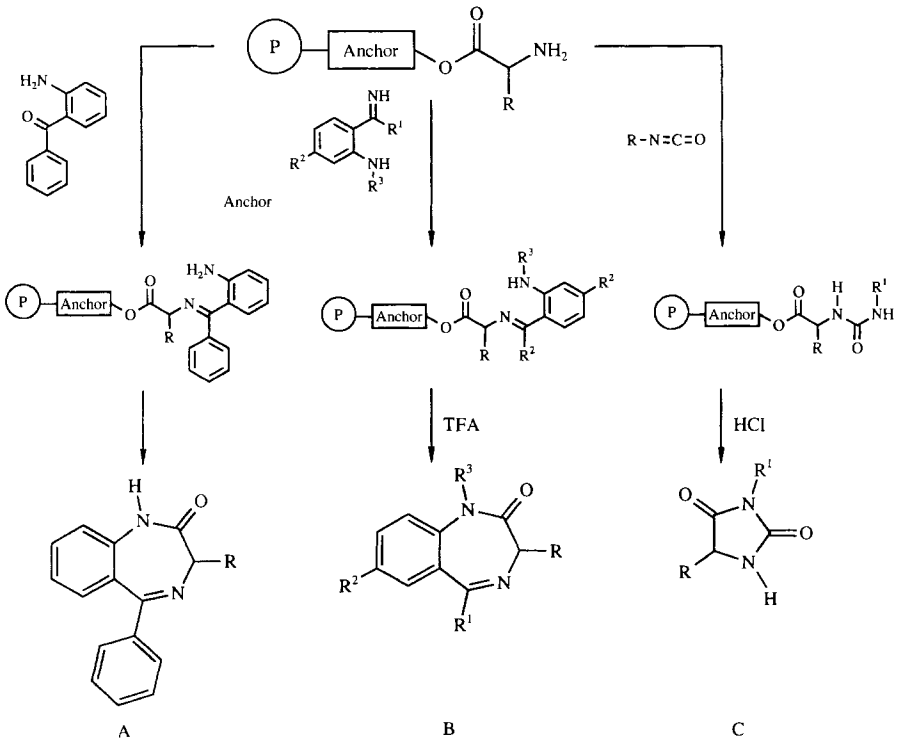
The benzodiazepine skeleton is a constituent of many bioavailable therapeutic agents. The CCK receptor A and B antagonists,[109] opiate receptor ligands[110] (e.g. valium), fibrinogen receptor antagonists (GP-IIbIIIa inhibitors),[111, 112] reverse transcriptase inhibitors,[113] and HIV-TAT-RNA antagonists[114] all have benzodiazepine frameworks.



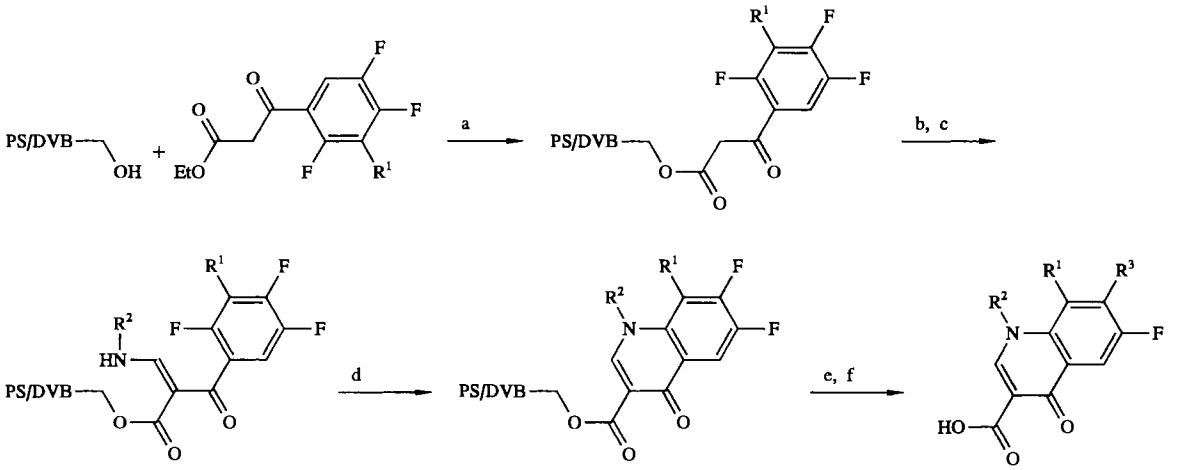
Scheme 24. Other heterocyclic compounds in addition to benzodiazepines and hydantoins prepared by Hobbs DeWitt et al. [117] on solid supports. Quinolones **7** (X = N, CH), (acylphenyl)ureas **8**, dioxopiperazines **9**, pyrimidindiones **10**, benzothiazolones **11** (X = N, CH), spirosuccinimides **12**. R^1, R^2, R^3 = alkyl, aryl.

Following the solid-phase synthesis of benzodiazepines reported by Camps, Castells, and Pi in 1974,[115] Hobbs DeWitt et al.[116] developed a method for the synthesis of benzodiazepines and hydantoins based on the Fmoc strategy (Scheme 23). The synthesis of Camps et al. begins with the coupling of Boc-protected amino acids to hydroxy-functionalized PS/DVB resin using carbonyldiimidazole (CDI) as a coupling reagent (Scheme 23). Benzodiazepines are obtained directly by cleavage of the Boc group, followed by the reaction with acetophenone.

A further development of this reaction led to the simultaneous multiple synthesis of benzodiazepines and hydantoins starting with the resin-bound Boc- or Fmoc-protected amino acids. Hobbs DeWitt et al.[116] synthesized sets of 40 benzodiazepines and hydantoins by reacting five differently loaded resins with eight different benzophenones and isocyanates, respectively. In addition, in a patent published in early 1994 Hobbs-DeWitt et al.[117] described the simultaneous multiple synthesis of a series of heterocyclic compounds starting with commercially available standard resins (hydroxy- or chloromethylated PS/DVB) (Scheme 24).



Scheme 23. Solid-phase synthesis of benzodiazepines and hydantoins. Benzodiazepine synthesis according to Camps, Castells, and Pi [115] (A); synthesis of benzodiazepines and hydantoins according to Hobbs DeWitt et al. [116] (B and C, respectively). Ⓟ = polymer; R = amino acid side chains; R^1, R^2, R^3 = alkyl, aryl.

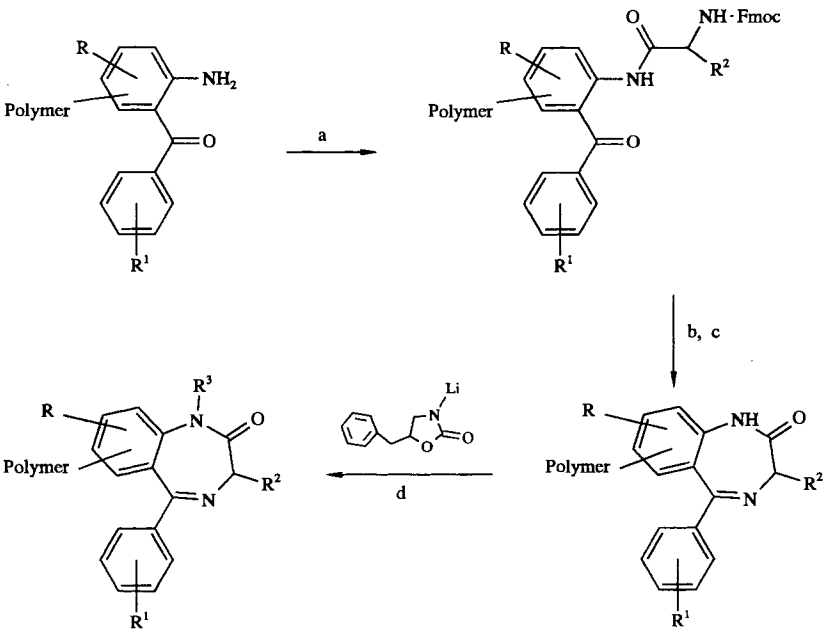


Scheme 25. Solid-phase synthesis of quinolones [188]. a) Toluene, DMAP, 110 °C, 16 h; b) $(CH_3O)_2CHN(CH_3)_2$, THF, 25 °C, 18 h; c) H_2NR^2, 25 °C, 72 h; d) tetramethylguanidine, CH_2Cl_2, 65 °C, 18 h; e) H_2NR^3, NMP, 110 °C, 4 h; f) TFA/CH_2Cl_2 (2/3), 25 °C, 1 h. R^1, R^2, R^3 = alkyl, aryl.

Recently MacDonald and Ramage,[118] in cooperation with Hobbs DeWitt and Hogan, described a procedure for the multiple parallel synthesis of quinolones (Scheme 25). In this approach ethyl 3-(3-alkyl-2,4,5-trifluorophenyl)-3-oxopropionate was coupled to commercially available Wang resin (Table 2) by transesterification and then treated with a series of amines to obtain enamines, which were cyclized by nucleophilic aromatic substitution. The quinolone skeleton was subsequently modified by a further nucleophilic aromatic substitution. The final product was cleaved from the anchor by trifluoroacetic acid/CH_2Cl_2.

Ellman et al.[119] described a slightly different procedure for synthesizing benzodiazepines (Scheme 26). The benzodiazepines were synthesized on a resin by using three different building blocks. An aminobenzophenone derivative (carboxylic acid or alcohol) was attached to the polymer through an acid-labile anchor and subsequently reacted with a Fmoc-protected amino acid fluoride. After deprotection, the diazepine ring was formed by addition of 5% acetic acid. After deprotonation and alkylation with one of a series of alkyl halides, the benzodiazepine product was cleaved from the resin by treatment with acids.

In further investigations, in addition to the solid-phase synthesis of benzophenone derivatives[120] (Scheme 27) a set of 192 benzodiazepines was synthesized simultaneously and their biological activity determined. Thus, microscale syntheses were carried out on derivatized polypropylene pins[121] loaded with two different benzophenones. A block of 96 of these pins was immersed in successive microtiter plates filled with N-protected amino acid fluorides or alkyl halides (a specific compound in each cavity) and subjected to standard reaction conditions.



Scheme 26. Benzodiazepine synthesis according to Ellman et al. [119, 120]. a) Fmoc-protected amino acid fluorides; b) piperidine/DMF (1/1); c) HOAc/DMF (5/95); d) alkyl iodides R^3I, DMF. R = Cl, OH; R^1 = OH; R^2 = Me, *i*Pr, 3-indoyl-CH_2; R^3 = H, Et, Bn.

Recently Plunkett and Ellman[122] developed a further method for preparation of benzodiazepines by the Stille reaction (see also Section 3.7) of polymer-bound N-Bpoc protected (2-aminoaryl)stannates with aromatic or aliphatic acyl halides. After removal of the Bpoc protecting group, the free amine was acylated and cyclized to give the benzodiazepine with 5% acetic acid.

Patek et al.[123] published a method for the simple solid-phase synthesis of thiazolidines by cyclocondensation of bound β-sulfanylalkylamine with ketones or aldehydes (Scheme 28). The β-sulfanylalkylamine moieties were introduced in the form of Fmoc-Cys(Trt)-OH, and the Fmoc and Trt groups were removed consecutively. Subsequent reactions with aldehydes or ketones generated the polymer-bound thiazolidine skeleton, which was acylated at the nitrogen atom by a condensation reaction with carboxylic acids in DMF. To enhance the acid-lability of the five-membered ring, the anchor was oxidized

with 3-chloroperbenzoic acid (MCPBA) before cleavage from the support to give the sulfoxide.

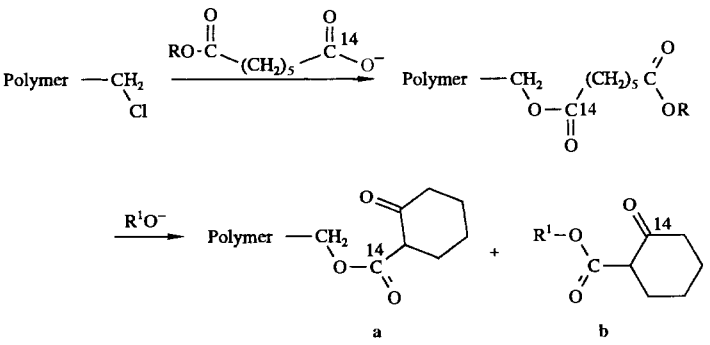
The thiazolidine synthesis was further investigated by employing a series of compounds containing carbonyl and carboxyl groups; the yields and ratios of diastereomeric products were determined and compared with the results of the analogous solution reactions. When low yields are obtained, the diastereoselectivity of the solid-phase reaction is on average higher than that of the solution synthesis. The yields ranged from <10 to 90% (in solution 66 to 92%) with d.r. values (d.r. $= 100 \times [(1R,4R)/\{(2R,4R) + (2S,4R)\}]$) of 65 to >97% (in solution 29 to >97%).

3.6. Further Ring Closures on Solid Supports

The intramolecular ester condensation (Dieckmann condensation) of asymmetrically substituted esters generally leads to a mixture of isomers. In the solid-phase procedure developed by Crowley and Rapoport,[124a] this ring-closing reaction is regioselective. An asymmetrically disubstituted diester was synthesized by deprotonation of pimelic acid monomethyl ester and reaction with chloromethylated polystyrene; the product was finally cyclized by addition of a base. By using the monoester labeled with ^{14}C at C1, it could be demonstrated that the condensation proceeds in both possible directions (Scheme 29). Hence, one product is removed from the resin by autocleavage, whereas the other remains immobilized on the resin. This product can be obtained by treatment with base.

By using the three building blocks, α-amino acids, bromocarboxylic acids, and aminoalkylthiols, Virgilio and Ellman[125] (Scheme 30) synthesized simultaneously a series of nine- and ten-membered ring systems that supposedly imitate the β-turn of proteins. Polypropylene pins or PEG/PS graft copolymers were used for the synthesis of β-turn mimetics possessing (*R*) configuration in the $i+1$ position and (*S*) configuration in the $i+2$ position. What makes the reaction interesting is that based on only commercially available building blocks a compound library containing more than 2000 components can be synthesized simultaneously.[126] The multiple-step synthesis (Scheme 30) began with the coupling of a bromocarboxylic acid to the support and displacement of bromine by aminoalkylthiol, protected as a disulfide. The secondary amine formed was condensed with an Fmoc-protected amino acid and, after removal of the Fmoc group, was acylated again with a further bromocarboxylic acid. The disulfide bond was cleaved with tributylphosphane and, finally, a ring-closing nucleophilic cyclization was effected by addition of *N*,*N*′,*N*″,*N*‴-tetramethylguanidine.

Solid-phase synthesis is not limited to the preparation of small-ring systems; syntheses of helicenes,[127] porphyrins,[128] and phthalocyanines[129] have also been reported. The first synthesis of unsymmetrically substituted tetraarylporphyrins on a PS/DVB support was reported in 1977. For this purpose, hy-



Scheme 29. Dieckmann cyclization of a polymer-bound substrate. The cyclohexanone product **a** remains immobilized on the resin during the reaction, whereas product **b** is liberated by self-cleavage. The polymer-bound product can be cleaved by saponification [124]. R = Et; R^1 = alkyl. 14 = ^{14}C-radiolabeled carbon atom.

Preparation of nonpeptidic β-turn mimetics on polymer supports [125]. a) Bromoacetic acid, DIC; b) 2-aminoethyl-*tert*-butylsulfide (or aminopropylthio-*tert*-butyldisulfide); c) Fmoc-protected amino acids, HATU; d) piperidine/DMF (1/1); e) symmetrical α-bromocarboxylic anhydride; f) PBu_3, H_2O; g) tetramethylguanidine; h) TFA/water/Me_2S (18/1/1). R^{i+1} = alkyl, aryl, protected amino acid side chains; R^{i+2} = alkyl, aryl.

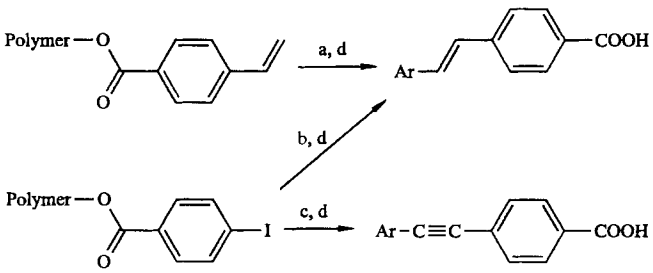
droxybenzaldehydes were bound to a resin by means of an acid-labile linker and allowed to react with *p*-methylbenzaldehyde, pyrrole, and propionic acid at high temperature for one hour. In addition to a soluble mixture of several porphyrins, which were removed by extraction, a polymer-bound unsymmetrically substituted porphyrin was also obtained in 4 to 5% yield . The product was obtained in pure form by alkaline saponification. Recently, unsymmetrically substituted phthalocyanines were also synthesized by a similar procedure.[129]

3.7. Palladium-Catalyzed C–C Bond Formation

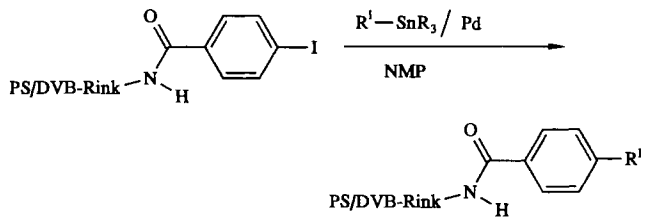
In recent years numerous articles have described the extension of reactions for C–C bond formation, which are frequently carried out in solution syntheses, to reactions on polymeric supports. A common feature of these solid-phase reactions is the use of soluble palladium compounds as catalysts. Based on the results of the elegant experiments described in this section, further successful applications in this area of combinatorial chemistry can be expected.

The Heck reaction[130] can be used for simple synthesis of disubstituted alkenes and alkynes. The reactions of aryl iodides with alkenes (alkynes) and of styrene with aryl halides in the presence of Pd^{II} acetate produce the correspondingly substituted alkenes (alkynes) with high purity and yields. Yu, Deshpande, and Vyas[131] immobilized the model compounds 4-vinyl- and 4-iodobenzoic acid on Wang resin and reacted them with a series of substrates under Heck conditions (Scheme 31; Table 6). With a few exceptions, such as ethyl propionate which did not react under the chosen conditions, alkenes and alkynes were obtained in high yields.

In related work immobilized 4-iodobenzoic acid was used to investigate the Stille reaction .[132] Reaction of iodobenzoic acid with vinyl- and arylstannanes in the presence of palladium and $As(Ph)_3$ generated substituted arenes and biphenyl derivatives, respectively, in yields of 85 to 92% based on the loading of iodobenzoic acid on the resin (Scheme 32).



Scheme 31. Palladium-catalyzed Heck reaction [130, 131] for the preparation of substituted arenes. a) Aryl halides, $Pd(OAc)_2$; b) arenes or olefins, Pd; c) aryl-substituted alkynes, $Pd(OAc)_2$; d) TFA/CH_2Cl_2 (9/1).



Scheme 32. Stille coupling reaction of a polymer-supported substrate [132]. Substituted arenes are obtained by the reaction of organotin compounds in the presence of Pd^0. The products are cleaved from the resin by TFA. R^1 = vinyl, aryl; R = Me.

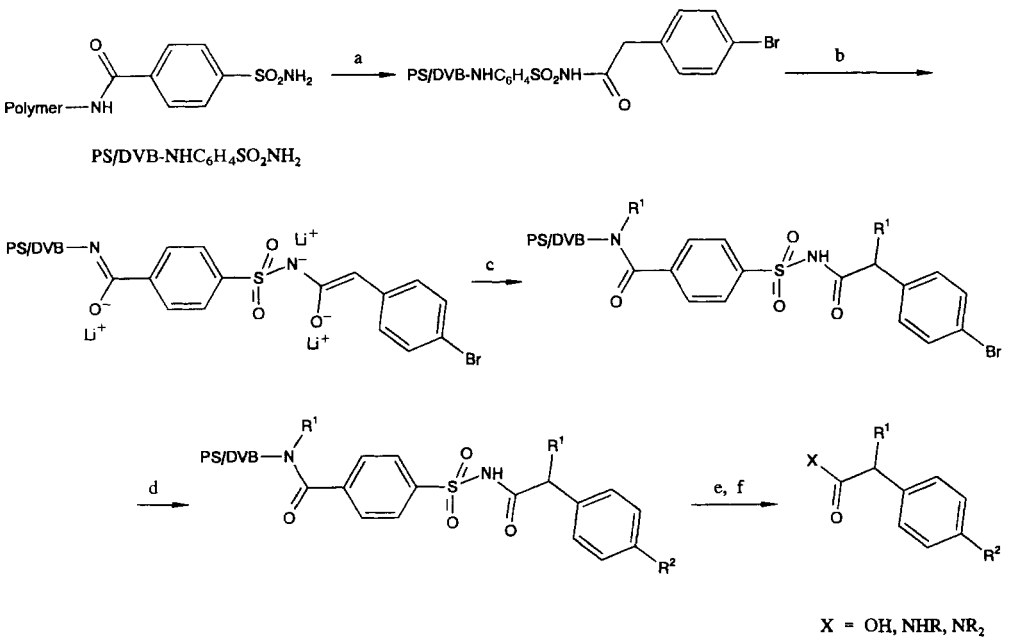
Backes and Ellman[134] synthesized a series of phenylacetic acid derivatives on supports by enolate alkylation and subsequent Suzuki reaction[133] (Scheme 33; Table 7). The rarely used Safety-Catch linker[37c] was used since it is stable under the chosen reaction conditions. The active ester pentafluorophenyl 4-bromophenylacetate was immobilized on the support in the presence of dimethylaminopyridine. Deprotonation with LDA gave a trianion, which was then alkylated with alkyl halides (Table 7). For the palladium-catalyzed Suzuki reaction, a series of either arylboronic acids or alkylboranes produced by in situ hydroboration of alkenes served as coupling partners. After methylation of



Scheme 33. Solid-phase synthesis of substituted phenylacetic acid derivatives by an enolate alkylation followed by a Suzuki reaction [133, 134]. Backes and Ellman used this procedure to prepare ibufenac (R^1 = H, R^2 = Me_2CHCH_2, X = OH), ibuprofen (R^1 = Me, R^2 = Me_2CHCH_2, X = OH), and felbinac (R^1 = H, R^2 = Ph, X = OH) (see Table 7). a) *p*-$BrC_6H_4CH_2CO_2C_6F_5$, DMAP; b) LDA, THF, 0 °C; c) alkyl halides, 0 °C; d) alkylated 9-BBN or an aryl boronic acid, $[Pd(PPh_3)_3]$, Na_2CO_3, THF, 65 °C; e) diazomethane; f) hydroxide or amine. the sulfonamide nitrogen atom of the safety-catch anchor, the reaction products were cleaved by treatment with hydroxide or an amine nucleophile.

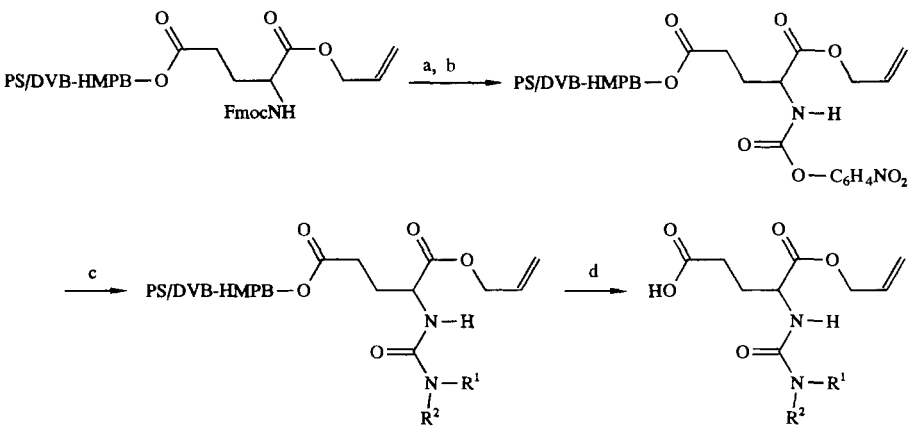
The methods presented for C–C bond formation are of particular significance for preparation of molecular diversity, since they allow the synthesis of novel skeletons.

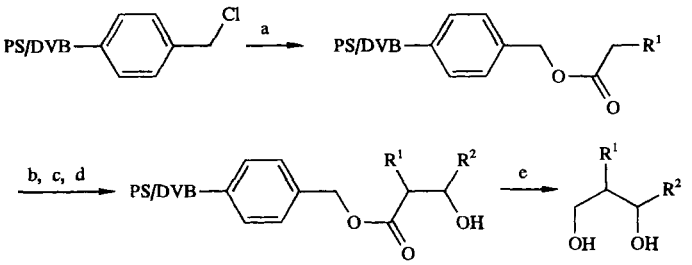
3.8. Further Reactions on Polymeric Supports

A generally applicable method for the synthesis of ureas was described by Hutchins and Chapman[135] (see also Section 4.4). The ureas were produced by treating polymer-bound *p*-nitrophenylcarbamates with primary and secondary amines. The carbamates were obtained in turn from the reaction of immobilized amines with *p*-nitrophenyl chloroformate. Thus, for example, Fmoc-protected glutamic acid was anchored to the polymer through its γ-carboxyl group while the α-carboxyl group was protected as an allyl ester. After removal of the Fmoc group, the free amino group was reacted with *p*-nitrophenyl chloroformate and several amines to obtain the corresponding ureas (Scheme 34). With the exception of *p*-nitroaniline, which did not react, all the amines employed yielded relatively pure products (90–98%, estimated by HPLC). It is also probable that this method can be adapted for the preparation of oligoureas (see Section 4.4).

Kurth et al.[136] described the three-step solid-phase synthesis of a series of 1,3-propanediols (Scheme 35). The synthesis began with the coupling of carboxylic acids (acetic acid, 2-methoxyacetic acid, and 3-phenylpropionic acid) to chloromethylated Merrifield resin. After deprotonation with LDA/THF, they were allowed to undergo an aldol condensation reaction with a series of aromatic carbonyl compounds. In the last step, the



Scheme 34. Preparation of polymer-bound ureas [135]. a) piperidine/DMF (1/4); b) $ClCO_2C_6H_4$-*p*-NO_2, DIPEA, THF/CH_2Cl_2, 0.5 h; c) R^1R^2NH, DMF, 15 min; d) TFA/CH_2Cl_2 (2/98), 10 min. R^1, R^2 = alkyl, aryl.



Scheme 35. Solid-phase synthesis of 1,3-propanediols [136]. a) R^1COO_2Na, Bu_4NBr (cat.), THF, Δ; b) LDA, THF; c) $ZnCl_2$, THF; d) aldehyde R^2CHO (or ketone); e) DIBAL-H, toluene. R^1, R^2 = aryl.

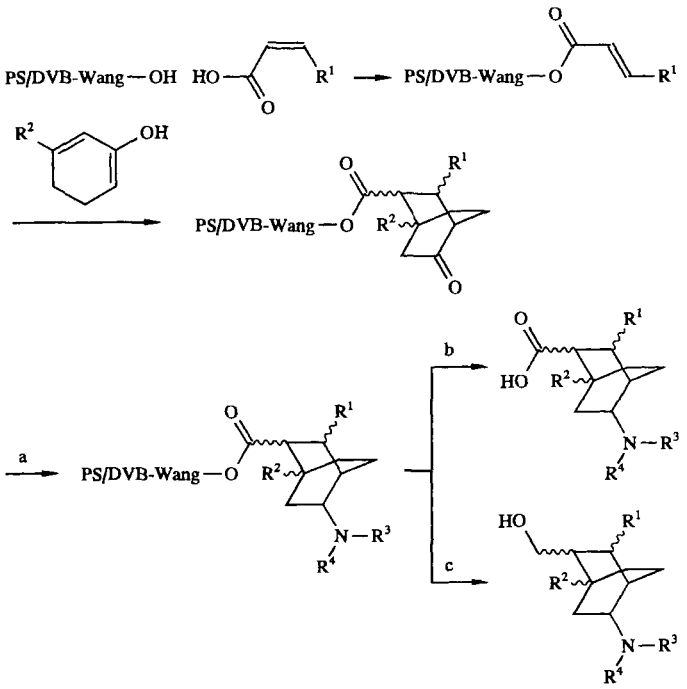
immobilized β-hydroxy esters were cleaved reductively (DIBAL-H/toluene, 0 °C) and converted into 1,3-diols. A set of 27 diols was prepared from three carboxylic acids and nine carbonyl compounds.

As already mentioned in Section 2.1, polymers have been used routinely to immobilize palladium hydrogenation catalysts.[19-21] Soluble palladium complexes have also been employed to cleave protecting groups and anchor linkages. Recently, the use of palladium catalysts for the asymmetric catalytic hydrogenation of polymer-bound substrates (alkenes) was also described.[137] For a catalytic reduction step in the synthesis of a tripeptide, various hydrogenation catalysts and reaction conditions were investigated. The tripeptide, which was synthesized in solution and then coupled to Wang resin, contained an α,β-didehydroamino acid, which was then reduced enantioselectively. The best results were achieved with the in situ prepared catalysts [Rh(dipamp)(nbd)]BF_4[138] and [Rh(ph-capp)(nbd)]BF_4[139] in toluene/2-propanol (100% yield; in dioxane a yield of only 46% was obtained). Moreover, the diastereomeric ratios (*R,S*):(*S,S*) were strongly affected by the catalyst and reaction conditions. For [Rh(dipamp)(nbd)]BF_4 diastereomeric ratios of 30.9:69.1 in dioxane and 6.2:93.8 in toluene/2-propanol were obtained; for [Rh(ph-capp)(nbd)]BF_4 these values were 43.6:69.1 and 94.9:5.1, respectively, under analogous conditions.

The most recent results in this area were presented in 1995 at numerous conferences and symposia on combinatorial chemistry and/or organic chemistry. A few reactions, especially those with interesting future prospects, should be mentioned here. Chabal et al.[140] described acylpiperidine and benzopyran libraries as well as the preparation of sulfonamides. Pavia[141] presented the synthesis of dibenzamide phenols by immobilization of 3-nitro-4-aminophenol on resin, followed by a selective reduction of the nitro group with tin(II) chloride and acylation of the new amino group. A tandem Michael addition[142] of phenolates to polymer-bound acrylic acid has also been used to prepare substituted bicyclo[2.2.2.]octanes on Wang resin (Scheme 36). These products were removed from the support either by TFA/CH_2Cl_2 or by reduction with DIBAL-H.

4. Synthesis of Oligomers

In the search for lead structures for therapeutic agents the systematic screening of peptide libraries[3b, 7] is being applied routinely and successfully. When biologically active peptides are



Scheme 36. Solid-phase synthesis of bicyclo[2.2.2]octanes [142]. a) R^3R^4NH, $NaBH(OAc)_3$, ultrasound; b) TFA/CH_2Cl_2; c) DIBAL-H. R^1–R^4 = alkyl, aryl.

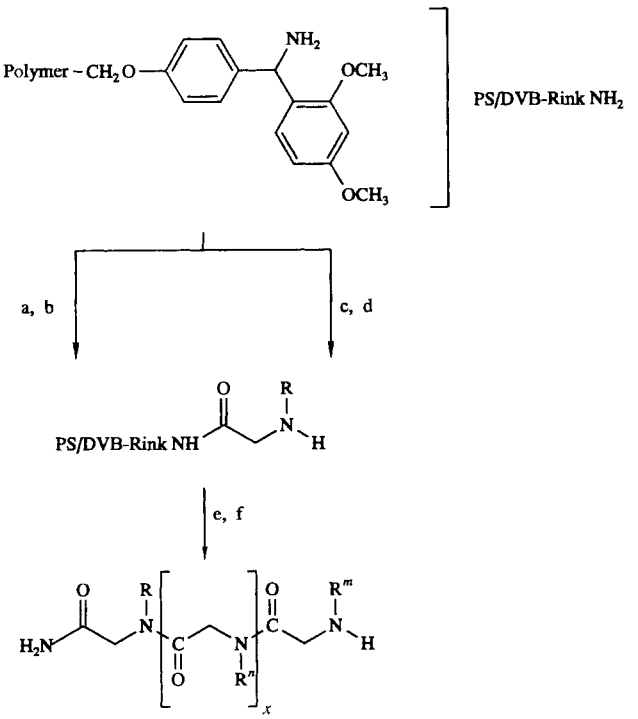
found, related low molecular weight peptidomimetics are painstakingly developed that can be applied orally as drugs.[143]

In Section 3.5 two methods were described that help to shorten this search. Thus, the compounds in benzodiazepine and hydantoin libraries are much more closely related to the final biologically active agents than a peptide is. An active compound found in such a library may be converted into more effective derivatives by a few additional steps. In addition to the peptide libraries, oligomer libraries from different building blocks also furnish interesting additional possibilities for the discovery of new biologically active compounds and/or lead structures. In contrast to biopolymers, these oligomer libraries are more stable toward enzymes and often have far higher bioavailability.

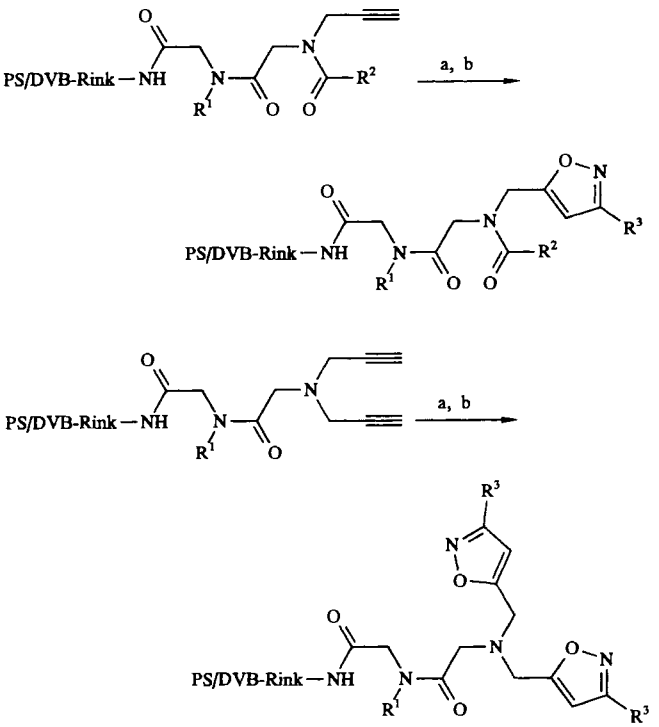
4.1. Peptoids

Peptoids, which possess N-substituted glycines (NSGs) as the smallest building blocks, are the compounds most closely related to peptides (Scheme 37). Simon et al.[144] reported a synthesis of peptoids, in which NSG building blocks, presynthesized in solution, are coupled according to a standard protocol with Fmoc protecting groups. Zuckermann[145] and co-workers synthesized NSGs directly on a polymeric support by the coupling of bromoacetic acid with diisopropylcarbodiimide and subsequent reaction of the bromoacyl group with an amine.

Since a tremendous range of amines are commercially available, peptoids with "unnatural" side chains can be used as well as those with natural side chains for the synthesis of a huge number of peptoid libraries. In principle, 10^{18} different hexa-



Scheme 37. Synthesis of peptoids on Rink resins. In the monomer method (a,b) of Simon et al. [144] the required monomers are prepared separately by solution procedures: a) *N*-Fmoc-*N*-alkylamino acids, DIC; b) piperidine/DMF (1/1). The submonomer method (c,d) of Zuckermann et al. [145] can be used to prepare immobilized N-substituted glycines from bromoacetic acid and amines: c) bromoacetic acid, DIC/DMF, 2 × 30 min; d) RNH_2, DMSO, 2 h; e) repetitive coupling; f) TFA/CH_2Cl_2. R, R‴, R″ = alkyl, aryl.



Scheme 38. Subsequent modification of *N*-alkenyl- and *N*-alkynylglycines by [3 + 2]cycloaddition of nitrile oxides prepared in situ [147]. a) Phenylisocyanate, nitroalkyl or nitroaryl compounds, triethylamine, toluene, 100 °C; b) TFA/CH_2Cl_2 (1/4). R^1 = alkyl; R^2 = alkyl, pyridyl, halogen; R^3 = Me, Bu, $HOCH_2$, Ph.

mers can be prepared from 1000 amines. Thus by screening a tetrapeptoid library (4500 individual compounds) with side chains chosen according to required diversity criteria, an α-1-adrenergic receptor antagonist was found in a short time.[146]

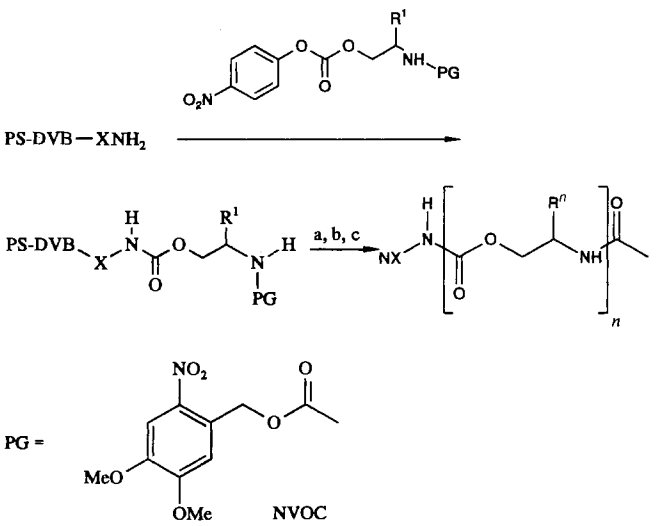
The possible variations are not restricted only to the choice of amines (side chains), since new classes of polymers can also be developed by varying the employed halocarboxylic acids. For example, α-alkyl- and ω-bromocarboxylic acids can be used to obtain N- and C_α-disubstituted peptoids or products with chain-extended backbones. Pei and Moos[147] synthesized isoxazoline- and isoxazole-substituted peptoids by reacting nitrile oxides[104, 108] (Section 3.4) with *N*-alkenyl- and *N*-alkynylglycines, respectively (Scheme 38). In these solid-phase syntheses, nitrile oxides were prepared in situ from nitro compounds, isocyanates, and triethylamine, or by oxidation of oximes with sodium hypochlorite in the presence of Et_3N. Nitrile oxides are usually very unstable and yield a series of side products by [3 + 2]cycloaddition. Here, however, the by-products were formed in the solution phase and could be removed by washing the support. Aside from two cases in this series,[147] isoxazoline and isoxazole derivatives were obtained with more than 80% purity (as measured by HPLC).

We carried out the automated synthesis of octa- and nonapeptoids on a preparative scale in our laboratories. Using ligand–receptor assays, we could show, for example, the interesting binding of peptide/peptoid hybrids to the MHC classI proteins[67] of the MHC haplotype K^b in competition with the CTL epitope SIINFEKL.[148] The identity and purity of the peptoids were established by electrospray-MS, HPLC, and for the first time by automated sequencing.[149] The sequencing was optimized for routine procedures and the products of the Edman degradation reaction could be identified. For this purpose, the monomeric NSG was synthesized on chlorotrityl-PS/DVB and converted into the corresponding phenylthiohydantoins (PTH-NSGs). The PTH-NSGs were isolated, purified, and characterized by MS and UV spectroscopy. Afterwards, an HPLC standard was constructed from PTH-NSGs; by coelution the degradation products of sequencing of peptoids and peptide–peptoid hybrids could be identified.

4.2. Oligocarbamates

The solid-phase synthesis of oligocarbamates offers another new source of potentially active oligomers for the search for lead structures. In contrast to the backbone in peptides, the oligocarbamate backbone consists of chiral *ethylene* units connected by relatively rigid carbamate units. As in peptides, the C_α atom can be substituted with different functional groups. Whereas in the first solid-phase synthesis of oligocarbamate by Cho et al.[148, 150] the C_β atom was left unsubstituted, further backbone modifications can be achieved by β-substitutions or by alkylation of the carbamoyl nitrogen atom. Compared to peptides, oligocarbamates are more hydrophobic and more stable toward proteases such as trypsin and pepsin.

Polymer-bound oligocarbamates are obtained by repetitive couplings of commercially available N-protected aminocarbonates (or aminocarbonates prepared by the reduction of protected pentafluorophenylamino acids), to an amino-functionalized resin (Scheme 39). Cleavage from the resin is carried out accord-



Scheme 39. Solid-phase synthesis of oligocarbamates [150]. a) Deprotection: *hν* = 350 nm (NVOC), piperidine/DMF (1/1) (Fmoc); b) repetitive monomer coupling; c) TFA/CH_2Cl_2. X = spacer or anchor; R^1, R^n = alkyl, aryl, protected amino acid side chain.

ing to routine procedures from peptide chemistry. To demonstrate that these methods can be used to synthesize oligocarbamate libraries, a set of 256 oligocarbamates was prepared using a photolabile amino protecting group (nitroveratroyloxycarbonyl, NVOC) in a photochemical parallel synthesis.[151] The screening of this surface-bound library with an anti-oligocarbamate antibody, obtained by immunization (antigen $AcX^cK^cF^cL^c$), showed the selective binding of antibody to this and to related sequences. The sequence segment F^cL^c was found to be the minimal epitope.

With commercially available amino acid alcohols and the Fmoc strategy, C_α-substituted free oligocarbamates were synthesized in our group on a preparative scale by employing fully automated and considerably simplified procedures.[152]

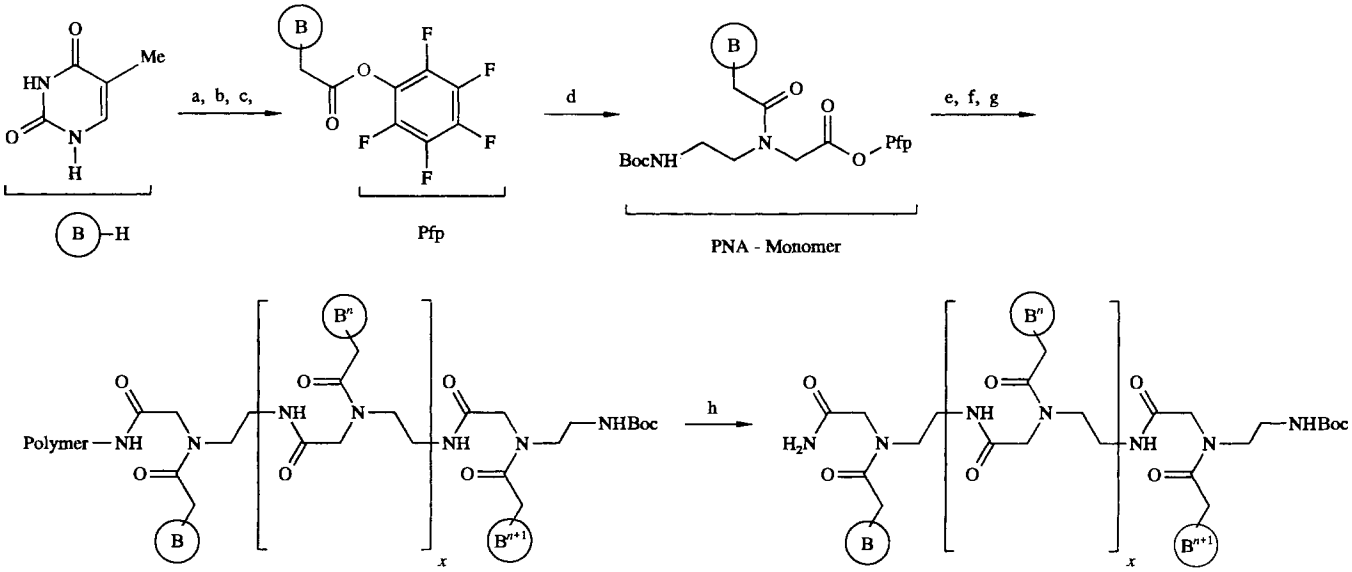
4.3. Peptide Nucleic Acids

Hybrid oligomers with the properties of both oligonucleotides and peptides were first described in 1991 and designated as peptide nucleic acids (PNAs).[153] Designed as DNA mimetics, these PNA compounds can be varied easily by convenient procedures. It could be shown that the complete DNA backbone can be replaced by a polyamide (pseudo-peptide) structure without impairing the base-specific hybridization. Thus, it is hoped that these compounds can find applications in antisense DNA therapy and in diagnostics.

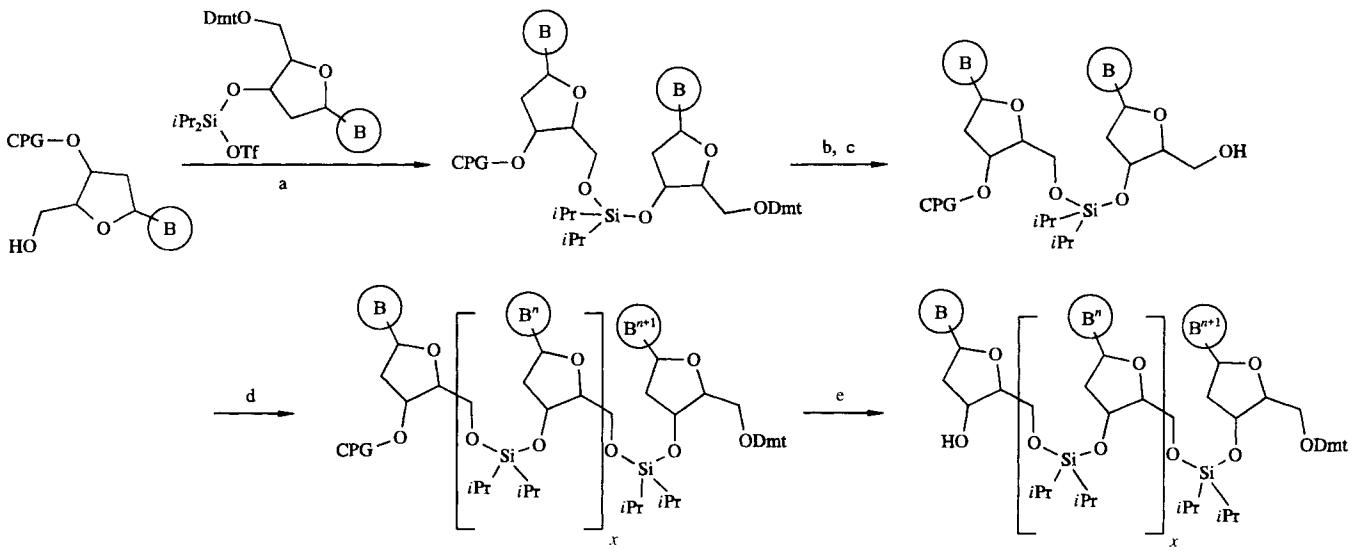
For the synthesis of PNAs, the nucleobases (only thymine and cytosine were used in initial studies) were first N-substituted using bromoacetic acid and converted into pentafluorophenyl esters (Pfp), which were then reacted with *N*-(*N*-Boc-aminoethyl)glycine (Scheme 40). After a second esterification with PfpOH, the monomers were coupled in situ by DCC according to a standard protocol.

The PNA–DNA binding characteristics were established by determining the melting points of two complementary PNA–DNA strands (dA_{10}, PNA-T_{10}) and the structure by NMR spectroscopic analysis.[153e] The homosequence dA_{10} forms a triple helix with PNA-T_{10} having a melting point of 73 °C.

Replacement of the phosphodiester group in DNA with a diisopropylsilyl analogue led to a DNA-compatible DNA backbone modification. Solid-phase synthesis of this class of compounds has been investigated thoroughly by Saha et al.[154] (Scheme 41). The oligonucleotide analogues were obtained by repetitive coupling of 3′-*O*-diisopropylsilyl deoxyriboucleotide to the already loaded controlled core glass (CPG) support. In addition to "all-silyl" analogues, diisopropylsilyl phosphonate hybrids (60–80% yields based on maximum loading) have also been synthesized and their binding to complementary DNA strands was investigated. By determining the melting temperature of the duplex strands, which depend on the chain length and degree of substitution, values have been obtained ranging from 2 to 5 °C lower than those of the native DNA duplex.



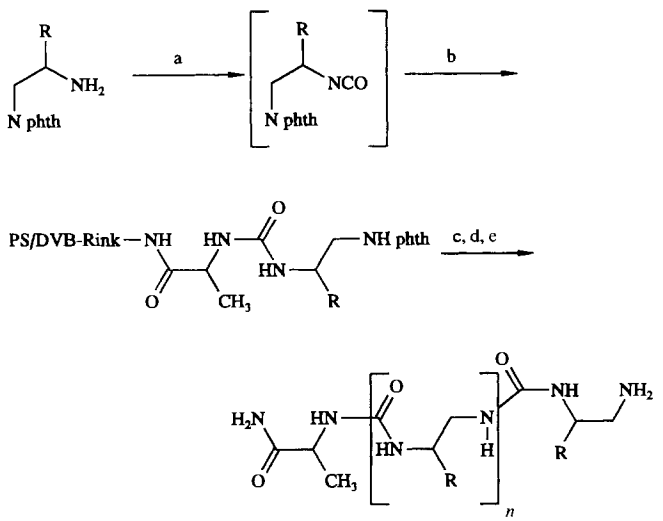
Scheme 40. Synthesis of peptide nucleic acids (PNAs) [153]. a) $BrCH_2CO_2Me$, K_2CO_3; b) NaOH/H_2O, 100 °C; c) PfpOH, DCC, DMF; d) 1. H_2N-Orn(Boc)-OH; 2. PfpOH, DCC, DMF; e) coupling to the amide resin, DMF/CH_2Cl_2; f) TFA; g) repetitive monomer coupling; h) HF. Ⓑ-H = thymine; B^n, B^{n+1} = nucleobases.



Scheme 41. Synthesis of the Si-bridged oligonucleotide analogues [154]. a) Imidazole; b) Ac_2O, *N*-methylimidazole; c) 3% trichloroacetic acid; d) repetitive monomer coupling; e) cleavage from the support. Ⓑ = nucleobase.

4.4. Oligoureas

Enzyme inhibitors[155] often contain a urea functional group as an important structural element. Recently Burgess et al.[156] reported the possibility of preparing oligoureas by solid-phase synthesis (Scheme 42). The starting point for their synthesis is



Scheme 42. Solid-phase synthesis of oligoureas [156]. a) 0.33 equiv $(Cl_3CO)_2CO$, Et_3N, CH_2Cl_2; b) PS/DVB-Rink-Ala-NH_2, CH_2Cl_2; c) 60% hydrazine hydrate, DMF, 15 h, 25 °C; d) repeated monomer coupling and protecting group removal; e) cleavage from the resin with TFA. R = H, Me, Ph.

the preparation of a phthaloyl-protected diamine. This monomer was prepared in solution from a Boc-protected amino acid, which was reduced and reacted with phthalimide under the conditions of the Mitsunobu reaction. This diamine was treated with triphosgene (bis(trichloromethyl)carbonate) to give a reactive isocyanate, which can be reacted with amino- or amino acid functionalized polymer supports. After hydrazinolysis (cleavage of the phthaloyl protecting group), the free amino group can be used for repetitive reaction steps. This solid-phase method was used to prepare oligoureas on a preparative scale. The overall yield of a tetrameric test substance was 46%, corresponding to an average coupling yield of 86%. This synthetic route is suitable for preparing not only oligoureas but also peptidomimetics, owing to the use of the hydrazine-labile phthaloyl protecting group.

5. Outlook

In solid-phase synthesis a high excess of reagents can be used without the associated problems of solution-phase organic chemistry. In addition to the possibility of obtaining higher yields, solid-phase organic synthesis has the advantage of facilitating complete automation of all the reaction steps as well as analytical monitoring. The required instrumentation for the automated synthesis of biopolymers has been nearly perfected in recent years. Excess reagents and all soluble by-products can be removed by washing the resin. The examples mentioned in this article demonstrate that almost all organic reactions can be conducted with solid-phase procedures. However, intensive optimization and special adaptation will be required to achieve methods as efficient as those currently in use in biopolymer synthesis.

The methods required for combinatorial chemistry cannot be developed with the equipment available to organic chemists today; instead new PC-controlled robots and reactors are necessary for the simultaneous and parallel syntheses of great numbers of compounds on the 100-mg scale. Therefore, future chemistry research laboratories may in part resemble the present-day assay laboratories for biological screening. Three-neck flasks, reflux condensers, filters, and distillation apparatus will be replaced by minireactors containing a large number of reaction vessels and sensors with fully automated devices for adding and removing reagents. Present investigations focus on new techniques for rapid heating with microwaves as well as on simultaneous and efficient workup procedures for the products of multiple synthesis.

Even though many small companies have been founded with the goal of synthesizing extensive compound libraries for pharmaceutical screening, it is essential that the "combinatorial chemist" systematically optimizes reactions for the simultaneous preparation of single compounds, since as always the problems of realizing extensive compound libraries lie in the experimental details.

In the case of biopolymer libraries and their analogues, as well as the low molecular weight products of combinatorial chemistry, interest will be focused on the free compounds and the strategies without encoding procedures. Practical implementation of label and tagging concepts in libraries already contaminated with by-products cannot be realized easily. In any case, with these libraries the desired and theoretically possible simplification in the discovery of biologically active products is not possible. Concepts relying on directly linking labels to the ligands under investigation have especially little prospect for general application.

Great successes in biological basic research as well as in medical diagnostics and therapy have become possible due to progress made in the multiple solid-phase synthesis of peptides and DNA. Therefore, it can be assumed with certainty that future developments in solid-phase organic chemistry will be revolutionary not only for chemical laboratories but also for the related sciences. The pharmaceutical industry is intensively involved in developing these new techniques. But the universities must also be prepared to train and familiarize students with these new tools.

What exactly are the limits of solid-phase organic chemistry, and in which direction might combinatorial chemistry develop in the coming years? Currently the expectations are very high for what can be achieved by combinatorial chemistry; however, the future will show which of these are reasonable. In addition, the results of future screening programs should demonstrate the feasibility of using combinatorial chemistry, for example, in the search for novel lead compounds. Presently the automation of peptide and nucleic acid synthesis is possible; however, the technical aspects of combinatorial chemistry are still comparatively primitive and fully functioning automatic synthesizers are not commercially available. The future of automation offers two alternatives: either known chemistry must be adapted to suit present technology or the currently available synthesizers and other machines must be radically redesigned to suit new chemistries. Either way, a great deal of developmental work is still needed.

Combinatorial chemists are best advised not to invest great effort in areas where nature excels. It is pointless to synthesize proteins containing more than 100 amino acids when biotechnology can provide cleaner products faster and more economically. Nature is better than combinatorial chemistry for constructing and derivatizing complicated natural products. Several strategies combining the strengths of both approaches have been discussed and described with the terms "combinatorial biosynthesis"[157] and "biological diversity".

An expansion of the pool of natural products is possible if, for example, microorganisms are led to produce new variants of a siderophore[158] or an antibiotic through feeding with unnatural building blocks. These modest possibilities of "directed fermentation" lag far behind the enormous diversity, which, for example, is achievable by polyketide biosynthesis. Using different combinations of polyketide biosynthesis genes, unimaginable numbers of combinations can be achieved[159] for the production of new molecules.

Finally, it should be mentioned that the genetic manipulation of precursor structural genes can lead to the production of a vast array of variants and analogues of ribosomally synthesized polycyclic peptide antibiotics. Thus, several novel enzymes have been found which can effect, for example, dehydration, cyclization, epimerization, and oxidative decarboxylation in the post-translational modification of lantibiotics precursor proteins.[160] In contrast to phage libraries, biosynthesis systems of lantibiotics have been used to prepare numerous conformationally restricted soluble active peptides.

We sincerely thank all of our colleagues who helped and supported us during preparation of this review article: Prof. Austel (Thomae), Dr. C. Tsaklakidis and Dr. R. Heck (Boehringer Mannheim), Dr. R. Jack, Dr. K.-H. Wiesmüller, Priv.-Doz. J. W. Metzger, Dr. J. Jauch, A. Fischer, H. Eickhoff, M. Winter, T. Redemann, W. Haap, and S. Kapitza.

Copper—A "Modern" Bioelement

Wolfgang Kaim* and Jochen Rall

Copper is a bioessential element in biology with truly unique chemical characteristics in its two relevant oxidation states +I and +II. Significant progress has been made in recent years in the elucidation of the frequently surprising biochemistry of this trace element. Those advances were especially furthered through mutual stimulation involving results from biochemistry, molecular biology, and medicine on one hand and the synthesis as well as the structural and spectroscopic characterization of low molecular weight model complexes on the other. The most notable features of protein-bound active copper are its almost exclusive function in the metabolism of O_2 or N/O compounds (NO_2^-, N_2O) and its frequent association with oxidizing organic and inorganic radicals such as tyrosyl, semiquinones, superoxide, or nitrosyl. This unique biological role of copper can be rationalized given its chemical and assumed evolutionary background.

Keywords: bioinorganic chemistry · copper proteins · enzymes · oxygen metabolism · radicals

1. Introduction

Although the bioessential character of copper has been established since about 1925,[1] its biological relevance and prevalence was fully recognized only during the last two decades when the bioinorganic chemistry of this trace element developed rapidly.[2, 3] This remarkable progress was made possible, inter alia, through a growing body of information from trace element analysis,[4] protein crystallography,[5] spectroscopy,[6] and molecular biology.[7, 8] In addition, the popularity of "bioinorganic chemistry" as a new, rapidly burgeoning subfield of inorganic chemistry has stimulated a highly successful interaction between the chemistry of model complexes and metalloprotein biochemistry.[3]

A particularly outstanding example for the usefulness of this interaction is the reinterpretation (end-on → side-on[9]) for the mode of coordination for O_2 in the oxygen-transporting copper protein hemocyanin (Hc) from the hemolymph, the "blood" of certain molluscs and arthropods.[10] This reevaluation came about only *after* a corresponding model complex had been found and structurally identified (Fig. 1).[12] Conversely, the preliminary evidence[13] for an intermediate containing NO coordinated to Cu^I centers in nitrite reductase enzymes of denitrifying bacteria[14, 15] prompted the synthesis of the first such low molecular weight complex to be structurally and electronically characterized (Fig. 2).[16]

This article provides a selective review of the bioinorganic chemistry of copper, emphasizing chemically *and* biologically relevant results from very recent research. The admittedly subjective selection includes generally interesting topics as well as representative special examples of the productive interaction between biological, medical-pharmaceutical, and chemical research. Among the chemical aspects underscored are the unique properties of the copper(I) ion and the peculiar association of the evolutionary rather "modern" bioelement copper (see Section 3) with dioxygen and its metabolites as well as with organic radicals.

2. Structural Preferences and Reactivity of the Copper Oxidation States: A Survey

According to its position as the lightest homologue of group 11 in the periodic table, copper is a very special element: The elements of the neighboring group 12 form only divalent monoions with d^{10} configuration (the oxidation state III has not been unequivocally established for mercury[18a, b]), and the elements of neighboring group 10 also prefer the divalent state, here with d^8 configuration. The coordination chemistry of the heavier homologues of copper, namely silver and gold, is characterized by a preference for even-numbered d electron configurations, very low coordination numbers, "soft" ligand donor centers, and by often unphysiologically high redox potentials. The bioavailability of these two elements is extremely small because of their low abundance in the earth's crust and in sea water.

Copper is distinguished by redox potentials for the transitions Cu^{II}/Cu^I and Cu^I/Cu^0 that can lie close together. A com-

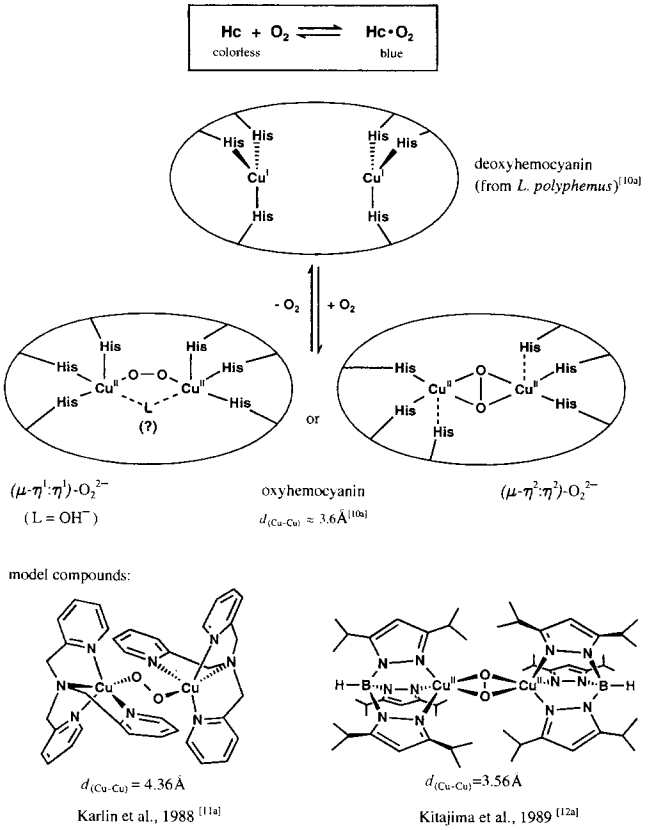

Fig. 1. Hemocyanin (Hc), a class of complex dioxygen transport proteins of arthropods (for example, crustaceans, spiders) or molluscs (for example, squid), contains two cooperatively interacting copper centers per subunit. These change between the colorless deoxy state [Cu^{I}–Cu^{I}] and the blue oxy form [Cu^{II}-O_2^{2-}-Cu^{II}] with antiferromagnetically coupled d^9 metal centers [9,10]. For some time, a μ-η^1:η^1 end-on bridging arrangement was assumed for reversibly coordinated O_2^{2-} ions in the deoxy form, an arrangement supported by model complexes [11]. Only in 1989 was a first synthetic dinuclear complex characterized by Kitajima et al. with sterically demanding tris(3,5-dialkylpyrazolyl)borate ligands and doubly (μ-η^2:η^2) side-on coordinated peroxide [12]. Spectroscopic studies [9] as well as crystal structure analyses [10] have meanwhile established the rather unusual μ-η^2:η^2 alternative coordination mode for oxyhemocyanin.

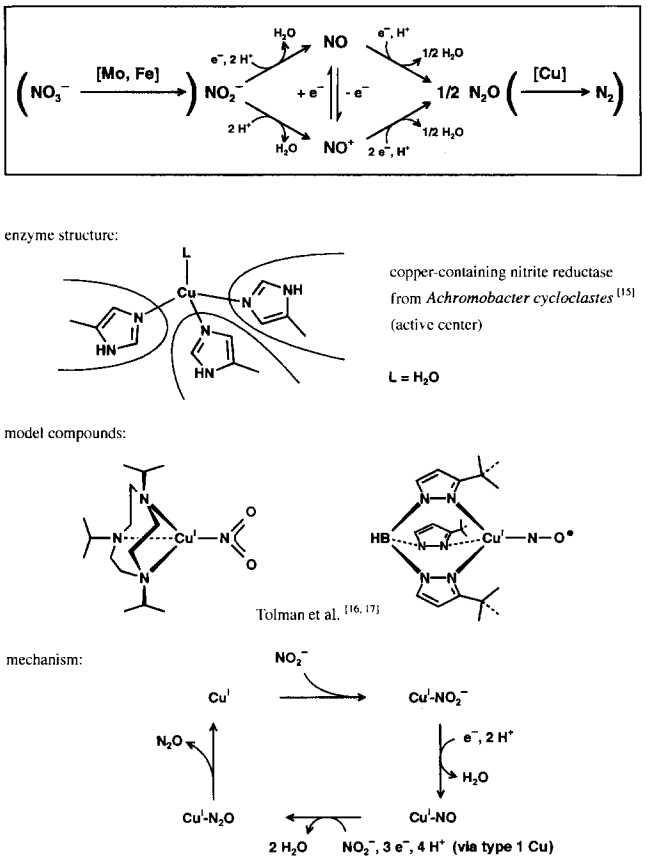

Fig. 2. Mechanistic studies on the transformation of the nitrite ion into dinitrogenoxide through nitrite reductase enzymes of denitrifying organisms in 1989 suggested the existence of a Cu^{I}–nitrosyl intermediate [13a]. This hypothesis [13] prompted the synthesis and structural characterization of several nitrite [17] as well as the first stable mononuclear and dinuclear nitrosylcopper(I) compounds, thus closing a gap in the otherwise well-established chemistry of metal nitrosyl complexes [16]. The catalytically active centers of copper-dependent nitrite reductase were identified as nearly tetrahedral ions even in the Cu^{II} form; they are each coordinated by three histidine ligands from three different protein subunits [15].

W. Kaim J. Rall

Wolfgang Kaim was born in 1951 and studied chemistry at the Universities in Frankfurt am Main and Konstanz. After he had obtained his doctorate under the supervision of Hans Bock in the field of main group organoelement radical chemistry in 1978, he spent the following year working with F. A. Cotton at Texas A & M University on metal–metal multiple bonds. In 1982 he submitted his Habilitation Thesis on the "Coordination Chemistry of Reduced N-Heterocycles" and was awarded a Winnacker Scholarship. In 1987 he moved to the University of Stuttgart as Full Professor of Inorganic Chemistry. Together with B. Schwederski he is the author of a textbook on "Bioinorganic Chemistry" (Literature Award 1993 of the Fonds der Chemischen Industrie). The leitmotiv of his work, as documented in more than 250 publications, is the activation of one or more electrons in novel "complex" compounds: organic and organometallic radical species, mono- and oligonuclear transition metal complexes, and charge-transfer excited states.

Jochen Rall was born in 1966 and studied chemistry at the University of Stuttgart and at the University of Cincinnati. In 1990 he completed his M. Sc. with E. Deutsch, and in 1993 obtained his Diplom in Stuttgart. His graduate studies since 1993 in the research group of W. Kaim have centered around biorelevant paramagnetic copper complexes.

parison of the Cu^{II}/Cu^{I} redox potentials of copper proteins with those of other biologically relevant couples, in particular the Fe^{III}/Fe^{II} redox pairs in functionally analogous,[3a, 19] iron proteins, reveals mostly higher potentials for the copper systems.

Cu^0 refers to metallic copper, which is now produced worldwide to a significant extent by a "geo-biotechnological process", that is, by microbial leaching[20] (Fig. 3). In contrast, neutral

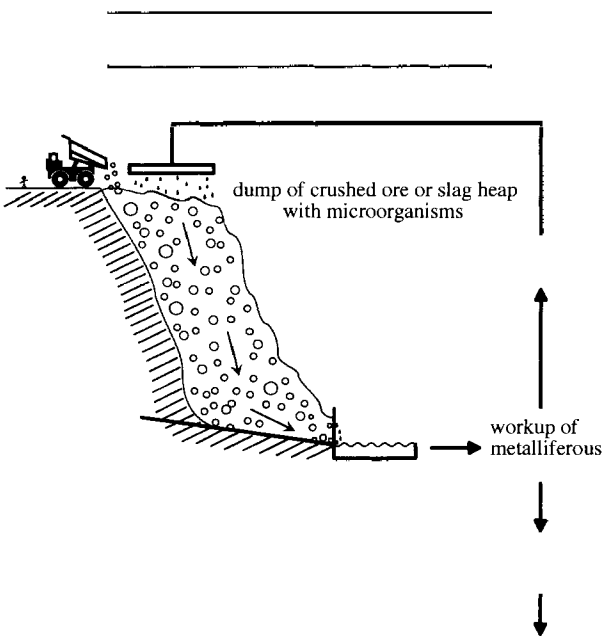

Fig. 3. The microbial leaching Cu^0 recovery process. More than one fourth of the annual world copper production is now estimated to come from microbial leaching (bacterial leaching, biomining), one of the most substantial biotechnological processes in terms of production volume and value ($>10^9$ US$) [20]. The acid-tolerant microorganism *Thiobacillus ferrooxidans* slowly dissolves insoluble sulfidic ores by oxidizing sulfide to sulfate and simultaneously assimilating CO_2. An environmentally friendlier and less expensive metal production is thus possible, not only of copper but also of included metals such as gold [20a].

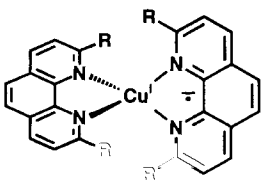
complexes such as $[Cu(phen)_2]$, which are often referred to as Cu^0 compounds,[21] have recently been identified as Cu^I complexes with one radical anion ligand[22] by using the 1,10-phenanthroline derivative **1** with R = phenyl. The nitrosyl copper complexes mentioned above (Fig. 2) have similarly been characterized as Cu^I–NO· systems by EPR spectroscopy; that is, contributions from formulations like Cu^0–NO^+ or Cu^{II}–NO^- play a subordinate role in the description of these compounds.[16b]



1

As a result of high redox potentials and a propensity for one-electron transfer reactions, organocopper compounds are quite reactive[23] and not biologically relevant—in contrast to organometallic compounds of nickel (methyl-F430 complex[24a])

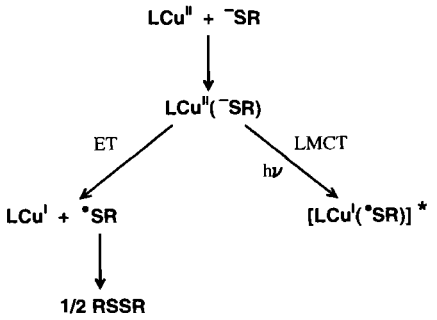
this unique coordination chemistry of copper are the almost "noble" character of the metal, the intermediate stability and reactivity of the d^{10} configuration in Cu^I,[25] and the comparatively small radius of the Cu^{2+} ion, which contributes to the high energy of hydration and thus to the stability of $Cu^{2+}(aq)$ over $Cu^+(aq)$. The character of the metal–ligand interaction in Cu^{II} complexes is frequently but not always ionic (see Section 7) and favors the stabilization of this state through pronounced Jahn–Teller distortion. Different extents of axial elongation of the octahedron can thus produce square-bipyramidal, square-pyramidal, or square-planar coordination geometries. Deviations from these energy minimum structures, which are necessary for rapid oxidation state changes Cu^{II}/Cu^{I} (and thus for efficient electron transfer), may require specific, strained conformations ("entatic state concept"[26a, b]) through elaborate ligand architecture, either in proteins (type 1 copper centers in "blue" copper proteins, see Section 7[26]) or in low molecular weight model compounds containing specially designed ligands.[27]

Contrary to an earlier[28] suggestion that was propagated in textbooks[18c] (see Section 9.3.2), the Cu^{III} state is *not* a biologically relevant oxidation state; the redox potentials for the transition Cu^{III}/Cu^{II} are generally very high. Instead, there may be one-electron oxidation of cofactors or protein components that can cooperate with the copper(II) centers.[29, 30] Authentic, stable Cu^{III} compounds exist only with very strong donor ligands such as O^{2-}, F^-, or R_2N^-,[31] the d^8 configuration favoring square-planar or square-pyramidal arrangements. In this context the layered structures of high-temperature superconductors, which invariably contain Cu^{III}/Cu^{II} mixed-valent centers,[32] have to be mentioned.

The prototypical Jahn–Teller ion Cu^{2+} is characterized not only by marked axial distortion in its complexes (the most typical result is a square-pyramidal coordination), but also by a strong preference for ligands with nitrogen donor centers. This pertains to complex stabilities (equilibrium aspect) and to the often inert N–Cu^{II} bonds that render a special fixation in biological systems, for example through tetrapyrrole macrocycles, unnecessary. Copper(II) centers form weaker, more labile bonds with normal oxygen donor ligands (that do not undergo back-bonding) or with neutral sulfur and phosphorus donor centers.

Chemically and spectroscopically interesting[6, 33] as well as biologically relevant[26] is the combination of copper(II) ions with potentially reducing thiolate ligands, such as the cysteinate anion. In that case, the usual electron transfer (ET) reaction to Cu^I and diorganodisulfide-forming thiyl radicals can be avoided through appropriate coordination arrangements (Scheme 1).[33a] However, exceptionally intense ligand-to-metal charge transfer (LMCT) absorptions are then observed in the visible spectral region ("blue" copper proteins, see Section 7), which indicate that charge transfer does occur, albeit in the LMCT excited state.[6]

The coordination number and geometry of copper(I) is rather flexible, not least because it has a d^{10} configuration and therefore exhibits no ligand field effects. The usually cited values for the preferred coordination number range from two to four with an optimum between three and four.[34] The metalla-supramolecular chemistry[35, 36] continues to make extensive



Scheme 1. Two possible reactions for thiolatocopper(II) complexes.

use of the tendency of copper(I) to bind organic ligands[37–42] quite strongly yet in a structurally flexible way, taking advantage of the low charge (that is, little polarization) and the high bond stability, in particular towards ligands with nitrogen donor centers (Fig. 4). The latter feature distinguishes Cu^{+} from other monovalent metal ions such as the alkali metal ions or Tl^{+}; Ag^{I} and Au^{I} display an intricate redox behavior and

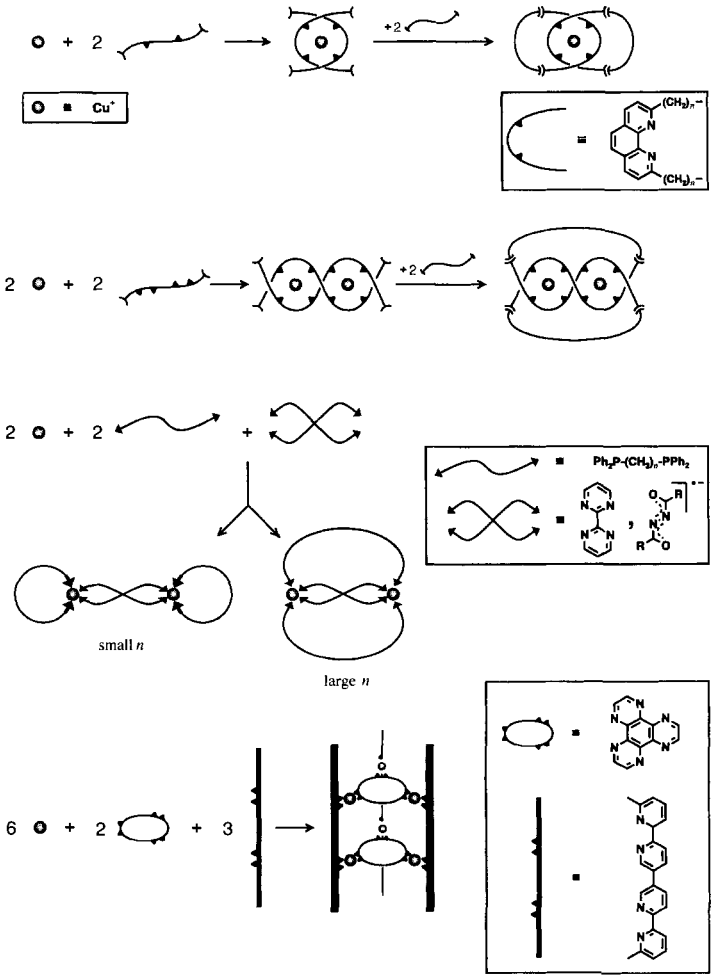


Fig. 4. The suitability of Cu^{+} ions as template for self-assembly processes in supramolecular chemistry is now documented by numerous examples of topologically interesting arrangements in coordination compounds. From top to bottom: catenates [37], molecular knots [38], inverse cryptates [39], molecular tubes [40]. Further examples not included in this figure are (double) helices [41], molecular grids [42a], rotaxanes [42a], or hinged triple-decker sandwiches [34c,d,39b].

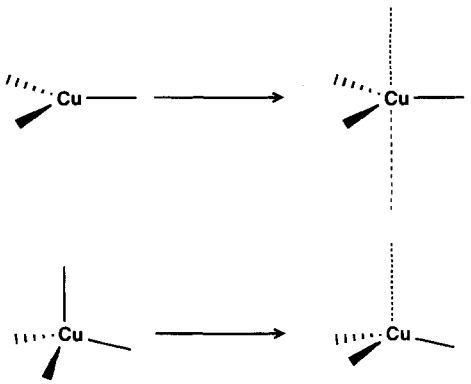
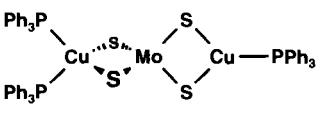
show less d_{π} back-donation than Cu^{I} to unsaturated ligands.[25,43]

In agreement with its position next to Ag^{I} (with preferred coordination number 2) and Zn^{II} (with preferred coordination number 4), Cu^{I} favors a coordination number 3 with trigonal-planar geometry.[34] However, this particular arrangement is often associated with coordinative unsaturation,[34b] which, indeed, is frequently complemented in Cu^{I} compounds through formation of weak axial interactions (Scheme 2, top). Some low molecular weight complexes and the type 1 copper centers in the reduced *and* oxidized state of blue copper proteins illustrate this particular situation[6,26,44] (see Section 7).



Scheme 2. Extension of the coordination number of three- and fourfold coordinated Cu^{I} centers.

On the other hand, small perturbations of tetracoordinate Cu^{I} may suffice to weaken the bond to one of the four donor atoms, resulting in a change of coordination geometry from approximately tetrahedral to trigonal pyramidal (Scheme 2, see also Scheme 5).[34c,d,39] The ambivalence between coordination number 3 and 4 of Cu^{I} compounds is most evident from the observation that apparently equivalent copper centers of the same molecule may show threefold as well as fourfold coordination (**2**).[45]



2

The oxidation state I can be stabilized in copper compounds by using "soft" coordinating atoms as in R_3P,[46a–c] R_2S,[46d] or RS^{-} ligands;[47] unsaturated nitrogen donor ligands are also well tolerated.

An outstanding feature of the copper(I) state is its ability to bind and reductively activate molecular oxygen ($^{3}O_2$) despite the closed 3d shell of Cu^{I}. Only three kinds of O_2-activating sites are known in biology; in addition to Cu^{I} centers these include high-spin iron(II) center with four unpaired 3d electrons and the formally antiaromatic 1,5-dihydroflavin system.[48] The affinity of copper(I) for the triplet molecule $^{3}O_2$[49] presumably relies on contributions from unoccupied 4s or 4p orbitals[6c] and thus possible 3d/4s or 3d/4p orbital mixing. Additional activation may result from metal–ligand or metal–metal interactions.[50]

The comparatively open and variable coordination sphere of both the Cu^{I} and Cu^{II} states and their readily accessible redox

transition in the positive potential region render copper a widely used metal in non-organometallic redox catalysis, including organic synthesis and industrial processes;[12c, 51] the majority of the biological functions of this trace element also involves oxidase or oxygenase activity (Fig. 5).

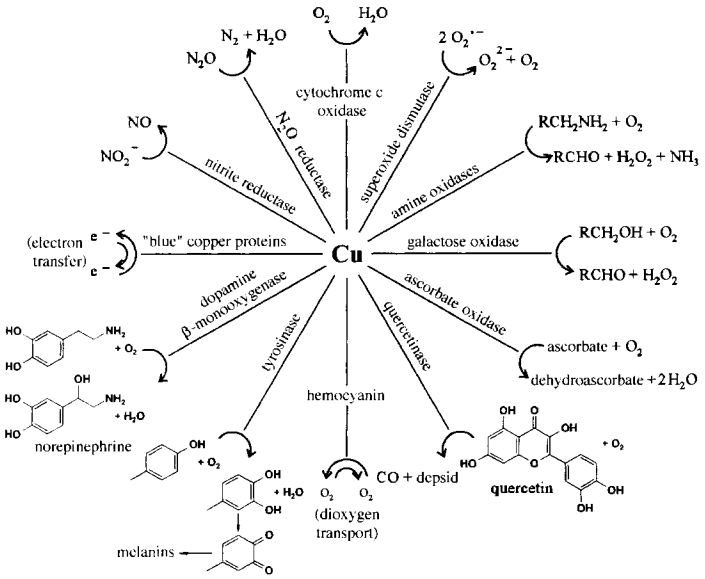


Fig. 5. The essential metabolic functions of copper-containing proteins (mostly enzymes) are summarized in the "biocopper dial". The close association of this bioelement with dioxygen and its secondary products is obvious. Not included are transport, regulatory, and storage proteins for copper.

3. Copper—a "Modern" Bioelement?

In many regards, copper can be designated as a modern bioelement. First of all, the essential trace element character of copper has been known for quite some time, yet the detailed structural background for many of its biological functions has long eluded determination. On a molecular level, such information has become available only in the last decade, allowing for the correction or specification of numerous (textbook) hypotheses. These include the binding of dioxygen in the O_2-transporting system hemocyanin[10] (Fig. 1), the role of copper-containing enzymes in the nitrogen cycle (denitrification)[13-15, 52] (Fig. 2), the precise copper content of the essential respiratory enzyme cytochrome c oxidase[4] (see Fig. 7), the nature of the quinonoid cofactor of copper-containing amine oxidases[53] (see Fig. 9), the oxidation states of the metal in galactose oxidase[29, 30] (see Fig. 10), and the trinuclear arrangement of the catalytic center in "blue oxidases"[5] (see Fig. 8).

However, as R. J. P. Williams has pointed out,[3c, 54] copper can also be regarded as a newcomer among the bioelements[19] under the aspect of the evolution of the biosphere and—as a consequence—of the atmosphere. Due to the high potential necessary for oxidation to the (+ II) state, copper was bioavailable only to a very small extent[55a, b] prior to the biogenic (photosynthetic) generation of an oxidizing environment; in the typical mineral form of halides or chalcogenides, Cu^I compounds are insoluble at pH 7. Only the massive production of oxidation equivalents (and, finally, O_2) by photosynthetic organisms about 3×10^9 years ago[55c] enabled significant oxidation of Cu^I to soluble Cu^{II}, with two important consequences:

- Through oxidation from Fe^{II} to Fe^{III}, the functionally competing iron became *less* bioavailable (iron as limiting trace element in today's seawater[56]), and required bioenergetically costly strategies like complexation and/or intermediate reduction to Fe^{II}.
- Secondly, the presence of an oxidizing atmosphere created the need for a catalytically redox-active metal with potentials between 0.0 and 0.8 V; the $Cu^{II/I}$ redox pair is thus almost ideally suited for catalysis of the typically inhibited reactions of O_2, as evident from many organic-synthetic and industrial reactions.[12c, 51]

It comes as no surprise, therefore, that copper enzymes participate particularly in reactions involving dioxygen (transport, utilization by oxidases and oxygenases) as well as in the degradation of unwanted side products of the O_2 metabolism such as $O_2^{\bullet-}$ radicals (Fig. 5). Similarly, copper enzymes are active within the nitrogen cycle by catalyzing transformations of certain N/O compounds such as NO_2^-, NO', or N_2O, which unavoidably occur in an O_2-containing atmosphere; iron-containing systems also participate in these reactions.[13b, 14, 52] The coexistence of copper compounds and O_2 is also related to the frequent association of copper with biogenic or synthetic radicals, as has been established in many cases;[16b, 29, 30, 39a, 46, 57-59] unusual cooperativities in enzymatic reactions (Figs. 9 and 10)[29, 30, 57] may result from this kind of association.

For an efficient catalysis of more complex redox processes, the accumulation and storage of several single electrons and their controlled release as "multielectron package" at a catalytic center[60] often require the coupling of two or more redox centers. Examples from the field of biological copper chemistry are the heterodimeric center Cu_B–heme a_3 of the terminal respiratory enzyme cytochrome c oxidase, which reduces O_2 to H_2O (see Section 9.3.3),[61, 62] or the trimeric cluster arrangement in "blue oxidases" like ascorbate oxidase or laccase (see Section 9.3.1).[4, 63] ("Blue oxidases" contain a "blue" type 1 copper center with electron transfer function in addition to the catalytic metal cluster.) "Non-blue oxidases" use a different strategy, namely the functional coupling of a single metal center (Cu^I or Cu^{II}) with an organic redox system such as a quinone (amine oxidases, see Figure 9),[57, 64] a modified tyrosyl radical (galactose oxidase, see Fig. 10),[29, 30] or possibly pterins (phenylalanine hydroxylase from *Chromobacterium violaceum*).[65] Such strategies of coupling *one* redox metal center with a redox active ligand are known from the heme system ($Fe^{II}/Fe^{III}/Fe^{IV}$ + porphinato ligand) and are postulated for the cofactor complex in pterin-containing molybdenum or tungsten enzymes.[3a, b, 66]

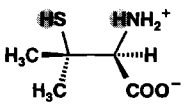
The rather "modern" status of biological copper (in evolutionary terms) relative to iron, cobalt, or nickel[3c, 54] may be related to the well-known toxicity of the metal for "lower" organisms such as algae or some bacteria[67] and with its predominant location in the extracellular space[54b] (exception: Cu,Zn superoxide dismutase). Another such indication may be seen in the late and only gradual stabilization of the copper metabolism in newborn infants, which can give rise to corresponding dysfunctions.[67a]

4. Medical and Toxicological Aspects

Although copper is definitely an essential element for many life processes in higher organisms (after iron, copper is the second most abundant "genuine" transition metal in the human organism[3a, b]), it is also a toxic (heavy) metal with low legal concentration limits, for example, for drinking water or sewage sludge.[3a, b, 67] The tolerance of an adult human being for, for instance, copper sulfate is surprisingly high,[67a] yet the "therapeutical width" between the concentrations causing deficiency symptoms and those responsible for poisoning is rather small and also quite variable, especially during growth periods or for lower organisms. Infants are particularly vulnerable, and the accumulation of copper in trace concentrations from cooking utensils or acidic (pH < 6) drinking water led through copper-containing pipes can cause "Indian" or "German Childhood Cirrhosis".[67a]

Best known among the environmentally caused disorders of copper metabolism is the molybdenum/copper antagonism in highly food-specific ruminants.[68] It appears to result from a complexation of Cu^{I} by $MoO_nS_{4-n}^{2-}$ as formed under reducing conditions in the stomach of ruminants; "molybdenosis" thus implicates a secondary copper deficiency. Not only are thiomolybdates readily soluble in water, they are also excellent chelating agents for metal centers in low oxidation states such as copper(I)[69] (**2**). The small therapeutic width of copper also leads to copper deficiency symptoms if other competing (Fe, Zn) or antagonistic (S, Se) elements are present.

In view of the increasingly realistic expectations for a therapy aimed at the biological cause of genetic disorders, two hereditary diseases concerning the copper metabolism, Wilson's disease and Menke's syndrome, have attracted special attention.[67] Both diseases occur with a probability of about 1 case per 100 000 births. Wilson's disease involves a pathological accumulation of copper in the liver and brain, and is lethal if left untreated.[67a, c, d] Consequently, the therapy of this disorder consists of the administration of copper-specific chelating agents, in particular D-penicillamine (**3**) or—in case of the not uncommon intolerance to **3**—of triethylenetetramine (**4**) or derivatives.[67a, c] Zinc compounds can stimulate an increased formation of the heavy metal storage protein, metallothionein (see Section 6), and thus also counteract the copper enrichment effects of Wilson's disease.



D-penicillamine

(HS : replaceable by Cu^{2+})

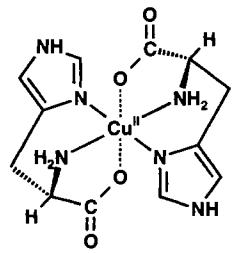
3

triethylenetetramine

4

D-Penicillamine is also indicated in the treatment of scleroderma, which involves the overproduction of collagen and an embrittlement of the skin. This disorder demonstrates the importance of copper for the controlled synthesis of connective tissue (see Section 9.3.2), as in Menke's syndrome.

In contrast to Wilson's disease, Menke's syndrome is caused by a hereditary dysfunction of the intracellular copper transport and thus insufficient copper storage.[7] If the disorder is not treated very early by continuously supplementing the essential element, for example as "copper histidine" (assumed structure (**5**)), a rapid and eventually lethal degradation occurs in the central nervous system.[70] A characteristic symptom of this disease is the occurrence of "kinky" hair, illustrating again the necessity for copper-containing proteins in the biosynthesis of structural proteins (see Section 9.3.2). Recently, the gene responsible for the disease was identified and isolated; it is situated on the X chromosome.[7] The produced membrane protein is a typical transport ATPase with several copper binding motifs (Cys-X-X-Cys) as they are similarly known from heavy metal regulation and storage proteins of the metallothionein type[71, 72] (Fig. 6).



5

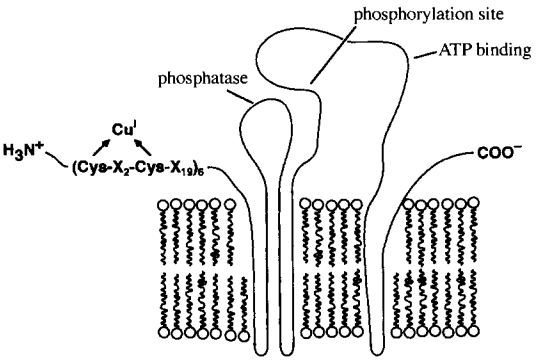


Fig. 6. Based on studies with cloned genetic material, the inadequate intracellular copper transport by an ATPase membrane protein with a cysteine-rich section [7] was found to be responsible for Menke's "kinky hair" syndrome of infants, a lethal disease if untreated. The cysteine-rich sequences are reminiscent of metal-binding sites in regulatory proteins such as CUP2 [78] and in metallothionein (MT) storage proteins as found in yeast cells. Unlike the better known mammalian metallothioneins, the yeast MT proteins are characterized by a special affinity for copper [71]. The genetic defect responsible for Menke's syndrome was localized on the X chromosome [7]. If the disease is recognized early, the subcutaneous administration of Cu^{II}/histidine preparations may contribute to a satisfactory development [70].

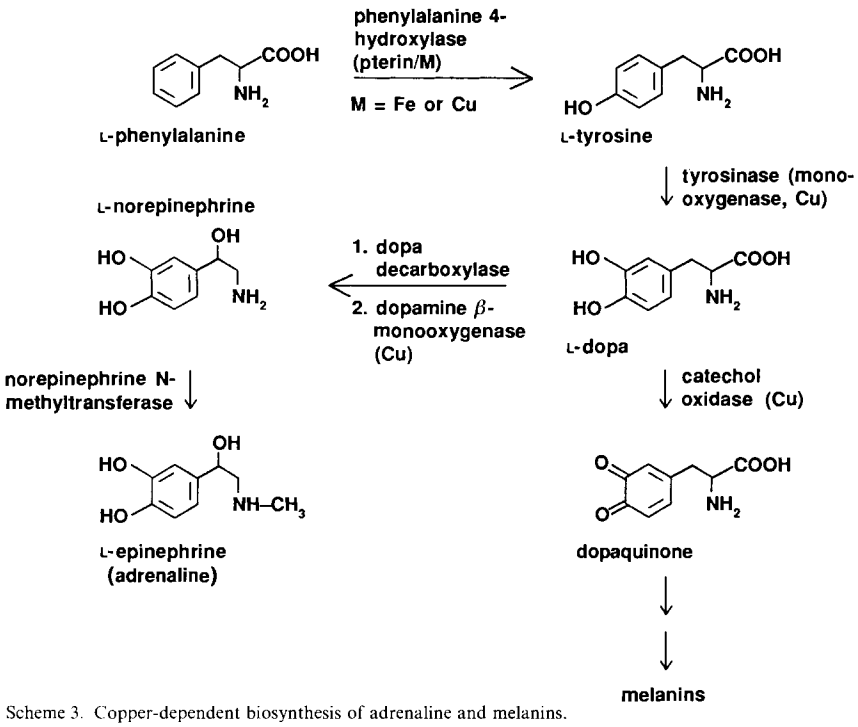
Genetic defects causing changes in the amino acid sequence of the antioxidant enzyme Cu,Zn superoxide dismutase (SOD) (see Section 9.4 and Fig. 11) are responsible for the familial form of amyotrophic lateral sclerosis (ALS).[8] ALS is a progressive, irreversibly neurodegenerative disease of the motoric system, which became widely known as the cause of paralysis of prominent persons such as the physicist Stephen Hawking.[8c] In the United States ALS is also known as "Lou Gehrig's disease", named after one of the most famous baseball players, the "iron horse" (first baseman of the New York Yankees), who died of this disease in 1941 at the age of 38.

In 1993 two research teams[8a, b] were able to show that the likely causes for familial ALS are defects in copper-containing SOD, which affect the protein structure and thus diminish the required optimal functioning of this detoxification enzyme (see Section 9.4).

Established symptoms of chronic copper deficiency include arterial weakness and enlargement of the heart; according to

recent research results these symptoms are caused by a decreased synthesis of catecholamine neurotransmitters.[73, 74] The biosynthesis of L-epinephrine (adrenaline), for example, requires a pterin-dependent phenylalanine hydroxylase (with Fe or Cu as metal component)[65] as well as the copper-dependent enzymes dopamine β-monooxygenase[65d, 75] and tyrosinase[76] (Scheme 3). Reduced production of neurotransmitters leads to a diminished formation of "heat shock" proteins (HSPs), which serve in the management of cellular stress.[74]



Scheme 3. Copper-dependent biosynthesis of adrenaline and melanins.

5. Old and New Types: The Classification of Biological Copper Centers

The standard division of biologically active copper centers from proteins into "type 1, type 2, and type 3 copper"[3, 6a, b] was initially necessary to correlate function with analytical features (optical absorption, EPR, magnetism). By now, these correlations are largely understood and refined because of increasingly available structural details. On the other hand, several additional biological copper centers have been found that do not fit the conventional scheme. Table 1 summarizes the characteristics of these new centers as well as those of the classical types.

The biological repertoire of copper centers is possibly not exhausted with the representative structures listed in Table 1; future structure determinations may well lead to corrections or to the discovery of further alternatives. Remarkable from the aspect of coordination chemistry is the occurrence of all forms of aggregation, starting from mononuclear species (type 1, and, in part, type 2) through homodinuclear (type 3 or Cu_A), heterodinuclear (Cu_B/Fe in cytochrome c oxidase, Cu/Zn in Cu,Zn superoxide dismutase) and trinuclear centers (for example in ascorbate oxidase), to apparently cysteinate-bridged clusters (6–8 Cu centers[71, 80]) in copper-containing metallothioneins of yeast.

Table 1. Important properties of copper centers in various biomolecules.

	Type 1	Type 2	Type 3	Type (2+3) trimer	Cu_A	MT-Cu
aggregation state	mononuclear (even in oligocopper proteins)	mononuclear	dinuclear	trinuclear	dinuclear	mononuclear to multinuclear (clusters)
specificity, biological function	electron transfer	catalysis and redox reactivity	O_2 activation for transport and oxygenation	O_2 activation for oxidase function	electron transfer	regulation, storage, and transport form
occurrence (examples)	"blue" copper proteins, e.g. plastocyanin, azurin; laccase	amine oxidases, galactose oxidase superoxide dismutase, cytochrome c oxidase (Cu_B)	hemocyanin, tyrosinase	ascorbate oxidase, laccase	N_2O reductase, cytochrome c oxidase	CUP2, metallothionein (MT), Cu transport ATPase (Fig. 6)
structural characteristics						
typical coordination number	3 (trigonal-planar), +1	4 or 5 (square-planar or -pyramidal)	Cu^I: 3 (trigonal-planar)	Cu^I: 3 (trigonal) Cu^{II}: 4	4	3 (trigonal-planar)
coordinated atoms	S^-(Cys$^-$), 2 N (His), +S(Met)	3 N(His), □	2 × 3 N(His); Cu^{II}:μ-η^2:η^2-O_2^{2-}	N(His), partly (O)OH^-	2 S^-(Cys$^-$), 2 N (His), S(Met) or O (peptide)	3 S^-(Cys$^-$)
spectroscopic characteristics of the oxidized or oxygenated form						
EPR	small $^{63}Cu/^{65}Cu$ hyperfine splitting ($A_\parallel$), low g factor ($g_\parallel$)	"normal" Cu^{II} EPR parameters	no signal (strong antiparallel spin–spin coupling)	"normal" Cu^{II} EPR parameters	very small Cu hyperfine splitting due to two equivalent Cu, low g factor	no oxidized form
light absorption	intense absorption in the visible, LMCT (Cys$^-$ → Cu^{2+})	no intense absorption, only "forbidden" ligand field transitions	intense absorptions; LMCT (O_2^{2-} → Cu^{2+})	intense absorptions; LMCT (O_2^{2-} → Cu^{2+})	absorption in the near infrared region (MMCT)	

□: free coordination site, special ligands (organic radicals), or adjacent metal centers (Zn, Fe).

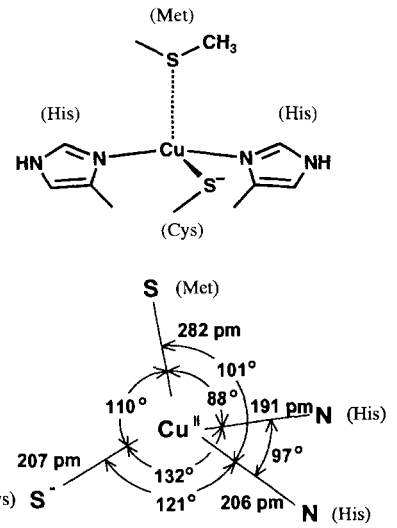
6. Regulation, Transport, and Storage of Copper in Biological Molecules

After resorption in the gastro-intestinal system (requirement about 2 mg per day)[67a] copper is bound by serum albumin, which contains M^{2+}-binding histidine residues.[77] Cysteine-rich metallothionein proteins,[71] which are responsible for homeostasis, transfer copper to ceruloplasmin, a large plasma protein[5a] that has six copper-binding sites and that can also function as ferroxidase by catalyzing the Fe^{III}/Fe^{II} transition.

The control of the copper metabolism requires a highly complex regulatory system, probably similar to that of the more thoroughly studied bioelement iron. A regulatory protein CUP2 (also termed ACE1)[78] is known, which contains several well-conserved cysteine residues. After uptake of several Cu^+ ions, specific DNA-binding of this regulatory protein causes the expression of copper-storing metallothionein. For the particularly good copper-binding metallothionein from the yeast *Saccharomyces cerevisiae*, clusters of six or eight copper(I) centers bridged by cysteinate residues are assumed.[71] Data from X-ray absorption studies (crystallographic data are not yet available) are in accord with a trigonal configuration at the copper(I) centers.[71] Just like numerous mononuclear and oligonuclear copper(I) complexes,[34c, d, 79] the Cu^I-metallothioneins of yeast can exhibit intense luminescence.[71, 80]

7. Type 1 Centers in Blue Copper Proteins: The Cu^I/Cu^{II} Structure Problem and the Quest for Electron Transfer Pathways

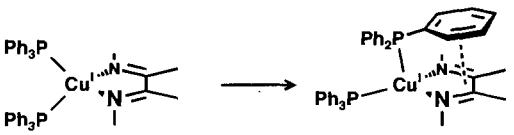
The unsymmetrical, but not accidental coordination arrangement (Scheme 4) at type 1 copper centers in blue copper proteins such as plastocyanin or azurin is well conserved according to protein crystallographic data[5a, 44, 81] and has played an important role for the understanding of the structural basis of protein and enzyme reactivity.[26]



Scheme 4. Coordination of type 1 copper centers in blue copper proteins. Top: general arrangement. Bottom: structural details for plastocyanin [81a].

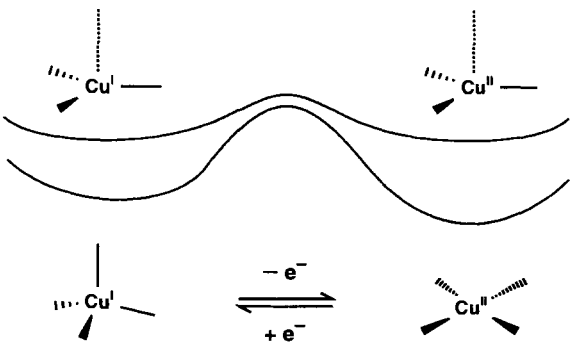
Especially for the Cu^{II} state, the large structural deviation from the energetically favored square-planar or square-pyramidal geometries has prompted the suggestion that the strain is "external", but enforced by the surrounding polypeptide. This strain implicates a higher potential energy at the start of the reaction, which in turn facilitates the approach to the transition state—in this case, of the Cu^{II}/Cu^I electron transfer reaction (see Scheme 6). The concepts of a "rack" mechanism (the protein as structure-enforcing framework[26c]) or of the "entatic state"[26a, b] of active proteins, in particular of enzymes, have been derived and refined to a substantial extent from attempts to understand the geometry of type 1 copper centers in blue copper proteins.

Detailed structural,[44, 81] kinetic,[82] and spectroscopic[6] studies of *both* copper oxidation states in blue copper proteins have shown that the two sulfur ligands, the π-electron-rich thiolate base of the cysteine anion and the thioether residue of methionine (a weak π-acceptor), contribute to the rapid, vectorial electron transfer at a relatively high potential. The typical coordination of type 1 copper centers is almost optimal for Cu^I, that is, an approximately trigonal-planar coordination by one cysteinate and two histidine residues with an additional long axial bond to methionine (Scheme 4), or glutamine in the case of stellacyanin.[81g] Similarly, weakly perturbed complexes of Cu^I with two N and two P donor ligands (Scheme 5) have a tendency towards trigonal-pyramidal coordination with one long bond to one of the (larger) donor atoms from the third period of the Periodic Table.[34c, d, 39b]



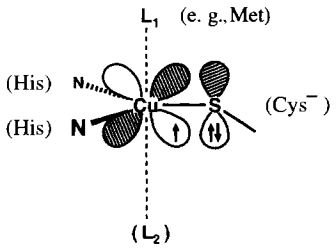
Scheme 5.

Not only does the protein enforce a structural distortion of higher energy; the π-acceptor ligand methionine also destabilizes the copper(II) state with the result that the Cu^{II}/Cu^I redox potentials of type 1 copper centers are rather more positive than those of complexes without such acceptor ligands. Because of this special, unsymmetrical geometry, the higher energy 3d orbitals are no longer degenerate; no reorganization energy (and time) is thus necessary to bring about Jahn–Teller distortion when Cu^I is oxidized to Cu^{II} (Scheme 6).[6c]



Scheme 6.

A strong π-interaction (Scheme 7) exists in the copper(II) state between the electron-deficient metal ion and the cysteinate anion. The short Cu–S bond has significantly covalent character, as shown by EPR spectroscopy (metal-to-ligand spin delocalization);[6, 83] the typical intense color of these blue copper proteins primarily results from ligand-to-metal charge transfer (LMCT) transitions (Scheme 1).[6]

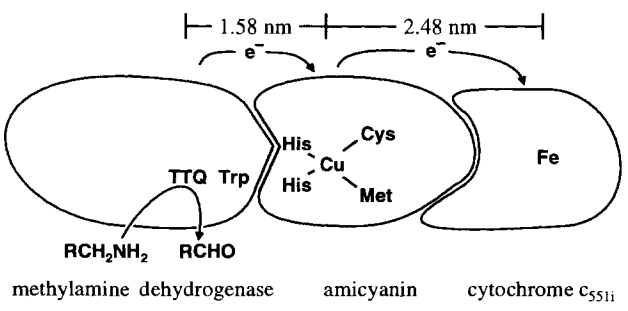


Scheme 7.

The covalency of the copper(II)–cysteinate bond was also confirmed by ENDOR measurements (ENDOR: *e*lectron *n*uclear *d*ouble *r*esonance[84]), which reveal that the unpaired electron density is distributed over the cysteinate sulfur atom and the neighboring β-methylene group to a considerable extent.[83] More sophisticated details of the coordination, such as the less pyramidalized copper (Scheme 4) in azurin, can now be correlated[81c, 82a] with different redox potentials and EPR properties (rhombic or axial *g* anisotropy, respectively). Specifically tailored ligands such as the tris(alkylpyrazolyl)borates (Figs. 1,2), which have become prominent in attempts to model biological copper sites, can be used to mimic the spectroscopic properties of type 1 copper centers while suppressing undesired side reactions such as disulfide formation (Scheme 1).[33]

Since the properties of isolated blue copper proteins are now well understood, the interest has shifted to their interaction with physiological reaction partners. Plastocyanin,[81a, b] for example, transfers electrons from cytochrome f in the photosynthetic membrane to photooxidized chlorophyll P700 of the photosystem I in green plants, whereas amicyanin[81d] is responsible for the specific transfer of electrons from the oxidoreductase enzyme methylamine dehydrogenase (MADH), a quinoprotein,[85] to cytochrome c. Although the actual dynamic situation may be quite complex, crystal structures of ternary protein complexes such as MADH/amicyanin/cytochrome c_{551i}[86] illustrate the crucial role of copper-containing electron transfer proteins (Scheme 8).

According to their function (see Scheme 8), simple blue copper proteins such as plastocyanin contain two preferred electron transfer routes,[82] a short pathway to the electron donor through a rather hydrophobic region and a longer pathway to the acceptor, ending at a polar group. With programs[87] for the calculation of matrix elements of the electronic coupling through π systems, lone pairs, or the σ framework, preferred electron pathways may be assessed and verified through site-directed mutagenesis experiments.[88]



Scheme 8. Amicyanin mediates the electron transfer from methylamine dehydrogenase to cyctochrome c_{551i} (TTQ = tryptophan tryptophylquinone) [85,86].

8. The Dinuclear Cu_A Centers in Cytochrome c Oxidase and N_2O Reductase: Biological Copper in the Oxidation State +1.5

Cytochrome c oxidase ("COX"), the *Atmungsferment* (respiratory enzyme) of Otto Warburg, serves as the terminal "complex IV" of the respiratory chain, yet its metal content has remained poorly defined[4, 61b, 89a] for a long time, despite its obvious importance as final acceptor and converting site for O_2 in mitochondria (Fig. 7).[62, 63] The two heme iron centers in heme *a* and heme a_3 were identified quite early (see Section 9.3.3), and two copper "centers", Cu_A and Cu_B, were differentiated by EPR spectroscopy.[90, 91] However, the Cu_A "center" active in electron transfer could not be classified under the conventional type 1–type 3 copper scheme (Table 1), and even after initial spectroscopic characterization and identification of two invariant cysteine and histidine residues as presumably primary ligands, the dinuclear nature of this center had long been overlooked.[91]

The difficulties in determining the proper metal content partly originated from the complexity of this enzyme, which, in the mammalian form, consists of 13 very different subunits (M_r 204 kDa)[4, 61, 133] and which is embedded in the mitochondrial membrane, thus complicating the collection and purification of the complete protein complex. The Cu_A center is located in subunit II (26 kDa), whereas the heme groups and Cu_B are components of subunit I (60 kDa). Careful trace elemental analyses prompted Buse and coworkers in 1987[4] to postulate a copper-content for COX of *three* copper atoms per enzyme and not—as had long been assumed and widely disseminated[91b–d]—only two. In the meantime, biological copper centers of the Cu_A type had also been detected[14c, 52] in N_2O reductase (Fig. 7) of *Pseudomonas stutzeri*, an enzyme participating in the denitrification process. While the unusual EPR characteristics of the oxidized Cu_A centers had previously been attributed to the coordination of two cysteinate ligands at *one* Cu^{II} center (Cu_A as "super type 1 copper"),[91] Kroneck and coworkers were able to show in 1990 that actually *one* unpaired electron interacts with *two* spectroscopically equivalent metal centers.[92] Natural copper consists of the isotopes ^{63}Cu (69.2% natural abundance, nuclear spin $I = 3/2$, nuclear *g* factor $g_N = 1.484$) and ^{65}Cu (30.8%, $I = 3/2$, $g_N = 1.588$), which leads to a characteristically split[59b] septet in the $A_{\parallel}$ region. These results were confirmed by EPR measurements at different microwave frequencies,[93] and several other groups have since verified the existence of a dinuclear Cu_A center.[94, 133]

There had been two hypotheses about the detailed structure of Cu_A (Fig. 7)[95a, b, d] before the structures of two COX forms were reported in August 1995 (see Chapter 9.3.3).[133] The suggestion by Blackburn et al. was based on reinterpreted[95b, c] EXAFS measurements[95d] and implied for the first time a metal–metal bond in a biomolecule.[95b] The still rather embryonic modeling[89] of both structural proposals does not strictly

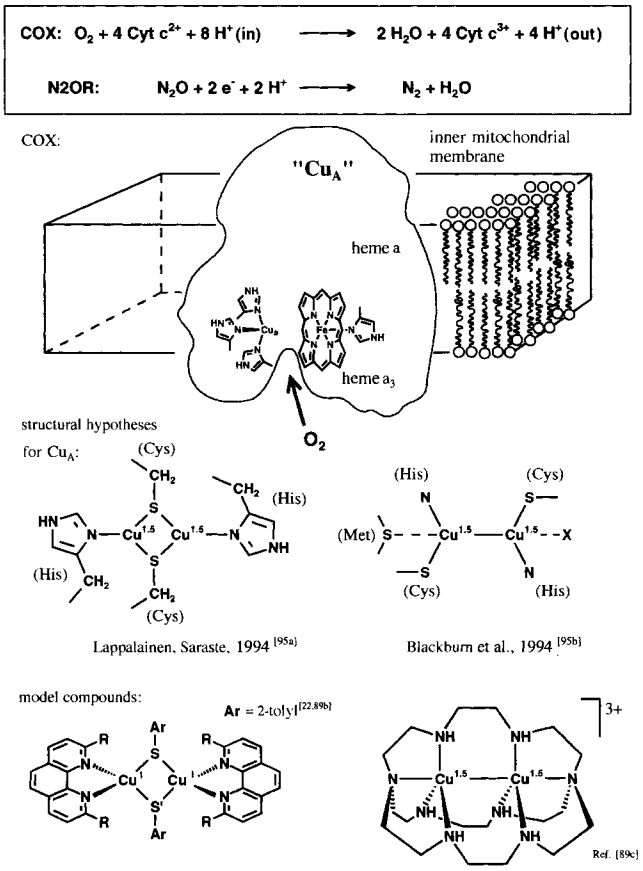


Fig. 7. The terminal respiratory enzyme cytochrome c oxidase [4,62] (COX) and the denitrification enzyme N_2O reductase (N2OR, which contains several copper centers) [52] both exhibit unusual noncatalytic "Cu_A" centers. These centers have an electron transfer function, and the oxidized state is characterized spectroscopically by a long-wavelength absorption at about 800 nm and by an unusual EPR spectrum, distinguished by diminished g anisotropy and small copper hyperfine splitting [91a]. Two histidine residues and two cysteinate anions were established as ligands for Cu_A [91]; however, only very detailed EPR studies at different microwave frequencies [93] revealed the interaction of *one* unpaired electron with *two* spectroscopically equivalent nuclei $^{63}Cu/^{65}Cu$ according to the natural isotopic abundance [59b]. This result, corresponding to a spin-delocalized mixed-valent formulation ($Cu^{1.5+}/Cu^{1.5+}$), confirmed the revised [4a] analytical value of *three* instead of two Cu centers for cytochrome c oxidase (Cu_A dimer and Cu_B/heme a_3 catalytic center). N_2O reductase, a protein dimer, contains eight copper ions, four in two dinuclear Cu_A centers [52]. A distance of about 2.5 Å for the mixed-valent Cu_A dimer was determined by EXAFS spectroscopy in a water-soluble domain of COX of *Bacillus subtilis*, assigned to a Cu–Cu distance, and interpreted as a first metal–metal bond in a biomolecule [95b]. Other structural hypotheses [95a,d] rather invoked two metal-bridging Cys^- ligands. Preliminary low-molecular weight model complexes are available for both structural concepts [89]; crystal structures reported in August 1995 for two COX forms confirmed the thiolate-bridged alternative (see Section 9.3.3) [133].

support this implication, particularly as it is not prudent to deduce the existence of a "bond" in the customary sense from short metal–metal and especially copper–copper distances of 2.3–2.6 Å.[50a, 89a, 96]

The existence of an obviously spin-delocalized mixed-valent (+ II/ + I) dinuclear unit in Cu_A centers[92, 93] suggests strong electronic coupling, either directly across the short distance of about 2.6 Å or through effectively bridging ligands such as cysteinate (thiolate) anions,[89] which are known to mediate "superexchange". As early as 1962, Beinert et al. discussed the possibility of different copper valencies in COX.[90] In comparison with other mixed-valent dimers or higher aggregates in biology,[97] the delocalization according to a $(Cu^{1.5+})_2$ formulation is quite remarkable: Mn^{IV}/Mn^{III} centers in water oxidase and other enzymes[98] as well as Fe^{III}/Fe^{II} systems bridged by oxygen ligands[99] and corresponding reduced [2Fe–2S] centers are spin-localized. Delocalization is only observed in higher iron–sulfur clusters.[100]

9. Copper Proteins and Dioxygen Species O_2^{n-}

9.1. O_2 Transport by Hemocyanin and Variable Coordination in the Cu_k^{II}/O^{n-} System

At the start of this article we drew attention to the reinterpretation[9] of the O_2 binding mode in the oxygen transport protein hemocyanin (Hc),[10] inspired by studies of low molecular weight models[12] (Fig. 1). Hc proteins occur in molluscs and arthropods and maintain an efficient supply of oxygen even in larger animals such as lobster or giant squid. Due to the advantage of allosteric behavior for cooperative O_2 binding, the hemocyanins are oligomeric proteins, like the hemoglobins.[10]

The Hc proteins allow efficient *and* reversible dissociation of the doubly *side-on* coordinated dioxygen molecule in spite of its fourfold contact with the copper centers and the two-electron transfer upon binding. Reim and Krebs[101] have recently published the structure of a tetranuclear complex with μ_4-$(\eta^1)_4$-peroxide surrounded by *four* Cu^{II} centers in which the dioxygen form is irreversibly bound. Iron-containing oxygen transport proteins, on the other hand, display invariably singly end-on coordinated O_2^{n-} ions in their oxy forms.[3, 99] In addition to oligonuclear copper(II) compounds with (μ-η^1:η^1)-,[11] (μ-η^2:η^2)- (Fig. 1),[10, 12] and (μ_4-$(\eta^1)_4$)-peroxide[101], the Cu_k^{II}/O_2^{n-} system ($k = 1-4$) encompasses compounds with end-on (η^1)[58a] and side-on (η^2) coordinated superoxide[58b] as well as bridging $O_2^{\cdot-}$ radical ions;[58c] end-on (η^1) coordinated are hydroperoxide anions in the oxygenated form of ascorbate oxidase (see Section 9.3.1)[5b] and the cumylperoxo ligand ($PhMe_2COO^-$) in a model complex with tris(3,5-dialkylpyrazolyl)borate as additional ligand.[102]

9.2. Copper-containing Monooxygenases in the Metabolism of Natural Products

Dinuclear type 3 copper centers do not only occur in the O_2-transport protein hemocyanin but also in polyphenol oxidases of the tyrosinase type.[76] These enzymes catalyze the *ortho*-hydroxylation of phenols such as tyrosine (monooxygenase reactivity) as well as the further oxidation of the resulting catechols to *ortho*-quinones (catechol oxidase function). Such copper enzymes participate in the biosynthesis of the very many polyphenolic natural products, in particular of catecholamine neurotransmitters (see Scheme 3),[73] in the metabolism of insect cuticula,[103a] in the enzymatic browning of fruit,[103b] and in other melanin-forming processes (Scheme 3).[104]

Mechanistic hypotheses for the function of tyrosinase imply the metal coordination of the phenolic oxygen and an ensuing attack of oxygen at the *ortho* carbon atom.[6, 105] However, there are also copper-dependent enzymes with copper centers other than type 3 that are capable of monooxygenating *aliphatic* C–H bonds. These include a particulate form of methane

monooxygenase that is assumed to contain a copper trimer,[106] as well as dopamine β-monooxygenase,[73] which is essential during neurotransmitter biosynthesis (Scheme 3) and which contains two different copper centers.[65d, 75] One of these centers has an electron transfer role (ascorbate as the physiological electron donor), whereas the other, the catalytic center, has not yet been conclusively defined.[75] As for the iron-containing methane monooxygenase[107] that was crystallized in the absence of copper, the copper-dependent forms are also assumed to generate radicals of the organic substrate as intermediates;[106] a similar assumption holds for dopamine-β-monooxygenase (abstraction of a benzylic hydrogen atom[75, 108]). In this context it is important to realize that recent model complexes with μ-η^2:η^2-coordinated dioxygen can activate C–H bonds (monooxygenation) in alkyl substituents.[109] Based on EPR measurements and in accord with studies on ascorbate oxidase (see Section 9.3.1), a $Cu^{II}OOH$ species may be envisaged as reactive intermediate prior to O–O bond cleavage.

9.3. Strategies for Multielectron Catalysis in Copper-Containing Oxidases

9.3.1. Cu_3 Clusters in "Blue" Oxidases (Ascorbate Oxidase, Laccase)

"Blue" oxidases like the structurally well-established ascorbate oxidase[5b] provide substrate-specific oxidation equivalents by four-electron reduction of O_2 to 2 H_2O. To meet the stringent requirements for multielectron catalysis,[60] these often dimeric enzymes contain four copper atoms per subunit, one center being a separate type 1 copper ion for electron transfer purposes, which is also responsible for the typical blue color of these enzymes. Early spectroscopic studies led to the description of the remaining three metal ions as one type 2 and one (dimeric) type 3 copper center, before more refined spectroscopic investigations[6d] as well as the crystal structure analysis by Messerschmidt et al.[5b] rendered this differentiation based on an artificial classification scheme obsolete (Fig. 8): The arrangement is trinuclear with partially hydroxo-bridged metal centers and metal–metal distances between 3.4 and 5.1 Å, depending on the coordination and on the oxidation state. Structure determinations of the oxidized form, the reduced state, the hydroperoxide-containing oxygenated form, and of a bis(azido) derivative have provided the crystallographic basis for a detailed reaction mechanism.[5b]

Starting from the completely oxidized, but not oxygenated form, a successive, controlled electron flow takes place from the substrate to the catalytic trimer through the type 1 copper center. The latter is separated from the cluster by more than 13 Å and is coordinatively saturated. After complete reduction, the enzyme reacts with oxygen to form a hydroperoxo adduct with oxidation of both "type 3" metal centers, one of which serves as coordination site for HOO^-. (Stable alkylperoxocopper(II) complexes have been isolated with tris(3,5-dialkylpyrazolyl)-borate ligands.[102]) Close to the transition state of the reaction, an additional intramolecular electron transfer from the remaining two Cu^I centers leads to O–O bond cleavage and to the release of two water molecules.[5b]

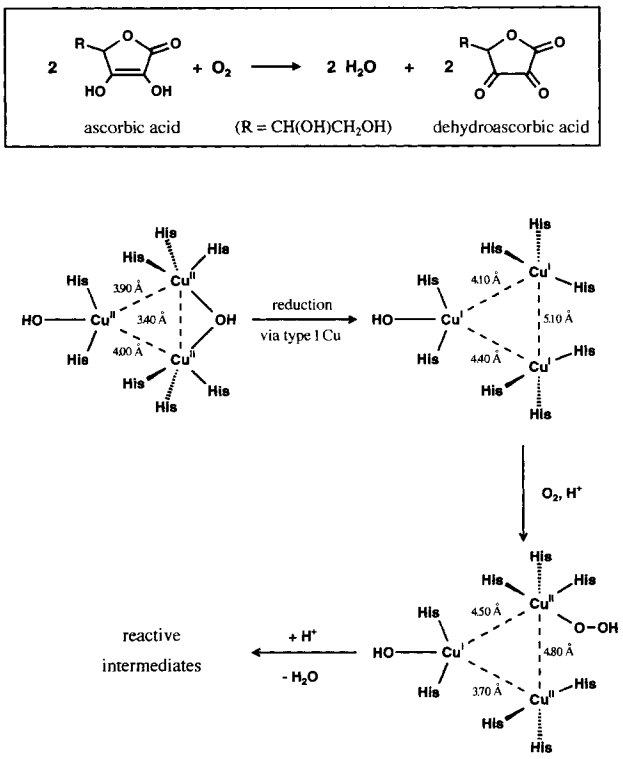

Fig. 8. "Blue" four-electron oxidase enzymes such as ascorbate oxidase contain four copper ions per subunit, one of which is a type 1 copper center for electron transfer. According to protein crystallography, the remaining three copper ions do not strictly behave as one type 2 and one type 3 center (dimer), but rather act as a new trinuclear catalytic site [5b]. Dioxygen is coordinated end-on as hydroperoxide [5b] by one copper center of the trimer, and a controlled electron flow is effected through the type 1 copper ion from the substrate.

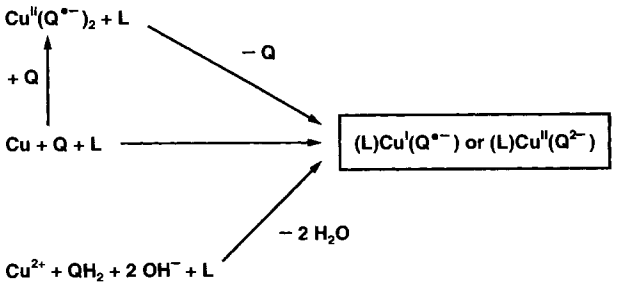
9.3.2. Interactions between Copper and "Built-In" Radical Cofactors in "Non-blue" Oxidases

In contrast to the blue oxidases, the non-blue oxidases utilize only the two-electron process $O_2 \rightarrow H_2O_2$ to generate oxidation equivalents for substrate oxidation. These enzymes also contain only one type 2 copper center per subunit, which for the purpose of multielectron catalysis is structurally and functionally linked to the redox system of organic cofactors, which are part of the protein framework. Since the two-electron reaction involves one copper center with a Cu^{II}-to-Cu^I oxidation state change, the cofactors also have to undergo a one-electron transition at relatively high potential—similar to that of the Cu^{II}/Cu^I pair—which should result in the temporary formation of radicals. The necessary requirements for the redox potential, the available coordination sites and catalytic centers, and the stability of radical intermediates are met by the tyrosine-derived "topaquinone/topasemiquinone/topahydroquinone" redox system (see Fig. 9)[53, 57, 64] in the case of copper-dependent amine oxidases, whereas a tyrosyl radical/tyrosine redox pair plays this role in galactose oxidase. There, the tyrosyl radical state is additionally stabilized through a covalent linkage with a cysteinate "substituent" in *ortho* (ε) position (see Fig. 10) and through π–π interaction with a tryptophan side chain.[29]

The foremost role of the metal center is to bind and activate O_2,[29, 30, 57] whereas the organic cofactors participate in substrate conversion. This functional division is particularly evi-

dent in copper-dependent amine oxidases, which, inter alia, serve in the formation and maturation of connective tissue (Scheme 8; see Fig. 9 for Cu-independent forms[85]): The metal participates in a "valence-tautomer" equilibrium Cu^{II}-$Q^{2-} \leftrightarrow Cu^{I}$-$Q^{\bullet -}$ [46, 57] (Q = quinone component), which allows for the controlled binding of O_2 to the copper(I) center. Copper(II) catecholate as well as copper(I) semiquinone and comparable radical complexes can be prepared as stable species (Scheme 9) and are readily identified and differentiated by EPR measurements.[46, 57] The position of the valence-tautomer equilibrium can be influenced by variation of the quinone component Q, by assumed steric and solvent effects,[110] and through the ancillary ligands at the metal:[46] nitrogen donor ligands L favor the Cu^{II}/catecholate form, whereas thioether donor ligands L favor the Cu^{I}/semiquinone state, as do triorganophosphanes, olefins, or carbon monoxide.[46a, d]



Scheme 9.

Like several other quinoprotein cofactors,[85] the six-membered ring of topaquinone (Q) shows a potentially *ortho*- and *para*-quinonoid structure,[111] protected by substitution in the γ-position. In the oxidized (quinone) state a carbonyl group serves to bind the primary amine substrate, which is eventually converted into the aldehyde product in the course of the reaction; topaquinone is thus reduced to aromatic topahydroquinone (the "catecholate" state) (Fig. 9).[112]

Galactose oxidase is excreted as an extracellular enzyme by some parasitic fungi. It catalyzes the oxidation of primary alcohols to the corresponding aldehydes in a regioselective, but not substrate-specific manner. The biological role of the enzyme is not completely understood; one possible function is the degradation of rotting wood by oxidation of oligosaccharide intermediates, which are preferred substrates of the enzyme. Perhaps, however, the coupled formation of hydrogen peroxide is just as important.[30] H_2O_2 is required for the degradation of lignin by special peroxidases (ligninases) or for chemical defense against bacteria. The most thoroughly studied galactose oxidase was isolated from a strain, previously classified as *Cladobotryum dendroides* (before 1986: *Dactylium dendroides*), but more recently identified as a member of the genus *Fusarium*.[113]

For some time it remained obscure how this enzyme with only one copper center can catalyze a two-electron reaction. The reaction mechanism was explained by a Cu^{III}/Cu^{I} redox pair,[28]

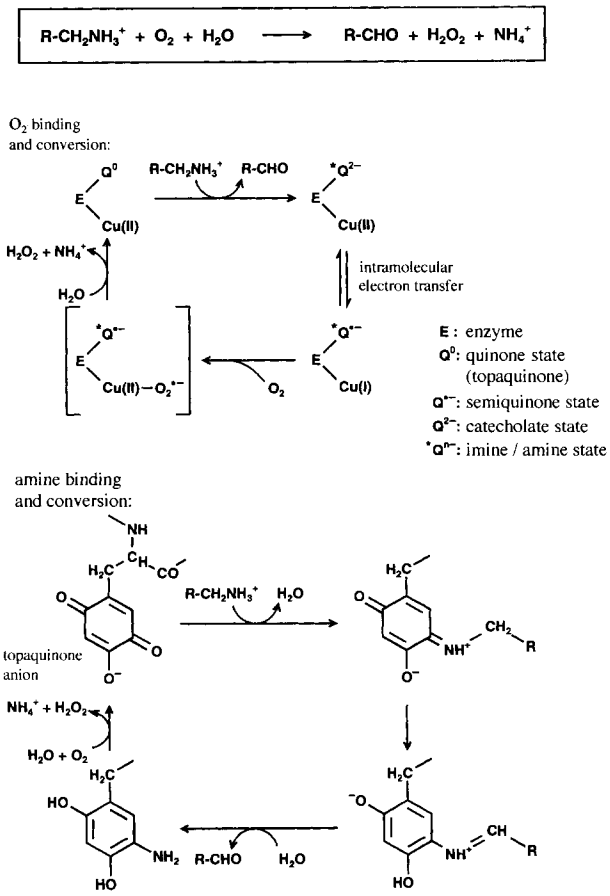


Fig. 9. Copper-containing quinoproteins are involved in amine oxidation, for instance, in the formation of connective tissue (lysyl oxidase) [85]. The coupling of the Cu^{II}/Cu^{I} redox function with that of a modified quinone (Q) firstly guarantees the activation of O_2 by Cu^{I} centers, following an EPR-detectable Cu^{II}-$Q^{2-} \rightarrow Cu^{I}$-$Q^{\bullet -}$ [57] valence tautomerization and secondly allows for the reaction of a free quinone carbonyl function with the primary amine. For some time, pyrroloquinolinequinone (PQQ) had been assumed to be the (dissociable) quinonoid cofactor [85b]; however, Klinman et al. [57] identified covalently anchored topaquinone (TQ) as that redox-active organic entity. TQ is a posttranslationally modified tyrosine which can alternatively form *ortho*- or *para*-quinonoid structures [111].

which seemed to be plausible at first since an external cofactor could not be found. However, detailed spectroscopic and magnetic studies later indicated the presence of a protein-bound, "built-in" organic radical cofactor. The crystal structure of the enzyme finally confirmed this conclusion (Fig. 10):[29] A tyrosine residue positioned in an equatorial coordination site of a square pyramidal arrangement is covalently linked *ortho* (ε) to the sulfur atom of a cysteinate side chain as donor substituent. This arrangement facilitates the oxidation to the tyrosyl radical by lowering the redox potential and allowing for spin delocalization.[114a] Further stabilization of the radical is apparently provided by a tryptophan residue, the indole part of which is situated in a position above the cysteinate-substituted tyrosine—well suited for π–π interactions. In view of this complexity of the metal-containing active center, there are currently few relevant studies with model complexes.[114b] Because they are specific for primary amines or alcohols, two quite important and widespread classes of organic substances, both the amine oxidases and galactose oxidase have become interesting enzymes for biosensor applications.[114c, d]

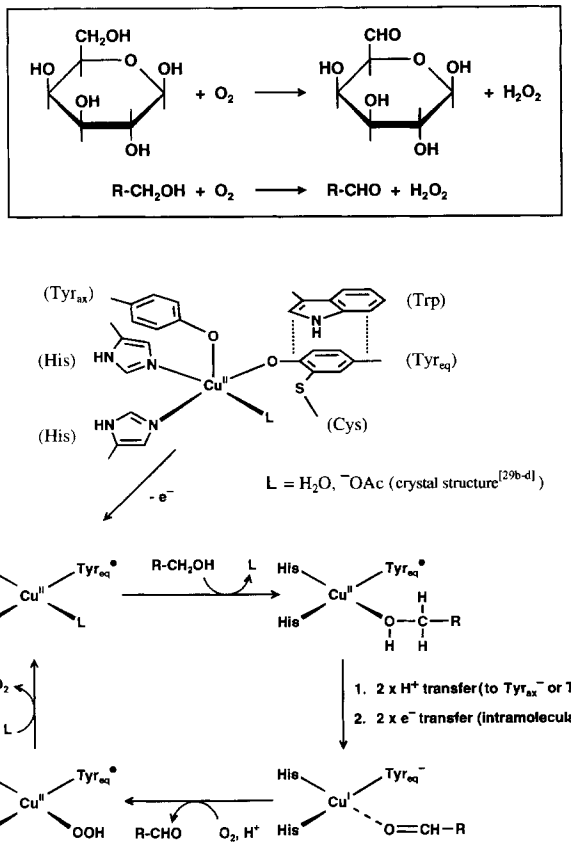

Fig. 10. The catalysis of the depicted two-electron process by galactose oxidase from parasitic fungi was originally attributed to a Cu^{III}/Cu^{I} transition [18c,28], since there is only *one* copper center available. However, the crystal structure of the enzyme showed that a type 2 Cu^{II}/Cu^{I} system is structurally as well as electronically coupled to an equatorially coordinated tyrosinate/tyrosyl radical redox pair. This very special tyrosyl group is further characterized by an unusual covalent linkage to a cysteine sulfur center in *ortho* (ε) position and by $\pi-\pi$ interactions with the indole ring system of a tryptophan residue: a highly sophisticated "built-in" cofactor.[29]

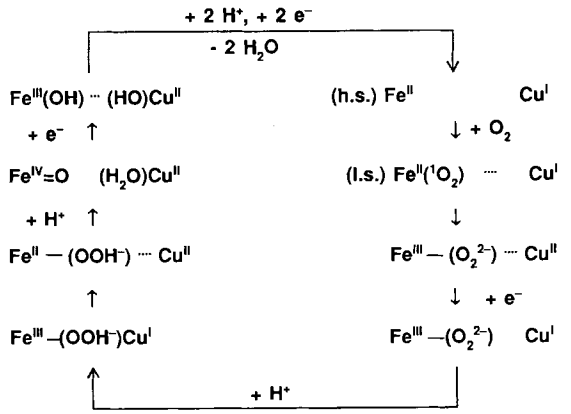
9.3.3. The Catalytic Cu/Fe Center of Cytochrome c Oxidase (COX)

While the dinuclear Cu_A center in subunit II (see Section 8) and the low-spin heme *a* in subunit I of COX have both electron transfer functions,[62d] the actual four-electron reduction of O_2[62] occurs at a heterodinuclear center Cu_B/heme a_3. The metals are separated by about 4–5 Å,[95d, 133] which suggests that the triplet dioxygen molecule possibly binds to the Cu^{I} as well as to the high-spin Fe^{II} center of heme a_3. Apparently, both biologically occurring O_2-activating metal ions (see Section 2) cooperate here to catalyze this mechanistically demanding[60] multielectron reduction. Hydroperoxocopper(II)[5b] and oxoferryl(IV) species[115] were postulated as intermediate species (Scheme 10).[62]

Whereas the Cu_B ion can be regarded as a type 2 copper center based on its ligation and spectroscopy (Fig.7), the special heme a_3 is characterized by a partially unsaturated farnesyl substituent[62a, 116] at the porphyrin ring. The tendency of copper(I) and iron in low oxidation states to form olefinic (Cu) or π-allylic (Fe) complexes led to suggestions aimed at an intermediate coordination of this porphyrin substituent with the heterodinuclear metal center.[116] The reduction of O_2 in this "complex IV" of the respiratory chain is closely linked to the translocation of



Scheme 10. Catalytic cycle for O_2 reduction by cytochrome c oxidase. h.s. = high spin; l.s. = low spin.

protons through the mitochondrial membrane[62, 133] to eventually form ATP as the energy storage product of this oxidative phosphorylation.

An increasing number of attempts to model the heterodinuclear Cu_B/heme a_3 center of COX structurally as well as functionally has been published since 1994.[117] In addition to the molecular design of the correct Cu–Fe distance and the proper oxidation and spin states, attention has been directed at the reactivity of O_2 activation[117f] and inhibition by bridging cyanide, μ-CN^-.[117c, e] Since cyanide is a diatomic anion that can bridge low-valent transition metal ions at a distance of 4.5–5.5 Å, it is an efficient inhibitor of O_2 coordination at the Cu_B/heme a_3 site and thus of cell respiration (toxicity of cyanide).[118]

Two research teams have recently reported the successful structural characterization of cytochrome c oxidase forms at 2.8 Å resolution. One of the enzymes is the mammalian form derived from bovine heart mitochondria (complete enyzme, "the largest membrane protein yet crystallized and analyzed at atomic resolution"),[133a] and the other is the form of soil bacterium *Parococcus denitrificans* (four subunits, complexed with an antibody fragment).[133b] These studies have revealed the following details concerning the copper centers: The Cu_A site outside the membrane region on the cytosolic side is dinuclear with the two copper ions bridged by two cysteinate residues (cf. the hypothesis on the left of Fig. 7). The copper–copper distance in the planar CuSCu'S' arrangement is 2.7 Å[133a] or 2.6 Å.[133b] Each metal center is coordinated to one histidine residue, while one is additionally connected to a methionine sulfur center and the other to a carbonyl oxygen atom of a peptide link to complete the tetracoordination (distorted tetrahedron). The Cu_B and Fe_{a3} ions are 4.5[133a] or 5.2 Å[133b] apart in the (oxidized) resting state. Cu_B is coordinated to three imidazole rings (ImH) from histidine side chains, one of which seems to be mobile (reported for bacterial COX[133b]) and to participate in the redox-coupled proton translocation. The research team from Frankfurt[133b] proposed a sequence $Cu^{2+}/Im^- \rightarrow Cu^+/ImH \rightarrow O_2/Cu^+ + HImH^+$ for the first stages that connect proton shuttling with dioxygen binding and conversion (cf. the reaction cycle of superoxide dismutase in Fig. 11). In the bovine heart COX the farnesyl side chain engages in hydrogen-bonding interactions that seem to contribute to the structural stabilization of Cu_B.[133a]

9.4. Cu,Zn Superoxide Dismutase (Cu,Zn-SOD)

Cu,Zn superoxide dismutase (SOD)[119, 120] is a widespread enzyme with a function that may go beyond that defined in its name. In addition to its well-established ability for detoxifying $O_2^{\bullet-}/HO_2^{\bullet}$ radicals through catalyzed disproportionation, the enzyme could also have a metal storage and transport function because of its abundance in eukaryotic tissue. The disproportionation ("dismutation") of the metastable superoxide (properly: hyperoxide ion) to give dioxygen and enzymatically further metabolized peroxide can be catalyzed by many redox-active transition metal ions[120] if they can function according to Equations (a) and (b).

$$M^{n+} + O_2^{\bullet-} \longrightarrow M^{(n-1)+} + O_2 \quad (a)$$

$$M^{(n-1)+} + O_2^{\bullet-} + 2H^+ \longrightarrow M^{n+} + H_2O_2 \quad (b)$$

It is therefore not surprising that there are superoxide dismutase enzymes with M = Cu, Fe, or Mn, the latter occurring especially in mitochondria[121, 122] and the former in erythrocytes.[119, 120] In view of the lability of the substrate and the substantial driving force of the reaction, the requirements for SOD enzyme functioning do not appear that compelling at first glance; however, the very rapid diffusion of $O_2^{\bullet-}$ radical ions to the active site has to be guaranteed, and the enzyme must exhibit long-term stability towards O_2, $O_2^{\bullet-}$ ions, H_2O_2, and the surrounding proteins.[126] The first condition is met by the "conduction" of the pseudohalide-type $O_2^{\bullet-}$ anion or its conjugated acid, $HO_2^{\bullet}$, along a funnel-shaped channel bordered by cationic and hydrogen-bond-forming amino acid residues to the active site. This site consists of a type 2 copper center coordinated to three imidazole groups from histidines and one imidazolate anion of a deprotonated and Zn^{2+}-bound histidine.[119, 123] A few years ago the exchange of anionic glutamate in the channel by neutral glutamine was accomplished by site-directed mutagenesis. Under certain conditions, this exchange gave rise to a further increase of the rate of diffusion and, thus, of the overall reaction rate: the optimization of an apparently "perfect" enzyme (Fig. 11).[124]

The second requirement for the high stability of this enzyme is certainly fulfilled, as illustrated most vividly by the largely intact activity of Cu,Zn-SOD from 3000-year-old mummified tissue.[125] In addition to the long-term stability of this enzyme, its structural integrity, and a high tolerance of the aggressive substrate and product molecules, the essential copper ion has to be tightly bound in Cu,Zn-SOD so that it cannot be extracted as Cu^{II} by other proteins such as serum albumin.[126] Presumably, the unusual arrangement with an additional dicationic metal (Zn^{2+}) and the biologically unique bridging imidazolate ion of a histidine side chain also enhance the stability; this stability but not the function of the enzyme seems to be impaired when the zinc ion is selectively removed.

The essential role of Cu,Zn-SOD is not only emphasized by its pharmacological use in the treatment of inflammatory diseases, in the prophylaxis of radiation damage, or by its increasingly recognized importance during the process of ageing.[128] As was pointed out in Section 4, even rather minute mutations can have grave consequences.[8] Although superoxide is produced in a controlled manner in phagocytic cells by the "respiratory burst" and then used for defense purposes in the immune system,[129] its uncontrolled occurrence during the transport of O_2 by erythrocytes,[120] in mitochondrial respiration,[122] or during the activity of molybdenum-containing xanthine oxidase is clearly undesirable.[8c]

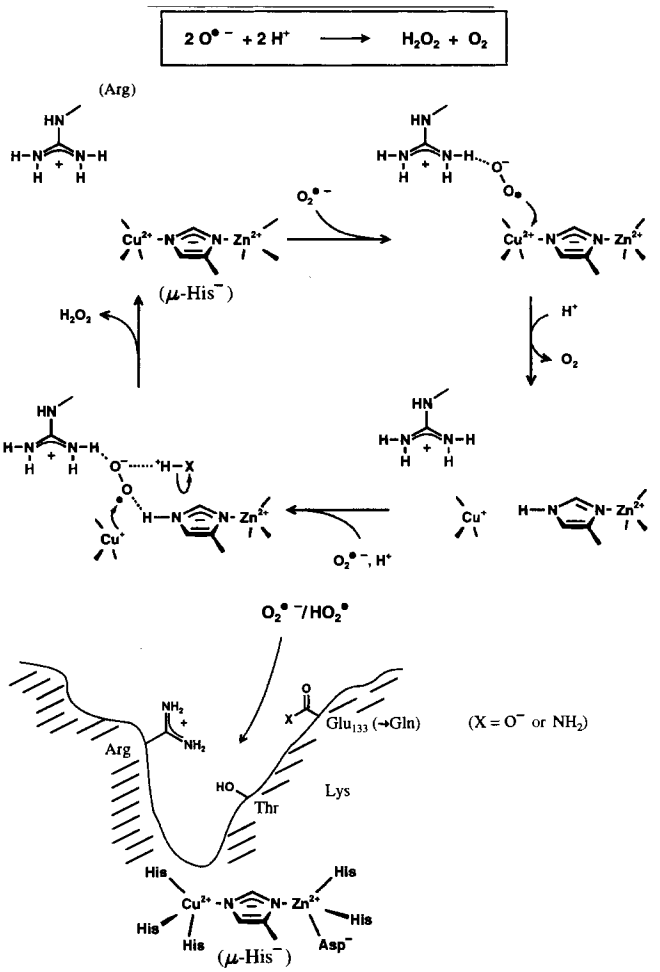


Fig. 11. The superoxide dismutase (SOD) from mammalian erythrocytes is a homodimeric enzyme that contains one zinc and one copper center per subunit. The two metal ions are connected in a biologically unique manner by the functionally essential imidazolate bridging ligand of a histidine side chain [119]. Copper is the redox active metal that reduces metastable superoxide to peroxide when in the Cu^{I} form and oxidizes it to O_2 when in the Cu^{II} state. While the enzyme itself must not be attacked by the aggressive dioxygen species, it has to convert the reactive $O_2^{\bullet-}/HO_2^{\bullet}$ radicals very efficiently, that is, in a diffusion-controlled manner. For proper functioning, rapid electron and proton transfer processes at the actual reaction site are thus crucial as is the supported diffusion of $O_2^{\bullet-}/HO_2^{\bullet}$ ions to the active center; the latter could be accelerated even further by the site-directed mutation $Glu^- \rightarrow Gln$ in the channel leading to the bimetallic site. On the other hand, defect variants of Cu,Zn-SOD are held to be responsible for to the familial form of amyotrophic lateral sclerosis (ALS), an irreversible neurodegenerative disease of the motoric system [8].

Cytotoxic radicals may also contribute to the development of insulin-dependent diabetes mellitus (type I diabetes). There is much evidence[130] that active oxygen species such as superoxide, hydroxyl radical, or peroxynitrite play an important role in the destruction of the insulin-producing β-cells of the pancreas. Experiments on mice with increased production of Cu,Zn superoxide dismutase showed that the the β-cells have a distinctly higher tolerance to induction of diabetes through oxidative stress.[130]

10. Copper in the Nitrogen Cycle

The production of oxidation equivalents and, as a result, of O_2 through photosynthetic organisms has not only led to an increased bioavailability of copper but also to the necessity for a biological metabolism of the nitrogen/oxygen compounds formed.[3a-c] In addition to iron and molybdenum (which became bioavailable[3c, 68b] as the $Mo^{VI}O_4^{2-}$ ion), copper-containing enzymes are also important in biological denitrification.[13b, 14, 15, 52]

Details about N_2O reductase (N2OR, see Fig. 7) from *Pseudomonas stutzeri*, which contains catalytically active "Cu_Z" dinuclear centers[14c, 52] as well as the dinuclear Cu_A centers introduced in Section 8 are known. A multicopper-containing form of microbial nitrite reductase has also been mentioned earlier in this article[14, 52] (Fig. 2); its catalytic metal centers (besides type 1 copper) show an unusual Cu^{II} coordination geometry (nearly tetrahedral) in the crystallographically determined resting state ("pseudo type 2" copper, Fig. 2).[15] Many new results from model complexes with tris(alkylpyrazolyl)borate ligands[16, 17] indicate that the catalytically relevant and spectroscopically remarkable[16b] Cu^{I}–nitrosyl radical complexes as well as the Cu^{II}–nitrite precursor complexes are important intermediates in the reaction. However, the pathway from the nitrosyl state to dinitrogen monoxide is not yet well understood (Fig. 2).[13]

11. Summary and Outlook

Although copper became bioavailable in significant amounts only as Cu^{II}, that is, after sufficient photosynthetic production of oxidation equivalents about 2–3 billion years ago, all biological functions involve copper in the monovalent form, either alone or in form of the Cu^{II}/Cu^{I} redox pair. In contrast to other stable metal monocations, the Cu^{I} state is characterized by high, but not unphysiological, *one-electron* oxidation potentials and by a preference for low coordination numbers (3–4) with a variable coordination geometry, uninfluenced by ligand field effects. Further remarkable properties include the ability to bind olefins and to activate O_2 in its triplet ground state; within biology, this latter, essential activity is only shared by the high-spin iron(II) state and by the formally antiaromatic 1,5-dihydroflavins.

The one-electron redox reactivity in the Cu^{II}/Cu^{I} system with potentials between 0.0 and +1.0 V renders copper centers compatible with weakly oxidizing organic and inorganic radicals in corresponding redox systems; redox pairs identified as such partners of copper centers include quinones/semiquinones, tyrosyl/tyrosine, $O_2/O_2^{\bullet-}/O_2^{2-}$ and $NO^{+}/NO^{\bullet}$.

In the light of the rapid parallel development of medical, microbiological, biochemical, and inorganic-chemical research in the area of copper coordination compounds during the last decade, more surprising discoveries can be anticipated, and new methodologies such as site-directed mutagenesis may be developed to enable targeted design of copper-containing proteins. There are still many intriguing questions open, such as the coordination environment in copper-dependent monooxygenases and the possible role of Cu^{I} sites in the receptor protein of the plant hormone ethylene.[131] Speculative yet fascinating remain the attempts to understand the temporal and functional development of this unique element in the evolution of life.[3c, 19, 54b, 132]

Our own research on the chemistry of copper has been funded by programs of the Deutsche Forschungsgemeinschaft (DFG) and by the Fonds der Chemischen Industrie, which we gratefully acknowledge. We also thank those co-workers directly involved, in particular Dr. Stephan Kohlmann, Dr. Conny Vogler, Dr. Michael Moscherosch, Dipl.-Chem. Eberhard Waldhör, Dipl.-Chem. Andreas Stange, Dipl.-Chem. Christoph Titze, and Dipl.-Chem. Manuela Schwach. We sincerely acknowledge the help of Mrs. Dipl.-Chem. Angela Winkelmann in preparing this manuscript.

Miller, R.J.D. (ed.)

Surface Electron Transfer Processes

1995. XII, 368 pages
with 137 figures and 3 tables.
Hardcover. DM 128.00.
ISBN 1-56081-036-X
(VCH, New York)

This book gives an extensive theoretical treatment of its theme. The emphasis is on electronic coupling of molecular potentials to conducting band states. The essential role of surface electron transfer in catalysis, electrochemistry, photo imaging, and virtually all charge transfer solid state devices make this process one of the most important single chemical events.

Sandifer, J. R.

Ion-Transfer Kinetics

1995. X, 142 pages with
38 figures and 16 tables.
Hardcover. DM 165.00.
ISBN 1-56081-508-6
(VCH, New York)

In six concise, well-referenced chapters, this book covers the essentials of ion-transfer principles and applications, including computer simulation techniques for ion-transfer kinetics models.

It is addressed to chemists in academia and industry, to physical chemists and to chemical engineers.

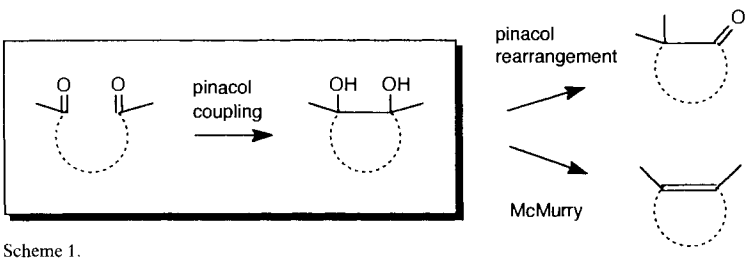
"New" Reagents for the "Old" Pinacol Coupling Reaction

Thomas Wirth*

An old-timer in the history of chemistry, the pinacol coupling, was first described over 130 years ago in a publication on the synthesis of pinacols.[1a] Today this reaction is still a versatile tool for chemists. This "longevity" can be explained by the continuous development of improved reagents and by the intrisic elegance of the method for the preparation of 1,2-diols (pinacols) by the reductive coupling of carbonyl compounds.[1] Starting with two carbonyl functionalities, a C–C bond is formed and two new adjacent stereocenters created. 1,2-Diols are versatile intermediates in synthesis; for example, they can be used for the preparation of ketones by the pinacol rearrangement or alkenes by the McMurry reaction (Scheme 1).



Scheme 1.

Whether the reductive coupling of carbonyl compounds leads to 1,2-diols or to the deoxygenated or rearranged products is dependent on the oxygen affinity of the reducing agent employed. The McMurry reaction uses low-valent titanium compounds, which under certain reaction conditions can transform the 1,2-diol intermediates into alkenes by rapid deoxygenation (Scheme 1). When this reaction was performed on the surface of reduced titanium dioxide, the intermediate 1,2-diols could be isolated.[2]

Reducing agents suitable for the synthesis of pinacols must allow the reaction to be stopped at the 1,2-diol stage. One of the first practical reductants for pinacol coupling reactions was the Mg/MgI_2 system reported by Gomberg and Bachmann.[3] More recently these reducing agents have been extended by a magnesium–graphite system, which is competitive with other currently available reductants.[4] Different low-valent titanium compounds have proved to have similar efficiency for pinacol coupling reactions.[5] They have been used for intramolecular couplings as well as for the formation of unsymmetrical pinacols, and have demonstrated their potential in several key steps of natural product syntheses.[6]

Typical mechanisms for pinacol couplings are shown in Scheme 2. In the first reduction step a ketyl radical is formed, which can dimerize (path A) or add to a second carbonyl group (path B) forming a C–C bond. In path B a second one-electron reduction must then follow. For pinacol coupling reactions mediated by transition metals the insertion of a carbonyl group into the metal–carbon bond of initially formed metal oxiranes has been proposed (path C).

Pinacol coupling reactions can lead to either the *syn*- or *anti*-diols. The stereochemical course of the reaction depends on the reducing agents and, of course, on the structure of the carbonyl compounds. Recent studies employing reagents that form the C–C bond according pathways B and C have met with success.

Previously, tin–ketyl radicals have been added to alkenes only in an intramolecular fashion.[7] In recent publications, however, pinacols and amino alcohols have been prepared by cyclization of dicarbonyl compounds[8] or keto-oximes[9] with tributyltin hydride. Cyclization of 1,5-ketoaldehydes **1** and 1,5-dialdehydes with tributyltin hydride yields *cis*-diols **2** with excellent stereoselectivities, whereas the keto-oxime **4** with four ben-

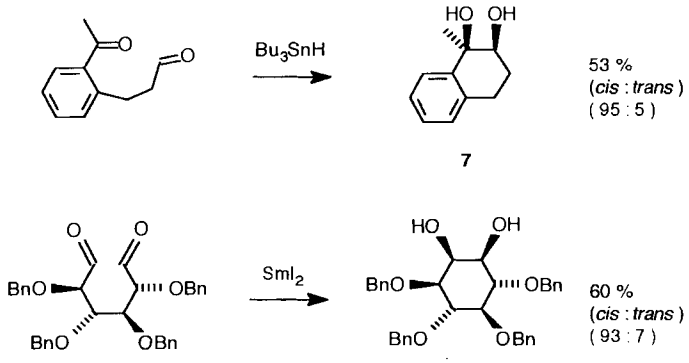
zyloxy substituents affords a 58:42 (*cis*:*trans*) mixture. The *trans* product was transformed in two more steps into the potent glycosidase inhibitor 1-deoxynojirimycin (**6**).[9b] The reversibility of both the addition of the tributyltin radical to the carbonyl group and the intramolecular radical C–C bond formation is believed to be responsible for the high selectivity in the formation of **2**. In the cyclization of 1,5-pentanedial the unhydrolyzed coupling product **3** could be isolated, therefore providing evidence for a new mechanistic variant of the pinacol reaction, in which only 1.2 equivalents of the reducing agent are necessary.

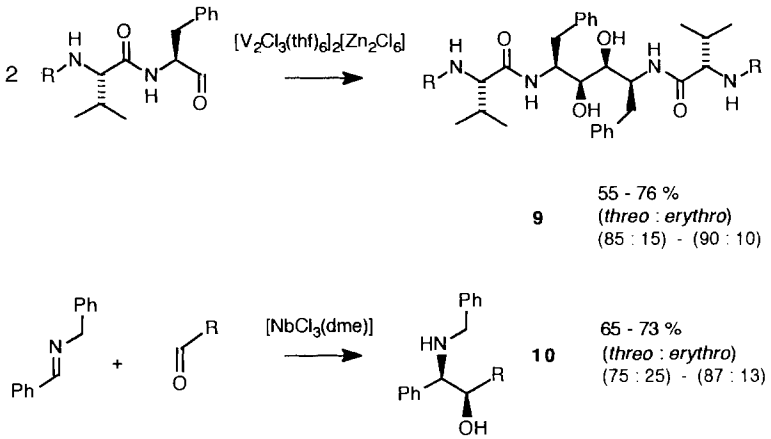
1,6-Dicarbonyl compounds can also be converted into the corresponding pinacols. Tributyltin hydride can again be used as an efficient reducing agent, this time for the stereoselective synthesis of **7**.[8] Other well-established pinacol-forming reagents such as low-valent titanium compounds[1b,c] and samarium diiodide[10] can cyclize 1,*n*-dicarbonyl compounds with comparable stereoselectivities to give 1,2-diols. X-ray crystal structures of a samarium ketyl complex and a samarium pinacolate are further evidence of the reversibility of the coupling reaction under appropriate conditions.[11] Samarium diiodide was used as pinacol coupling reagent for the synthesis of the optically active inositol derivative **8**.[10b]



7 8

Low-valent compounds of other early transition metals were shown to be effective reagents for the pinacol coupling. Zirconium, niobium, and ytterbium reagents form metal oxiranes with carbonyl compounds; however, the mechanism of the reaction with vanadium compounds is not clear at present. The mechanism of the pinacol coupling via metal oxiranes is supported by X-ray structure analysis of an intermediate.[12] Vanadium and niobium compounds seem to be particularly attractive reagents for intermolecular pinacol coupling reactions.

The vanadium complex $[V_2Cl_3(thf)_6]_2[Zn_2Cl_6]$ is suitable for the intramolecular coupling of functionalized aldehydes bearing further coordination sites, for example amino aldehydes.[13] The formation of a bidentate or tridentate metal–aldehyde complex is proposed to be the origin of the *threo* selectivity observed in this reaction. The coupling products **9** are interesting target structures because they are potential inhibitors of HIV proteases. They can even be synthesized on a kilogram-scale with good yields.[13b] The niobium reagent $[NbCl_3(dme)]$ can be used to couple imines with carbonyl compounds giving amino alcohols such as **10**, although generally



9 10

lower stereoselectivity is observed.[14] In analogy to reactions with other early transition metals, the mechanism is believed to proceed via a niobaziridine, which adds to the carbonyl functionality.

The relative and absolute stereochemistry in pinacol coupling reactions, for instance in the natural product syntheses mentioned earlier,[6] is always controlled by the stereocenters of the substrates. Very little work has concentrated on the control of the absolute stereochemistry in pinacol coupling reactions.[1b] Because of the potential of the reagents presented here, the development of chiral coupling reagents will no doubt be reported in the near future.

Selective Catalytic Reactions at the External Surface of Zeolite Crystals

Stefan Ernst*

Zeolites are crystalline microporous aluminosilicates consisting of SiO_4 and AlO_4 tetrahedra as the primary building units. One salient feature of the crystalline structure of zeolites is the occurrence of strictly regular cavities and pores with sizes of the same order of magnitude as molecular dimensions (0.3–1.5 nm). Zeolites have found widespread applications as catalysts in the petroleum refining industry, in petrochemical processes, and for the manufacture of organic intermediates. Furthermore, they are used as selective adsorbents in separation and purification processes and as phosphate substituents in detergents.[1, 2] Many of the catalytic applications of zeolites are based on the principle of shape-selective catalysis. Shape selectivity effects in microporous solids may occur if the pore width of the solid and the dimensions of the reactant molecules, product molecules, and transition states, which take part in the catalytic reaction, are similar.[3] Consequently in the nomenclature adopted by Csicsery,[4] distinctions are made between *reactant shape selectivity*, *product shape selectivity*, and *restricted transition state shape selectivity* (Fig. 1). Reactant shape selectivity occurs when from at least two reactants only one is "slim" enough to enter the pores of the zeolite where most of the catalytically active (acid) sites are located. Hence, only the less bulky molecule is catalytically converted, whereas the bulky reactants are not. Product shape selectivity may be regarded as the reverse of reactant shape selectivity: all reactants are small enough to enter the zeolite pores, but of the potential products only one species is small enough to leave the pore system. Restricted transition state shape selectivity finally takes place if one of at least two parallel or consecutive reactions is suppressed because it requires a bulky transition state. Thus, this reaction cannot occur if there is insufficient space within the pore system.

There are numerous examples for the three classical types of shape-selective catalysis in zeolites. In some cases, however, experimentally observed selectivities could not be explained based on this early classification. Hence, a number of new concepts

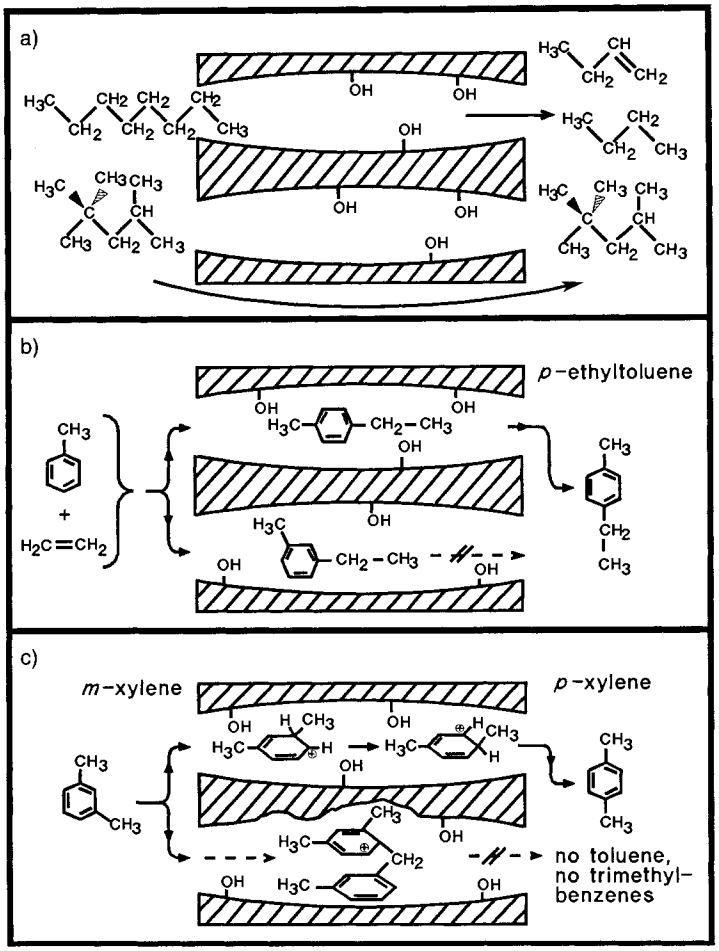

Fig. 1. Examples for the three classical types of shape-selective catalysis in zeolites. a) Reactant shape selectivity: from a mixture consisting of *n*-octane and 2,2,4-trimethylpentane, only the "slim" isomer is able to diffuse to the active sites inside the zeolite pores where it is catalytically cracked. b) Product shape selectivity: the reactants are small enough to enter the zeolite pores, but of the potential products (*o*-, *m*-, and *p*-ethyltoluene), only the "slim" *para* isomer is small enough to leave the pore system. c) Restricted transition state shape selectivity: disproportionation of *m*-xylene into toluene and trimethylbenzenes is suppressed because the required formation of the relatively bulky bimolecular transition state is inhibited due to steric constraints.

have been developed which have found varying degrees of acceptance. Examples include the "cage- or window effect",[5] and "molecular traffic control".[6] Also, several attempts have been made to assign shape-selective properties even to the external surface of zeolite crystals[7, 8] (see for example the "nest effect"). However, sophisticated catalytic experiments[10] revealed that the selectivities described earlier, in particular in references [7, 8], can be alternatively explained in a straightforward manner by classical shape-selectivity concepts.

In light of this, recent work by Martens et al.,[11] describing the selective isomerization of long-chain *n*-alkanes over zeolite ZSM-22, is particularly interesting. The pore system of zeolite ZSM-22 consists of linear, non-interconnected channels with crystallographic diameters of about 0.45 nm × 0.55 nm. If this zeolite is modified into its Brønsted acid (H^+) form and loaded by ion exchange with a small amount of a noble metal (for example 0.5 wt.% of platinum), a bifunctional catalyst (i.e., acidic and with hydrogenation/dehydrogenation activity) is obtained which is capable of converting unbranched alkanes into their branched isomers. In their experiments, Martens et al., used *n*-heptadecane (n-$C_{17}H_{36}$) as the model *n*-alkane. At low conversions, monobranched isomers with one methyl group are formed exclusively, namely 2-, 3-, 4-, 5-, and 6-methylhexadecane. Among them, 2-methylhexadecane, that is the isomer with the methyl branching near the end of the hydrocarbon chain, strongly predominates. Isomers with longer side chains (for example ethylpentadecanes or propyltetradecanes) are virtually absent, presumably due to the limited space in the relatively narrow pores of zeolite ZSM-22. The preponderance of methyl branching in the 2-position over this zeolite is in sharp contrast to what is typically observed with zeolites of larger pore widths (for example, zeolite Y): In such a large pore zeolite catalyst, methyl isomers having the branching at or near the center of the long chain are preferentially formed over those with terminal branching (which would be also expected on the basis of the reaction mechanism via protonated cyclopropanes[12]). Furthermore, isomers with ethyl or propyl branchings are also formed over large pore zeolites, even at low conversions. The pronounced selectivity of zeolite ZSM-22 for the formation of the terminal methyl-branched isomer (2-methylhexadecane) has been ascribed in a previous publication to a pore mouth catalysis mechanism, by which isoalkanes with the longest possible linear chain are favored.[13] In this picture, the catalytic reaction does indeed occur inside the pores of the zeolite, however, due to the slow diffusion of the reactant molecules, near the mouths of the pores. The recent work from the same research group takes this one step further.[11] It is postulated that 2-methylhexadecane, which is preferentially formed in the first branching step, arranges on the surface of the zeolite crystals in such a manner that the methyl group is pinned in one pore mouth while the rest of the molecule is stretched across an external [001] crystal face. The second branching is then introduced in a position were a neighboring pore mouth and its active site can be reached. In agreement with this hypothesis, of the 219 theoretically possible dibranched isoheptadecanes essentially only five are formed over zeolite ZSM-22, namely 2,7-, 2,8-, 2,9-, 2,10-, and 2,11-dimethylpentadecane. The distance between the two methyl branchings in these five compounds correlates well with the distance between two adjacent pore entrances in the [001] plane of the zeolite ZSM-22 surface. Supplementary experiments with selected additional reactant molecules (1-nonylcyclopentane; icosane (n-$C_{20}H_{42}$)) seem to support the concept advanced by Martens et al. The authors therefore concluded that, at least for the examples reported in their study, shape-selective catalysis at the external surface of zeolite crystals may occur during which the geometric arrangement of the pore mouths acts as a template for the positions of the methyl branchings. This model may be also helpful for a refined interpretation of previously reported results from the isomerization of long-chain *n*-alkanes over zeolite ZSM-22 and the structurally closely related zeolite ZSM-23.[14]

Although there is already important experimental evidence supporting the new concept advanced by Martens et al., there are still several questions that remain to be answered. For instance: Can the concept be transferred to other reactants and other zeolite structures? Which role do the active sites at the external surface of the zeolite crystals play? What is the influence of the crystal size (and, hence, the proportion of the external as compared to the total surface area) on activity and selectivity of the zeolite? The answers to these (and probably other) questions will determine the future acceptance of the proposed model by the scientific community.

Tetrasupersilyldiindium(*In–In*) and Tetrasupersilyldithallium(*Tl–Tl*): $(t\mathrm{Bu_3Si})_2\mathrm{M}-\mathrm{M}(\mathrm{Si}t\mathrm{Bu_3})_2$ (M = In, Tl)**

Nils Wiberg,* Kerstin Amelunxen, Heinrich Nöth, Martin Schmidt, and Holger Schwenk

Dedicated to Professor Heinz Peter Fritz

Donor-free, uncharged molecular compounds $(RM)_n$ and $(R_2M)_2$ with clusters formed from the boron homologues M = Al, Ga, In, Tl have—unlike such compounds with boron clusters[1]—only been known for about ten years. In fact, the compounds of the boron homologues have a tendency to disproportionate ($6\,RM \rightarrow 3\,R_2M + 3\,M \rightarrow 2\,R_3M + 4\,M$); however, this process can be stopped at the $(RM)_n$ stage (very bulky groups) or at the $(R_2M)_2$ stage (medium-sized bulky groups) by employing bulky substituents R such as C_5Me_5 (Cp*), $C_5(CH_2Ph)_5$ (Cp**), $CH(SiMe_3)_2$ (Disyl), $C(SiMe_3)_3$ (Trisyl), 2,4,6-$i\mathrm{Pr_3C_6H_2}$ (Trip), 2,4,6-$(CF_3)_3C_6H_2$ (R^F), $Si(SiMe_3)_3$ (Hypersilyl), and $Si t\mathrm{Bu_3}$ (Supersilyl). Known examples of R_4M_2 and $(RM)_n$ compounds with normal covalent M–M bonds are $[(Me_3Si)_2CH]_4M_2$ (M = Al, Ga, In),[1] (2,4,6-$i\mathrm{Pr_3C_6H_2}$)$_4M_2$ (M = Al, Ga),[2] $[2,4,6\text{-}(CF_3)_3C_6H_2]_4M_2$ (M = Ga, In),[1] or $[(Me_3Si)_3Si]_4Tl_2$,[3] and $(RAl)_4$ (R = $Si t\mathrm{Bu_3}$, Cp*),[4] $(RGa)_4$ (R = $C(SiMe_3)_3$,[1] $Si(SiMe_3)_3$[5]) or $[(Me_3Si)_3CIn]_4$,[6] respectively. Only very weak M–M interactions are present in the compounds $(Cp^*In)_6$[7] and $(Cp^{**}M)_2$ (M = In, Tl).[8]

It should be possible to stabilize compounds of the type $(RM)_n$ by using, as we have done previously, the readily accessible and chemically comparably inert supersilyl group.[4a] The ability of this group to potentially stabilize such compounds arises from its very high steric demand[9] and its prominent tendency to donate electrons to its bonding partners[1, 4c] with this donation having a cluster stabilizing effect. Indeed, the reaction of aluminum monochloride in toluene/diethyl ether[10] with supersilylsodium $t\mathrm{Bu_3SiNa}$ in dibutyl ether at −78 °C gave, among others, the deep violet tetraalatetrahedrane $(t\mathrm{Bu_3SiAl})_4$ **1** [Eq. (a)], which as expected was metastable (sublimation at 180 °C under high vacuum; Al–Al: calcd. 2.64 Å, Al–Al dissociation energy per edge of the tetrahedron: calcd. ca. 100 kJ mol^{-1}; for comparison $(Cp^*Al)_4$: thermolysis at 70 °C; Al–Al: found 2.77 Å; Al–Al dissociation energy per edge of the tetrahedron: calcd. 25 kJ mol^{-1}).[4, 11]

$$4\,\mathrm{AlCl} + 4\,t\mathrm{Bu_3SiNa} \xrightarrow[-4\,\mathrm{NaCl}]{\text{(toluene, } Et_2O, Bu_2O)} t\mathrm{Bu_3Si}-\mathrm{Al}\langle(\mathrm{Al}-\mathrm{Si}t\mathrm{Bu_3})_3 \quad \text{(a)}$$

1

To our surprise the reactions of indium bromide and thallium bromide with supersilyl sodium $t\mathrm{Bu_3SiNa}$ in tetrahydrofuran at −78 °C did not lead to the tetrahedranes $(t\mathrm{Bu_3SiM})_4$ (M = In, Tl)[6] but gave the diindium compound **2** and indium and the dithallium compound **3** and thallium, respectively, [Eq. (b)]. In addition, $t\mathrm{Bu_3SiH}$, $t\mathrm{Bu_3SiBr}$, and $(t\mathrm{Bu_3Si})_2$ were formed in these reactions.

$$4\,\mathrm{MBr} + 4\,t\mathrm{Bu_3SiNa} \xrightarrow[-4\,\mathrm{NaBr}]{\text{(THF)}} (t\mathrm{Bu_3Si})_2\mathrm{M}-\mathrm{M}(\mathrm{Si}t\mathrm{Bu_3})_2 + 2\,\mathrm{M} \quad \text{(b)}$$

2 (M = In); **3** (M = Tl)

That **2** and **3**, respectively, are formed in these reactions is probably a result of how the reaction was carried out, since the tetraindatetrahedrane $[(Me_3Si)_3CIn]_4$ is accessible from corresponding starting materials.[6] Possibly, **2** and **3** are formed on the surface of the MBr crystals, which are insoluble in THF. The formation of $(t\mathrm{Bu_3Si})_2$ in high yields indicates the existence of intermediary $t\mathrm{Bu_3Si}^{\cdot}$ radicals.

Compound **2** is obtained as deep violet and compound **3** as black-green crystals, which decompose at about 125 and about 52 °C, respectively. The thermolysis of **2** in [D$_8$]toluene at 40 °C occurs slowly ($t_{1/2} \approx 8$ d), that of compound **3** very quickly; $t\mathrm{Bu_3SiD}$ and $(t\mathrm{Bu_3Si})_2$ are formed in these reactions, together with other $t\mathrm{Bu_3Si}$-containing compounds and elemental thallium, respectively.[12] Compound **2** is attacked only very slowly by methanol at room temperature.[12]

The structures of compounds **2** and **3**, which crystallize isomorphically, were determined by X-ray diffraction (Fig. 1).[13] However, due to the decomposition of compound **3** in the X-ray beam, only its Tl and Si positions could be determined with sufficient precision; thus, in this case the crystal structure analysis should only be considered as evidence for the constitution of the compound. The central structural element of both compounds is the M–M grouping. The M atoms are each coordinated in a trigonal planar fashion by two Si atoms and one M atom; the $MMSi_2$ planes are orthogonal (Si-In-In-Si angle between 89.5 and 90.5°, Fig. 1). The high steric demand of the supersilyl groups leads to the very long M–M distances of 2.921 Å (**2**; for comparison $[(Me_3Si)_2CH]_4In_2$: 2.828 Å[1]) and 2.966 Å (**3**; for comparison $[(Me_3Si)_3Si]_4Tl_2$: 2.914 Å[3]). The angles between the MMR_2 planes are significantly smaller in R_4M_2 compounds with less bulky substituents R, (e.g. $[(Me_3Si)_2CH]_4M_2$:[1] 8° (M = Al), 5.0° (M = Ga), 6.7° (M = In); (2,4,6-$i\mathrm{Pr_3C_6H_2}$)$_4Ga_2$: 43.8°;[2] with regard to the conformation of R_4M_2 see ref.[1]). The Si-M-Si and M-M-Si angles in both compounds are about 130 and 115°, respectively. The C-Si-C angle (av 109.7°) of the supersilyl group $t\mathrm{Bu_3Si}$ in **2** is at the lower end of the normal range of 110–112° (extreme C-Si-C angles are exhibited by the very sterically bulky $(t\mathrm{Bu_3Si})_2$ (107.3°[9a]) and by the less bulky $t\mathrm{Bu_3SiH}$ (113.7°[14])).

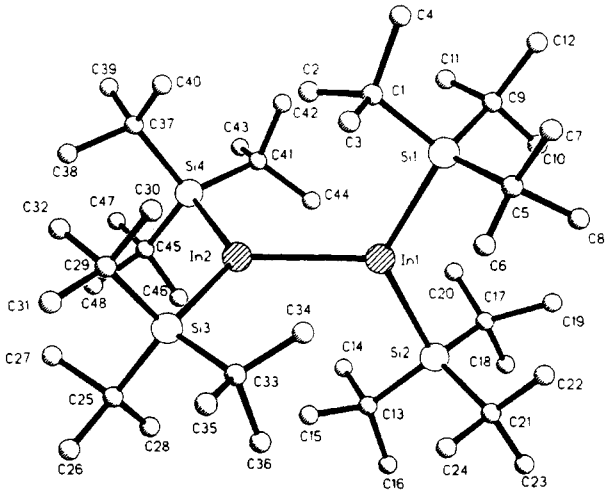

Fig. 1. Crystal structure of **2**. The H atoms were omitted for clarity. Important bond lengths [Å] and angles [°]: In1–In2 2.9217(11), In1–Si1 2.778(4), In1–Si2 2.779(4), In2–Si3 2.778(4), In2–Si4 2.778(4), Si1–C1 1.95(2), Si1–C5 1.94(2), Si1–C9 1.95(2) [mean value of Si–C distances 1.95], C1–C2 1.50(3), C1–C3 1.48(3), C1–C4 1.59(3); Si1-In1-Si2 129.43(11), Si3-In2-Si4 129.25(12), In2-In1-Si1 115.27(9), In2-In1-Si2 115.30(9), In1-In2-Si3 115.15(9), In1-In2-Si4 115.60(9), In1-Si1-C1 108.0(5), In1-Si1-C5 109.7(6), In1-Si1-C9 110.1(6), C1-Si1-C5 110.8(8), C1-Si1-C9 109.0(7), C5-Si1-C9 109.2(9) [mean value of the C-Si-C angles 109.7°]. Crystal structure of **3** (Tl instead of In in Fig. 1). The compound is isomorphic to **2**. Only the Tl and the Si positions can be given with sufficient precision: bond lengths [Å] and angles [°]: Tl1–Tl2 2.966(2), Tl1–Si1 2.801(11), Tl1–Si2 2.765(12), Tl2–Si3 2.800(12), Tl2–Si4 2.790(11) [the Tl–Si bond lengths are of the same length within the limits of error]; Si1-Tl1-Si2 130.3(4), Si3-Tl2-Si4 130.1(3), Tl2-Tl1-Si1 114.4(2), Tl2-Tl1-Si2 115.2(3), Tl1-Tl2-Si3 114.7(2), Tl1-Tl2-Si4 115.2(3) [the bond angles are the same within the limits of error].

Experimental Procedure

2: tBu$_3$SiNa (2.91 mmol) in THF (10 mL) was added dropwise to a suspension of InBr (0.566 g, 2.91 mmol) in THF (15 mL) at −78 °C. The deep brown reaction solution was stirred for 12 h at −78 °C and then allowed to slowly warm to room temperature. According to the ^{1}H NMR spectrum of the crude mixture, compound **2** (33%), tBu$_3$SiH (5%), tBu$_3$SiBr (4%), and (tBu$_3$Si)$_2$ (58%, yields based on the amount of tBu$_3$SiNa employed) were formed. All the volatile compounds were removed in the oil pump vacuum, the residue was taken up in pentane (20 mL) and the dark precipitate (In) was filtered off from the dark violet solution. Compound **2** (0.483 g, 0.47 mmol, 16.2%) precipiated from the latter solution at −23 °C within one week in the form of deep violet crystals. These dissolved very well in nonpolar solvents such as benzene and alkanes, but not very well in polar solvents such as THF and acetone. Heating the crystalline compound **2** obtained from pentane led to the evolution of a gas (pentane?) at 105 °C and subsequent decomposition at 125 °C which was accompanied by an irreversible change in color first to orange and then to black under concomitant formation of (tBu$_3$Si)$_2$. ^{1}H NMR (C_6D_6, TMS, internal): δ = 1.35 (s; 12 tBu); ^{13}C{^{1}H} NMR (C_6D_6, TMS, internal): δ = 26.82 (12 CMe_3), 34.00 (12 CMe_3); ^{29}Si NMR (C_6D_6, INEPT, TMS, external): δ = 76.83 (4 SitBu$_3$); MS: m/z: 513 [$(M/2)^+$]; C,H analysis ($C_{48}H_{108}In_2Si_4$, 1027.4): calcd. C 56.12, H 10.60; found 55.75, H 10.53.

3: tBu$_3$SiNa (2.88 mmol) in THF (10 mL) was added dropwise to a suspension of TlBr (0.826 g, 2.88 mmol) in THF (15 mL) at −78 °C. The resulting solution changed color first to red, then green, and finally brown. The reaction mixture was stirred for 12 h at −78 °C and then slowly allowed to warm to room temperature. According to the ^{1}H NMR spectrum of the crude mixture, compound **3** (27%), tBu$_3$SiH (12%), tBu$_3$SiBr (4%), and (tBu$_3$Si)$_2$ (57%, yields based on the amount of tBu$_3$SiNa employed) were formed [15]. All the volatile compounds were removed in the oil pump vacuum, the residue was taken up in Et$_2$O (20 mL), and the dark precipitate (Tl) was filtered off from the deep green solution. Compound **3** (0.314 g, 0.26 mmol, 9.0%) precipiated from the latter solution at −23 °C within one week in the form of black-green crystals. Compound **3** exhibited a similar solubility to **2**. It decomposed above 52 °C with a change in color to black and concomitant formation of silyl compounds such as (tBu$_3$Si)$_2$. ^{1}H NMR (C_6D_6, TMS, internal): δ = 1.32 (d; ^4J(H,Tl) = 6.7 Hz; 12 tBu); ^{13}C{^{1}H} NMR (C_6D_6, TMS, internal): δ = 28.57 (d, ^2J(C,Tl) = 155.8 Hz; 12 CMe_3), 33.12 (d, ^3J(C,Tl) = 49.9 Hz; 12 CMe_3); ^{29}Si NMR (C_6D_6, INEPT, TMS, external): δ = 100.2 (d, $^1J(^{29}Si,^{205}Tl)$ = 1451, $^1J(^{29}Si,^{203}Tl)$ = 1436 Hz; 4 SitBu$_3$); MS: m/z: 601/603 [$(M/2)^+$; with ^{203}Tl and ^{205}Tl, respectively]; C,H analysis ($C_{48}H_{108}Tl_2Si_4$, 1206.4): calcd. C 47.79, H 9.02; found 53.54, H 10.08.

[11] Additional information to ref.[4a] (established together with H. Schnöckel, T. Passler, C. Dohmeier): On warming a solution of AlCl (4.70 mmol) in toluene/Et$_2$O [10] (20 mL) and tBu$_3$SiNa (4.75 mmol) in Bu$_2$O (25 mL) from −78 °C, the solution became dark red at about 0 °C. According to the ^{1}H NMR spectrum of the crude mixture, tBu$_3$SiH (60%), (tBu$_3$Si)$_2$ (27%), and **1** (13%) are formed together with intermediary traces of a radical (as revealed by the ESR spectrum which shows a line-rich signal indicating a species containing three Al atoms). Compound **1** could so far not be isolated by crystallization from the reaction solution; however, by sublimation of the reaction mixture at 180 °C under high vacuum, **1** was obtained as a deep violet, X-ray amorphous, pentane-soluble, oxygen- and moisture-sensitive solid. ^{1}H NMR (C_6D_6, TMS, internal): δ = 1.35 (br., 12 tBu); ^{29}Si NMR (C_6D_6, TMS, external): δ = 15.34 (br., 4 SitBu$_3$); ^{27}Al NMR (C_6D_6, Al(NO$_3$)$_3$, external in D$_2$O): δ = 64.48 (line width = 148 Hz); MS: m/z: 904 [M^+].
[12] N. Wiberg, K. Amelunxen, unpublished results. Additional properties of **2** and **3**: Compound **2** reacted with AgF$_2$ in heptane at room temperature to give among others (tBu$_3$Si)$_2$InF ($C_{24}H_{54}FInSi_2$ (532.7); ^{1}H NMR (C_6D_6, TMS, internal): δ = 1.27 (s, 6 tBu); ^{29}Si NMR (C_6D_6, INEPT, TMS, internal): δ = 50.27 (d, ^2J(Si,F) = 6.5 Hz; 2 SitBu$_3$); MS: m/z: 532 [M^+]). Its thermolysis in C_6D_6 at 40 °C yields tBu$_3$SiF, (tBu$_3$Si)$_2$, and In. The reaction of **3** with AgF$_2$ in Et$_2$O at room temperature led, possibly via (tBu$_3$Si)$_2$TlF, to tBu$_3$SiF, (tBu$_3$Si)$_2$, and Tl. The reaction of **2** with Na in C_6D_6 at 40 °C led after 3 d to tBu$_3$SiNa, (tBu$_3$Si)$_2$, tBu$_3$SiD, tBu$_3$SiC$_6$D$_5$, and In, whereas the reaction of **3** with Na in C_6D_6 at 40 °C led after 1 d to tBu$_3$SiNa, tBu$_3$SiD as well as to two additional tBu$_3$Si-containing compounds and Tl. Compound **3** shows a line-rich ESR signal in C_6D_6 at room temperature (dissociation in intermediary (tBu$_3$Si)$_2$Tl$^{\cdot}$ radicals?). Compounds **2** and **3** are intensely colored (deep violet and black green; in comparison [(Me$_3$Si)$_2$CH]$_4$In$_2$ and [2,4,6-(CF$_3$)$_3$C$_6$H$_2$]$_4$In$_2$: orange [1]; [(Me$_3$Si)$_3$Si]$_4$Tl$_2$: dark red [3]), which might be attributed to the presence of radicals such as (tBu$_3$Si)$_2$Tl$^{\cdot}$.
[13] Crystallographic data of **2**: $(C_{48}H_{108}In_2Si_4 \cdot C_5H_{12}$, M_r = 1027.34): a = 20.471(3), b = 15.553(3), c = 41.746(6) Å, β = 99.84(1)°, V = 13095(4) Å^3, monoclinic, space group $C2/c$, Z = 8, ρ_{calcd} = 1.042 g cm^{-3}, μ = 8.01 cm^{-1}, $F(000)$ = 4400. Crystal dimensions = 0.6 × 0.6 × 0.5 mm^3. The single crystal was mounted in perfluoroether oil and all measurements were performed at 183 K. Data collection: ω scans, 2θ = 3–50° in $-24 < h < 3$; $0 < k < 18$; $-47 < l < 48$. 11816 measured reflections, 10938 symmetry independent, 6720 with $F > 4\sigma(F)$, max/min transmission: 0.645/0.569. Structure solution and refinement: heavy atom method, full matrix refinement against F^2, 604 parameters refined, 105 restraints, R_1 = 0.086, $wR2$ = 0.229, GOF = 1.129; largest residual electron density = 1.889 e Å^{-3}. The non-hydrogen atoms were refined with anisotropic temperature parameters, the H atoms were included into the refinement in calculated positions with a riding model. The temperature factors indicated that the *tert*-butyl groups were rotationally disordered. For eight of these 36 methyl groups this disorder was taken into consideration by refinement of the sites into two positions. The relatively large residual electron density, which was not located near the In or Si atoms, indicated the presence of a possible additional disordered solvent molecule in the unit cell. Crystallographic data of **3** ($C_{48}H_{108}Tl_2Si_4$, M_r = 1206.4): a = 20.309(6),

$b = 15.387(4)$, $c = 41.57(2)$ Å, $\beta = 99.44(3)^\circ$, $V = 12814.5$ Å^3, monoclinic, space group $C2/c$, $Z = 8$, $\rho_{calcd} = 1.251$ g cm^{-3}, $\mu = 51.2$ cm^{-1}, $F(000) = 4912$. Crystal mounted in perflouroether oil; measurements at 213 K. Data collection: ω scans, $2\theta = 3-46^\circ$ in $h, k, \pm l$. 7738 measured reflections, 7354 of which were independent and 4339 with $F > 4\sigma(F)$. Structure solution and refinement: heavy atom method, Tl and Si atoms anisotropically refined, C atoms isotropically. The structure solution converged without inclusion of H atoms and possible solvent molecules at $R_1 = 0.135$, $wR2 = 0.417$, GOF = 1.097. The crystal decomposed considerably during the measurement; the measurement was stopped when the intensity of two standard reflections became smaller than 50%, which is why the C atoms were not refined anisotropically. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-404429.

[14] S. H. Down, L. S. Wartell, *J. Molec. Struct.* **1980**, *67*, 249.

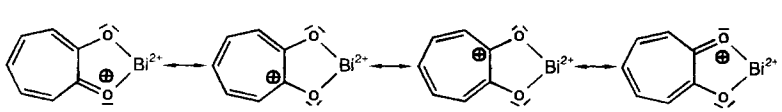
[15] The solution contains an additional tBu$_3$Si-containing thallium compound in traces [^{29}Si NMR (C_6D_6, INEPT, TMS, external): $\delta = 99.79$ (d, $^1J(^{29}Si,^{205}Tl) = 1652$, $^1J(^{29}Si,^{203}Tl) = 1636$ Hz)]. This compound was formed from the reaction of CpTl with tBu$_3$SiNa in THF (red reaction solution) in higher yields.

Synthesis and Structure of Seven-Coordinate Bismuth(v) Complexes with Benzenoid and Non-Benzenoid Arene Ligands: Tri(aryl)tropolonatobismuth(v) Complexes**

Uwe Dittes, Bernhard Klaus Keppler,* and Bernhard Nuber

To obtain stable bismuth(v) compounds, starting materials are required that behave as strongly electronegative bonding partners or, at least, show rather large group electronegativities, as is true for substituted phenyl groups and similar aromatic systems.[1] By far the best known example of an arylbismuth(v) compound is pentaphenylbismuth which was prepared by G. Wittig and K. Clauss, and later crystallographically characterized in 1987.[2, 3] Many of the bismuth(v) compounds prepared to date are five-coordinate; the synthesis of the hexaphenylbismutate complex ion provided a six-coordinate bismuth(v) ion.[4, 5] Tri(organo)bismuth sulfonates and tri(aryl)bismuth dicarboxylates are compounds for which a five- and seven-coordinate bismuth(v) ion, respectively, are discussed.[6–9] Little information is available regarding the biological activity of bismuth(v) compounds, since most of these complexes are too unstable for biological and medicinal studies. We now report the synthesis of tri(aryl)tropolonatobismuth(v) complexes that are suitable for such investigations.

Tropolone and its derivatives are well-studied non-benzenoid aromatic systems.[10] Following removal of the proton of the hydroxy group, metals can bind to the two oxygen atoms, resulting in the formation of chelates (Scheme 1). Tropolonatobismuth(III) complexes are stable compounds that have been shown to exhibit biological activity, for example, against *Helicobacter pylori* bacteria, which are responsible for gastritis and other gastrointestinal diseases.[11] The heretofore unknown tropolonatobismuth(v) complexes might have similar properties and for this reason we decided to pursue their synthesis and characterization.



Scheme 1. Mesomeric structures of the tropolone ligands in the tropolonato complexes.

Treatment of diacetetotri(aryl)bismuth(v) compounds with tropolone derivatives results in the cleavage of the two acetate groups and their exchange for two tropolone rings. Diacetatotri(phenyl)bismuth(v) **4** can be prepared readily in ether from triphenylbismuth and acetic acid in the presence of *tert*-butylhydroperoxide.[12] We employed this method to synthesize diacetatotri(*p*-tolyl)bismuth(v) **1** in good yield. The reaction of **1** with tropolone **2** in methanol (heating under reflux for 30 min, yield 69%) led to water- and air-stable yellow crystals of di(*O,O*-tropolonato)tri(*p*-tolyl)bismuth(v) **3**, suitable for a crystal structure analysis (Fig. 1).[13] Complex **3** has a distorted pentagonal-bipyramidal structure; the base of the pyramid comprises a tolyl group (C17) and two tropolone rings (twist angle 11.7°). The remaining two tolyl groups occupy axial positions; the angle between them (C32-Bi1-C20) is 158.8°. The interaction between the oxygen atoms of the tropolone rings and the bismuth atom leads to Bi–O bonds of different lengths; two are shorter (Bi–O1 2.316, Bi–O3 2.310 Å) and two are longer (Bi–O2 2.497, Bi–O4 2.455 Å). Opposite bonds are of approximately similar length. The measured Bi-O-C angles lie in the range 119.5–121.5°, a finding consistent with sp^2-hybridization of the oxygen atoms. For the short Bi–O bond lengths we expected elongation of the corresponding C–O bonds, since the electron pull exerted by the bismuth atom and transmitted through the oxygen atom should weaken the C–O bond. This prediction was indeed confirmed for the O3–C8 bond (1.286 Å) and the O4–C14 bond (1.263 Å); however, the short Bi–O1

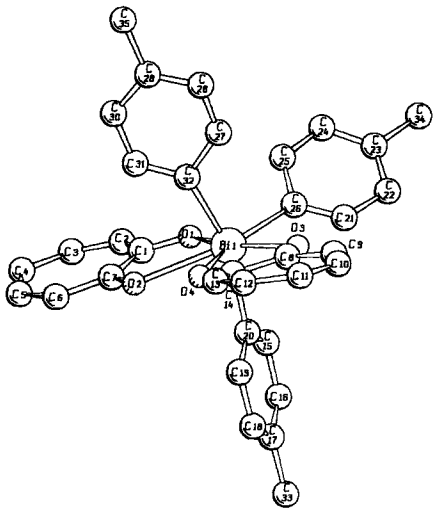


Fig. 1. Molecular structure of **3** in the crystal. Selected distances [Å] and angles [°]: Bi(1)-O(1) 2.317(16), Bi(1)-O(2) 2.498(15), Bi(1)-O(3) 2.310(16), Bi(1)-O(4) 2.456(14), Bi(1)-C(20) 2.215(23), Bi(1)-C(26) 2.156(24), Bi(1)-C(32) 2.119(28), O(1)-C(1) 1.266(31), O(2)-C(7) 1.316(33), O(3)-C(8) 1.286(26), O(4)-C(14) 1.263(31); O(1)-Bi(1)-O(2) 67.6(6), O(1)-Bi(1)-O(3) 156.7(5), O(2)-Bi(1)-O(3) 134.7(5), O(1)-Bi(1)-O(4) 137.4(5), O(2)-Bi(1)-O(4) 70.0(5), O(3)-Bi(1)-O(4) 65.7(5), C(20)-Bi(1)-C(26) 101.7(9), C(1)-Bi(1)-C(32) 93.5(8), O(2)-Bi(1)-C(32) 82.4(7), O(3)-Bi(1)-C(32) 96.0(8), O(4)-Bi(1)-C(32) 76.9(8), C(20)-Bi(1)-C(32) 158.8(9), C(26)-Bi(1)-C(32) 99.4(9), Bi(1)-O(1)-C(1) 121.5(14), Bi(1)-O(2)-C(7) 112.6(13), Bi(1)-O(3)-C(8) 120.7(14), Bi(1)-O(4)-C(14) 119.5(13).

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

bond (2.316 Å) is accompanied by a short C1–O1 bond (1.266 Å), and the long Bi–O2 bond (2.497 Å) is accompanied by a long C7–O2 bond (1.315 Å). The Bi–C distances in **3** range from 2.119–2.215 Å, differing at most by 4.5% from each other; the observed bond lengths are within the range of values previously reported for covalent Bi–C bonds. This finding provides conclusive evidence that the central bismuth atom is seven-coordinate.

We obtained a second seven-coordinate bismuth(v) complex in 73.8% yield in an analogous way by treating diacetatotri(phenyl)bismuth(v) **4** with 5-nitrotropolone **5**.[14] Di(*O*,*O*-5-nitrotropolonato)tri(phenyl)bismuth(v) **6** is likewise air-stable and exhibits a similarly distorted, albeit more symmetric, pentagonal-bipyramidal structure as **3** (Fig. 2).[15] One phenyl ring

Fig. 2. Molecular structure of **6** in the crystal. Selected distances [Å] and angles [°]: Bi(1)-O(1) 2.594(14), Bi(1)-O(2) 2.315(15), Bi(1)-C(13) 2.141(18), Bi(1)-C(17) 2.391(39), Bi(1)-O(1A) 2.594(14), Bi(1)-O(2A) 2.315(15), Bi(1)-C(13A) 2.141(18), O(1)-C(1) 1.243(27), O(2)-C(7) 1.282(30); O(1)-Bi(1)-O(2) 64.7(5), O(1)-Bi(1)-O(1A) 72.3(6), O(2)-Bi(1)-O(1A) 137.1(5), O(1)-Bi(1)-O(2A) 137.1(5), O(2)-Bi(1)-O(2A) 158.2(7), O(1A)-Bi(1)-O(2A) 64.7(5), C(13)-Bi(1)-C(13A) 154.8(7), C(17)-Bi(1)-C(13A) 102.6(3), O(1A)-Bi(1)-C(13A) 76.5(7), O(2A)-Bi(1)-C(13A) 87.9(10), Bi(1)-O(1)-C(1) 114.6(13), Bi(1)-O(2)-C(7) 126.2(13), O(1)-Bi(1)-C(13) 76.5(7), O(2)-Bi(1)-C(13) 87.9(10), O(1)-Bi(1)-C(17) 143.8(3), O(2)-Bi(1)-C(17) 79.1(4).

(C17) and the tropolone rings, which are twisted relative to each other by only 2°, collectively form the base of the pentagonal pyramid. The two remaining phenyl groups occupy axial positions; the measured axial Bi–C distances are the same length (Bi–C13(A) 2.141 Å) and the angle between the phenyl groups is 154.8°. The bonding between the tropolone oxygen atoms and the bismuth atom corresponds to that previously discussed for **3**: the tropolone oxygen atoms are also sp^2-hybridized (Bi-O-C angles 114.6, 126.3°). A long C–O distance (C7(A)–O2(A) 1.281 Å) follows a short Bi–O distance (Bi–O2(A) 2.315 Å), and a short C–O distance (C1(A)–O1(A) 1.243 Å) follows a long Bi–O distance (Bi–O1(A) 2.593 Å). The Bi–C17 (2.390 Å) bond is markedly longer than the other two axial Bi–C bonds (2.141 Å) making it one of the longest Bi–C bonds reported to date. The NMR spectra of complexes **3** and **6** in $CDCl_3$ not only show a significant shift of the tropolone ring protons to lower field, but also loss of the partial C=O double bond character.[16] The latter was also apparent in the shift of the C=O stretching frequencies in the IR spectrum to lower wavenumbers. This finding can be rationalized in terms of ligand deshielding by the electron-pulling nature of the coordinated bismuth(v) cation.

Stability studies show that the new complexes **3** and **6** do not undergo decomposition in aqueous medium, which is attributed to the steric shielding of the bismuth(v) cation. Thus, compounds **3** and **6** are suitable for studying the biological properties of these classes of complexes.

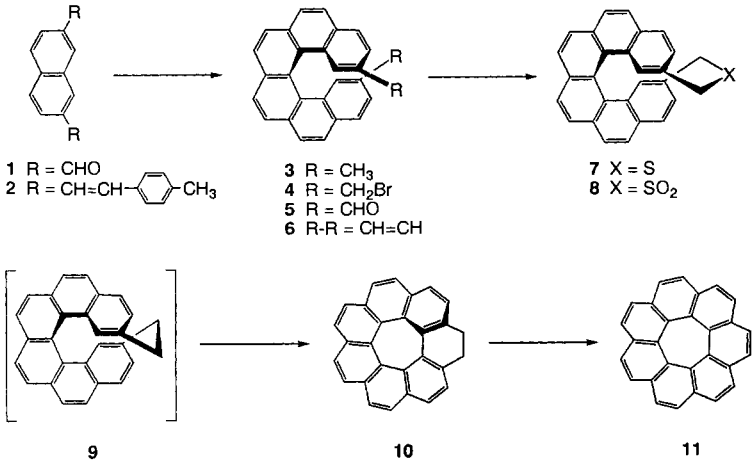
Convenient New Synthesis of [7]Circulene**

Koji Yamamoto,* Hiroyuki Sonobe,
Hiroshi Matsubara, Masaaki Sato,
Susumu Okamoto, and Kazuo Kitaura*

Recent advances in carbon cluster chemistry (fullerenes) have renewed the interest in nonplanar polycyclic aromatic compounds with a circular arrangement of benzene rings, known as circulenes.[1] We previously reported the preparation of [7]circulene **11**[2] (pleiadannulene)[3] whose twisted, saddle-shaped structure resulting from a circular arrangement of seven benzene rings can be considered as a subunit of the inner surface of helix-shaped nanotubes.[4] We report here a convenient new synthesis of **11** via the 2,15-ethano-bridged hexahelicene intermediate **9**, and the electrochemical properties of **11**.

The Wittig condensation of 2,7-naphthalenedicarboxaldehyde **1**[5] with triphenyl-*para*-xylylphosphonium bromide in sodium methoxide/DMF gave a mixture of stereoisomers **2**.



This mixture was dissolved in benzene and irradiated with a high-pressure mercury lamp[6] for 2 h to give 2,15-dimethylhexahelicene **3** (m.p. 212–214 °C, 59% yield from **1**).[7] Bromination of **3** with *N*-bromosuccinimide afforded the dibromide **4** (m.p. 196–198 °C, 40%),[8] which was oxidized with *O*-natrio-2-*aci*-nitropropane in ethanol/benzene to give the dialdehyde **5** (m.p. 202–204 °C, 72%).[9]

Although, reductive coupling of **5** to give the bridged hexahelicene **6** by using low-valent titanium[10] was unsuccessful, invariably giving a polymer as the product, intramolecular cyclization of **4** with sodium sulfide nonahydrate in refluxing benzene/ethanol afforded the hexahelicene sulfide **7** (m.p. 252–254 °C, 48% yield)[11] whose oxidation with hydrogen peroxide gave the sulfone **8** (m.p. >300 °C) in quantitative yield. Flash vacuum pyrolysis (550 °C, 0.01 Torr) of **8** gives the dihydro[7]circulene **10** directly which, as expected from the examination of its molecular model, has a chiral, saddle-shaped structure (yellow prisms, m.p. 225–227 °C, 24% yield)[12] and was isolated by chromatography on silica gel.

The mechanism for this striking transformation presumably involves the initial formation of the ethano-bridged hexahelicene **9** by pyrolysis, followed by dehydrogenation at both ends of the hexahelicene.[13] MM3 calculations[14] predict a strain energy about 32.2 kcal mol^{-1} for **10**, which should make it more than 12 kcal mol^{-1} more stable than **9** (44.3 kcal mol^{-1}). The 500 MHz ^{1}H NMR spectrum of **10** in $CDCl_3$ shows a single peak for the two enantiotopic methylene groups at room temperature ($\delta = 2.70$), but sets of peaks for the aliphatic hydrogens centered at $\delta = 2.98$ and 3.75 at -50 °C ($\Delta\nu = 149.5$ Hz) characteristic of an AA'BB' pattern. The coalescence temperature for those two signals was found to be -10 °C, from which we calculate the barrier for ring inversion in **10** to be $\Delta G^{\ddagger} = 12.2$ kcal mol^{-1} at this temperature.

Finally, dehydrogenation of **10** with 5% Pd/C in 1-methylnaphthalene at 280 °C for 3 h led to [7]circulene **11** (m.p. 295–296 °C, 85% yield) with a twisted saddle-shaped geometry.[2]

The electrochemical properties of **11** were examined by cyclic voltammetry. The voltammograms exhibited one irreversible oxidation peak and two reduction waves, the first of which was reversible, the second irreversible, as in the case of coronene itself (Table 1). A comparison of the oxidation and redox potentials of **11** with those of coronene[15] indicate that it is easier to remove or add electrons to **11**. This observation reveals that structures such as **12** and **13** make a large contribution to the electronic structure of the radical cation and anion, respectively, of the non-alternated benzenoid hydrocarbon **11**.[16]

For a better understanding of the radical ions of [7]circulene, ab initio MO calculations were performed with the GAUSSIAN 92 program.[17] The calculated HOMO energy of [7]circulene is -7.1 eV at the 3-21G SCF level, whereas that of coronene is -7.3 eV.[18] Thus the calculations predict that the ionization potential is smaller for [7]circulene than for coronene, which is consistent with the observed redox potentials. The geometry optimizations of the radical cation and anion of **11** were carried out at the STO-3G UHF level. The doublet spin state was assumed for both ions. Both of the calculated geometries are saddle-shaped with C_2 symmetry, and are remarkably similar. They are also very similar to the structure of the neutral molecule.

Table 1. Results of cyclic voltammetric studies [a].

Compound	E_{ox} [b, d]	E_{red1} [c, e]	E_{red2} [c, f]
coronene	+0.90	−2.05	−2.47
11	+0.73	−1.94	−2.29

[a] Tetrabutylammonium perchlorate (0.2 mol dm^{-3}) as a supporting electrolyte, scan rate 0.3 Vs^{-1}, at 25 °C. [b] Potential in Volts vs. Ag/Ag$^+$ with a glassy carbon working electrode in dichloromethane. [c] Potential in Volts vs. SCE with a hanging mercury drop working electrode in DMF. [d] Irreversible oxidation. [e] Reduction peak potential of a quasi-reversible redox reaction. [f] Irreversible reduction.

The major differences are that the out-of-plane distortion is a little greater and that the bonds *a* and *b* are about 0.05 Å longer in the radical ions. This suggests some contribution of the localized Kekuléan forms **12** and **13** or of other unidentified localized forms to the resonance hybrids of cation and anion. Details of the calculations will be reported elsewhere.

We are currently investigating the potentially fascinating chemistry of **11** including the energy barrier for the inversion of the twisted saddle structure in mono-substituted derivatives and the synthesis of metal complexes.

2-Nucleos-5′-*O*-yl-4*H*-1,3,2-benzodioxaphosphinin-2-oxides—A New Concept for Lipophilic, Potential Prodrugs of Biologically Active Nucleoside Monophosphates**

Chris Meier*

Nucleoside analogues such as 3′-azido-2′,3′-dideoxythymidine (AZT), 2′,3′-dideoxy-2′,3′-didehydrothymidine (d4T), 2′,3′-dideoxyinosine (ddI), and 2′,3′-dideoxycytidine (ddC) are used in antiviral chemotherapy against AIDS.[1] One of the major problems in the use of this type of compounds is the intracellular bioavailability of their 5′-phosphorylated derivatives. One concept to overcome this limitation is the intracellular delivery of the 5′-monophosphates from prodrugs ("kinase-bypass").[2] In view of the high antiviral activity of nucleoside analogues, the development of nucleotide prodrugs is a challenging goal.[3]

As part of our ongoing program[4] to develop new prodrug systems, the synthesis of the title compounds **3a–e** and **4a–e** of the nucleoside analogues 2′,3′-dideoxythymidine (ddT) **1** and d4T **2**, respectively, bearing different donor and acceptor substituents on the benzene ring is reported. Furthermore the partition coefficients of **3** and **4** in 1-octanol/phosphate buffer and their hydrolysis behavior in phosphate buffer (pH 7.5) at 37 °C will be discussed.[4a, 5]

The approach reported here differs from other prodrug concepts in that it leads to nucleotides after a *coupled* cleavage of the phenyl- and the benzylester bond in the phosphotriesters **3** and **4**, respectively. The difference in hydrolytic stability of phenyl-[6] and benzylphosphotriesters[7, 8] has already been reported: whereas *acceptor*-substituted phenylphosphotriesters are rapidly hydrolyzed under alkaline conditions, a fast hydrolysis of benzylphosphotriesters was only observed in the case of their *donor*-substituted derivatives.[9] Regardless of the type of phosphotriester, the resulting phosphodiesters are very stable against nonenzymatic hydrolysis.[10] The herein reported prodrug concept of the title compounds **3** and **4** uses precisely this difference in stability of the phenyl and the benzyl phosphate esters for the design of a three-parted prodrug for the selective liberation of phosphorylated nucleosides. The hydrolysis should proceed as follows: in the initial step the phenolic phosphate ester bond is cleaved selectively, since the resulting negative charge can be delocalized over the phenolic oxygen atom in the aromatic ring. The acceptor substituent in the *ortho* position prevents the cleavage of the benzylester bond. As a consequence of this cleavage, together with the "umpolung" of the substituent in the *ortho* position to the methylene group, the second step, the cleavage of the 2-hydroxybenzyl group is induced. The presence of the electron-donating substituent allows cleavage of the benzylic phosphate ester bond, releasing the nucleotides **7** or **8** and the 2-hydroxybenzyl alcohols **9**[3d, 9] (tandem-reaction; Scheme 1).

Furthermore, according to this concept it should be possible to control the initial activation step by varying the substituents in the *para* position to the phenolic phosphate ester bond. For this reason, different *para*-substituted salicyl alcohols **9a, b, d, e** were used as precursors in the synthesis of **3** and **4**. In addition, the different substitution in the *para* position allows one to

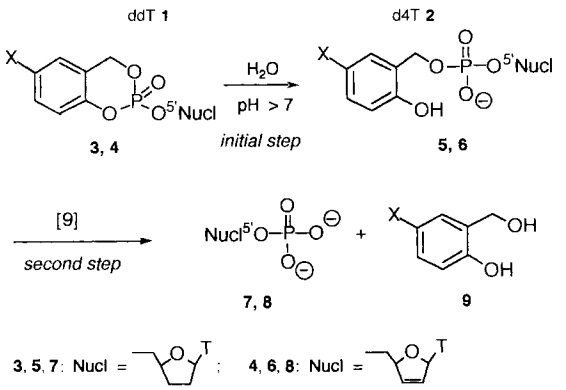
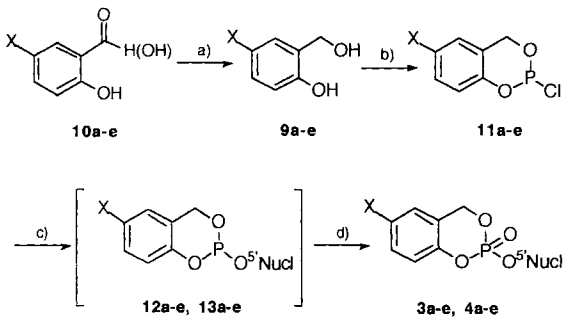


Scheme 1. Hydrolytic degradation of the title compounds **3** and **4** following the tandem mechanism. X = donor or acceptor substituent (see Table 1).

study which of the two steps is rate-determining for the liberation of the nucleotide. Prior to hydrolysis, the phosphotriesters **3** and **4** serve as lipophilic, neutral prodrugs.

The 2-chloro-4*H*-1,3,2-benzodioxaphosphinines **11**, used as starting materials for the synthesis of the cyclic phosphotriesters **3** and **4**,[11] were isolated by distillation under an argon atmosphere in 60–80% yield. The target compounds **3a–e** and **4a–e** were obtained in a one-pot reaction by reacting the nucleoside analogues **1** or **2** with 1.5 equivalents of the chlorophosphinines **11a–e** at 0 °C in the presence of distilled diisopropylethylamine (DIPEA) to give the phosphites **12a–e**, **13a–e** and subsequent in situ oxidation with *tert*-butylhydroperoxide (Scheme 2).



Scheme 2. Synthesis of the title compounds **3a–e** and **4a–e** (X see Table 1, Nucl see Scheme 1). a) $NaBH_4$ ($LiAlH_4$); b) PCl_3, pyridine, Et_2O, −10 °C, 2 h; c) ddT **1** (gives **3** via **12**) or d4T **2** (gives **4** via **13**), DIPEA, CH_3CN, 0 °C, 20 min; d) *t*BuOOH, CH_3CN, 20 °C, 30 min.

After purification (70–85% yield) the phosphotriesters **3** and **4** were obtained as 1:1.2 diastereomeric mixtures with respect to the configuration at the phosphorus atom (Table 1). The diastereomers were not separable in all cases by common chromatographic procedures, but could be distinguished by ^1H, ^{13}C, and ^{31}P NMR spectroscopy. Furthermore **3** and **4** were characterized by circular dichroism (CD),[12] UV spectroscopy, and electrospray mass spectrometry (negative mode).

As a qualitative estimation of the lipophilic properties of the described compounds their partition coefficients (log(PC) values) in 1-octanol/phosphate buffer (pH 6.5) were determined[13] (Table 1). All compounds **3** and **4** showed positive log(PC) values and partition coefficients a factor of 8.1 to 50.5 higher than those of the parent nucleosides ddT **1** and d4T **2**, respectively (Table 1). Consequently, the passive diffusion through a membrane should be easier for these compounds than for the free nucleoside.

Table 1. Partition coefficients and half-lives of the title compounds **3** and **4** and their dependence on the substituents X. Compound **3** is hydrolyzed to **7** and **9**, and compound **4** is hydrolyzed to **8** and **9**. σ_p = Hammett parameters.

[a] In 1-octanol/phosphate buffer (pH 6.5). [b] In 30 mM phosphate buffer (pH 7.5) at 37 °C.

As a model for the physiological milieu, hydrolysis studies of the new phosphotriesters **3** and **4** were carried out in 30 mM phosphate buffer (pH 7.5) at 37 °C.[14] In all studied cases, **3** and **4** were degraded following pseudo-first order kinetics. The nucleoside monophosphates of ddT **7** or d4T **8** as well as the salicyl alcohols **9** were detected by HPLC analysis as the exclusive products of the hydrolysis. Furthermore, the identification of **7** and **8** was accomplished directly from the hydrolysis mixture by electrospray mass spectrometry. In an additional hydrolysis experiment, the degradation of triester **3d** in borate buffer (30 mM, pH 9) was studied by ^{31}P NMR spectroscopy. Only one signal, which showed the characteristic chemical shift of nucleoside monophosphates and a triplet fine splitting, was observed in the ^{31}P NMR spectrum. Besides the selective hydrolysis to the nucleoside monophosphate, the expected effect of the substitution of the aromatic ring on the $t_{1/2}$ values as well as on the rate-determining step was observed. In the case of the donor-substituted derivatives of **3** and **4**, only their decrease and the increase of the nucleoside monophosphates **7** and **8** could be followed by HPLC. In contrast, the intermediate phosphodiesters **5d**, **5e** and **6d**, **6e**, respectively, were also detected for the acceptor-substituted derivatives **3d**, **3e** and **4d**, **4e**. Consequently, in the latter cases the second step (**5**, **6** → **7**, **8**) is rate-determining (Scheme 1). These results are consistent with the postulated pathway for the hydrolysis shown in Scheme 1.[15] In all studies, no difference was detected between the ddT or the d4T derivatives (Table 1). As a result, the donor-substituted compounds of **3** and **4** should act as suitable prodrugs because their hydrolytic stability ($t_{1/2}$ value) seems to be sufficiently high (Table 1).

In summary, it has been possible for the first time to deliver phosphate monoesters of type **7**, **8** selectively and in a controllable manner from a phosphotriester hydrolytically at physiological pH according to the newly developed tandem-reaction. Thus, an enzymatically catalyzed activation is not a prerequisite for the liberation of nucleotides. We are currently investigating the hydrolysis of **3** and **4** in a RPMI-culture medium containing 10% fetal calf serum, as well as the antiviral activity of our compounds against HIV-1 and HIV-2.

Experimental Procedure

To a solution of dried nucleoside **1** or **2** (0.64 mmol) in acetonitrile (10 mL), diisopropylethylamine (DIPEA) (1.27 mmol) was added at 0 °C. Then the cyclic chlorophosphinines **11** (2.0 equiv., 1.28 mmol in 1 mL acetonitrile) were slowly added. The generated phosphites **12** and **13**, respectively, were oxidized in situ with *tert*-butylhydroperoxide (200 μL) after 20 min. After evaporation of the solvent, the residue was purified by chromatography on a Chromatotron (solvent gradient of

ethyl acetate and methanol: 40–30% methanol). Further purification was achieved by semipreparative HPLC (70–85% yield). After lyophilization the triesters **3** and **4** were isolated as colorless solids.

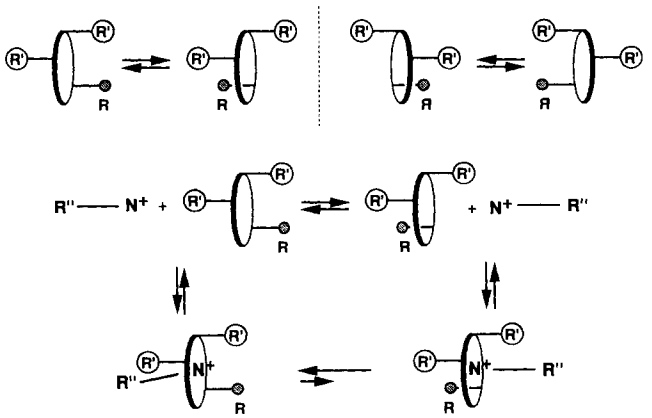
[15] It should be mentioned that at pH < 7 no or only a very slow hydrolysis of **3** or **4** was observed, whereas at pH > 7 a pH-dependent hydrolysis occurred.

Chiral Recognition of α-Amino Acid Derivatives with a Homooxacalix[3]arene: Construction of a Pseudo-C_2-Symmetrical Compound from a C_3-Symmetrical Macrocycle

Koji Araki, Kousuke Inada, and Seiji Shinkai*

The NH_3^+ moiety of primary alkylammonium ions (RNH_3^+) possesses C_3 symmetry, and therefore complementary hosts might best possess C_3 symmetry as well. In chiral molecules with two complexing faces, the importance of having the two faces related by C_2 symmetry has been emphasized.[1] A chiral guest molecule interacts identically with the homotopic faces of this type of chiral host. Therefore, for the enantioselective recognition of primary alkylammonium ions, it is desirable for a chiral host molecule to possess a C_2 axis perpendicular to a local C_3 symmetry element. Satisfying these requirements is quite difficult. [18]Crown-6 is one of the few compounds that has these two local symmetry elements—at least when it binds K^+ or RNH_3^+ ions in the solid state. In fact, several chiral [18]crown-6 derivatives are known to bind racemic substrates containing NH_3^+ centers with high enantioselectivity.[2] Here we describe how such a host molecule for chiral recognition can be prepared from a homooxacalix[3]arene.

As the starting material we chose 7,15,23-tri-*tert*-butyl-25,26,27-trihydroxy-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (**1**H_3),[3] which possesses C_3 symmetry[4] and shows high affinity for primary alkylammonium ions.[5] When two hydroxyl groups in **1**H_3 are converted into ethers (R′) with bulky alkyl groups, which can suppress rotation of the phenylene group, and the third hydroxyl group is transformed into an ether (R) having a small alkyl group, the product, *anti*-**1**RR'_2, is optically active. It behaves like a C_2-symmetrical macrocycle as a result of the free rotation of the phenylene group having the less bulky ether group (Scheme 1). A guest



Scheme 1. Schematic representation of the binding of an RNH_3^+ ion (R″–N^+) to a pseudo-C_2-symmetric host.

molecule meets the "same chiral face" of *anti*-**1**RR'_2 regardless of the direction from which it approaches. For this reason we consider *anti*-**1**RR'_2 to have "pseudo-C_2-symmetry".

It is known that rotation of the phenylene groups in **1**H_3 can be suppressed when the substituent on the O atom is bulkier than an *n*-propyl group.[5a] In this study we used *n*-butyl groups (R′ = Bu) to fix the conformation. The reaction of **1**H_3 and *n*-butyl iodide in the presence of NaH gave *anti*-**1**HBu_2 in 48% yield (Scheme 2). Although the unmodified OH group can still pass through the ring, this calix[3]arene is already optically active. As the smaller R group, which can also pass through the annulus, we chose the methyl group. The OH group in *anti*-**1**HBu_2 was methylated with methyl iodide and NaH to give *anti*-**1**$MeBu_2$ in 70% yield. The IR spectrum and elemental analysis data were in satisfactory agreement with expected values. X-ray crystallographic analysis of *anti*-**1**$MeBu_2$ shows that one of the OBu groups is directed upward and the second downward, and that the OMe group points downward (Fig. 1).[6, 7] However, the ^1H NMR spectra of *anti*-**1**$MeBu_2$ are characteristic of a C_2-symmetrical structure: two singlets are observed for the *t*Bu protons with a 1:2 integral intensity ratio, and these signals did not split into doublets even at −85 °C. The results

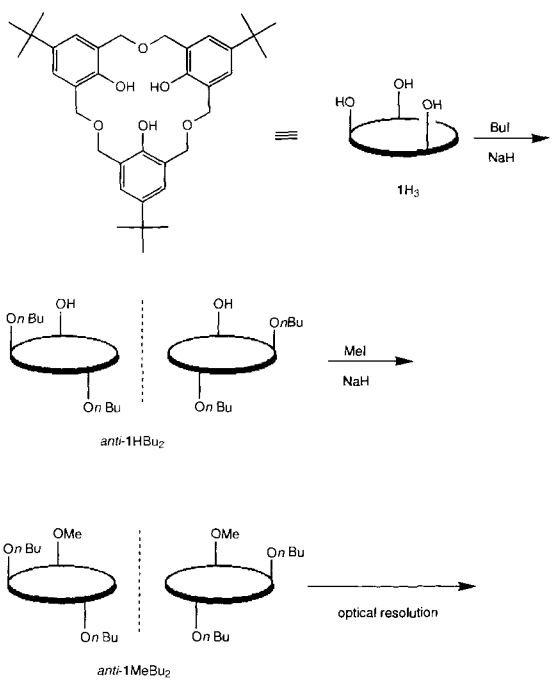

Scheme 2. Synthesis of the pseudo-C_2-symmetrical macrocycle *anti*-$1MeBu_2$ starting from the C_3-symmetrical compound $1H_3$.

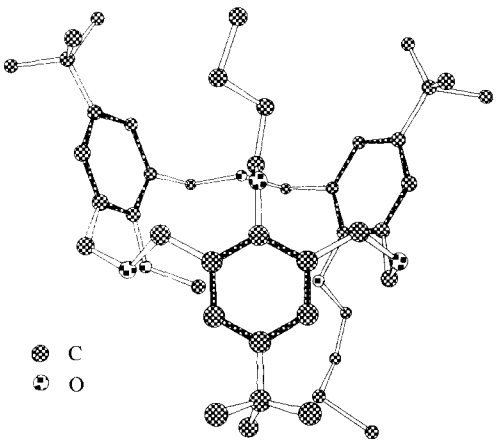

Fig. 1. X-ray crystal structure of *anti*-$1MeBu_2$; only one of the two molecules in the unit cell is shown.

can be explained by two possibilities: either the OMe group lies in the plane of the homooxacalix[3]arene resulting in C_2 symmetry, or in solution the OMe group rotates rapidly on the NMR time scale to give pseudo-C_2-symmetry. However, judging from CPK molecular models and MM3 computations, the first possibility is not likely.[8]

We measured ^1H NMR spectra of *anti*-$1MeBu_2$ in the presence of L-phenylalanine ethyl ester hydrochloride (25 °C, $CDCl_3/CD_3CN$ (3/1), 250 MHz). Most of the signals split into pairs, indicating that *anti*-$1MeBu_2$ is a pair of enantiomers. This compound can bind primary alkylammonium ions through hydrogen-bonding interactions with three oxygen atoms. Judging from the chemical shift changes of $1MeBu_2$, at least two phenolic oxygens and possibly an oxygen atom from à CH_2OCH_2 group may be involved. CPK molecular models indicate that it is sterically impossible for the oxygen atoms from three CH_2OCH_2 groups to form hydrogen bonds with RNH_3^+ ions.

To obtain further insight into the complex structure we measured NOE spectra of the complex of $1MeBu_2$ and neopentylammonium picrate. When the resonance frequency of the *tert*-butyl protons in the neopentyl group was irradiated, the difference NOE signal for the ArH protons in the OMe-substituted phenylene unit was larger than that for those in the OBu-substituted phenylene unit (Fig. 2). This result clearly shows that the alkyl group of this guest is located in the cavity formed by an OMe-substituted and one OBu-substituted phenylene ring.

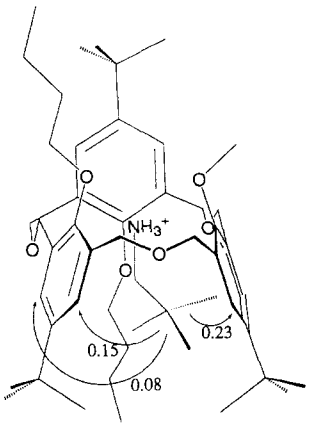

Fig. 2. NOE signal intensities of the ArH protons on irradiation of the resonance frequency of the *t*Bu protons in the *anti*-$1MeBu_2$/neopentylammonium complex (5.0×10^{-3} mol dm^{-3}, 25 °C, $CDCl_3/CD_3CN$ (3/1)).

anti-$1MeBu_2$ was optically resolved by HPLC method (Chiralpak OP(+), *n*-hexane/2-propanol (1/1)). The first fraction ((−)-*anti*-$1MeBu_2$) and the second fraction ((+)-*anti*-$1MeBu_2$) gave symmetrical CD spectra with $\lambda_{max} = 232$ nm and $\theta_{max} = \pm 20200$ deg cm^2 dmol^{-1} (Fig. 3).

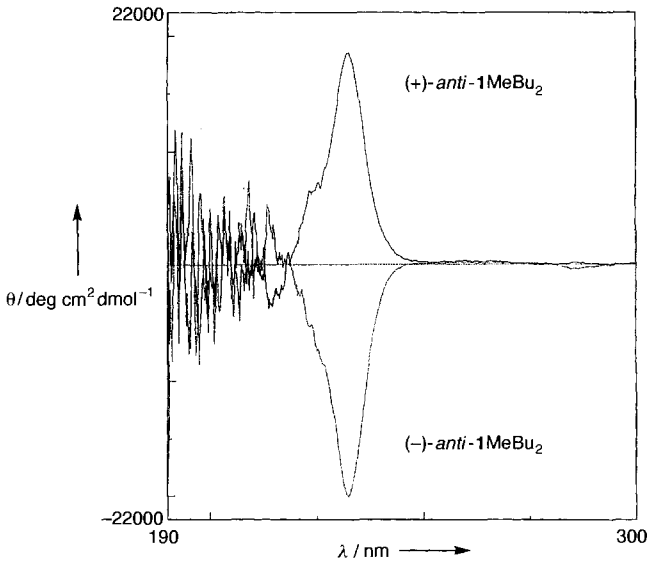

Fig. 3. CD spectra of (−)- and (+)-*anti*-$1MeBu_2$ (1.0×10^{-3} mol dm^{-3}, 25 °C, *n*-hexane).

The association constants (K_{ass}) for α-amino acid ethyl ester picrates and 1-arylethylammonium picrates were determined at 25 °C in chloroform/THF (99/1) by monitoring the change in the absorption spectrum ([picrate] = 1.00×10^{-5} mol dm^{-3}, [*anti*-$1MeBu_2$] = $(0.2-14)\times10^{-5}$ mol dm^{-3}, λ_{max}(picrates) = 345 nm, λ_{max}(complexes) = 380 nm; Table 1).[9] Plots of the absorption A_{380} versus [*anti*-$1MeBu_2$] give an inflection point at [*anti*-$1MeBu_2$]/[picrate] = 1.0, indicating that the complexes have a 1:1 stoichiometry. The association constants for the L-configurated isomers are greater with (−)-*anti*-$1MeBu_2$ than with (+)-*anti*-$1MeBu_2$. The largest chiral discrimination (74% *ee*) was observed for the picrate salt of L-phenylalanine ethyl ester.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3501-0073 $ 10.00+.25/0

Table 1. Association constants K_{ass} [$dm^3 mol^{-1}$] for the complexes of *anti*-1MeBu$_2$ and picrate salts of α-amino acid ethyl esters and 1-arylethylamines (25 °C, chloroform/THF (99/1)).

Picrate salt	(−)-*anti*-1MeBu$_2$	(+)-*anti*-1MeBu$_2$	K_{ass} (large)/K_{ass} (small)
L-alanine ethyl ester picrate	4500	3200	1.4
L-phenylalanine ethyl ester picrate	1200	180	6.7
(*R*)-1-phenylethylamine picrate	2200	3000	1.4
(*R*)-1-naphthylethylamine picrate	2000	2400	1.2

The foregoing results prove that the molecular design concept proposed in this paper, a pseudo-C_2-symmetrical compound based on a C_3-symmetrical skeleton, is very effective for chiral recognition of optically active primary alkylammonium ions. We believe that the chiral discrimination ability of *anti*-1RR$'_2$ can be further enhanced by elaborating the bulkiness and polarity of the substituents R and R'.

[4] Strictly speaking, 1H$_3$ may not be C_3-symmetrical since the direction of OH groups (above, below the annulus) and the conformation of the ArCH$_2$OCH$_2$Ar groups may be in constant flux. However, the complementarity of 1H$_3$ with C_3-symmetrical RNH$_3^+$ ions described here indicates that this molecule can be considered to be C_3-symmetrical.

[7] "Upward" and "downward" have been defined by Gutsche et al. (S. Kanamathareddy, C. D. Gutsche *J. Am. Chem. Soc.* **1993**, *115*, 6572).

[8] This structure is difficult to construct with CPK molecular models, because the bulky OMe group must be included in the cavity of the homooxacalix[3]arene. MM3(92) calculations also predict that the most stable conformations of 1MeBu$_2$ are cone and partial-cone, whereas the structure in which the MeO group is lies in the plane of the ring is much less stable (by at least 1.5 kcal).

A Convergent, Enantioselective Total Synthesis of Hapalosin: A Drug with Multidrug-Resistance Reversing Activity**

Arun K. Ghosh,* Wenming Liu, Yibo Xu, and Zhidong Chen

Hapalosin (**1**), a novel cyclodepsipeptide isolated recently[1] from the blue-green alga *Hapalosiphon welwitschii*, has shown important multidrug-resistance reversing activity.[2] The term multidrug-resistance (MDR), is defined as the ability of tumor cells exposed to one drug to develop cross resistance to seemingly unrelated drugs. This phenomenon is apparently caused by an overexpression of P-glycoprotein, a 170–200 kDa transmembrane protein that acts as an ATP-dependent drug efflux pump.[3] As a consequence, chemotherapy very often becomes ineffective. Thus, the agents that are capable of reversing this P-glycoprotein-induced MDR effect, may have therapeutic potential for patients undergoing cancer chemotherapy. Preliminary biological studies indicated that hapalosin inhibits the P-glycoprotein efflux pump.[1] Also, hapalosin has already been shown to have better MDR-reversing activity than verapamil which is currently under active investigation to test the MDR-reversing hypothesis in the clinic.[4] The structure of hapalosin was assigned by Moore et al.[1] through spectroscopic and degradation studies. Besides important MDR-reversing activity, one of the intriguing features of hapalosin is that the molecule exists as a mixture of two conformers, as shown by ^{1}H and ^{13}C NMR spectroscopy. Perhaps, only one of these conformers is responsible for the potent MDR-reversing activity. In order to study the structure–function relationships as well as to gain information regarding the bioactive conformation, we sought a flexible, enantioselective synthesis of hapalosin. We describe here a convergent and stereocontrolled first total synthesis of hapalosin.

The synthesis of (3*R*,4*S*-4-(*N*-benzyloxycarbonyl-*N*-methylamino)-3-methoxymethoxy-5-phenylpentanoic acid **5** was carried out stereoselectively starting from Weinreb amide **2** (Fig. 1).[5] Treatment of **2** with allylmagnesium bromide (2.2 equiv) in THF at −20 °C afforded the corresponding ketone, which was subsequently reduced with sodium borohydride in propanol at 0 °C to provide the alcohol **3** as a mixture (5:1) of diastereomers in 73% yield.[6] The isomers were separated by chromatography (silica gel, 15% ethyl acetate/hexane). Protection of the major isomer **3** as a methoxymethyl (MOM) ether followed by *N*-methylation with sodium hydride (2 equiv) and methyl iodide (3 equiv) in a mixture of THF/DMF (10:1) at 23 °C afforded the protected amino alcohol **4** in 68% yield after silica gel chromatography.[7] The cleavage of the double bond in **4** with ruthenium trichloride and excess of sodium periodate in a mixture of acetonitrile, carbon tetrachloride, and water at 23 °C for 12 h provided the acid **5** in 84% yield.[8]

The protected β-hydroxy acid **7** was conveniently prepared by an asymmetric aldol reaction utilizing an (1*S*,2*R*)-aminoindan-2-ol derived chiral auxiliary.[9] Thus, reaction of *n*-octanaldehyde and the corresponding chiral propionimide using di-*n*-butylboryl trifluoromethanesulfonate and triethylamine at −78 °C furnished the aldol product **6** in 90% yield after silica

gel chromatography.[10, 11] The hydroxyl group was protected as the tetrahydropyranyl ether by treatment with dihydropyran (2 equiv) and a catalytic amount of pyridinium *p*-toluenesulfonate in CH_2Cl_2 at 23 °C for 6 h. The removal of chiral auxiliary was effected with lithium hydroperoxide under standard reaction conditions[12] to provide the acid **7** in 84% yield. Alcohol **8** was prepared by diazotization[13] of L-valine and subsequent esterification with benzyl alcohol in the presence of dicyclohexylcarbodiimide (DCC) (2 equiv) and dimethylaminopyridine (DMAP) (2 equiv) in CH_2Cl_2.[14] The acid **7** was esterified by reaction with 2,4,6-trichlorobenzoyl chloride (1.0 equiv), triethylamine (1.2 equiv), and alcohol **8** (1.2 equiv) to afford the diester **9** in 91% yield.[15] The removal of the THP protecting group of **9** with *p*-toluenesulfonic acid in methanol followed by esterification of the resulting alcohol with acid **5** using an analogous procedure to that described above furnished the tri-ester derivative **10** in 76% yield.[16] Catalytic hydrogenation of **10** over Pearlman's catalyst in ethyl acetate under a hydrogen filled balloon for 5 h provided the requisite precursor **11** for macrocyclization.[17] The amino acid **11** was subjected to macrocyclization conditions without further purification. Thus, the desired cyclization was effected by slow addition of a solution of **11** in DMF with a syringe pump to a mixture of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (1.5 equiv) and HOBt (1.5 equiv) in the presence of triethylamine (3 equiv) in DMF (0.01 molar solution) at 60 °C to furnish the macrolactam **12** ($[\alpha]_D^{23} = -80.8$, $c = 0.7$, CH_2Cl_2; 30–37% yield after silica gel chromatography). Attempts to improve the yield of the cyclization step by using a variety of reagents and reaction conditions have so far been unsuccessful. Interestingly, the ^1H NMR (400 MHz) spectrum of macrolactam **12** ($CDCl_3$) revealed the presence of a 2:1 mixture of conformers at 23 °C. Removal of the MOM protecting group[18] of **12** by exposure to tetra-*n*-butylammonium bromide (5 equiv) and trimethylsilyl chloride (5 equiv) in CH_2Cl_2 at 23 °C for 24 h furnished the synthetic (−)-hapalosin **1** ($[\alpha]_D^{23} = -40.9$, $c = 0.11$, CH_2Cl_2; ref. [1], $[\alpha]_D^{23} = -49.2$, $c = 0.35$, CH_2Cl_2) as a mixture (2:1) of conformers at 23 °C. Spectral data (IR and 400 MHz ^1H NMR) for the major conformer is identical to that reported for the natural product.[1] The R_f value (0.3 in $MeOH/H_2O$ 9/1) is also identical to the reported value. Thus, the synthesis of hapalosin has provided confirmation of the absolute configurational assignments. To gain insight into the bioactive conformation of hapalosin, we are currently studying the design and synthesis of conformationally restricted structural variants of hapalosin.

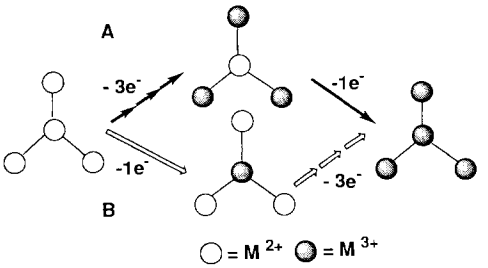
Proton-Induced Switching of Electron Transfer Pathways in Dendrimer-Type Tetranuclear $RuOs_3$ Complexes**

Masa-aki Haga,* Md. Meser Ali, and Ryuichi Arakawa

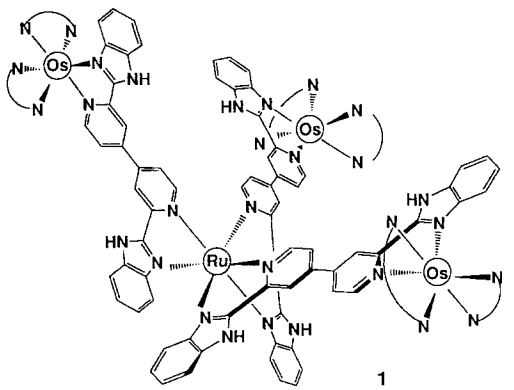
Supramolecular complexes as precursors for molecular devices have attracted much attention in recent years.[1] Molecular switching by an external stimulus is one of the fundamental functions of supramolecular complexes. Protonation can act as an external trigger in complexes containing basic sites. Recently, protonation has been shown to induce the switching of fluorescence,[2] redox properties,[3] and electron transfer reactions.[3a,4] The chemical principle underlying the switching of redox potential, for example the reversible protonation of an uncoordinated nitrogen site in 2-(2-pyridyl)benzimidazole Ru complexes, has been developed.[3a,c] We have extended this chemistry to dendrimer-type tetranuclear complexes. Two oxidation patterns shown have been reported in ligand-bridged dendrimer tetranuclear complexes (Scheme 1).[5] Pattern A consists of simultaneous oxidation of three peripheral Os^{II} atoms at almost the same potentials prior to one-electron oxidation of the central Ru^{II} atom. Pattern B is the reverse. The two redox patterns can be interchanged by protonation/deprotonation of basic sites.



Scheme 1. Two redox patterns in dendrimer-type ligand-bridged tetranuclear metal complexes.

Complex **1** is composed of a central Ru^{II} atom surrounded by three pyridine and three benzimidazole ligands, which are complexed to three $Os^{II}(bpy)_2$ units (Scheme 2). The coordination of Ru and Os by ligands containing extra Brönsted basic sites makes the redox potentials of the metal sensitive to ligand protonation/deprotonation reactions.

$[\{Os(bpy)_2(bbbpyH_2)\}_3Ru](ClO_4)_8$ **1**-$(ClO_4)_8$
bpy = 2,2′-bipyridine
$bbbpyH_2$ = 2,2′-bis(benzimidazol-2-yl)-4,4′-bipyridine



Scheme 2. Schematic representation of **1**.

Complex **1**-$(ClO_4)_8$ was synthesized by the reaction of $RuCl_3 \cdot 3H_2O$ with $[Os(bpy)_2(bbbpyH_2)](ClO_4)_2$ using the "complexes-as-ligands" strategy. Complex **2**-$(ClO_4)_2$, the perchlorate salt of the fully deprotonated product, was obtained by reaction of **1**-$(ClO_4)_8$ with an equimolar amount of sodium methoxide.

$[\{Os(bpy)_2(bbbpy)\}_3Ru](ClO_4)_2$ **2**-$(ClO_4)_2$

The cyclic voltammogram of the perchlorate salt of **1** in CH_3CN with 0.15 mM $HClO_4$ (Fig. 1, top) shows two oxidation waves centered at + 0.38 and + 0.71 V (versus ferrocenium/ferrocene (Fc^+/Fc)), which are assigned to three-electron $Os^{II/III}$-based and one-electron $Ru^{II/III}$-based oxidations, respectively. In the cyclic voltammogram of the fully deprotonated complex **2** (Fig. 1, bottom) the order of the two waves is reversed, and they are shifted to − 0.34 V and + 0.06 V. Thus, deprotonation has switched the site of the first oxidation from the peripheral Os

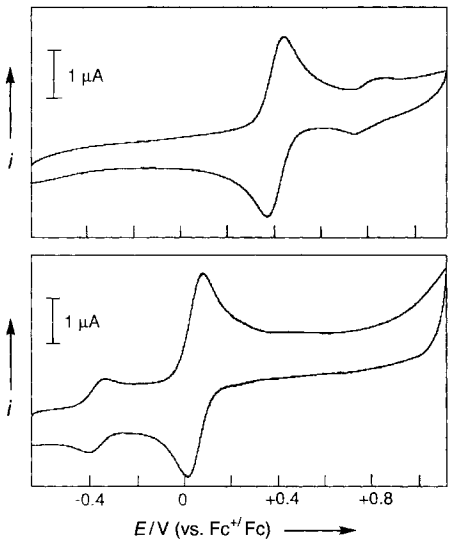

Fig. 1. Cyclic voltammograms of **1**-$(ClO_4)_8$ (top) and **2**-$(ClO_4)_2$ (bottom) in CH_3CN (0.1 M NBu_4BF_4; with added 0.15 mM $HClO_4$ for **1**-$(ClO_4)_8$) recorded with a Pt working electrode at a scan rate of 0.1 Vs^{-1}.

centers to central Ru site. This change is accompanied by negative potential shifts.

Plots of the oxidation potential $E_{1/2}$ versus pH (Pourbaix diagrams, Fig. 2) give lines with slopes of 60 and 120 $mVpH^{-1}$ for the Os- and Ru-based oxidations, respectively, which cross around pH 5.

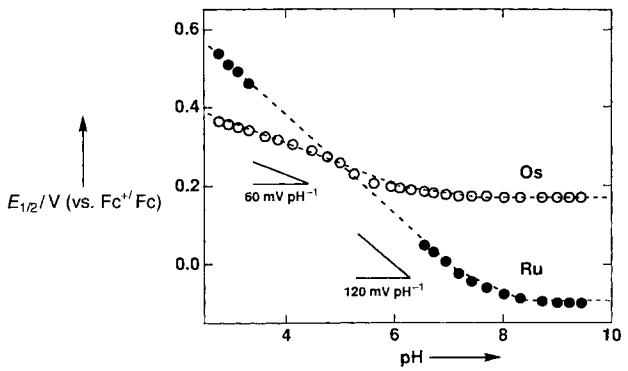

Fig. 2. Plots of the oxidation potential versus pH (Pourbaix diagrams) for **1**-$(ClO_4)_8$ in CH_3CN/Britton-Robinson buffer (1/1) at 25 °C. In this diagram the pH value refers to the apparent pH, which is a direct reading of a pH meter in CH_3CN/Britton-Robinson buffer (1/1).

The one-electron oxidized form of the deprotonated complex $\mathbf{2}^+$ ($Ru^{III}Os^{II}_3$) was generated quantitatively by bulk electrolysis at -0.2 V. The rotating disk voltammogram of this one-electron oxidation product in CH_3CN is shown in Figure 3. The cathodic current at negative potentials is due to the one-electron $Ru^{III} \rightarrow Ru^{II}$ reduction at $E_{1/2} = -0.34$ V. The anodic current is due to the three-electron oxidation $Os^{II} \rightarrow Os^{III}$ of the peripheral sites at $E_{1/2} = +0.06$ V (Fig. 3a).

Following acidification of this solution, positive potential shifts and reversed order of the $3e^-$ and $1e^-$ processes were observed. A significant observation in this case is that a small part of the cathodic current, which is superimposed on the anodic current, remained for the three-electron Os-based process at $E_{1/2} = +0.38$ V. This observation indicates that the electron

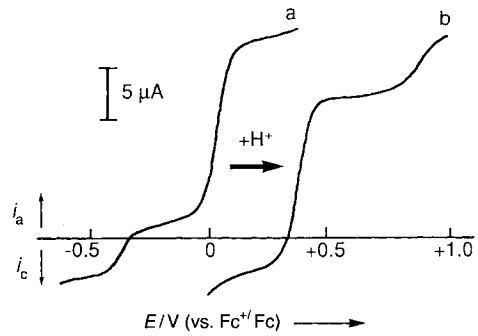

Fig. 3. Rotating disk voltammograms of the deprotonated complex $\mathbf{2}^+$ after one-electron oxidation in CH_3CN (0.1 M NBu_4BF_4) before (a) and after (b) addition of $HClO_4$ (1 mM). The voltammograms were recorded with a glassy-carbon electrode at a rotation rate of 1000 rpm and sweep rate of 0.02 Vs^{-1}.

transfer from the peripheral Os^{II} sites to the central Ru^{III} moiety occurs upon protonation. Addition of base (NBu_4OH) to the acidic solution restores the original voltammogram. Therefore, the process is reversible. To confirm the electrochemical detection of the proton-induced electron transfer reaction, the near-IR spectrum of the complex after one-electron oxidation was recorded. After one-electron oxidation the deprotonated complex does not show absorption in the near-IR region, but protonation induces a drastic change: new bands at 1050, 1900, and 2300 nm appear (Fig. 4). The latter two can be assigned to $d\pi-$

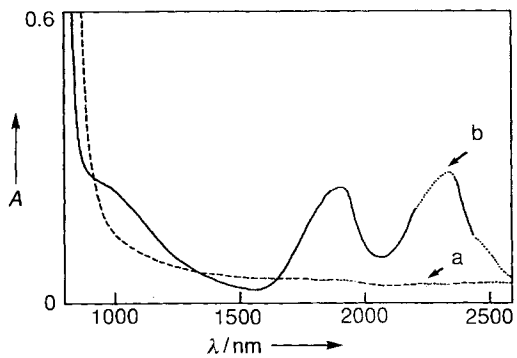

Fig. 4. Near-IR spectra of the deprotonated complex $\mathbf{2}^+$ after one-electron oxidation ($d = 1$ cm, $c = 0.7$ mM) in CH_3CN (0.1 M NBu_4BF_4) before (a) and after (b) addition of $HClO_4$ (1 mM). A = absorption in arbitrary units.

$d\pi$ transitions within the Os^{III} part of the complex.[6] The band at 1050 nm may be assigned to the Ru^{II} to Os^{III} intervalence charge transfer band. Thus, the Os→Ru electron transfer reaction [Eq. (a)] can be induced by protonation of the ligand Brönsted basic sites.

$$[\{Os^{II}(bpy)_2(bbbpy)\}_3Ru^{III}]^{3+} + 6H^+ \longrightarrow [\{Os^{III}(bpy)_2(bbbpyH_2)\}\{Os^{II}(bpy)_2(bbbpyH_2)\}_2Ru^{II}]^{9+} \quad (a)$$

A similar proton-induced electron transfer reaction has been reported for related dinuclear RuOs complexes.[4a,b]

Experimental Procedure

1-$(ClO_4)_8$: A suspension of $RuCl_3 \cdot 3H_2O$ (0.026 g, 0.1 mmol) in 20 mL of glycerol was stirred at 100 °C under nitrogen for 1.5 h. During this period, the color of the suspension changed to green. Then $[Os(bpy)_2(bbbpyH_2)](ClO_4)_2 \cdot 2H_2O$ (0.34 g, 0.3 mmol) was added, and the solution temperature was maintained at 120 °C for 24 h. The violet solution was cooled to room temperature, and 50 mL of H_2O was added to the solution. A saturated solution of $NaClO_4$ was added until complete

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3501-0077 $ 10.00+.25/0

precipitation occurred. The precipitate was collected by filtration and dissolved in a minimum amount of CH_3CN. This solution was loaded onto an SP-Sephadex C-25 column and eluted with CH_3CN/buffer (1/1) by raising the pH of the solution. The desired tetranuclear complex was eluted by adjusting the solution pH to 7.5 with 0.05 M NaCl. The eluate was collected and concentrated by evaporation to half its volume. The complex was precipitated from the resulting solution by addition of $NaClO_4$. The precipitate was collected by filtration and dried under vacuum. Yield: 0.18 g (50%). UV/Vis(CH_3CN): λ_{max} (ε) = 708 (18800), 535 (78800), 345 (118000), 291 nm (221000). Electrospray MS [7]: m/z 1089 $[M-3X^-]^{3+}$, 1055.4 $[M-4X^-+H^+]^{3+}$, 1022.7 $[M-5X^-+2H^+]^{3+}$, 988.4 $[M-6X^-+3H^+]^{3+}$, 955.2 $[M-7X^-+4H^+]^{3+}$, 794.6 $[M-4X^-]^{4+}$, 768.5 $[M-5X^-+H^+]^{4+}$, 743.3 $[M-6X^-+2H^+]^{4+}$, 718.1 $[M-7X^-+3H^+]^{4+}$, 693.8 $[M-8X^-+4H^+]^{4+}$, 595.7 $[M-6X^-+H^+]^{5+}$, 575.4 $[M-7X^-+2H^+]^{5+}$, 555 $[M-8X^-+3H^+]^{5+}$, 496.5 $[M-6X^-]^{6+}$, 480 $[M-7X^-+H^+]^{6+}$, 462.9 $[M-8X^-+2H^+]^{6+}$, where $M = C_{132}H_{96}N_{30}O_{32}Cl_8RuOs_3$, $X^- = ClO_4^-$. Satisfactory C, H, N analysis was obtained for the salt with the formula $C_{132}H_{96}N_{30}O_{32}Cl_8RuOs_3 \cdot H_2O$.

2-$(ClO_4)_2$: A solution of **1**-$(ClO_4)_8$ (0.16 g, 0.045 mmol) in methanol (25 mL) was added to a solution of sodium methoxide formed by the addition of sodium metal (0.006 g, 0.26 mmol) to methanol (3 mL). The mixture was stirred for 10 min with heating and then cooled. The black solution was concentrated to half of its volume and kept in a refrigerator. Analytically pure black microcrystalline solid was obtained. Yield: 0.09 g (69%). UV/Vis (CH_3CN): λ_{max} (ε) = 596 (54000), 513 (55700), 465sh, 347 (108000), 294 nm (203000). Electrospray MS [7]: m/z 922.1 $[M-2X^-+H^+]^{3+}$, 718.1 $[M-X^-+3H^+]^{4+}$, 693.8 $[M-2X^-+2H^+]^{4+}$, 574.6 $[M-X^-+4H^+]^{5+}$, 554.6 $[M-2X^-+3H^+]^{5+}$, 462.7 $[M-2X^-+4H^+]^{6+}$, where $M = C_{132}H_{90}N_{30}O_8Cl_2RuOs_3$ and $X^- = ClO_4^-$. Satisfactory C, H, N analysis was obtained for the salt with the formula $C_{132}H_{90}N_{30}O_8Cl_2RuOs_3 \cdot 33H_2O$.

[7] The electrospray ionization mass spectra of both **1**-$(ClO_4)_8$ and **2**-$(ClO_4)_2$ in CH_3CN can be explained by the general formulas $[M-nX^-+mH]^{(n-m)+}$ for **1**-$(ClO_4)_8$ and $[M-nX^-+mH]^{(n+m)+}$ for **2**-$(ClO_4)_2$, where n and m are the numbers of perchlorate anions and protons, respectively. This spectra indicates that protonation/deprotonation reactions occur during the ionization [8].

$[N(CH_3)_4][Mn(N_3)_3]$: A Compound with a Distorted Perovskite Structure through Azido Ligands**

Franz A. Mautner, Roberto Cortés, Luis Lezama, and Teófilo Rojo*

In the last few years the azide ion has been shown to be a very versatile ligand in bridging different transition metals. By using its two possible bridging modes, end-to-end (EE) and end-on (EO), dinuclear,[1–3] tetranuclear,[4] one-dimensional (1D),[2b, 5] and two-dimensional (2D) polymeric complexes[6] have been characterized for the azido ligand. The EE bridges give rise to antiferromagnetic interactions,[5a–c] the EO bridges lead to ferromagnetic coupling[1, 3] even for the manganese(II) ion with $S = 5/2$,[7] and in a 1D compound containing both types of bridging, alternating ferro- and antiferromagnetic interactions are observed.[5d]

Three-dimensional (3D) compounds are of interest in the field of molecular magnets because on the one hand they should help researchers gain a better understanding of the correlation between magnetism and structure, and on the other hand 3D antiferro- or ferromagnets are attractive for possible technical applications. Only a few molecular magnets based on 3D systems are known; however, by employing the versatile coordination ability of the azido ligand it should be possible to tailor systems of this kind.

With this aim in mind we developed a synthesis strategy in which the six vacant coordination sites around the metal ion could be filled by azido ligands. To obtain the desired conformation of a 3D system, the tetramethylammonium ion was selected as positive counterion because of its small size. By using this method, we isolated a 3D Mn^{II} compound of the empirical formula $[N(CH_3)_4][Mn(N_3)_3]$. To our knowledge, this is the first three-dimensional azide compound.

The crystal structure (Fig. 1)[8] of the room temperature phase may be described as a distorted Perovskite structure, that is, the Mn^{II} ion is shifted from the origin of the unit cell by about 0.25 along the b axis. The azido groups act as end-to-end bridging ligands between the manganese centers, thereby forming the three-dimensional network. Each manganese ion shows a slightly distorted octahedral coordination sphere. The $[N(CH_3)_4]^+$ ions are located in the cavities of the manganese(II)-azido sublattice (Fig. 1). The EE azido ligands asymmetrically bridge the metal centers: the Mn-N-N and N-N-Mn′ angles are about 165° and 135°, respectively, the Mn···Mn distance about 6.4 Å. The compound undergoes a reversible phase transformation at approximately 303 K. The pseudo-cubic high-temperature (HT) phase at 310 K has a cell length of 6.446(4) Å, and each unit cell contains one formula unit. The crystal structure of this HT phase is currently under investigation.

EPR measurements on this compound at low (cooling with liquid nitrogen) and high temperatures were carried out on powdered samples with a Bruker ESP 300 spectrometer. They show an isotropic signal for the manganese(II) ion, $g = 2.00$. This signal is very sharp and intense and does not change significantly on varying the temperature, which indicates that the octahedral environment of the Mn^{II} ion does not alter to a great extent.

Variable-temperature magnetic susceptibility measurements were performed on a powdered sample in the range 350 to 2 K with a SQUID Quantum Design MPMS-2 magnetometer. Global antiferromagnetic behavior is evident from the magnetic measurements as is shown in Figures 2 and 3. The χ_m value increases as the temperature decreases (Fig. 2), reaching a sharp

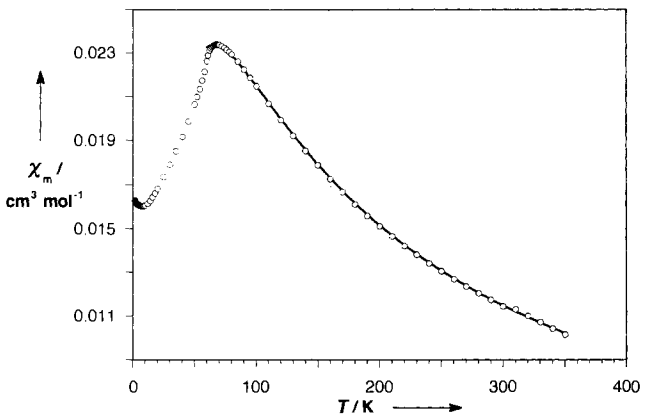

Fig. 2. Plot of χ_m (○) of $[N(CH_3)_4][Mn(N_3)_3]$ versus T. Solid line: best-fit susceptibility curve for an $S = 5/2$ simple cubic Heisenberg antiferromagnetic system derived from the HTS model developed by Rushbrook and Wood [9].

maximum at about 70 K, and then decreases on cooling down to 2 K. The extrapolated value of the susceptibility at 0 K is found to be approximately two-thirds of the value of the susceptiblity maximum. The latter, together with the existence of a sharp maximum on the curve, indicates that three-dimensional antiferromagnetic behavior can be inferred from the susceptibility measurements. Indeed, investigations on single crystals, AC susceptibility measurements, and neutron diffraction would be suitable methods to unambiguously confirm 3D ordering. The $\chi_m T$ value at room temperature is 3.5 $cm^3 K mol^{-1}$ (Fig. 3),

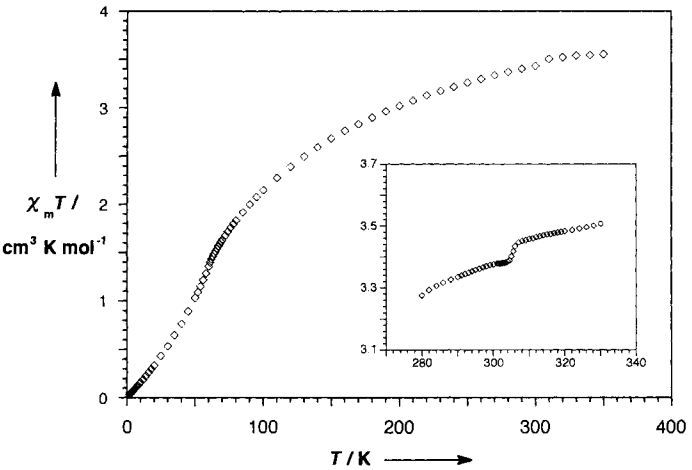

Fig. 3. Thermal variation of $\chi_m T$ (○). Inset: phase transition.

smaller than the value expected for an uncoupled Mn^{II} ion. This value decreases with decreasing temperature tending to zero. The reversible phase transition (305 K) was also evident from these measurements (inset in the $\chi_m T$ vs. T plot). This could be indicative of changes in the Mn-azido-Mn angles in the high-temperature phase, which would lead to a variation in the strength of J and consequently to a modification of the magnetic behavior.

The magnetic behavior of this compound must be explained by assuming a regular three-dimensional network as indicated by the crystal structure. The expression of the magnetic susceptibility for a simple cubic Heisenberg antiferromagnetic system was derived from the high-temperature series expansion (HTS) model developed by Rushbrook and Wood.[9] By taking the exchange Hamiltonian $\mathcal{H} = -2J \sum_{i \neq j} S_i S_j$ into consideration, the expression given in Equation (a) was obtained for the sus-

$$\chi = \frac{35Ng^2\beta^2}{12kT}(1 + C_1x + C_2x^2 + C_3x^3 + C_4x^4 + C_5x^5 + C_6x^6) \qquad \text{(a)}$$

$x = Jk^{-1}T^{-1}$; $C_1 = 35$, $C_2 = 221.67$, $C_3 = 608.22$, $C_4 = 26049.66$, $C_5 = 210986$, $C_6 = 8014980$

ceptibility. Equation (a) is only valid around the maximum (paramagnetic region). The solid line in Figure 2 shows the best least-squares fit of the susceptibility data for $[N(CH_3)_4][Mn(N_3)_3]$ by using Equation (a). The parameters obtained are $Jk^{-1} = -2.5$ K and $g = 2.01$, in good agreement with the results from the EPR measurements.

Experimental Procedure

Manganese nitrate tetrahydrate (2.1 g, 8.4 mmol) was dissolved in a hot aqueous solution of tetramethylammonium azide (45 mL, 48 mmol, $T = 340$ K), saturated with hydrazoic azide. The clear solution was allowed to cool, and colorless, transparent, prismatic crystals were obtained. Elemental analysis: calc. (found): Mn 21.5 (21.4), N 54.9 (54.8), C 18.8 (18.9) H 4.7 (4.7)%.

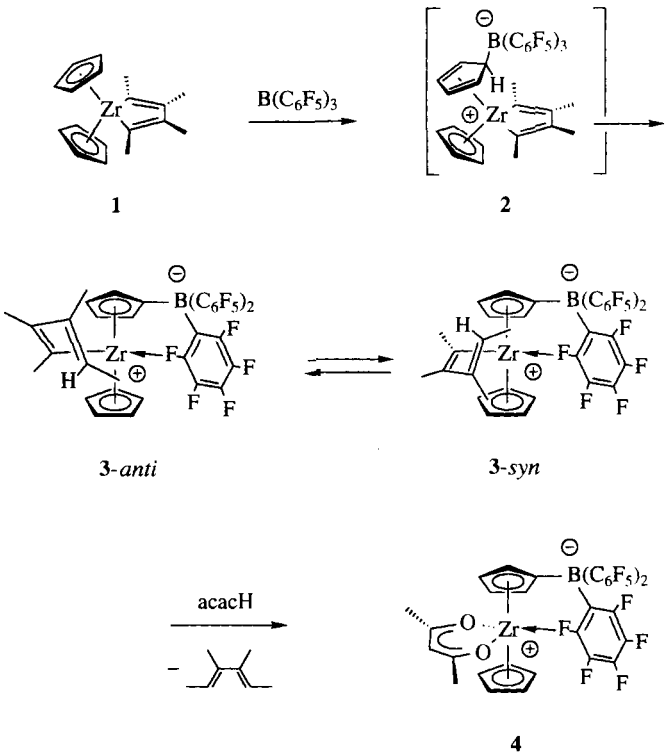
Formation of a Zirconocene–Betaine System by Electrophilic Substitution with $B(C_6F_5)_3$ at a Cyclopentadienyl Ligand**

Johannes Ruwwe, Gerhard Erker*, and Roland Fröhlich

Cyclopentadienyl complexes of the late transition elements often readily undergo electrophilic aromatic substitution reactions at the η^5-cyclopentadienyl rings. The corresponding substitution reactions of ferrocene are well-known general examples.[1] Analogous reactions of the bent metallocene complexes of titanium, zirconium, and hafnium are to our knowledge not known. For this reason bent metallocenes with Group 4 metals containing substituted or functionalized Cp ligands are typically synthesized by other routes utilizing suitably functionalized Cp ligand precursors.[2] The development of new methods for synthesizing Cp-functionalized derivatives starting from simple metallocenes would be of great importance because of the general catalytic potential of Group 4 metallocene complexes.[3] We have now found an example of a reaction of a zirconocene complex that can be regarded as a functionalization of a Cp ligand by an electrophilic aromatic substitution reaction similar to that often observed with the ferrocene system. The products, novel metallocene–betaine complexes, may be of interest in the development of new catalysts.[4]

We treated 1,1-bis(cyclopentadienyl)-2,3,4,5-tetramethylzirconacyclopentadiene (**1**) with tris(pentafluorophenyl)borane in toluene solution at ambient temperature. Product **3** formed cleanly and was isolated as a pale yellow solid in 78% yield. Single crystals of **3** suitable for X-ray crystal structure determination were obtained from ether.



The crystal structure analysis reveals that a zirconium–carbon σ bond is cleaved during the reaction of **1** with $B(C_6F_5)_3$ (Fig. 1). Complex **3** contains a σ-bound trimethylpentadienyl ligand at zirconium. The C1–C2 double bond is oriented coplanar with the Zr–C σ bond in the σ ligand plane of the bent metallocene (dihedral angle Zr-C1-C2-C3 −8.6(5)°). The adjacent C3–C4 double bond is rotated about the C2–C3 σ bond such that the diene conjugation is almost completely lost (dihedral angles C1-C2-C3-C4 −66.9(5)°, C6-C2-C3-C7 −61.0(5)°). Despite this, there is a marginal coordinative interaction between the C3–C4 double bond and the electrophilic zirconium center in **3** (distances C3–Zr 2.932(4) Å, C4–Zr 3.040(4) Å).[5] Complex **3** contains a normal η^5-bound Cp ligand [η^5-C_5H_5] at zirconium and as the most characteristic feature a tris(pentafluorophenyl)borane-substituted cyclopentadienyl unit [η^5-$C_5H_4B(C_6F_5)_3$].[6, 7] Thus, complex **3** formally exhibits a betaine structure with positive partial charge on zirco-

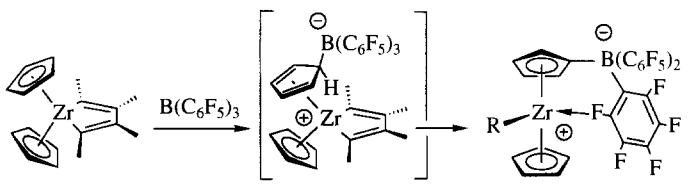
nium and negative partial charge on boron. But the resulting electron deficiency at zirconium is very efficiently compensated in **3**: an *ortho*-fluorine substituent of one of the C_6F_5 groups



1 **2** **3**

R = -C(CH$_3$)=C(CH$_3$)-C(CH$_3$)=CH(CH$_3$)

occupies the free coordination site. In this way the pseudo-tetrahedral coordination environment at zirconium is retained: the D1-Zr-D2 angle (D1 and D2 denote the centroids of the Cp ring systems) is 130.4°, and the "divalent" fluorine atom F42 is oriented coplanar with the C1–Zr σ bond in the σ ligand plane of the bent metallocene [C1-Zr-F42 130.4(1)°].

Complex **3** is chiral in the crystal, and its chirality is retained in solution. This follows from the characteristic features of its NMR spectra. The η^5-$C_5H_4B(C_6F_5)_3$ ligand gives rise to four ^{1}H NMR signals at δ = 6.34, 5.69, 5.55, 4.82 (^{13}C NMR signals for the Cp ligand at δ = 125.0, 124.8, 119.3, 115.5, 114.3). Therefore, one must assume that the coordination of the fluorine atom to the zirconium center is retained under the conditions of the NMR measurement. Complex **3** exhibits dynamic NMR behavior when the temperature is lowered. At 213 K in [D_8]toluene the expected ^{19}F NMR signal of the bridging fluorine substituent is found at δ = −185. When the temperature is lowered to 188 K, this signal splits into two resonances of almost equal intensity at δ = −184 and −186. In the ^{1}H and ^{13}C NMR spectra there is also evidence for the presence of two almost equally populated diastereomeric complexes [^{1}H NMR in CD_2Cl_2 at 200 K: δ = 6.21/6.00 (s, Cp), 1.28/1.27 (d, each $^3J_{HH}$ = 5.6 Hz, =CHC*H*$_3$); ^{13}C NMR in CD_2Cl_2 at 200 K: pairs of signals for C1 at δ = 182.2/180.0, the η^5-C_5H_5 ligand at δ = 112.7/112.0, and the methyl groups at δ = 22.1/21.1, 15.8/15.5, 13.8/13.7, and 13.2/12.9]. Apparently the characteristic nonplanar conformation of the σ-dienyl ligand is retained in solution. We assume that these diastereomers are the complexes **3**-*syn* and **3**-*anti*, which may rapidly interconvert in solution at room temperature by rotation around the C2–C3 σ bond. The isomers can be observed when this rotation is "frozen" on the NMR time scale at low temperature [$\Delta G^{\neq}$ (267 K) = 12.7 ± 0.5 kcal mol^{-1}]. The majority of the crystals formed from the equilibrating isomers contain the diastereomer **3**-*syn*, in which the C3–C4 double bond and the η^5-$C_5H_4B(C_6F_5)_3$ ligand are *syn* oriented (see Fig. 1).

In the course of the reaction of **1** with $B(C_6F_5)_3$ to yield **3** a hydrogen atom was transferred to an α-carbon center of the metallacyclic five-membered ring system to form the trimethyl-substituted σ-bound pentadienyl ligand [^{1}H/^{13}C NMR at room temperature: δ = 5.36 (q, 1H, ^3J = 6.0 Hz, =C*H*CH$_3$)/ δ = 105.9 ($^1J_{CH}$ = 168 Hz, =*C*HCH$_3$)]. We assume that this hydrogen atom was abstracted from a Cp ring during the course of the reaction.[7] Typically $B(C_6F_5)_3$ abstracts σ-alkyl groups or hydride from organometallic substrates with formation of ionic products.[8] These reactions are apparently so unfavorable with **1** that the usually less favorable addition of the electrophilic reagent to a Cp ring takes place. The addition may lead to the (η^4-cyclopentadienyl)metal complex **2** containing an *exo*-positioned $B(C_6F_5)_3$ substituent and an *endo*-oriented hydrogen atom at C5. The subsequent acid–base reaction to give **3** is probably facilitated by the close spacial proximity of the proton and the Zr–C(sp^2) bond in the intermediate **2**.

Compound **3** is readily available by this route, and it may potentially serve as starting material in studies of the metallocene–betaine chemistry of Group 4 metal complexes containing an internal borate anion covalently bound to a Cp ligand. We have conducted exploratory experiments in this direction. Compound **3** reacts cleanly with acetylacetone at room temperature in toluene solution by protolytic liberation of 3,4-dimethylhexa-2,4-diene and formation of the (acetylacetonato)zirconium–betaine complex **4**. Product **4** exhibits an unsymmetrical acac coordination mode (Fig. 2). This is confirmed in solution by the low-temperature (203 K) ^{1}H NMR spectrum, which shows a pair of methyl resonances of the acac ligand at δ = 2.06 and 1.73 (acac-CH signal at δ = 5.73, η^5-C_5H_5 resonance at δ = 6.16). Complex **4** is apparently chiral due to *o*-fluorine coordination, and

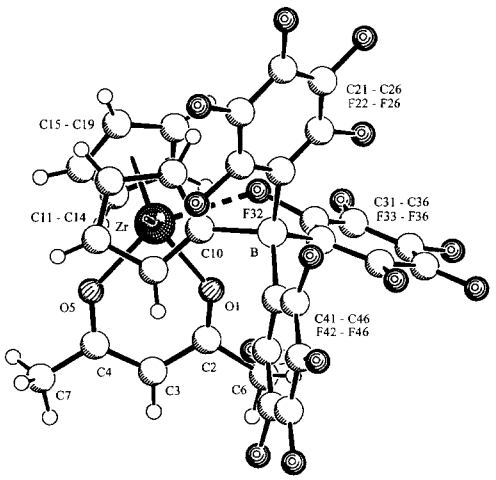


Fig 2. Molecular structure of **4** in the crystal.

four methine resonances of the η^5-$C_5H_4B(C_6F_5)_3$ ligand are evident in the ^1H NMR spectrum at low temperature (δ = 6.65, 6.54, 5.93, and 5.79). At room temperature rapid enantiomerization takes place on the NMR time scale, which results in a much simpler ^1H NMR spectrum after coalescence of the corresponding pairs of resonances. The unsymmetrical coordination of acac and the *o*-fluorine coordination is also confirmed by the structure of **4** in the crystal (Fig. 2). Because of the rather high *R*-value (0.12) details of this structure will not be discussed.

Experimental Procedure

Reaction of **1** with tris(pentafluorophenyl)borane: Compound **1** [9] (640 mg, 1.94 mmol) was dissolved in 50 mL of toluene. Then a solution of $B(C_6F_5)_3$ (980 mg, 1.94 mmol) in 35 mL of toluene was added and the reaction mixture was stirred for 8 h at ambient temperature. The solvent was removed in vacuo. The residue was washed with pentane (2 × 25 mL) and then dired in vacuo to give 1.12 g (78%) of complex **3** as a pale yellow solid. M.p. 101 °C (decomp, DSC); Elemental analysis: $C_{36}H_{22}F_{15}BZr$ (841.6) calcd C 51.35, H 2.64; found C 50.72, H 2.97; ^1H NMR ([D$_6$]benzene, 200 MHz, 300 K): δ = 6.34, 5.69, 5.55, 4.82 (m, each 1H, C_5H_4[B]), 5.51 (s, 5H, Cp), 5.36 (q, ^3J = 6.0 Hz, 1H, $=CHCH_3$), 1.39, 1.31, 1.25 (s, each 3H, CH_3), 0.99 (d, ^3J = 6.0 Hz, 3H, $=CHCH_3$); ^{13}C NMR ([D$_6$]benzene, 50 MHz, 300 K): δ = 182.0 (Zr–C=), 148.9, 139.5 137.7 ($^1J_{CF}$ = 242, 264, 266 Hz, $B(C_6F_5)_3$), 136.7, 125.0, 124.8, 119.3, 115.5, 114.3, 112.7 (Cp), 105.9 ($=CHCH_3$), 22.7, 21.6, 15.8, 15.2 (CH_3); ^{11}B NMR ([D$_6$]benzene): δ = − 16.5; ^{19}F NMR ([D$_6$]benzene, 300 K): δ = − 131.0 to −142.0 (br. m, 6F, *o*-C_6F_5), −153.2 (m, 3F, *p*-C_6F_5), −163.2 (m, 6F, *m*-C_6F_5). X-ray crystal structure analysis of **3** (single crystals from ether): formula $C_{36}H_{22}BF_{15}Zr$, M = 841.57, crystal size 1.4 × 0.5 × 0.2 mm, a = 10.878(1), b = 17.529(1), c = 17.494(1) Å, β = 96.91°, V = 3311.5(4) Å^3, ρ_{calcd} = 1.688 g cm^{-3}, μ = 4.44 cm^{-1}, empirical absorption correction, Z = 4, monoclinic, space group $P2_1/n$ (No. 14), Enraf-Nonius Mach III diffractometer, λ = 0.71073 Å, T = 223 K, 7067 measured reflections (+ h, − k, ± l), $[(\sin\theta)/\lambda]_{max}$ = 0.59 Å^{-1}, 6707 independent and 4745 observed reflections [$I > 2\sigma(I)$], 482 refined parameters, R = 0.044, wR^2 = 0.145, programs used: SHELXS-86, SHELXL-93, SCHAKAL-92. Further details of the X-ray crystal structure analyses may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-404021.

Reaction of **3** with acetylacetone: Compound **3** (380 mg, 0.45 mmol) was dissolved in 25 mL of toluene. A solution containing 100 mg (1.00 mmol) of acetylacetone in 5 mL of toluene was added and the mixture was stirred for 1 h at room temperature. The solvent was removed in vacuo and the residue washed with pentane (3 × 20 mL) and then dried in vacuo to give 306 mg (81%) of **4** as a white solid. M.p. 152 °C (decomp, DSC). ^1H NMR ([D$_6$]benzene, 200 MHz, 300 K): δ = 6.05, 5.69 (m, each 2H, C_5H_4[B]), 5.54 (s, 5H, Cp), 4.88 (s, 1H, acac), 1.27 (s, 6H, acac); ^1H NMR (CD_2Cl_2, 200 MHz, 300 K): δ = 6.30 (br. s, 4H, C_5H_4[B]), 6.24 (s, 5H, Cp), 5.82 (s, 1H, acac), 1.96 (s, 6H, acac); ^{13}C NMR ([D$_8$]toluene, 50 MHz, 300 K): δ = 193.2 (acac, *C*), 149.0 ($^1J_{CF}$ = 252 Hz) and 138.0 ($^1J_{CF}$ = 227 Hz, *o*- and *m*-C_6F_5; *p*- and *ipso*-C_6F_5M signals not located), 121.3, 119.3, 117.5 (C_5H_4[B]), 115.5 (Cp), 104.1 (acac, CH), 25.6 (acac, CH_3); ^{11}B NMR ([D$_6$]benzene): δ = −15.8; ^{19}F NMR ([D$_6$]benzene): δ = −138.5, −153.6, −161.8 (*o*, *p*, *m*-C_6F_5). X-ray structure analysis of **4**: formula $C_{33}H_{16}O_2F_{15}BZr$, M = 831.49, crystal size 0.5 × 0.2 × 0.05 mm, a = 13.207(2), b = 14.918(4), c = 15.891(2) Å, V = 3130.9(10) Å^3, ρ_{calcd} = 1.764 g cm^{-3}, μ = 4.73 cm^{-1}, Z = 4, orthorhombic, space group $P2_12_12_1$ (No. 19), Enraf-Nonius Mach III diffractometer, λ = 0.71073 Å, T = 173 K, 3107 measured reflections (+ h, ± k, ± l), $[(\sin\theta)/\lambda]_{max}$ = 0.62 Å^{-1}, 3096 independent and 1815 observed reflections [$I > 2\sigma(I)$], 469 refined parameters, R = 0.121, wR^2 = 0.351.

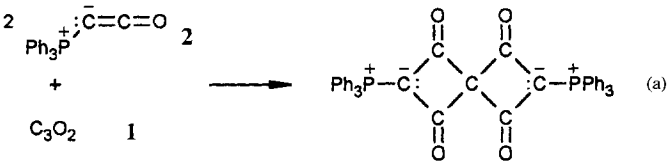
Heterocumulenes: Reaction of C_3O_2 with Ketenylidenetriphenylphosphorane; Synthesis and Structure of a Spirobis(cyclobutanedione)**

Luciano Pandolfo,* Giacomo Facchin,*
Roberta Bertani, Paolo Ganis,* and Giovanni Valle

Acylketenes (α-oxoketenes) are subject to increasing interest and are used extensively as synthetic building blocks for a large number of interesting compounds.[1] Recently we reported[2] that the simplest stable bis(ketene), carbon suboxide (**1**),[3] reacts with stabilized phosphonium and arsonium ylides[4] bearing a hydrogen atom on the ylidic carbon atom. Depending on the ylide, bis(ylidic) malonil derivatives or zwitterionic pyrone derivatives are formed, but Wittig-type reactions were never observed.

Ketenylidenetriphenylphosphorane **2**[5] is a readily accessible molecule containing both an ylidic and a ketenic function. In contrast to ketenes, **2** displays no tendency to dimerize, and when it is protonated the resulting phosphonium ion shows typical ketene behavior.[6] Thus protonated **2** can undergo [2 + 2]cycloaddition with **2** to form, after reaction with base, the bis(ylidic) cyclobutanedione **3**.[7] Compound **3** reacts with carbonyl compounds yielding the cyclobutane-1,3-dione derivatives **4** by a Wittig-type process.[6, 7] Moreover, cyclobutanedionic derivatives **5** have been obtained through [2 + 2]cycloaddition of **2** with ketenes.[8] Bestmann et al. reported the syntheses and determined the structures of the cyclobutanetrione **6**, obtained by oxidation of **3**, and of the bicyclic bis(ylidic) derivative **7**.[9]

We report the synthesis of the bis(ylidic) spirocyclobutanedione **8** by the double [2 + 2]cycloaddition reaction of two molecules of **2** with one molecule of **1** [Eq. (a)]. The $^{31}P\{^1H\}$ NMR



(a)

8

spectrum of **8** shows one singlet at $\delta = -2.91$, which is in the typical range for acyl ylides having a cyclobutane structure.[8-10] The $^{13}C\{^1H\}$ NMR spectrum, in addition to resonances due to the phenyl groups, shows signals at $\delta = 122.59$ and 185.11 attributable to C–P and C=O groups, respectively. A complex signal is also observed at $\delta = 83.10$, which agrees with the values reported for the central carbon atom of related spirocyclobutenones ($\delta = 79.7-84.8$).[11]

In the mass spectrum of **8** under electron impact ionization conditions no molecular ion was detected; however, the protonated molecule was easily generated by fast atom bombardment and detected at *m/z* 673. Accurate mass measurements with PEG 500 as a standard gave a value of 673.1657 (±0.005), in agreement with the proposed structure ($C_{43}H_{31}O_4P_2$, calcd 673.1688). The fragmentation pattern in the mass spectrum will be described elsewhere.

Single crystals of **8** suitable for X-ray structure analysis[12] were obtained by slow evaporation of a CH_2Cl_2 solution. The independent structural unit consists of two molecules of **8** (A and B). They differ mainly in the orientation of the phenyl groups with respect to the molecular backbone. The structures of these two nonequivalent molecules are shown in Figure 1.

Although the molecules of **8** are in principle C_2-symmetric, owing to crystallographic demands they display a total absence of symmetry. Thus, in **8** the molecular structures of four independent cyclobutanedione moieties can be compared.

The lengths of the ylidic P–C bonds, with an average value of 1.737(5) Å, are indicative of substantial double bond character and in agreement with values given in several similar cases.[13a, c, 14] The C=O bonds, with the exception of C(1)B′–O(1)B′ (1.194(9) Å), have an average length of 1.215(7) Å, which is virtually identical with the value reported in the literature (1.217(5) Å) for a C=O bond having partial triple bond character due to dipole formation ($C^{\delta+}=O^{\delta-}$).[13] For comparison, the length of a "normal" C=O bond is 1.230(5) Å.[13c, d, 14] The distances between the P-substituted C atoms and the adjacent O-substituted C atoms are in the range of 1.433(7)–1.464(7) Å. These values correspond with the lengths of C–C bonds in conjugated systems such as C=C–C=C or C=C–C≡C, which are reported to be in the range of 1.43–1.48 Å.[15]

[**] This work was supported by the Ministero dell' Università e della Ricerca Scientifica e Tecnologica (MURST) and by the Consiglio Nazionale delle Ricerche (CNR).

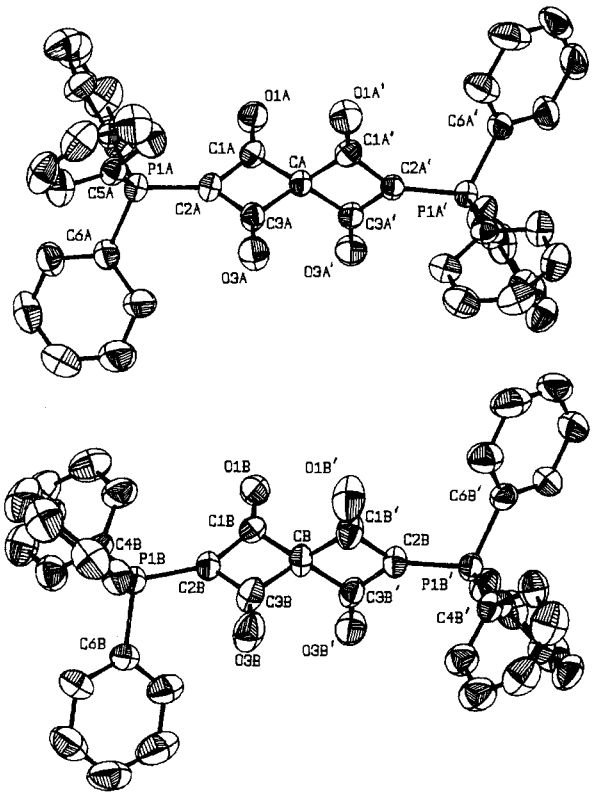

Fig. 1. Molecular structures of the two independent molecules A and B in a crystal of **8**; the two molecules have similar structural parameters and the pseudo-C_2 symmetry. Selected bond lengths [Å] for molecule A (top): P(1)A-C(2)A 1.736(5), P(1)A'-C(2)A' 1.735(5), C(1)A-O(1)A 1.211(6), C(3)A-O(3)A 1.219(6), C(1)A'-O(1)A' 1.204(7), C(3)A'-O(3)A' 1.215(7), C(1)A-C(2)A 1.455(6), C(2)A-C(3)A 1.433(7), C(1)A'-C(2)A' 1.457(7), C(2)A'-C(3)A' 1.462(7), CA-C(1)A 1.533(7), CA-C(3)A 1.549(6), CA-C(1)A' 1.558(6), CA-C(3)A' 1.554(7); for molecule B (bottom): P(1)B-C(2)B 1.741(5), P(1)B'-C(2)B' 1.737(5), C(1)B-O(1)B 1.221(6), C(3)B-O(3)B 1.217(7), C(1)B'-O(1)B' 1.194(9), C(3)B'-O(3)B' 1.217(7), C(1)B-C(2)B 1.444(6), C(2)B-C(3)B 1.447(8), C(1)B'-C(2)B' 1.458(8), C(2)B'-C(3)B' 1.464(7), CB-C(1)B 1.540(7), CB-C(3)B 1.541(8), CB-C(1)B' 1.541(7), CB-C(3)B' 1.558(8).

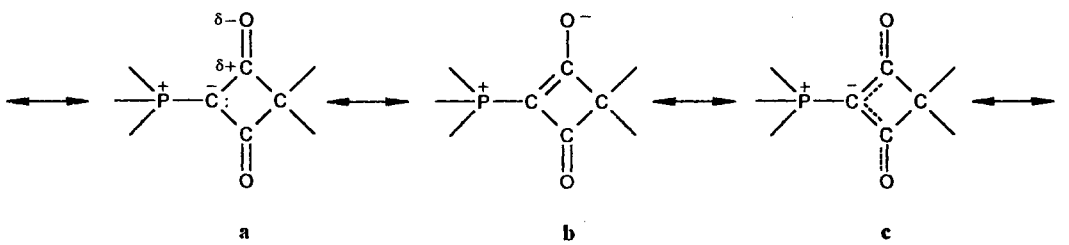
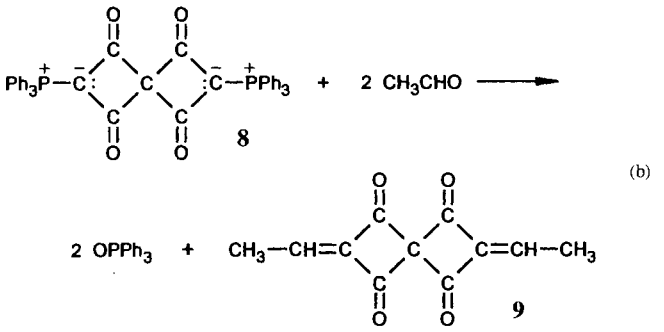
This structural data is consistent with formal resonance structures in which both mesomeric and inductive effects are supposed to operate (Scheme 1). In **8** the limiting resonance form **a** seems to dominate; form **c**, suggested for compound **6**,[9] cannot explain our data alone, since in this case the C=O bonds would be somewhat longer than those in "normal" keto groups. The other molecular parameters of molecules A and B, including bond and torsion angles, are quite similar to those of analogous compounds;[9, 11] they do not depend upon electronic factors but are chiefly controlled by intramolecular steric requirements and/or crystal field forces.

The ylidic character of **8** is in agreement with the results obtained in the reaction with acetaldehyde [Eq. (b)]. When a



Scheme 1.



(b)

suspension of **8** in CH_3NO_2 is heated at 60 °C in a sealed vial with two equivalents of CH_3CHO, the solid dissolves rapidly. The $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$) of the sticky orange compound obtained by evaporation of the solvent shows a unique signal at $\delta = 27.84$ due to $OPPh_3$. The ^1H NMR spectrum of this compound presents two relevant signals at $\delta = 4.40$ (q, $^3J(HH) = 6.1$ Hz) and 1.19 (d, $^3J(HH) = 6.1$ Hz) in a 1:3 ratio, which are attributed to the =CH and CH_3 protons, respectively. In the IR spectrum of the new orange substance the band at 1622 cm^{-1} characteristic of **8** is gone and new intense absorptions at 1678 and 1553 cm^{-1} are evident. These data indicate that **8** undergoes a Wittig reaction to afford compound **9**. At present, the reactivity of compound **8** toward organic and organometallic reagents is under investigation.

Experimental Procedure

8 : A solution of **1** in toluene (0.044 M, 15 mL, 0.66 mmol) was added at room temperature to a stirred solution of **2** (0.395 g, 1.31 mmol) in 25 mL of toluene. A yellow solid immediately precipitated, which was filtered, washed with acetone, and dried under vacuum to give **8** as creamy white crystals. Yield: 0.380 g (86%). M.p. 245–250 °C (decomp); correct C, H analysis. IR (Nujol): 1622 cm^{-1} (ν_{CO}); ^1H NMR (200 MHz, CD_2Cl_2, 25 °C): $\delta = 7.73$–7.55 (m, C_6H_5); $^{13}C\{^1H\}$ NMR (100 MHz, CD_2Cl_2, 25 °C): $\delta = 185.11$ (dd, $^2J(CP) = 5.3$ Hz, $^4J(CP) = 2.6$ Hz, C=O), 122.59 (d, $^1J(CP) = 91.6$ Hz, C=P), 83.10 (m, central C); $^{31}P\{^1H\}$ NMR (80 MHz, $CDCl_3$, 25 °C): $\delta = -2.91$ (s); FAB MS in glycerol: *m/z* (%): 673 (3) $[M + H]^+$, 672 (2) $[M]^+$; FAB MS in *m*-nitrobenzyl alcohol: 673 (30) $[M + H]^+$, 644 (4) $[M - CO]^+$.

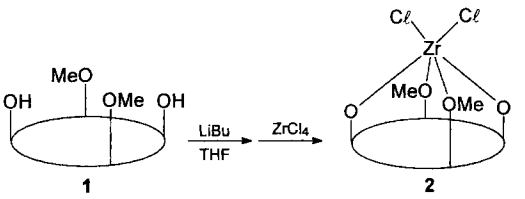
The Organometallic Chemistry of Zirconium on an Oxo Surface Provided by *p-tert*-Butylcalix[4]arene**

Luca Giannini, Euro Solari, Antonio Zanotti-Gerosa, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

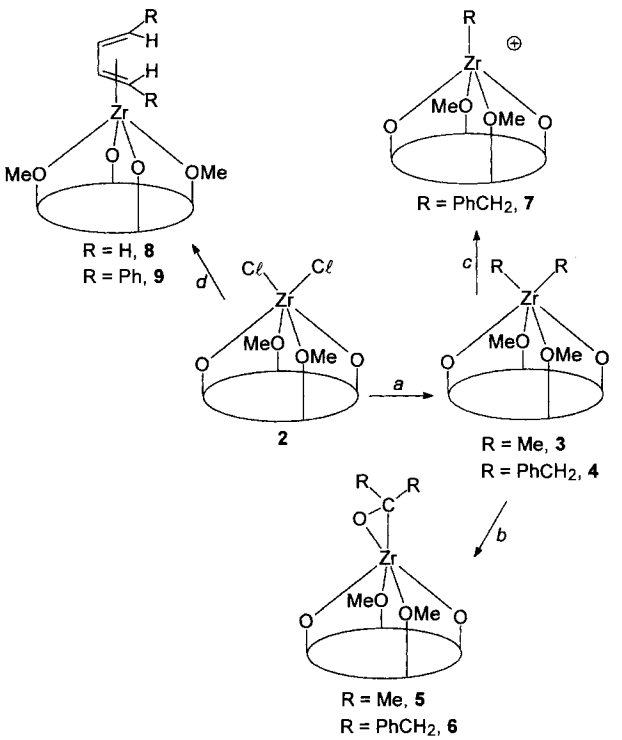
The chemistry of calix[*n*]arenes and transition metal complexes[1] is a very young and rather unexplored area.[2–6] Previous applications of calix[*n*]arenes did not extend much beyond their use as a conventional polyoxo coordination environment and, in a few cases, for the *endo* coordination of substrates in their cavity.[3–6]

Calix[*n*]arenes have never been exploited as polyoxo matrices for reactive organometallic functionalities. Their use as ancillary ligands in organometallic chemistry is an interesting application due to their unique structural properties. In this context, some target functionalities that are versatile in organic synthesis were chosen and fixed on a *p-tert*-butylcalix[4]arene tetraoxo matrix to give $[ZrR_2]$,[7] $[ZrR]^+$,[8] and [Zr(diene)] complexes.[9] The starting material, the functionalizable $[ZrCl_2]$ complex **2**, was prepared in two steps from dimethoxy-*p-tert*-butylcalix[4]arene[10] dianion (Scheme 1). Even very small amounts of



Scheme 1.

impurities in **1** and **2** are particularly troublesome for the further functionalization. Scheme 2 shows how **2** was converted into a number of complexes in which organometallic functionalities are bonded to a polyoxo matrix. This scheme outlines a general entry to the organometallic chemistry of zirconium on a *p-tert*-butylcalix[4]arene support. The present report concerns only the synthesis and the characterization of the compounds; reactivity studies will be conducted later.



Scheme 2. a) MeLi, toluene, −30 °C; $PhCH_2MgCl$, toluene, −35 °C. b) CO, benzene, 8 °C. c) $[Cp_2Fe]BPh_4$, toluene, −35 °C. d) $[Mg(C_4H_6)(thf)_2]$, toluene, −25 °C; $[Mg(C_{16}H_{14})(thf)_3]$, toluene, −30 °C.

When reaction *a* was carried out with a 1:1 molar ratio of **2** and alkylating agent, a mixture of **2**, **3**, and the monoalkylated analogue were obtained in an approximate 1:1:2 ratio (determined by ^{1}H NMR spectroscopy). Furthermore, the same 1:1:2 mixture was obtained when equimolar solutions of **2** and **3** were mixed. Thus, under the conditions mentioned above, the monoalkylated form cannot be obtained in pure form. Both dialkyl derivatives **3** and **4** show high thermal stability (65 °C for 14 h), while only **4** was found to be photolabile in

[**] This work was supported by the Fonds National Suisse de la Recherche Scientifique (grant no. 20-40268.94) and by Ciba-Geigy SA (Basel, Switzerland). We thank Dr. Marc Weydert for preliminary work on the synthesis of **2**.

C_6D_6. Their reaction with carbon monoxide (reaction *b*) resulted in the migratory insertion of both alkyl ligands affording the corresponding η^2-ketone derivatives.[11] Compounds **5** and **6**, although thermally stable (65 °C for 14 h), are both photolabile and rather reactive. The oxidative cleavage of the Zr–C bond in **4** using the ferrocenyl cation (reaction c)[12] led to the cationic species **7**; the relevance of analogous complexes with ancillary ligands other than *p-tert*-butylcalix[4]arenes is well known.[8]

All the compounds in Scheme 2 were characterized by X-ray structure analyses, except **7**, whose analytical and NMR data are consistent with the formulation given. Compounds **2**–**4** and **7** have C_{2v} symmetry and their ^{1}H NMR spectra show one pair of doublets for the bridging methylene groups and a singlet for the MeO groups. Compounds **5**, **6**, and **9** have C_s symmetry; their ^{1}H NMR spectra show two pairs of doublets for the methylene protons and two singlets for the MeO groups. The diene complex **8** also has C_s symmetry, as evidenced by its ^{1}H NMR spectrum at temperatures below −10 °C (in [D_8]toluene), which is similar to those of the other low-symmetry compounds. However, at temperatures above 40 °C complex **8** exhibits a ^{1}H NMR spectrum similar to those of the previously mentioned C_{2v}-symmetrical compounds. A dynamic process (probably the rotation of the butadiene ligand) increases the apparent symmetry of the compound in solution.

In the X-ray crystal structures of **3**[13] (Fig. 1) and **9**[14] (Fig. 2) with σ- and π-bonded carbon fragments, respectively,

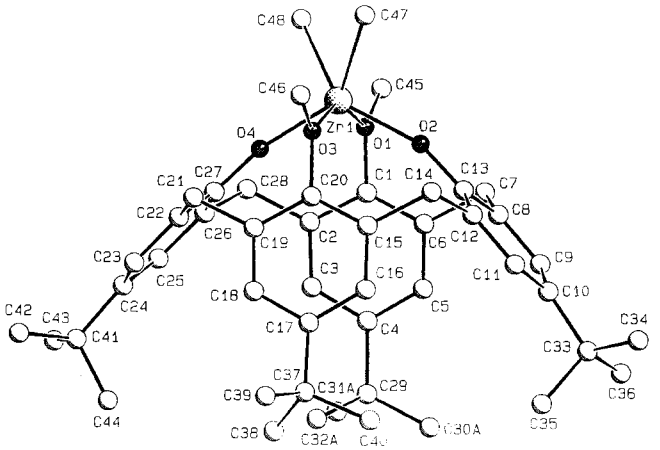

Fig. 1. Crystal structure of complex **3** (SCHAKAL representation). Selected distances [Å]: Zr1-O1 2.401(3), Zr1-O2 1.974(3), Zr1-O3 2.410(4), Zr1-O4 1.964(3), Zr1-C47 2.275(5), Zr1-C48 2.294(7). Selected bond angles [°]: C47-Zr1-C48 77.7(3), O3-Zr1-C47 75.6(2), O3-Zr1-O4 76.8(1), O2-Zr1-O4 120.8(1), O2-Zr1-O3 87.7(1), O1-Zr1-C48 74.6(2), O1-Zr1-O4 88.3(1), O1-Zr1-O3 150.9(1), O1-Zr1-O2 78.6(1), Zr1-O2-C13 161.4(3), Zr1-O4-C27 167.3(3). Disorder affecting the C30–C32 methyl groups has been omitted for clarity.

the structure of the *p-tert*-butylcalix[4]arene moiety is elliptical in cross-section, as dictated by a hexacoordinate metal center.[4] The Zr1–O2 and Zr1–O4 distances, and the related Zr1-O2-C13 and Zr1-O4-C27 angles (see legends of Figs. 1 and 2) support a very strong metal–oxygen π bond.[3–6] The Zr–O1 and Zr–O3 distances are not only much longer than Zr–O2 and Zr–O4, but they also differ significantly for the two complexes. The steric constraints, specifically the methyl···methoxy repulsion, may be the reason why the Zr–O1 distance in **3** is longer than that in **9**, the C47-Zr-C48 angle is very small [77.7(2)°], and C47···C48 distance is rather short [2.865(10) Å]. In complex **9** the plane of the butadiene carbon atoms is nearly parallel to the O_4 plane (dihedral angle −7.2(8)°). The η^4 bonding mode of the butadiene fragment is

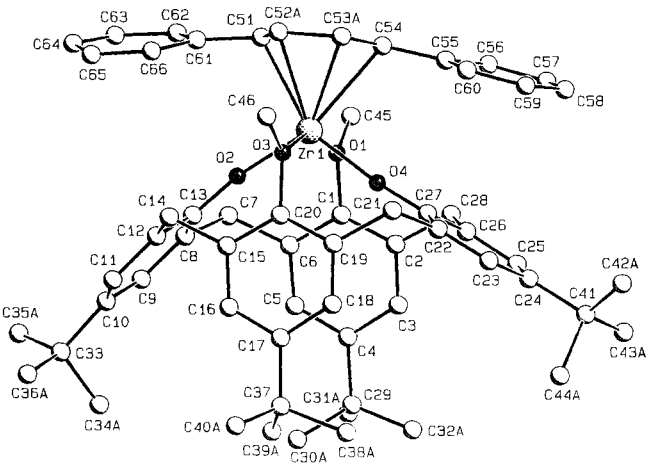

Fig. 2. Crystal structure of complex **9** (SCHAKAL representation). Selected distances [Å]: Zr1-O1 2.304(9), Zr1-O2 1.949(7), Zr1-O3 2.345(9), Zr1-O4 1.950(7), Zr1-C51 2.427(13), Zr1-C52A 2.46(2), Zr1-C53A 2.49(2), Zr1-C54 2.513(12). Selected bond angles [°]: C53A-Zr1-C54 31.4(5), C52A-Zr1-C53A 34.1(6), C51-Zr1-C52A 30.5(6), O3-Zr1-O4 82.5(3), O2-Zr1-O4 112.0(3), O2-Zr1-O3 83.8(3), O1-Zr1-O4 82.2(3), O1-Zr1-O3 155.2(3), O1-Zr1-O2 84.0(3), Zr1-O2-C13 171.0(7), Zr1-O4-C27 174.2(7). Disorder affecting the C52A and C53A carbon atoms and the methyl carbons of all *t*-butyl groups groups is not reflected in this representation.

supported by the Zr–C distances, which fall within a very small range. The lengths of the C–C bonds within the butadiene ligand, for which we have averaged the A and B positions and have considered a large standard deviation, follow the sequence C=C–C=C. Thus, the bonding mode of the diphenylbutadiene in **9** can be described as π^2,η^4. The structural and spectroscopic characteristics of the Zr–diene fragment should be compared to those in the [Cp_2Zr][9] and [(tmtaa)Zr] derivatives (tmtaa = dibenzotetramethyltetraaza[14]annulene dianion];[15] compound **9** is more closely related to the tmtaa complexes. In particular, we can say both for **8** and **9** (although the structure of **8** is approximate) that the *cis* form is the only butadiene conformer detected in the solid state; we did not observe any *cis–trans* isomerization upon heating of **8** or **9**. The ^{1}H NMR signals for **8** and **9** were assigned by a computer simulation.

The splitting patterns for the signals of the butadiene protons in the ^{1}H NMR spectrum for **8** are temperature independent though the chemical shifts are slightly temperature dependent. The data mentioned above emphasize the difference between the butadiene complexes **8** and **9** (π^2,η^4) and the cyclopentene complexes (σ^2,π) in the [Cp_2Zr] series.[9] A variety of bonding modes for zirconium–butadiene compounds ranging from π,η^4 to σ^2,π,η^4 can be found in complexes having subunits other than Cp_2Zr.[15]

Experimental Procedure

2: A solution of BuLi (94 mL, 1.65 M in hexane, 155.1 mmol) was added dropwise to a solution of **1** (51.55 g, 76.25 mmol) in THF (300 mL) to give a golden solution, which was added dropwise to a stirred suspension of [$ZrCl_4(thf)_2$] (29.26 g, 77.58 mmol) in THF (300 mL). The resulting pale yellow solution was stirred at room temperature for 2 h, the volatiles were removed in vacuo, and the residue was extracted overnight with benzene (400 mL). The solvent was evaporated and the residue was extracted again over 2 d with a mixture of hexane (600 mL) and benzene (70 mL) to remove residual LiCl. The resulting suspension was allowed to stand at room temperature for 18 h. A white, microcrystalline powder consisting of **2** with 1.5 molecules of cocrystallized benzene was collected and dried in vacuo (51.2 g, 70%). The X-ray analysis was performed on crystals containing two C_6H_6 molecules of crystallization. Anal. calcd for $C_{55}H_{67}Cl_2O_4Zr$: C 69.23, H 7.08; found: C 69.11, H 7.13; ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.37 (s, 9H, benzene), 7.15 (s, 4H, Ar H), 7.11 (s, 4H, Ar H), 4.53 (s, 6H, MeO), 4.33 (d, J = 13.1 Hz, 4H, *endo*-CH_2), 3.43 (d, J = 13.1 Hz, 4H, *exo*-CH_2), 1.29 (s, 18H, *t*Bu), 1.16 (s, 18H, *t*Bu); ^{1}H NMR (C_6D_6, 25 °C): δ = 7.19 (s, 4H, Ar H), 6.77 (s, 4H, Ar H), 4.42 (d, J = 13.0 Hz, 4H,

endo-CH_2), 3.92 (s, 6H, MeO), 3.15 (d, J = 13.0 Hz, 4H, *exo*-CH_2), 1.43 (s, 18H, *t*Bu), 0.65 (s, 18H, *t*Bu).

3: A solution of MeLi (7.7 mL, 1.71 M in Et_2O, 13.17 mmol) was added dropwise to a solution of **2** (6.38 g, 6.69 mmol) in toluene (200 mL) at −30 °C. The mixture was stirred and allowed to warm to room temperature, volatiles were removed in vacuo, and benzene (150 mL) was added. The mixture was heated to reflux, filtered while hot, and concentrated by evaporation in vacuo to a volume of ca. 30 mL. Hexane (200 mL) was added to the resulting white creamy suspension and the mixture was heated to reflux to give a colorless solution. This solution was kept at 9 °C for 3 d to yield colorless crystals of **3**·benzene, which were collected and dried in vacuo (3.66 g, 63%). Anal. calcd for $C_{54}H_{70}O_4Zr$: C 74.18, H 8.07; found: C 74.38, H 8.18. ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.36 (s, 6H, benzene), 7.09 (s, 4H, Ar H), 6.95 (s, 4H, Ar H), 4.41 (d, J = 12.5 Hz, 4H, *endo*-CH_2), 4.22 (s, 6H, MeO), 3.31 (d, J = 12.5 Hz, 4H, *exo*-CH_2), 1.25 (s, 18H, *t*Bu), 1.06 (s, 18H, *t*Bu), 0.60 (s, 6H, Me-Zr); ^{1}H NMR (C_6D_6, 25 °C): δ = 7.23 (s, 4H, Ar H), 6.79 (s, 4H, Ar H), 4.46 (d, J = 12.5 Hz, 4H, *endo*-CH_2), 3.69 (s, 6H, MeO), 3.18 (d, J = 12.5 Hz, 4H, *exo*-CH_2), 1.46 (s, 18H, *t*Bu), 1.24 (s, 6H, Me-Zr), 0.77 (s, 18H, *t*Bu). Crystals suitable for X-ray analysis were obtained by preparing a saturated solution of **3** in pentane at room temperature and storing it at 8 °C. (The solution was obtained by using pentane instead of benzene in the workup; the workup with benzene/hexane gave better yields). The product is stable to prolonged heating (65 °C, 14 h) in C_6D_6 and CD_2Cl_2, as judged by its ^{1}H NMR spectrum; it is not photosensitive in C_6D_6. The exchange reaction between $[(CalMe_2)Zr(Me)_2]$ and $[(CalMe_2)Zr(Cl)_2]$ is fast: when equimolar amounts of the two compounds were dissolved in CD_2Cl_2, an equilibrium mixture of the two reagents and a new product were obtained in an approximate 1:1:2 ratio, as judged by the ^{1}H NMR spectrum. Data for the new species: δ = 7.13 (s, 4H, Ar H), 7.04 (s, 4H, Ar H), 4.43 (d, J = 12.5 Hz, 4H, *endo*-CH_2), 4.36 (s, 6H, MeO), 3.37 (d, J = 12.5 Hz, 4H, *exo*-CH_2), 1.27 (s, 18H, *t*Bu), 1.13 (s, 18H, *t*Bu), 0.82 (s, 3H, Me-Zr). Some peaks overlap with those of the two starting compounds.

9: Complex **2** (8.26 g, 8.66 mmol) and $[Mg(C_{16}H_{14})(thf)_3]$ (3.9 g, 8.73 mmol) were suspended in toluene (250 mL) at −30 °C. The mixture, which became deep red in seconds, was stirred and allowed to warm to room temperature. Dioxane (5 mL) was added and the mixture was stirred for 1 h. Volatiles were then removed in vacuo (heating to 50 °C). The residue was extracted overnight with a mixture of hexane (230 mL) and benzene (30 mL). The red suspension was kept at −25 °C for 24 h to give **9** with 1.5 molecules of cocrystallized benzene as a deep red microcrystalline solid, which was collected and dried in vacuo (5.79 g, 61.4%). Anal. calcd for $C_{71}H_{81}O_4Zr$: C 78.26, H 7.49; found: C 78.31, H 7.73. ^{1}H NMR (C_6D_6, 25 °C): δ = 7.36–6.63 (m, 27H, Ar H, benzene), 6.07 (m, 2H, H(5,6)), 4.48 (s, 3H, MeO), 4.31 (d, J = 12.5 Hz, 2H, *endo*-CH_2), 4.00 (m, 2H, H(1,2)), 3.92 (d, 2H, *endo*-CH_2) overlapping with 3.89 (s, 3H, MeO), 3.30 (d, J = 12.5 Hz, 2H, *exo*-CH_2), 2.94 (d, J = 12.5 Hz, 2H, *exo*-CH_2), 1.37 (s, 18H, *t*Bu), 0.70 (s, 9H, *t*Bu), 0.64 (s, 9H, *t*Bu); ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.37–6.50 (m, 27H, Ar H, benzene), 6.09 (m, 2H, H(5,6)), 4.97 (s, 3H, MeO), 4.72 (s, 3H, MeO), 4.29 (d, J = 12.5 Hz, 2H, *endo*-CH_2), 3.80 (m, 2H, H(1,2)), overlapping with 3.72 (d, 2H, *endo*-CH_2), 3.32 (d, J = 12.5 Hz, 2H, *exo*-CH_2), 2.86 (d, J = 12.5 Hz, 2H, *exo*-CH_2), 1.20 (s, 18H, *t*Bu), 1.06 (s, 9H, *t*Bu), 1.00 (s, 9H, *t*Bu). Crystals suitable for X-ray analysis were obtained at room temperature from a supersaturated solution of **9** in hexane/benzene (10/1). The product can be refluxed in benzene for hours without appreciable decomposition, as judged by its NMR spectrum, and it is photosensitive (benzene solutions become colorless when exposed to sunlight and the calixarene species formed is the same as that formed in photolysis of **9**). Complex **9** is stable to CO (1 bar) in benzene.

[13] a) Crystal structure analysis of **3**: $C_{48}H_{69}O_4Zr$, M = 801.25, monoclinic, space group $P2_1/c$, a = 16.299(2), b = 13.757(4), c = 20.250(2) Å, β = 93.35(1)°, V = 4533(2) Å^3, Z = 4, ρ_{calcd} = 1.174 g cm^{-3}, F(000) = 1716, $Cu_{K\alpha}$ radiation (λ = 1.54178 Å), $\mu(Mo_{K\alpha})$ = 22.83 cm^{-1}; crystal dimensions 0.15 × 0.26 × 0.43 mm. The structure was solved by the heavy-atom method and refined anisotropically for all non-hydrogen atoms. One of the four *t*-butyl groups was disordered. The hydrogen atoms (except for those of the disordered group) were located from a difference map and introduced as fixed contributors in the last stage of refinement (U_{iso} = 0.10 Å^2). For 5580 unique observed reflections [$I > 2\sigma(I)$] collected at room temperature on a Rigaku AFC6S diffractometer ($5° < 2\theta < 140°$) and corrected for absorption the final R value was 0.052 ($wR2$ = 0.132). b) Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[14] Crystal structure analysis of **9**: $C_{62}H_{70}O_4Zr \cdot 5C_6H_6$, M = 1087.56, triclinic, space group $P\bar{1}$, a = 14.684(2), b = 17.992(2), c = 13.033(2) Å, α = 109.64(1), β = 103.51(1), γ = 86.55(1)°, V = 3152.6(7) Å^3, Z = 2, ρ_{calcd} = 1.146 g cm^{-3}, F(000) = 1154, $Cu_{K\alpha}$ radiation (λ = 1.54178 Å), $\mu(Mo_{K\alpha})$ = 17.73 cm^{-1}; crystal dimensions 0.15 × 0.26 × 0.43 mm. A statistical distribution around the C51···C54 line in the diphenylbutadiene ligand was evident from a ΔF map calculated after the anisotropic refinement. The two orientations (A and B) of the butadiene framework share the C51 and C54 terminal carbon atoms and form a dihedral angle of 19.9(1.9)°, such that only C52 and C53 appear to be disordered. Refinement of the relative occupancies resulted in a value of 0.69(2) for C52A, C53A and 0.31(2) for C52B, C53B. The four *t*-butyl groups are severely disordered. All the hydrogen atoms except those of the *t*-butyl groups were located in a difference map (including those attached to C52A and C53A) and used in the structure factor calculations (U_{iso} = 0.10 Å^2). For 4273 unique observed reflections [$I > 2\sigma(I)$] collected at room temperature on a Rigaku AFC6S diffractometer ($6° < 2\theta < 140°$) and corrected for absorption the final R value was 0.080 ($wR2$ = 0.194). All calculations were performed by using SHELX76 for the early stages of solution and SHELXL92 for refinements on an Encore 91 computer. See ref. [13b].

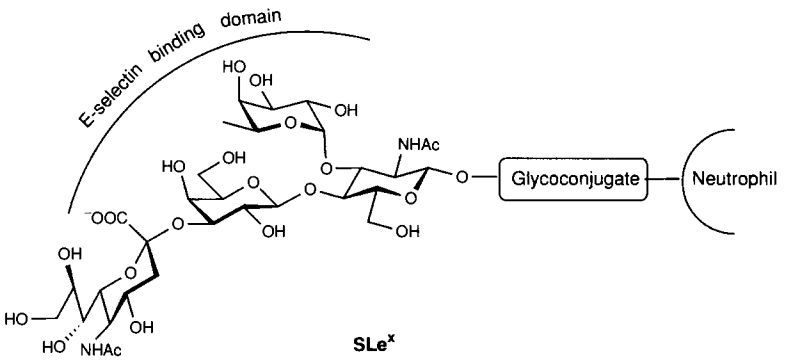
Synthesis of Fucopeptides as Sialyl Lewis^x Mimetics**

Shih-Hsiung Wu, Makoto Shimazaki, Chun-Cheng Lin, Lei Qiao, Wilna J. Moree, Gabriele Weitz-Schmidt, Chi-Huey Wong*

The Ca^{2+}-dependent interaction between E-selectin of endothelial cells and sialyl Lewis^x (SLe^x) of neutrophils is a critical carbohydrate–protein recognition event that occurs shortly after tissue injury and leads to acute and chronic inflammations.[1] E-selectin is also inducibly expressed in response to inflammatory factors such as tumor necrosis factor (TNF), interleukin-1b (IL-1b), leukotriene B_4, neurotoxins, and endotoxins, while SLe^x is presented by glycoproteins and/or glycolipids on the neutrophil surface. Thus, blocking the SLe^x/E-selectin



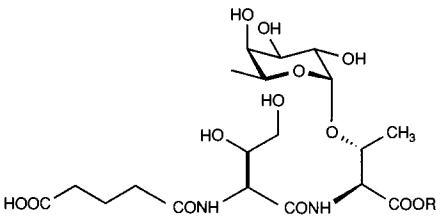
SLe^x

interaction has been considered to be an effective way to treat neutrophil-mediated inflammatory diseases.[2] Although SLe^x has been considered as an antiinflammatory agent, this tetrasaccharide can only be used in acute cases, as it is unstable in the blood and orally inactive. In addition, it is generally difficult to synthesize oligosaccharides on a large scale. It is therefore of great interest to develop oligosaccharide mimetics that are more stable and active, possess better bioavailability, and are easier to make.

The conformation of SLe^x in solution[3] and the three-dimensional structure of the human E-selectin[4] have been determined. The key structural features of SLe^x required for recognition by E-selectin have also been determined.[5] The L-fucose, D-galactose (Gal), and sialic acid moieties of SLe^x are the major components that interact with E-selectin, and the *N*-acetylglucosamine unit acts merely as a linker connecting L-fucose and sialyl galactose. Six functional groups of the SLe^x molecule—the 2-, 3-, and 4-hydroxyl groups of L-fucose, the 4- and 6-hydroxyl groups of Gal, and the carboxylate group of sialic acid—are essential for E-selectin recognition. Compounds containing these functional groups, which mimic the active conformation of SLe^x in space, have been designed and synthesized,[6] and two of them exhibit activities similar to that of SLe^x in the E-selectin binding assay.[6d] Although the C-linked fucopeptide[6d] is highly active, the fucose and the galactose equivalents may not be in the same positions in space as those in SLe^x. We report here the design and synthesis of a simple fucopeptide as a SLe^x mimetic, which has the same activity as SLe^x in the E-selectin binding assay, and compare the binding activity of this mimetic to that of related compounds.

The fucopeptide **1a** contains an L-fucose residue, two hydroxyl groups from (2*S*,3*R*)-2-amino-3,4-dihydroxybutyric acid corresponding to the 4- and 6-hydroxyl groups of the Gal residue, and a carboxylate group from the glutarate residue to mimic the negatively charged group in the sialic acid residue. When L-threonine is used to replace *N*-acetylglucosamine, the configuration of the glycosidic linkages is expected to be retained. Molecular modeling indeed indicates that the six key functional groups in compound **1a** have the same arrangement in space as the analogous groups of the active SLe^x. Compounds **2** and **3** were designed in a similar way except that the dihydroxy amino acid is replaced with another amino acid in order to address its role in recognition.

The synthesis of **1a** is shown in Scheme 1. L-Fucose was first converted into tribenzylfucosyl phosphite by the established method[7] and successfully coupled to Boc-L-Thr-OEt with trifluoromethanesulfonic acid (TfOH) or trimethylsilyl trifluoromethanesulfonate (TMSOTf) as catalyst to give the Boc-(αFuc3,4,5Bn_3)-L-ThrOEt (**4**) in 80% yield. The Boc group was removed from **4** without cleavage of the fucosidic bond by treatment with 30% TFA in CH_2Cl_2 (25 °C, 30 min). The resulting amine was coupled with (2*S*,3*R*)-*N*-Boc-2-amino-4-benzyloxy-3-hydroxy butyric acid[8] to provide **5**. Removal of the Boc protecting group, followed by coupling with monobenzyl glutarate, provided



1a, R = Et
1b, R = H

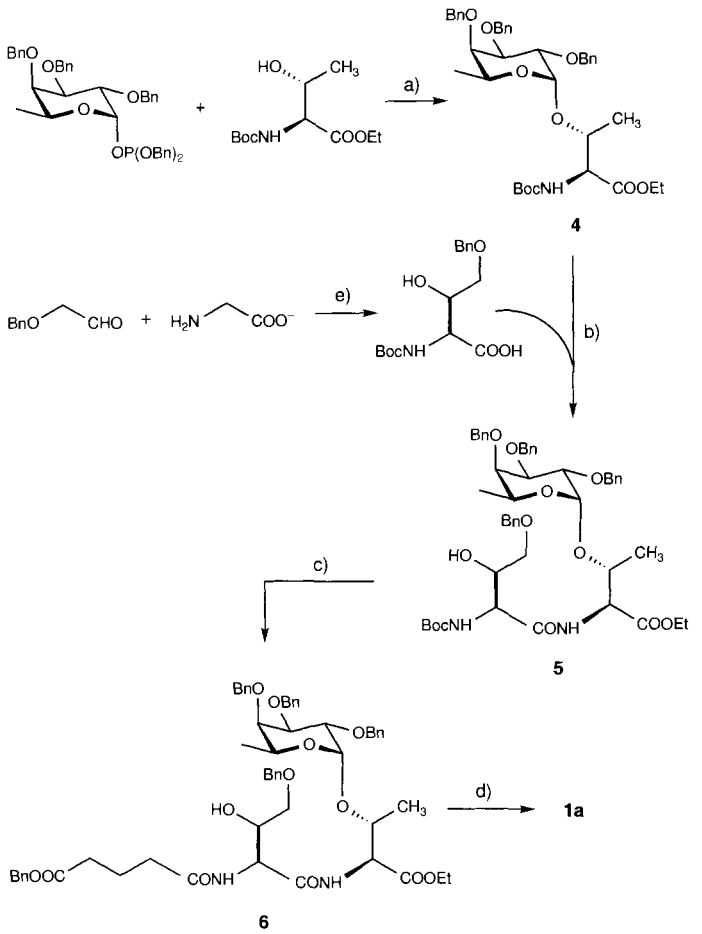
[**] Financial support of this work was provided by the National Science Foundation (USA), Sandoz Pharmaceuticals Ltd. (Switzerland), the National Science Council of Taiwan (grant to S.-H. W.), and NATO (fellowship to W. J. M.).



Scheme 1. a) TfOH, CH_2Cl_2, −15 °C, 1 h, 84%; b) 1. 30% TFA in CH_2Cl_2, 25 °C, 30 min; 2. 1.5 equiv HOBt, 1.5 equiv EDCI, CH_2Cl_2, 0 °C, 30 h, 60%; c) 1. 30% TFA in CH_2Cl_2, 25 °C, 30 min; 2. monobenzyl glutarate, 1.5 equiv HOBt, 1.5 equiv EDCI, CH_2Cl_2, 25 °C, 20 h, 70%; d) H_2 (1 atm), 20% $Pd(OH)_2/C$, MeOH, 24 h, 50%; e) 1. threonine aldolase, 86%; 2. $BocN_3$, 90%. Bn = $PhCH_2$; Boc = *tert*-butoxycarbonyl; Tf = CF_3SO_2; TFA = trifluoroacetic acid; HOBt = hydroxybenzotriazole; EDCI = *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide.

compound **6**. The benzyl groups of **6** were cleaved by hydrogenation over 20% $Pd(OH)_2/C$ in MeOH, and the crude product was purified by Biogel P-2 chromatography to give **1a** (54%). Compound **1a** and other key intermediates were characterized by ^1H NMR spectroscopy and high-resolution mass spectrometry (Table 1). Compounds **2** and **3** were synthesized from the key intermediate **4** by the same methods (Table 1).

An analysis of these compounds as inhibitors of E-selectin gave the following IC_{50} values: **1a**, 0.5 mM; **2**, 1.0 mM; **3**, 1.3 mM.[9] Conversion of **1a** to **1b** decreases the activity (IC_{50} = 1.0 mM). Since compound **1a** has the same biological activity as SLe^x (0.50 mM), all the functional groups required for E-selectin binding in SLe^x must exist in **1a**. Compounds **1b** and **2** are slightly less active than SLe^x, probably due to the presence of the free carboxyl group in the Thr moiety. Compound **3** is, however, surprisingly active, as the OH group of Tyr in **3** does not correspond spatially to the essential OH groups of the Gal residue in SLe^x. Whether the hydrophobic nature of the aromatic group or the additional amino group contributes to binding is unclear. Replacement of the dihydroxy amino acid with L-Thr, L-Ser, Phe, Ala, or Gly, however, results in a nearly complete loss of activity (IC_{50} > 10 mM).

This study thus confirms the minimum structural elements required for E-selectin recognition and provides a new direction for the development of SLe^x mimetics. Compared to the synthesis of SLe^x, the preparation of **1a** is very straightforward and can be scaled up easily. Work is in progress to couple an Arg-Gly-Asp (RGD) containing peptide to the carboxylate group of the Thr residue of **1b** to obtain a potential inhibitor of P- and L-selectins.[10]

Table 1. NMR spectroscopic and mass spectrometric data for **1**–**6**.

1 (amorphous): ^1H NMR (400 MHz, D_2O): δ = 4.98 (d, J = 3.2 Hz, 1H), 4.61 (d, J = 2.2 Hz, 1H), 4.56 (d, J = 7.2 Hz, 1H), 4.46–4.44 (dd, J = 2.2, 6.4 Hz, 1H), 4.28–4.13 (m, 3H), 4.02–3.98 (m, 1H), 3.86–3.59 (m, 5H), 2.42–2.22 (m, 4H), 1.90–1.79 (m, 2H), 1.30–1.18 (m, 9H); electrospray negative-ion mass (−80 V): *m/z*: 523 $[(M-H)^-]$; calcd for $C_{21}H_{36}N_2O_{13}$: 524].

2 (amorphous): ^1H NMR (400 MHz, D_2O): δ = 4.96 (d, J = 3.2 Hz, 1H), 4.68–4.37 (m, 3H), 4.07–3.63 (m, 7H), 2.43–2.37 (m, 4H), 1.85–1.75 (m, 2H), 1.23–1.13 (m, 6H); electrospray negative-ion mass (−80 V): *m/z*: 495 $[(M-H)^-]$; calcd for $C_{19}H_{32}N_2O_{13}$: 496].

3 (amorphous): ^1H NMR (500 MHz, D_2O): δ = 7.02 (d, J = 8.4 Hz, 1H), 6.69 (d, J = 8.3 Hz, 1H), 4.81 (d, J = 4.0 Hz, 1H), 4.57 (dd, J = 4.8, 9.0 Hz, 1H), 4.29–4.07 (m, 3H), 3.85 (q, J = 6.5 Hz, 1H), 3.74–3.55 (m, 3H), 3.05–2.99 (m, 1H), 2.81–2.72 (m, 2H), 2.58–2.50 (m, 1H), 1.01 (d, J = 6.5 Hz, 3H), 0.97 (d, J = 6.0 Hz, 3H); electrospray negative-ion MS (−80 V): *m/z*: 542 $[(M-H)^-]$; calcd for $C_{23}H_{33}N_3O_{12}$: 543].

4: ^1H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.25–7.40 (m, 15H; 3 × Ph), 5.34 (d, J = 9.6 Hz, 1H; NH), 4.92 (d, J = 11.6 Hz, 1H; PhCH), 4.84 (d, J = 3.8 Hz, 1H; Fuc 1-H), 4.79 (d, J = 11.4 Hz, 1H; PhCH), 4.76 (d, J = 11.5 Hz, 1H; PhCH), 4.67 (d, J = 11.7 Hz, 1H; PhCH), 4.62 (d, J = 11.9 Hz, 1H, PhCH), 4.60 (d, J = 11.6 Hz, 1H; PhCH), 4.32–4.28 (m, 2H; Thrα- and β-H), 4.18 (dd, J = 7.2, 10.8 Hz, 1H; Fuc 2-H), 4.10–3.99 (m, 1H; Fuc 5-H), 3.80 (dd, J = 2.8, 10.1 Hz, 1H; Fuc 3-H), 3.69 (q, J = 7.0 Hz, 2H; CH_3CH_2O), 3.60 (d, J = 2.4 Hz, 1H; Fuc 4-H), 1.48 (s, 9H; *t*Bu), 1.24 (t, J = 7.2 Hz, 3H; CH_3CH_2O) 1.21 (d, J = 6.5 Hz, 3H; Thr Me), 1.06 (d, J = 6.4 Hz, 3H; Fuc 6-H); HR-MS for $(C_{38}H_{49}NO_9+Cs)^+$ $[M+Cs^+]$: calcd 796.2462, found 796.2485.

5: ^1H NMR (400 MHz, $CDCl_3$, TMS):δ = 7.21–7.50 (m, 20H; 4 × Ph), 5.38 (d, J = 9.4 Hz, 1H; NH), 4.95–4.57 (m, 9H; 4 × $PhCH_2$), 4.35–3.99 (m, 5H; Thrα- and β-H, $CH(OH)CH_2OBn$, Fuc 2- and 5-H), 3.80–3.60 (m, 7H; CH_3CH_2O, $NHCH(CH(OH)CH_2OBn)$, Fuc 3- and 4-H), 1.48 (s, 9H; *t*Bu), 1.24 (t, J = 7.2 Hz, 3H; CH_3CH_2O), 1.21 (d, J = 6.5 Hz, 3H; Thr Me), 1.06 (d, J = 6.4 Hz, 3H; Fuc 6-H); HR-MS for $(C_{49}H_{62}N_2O_{12}+Cs)^+$ $[M+Cs^+]$: calcd 1003.3357, found 1003.3315.

6: ^1H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.28–7.64 (m, 25H; 5 × Ph), 5.09 (s, 2H; $COOCH_2Ph$), 4.97–4.54 (m, 9H; 4 × $PhCH_2$, Fuc 1-H), 4.27–4.15 (m, 3H; Thr α- and β-H, $CH(OH)CH_2OBn$), 4.05–3.98 (m, 2H; Fuc 2- and 5-H), 3.80 (dd, J = 2.8, 10.2 Hz, 1H; Fuc 3-H), 3.67–3.52 (m, 6H; $NHCH(CH(OH)CH_2OBn)$, CH_3CH_2O, Fuc 4-H), 2.47–2.33 (m, 4H; $OCH_2CH_2CH_2O$), 2.01–1.91 (m, 2H; $OCH_2CH_2CH_2O$), 1.24 (t, J = 7.2 Hz, 3H; CH_3CH_2O), 1.21 (d, J = 6.5 Hz, 3H; Thr Me), 1.07 (d, J = 6.5 Hz, 3H; Fuc 6-H); HR-MS for $(C_{56}H_{66}N_2O_{13}+Cs)^+$ $[M+Cs^+]$: calcd 1107.3614, found 1107.3667.

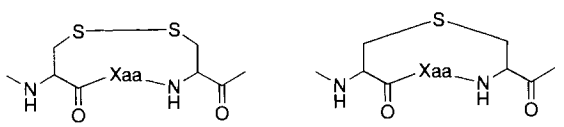
β,β-Dimethylcyclolanthionines, New Constrained Dipeptide Mimetics: Synthesis, Crystal Structures, and Conformational Studies**

Hui Shao, Chang-Woo Lee, Qin Zhu, Peter Gantzel, and Murray Goodman*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

In the past decade extensive efforts have been focused on the design of novel peptidomimetics for biomedical applications.[1] Recently, lanthionine,[2] a monosulfide cystine analog, has been examined by us as a new peptidomimetic (Scheme 1). The results of the chemical, biological, and physiological investigations indicate that lanthionine is an effective building block with conformational constraint and metabolic stability.[3] In this communication, we describe the design and synthesis of new constrained dipeptide mimetics based on β,β-dimethylcyclolanthionine.

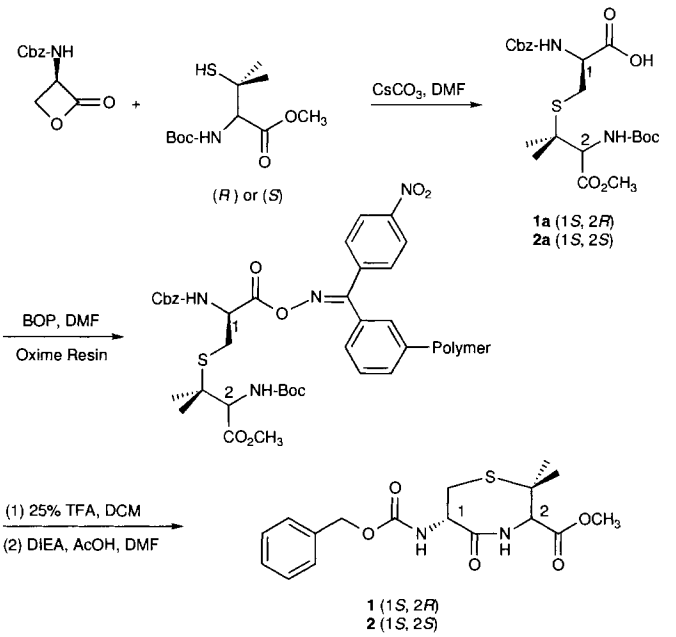


peptide chain with disulfide bridge lanthionine-modified peptide chain

Scheme 1. Representative disulfide and lanthionine structures in peptide chains. Xaa = amino acid residue.

The disulfide bridges between cysteine (Cys) residues in a peptide chain are most important covalent cross-linkages in proteins and peptide hormones[3, 4] (Scheme 1). In particular, the cysteinyl-cysteinyl motif (abbreviated as Cys-Cys), in which the two adjacent cysteine residues are connected by both amide and disulfide bridges, is a unique sequence in some naturally occurring peptides and proteins including malformin A, the γ-subunit of transducin, the nicotinic acetylcholine receptor (AChR), and mercuric reductase.[5, 6] It has been reported that the amide bond in Cys-Cys exists predominantly in the *cis* conformation and in solution it interconverts with the *trans* amide structure; in the solid state only the *cis* amide conformation is found.[5, 7] Furthermore, when Cys-Cys is changed to its penicillamine (Pen, β,β-dimethylcysteine) analog, Cys-Pen, a *trans* amide bond exists both in solution and in the solid state.[8] Our previous studies on cyclolanthionine showed that a *cis* amide bond in the seven-membered ring structure is the only conformation observed both in solution and in the solid state.[3g]

Two stereoisomers of β,β-dimethylcyclolanthionine, **1** and **2**, were prepared stereoselectively by regioselective ring-opening of *N*-Cbz-(*R*)-serine-β-lactone with the methyl esters of *N*-Boc-(*R*)- and -(*S*)-penicillamine, respectively (Scheme 2).[3a] Cyclizations were carried out on an oxime resin to provide the β,β-dimethylcyclolanthionine analogs **1** and **2** in high yields. The structures of these compounds have been analyzed by X-ray crystallography (Fig. 1).[9] Although the two isomers differ in the configuration of one chiral center, the ring structures adopt very similar conformations in the solid state with *cis* amide bonds rather than *trans* amides (Table 1). The only difference between the two diastereomers is the orientation of the carboxymethyl groups relative to the ring structures. The (1*S*,2*R*) configuration of isomer **1** orients the C- and N-terminal groups perpendicular to each other. On the other hand, the (1*S*,2*S*) isomer **2** has an extended conformation. Both conformations



Scheme 2. Synthesis of β,β-dimethylcyclolanthionine analogs **1** and **2**. Bcz = benzyloxycarbonyl, Boc = *tert*-butoxycarbonyl, BOP = benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate, DMF = dimethylformamide, TFA = trifluoroacetic acid, DCM = dichloromethane, DIEA = ethyldiisopropylamine.

are identical to those we observed for the corresponding unsubstituted cyclolanthionine analogs.[3g]

The conformational preferences of the two isomers in solution were determined by NMR measurements in [D_6]DMSO and by subsequent computer simulations. Both isomers are characterized by *cis* amide bonds between the first and the second residue as indicated by NOE data. The most preferred ring conformations for both isomers in solution were compared with the solid-state conformations (Table 1). For isomer **2** the two conformations are similar. However, for isomer **1** the preferred conformation in solution differs dramatically from that in solid state (Fig. 2). In the X-ray crystal structure the N-terminal group is in the equatorial position of a boat conformation, while the C-terminal group prefers the axial position. In solution the ring structure of **1** exists in a unique folded boat conformation,

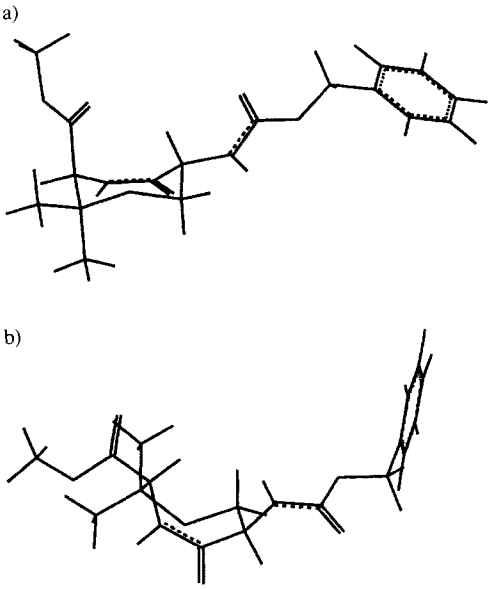

Fig. 2. Comparison of the conformations **1** in the solid state (a) and in solution (b).

which makes the orientations of the N-terminal and C-terminal groups different from the arrays in solid states. Comparison of the two conformations shows that the solid-state conformation is about 2.6 kcal mol^{-1} higher in energy than the conformation in solution. Since the conformations of β,β-dimethylated cyclolanthionines in the crystal structures are similar to the conformations of their corresponding unsubstituted analogs both in the solid state and in solution, the comparison indicates that β,β-dimethylation alters only the conformational preference in solution. In the solid state intermolecular interactions play an important role in stabilizing certain conformations as a result of molecular packing effects. The favorable conformations for molecular packing, of course, are not found in solution. This case illustrates the effect of solvent and crystal packing forces on preferred conformations of peptide-based structures.

We have described the synthesis and structural features of two new dipeptide mimetics, the diastereomeric β,β-dimethylcyclolanthionines **1** and **2**. An interesting feature is the discovery of two different conformations in the solid state and in solution. Our synthetic methods can also lead to (1*R*,2*S*) and (1*R*,2*R*) diastereomers of **1** and **2** if we start with appropriate amino acids. The stereoisomers of β,β-dimethylcyclolanthionine have distinctive structural features that depend on the chirality at each asymmetric center, which make them attractive building blocks or templates for the design of peptidomimetic drugs.

Experiment Procedure

Synthesis of compounds **1** and **2**: Compounds **1a** and **2a** were prepared by methods developed in our group [3]. The synthesis of compounds **1** and **2** were carried out on a Kaiser oxime resin [3] (5 g), which was suspended in CH_2Cl_2 (60 mL) for 1 h. After removal of the solvent the resin-containing vessel was charged with **1a** or **2a** (485 mg, 1 mmol), BOP (664 mg, 1.5 mmol) and anhydrous DMF (20 mL, dried over molecular sieves). Diisopropylethylamine (517 mg, 0.70 mL) was added, and the mixture was shaken for 24 h on a wrist action shaker (model 75, Burrell Corp.). The cyclization and isolation were carried out using procedures described for peptide cyclization on an oxime resin [3]. The crude product was purified by silica gel chromatography with ethyl acetate/hexane (1/1, v/v). The crystals were grown in ethyl acetate solution at room temperature.

1: Colorless solid; m.p. 142 °C; $[\alpha]_D^{20} = -4.4$ ($c = 0.16$, $CHCl_3$); ^{1}H NMR (500 MHz, [D_6]DMSO): $\delta = 1.336$ (3H, s), 1.38 (3H, s), 2.53 (1H, m), 2.82 (1H, m),

3.72 (3H, s), 4.08 (1H, d, J = 7.7 Hz), 4.61 (1H, m), 5.02 (2H, s), 7.31 (1H, m), 7.35 (5H, m), 7.80 (1H, d, J = 7.8 Hz); FAB-MS: m/z: 367 (MH^+); HRMS: m/z calcd for $C_{17}H_{23}O_5N_2S$: 367.1328; found: 367.1348; Anal. calcd for $C_{17}H_{22}O_5N_2S$: C 55.72, H 6.05, N 7.64; found: C 55.64, H 6.16, N 7.51.

2: Colorless solid; m.p. 140 °C; $[\alpha]_D^{20} = -30.9$ (c = 0.57, $CHCl_3$); ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 1.36 (3H, s), 1.38 (3H, s), 2.54 (1H, m), 2.82 (1H, m), 3.71 (3H, s), 4.09 (1H, d, J = 7.8 Hz), 4.61 (1H, m), 5.02 (2H, s), 7.31 (1H, m), 7.35 (5H, m), 7.80 (1H, d, J = 6.8 Hz); FAB-MS: m/z: 367 (MH^+); HRMS: m/z calcd for $C_{17}H_{23}O_5N_2S$: 367.1328; found: 367.1333; Anal. calcd for $C_{17}H_{22}O_5N_2S$: C 55.72, H 6.05, N 7.64; found: C 55.70, H 6.20, N 7.53.

NMR Spectroscopy: The ^{1}H NMR spectra were recorded with a Bruker AMX 500 spectrometer at 300 K. Samples were prepared in [D$_6$]DMSO at concentrations of 30–40 mM. The resonance of [D$_5$]DMSO (δ = 2.49) was used as an internal standard. The one-dimensional spectra were collected with 32 K data points and with spectral widths of ±3000 or ±2000 Hz. The two-dimensional DQF COSY experiments were acquired with 2 K data points in the t_2 domain and with 256 data points in the t_1 domain. The ROESY experiments were carried out with a mixing time of 150 ms and a spin lock field of 2.5 KHz, and with 2 K data points in the t_2 domain and 256 data points in the t_1 domain. Zero-fillings were applied in the t_1 domain. Multiplication with phase-shifted sine function was employed in all spectra.

Computer Simulations: All calculations were carried out on an Iris 40-25 and a Challenge L computer. The distance geometry program DGEOM was used to generate structures compatible with NOE constraints. Energy minimizations were carried out with the DISCOVER force field program. Distance-dependent dielectric constants were used for all calculations. Structures generated from DGEOM were minimized by the steepest descent algorithm for 100 steps followed by the VAO9A algorithm until all the derivatives were smaller than 0.001 kcal mol^{-1} Å^{-1}.

A Sequential Electron-Transfer Relay in Diporphyrin–Porphyrin–Pyromellitimide Triads Analogous to That in the Photosynthetic Reaction Center**

Atsuhiro Osuka,* Satoshi Nakajima, Tadashi Okada,* Seiji Taniguchi, Koichi Nozaki, Takeshi Ohno, Iwao Yamazaki, Yoshinobu Nishimura, and Noboru Mataga*

The reaction center (RC) of photosynthetic bacteria contains a number of cofactors that mediate a series of fast electron transfers, yielding an oxidized electron donor and a reduced electron acceptor on the opposite sides of a membrane. The key steps in this process are the initial charge separation (CS) between tetrapyrrolic pigments and the subsequent charge-shift reaction (CSH) to a quinone acceptor to generate a stable, long-lived, charge-separated state.[1] Numerous model compounds have been prepared to understand the factors controlling electron transfer (ET) reactions in these highly complex systems.[2, 3] In the past decade the advantages of multiple electron transfers have been amply demonstrated.[4, 5] Nevertheless, modeling the sequential electron transfer relay of the reaction center remains very difficult, particularly with regard to the ET reaction scheme outlined above.[6]

Recently, we described the intramolecular charge separation in triads **13** and **14**, which comprise a zinc diporphyrin (Dp), a zinc monoporphyrin (Mp), and a pyromellitimide (Im).[7] Upon photoexcitation in THF at 532 nm, these triads give Dp$^+$-Mp-Im$^-$ ion pairs with lifetimes of 0.25 μs (**13**) and 2.4 μs (**14**) in relatively low quantum yield by the pathway Dp-^{1}Mp*-Im → Dp-Mp$^+$-Im$^-$ → Dp$^+$-Mp-Im$^-$. The low quantum yields are due mainly to efficient intramolecular singlet–singlet energy

transfer from ^{1}Mp* (2.13 eV) to Dp (1.97 eV); the ^{1}Dp*-Mp-Im thus formed does not undergo electron transfer (ET) reactions.

We report here on the synthesis of triads **1** and **2**, which consist of a zinc diporphyrin, an uncomplexed porphyrin, and pyromellitimide (Dp-Hp-Im). These triads serve as functional models for the photosynthetic RC, since they display an efficient ET relay, ^{1}Dp*-Hp-Im → Dp$^+$-Hp$^-$-Im → Dp$^+$-Hp-Im$^-$, which is quite similar to the primary ET events in the RC. The triads **1** and **2** are designed such that 1) the energy gradient ^{1}Dp*-Hp-Im or Dp-^{1}Hp*-Im > Dp$^+$-Hp$^-$-Im > Dp$^+$-Hp-Im$^-$ allows the occurrence of the ET relay, and 2) the respective oxidized or reduced chromophores exhibit characteristic absorption bands, making the analysis of ET dynamics very easy.[7] The former condition is satisfied by **1**, as shown in Figure 1. Here the energies of the charge-separated pair states were estimated with corrected solvation energies, which were calculated by the Born equation using the one-electron oxidation and reduction potentials.[8]

The synthetic route to **1** is shown in Scheme 1. The acid-catalyzed condensation of formyl-substituted diporphyrins **8**[7] and pyromellitimide-substituted benzaldehyde **9**[9] with dipyrrolylmethane **10**[10] under the previously reported conditions[11] gave triporphyrin **11** in 30% yield (based on **8**). Selective zinc-metalation was performed by careful treatment of **11** with exactly two equivalents of $Zn(OAc)_2$, giving **1** in 60% yield. The eight β-alkyl substituents seem to enhance the basicity of the porphyrin ligand by their electron-donating property, which leads to an enhanced affinity toward zinc(II) ions. The ^{1}H NMR spectrum of **11** shows a broad signal at $\delta \approx 6$ due to the four inner NH protons of the diporphyrin and a signal at $\delta \approx -3$ attributed to the two inner NH protons of the monoporphyrin. The former signal is diagnostic of 1,2-phenylene-bridged diporphyrins. In contrast, the spectrum of **1** exhibits only peaks due to the two inner NH protons at $\delta \approx -3$. Another triad, compound **2**, which bears a 4,4'-biphenylene spacer between Dp and Hp, was prepared from **12**[7] in essentially the same manner as **1** was synthesized from **8**. Pyromellitimide-free molecules **3** and **4** as well as compounds **5**–**7** were also prepared as references.

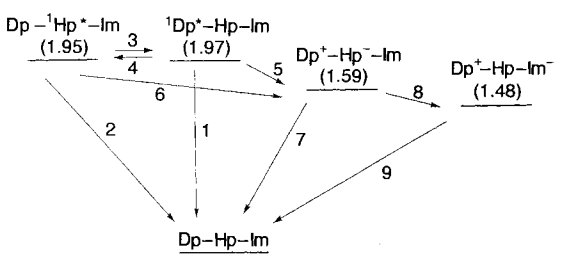

Fig. 1. Reaction scheme and energy diagram for **1** in THF. Numbers in parentheses indicates the approximate energies in eV [8].

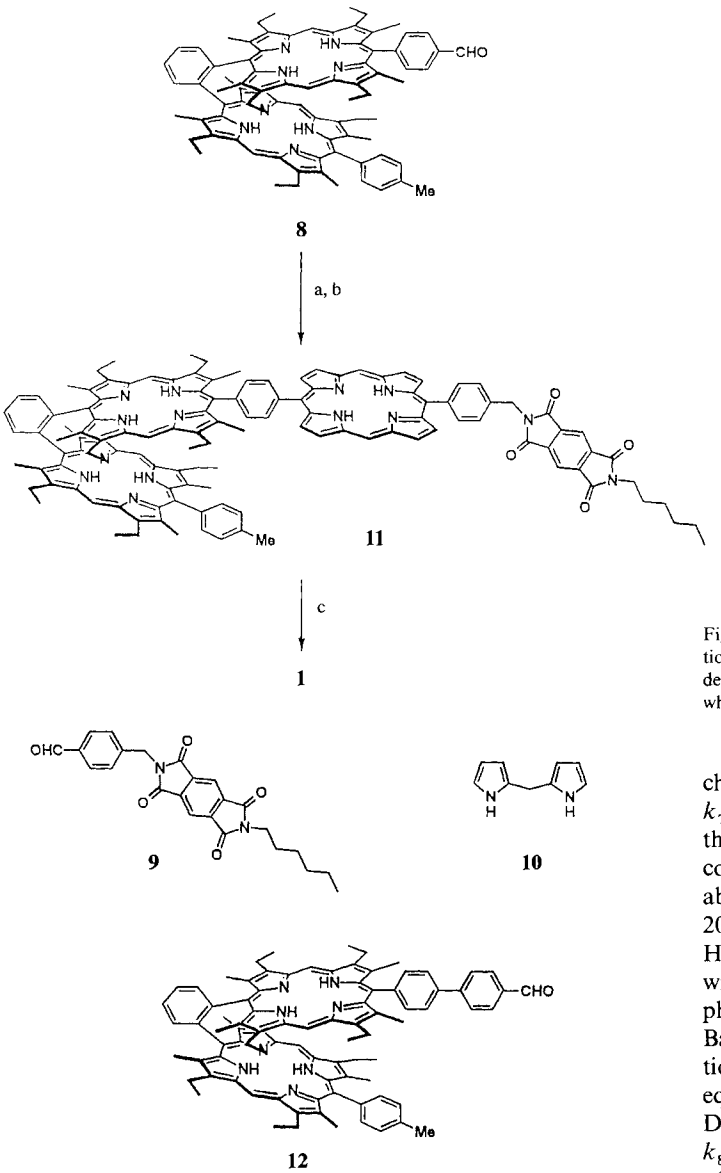
The UV/Vis absorption spectra of **1**–**4** are nearly identical to the sum of the spectra of the chromophores **5** and **6**, indicating that electronic interaction is weak in the ground states of **1**–**4**. To understand the dynamics of the photoexcited states of the triads it is appropriate to first consider some simpler reference molecules. The fluorescence intensity of **7** is identical to that of **6** in a wide range of solvents (e.g. benzene, THF, and DMF), indicating that there is no CS in the ^{1}Hp*-Im subunit. This has been confirmed by measurements of the fluorescence lifetime and transient absorption spectra as well.

In contrast, a strong fluorescence quenching in the Dp-Hp subunit has been observed for **1**–**4** in THF. Since the excitation energies to ^{1}Dp* (1.97 eV) and ^{1}Hp* (1.95 eV) are nearly the same, it is very difficult to selectively excite one chromophore.



Scheme 1. Synthesis of **1**. a) **9**, **10**, TFA, CH_2Cl_2, ca. 20 °C, 10 h; b) DDQ, ca. 20 °C, 10 h, 30%, c) $Zn(OAc)_2$ (2 equiv), $CHCl_3$/MeOH, ca. 20 °C, 20 min, 60%.

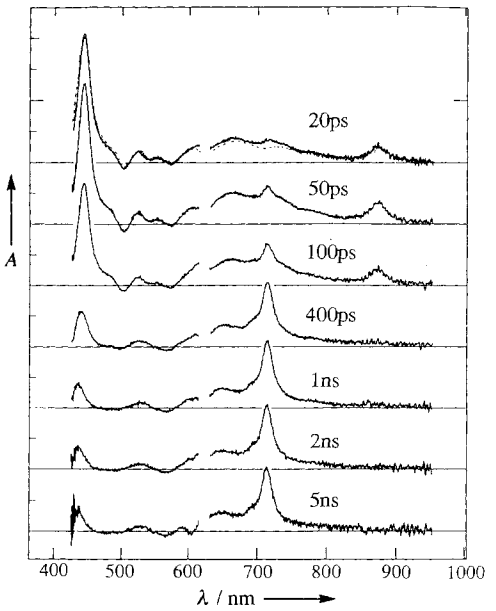


Fig. 2. Transient absorption spectra on the picosecond range of a 1×10^{-4} M solution of **1** in THF with 8 ps, 818 nm pulses. The dotted line in the spectrum at 20 ps delay time is for **3**. The details of the measuring system have been described elsewhere [13]. A = absorbance in 0.2 units per division.

We measured the transient absorption spectra by exciting at 618 nm; at this wavelength the incident light is absorbed by Dp and Hp in a ratio of 3:1. The transient absorption spectrum of **3** in THF recorded after a delay time of 20 ps (the dotted line in Fig. 2, top) shows immediate build-up of the absorption bands at 670 and 870 nm, which are characteristic of Dp^+ and Hp^-, respectively.[12] Figure 2 also displays the transient absorption spectra of the triad **1** recorded after delay times of 20 ps to 5 ns. The spectrum measured with a 20 ps delay time is nearly the same as that of **3** with a 20 ps delay time except for a weak absorption at 715 nm due to Im^-. These two spectra clearly indicate that Dp^+-Hp^--Im and Dp^+-Hp^- form from **1** and **3**, respectively, in high yield within 20 ps. Therefore, the rates of the formation of Dp^+-Hp^--Im and Dp^+-Hp^- are larger than 5×10^{10} s^{-1}n and the CS reactions (steps 5 and 6 in Fig. 1) are almost quantitative for the both models; when the lifetimes of $^1Dp^*$ (900 ps) and $^1Hp^*$ (12 ns) are also considered, estimated values of $k_1 = 1.1 \times 10^9$ s^{-1} and $k_2 = 8.3 \times 10^7$ s^{-1} result. Analysis of the time profile of the 870 nm absorption reveals that the Dp^+-Hp^- state of **3** decays to the ground state by charge recombination with a time constant of 1.2 ns (step 7, $k_7 = 8.3 \times 10^8$ s^{-1}). In the case of the Dp^+-Hp^--Im state of **1**, the decay of the Hp^- absorption is much faster with a time constant of 200 ps. Concomitantly the increase in the 715 nm absorption due to Im^-[7] has exactly the same time constant of 200 ps. These data clearly show that the CSH reaction of Dp^+-Hp^--Im to give Dp^+-Hp-Im^- (step 8, Fig. 1) is in competition with CR to the ground state. Therefore, the behavior of **1** after photoirradiation can be summarized as shown in Figure 1. Based on this scheme, the rate constant of the charge-shift reaction (k_8) was determined to be 4.1×10^9 s^{-1} by the following equation: $k_8 = 1/\tau_2 - 1/\tau_1$, where τ_1 and τ_2 are the lifetimes of Dp^+-Hp^- and Dp^+-Hp^--Im, respectively. It is now evident that k_8 is roughly five times larger than k_7. Therefore, the formation of Dp^+-Hp-Im^- from Dp^+-Hp^--Im is favored, and the overall quantum yield is greater than 0.8. Finally, the lifetime of the secondary ion pair Dp^+-Hp-Im^- was determined to be 280 ns.

Examination of the transient absorption spectra of 4,4′-biphenyldiyl-bridged models **2** and **4** reveal essentially the same type of ET relay. The initial ion pair Dp^+-Hp^--Im, which is formed with a time constant of 120 ps, undergoes a productive CSH reaction to provide Dp^+-Hp-Im^- with $k_8 = 4.6 \times 10^9$ s^{-1}; the CSH reaction is in competition with CR to the ground state with $k_7 = 4.0 \times 10^8$ s^{-1}. The quantum yield for the formation of Dp^+-Hp-Im^- therefore is still as high as 0.79; however, Dp^+-Hp-Im^- has a much longer lifetime (2.1 μs), reflecting the larger separation between the two charges. Comparison of k_8 values in **1** and **2** might be interesting, since it should reflect the electric-field effect exerted by Dp^+ upon the CSH reaction, which should be very significant in nonpolar media. The small differences in the k_{CSH} values (k_8) observed here indicate substantial dielectric shielding in THF. According to the Born equation, the difference in the free energies of the CSH reaction between **1** and **2** is only 0.02 eV.

In the more polar solvent DMF the excitation of **3** leads to the formation of Dp^+-Hp^- within 10 ps, which decays rapidly to the ground state by CR with $k_7 = 1.8 \times 10^{10}$ s^{-1}. The increase of k_7 in polar DMF is notable. Since the very poor solubility of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3501-0094 $ 10.00+.25/0

1 in DMF hampered the measurement of its transient spectra, we examined the dynamics of the photoexcited states of **2** and **4** in DMF. The energy levels of the ion pairs were calculated to be 1.41 eV for Dp^+-Hp^--Im and 1.19 eV for Dp^+-Hp-Im^-. Analysis of the transient absorption spectra of **2** and **4** reveals the formation of Dp^+-Hp^--Im within 30 ps, and the values of k_7 and k_8 were determined to be 1.0×10^{10} and $1.1 \times 10^9\ s^{-1}$, respectively. Here again the increase of k_7 is large in DMF, while k_8 is slightly smaller. As a consequence, the overall quantum yield decreases to roughly 0.1. The polar environment is of course favorable in lowering the energy level of the charge-separated states for the ET process. But it often accelerates the energy-wasteful CR reaction, which is accompanied by a concomitant decrease of the overall quantum yield of the charge separation, as observed in our system. This kinetic aspect may be quite common and should be taken into account in the future design of more elaborate photosynthetic model systems.

In summary, a sequential ET relay resembling that in the RC and ultimately leading to the formation of long-lived charge separated states has been realized in the Dp-Hp-Im triads **1** and **2**, which have a molecular composition quite similar to that of the RC. The polarity of solvent is crucial in determining the overall CS quantum yield. The polarity of the solvent is crucial for the overall CS quantum yield.

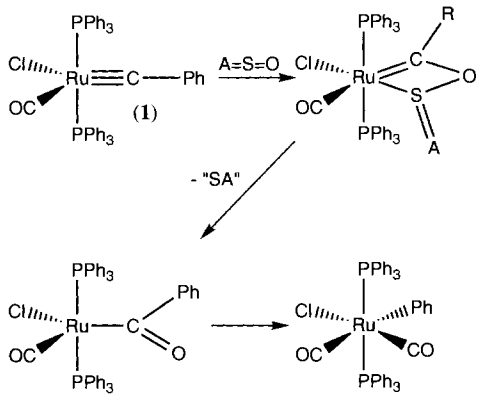
Cycloadditions of Ruthenium Alkylidyne Complexes with Carbonyl or Thiocarbonyl Compounds**

Robin B. Bedford, Anthony F. Hill,*
Andrew J. P. White, and David J. Williams

Whilst the cycloaddition of carbon–carbon and metal–carbon multiple bonds is central to alkene and alkyne metathesis processes,[1] the addition of heteroallenes and heteroalkenes to alkylidyne complexes has been less intensely studied[2] despite the added intrigue of multiple bond polarity. Reactions of alkylidyne complexes of Group 6 metals with carbon disulfide have been discussed recently by Mayr and Lee,[3] and the processes observed typically involve C–C bond formation. We have been previously concerned with the cycloaddition of SO_2 and iminooxosulfuranes to Group 8 alkylidyne complexes[4] and have suggested that the products derive from M–S and C–O bond formation (Scheme 1).[5] Herein we report the reactions of



Scheme 1. Addition of sulfur dioxide and iminooxo-λ^4-sulfuranes to a ruthenium benzylidyne complex. A = O, NC_6H_4-4-Me.

a ruthenium benzylidyne complex with CO_2, MeNCS, and CS_2, in which the orientation of addition is opposite to that observed in the analogous reactions with the Group 6 alkylidyne complexes.

Treating a solution of $[Ru(\equiv CPh)Cl(CO)(PPh_3)_2]$ (**1**)[6] with carbon disulfide leads to clean formation of a carbonyl-free complex, spectroscopic data (Table 1) for which are consistent with the formulation $[Ru(\eta^2\text{-}SCPh)Cl(CS)(PPh_3)_2]$ (**2a**) (Scheme 2). The corresponding carbonyl analogue **2b** could be prepared by the route outlined in Scheme 2, and spectroscopic data for the two analogues compare well in all respects but those associated with the thiocarbonyl/carbonyl ligand. This route to **2b** has precedent in the preparation of the complexes $[Os(\eta^2\text{-}SCC_6H_4\text{-}4\text{-}Me)Cl(CO)(PPh_3)_2]$ and $[Ru(\eta^2\text{-}SCSiMe_2OEt)Cl(CO)(PPh_3)_2]$.[7]

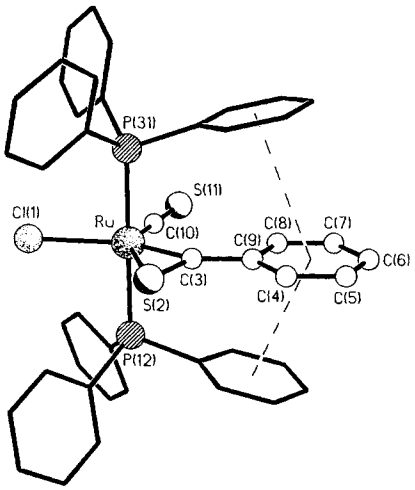

Fig. 1. The structure of **2a** in the crystal, showing the π-π stacking of the phosphane phenyl and thiobenzoyl rings.

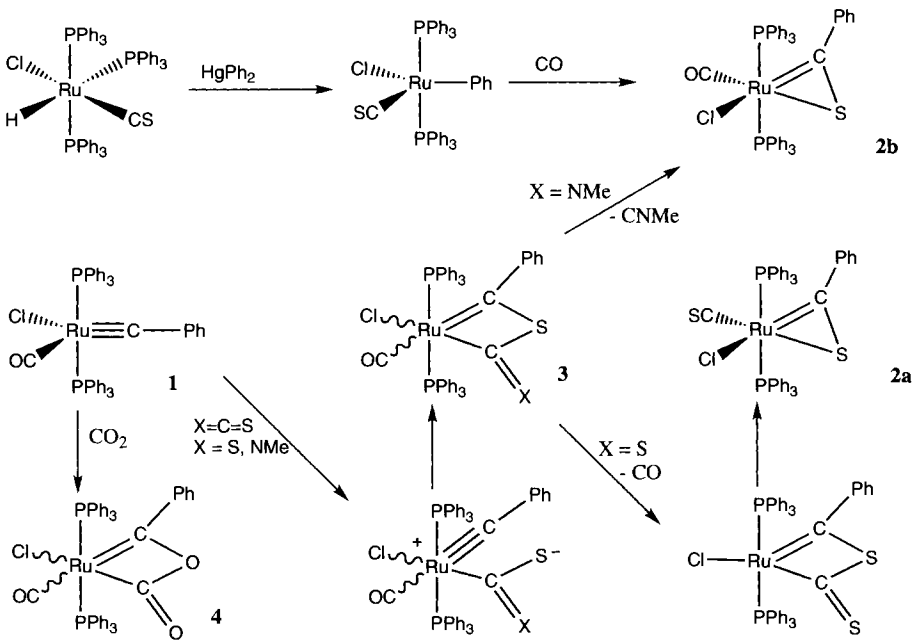

Scheme 2. Preparation of ruthenium(II) thiobenzoyl complexes.

The formulation of $[Ru(\eta^2\text{-SCPh})Cl(CS)(PPh_3)_2]$ (**2a**) was also confirmed by X-ray crystallography.[8] Although the structure is definitive (Fig. 1), detailed analysis of the relative molecular dimensions is precluded by positional disorder (35:65) of the thiocarbonyl and thiobenzoyl ligands about an axis approximately colinear with the Ru–Cl(1) bond such that there is almost perfect overlap between the Ru–S(2) linkage and the thiocarbonyl grouping. Considering the thiobenzoyl group as one ligand, the geometry at the ruthenium center is a distorted trigonal bipyramid; the S(2)-Ru-Cl(1) and C(10)-Ru-Cl(1) angles are noticeably contracted to about 109.0(2) and 104.4(9)°, respectively, and the P(31)-Ru-P(12) angle is 177.6(1)°. Interestingly, the carbon atoms of the thiobenzyl phenyl ring lie in the plane formed from the atoms Cl(1), S(2), C(3), and C(10). This orientation is consistent with conjugation between the aromatic ring and the C–S group of the thiobenzoyl ligand, which enhances the donor role of the ligand. The orientation is further stabilized by face-to-face π-π stacking relationships between the thiobenzoyl phenyl ring and one each of the phosphane phenyl groups (Fig. 1). The associated ring-centroid to ring-centroid distances are about 3.60 and 3.72 Å. This mode of ring stacking is also present for the alternatively disordered structural arrangement.

We favor the following mechanism for the formation of **2a**: Electrophilic attack at the ruthenium center by the carbon atom of CS_2 and subsequent ring closure provide the metallacyclic ruthenium(II) carbene complex **3**. Loss of CO from **3** is then presumably followed by C–S bond cleavage to generate the thiocarbonyl and thiobenzoyl ligands of the product.[9] The facile formation of **2a** raises the question of cycloaddition reactions with other heterocumulenes. We note that the reaction of **1** with MeN=C=S provides low yields of **2b**, whilst **1** reacts with carbon dioxide to give the stable oxoruthenacyclobutenone **4**. This latter metallacycle is noteworthy for two reasons. First, it supports the intermediacy of the related sulfur-based analogue **3** in the formation of **2a**, and second, the orientation of CO_2 in the cycloaddition is opposite to that found in $Et_4N[Et_2N{-}C{\equiv}W(CO)_2(\mu\text{-}PPh_2)_2Mo(CO)_4]$, the product of the carboxylation of $Et_4N[WOC(O)C(NEt_2)(CO)_2(\mu\text{-}PPh_2)_2Mo(CO)_4]$.[2d] We therefore suggest that for low-valent (formally d^8) Group 8 alkylidyne complexes, it is the metal center which is attacked by electrophiles rather than the alkylidyne carbon atom. Indeed, to date all reports of electrophilic attack at such complexes[4, 6] may actually be reinterpreted as proceeding in this way, even when the electrophile ultimately resides on the alkylidyne carbon atom.

Whilst much previous work has focussed on the addition of multiple bonds to alkylidyne complexes of metals of Groups 5–7, clearly the reactivity profile of later transition metal alkylidyne complexes is, as illustrated here, distinct from those of earlier metals and merits further study.

Experimental Procedure

2a: A solution of **1** (0.100 g, 1.30 mmol) in dichloromethane (10 mL) was treated with carbon disulfide (0.5 mL, excess) and stirred for 2 h and then freed of volatiles. The residue was chromatographed (silica gel, dichloromethane eluant, 25 °C) to provide **2a**. Yield 0.061 g (61 %).

2b: A solution of $[RuHCl(CS)(PPh_3)_3]$ [10] (0.50 g, 0.50 mmol) and $[HgPh_2]$ (0.20 g, 0.56 mmol) in toluene (45 mL) was heated under reflux for 30 min, cooled, and filtered through Kieselguhr. Addition of ethanol to the filtrate and concentration under reduced pressure provided $[Ru(Ph)Cl(CS)(PPh_3)_2]$. Yield 0.31 g (80%). Carbon monoxide was passed through a solution of $[Ru(Ph)Cl(CS)(PPh_3)_2]$ (0.20 g, 0.27 mmol) in dichloromethane (20 mL) for 5 min and then freed of volatiles. The residue was chromatographed (silica gel, dichloromethane eluant, 25 °C) to provide **2b**. Yield 0.14 g (67%).

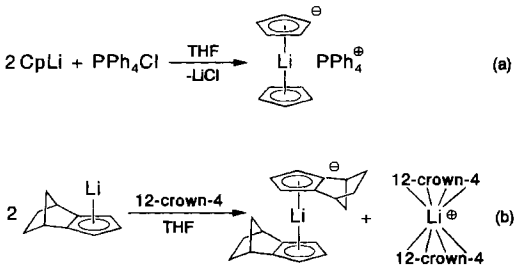
The Heaviest Alkali Metallocene: Structure of an Anionic Cesocene Triple-Decker**

Sjoerd Harder* and Marc Heinrich Prosenc

We recently reported the synthesis and structure of the simplest metallocene sandwich complex, the lithocene anion, which was obtained by reacting two equivalents of CpLi with PPh_4Cl in THF [Eq. (a)].[1] The approximate D_{5d} staggered lithocene sandwich is remarkably similar to the isovalent, diagonally related, alkaline earth analogue Cp_2Mg.[2] At the same time Paquette et al. published the structure of a substituted lithocene anion in which the noncoordinating cation is a bis([12]crown-4) solvated Li cation [Eq. (b)].[3] Since this new class of anionic alkali metallocenes is particularly interesting from a theoretical point of view, we have now focused our attention on the heavier alkali metal analogues.



Treatment of cyclopentadienylcesium, prepared from cyclopentadiene and cesium metal, with 0.5 equivalents of PPh_4Cl in THF[4] resulted in the immediate formation of a red solution and rapid precipitation of very small orange-red needles. Recrystallization from warm pyridine yielded larger good quality single crystals of the same color and needlelike habitus which were suitable for X-ray diffraction.

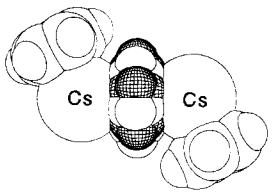


Fig. 1. A space-filling model of the strongly bent $[Cp_3Cs_2]^-$ triple-decker. The bridging Cp ring is positioned on a crystallographic center of inversion and therefore disordered over two positions (50% occupation).

X-ray structure analysis reveals the product formula $[Cp_3Cs_2]^-$·$[PPh_4]^+$.[5] The $[Cp_3Cs_2]^-$ ion (Fig. 1) is a strongly bent triple-decker ($Cp_{centroid}$-Cs-$Cp'_{centroid}$ 115.6(2)°), which closely resembles a recent structure of the first triple-decker structure of a main group metal, the $[Cp_3Tl_2]^-$ ion, in which the $Cp_{centroid}$-Tl-$Cp'_{centroid}$ angle is 134.2°.[6] The bridging Cp ring is positioned on a crystallographic center of inversion and is consequently disordered in a 50/50 ratio. The centers of both disordered Cp rings are only 0.01(1) Å removed from the crystallographic center of inversion and this results in a perfect ring of electron density between the Cs cations. The Cs–C bond lengths for the terminal Cp ligands lie in the range 3.313(6)–3.385(5) Å (av 3.350(5) Å; Cs–$Cp_{centroid}$ = 3.134(5) Å) and

compare well with the two sets of Cs–C bonds observed for the disordered bridging Cp rings which range from 3.30(2) Å to 3.36(2) Å (av 3.33(2) Å; $Cs-Cp_{centroid} = 3.10(2)$ Å) and from 3.31(2) Å to 3.38(2) Å (av 3.35(2) Å; $Cs-Cp_{centroid} = 3.13(2)$ Å). This narrow range of Cs–C bond lengths leads to a near perfect η^5-Cp–Cs bonding geometry (the largest deviation from the average Cs–C bond length is only 1.2%). The Cp–Cs bonds are extremely long and probably the longest Cp–metal bonds encountered (apart from Cp–metal distances in the hypothetical francocene). The Cp–Cs bonds in the $[Cp_3Cs_2]^-$ ion should be considered as highly ionic; that is, these very long electrostatic $Cp^- - Cs^+$ bonds are weak.[7] It is therefore even more remarkable that these loosely bound Cp ligands show such a perfect η^5-bonding mode. Also remarkable is the similarity in the Cp–Cs bond lengths for terminal and bridging Cp rings. Apparently, the Cs cations in the triple-decker are too far apart ($Cs \cdots Cs' = 6.236(3)$ Å) for a significant repulsive $Cs^+ \cdots Cs^+$ interaction and thus have little influence on the inner Cp–Cs distances.

The huge coordination sphere of the Cs^+ ion cannot be filled by only contacts to two Cp ligands and is therefore supplemented by additional intermolecular interactions. A space-filling packing model of the structure shows alternating layers of $[Cp_3Cs_2]^-$ and $[Ph_4P]^+$ ions (Fig. 2a). The shortest interaction

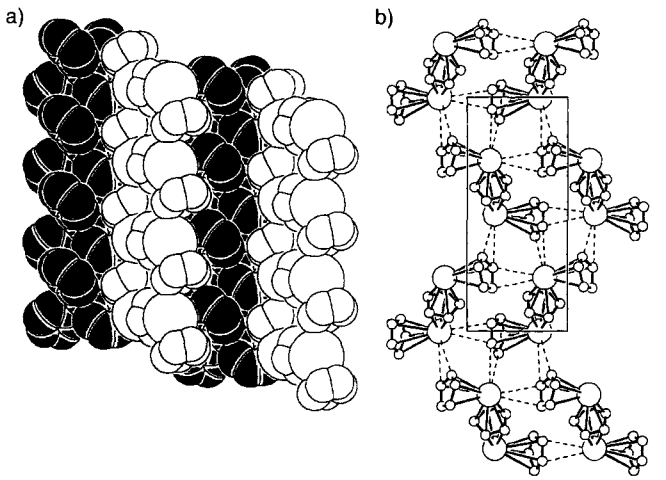

Fig. 2. a) Packing of the alternating layers of $[Cp_3Cs_2]^-$ ions (white) and $[PPh_4]^+$ ions (black) viewed along the *c* axis. b) The layer of $[Cp_3Cs_2]^-$ ions viewed along the *a* axis. The intermolecular Cs···C contacts are denoted by dashed lines.

between the layers corresponds to a (phenyl)C···Cs contact of 3.760(5) Å. More important are the short intermolecular $Cp^- \cdots Cs^+$ contacts within the layers of $[Cp_3Cs_2]^-$ ions. These layers form two-dimensional coordination polymers in which the intermolecular Cp···Cs contacts range from 3.699(5) to 3.810(5) Å (depicted in Fig. 2b by dotted lines). The complete coordination sphere of the Cs cation is shown in Figure 3. One of the Cp rings is bonded "side-on" to the Cs cation and shows close C-H···metal interactions similar to those found between the linear strands in the polymeric chain structure of $(Me_3SiCpK)_\infty$.[8] The other Cp ring is orientated "face-on" and shows π-$Cp^- \cdots Cs^+$ interactions. The intermolecular Cs···Cp contacts are only 10% longer than the intramolecular bonds and should therefore be considered as significant bonding interactions.

The crystal structure of the lithocene anion closely resembles that of the isovalent, diagonally related, magnesocene. Is there

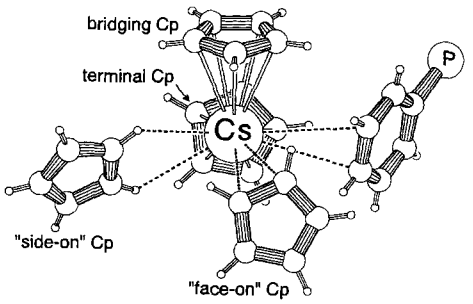

Fig. 3. Complete coordination sphere of the Cs cation (partial structure). Short intermolecular contacts are denoted by dashed lines; (phenyl)C···Cs distances are 3.760(5) and 3.881(5) Å; ("face-on" Cp)C···Cs distances are 3.699(5) and 3.719(5) Å; ("side-on" Cp)C···Cs distances are 3.754(5) and 3.810(5) Å (short H···Cs distances are 3.139 and 3.263 Å).

also structural conformity between the heavy anionic alkali metallocenes and alkaline earth metallocenes? The heavier alkaline earth metallocenes are typified by their bent structures which violate VSEPR rules and simple electrostatic bonding models.[9] It is believed that packing effects do not play a significant role in the solid-state structures of Cp^*_2Ca and Cp^*_2Ba ($Cp^* = C_5Me_5$) and, in particular, are not responsible for the bending at the metal atom (Cp-Ca-Cp 146.3° and Cp-Ba-Cp 131.0°).[10] This argument is supported by the results of the structural analyses of these metallocenes in the gas phase which likewise indicate bent structures.[11] Arguments advanced as explanations for the bending (attractive van der Waals forces between the Cp rings, induced polarization of the metal center by the ligands, and involvement of d orbitals) could to a certain extent similarly be applied to the heavier anionic alkali metallocenes.

Indeed, qualitative high level ab initio calculations show that bent structures play a role in the coordination chemistry of the Cs cation: the minimum energy structure of $Cs^+(H_2O)_2$ is bent with a O-Cs-O angle of 113.3° (cf. the angle of 109.6° in $Ba^{2+}(H_2O)_2$).[12] However, the extremely small linearization energy of only 0.26 kcal mol^{-1} indicates that the potential surface is very shallow (the linearization energy for $Ba^{2+}(H_2O)_2$ is 1.03 kcal mol^{-1}). The energy involved with the intermolecular contacts in the solid-state structure of $[Cp_3Cs_2]^-[PPh_4]^+$, is expected to be much larger. The bent structure as a typical energy minimum for sandwich or triple-decker cesocene complexes is therefore not confirmed by our experimental data. The use of bulky substituted Cp ligands could probably yield anionic cesocene sandwich complexes in which intermolecular $Cp^- \cdots Cs^+$ interactions are neglible. The elucidation of the structures of such compounds will reveal more about their similarity with the bent structures of the heavier alkaline earth metallocenes.

We had expected to isolate a $[Cp_2Cs]^-$ sandwich compound from the $Cp^-/CpCs$ solution, but instead obtained an anionic triple-decker complex. This suggests that the remaining mother liquor might contain species of interesting composition such as $[Cp_3Cs]^{2-}$ or $[Cp_2CsCpCsCp_2]^{3-}$. We anticipate that the $[Cp_2Cs]^-$ sandwich complex and these di- and trianions will be obtained in future research by variation of the reaction conditions.

[4] The syntheses were carried out under argon with use of Schlenk techniques and predried solvents. Cyclopentadiene (ca. 5 mL, ca. 75 mmol) was added dropwise to metallic cesium (5.90 g, 42.1 mmol) in THF (90 mL). The blue color of the solvated electrons disappeared and the solution was slowly warmed to reflux temperature. After complete addition, the yellow solution was heated to reflux for 30 minutes. The solvent was removed under reduced pressure and the crystalline needles were dried under high vacuum for 4 h at 80 °C. This yielded CpCs as a white powder. ^{1}H NMR (250 MHz, [D$_5$]pyridine, 25 °C, TMS): δ = 5.47 (s, Cp); ^{13}C NMR: δ = 106.9 (Cp). A suspension of PPh_4Cl (0.38 g, 1.01 mmol) in THF (6 mL) was added to a solution of CpCs (0.40 g, 2.0 mmol) in THF (10 mL). This immediately resulted in the formation a red reaction mixture from which small orange-red needles rapidly crystallized. The crystals were only slightly soluble in pyridine at room temperature. ^{1}H NMR (250 MHz, [D$_5$]pyridine, 25 °C, TMS): δ = 6.25 (s, Cp); 7.56–7.67 (m, PPh_4^+), 7.78–7.82 (m, PPh_4^+). The $C_5H_5^-/PPh_4^+$ ratio cannot be accurately determined due to partial decomposition of $C_5H_5^-$ (probably partial H/D exchange with pyridine). Recrystallization of the needles from warm pyridine gave larger single crystals (0.29 g; 54% calculated on CpCs) with an identical NMR spectrum which are suitable for X-ray diffraction. Elemental analyses on crystals: found C 58.89, H 4.50%; calcd C 58.52, H 4.41%.
[5] Crystal structure data for $[Cp_3Cs_2]^-[Ph_4P]^+$: monoclinic, a = 29.513(15), b = 6.898(4), c = 18.166(8) Å, β = 116.94(4)°, V = 3297(3) Å^3, space group $C2/c$, formula $\{(C_{15}H_{15}Cs_2)\cdot(C_{24}H_{20}P)\}$, M = 800.5, Z = 4, ρ_{calcd} = 1.613 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 2.267 mm^{-1}; 5342 reflections were measured on a Siemens R3m/V diffractometer ($Mo_{K\alpha}$, graphite monochromator, T = −35 °C), 3237 unique reflections after merging (R_{int} = 0.018), 2541 observed reflections with $F > 4.0\ \sigma(F)$. Solution by Patterson methods with the SHELXTL program, refinement by minimization of $\Sigma w(|F_o| - |F_c|)^2$ to $R(F)$ = 0.032, $wR(F)$ = 0.032 (221 parameters; $w = 1/(\sigma^2(F) + 0.0001(F)^2)$. Non-hydrogens, except those from the disordered Cp rings, were refined anisotropically; hydrogens on $[Cp_3Cs_2]^-$ were calculated and those on $[PPh_4]^+$ were found. Geometry calculations and plots were made with the EUCLID package [13]. Further details of the crystal structure investigation may be obatined from the Fachinformationzentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depositary number CSD-59137.

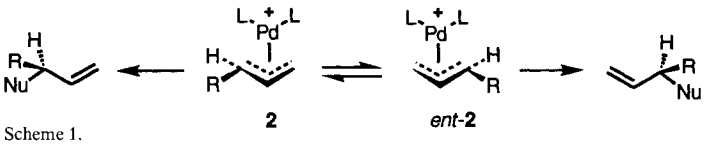
On Ligand Design for Catalytic Outer Sphere Reactions: A Simple Asymmetric Synthesis of Vinylglycinol**

Barry M. Trost* and Richard C. Bunt

The importance of enantiomerically pure vinylglycinol as a building block has stimulated much synthetic effort.[1] Not only is it an obvious precursor of vinylglycine; many biologically important targets may be derived from it, such as the tuberculostatic (+)-ethambutol,[2] the antimetabolite antibiotic acivicin,[3a, b] the antibiotic phosphinotricin,[3c] the selective enzyme-activated inhibitor of GABA-T vigabatrin,[4] an inhibitor of calmodulin-activated brain phosphodiesterase pseudodistomin B,[5] adenosine deamimase inhibitor pentostatin,[6] metal-chelating polyamino acid aspergillomarasamine A,[7] and the antibiotic subunit galatinic acid.[8] The most effective syntheses of vinylglycine to date begin with amino acids, only one enantiomer of which is generally available inexpensively.[1] Therefore, a simple asymmetric synthesis that would provide access to both enantiomers is most desirable.

The ready availability of one of the potential starting materials, 3,4-epoxy-1-butene (butadiene monoepoxide, **1**) from the selective, catalytic oxidation of butadiene with dioxygen,[9] makes it quite attractive. However, two hurdles not yet addressed in our asymmetric allylic alkylation program must be overcome to convert racemic epoxide **1** to vinylglycinol: 1) the control of the regioselectivity of alkylation to give the 1,2-adduct, and 2) the design of a racemization step (Scheme 1, **2** to



Scheme 1.

ent-**2**) that occurs faster than alkylation so that one of the two complexes (which are diastereomeric when L is chiral) reacts faster than the other.[10] Because most nucleophiles, including amines, add to give 1,4-adducts with **1**,[11] the simplest solution to the regioselectivity problem is to tether the nitrogen nucleophile to the oxygen atom.[12] However, preliminary results with the bisisocyanate of chiral 1-buten-3,4-diol and (*S*,*S*)-**3** gave the

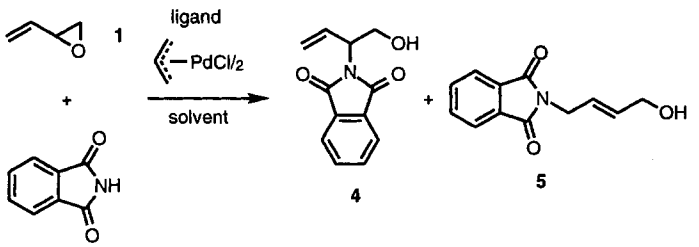
vinyloxazolidin-2-one with only 2% *ee* (Scheme 2), which suggested that racemization did not compete with cyclization.[13] We therefore turned to a bimolecular process in the hope that slowing the attack of nucleophile would enable racemization to compete effectively.

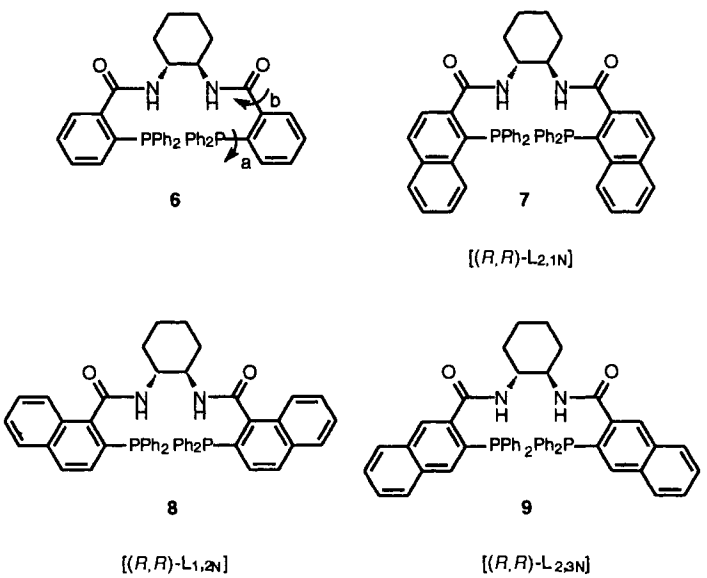
We postulated that increasing the acidity of the N–H of the pronucleophile should increase 1,2-adduct formation because of hydrogen bonding to the oxygen leaving group.[14] Indeed, with triphenylphosphane as the ligand in THF, phthalimide reacted with epoxide **1** to give an approximately 9:1 ratio of the 1,2 or proximal adduct (**4**) to the 1,4 or distal (**5**) adduct but in yields of only 30–40% (Scheme 3). With our standard chiral ligand



Scheme 3.

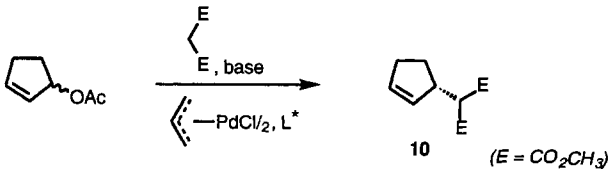
6[15] in THF, two quite gratifying observations were made. First, the yield of isolated **4**[16] increased significantly to 87%. Second, the ratio of *S*-**4**:*R*-**4** was 88:12 in THF. Switching the solvent to dichloromethane, which increased the enantioselectivity in other alkylations,[17] led to a slight decline to 83:17 (83% yield of isolated product **4**).

As further attempts to improve the enantiomeric ratio (er) by varying the reaction conditions failed, we turned our attention to the modification of our chiral ligand. We chose to rigidify bonds *a* and *b* (see **6**) by introducing a *peri* interaction as in the naphthalene-derived ligands **7**[16] (bond *a*) and **8**[16] (bond *b*).



Restricting rotation about bonds *a* or *b* should affect how the chiral scaffold (the diaminocyclohexane unit) communicates its chirality to the conformationally chiral space created by the diphenylphosphino unit. This transference of chirality is critical, because the asymmetric bond-forming process occurs outside the direct coordination sphere of the metal. We hoped that a more rigid ligand would possess a better defined "chiral pocket" and thus give higher levels of asymmetric induction. For completeness, we also synthesized ligand **9**,[16] which, lacking such restraints, was expected to behave like ligand **6**. All three diphenylphosphinonaphthoic acids are readily available from the corresponding hydroxynaphthoic acids by cross-coupling reactions.[18]

To compare these new ligands, we explored the alkylation of 3-acetoxycyclopentene (Scheme 4), since we had a great deal of



Scheme 4.

experience with this substrate.[17] Each ligand was tested with sodium hydride and cesium carbonate as the base in both THF and dichloromethane under a range of conditions known to influence enantiomeric excesses. Table 1 summarizes these results, and several points are worth noting. First, (R,R)-$L_{2,3N}$ (**9**) and (R,R)-**6** did behave similarly and give very high er's with cesium carbonate as the base in dichloromethane (entries 4 and 8). Second, restricting the diphenylphosphino unit as in (R,R)-$L_{2,1N}$ (**7**) effectively destroyed the chiral recognition (entries 9–12). Third, restricting the carboxylate group as in (R,R)-$L_{1,2N}$ (**8**) maintained a reasonable level of chiral recognition, although somewhat less than for (R,R)-**6** or (R,R)-$L_{2,3N}$ (**9**). In contrast to (R,R)-**6** or (R,R)-$L_{2,3N}$ (**9**), with (R,R)-$L_{1,2N}$ (**8**) the sodium salt of malonate ester gave a higher er than the cesium salt (entries 14 and 16). This reversal of behavior suggests that

Table 1. Comparison of ligands for the alkylation of dimethyl malonate with 3-acetoxycyclopentene. For spectroscopic data, see Table 2.

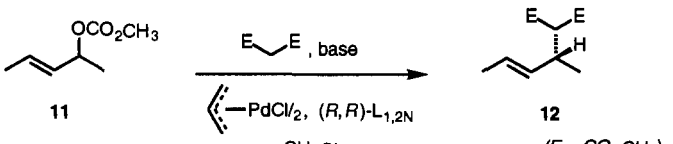
we may have altered the conformational properties of the chiral pocket as intended.

To further probe the usefulness of (R,R)-$L_{1,2N}$ (**8**), we explored the reaction of the acyclic substrate **11** with dimethyl malonate (Scheme 5) for which the maximum er previously



Scheme 5.

recorded was 85:15.[19] With our newly developed ligand, the er of **12** produced was 70:30 for the sodium salt but 93:7 for the cesium salt, the highest yet recorded.

The most dramatic result of this new ligand occurred for the type of chiral recognition required in the case of epoxide **1** (Scheme 2). Adding neat epoxide **1** to a mixture of phthalimide (110 mol%), sodium carbonate (5 mol%), π-allylpalladium chloride dimer (2.5 mol%), and (R,R)-$L_{1,2N}$ (**8**) (7.5 mol%) in dichloromethane (all at ambient temperature) gave a 99% yield of **4** and **5** in a ratio greater than 75:1. The er was assayed by conversion to the *O*-methylmandelate ester **13**[20] followed by HPLC analysis and found to be 99:1 (Scheme 6). Further confirmation of the er, as well as establishment of the absolute configuration, was accomplished by removal of the phthalic acid moiety[21] and formation of the known CBZ derivative **14**[7] (Scheme 6). The observed optical rotation of **14** $[\alpha]_D^{25} = -32.2°$ ($c = 1.47$, $CHCl_3$) is in excellent agreement with the literature value of $[\alpha]_D^{25} = -32.1°$ ($c = 3.1$, $CHCl_3$) for the compound having the *S* absolute configuration. In contrast to **6**, in which a slightly higher er was obtained in THF than dichloromethane, the er in THF with (R,R)-$L_{1,2N}$ (**8**) was only 84:16.

The new ligand **8** permits high enantiodiscrimination between equilibrating diastereomeric complexes. Combined with the unorthodox control of regioselectivity, vinylglycinol of high enantiomeric purity and in either enantiomeric series is available quite simply from racemic 3,4-epoxy-1-butene. Since the conversion of vinylglycinol to vinylglycine is known,[3b] this route provides a synthesis of the latter as well. In this type of asymmetric induction, which requires a kinetic bias for the reaction of one diastereomeric π-allyl palladium complex of a rapidly interconverting pair (cf. Scheme 1), rigidifying the carboxylate group has a dramatic effect in enhancing the selectivity. This same ligand effectively discriminates the enantiotopic termini of the 1,3-dimethylallyl system (cf. Scheme 5). The nature of the chiral cavity of (R,R)-$L_{1,2N}$ (**8**) seems quite distinct from the other ligands **6**, **7**, and **9**. For example, **6** always shows an enhanced er on going from the sodium salt to the cesium salt of malonate as the nucleophile, but (R,R)-$L_{1,2N}$ (**8**) is incongruous, showing the opposite trend with a cyclic substrate and the same trend with an acyclic one. With the larger, cyclic substrate, this tighter pocket less selectively accommodates the larger cesium counterion. However, with the narrower, acyclic substrate (**11**), the larger cesium counterion again shows a higher er than sodium. The differences between achiral and chiral ligands are not limited to asymmetric induction. Quite notably, upon switching from triphenylphosphane to (R,R)-$L_{1,2N}$ (**8**), the regioselectivity increased from about 9:1 to greater than 75:1, and the yield almost tripled (**1** → **4**). Thus, the systematic rigidification of the bonds involved in transmitting the chiral information through the ligand–metal complex resulted in a new chiral ligand, which shows many desirable properties for applications in synthesis.

O-Protonation at a Neutral Ditungsten Carbonyl Dimer to Give a Stable Hydroxycarbyne Complex**

M. Angeles Alvarez, Claudette Bois, M. Esther García, Victor Riera, and Miguel A. Ruiz*

Metal–metal bonds in organometallic compounds behave as nucleophilic centers and, accordingly, they can be often protonated to afford hydrido-bridged complexes.[1] Protonation can also occur at the coordinated ligands, and in this way a wide variety of products can be obtained.[2] The latter, however, is a very rare reaction for coordinated carbon monoxide. The few examples reported so far all involve protonation of bridging CO ligands in anionic carbonyl clusters such as $[M_3H(CO)_{10}]^-$ (M = Fe, Ru, Os),[3] $[Fe_4H(CO)_{13}]^-$,[4] and $[Co_3(CO)_{10}]^-$.[5] The resulting hydroxycarbyne clusters are without exception thermally unstable and could be only characterized at low temperatures. In this paper we report on the unexpected O-protonation of **1**[6] (dppm = $Ph_2PCH_2PPh_2$; Cp = η^5-C_5H_5), which gives the cationic and unsaturated hydroxycarbyne complex **4**.

$[W_2(CO)_4(\mu\text{-dppm})Cp_2]$ **1**

To our knowledge, this is the first example of protonation of a carbonyl ligand in a complex lacking bridging CO ligands,[7] and also in a neutral species. In addition, **4** is stable at room temperature, both in solution and in the solid state, thus allowing the study of its reactivity. The chemical behavior of hydroxycarbyne species is of interest in the context of carbon monoxide reduction.[8]

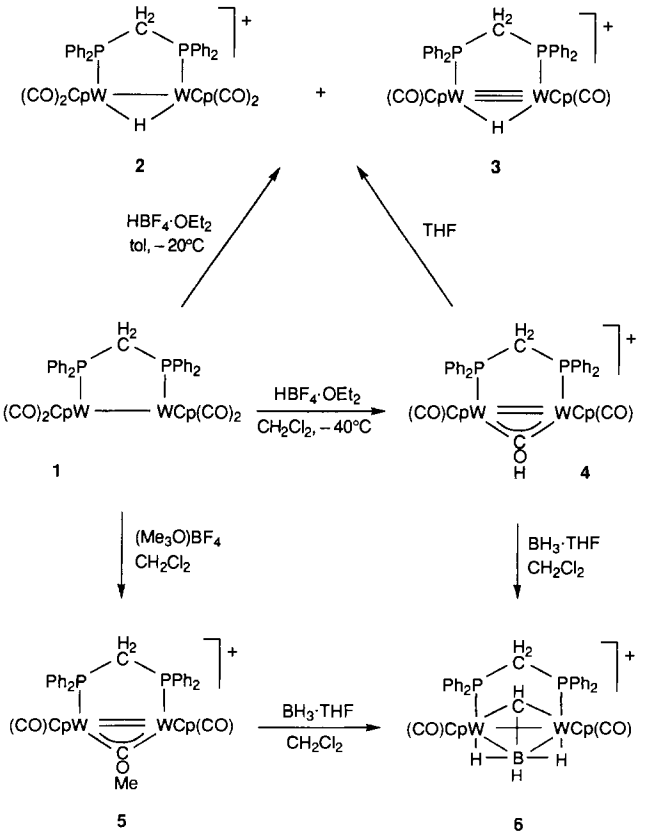
The reaction of **1** with $HBF_4 \cdot OEt_2$ is strongly dependent on the solvent. Thus, when the reaction is carried out in toluene, a mixture of the known hydrido complexes[9] **2** and **3** is obtained.

$[W_2(\mu\text{-H})(CO)_4(\mu\text{-dppm})Cp_2]BF_4$ **2**-BF_4

$[W_2(\mu\text{-H})(CO)_2(\mu\text{-dppm})Cp_2]BF_4$ **3**-BF_4

$[W_2(\mu\text{-COH})(CO)_2(\mu\text{-dppm})Cp_2]BF_4$ **4**-BF_4

By contrast, the protonation of **1** in CH_2Cl_2 gives the hydroxycarbyne complex **4** almost quantitatively. The salt **4**-BF_4 is stable at room temperature both in the solid state and dissolved in CH_2Cl_2; however, when **4**-BF_4 is dissolved in THF or acetone, a mixture of the hydrido complexes **2** and **3** is instantaneously formed. This strongly suggests that the formation of **2** and **3** in toluene is likely to proceed through **4**, which then rapidly undergoes a proton rearrangement, probably assisted by the solvent. The reactions discussed here are summarized in Scheme 1.



Scheme 1. Tol = toluene; counterion = BF_4^-.

The carbonyl ligands in **1** are also susceptible to alkylation. Thus, **1** reacts with $(Me_3O)BF_4$ to give the methoxycarbyne complex **5**, which is isostructural with **4**. The crystal structure of **5**-BF_4 (Fig. 1)[10a] confirms the presence of a rather symmetrical

$[W_2(\mu\text{-COMe})(CO)_2(\mu\text{-dppm})Cp_2]BF_4$ **5**-BF_4

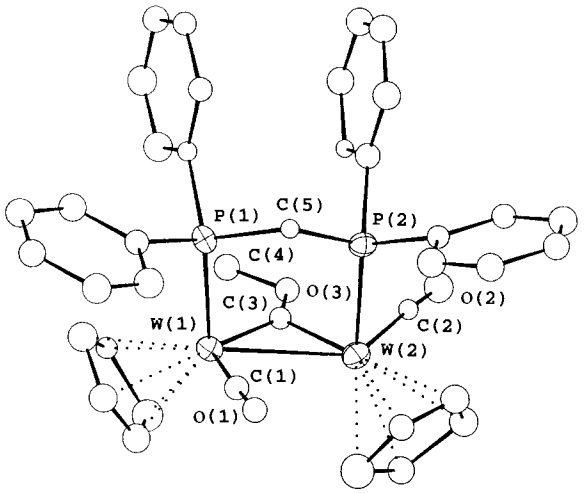

Fig. 1. Molecular structure of **5** in the crystal [10a] (thermal ellipsoids for 30% probability, hydrogen atoms omitted). Selected interatomic distances [Å] and angles [°]: W(1)–W(2) 2.781(3), W(1)–C(1) 1.82(6), W(2)–C(2) 2.02(5), W(1)–C(3) 1.95(5), W(2)–C(3) 1.99(5), C(3)–O(3) 1.42(5), O(3)–C(4) 1.42(6), W(1)–P(1) 2.47(1), W(2)–P(2) 2.45(2); C(1)-W(1)-C(3) 119.8(23), C(2)-W(2)-C(3) 75.2(20), W(1)-W(2)-P(2) 90.6(4), W(2)-W(1)-P(1) 94.7(3), C(1)-W(1)-P(1) 82.3(18), C(2)-W(2)-P(2) 90.7(14), C(3)-O(3)-C(4) 120.3(39).

methoxycarbyne ligand bridging the metal atoms in the cation. The conformation of this ligand is similar to that of other edge-bridging alkoxycarbyne ligands.[11] According to the 18-electron rule, a metal–metal double bond should be formulated for the cations **4** and **5**. In agreement with this, the intermetallic separation in **5** (2.781(3) Å) is about 0.25 Å shorter than those found for related electron-precise species.[9]

In spite of their electronic unsaturation, cations **4** and **5** exhibit some interesting nucleophilic properties. Thus, they are able to react with $BH_3 \cdot THF$ to yield the methylidyne–borane complex **6**. The crystal structure of **6**-BF_4 (Fig. 2)[10b] reveals

$[W_2(\mu\text{-CHBH}_3)(CO)_2(\mu\text{-dppm})Cp_2]BF_4$ **6**-BF_4

that the $CHBH_3$ ligand (H atoms not located) bridges symmetrically a singly bonded ditungsten center (W–W = 3.074(1) Å). The above, together with the NMR data, clearly indicates that one H atom bridges each of the W–B edges, thus formally making the $[CHBH_3]^-$ ligand a 6e-donor group. Only two other complexes containing this type of ligand are known: $[W_2\{\mu\text{-CRBH}_2(CH_2R)\}(CO)_4Cp_2]^+$; R = Me, C_6H_4Me).[12] In the latter, however, it was suggested that the H atoms bridge a B–W edge and a BW_2 face.

In summary, the transformations **1** → **4** → **6** imply a carbonyl to methylidyne reduction, which proceeds via an hydroxycarbyne intermediate and uses BH_3 as reductant. This is in contrast to the more usual carbonyl reduction via formyl intermediates, thought to be an operative pathway in the Fischer–Tropsch synthesis.[13] Further studies on the activity of the hydroxycarbyne complex **4** in C–H and C–C bond formation reactions are now in progress in our laboratory.

Selected interatomic distances [Å] and angles [°]: W(1)–W(2) 3.074(1), W(1)–C(1) 1.92(2), W(2)–C(2) 1.95(3), W(1)–C(3) 2.14(2), W(2)–C(3) 2.09(2), W(1)–B(1) 2.40(3), W(2)–B(1) 2.40(3), W(1)–P(1) 2.494(5), W(2)–P(2) 2.465(6), B(1)–C(3) 1.60(4); W(1)-B(1)-W(2) 79.6(8), W(1)-C(3)-W(2) 93.2(9), P(1)-W(1)-B(1) 130.6(8), P(2)-W(2)-B(1) 124.5(8).

Experimental Procedure

4: $HBF_4 \cdot OEt_2$ (12 μL, 0.1 mmol) was added to a solution of **1** (100 mg, 0.1 mmol) in CH_2Cl_2 (30 mL) at −40 °C, and the mixture was stirred for 45 min. The solvent was then removed under vacuum, and the residue washed with toluene and petroleum ether to afford 94 mg (89%) of **4** as a brown powder. Selected spectroscopic data: IR (CH_2Cl_2): $\tilde{\nu}$(CO) [cm^{-1}] = 1943 vs, 1853 s. ^1H NMR (200.13 MHz, CD_2Cl_2, 198 K): δ = 12.97 (br, 1H; COH), 5.36 (s, br, 10H; Cp); $^{31}P\{^1H\}$ NMR (121.50 MHz): δ = 23.9, 13.2 (2 × d, J(P,P) = 48 Hz). $^{13}C\{^1H\}$ NMR (50.32 MHz): δ = 357.8 (s, J(C,W) = 121 Hz; COH), 96.4, 92.6 (2 × s; Cp).

5: $[Me_3O]BF_4$ (10 mg, 0.07 mmol) was added to a solution of **1** (50 mg, 0.05 mmol) in CH_2Cl_2 (15 mL) at room temperature, and the mixture was stirred for 2.5 h. The solution was then filtered, the solvent removed under vacuum, and the residue washed with toluene to give compound **5** as a brown powder (36 mg, 65%). Selected spectroscopic data: IR(Me_2CO): $\tilde{\nu}$(CO) [cm^{-1}] = 1946 vs, 1842 s. ^1H NMR (300.13 MHz, $[D_6]Me_2CO$, 188 K): δ = 5.68 (s, br, 5H; Cp), 5.61 (s, br, 6H; Cp, CH_2), 4.87 (s, 3H; Me), 4.85 (br, 1H; CH_2); $^{31}P\{^1H\}$ NMR (121.50 MHz): δ = 19.3, 13.4 (2 × d, J(P,P) = 48 Hz). $^{13}C\{^1H\}$ NMR (100.61 MHz): δ = 368.5 (s; COMe).

6: $BH_3 \cdot THF$ (2 mL of a 1 M solution in THF, 2 mmol) was added to a solution of **5** (100 mg, 0.1 mmol) in CH_2Cl_2 (15 mL) at −20 °C. The solution was stirred for 1 h and allowed to reach room temperature slowly. Solvent was then removed under vacuum, and the residue washed with toluene/petroleum ether 1/1, extracted with CH_2Cl_2, and filtered. Removal of solvent from the filtrate under vacuum yielded compound **6** as a yellow-orange powder (78 mg, 79%). Selected spectroscopic data: IR (CH_2Cl_2): $\tilde{\nu}$(CO) [cm^{-1}] = 1963 vs, 1841 s. ^1H NMR (400.13 MHz, CD_2Cl_2, 291 K): δ = 7.82 (br, 1H; $HCBH_3$), −1.56 (br, 1H; BH), −12.58 (br, 1H; BHW), −12.95 (br, 1H; BHW). ^{13}C NMR (100.61 MHz): δ = 111.1 (d, br, J(C,H) = 178 Hz; $HCBH_3$).

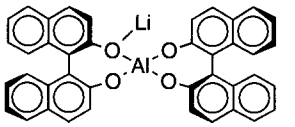
A New Multifunctional Heterobimetallic Asymmetric Catalyst for Michael Additions and Tandem Michael–Aldol Reactions**

Takayoshi Arai, Hiroaki Sasai, Kei-ichi Aoe, Kimio Okamura, Tadamasa Date, and Masakatsu Shibasaki*

Although numerous asymmetric catalysts (chemzymes) have been developed utilizing nearly all the elements in the periodic table, the abilities of chemzymes have, in general, proven inferior to those of enzymes, probably because chemzymes have only one function with which to control asymmetric reactions. It is possible that multifunctional heterobimetallic asymmetric catalysts could compensate for the shortcomings of chemzymes by providing positive cooperation between different metals. Recently, for catalytic asymmetric carbon–carbon bond-forming reactions we introduced a new class of heterobimetallic complexes that consist of a rare earth metal center, an alkali metal center (Li, Na, K), and 2,2′dihydroxy-1,1′-binaphthyl (BINOL).[1, 2] For example, the LaLi–BINOL complex is quite effective in catalyzing asymmetric nitroaldol reactions, and LaNa–BINOL is a very efficient catalyst for asymmetric Michael reactions. Mechanistic studies on LaNa–BINOL-catalyzed Michael reactions have revealed that though this complex acts as a base catalyst (ONa), it simultaneously shows Lewis acid character (La), which makes highly enantioselective reactions possible even at room temperature.[2] This result suggested that extension of the "heterobimetallic concept" to metal centers other than rare earths could lead to heterobimetallic asymmetric catalysts with novel properties. In this paper we report the new heterobimetallic asymmetric catalyst **I** consisting of aluminum, lithium, and BINOL, which makes possible for the first time catalytic asymmetric tandem Michael–aldol reactions.



I

We began with the development of an amphoteric asymmetric catalyst made with aluminum and an alkali metal.[3] Initially, in an attempt to prepare the AlLi–BINOL complex **I**, diisobutylaluminum hydride (1.0 M solution in THF) was treated with two equivalents of (*R*)-BINOL in THF at 0 °C for half an hour, and the resulting solution was further treated with one equivalent of BuLi (1.73 M solution in hexane) at 0 °C for half an hour. We were pleased that this new asymmetric catalyst (10 mol%[4]) was also effective in the Michael reaction of cyclohexenone (**6**) with dibenzyl malonate (**4**), giving **7** in 98% *ee*[5] and 46% yield at room temperature. In addition, we observed that the same catalyst **I** was prepared more efficiently from $LiAlH_4$ and two equivalents of (*R*)-BINOL (THF, 0 °C, 1 h). This catalyst (10 mol%[4]) provided high yields of **7** in 99% *ee*, as well as excellent yields of the various Michael adducts **3**, **5**, **9**, and **11** in enantiomeric excesses ranging from 91% to 98% (Table 1).[2]

7	**6**	**8**	**9**	Li	72	90	93
8	**6**	**10**	**11**	Li	72	87	95

These are the highest enantiomeric excesses of all known catalytic asymmetric Michael reactions.[2, 6] Although LaLi–BINOL and LaNa–BINOL complement each other in their ability to catalyze asymmetric nitroaldol and Michael reactions,[1, 2] Al–M–(*R*)-BINOL complexes (M = Li, Na, K, and Ba)[7] are commonly useful for the catalytic asymmetric Michael reaction (entries 3–6).

With these excellent results in hand, we set out to determine the structure of **I** unequivocally. Although an X-ray quality crystal[8] of **I** was obtained, it was prone to decomposition during X-ray diffraction studies. However, the complex **II** generated from **I** and cyclohexenone (**6**) in THF provided a crystal that was stable to X-ray crystal analysis.[9] The structure is shown in

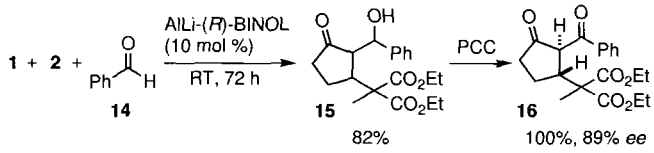
II

Fig. 1. Crystal structure of $C_{40}H_{24}O_4AlLi/C_6H_8O/(C_4H_8O)_3$ (**II**).

Figure 1.[10] The complex has tetrahedral geometry around the aluminum center with average Al–O distances of 1.75 Å. The long Li–O(1) distance of 1.96 Å is indicative of the ionic character of the interaction between Li^+ and $[Al(binol)_2]^-$.[11] The structure of the AlLi–BINOL complex is thus assumed to be **I** or a corresponding dimeric structure.

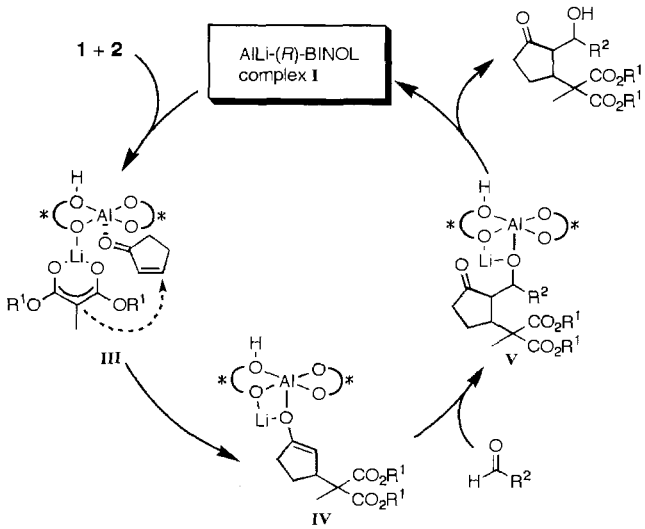
The small electronegativity value of lithium (1.0) relative to that of aluminum (1.5) suggests that a lithium enolate should be generated from a malonate derivative. However, the role of aluminum in this reaction is not well understood. To study the interaction between the enone and the aluminum atom, an ^{27}Al NMR study was performed.[12] One broad signal was observed for the AlLi–(*R*)-BINOL complex **I** at $\delta = 75$ (S_0). Upon addition of three equivalents of cyclohexenone (**6**) to the complex, two additional signals were obtained at $\delta = 40$ (S_1) and 23 (S_2). The S_2 signal became more intense and was a major peak under conditions of the Michael reaction. This is strong evidence for an octahedral arrangement of six magnetically equivalent ligands around the aluminum cation in THF solution, since all other shifts are upfield relative to S_0.[13] These NMR studies clearly indicate that the carbonyl groups of the enones are coordinated to the aluminum. Consequently, this AlLi–(*R*)-BINOL complex **I** probably also acts as a heterobimetallic multifunctional asymmetric catalyst,[2] making possible efficient Michael reactions even at room temperature.

This aspect of the mechanism suggested that the reaction of a lithium enolate derived from a malonate derivative with an enone would lead to an aluminum enolate intermediate. Further studies were carried out to obtain direct evidence for an aluminum enolate in an effort to learn how to enhance the aluminum enolate's influence on the chemical fate of the Michael adducts. On the basis of the electronegativity of aluminum, the protonation of the aluminum enolate should be slower than that of the corresponding lithium, sodium, or lanthanoid enolates. Could such an Al-enolate then be trapped by an electrophile such as an aldehyde? As was anticipated, the reaction of cyclopentenone (**1**), diethyl methylmalonate (**2**), and 3-phenylpropanal (**12**) in the presence of 10 mol% of the AlLi–(*R*)-BINOL complex gave the three-component coupling product **13** as a single isomer in 91% *ee* (64% yield; Table 2). Quite interestingly, the use of LaLi–BINOL, LaNa–BINOL, or a lithium-free La–BINOL complex[6] gave very unsatisfactory results in the three-component coupling reaction. This is probably because the lanthanum enolate is more reactive toward the acidic proton.[14] Moreover, the use of benzaldehyde (**14**) instead of **12** gave the three-component coupling product **15** in 82% yield. Although **15** was a mixture of diastereomers, its oxidation gave the corresponding diketone derivative **16** as a single isomer in 89% *ee*. This is the first example of a catalytic asymmetric tandem Michael–aldol reaction.



14 **15** 82% **16** 100%, 89% *ee*

We therefore describe the reaction pathway in these three-component coupling reactions as follows (Scheme 1). The reaction of diethyl methylmalonate (**2**) with the AlLi–(*R*)-BINOL complex gives the corresponding lithium enolate (**III**). Enolate **III** then reacts with cyclopentenone (**1**), which is pre-coordinated to the aluminum, to give the aluminum enolate **IV** enantioselectively. Further reaction of enolate **IV** with aldehyde would lead to an alkoxide (**V**). Although it is unclear whether the



Scheme 1. Possible mechanism for the catalytic asymmetric tandem Michael–aldol reaction promoted by the AlLi–(*R*)-BINOL complex (**I**).

aluminum or lithium alkoxide is generated, the resulting alkoxide then abstracts a hydrogen atom from an acidic OH group to give the three-component coupling product and regenerate the AlLi–(*R*)-BINOL complex, thereby completing the catalytic cycle.

In conclusion, we have succeeded in developing highly efficient Al–M–(*R*)-BINOL (M = Li, Na, K, or Ba) catalysts for asymmetric Michael reactions. Mechanistic studies on AlLi–(*R*)-BINOL complex revealed that this complex also acts as a multifunctional heterobimetallic asymmetric catalyst. Furthermore, three-component coupling reactions were achieved by trapping the aluminum enolate intermediate with an aldehyde for the first time. These results will provide a very useful method for the catalytic asymmetric synthesis of complex molecules.

Experimental Procedure

I: To a solution of $LiAlH_4$ (94.9 mg, 2.5 mmol) in THF (5.0 mL) was added a solution of (*R*)-BINOL (20 mL, 5.0 mmol, 0.25 M in THF) at 0 °C. After 30 min stirring at 0 °C, this solution of **I** (0.1 M in THF) was directly used for Michael reactions.

7: To a stirred solution of the catalyst **I** (0.05 mmol) in THF (0.5 mL) was successively added cyclohexenone (**6**) (48 μL, 0.5 mmol) and dibenzyl malonate (**4**) (125 μL, 0.5 mmol) at 0 °C. After 72 h stirring at room temperature, the reaction mixture was treated with 1 N HCl (2.0 mL) and extracted with EtOAc (3 × 10 mL). The combined organic extracts were washed with brine, dried ($NaSO_4$), and concentrated to give an oily residue. Purification by flash chromatography (SiO_2, 25% acetone/hexane) gave the Michael adduct **7** (172.0 mg, 88% yield) in 99% *ee*. The spectral and analytical data of **7** were in agreement with those of Ref. [2].

13: To a solution of cyclopentenone (**1**) (84 μL, 1.0 mmol), methyl diethylmalonate (**2**) (138 μL, 1.0 mmol) and 3-phenylpropanal (**12**) (158 μL, 1.2 mmol) in THF (1.0 mL) was added a solution of the AlLi-(*R*)-BINOL complex **I** (1.0 mL, 0.1 M in THF, 0.1 mmol) at 0 °C. After 36 h stirring at room temperature, the reaction was quenched with 1 N HCl at 0 °C and worked up as described for **7**. The oily residue was purified by flash chromatography (SiO_2, acetone:hexane 1:9) to give **13** (250 mg, 0.64 mmol, 64% yield). The optical purity of **13** was determined by HPLC analysis on a chiral phase (DAICEL CHIRALPAK AD, *i*PrOH:hexane 1:9). $[\alpha]_D^{24} = +18.3$ ($c = 0.66$ in chloroform) (91% ee); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 7.40-7.13$ (m, 5 H), 4.13 (q, $J \approx 7.0$ Hz, 2 H), 4.11 (q, $J = 7.0$ Hz, 1 H), 4.06 (q, $J = 7.0$ Hz, 1 H), 3.75 (dt, $J = 3.8$, 9.6 Hz, 1 H), 2.97 (dt, $J = 6.3$, 8.0 Hz, 1 H), 2.89-2.76 (m, 1 H), 2.70-2.57 (m, 2 H), 2.35 (dd, $J = 3.8$, 6.3 Hz, 1 H), 2.24 (t, $J = 8.4$ Hz, 2 H), 2.19-2.01 (m, 2 H), 1.87-1.68 (m, 2 H), 1.40 (s, 3 H), 1.22 (t, $J = 7.0$ Hz, 3 H), 1.19 (t, $J = 7.0$ Hz, 3 H); ^{13}C NMR ($CDCl_3$): $\delta \approx 218.9$, 171.8, 171.6, 141.8, 128.4, 125.9, 72.0, 61.6, 56.9, 55.9, 43.3, 38.5, 36.1, 32.5, 22.9, 18.6, 14.0, 13.9; IR (neat): $\tilde{\nu} = 3518$, 3085, 1728, 1253 cm^{-1}; MS: *m/z* (%) 391 [M^+], 373 [$M^+ - H_2O$], 175 (100); anal. calcd for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74; found: C, 67.41; H, 7.70.

16: To a solution of cyclopentenone (**1**) (84 μL, 1.0 mmol), methyl diethylmalonate (**2**) (138 μL, 1.0 mmol) and benzaldehyde (**14**) (122 μL, 1.2 mmol) in THF (1.0 mL) was added a solution of the AlLi-(*R*)-BINOL complex (1.0 mL, 0.1 M in THF, 0.1 mmol) at 0 °C. After 72 h stirring at room temperature, the reaction was quenched with 1 N HCl at 0 °C and worked up as described for **7**. The crude product was purified by flash chromatography (SiO_2, acetone:hexane 1:9) to give the diastereomixture of **15** (297 mg, 82%). To a solution of **15** (100 mg, 0.277 mmol) was added molecular sieves (4Å, 200 mg) and pyridinium chlorochromate (PCC, 65 mg, 0.3 mmol) at 0 °C. After 1h of stirring at room temperature, the reaction mixture was diluted by Et_2O (20 mL). The insoluble materials were filtered off through a Celite pad. The filtrate was evaporated to dryness in vacuo. The residue was purified by silica gel chromatography (SiO_2, acetone:hexane 1:9) to give **16** (100 mg, 100% yield). The optical purity of **16** was determined by HPLC analysis on a chiral phase (DAICEL CHIRALCEL OJ, *i*PrOH:hexane 1:4). $[\alpha]_D^{24} = -22.0$ ($c = 1.02$ in chloroform) (89% ee); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 8.00-8.05$ (m, 2 H), 7.62-7.55 (m, 1 H), 7.52-7.45 (m, 2 H), 4.77 (d, $J = 8.6$ Hz, 1 H), 4.13 (q, $J = 7.3$ Hz, 2 H), 4.03 (dq, $J = 7.3$, 10.9 Hz, 1 H), 3.87 (dq, $J = 7.3$, 10.9 Hz, 1 H), 3.68-3.55 (m, 1 H), 2.48-2.26 (m, 3 H), 2.03-1.03 (m, 1 H), 1.49 (s, 3 H), 1.21 (t, $J = 7.3$ Hz, 3 H), 1.04 (t, $J = 7.3$ Hz, 3 H); ^{13}C NMR ($CDCl_3$): $\delta = 211.0$, 195.1, 171.1, 136.5, 133.3, 129.4, 128.5, 61.4, 59.4, 55.6, 44.4, 38.9, 22.7, 19.7, 13.9, 13.6; IR (neat): $\tilde{\nu} = 3463$, 1728, 1677, 1260 cm^{-1}; MS: *m/z* (%) 361 [$M^+ + 1$]), 360 [M^+], 105 (100); anal. calcd for $C_{20}H_{24}O_6$: C, 66.65; H, 6.71; found: C, 66.38; H, 6.76.

Enzymatic Synthesis of Peptides and *Ras* Lipopeptides Employing Choline Ester as a Solubilizing, Protecting, and Activating Group**

Michael Schelhaas, Simone Glomsda, Marion Hänsler, Hans-Dieter Jakubke,* and Herbert Waldmann*

For the synthesis of peptides and sensitive complex peptide conjugates, enzymatic transformations offer advantageous alternatives to classical chemical methods.[1, 2] Thus, for instance, biocatalyzed deblocking reactions[1] have proven their efficiency in the construction of glyco-[3] and lipopeptides,[4] and protease-mediated peptide synthesis in ice[5] can be used to couple amino acids and peptides without racemization.

However, enzymatic reactions often are hampered or even prevented by the low solubility of the protected peptides in aqueous reaction media, resulting in limited accessibility of the substrates to the biocatalysts. This difficulty can be overcome by employing solubilizing blocking groups.[6] Their removal, however, often requires reaction conditions that cannot be tolerated in the construction of sensitive peptide conjugates. We now report that choline esters are advantageous solubility-enhancing protecting groups for the synthesis of peptides and lipopeptides under extremely mild conditions.

Peptide choline esters (peptide-Cho) **1** (Scheme 1) can be constructed by treating the corresponding 2-bromoethyl esters with trimethylamine.[7] Alternatively, they are accessible by condensation of amino acid choline ester hydrobromides with C-terminally deblocked peptides (vide infra; Scheme 2).

The high solubility of these amorphous hygroscopic solids in water, water/dioxane, and water/methanol mixtures is advantageous for the selective removal of the C-terminal protecting group by means of the enzymes butyrylcholine esterase (EC 3.1.1.8) from horse serum or acetylcholine esterase (EC 3.1.1.7) from electric eel. Butyrylcholine esterase accepts a variety of dipeptides as substrates and removes the C-terminal choline ester in high yield under very mild conditions (pH 6.5, room temperature) and with complete selectivity (Scheme 1, Table 1). In the majority of the cases the protected dipeptide

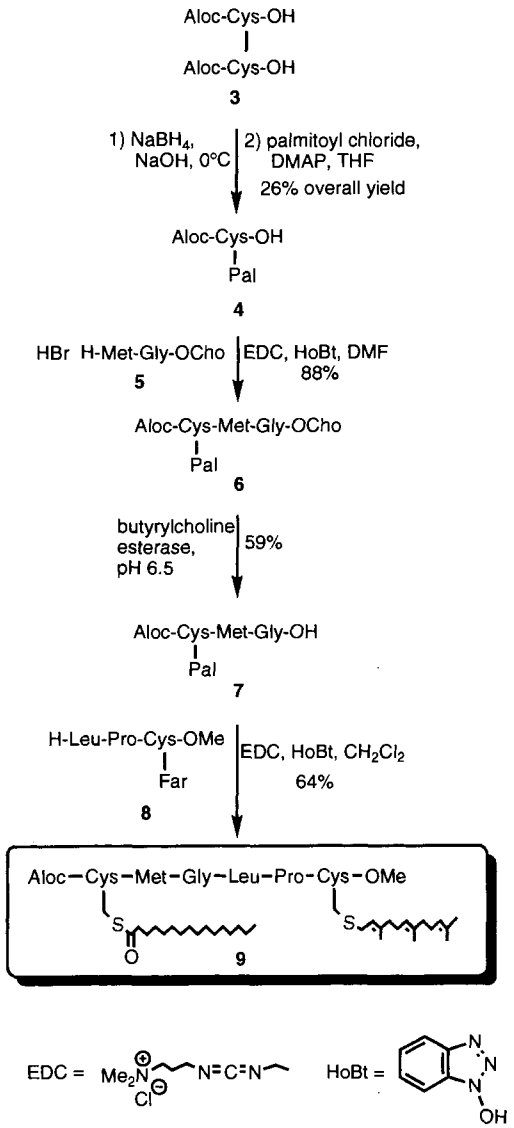
[a] BE = butyrylcholine esterase from horse serum; AE = acetylcholine esterase from electric eel. [b] Yields refer to pure deprotected dipeptide **2**. All dipeptide carboxylic acids **2** were characterized by means of their 200 MHz ^1H NMR spectra (in $CDCl_3$) and their FAB mass spectra. The analytical purity of the carboxylic acids **2** was confirmed by HPLC.

esters **1** are freely soluble in the aqueous buffer, and a solubilizing cosolvent is not needed (Table 1). In the enzymatic removal of the N-terminal phenylacetamido (PhAc) group[8] and the C-terminal heptyl (Hep) esters, in particular, the combination of two sterically demanding hydrophobic amino acids posed serious problems due to the low solubility of the respective peptide derivatives in the aqueous media. However, butyrylcholine esterase accepts these combinations, too, and deprotects substrates **1a**, **b**, **g**, **h**, and **1i** in high yield. Since the acetylcholine esterase catalyzed deprotection of peptide choline esters under these mild conditions is slow (Table 1, nos. 2, 4, and 6), butyrylcholine esterase is preferred.

The conditions for the enzymatic deprotection of the choline esters are so mild that this method can be employed to synthesize sensitive S-palmitoylated and S-farnesylated cysteinyl lipopeptides, which, for instance, represent the characteristic partial structures of the *Ras* lipoproteins.

The *Ras* proteins are a class of membrane-bound lipoproteins found in organisms as diverse as mammals, flies, worms, and yeast, and serve as central molecular switches.[10] They translate the signals given by growth factors through a well-balanced series of noncovalent protein/protein interactions into a cascade of highly specific protein phosphorylations terminating in the activation of transcription factors, which then may influence the transcription of the genetic code. Cell growth and proliferation are regulated by this pathway, and if it is disturbed or interrupted, uncontrolled proliferation and finally cancer may occur. Thus, in roughly 40% of all human cancers a point mutation in the *ras* oncogenes coding for the *Ras* proteins is found, a figure that increases to 85% for some of the major malignancies like lung, colon, and pancreas cancer.[11] The human H- and N-*Ras* proteins terminate in an S-farnesylated cysteine methyl ester, and towards the N-terminus one or more S-palmitoylated cysteines are found[12] (see for instance the C-terminal lipohexapeptide of the human N-*Ras* protein **9** (Scheme 2)). The



Scheme 2. Enzymatic synthesis of the S-palmitoylated and S-farnesylated *Ras* lipopeptide **9**.

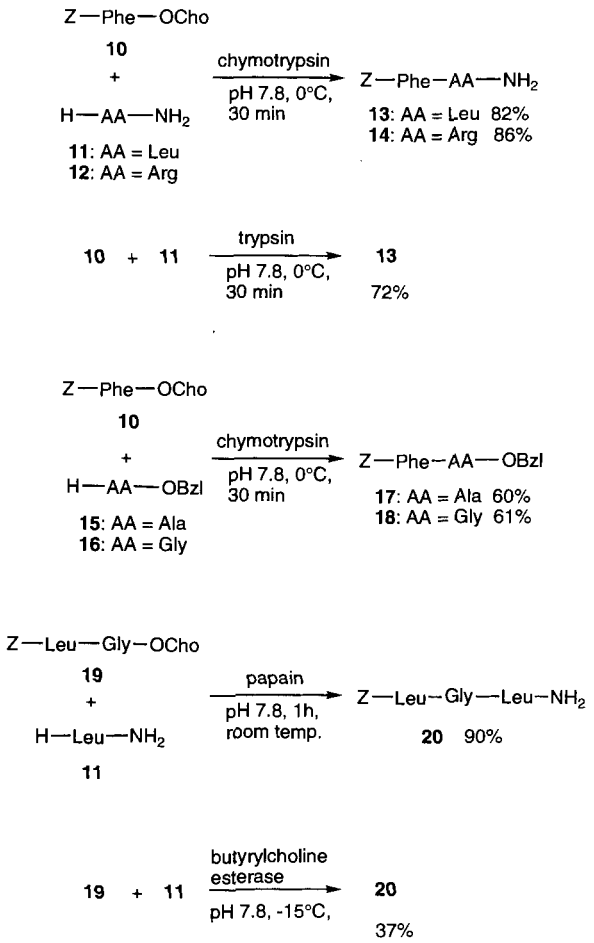
synthesis of characteristic *Ras* peptides is severely complicated by the acid sensitivity of the farnesyl residue and the pronounced base lability of the palmitic acid thioester (vide infra) and excludes the use of acid- or base-labile blocking functions.[4] For this purpose protecting groups have to be employed that can be removed selectively under extremely mild, preferably neutral conditions.

In a retrosynthetic sense the *Ras* peptide **9** was divided into the masked S-palmitoylated tripeptide **7** and the N-terminally deprotected S-farnesylated tripeptide ester **8** to ensure that the final coupling would proceed efficiently (Scheme 2). For the synthesis of **7**, bis[allyloxycarbonyl(Aloc)]-protected cystine **3** was reduced to Aloc-cysteine, which was immediately acylated with palmitoyl chloride to give the correctly functionalized cysteine derivative **4**. Compound **4** was then condensed in high yield with the dipeptide choline ester **5**, which was readily obtained from the corresponding Boc-protected dipeptide choline ester by treatment with HBr/AcOH. The selective removal of the choline ester group from the fully protected tripeptide **6** in the presence of the base-labile thio ester posed a serious challenge. Preliminary experiments revealed that palmitic acid is cleaved from **6** in aqueous solution by nonenzymatic hydrolysis already at pH 6.5, in other words under virtually neutral conditions, without saponification of the choline ester. However, when **6** was treated with the enzyme butyrylcholine esterase at pH 6.5, the chemoselectivity of the hydrolysis was completely reversed, and the C-terminally deprotected lipotripeptide **7** was obtained in 59% yield. We would like to stress that under these extremely mild reaction conditions absolutely no β-elimination of the S-acyl group is observed, a disturbing side reaction that occurs readily for acylated serine and cysteine derivatives at weakly basic pH.[13] The synthesis of the completely functionalized lipopeptide **9**[14] was finally completed by carbodiimide-mediated condensation of the S-palmitoylated peptide carboxylic acid **7** with the S-farnesylated N-terminally deblocked peptide ester **8**[4] (Scheme 2).

Besides the choline esterases, proteases like chymotrypsin, papain, trypsin, subtilopeptidase A, nagarse, and proteinase K also cleave N-protected amino acid and peptide choline esters under mild conditions. For instance, in the chymotrypsin-catalyzed hydrolysis of Z-Phe-OCho **10** the specificity constant[15] has a value of 1.2×10^6 mM^{-1}s^{-1}, which is significantly higher than the values determined for comparable water-soluble *N*-maleinamido amino acid and peptide benzyl and *p*-nitrobenzyl esters. This difference is caused in part by the P'_1 specificity of chymotrypsin for positively charged residues, as we determined previously,[16] and also by the coulombic effect of the positive charge, which leads to enhanced reactivity of the choline ester bond.[17] Due to these excellent substrate properties, we tested choline esters as acyl donors in kinetically controlled peptide syntheses.

In these reactions, too, the excellent solubility of the protected amino acid choline esters in aqueous solvents is a great advantage. Thus, in the presence of chymotrypsin the Z-protected phenylalanine choline ester **10** is coupled in only 30 min with the amino acid amides **11** and **12**, and also with the amino acid benzyl esters **15** and **16**, to give the fully protected peptides **13**, **14**, **17**, and **18**, respectively, in high yield (Scheme 3). The undesired competing hydrolysis of the choline ester can be suppressed simply by adding a precooled solution (0 °C) of the acyl donor slowly to an ice-cold solution (pH 7.8) of the acyl acceptor and the biocatalyst.

The application of the amino acid choline esters for enzymatic peptide synthesis is not restricted to reactions with chymotrypsin as the biocatalyst. For instance, the dipeptide **13** also



Scheme 3. Enzymatic peptide synthesis employing amino acid and peptide choline esters as acyl donors.

is obtained in high yield by employing trypsin (Scheme 3). In addition, the N-protected peptide choline ester **19** and leucine amide **11** are condensed by papain to give the tripeptide **20** in 90% yield (Scheme 3). Particularly surprising is the finding that butyrylcholine esterase is also able to transfer the acyl moiety from amino acid choline esters to N-nucleophiles; in other words, it catalyzes not only the hydrolysis of choline esters but also the formation of peptide bonds. However, in initial experiments with this biocatalyst tripeptide **20** was obtained from **19** and **11** in 37% yield only at −15 °C in a frozen aqueous system[5] but not at room temperature.

Experimental Procedure

General procedure for the enzymatic cleavage of choline esters by means of butyrylcholine esterase: A solution of 1 mmol of the choline ester and 1000 u of butyrylcholine esterase in 50 mL of 0.05 M Na_3PO_4 buffer (pH 6.5; when necessary 5–10 vol% of methanol was added as cosolvent) was shaken at 37 °C. After the conversion was complete (24–36 h; reaction monitored by thin-layer chromatography with *n*-hexane/ethyl acetate/methanol), the pH was adjusted to 2–3 with 1 N HCl. Depending on the substrate the solution was extracted four to eight times with 40 mL of dichloromethane. The combined organic layers were dried over $MgSO_4$, the solvent was removed in vacuo, and the residue was purified by chromatography on silica gel eluting with *n*-hexane/ethyl acetate/methanol.

7: Colorless oil; $R_f = 0.25$ (*n*-hexane/ethyl acetate/methanol 60/30/5 [v/v/v]); $[\alpha]_D^{22} = -59$ ($c = 0.5$ in CH_3OH); ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.88$ (t, $J = 7$ Hz, 3H, ω-CH_3 Pal), 1.25 (m, 24H, CH_2 Pal), 1.60–1.68 (m, 2H, β-CH_2 Pal), 1.95–2.09 (m, 2H, β-CH_2 Met), 2.10 (s, 3H, CH_3 Met), 2.53–2.57 (m, 4H, α-CH_2 Pal, γ-CH_2 Met), 3.15–3.27 (m, 2H, β-CH_2 Cys), 3.83–3.93 (m, 1H, CH_{2a} Gly), 4.10–4.20 (m, 1H, CH_{2b} Gly), 4.39–4.78 (m, 4H, α-CH Met, α-CH Cys, OCH_2 Aloc), 5.18–5.38 (m, 3H, CH_2=CH Aloc); FAB-MS (2-NBA/TFA 5/1): *m/z* (%): 654 (63) [M + Na]$^+$.

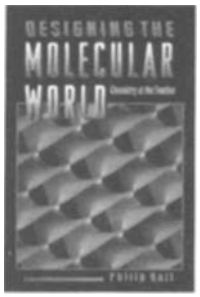
At Last! A Positive Perspective For Chemistry

Designing the Molecular World. Chemistry at the Frontier. By *P. Ball.* Princeton University Press, Princeton, 1994. 376 pp., hardcover $ 29.95.—ISBN 0-691-00058-1

It was high time that this book be written. Chemical research and its applications nowadays receive almost exclusively adverse criticism from the public, and even chemists themselves often take the view that research has exhausted its potential and little new knowledge of importance can be expected. This book is like a clean fresh breeze, and puts the image of chemistry back into proper perspective. In it Philip Ball gives a comprehensive survey of the most recent chemical research. Many of the concepts explained here were unheard of in 1960. All the major research topics that have occupied the universities in recent times are mentioned: the use of flash photolysis and laser techniques to elucidate reaction mechanisms and molecular structures, quasicrystals, interpenetrating networks, the chemistry of life processes and of the self-organization of molecules, crown ethers, cage structures, amphiphilic systems, and so on. No book quite like this has ever appeared before!



The blurb on the dust-jacket claims that the book is also suitable for readers without a scientific education. This strikes me as somewhat over-optimistic, as Ball rushes with seven-league boots through Rutherford's model of the atom and continues to the frontiers of current research. No lay-person is likely to be able to follow him. On the other hand, the book should be compulsory reading for scientists and for everyone with a basic scientific education. But there is no need to fear such a "duty"; right from the first few pages the book is a pleasure to read. The author's lively and gripping style, in which he does not shrink from phrases containing the word "I", and the clearly constructed sentences serve to clarify even the most complicated relationships in a way that is easy to understand. (Incidentally, a German translation of the book, which one hopes will soon appear, will also need to match this high standard.) The text is illustrated by excellent diagrams and photographs, and together with their accurate and detailed legends these are essentially self-contained units which can be understood independently of the text. Evidently the experience of a skilled scientific editor has helped here. It is certainly to be hoped that the success of this first book by Philip Ball will encourage him to write more. Most importantly of all, the book should be used by every chemistry teacher, from university professor to high school, to help convey to students something of the book's enthusiasm for modern research. I especially liked the chapter "Caught in the Act, Watching Atoms Dance"; it vividly makes the point that all the ideas concerning transition states that were constructed by earlier generations of chemists as a way of understanding reaction mechanisms were not just mental aids, but they actually exist in nature and one can see and almost take hold of them. A significant development that should be noted by epistemologists!

Anyone who has had difficulty up to now in understanding fractals and chaos theory will find this book very helpful, and after reading it will wonder why the subject was made to seem so formidable. Of course the book had to include a chapter on the chemistry of the atmosphere and pollution from human activities. On this subject the book reminds us that long before politicians became concerned about these matters there were already scientists who recognized the problems, studied their causes, and even proposed solutions.

Ball makes an effort in the book to relate chemistry to developments in information technology, microelectronics, consumer electronics, video recorders, color television, news transmission, and the electronics industry. One would perhaps have liked these connections to be explained in more detail, thereby bringing the book even closer to everyday life. Nevertheless, they are adequately sketched here, so that at the end of the book one is convinced that "Not everything is chemistry, but without chemistry nothing can exist."

Aluminum(I) and Gallium(I) Compounds: Syntheses, Structures, and Reactions

Carsten Dohmeier, Dagmar Loos, and Hansgeorg Schnöckel*

In memory of Wilhelm Klemm

By the end of the last century there were already the first indications of the possible existence of Al^I halides. However, it was only through the pioneering works of W. Klemm, who would have celebrated his 100th birthday on January 6, 1996, that detailed spectroscopic investigations became possible. Since the end of the 1970s the reactivity of AlX and GaX species in solid noble gases has been confirmed by numerous examples. In recent years formally monovalent Al and Ga species have been successfully synthesized on a preparative scale. In addition to the first halides, organometallic compounds with metal–metal bonds have been isolated and investigated with regard to their chemical properties. The fundamental importance of such species has been documented in this journal among others in the form of two highlight articles in which experimental and theoretical aspects have been examined with examples, and parallels and differences with respect to boron chemistry have been illustrated. This review is intended to give an account of the chronological development of this research area over the last few years, but an attempt is also made to categorize the experimental results achieved not only with respect to structure, thermodynamics, and reactivity, but also with the aid of quantum chemical calculations and by comparative considerations.

Keywords: aluminum compounds · gallium compounds · matrix isolation · subvalent compounds

1. Introduction

A review article from W. Uhl appeared in this journal in 1993,[1] in which mainly organometallic compounds of the formally divalent elements Al and Ga with metal–metal bonds were discussed. Herein, we report on compounds of the formally monovalent elements.[2] Subvalent hydrides,[3] the chalcogenides,[4] and the wide area of intermetallic compounds[4, 5] are omitted to the most part. The main focus is directed towards halogen compounds and organometallic species.

Why are Al^I and Ga^I compounds currently the focus of so much attention? Compared with the fascinating variety of the borane structures or the vast field of the subhalides of indium and thallium, our knowledge of subvalent Al and Ga compounds appears rather scanty. Al^I and Ga^I compounds were only known as high-temperature molecules and considered to be somewhat exotic—something which only spectroscopists would occupy themselves with. For the preparative chemist, this field seemed to be a taboo and hardly fruitful. It was only after this prejudice was eliminated by individual, yet spectacular examples[2, 6] (discussed in the following) that the unanticipated possibilities of this class of compounds became visible.

That Al^I and Ga^I compounds should take up a special place in the third main group is not at all evident at first, because compounds of the monovalent elements have been long known now for both the heavier and lighter homologues of this group. There are, for example, a large number of polyhedral molecular compounds of the type B_nX_n with X = Cl, Br, I.[7] The great variety feigns a general availability, however, because most of these compounds have only been prepared on a mg scale. In contrast, the ionically built-up halides of the heavier homologues In and Tl are readily accessible and known to every freshman in chemistry. When considered from this point of view, it is perhaps astonishing that Al^I and Ga^I compounds that are stable at room temperature were unknown until recently.[8] In the following we aim to show that this can be attributed to the lack of stability on the one hand, for example with regards to disproportionation, and on the other hand to the absence of suitable synthetic methods. The preparative chemistry of analogous compounds with elements from the neighboring groups such as dimeric and even monomeric silylenes has only been achieved in the last few years. Examples are $[SiCp^*_2]$[10] and disilenes with Si=Si bonds.[11]

Based on certain thermodynamic considerations, the energetic situation will first be illustrated taking the monochlorides of the third main group of elements as an example.

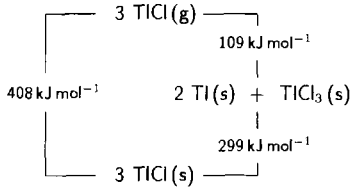
2. Monohalides of the Third Main Group Elements

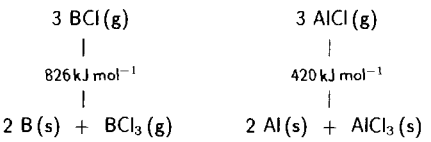
2.1. Thermodynamic Considerations

In contrast to solid TlCl, gaseous TlCl is unstable with regard to disproportionation to give metal and solid trichloride ($\Delta_R H = -109\ kJ\,mol^{-1}$). As the stabilization of TlCl in the form of an ionic crystal with Tl-Cl-Tl bridges is clearly more favorable with respect to Tl(s) and $TlCl_3$(s) by $299\ kJ\,mol^{-1}$, gaseous TlCl does not disproportionate on cooling (Scheme 1). Only TlCl(g) is suitable for comparative stability considerations, because for the lighter homologues the only data available as yet is on the gaseous monochlorides. Similar relationships are found for molecular InCl, but the energy gain on disproportionation is considerably larger ($267\ kJ\,mol^{-1}$). The instability of the monovalent compounds thus increases, as expected for the lighter homologues. Solid InCl is still slightly favored with respect to the disproportionation products, however ($66\ kJ\,mol^{-1}$). An ionic stabilization of this type has not yet been observed in the case of the monochlorides of the elements Ga, Al, and B, but it is conceivable only for GaCl. For the gaseous monochlorides of Al and B, the disproportionation is so exothermic that the formation of $2M + MCl_3$ from 3 MCl probably represents the energetic minimum in both these systems (Scheme 2).

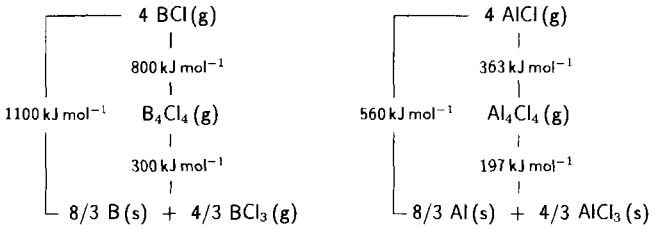


Scheme 1. Energy diagram for the disproportionation of TlCl.

In the case of gaseous BCl, metastable polyhedron compounds with B—B bonds can be isolated in place of an ionic stabilization product, for example molecular B_4Cl_4 with a tetrahedral B_4 framework and terminal chlorine atoms. The energetic relationships between B_4Cl_4(g), BCl(g), and B(s) $+ BCl_3$(g) are illustrated in Scheme 3. They result from a combination of



Scheme 2. Energy diagrams for the disproportionations of BCl and AlCl.



Scheme 3. Energy diagrams for the disproportionations of BCl and AlCl through oligomers.

experimentally determined thermodynamic data [12] and the results of quantum chemical calculations.[13]

Similar oligomers are to be expected in the Al/Cl system as well (Scheme 3), as shown by quantum chemical calculations.[14] For example, Al_4Cl_4 with a tetrahedral structure analogous to that of B_4Cl_4 is energetically favored with respect to a compound with a heterocubane structure. The isolation of this species thus represents a challenge for the preparative chemist. Albeit this synthetic goal has not yet been fully achieved, considerable partial successes have been secured, which will be discussed in Sections 2.3 and 3.[15]

2.2. Spectroscopic Studies on Structure and Reactivity

Spectroscopic studies on low molecular weight species are most appropriate for the systematic analysis of a new class of compounds with regards to structure, thermodynamics, and reactivity. It is advisable to complement these with quantum

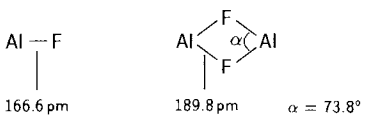
Hansgeorg Schnöckel, born in Marienburg, Westpreußen, studied chemistry at the Universität Münster, where he did his doctorate in 1970 under the direction of H. J. Becher. His dissertation was concerned with the spectroscopic investigation of molecules containing boron. Following this, matrix investigations of reactive high-temperature molecules led to his Habilitation in 1981. In 1987 he was named Professor at the Universität Münster and moved to take up a Professorship at the Institut für Anorganische Chemie der Universität München in 1989. He has been Professor für Analytische Chemie at the Universität Karlsruhe since 1993. His research interests are concentrated on spectroscopic and quantum chemical investigations of reactive molecules. Based on works such as these, preparative chemistry involving high-temperature molecules such as aluminum monohalides has become increasingly more important over the last few years.

Carsten Dohmeier, born 1963 in Osnabrück, studied chemistry at the Universität Münster. He did his doctorate in 1994 under the direction of H. Schnöckel at the Ludwig-Maximilians-Universität München. Since then he has worked at the Universität Karlsruhe in the field of low-valent aluminum compounds.

Dagmar Loos, born in München in 1964, studied chemistry at the Ludwig-Maximilians-Universität München where she did her doctorate in 1994 under the direction of H. Schnöckel. Since 1994 she has worked as a post doctoral researcher in the group of A. J. Downs at the University of Oxford investigating low-valent gallium compounds.

chemical calculations. We will not dedicate a separate section to the latter topic, but rather present the results of the theoretical calculations together with the results of the experimental investigations for the individual compounds.

The geometries of the monomeric monohalides, which are only thermodynamically stable as high-temperature molecules in the singlet ground state, have been known for some time.[16] They were identified by analysis of the fine structure of electronic spectra. However, it is not possible to draw conclusions as to the reactivity of the monohalides from these gas phase investigations. Even the simplest of reactions, dimerization, cannot be studied under these conditions, because, due to the low dimerization energy, the proportion of dimeric species at higher temperatures is very small: The ratio of the concentration of dimers to monomers for AlF is only about 10^{-11}:1 at 1473 K (dimerization energy $-55\ kJ\,mol^{-1}$). The thermodynamic data required for an estimation of this type are derived from quantum chemical calculations.[17] A four-membered ring with D_{2h} symmetry was calculated as the equilibrium structure for Al_2F_2 (Scheme 4).



(exp.: 165.4 pm [16])

Scheme 4. Geometric parameters of AlF and Al_2F_2.

The Al—F bonds in Al_2F_2 are significantly weaker than those in monomeric AlF. This is also the reason for the low dimerization energy of AlF. As Al^+ has a relatively large ionic radius due to the doubly occupied 3s AO, d(Al—F) is larger than in AlF_3 for example (163 pm).[18] The geometry of Al_2F_2 is affected by the F—F repulsion. This results from the increase in the dimerization energy when using a larger F basis, which better describes the diffuse charge cloud of F^-. The small F-Al-F angle shows, however, that the Al—Al repulsion dominates. This seems plausible, because the HOMOs in both AlF and Al_2F_2 have Al-3s character.[19] The MOs formed from the F(2p) AOs lie between -0.6 and -0.74 Hartree. We have here, in contrast to the alkali metal halides, the unusual case of an ionogenic compound, in which the MOs localized predominantly on the anion lie energetically lower than those localized on the cation. This is typical for valence unsaturated Al compounds and reflects their strong reduction potential. As the orbital energy ε is a measure of the spatial expansion of an AO ($r^{-1} \sim \sqrt{|\varepsilon|}$),[20] Al^+ with the electronic configuration [Ne] $3s^2$ has an unusually large cation radius which exceeds that of the F^- ion. Even after these considerations, the relatively large Al—F distances and the small F-Al-F angles for AlF and Al_2F_2 are understandable.

Matrix isolation spectroscopy provides an experimental route to oligomeric AlF species. The monomeric high-temperature molecules are first deposited together with a large excess of noble gas onto a cold surface (ca. 15 K).[21] In this way the disproportionation [Eq. (1)], which occurs in the gas phase on cooling due to shifts in the equilibrium, can be avoided.

$$3\ AlF(g) \rightleftharpoons 2\ Al(s) + AlF_3(g) \qquad (1)$$
$$\Delta_R H = -614\ kJ\,mol^{-1}$$

When the monomers are trapped from the gas phase, different amounts of dimeric AlF are formed depending on the reaction conditions (temperature of the cold surface, dilution by the noble gas). Certain statements may be made as to the structure of Al_2F_2 based on its vibrational spectrum: The two IR-active stretching vibrations indicate a four-membered ring structure, and the Al—F force constants calculated from the spectra show that the Al—F bond in Al_2F_2 ($1.2\ N\,cm^{-1}$) is considerably weaker than that in monomeric AlF ($3.92\ N\,cm^{-1}$). These experimental data have been subsequently confirmed by quantum chemical calculations which show that the bond length is elongated from 166.6 pm (AlF) to 189.8 pm (Al_2F_2). The two IR-active stretching vibrations for selected dimeric monohalides with planar ring structures (D_{2h}) found from matrix studies are listed in Table 1. Unfortunately there are no analogous Raman measurements as yet, so there are no complete experimental data on structure or on the force constants matrix.

Table 1. Calculated and experimentally determined frequencies of the IR-active stretching vibrations of some planar [M(μ-X)$_2$M] compounds as well as their calculated geometric parameters and dimerization energy ΔE (2MX → M_2X_2) [25].

[a] See ref. [17, 26]. [b] See ref. [27].

As these results show, the matrix technique is the method of choice for studying the reactivity of monomeric species—the simplest reaction is the dimerization—and for measuring the vibrational transitions of the reaction products. Trimers, or even larger AlX or GaX oligomers have not yet been identified by the matrix technique, because their concentrations under comparable conditions[22] should be significantly lower than those of the dimers.[23] As in more recent times more sensitive measurement techniques have become available, the detection of additional oligomers should be possible in the near future. Studies of this type are particularly promising, because the vibrational spectra that are expected can be calculated very reliably with quantum chemical methods, and the assignment of the vibrational bands observed can thus be confirmed.[24]

In addition to the dimerization reactions, the reactivity with respect to other species such as atomic oxygen, hydrogen chloride, and molecular hydrogen can also be investigated with the aid of the matrix technique. Oxygen atoms produced from O_2 by microwave discharge react with the monohalide molecules in the matrix to give linear triatomic halide oxides. It was in these compounds that element–oxygen double bonds for Al and Ga were first detected [Eqs. (2a)–(2c); Scheme 5].[28]

$$AlF + O^* \longrightarrow O=AlF \quad [29] \qquad (2a)$$

$$AlCl + O^* \longrightarrow O=AlCl \quad [29] \qquad (2b)$$

$$GaF + O^* \longrightarrow O=GaF \quad [30] \qquad (2c)$$

Scheme 5. Synthesis of molecular halide oxides of Al and Ga in solid noble gases.

AlCl and GaCl react in solid noble gases with hydrogen chloride or molecular hydrogen to form AlH and GaH bonds, respectively [Eqs. (3a)–(3c); Scheme 6].

$$AlCl + HCl \xrightarrow{h\nu} AlCl_2H \quad [31] \qquad (3a)$$

$$GaCl + HCl \xrightarrow{h\nu} GaCl_2H \quad [32] \qquad (3b)$$

$$GaCl + H_2 \xrightarrow{h\nu} GaClH_2 \quad [33] \qquad (3c)$$

Scheme 6. Synthesis of molecular halide hydrides of Al and Ga in solid noble gases.

The study of simple (and subvalent) AlH and GaH compounds takes on a special importance,[3] since here the bonding relationships can be examined particularly reliably by both quantum chemical and spectroscopic methods.[34] With the matrix technique it has been possible to obtain AlH and GaH compounds, starting from monovalent compounds and without the need for bulky substituents, in which the metal atom is only tricoordinate. As regards, for example, the GaH bonds, it remains to be mentioned that they become stronger with increasing chlorine substitution: $GaH_3 < GaClH_2 < GaCl_2H$.[33] For other results concerning the hydride compounds of the trivalent elements the reader is referred to the original works and the review articles cited.[3]

In 1972 indications were that the high-temperature molecule AlCl was unsuitable for synthetic purposes.[35] In the following years the reactivity of such species was confirmed for the first time by matrix experiments, and in recent times it has proved possible to produce Al and Ga monohalides on a preparative scale and use these for syntheses. These results are discussed in the following section.

2.3. Syntheses of Subvalent Al and Ga Halides

For Tl and In the values of the redox potentials M^+/M and M^{3+}/M^+ alone show that only Tl^+ is stable with regards to disproportionation in aqueous solution.[36] It is thus very simple to prepare thallium monohalides by oxidation of the metal with aqueous HX solution. In contrast, the monohalides of the lighter homologues are oxidized under these conditions producing H_2.[37] Recent studies show, however, that InX compounds represent an exception. It has already been mentioned in Section 2.1 that solid InCl is thermodynamically stable with regards to disproportionation. It seems plausible, therefore, that In monohalides may also be isolated from aqueous media under suitable conditions thanks to their low solubilities.[38] The yields obtained are admittedly very low, however. For the synthesis of InX more favorable stoichiometric amounts of suitable starting materials (e.g. indium and InX_3) were heated to 300–400 °C in sealed ampoules.[39]

Al and Ga monohalides that are thermodynamically stable at room temperature are not known.[8] To access metastable AlX and GaX compounds, the gaseous MX species that are thermodynamically stable at high temperatures have to be made first. There are a variety of methods available for their preparation and some examples are shown in Equations (4a)–(4c) (Scheme 7).

$$M + HX \xrightarrow{\Delta} MX + 1/2\,H_2 \qquad (4a)$$

$$2M + X_2 \xrightarrow{\Delta} 2MX \qquad (4b)$$

$$2M + MX_3 \xrightarrow{\Delta} 3MX \qquad (4c)$$

Scheme 7. Possible synthetic routes to MX species (M = Al, Ga; X = halogen).

To largely suppress the formation of the trihalide which is preferred at low temperatures, temperatures of 800–1000 °C are necessary.[40] The gaseous MX species thus formed have to be subsequently quenched at low temperatures in order to prevent the disproportionation which occurs on slow cooling.

The preparation of MX(g) (M = Al, Ga) by the reaction of HX(g) with liquid Al or Ga has already proved itself in the matrix experiments mentioned in Section 2.2. This method also has the advantage that the MX gas stream can be easily added in the correct doses by controlling the amount of HX fed in. Thus, this method of preparation was also used in the synthesis. The apparatus used (Fig. 1) is, in principle, comparable to the experimental construction that was used by Timms for the

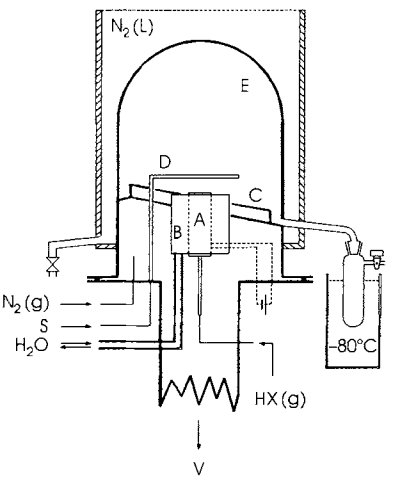

Fig. 1. Schematic representation of the apparatus used for the preparative syntheses. A: Graphite cell, B: Cooling plate, C: Run-off rim, D: Solvent inlet, E: Stainless steel vessel, S: Solvent, V: To vacuum pump.

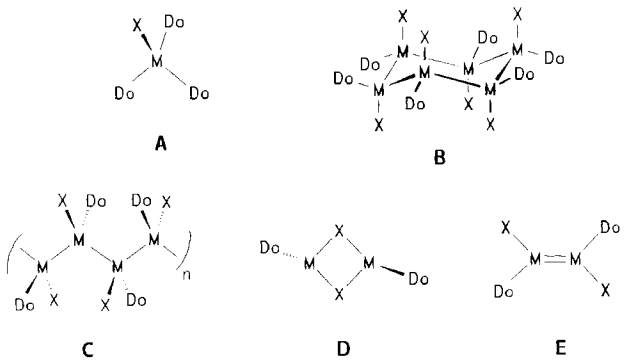
preparation of other high-temperature molecules (e.g. BF).[35,41] Similar apparatus has been in use for some time now for metal vapor syntheses.[42] The reaction between metal and hydrogen halide (HCl, HBr, or HI) takes place in a graphite cell, located in a stainless steel vessel that can hold about 30 L and is evacuated to approximately 5×10^{-5} mbar. Under these conditions a gaseous equilibrium mixture is formed which—depending on M, HX, and the particular reaction conditions—is made up of between 90% and 100% MX and H_2. The gaseous monohalides continually streaming out of the graphite cell are condensed together with solvent on the inner surface of the stainless steel vessel which is cooled to 77 K. The hydrogen is removed continuously by a high-performance pump system. Approximately 45 mmol MX can be prepared in this way over a period of about two hours. The coolant is subsequently removed and

the melting condensate then collected in a Schlenk vessel located under the run-off rim. The solution thus obtained can be studied by using conventional techniques. To prevent disproportionation of the MX species on melting the condensate, solvents have to be selected that are capable of stabilizing these metastable compounds.[43] The choice of solvents that may be used in this process is limited, especially since protic solvents and halogenated hydrocarbons must be ruled out because of their high reactivity with respect to MX bonds. The possibilities are further limited by the demands placed on the solvent with regards to their physical properties; they must be readily volatile and have good solvating properties at temperatures as low as possible.

Initial attempts at stabilizing AlCl were carried out using pentane. The dark red condensate obtained at 77 K spontaneously turns black on warming above approximately 170 K due to the formation of aluminum as a result of disproportionation ($3\,AlCl \rightarrow 2\,Al + AlCl_3$). Subvalent Al species could not be identified in the solution obtained. Experiments in which pentane was replaced by toluene or other aromatic solvents were similarly unsuccessful.[44] On the other hand, the use of THF appeared promising initially. After melting the condensate, a deep red solution was obtained at $-78\,^{\circ}C$ that reacted violently with water under H_2 evolution. The initial euphoria was quickly followed by sobriety, however, because the THF solutions discolored over a period of several hours or on warming slowly to room temperature. It was shown spectroscopically that this behavior was attributed to ether cleavage reactions,[45, 46] which are also known to occur with boron halides.[47] These undesired reactions can easily be avoided by using a less reactive ether such as diethyl ether for example. Admittedly, it also became apparent that toluene had to be added to the latter to fully dissolve the condensed species on warming. The likewise deep red solution thus obtained can be stored without change for several weeks at about $-50\,^{\circ}C$. The analysis of the elemental ratio of Al to Cl and the amount of hydrogen produced on hydrolysis of the solution ($Al^+ + 2H^+ \rightarrow Al^{3+} + H_2$) seems to support the existence of solvated "AlCl".[44]

Recent studies confirm that "AlBr",[48] "AlI",[49] and "GaX" (X = Cl, Br, I)[50, 51] can be stabilized analogously. As expected, the MX compounds become more stable with respect to disproportionation with increasing atomic numbers of M and X. As exemplified by "AlBr", it was established that the solvent combination toluene/diethyl ether can be replaced by other nucleophilic solvents;[52] the thermal stability increasing with increasing Lewis basicity of the solvent. The addition of an aromatic component further increases the thermal stability.[53] The addition of an arene was as yet only of absolute necessity in combination with diethyl ether, a relatively weak and only slightly polar Lewis base.

Which structures can be expected for the solvated "AlX" species? The influence of the solvent on the stability of the solutions would indicate structures with coordinated solvent molecules. These structures are supported by the ^1H NMR spectra in which the resonances of the particular donors in question are detected greatly shifted in comparison to the noncoordinated solvents. The structures shown in Scheme 8 represent some proposed structures for coordination compounds of the type $[M_nX_n(Do)_m]$ (Do = donor) that are possibly formed; these are based on analogy considerations and quantum chemical calculations. Cyclic or chain structures, for example, show analogies to those of polysilanes, because donor-stabilized Al and Ga monohalides [MX·Do] are isoelectronic with SiR_2 units (Scheme 8, **B**, **C**, **E**).



Scheme 8. Proposed structures for donor-stabilized "MX" (M = Al, Ga; X = halogen; Do = donor).

Direct proof of species of these types was not available for a long time. After numerous experiments searching for suitable donors, the stabilization of "AlBr" was finally achieved in a triethylamine/toluene mixture. The adduct of NEt_3 with AlBr can be isolated from the resulting solution in relatively good yield (ca. 50%). The light yellow solid first disproportionates at 95 °C to give metallic aluminum and $AlBr_3 \cdot NEt_3$. The results of the X-ray structure analysis show that the adduct exists as tetrameric $[Al_4Br_4(NEt_3)_4]$ (**1**) and contains a square four-membered Al ring (Fig. 2). The bromine atoms and the donor molecules are arranged in an alternating fashion above and below the ring so that a molecular structure analogous to that of cyclobutane results.[54] Analogously, the isostructural iodine compound $[Al_4I_4(NEt_3)_4]$ **2** was recently isolated from the "AlI"/triethylamine system.[55]

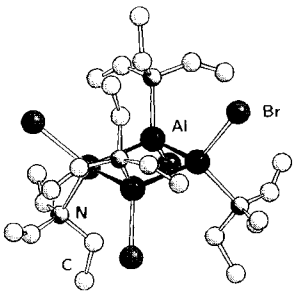


Fig. 2. Molecular structure of $[Al_4Br_4(NEt_3)_4]$ **1** in the solid state (H atoms not shown).

As **1** and **2** were the first Al monohalides whose structures were determined by diffraction methods, only results from quantum chemical calculations are available for evaluation of the observed bond lengths. The structure calculated for the model compound $[Al_4Br_4(NH_3)_4]$ **3** (SCF level)[54] does not differ significantly from that of **1**. For instance, the Al–Al distance calculated for **3** is the same as that experimentally determined for **1** (264 pm). The iodide **2** also has an insignificantly longer metal–metal distance of 265.2 pm. As expected, the Al–halogen distance (d(Al–I) = 264 pm; d(Al–Br) = 242 pm) is longer in both cases than in the gaseous monomeric AlX molecules: d(Al–I) = 254 pm; d(Al–Br) = 230 pm.[16] The long Al–N bonds (**1**: 209.5 pm; **2**: 208.2 pm) also infer Al^I species, because in the trimethylamine adduct of $AlCl_3$, for example, the Al–N distance of 196 pm is considerably shorter.[56]

In addition to the importance of **1** and **2** for structural systematics, these compounds may find numerous uses, particularly as defined starting materials in the synthesis of other Al^I species.

Structures of other donor-stabilized monohalides of Group 13 elements are not known as yet. [InX·0.5tmeda] (tmeda = *N*,*N*,*N'*,*N'*-tetramethylethane-1,2-diamine) has been isolated, but has not yet been characterized by X-ray methods.[57] To our knowledge there are no boron compounds of the type $[B_nX_n(Do)_m]$.

If anisole is used for stabilizing AlX in place of triethylamine, an aluminum monohalide cannot be isolated. Attempts to grow single crystals are made difficult by disproportionation and ether cleavage reactions. These consecutive reactions also occur in "AlX" solutions with other "methylethers".[48, 55] Under suitable conditions, the anisole adduct of $AlBr_2$, **4**, can be isolated in small yields as the least soluble component from a solution of "AlBr" in anisole.[58] $[Al_2Br_4(MeOPh)_2]$ (**4**) is the first Al^{II} halide stable at room temperature.[59] It is presumably formed at low temperatures from "AlBr" and $AlBr_3$, which is produced as a side product in the high-temperature synthesis.[60, 61] Donor-stabilized $AlBr_2$ occurs as a dimer with an Al–Al bond. The coordination spheres of the Al atoms are each completed by one anisole molecule acting as a donor (Fig. 3). An analogous dialane can be characterized in the AlI_2/PEt_3 system.[62]

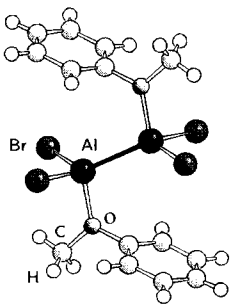

Fig. 3. Molecular structure of $[Al_2Br_4(MeOPh)_2]$ **4** in the solid state.

The Al–Al bond in **4** (d(Al–Al) = 253 pm) is about 11 pm shorter than that in **1**. This considerable difference is probably due to electronic effects rather than steric effects. For instance, a comparison of the Al–Br distances in Al_2Br_6,[18] $[Al_2Br_4(MeOPh)_2]$, and $[Al_4Br_4(NEt_3)_4]$ reveals a continuous increase in the bond lengths (222 (terminal), 230, and 242 pm, respectively). It appears reasonable to attribute both this trend and the different Al–Al distances in **1** and **4** to the increase in the radii in the series Al^{III}, Al^{II}, Al^{I}. The values of the formal oxidation state are reflected in the charge of the Al atoms as calculated by Ahlrichs and Heinzmann:[63] in the model compound $[Al_4Br_4(NH_3)_4]$ **1**, $Q_{Al} = +0.32$, in **4**, $Q_{Al} = +0.62$ (SCF level).[64]

With the exception of Tl, similar ethane-analoguous compounds of the type $[X_2(Do)E–E(Do)X_2]$ with element–element bonds are known for all Group 13 elements.[65] In contrast, under similar conditions, thallium preferentially adopts the mixed-valent ionic form $M^I[M^{III}X_4]$. In the absence of donors, this structure type is also energetically favored for InX_2 and GaX_2 species.[66]

The adduct **4** reacts in solution at room temperature to form Al metal and the anisole adduct of $AlBr_3$. The Al^{II} compound is thus considerably more labile with respect to disproportionation than the homologous $[X_2(Do)M–M(Do)X_2]$ compounds of Ga and In.[67] This stability series of the M^{II} compounds changes when the possibility of disproportionation is blocked, or at least made considerably more difficult, by the use of sterically demanding ligands. For instance, when the alkyl compounds of the formally divalent metals extensively discussed by Uhl ($[R_2M–MR_2]$ with R = $CH(SiMe_3)_2$) are compared with one another,[68] the thermal stability decreases in the same direction in which the M–C and M–M bond energies decrease (Al > Ga > In). The Al compound does not decompose before 217 °C, whereas in the case of the In counterpart, metal deposition occurs at 100 °C.

With sufficiently bulky ligands, it is even possible to force the formation of a Tl–Tl bond. The first example is $[\{(Me_3Si)_3Si\}_2Tl–Tl\{Si(SiMe_3)_3\}_2]$. The Tl^{II} compound is formed together with Tl as a disproportionation product from $[Tl^I(NMe_2)]$ and $Rb[Si(SiMe_3)_3]$.[69] In similar attempts with sterically less demanding σ-bonded substituents, Tl and an organo-Tl^{III} compound are formed as a rule as a result of disproportionation.

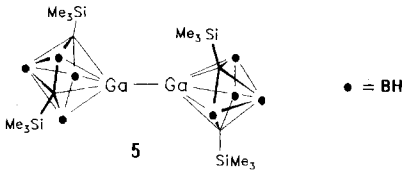
If the molecular structures of the donor-stabilized dihalides are compared with those of the organometallic compounds of the type $[R_2M–MR_2]$,[68, 70] it is remarkable that the M–M bonds (see Table 2) in the halogen compounds of Al and Ga are

Table 2. M–M distances [pm] for selected dimetallic compounds. R = aryl, X = halogen, Do = donor.

M	$[R_2M–MR_2]$	Ref.	$[R_2M–MR_2]^{\bullet-}$	Ref.	$[X_2(Do)M–M(Do)X_2]$	Ref.
Al	265–266	[68, 70]	247–253	[71]	253–256	[58, 62]
Ga	248–254	[68, 70]	234	[71]	239–242	[65, 72]

about 5% shorter in spite of the higher coordination number. Even in the reduction of certain $[R_2Al–AlR_2]$ or $[R_2Ga–GaR_2]$ species to their radical anions $[R_2M–MR_2]^{\bullet-}$, the bond is only shortened by between 5–7%, although in this case the metal–metal σ bond is strengthened by a single electron π bond.[71] The reduced coulombic repulsion between the positively charged metal cores as a result of π bonding contributions between the halogen atom and the metal atom and also the coordinated donor can be cited as reasons for the small distance between the metal atoms in the $[X_2(Do)M–M(Do)X_2]$ compounds. Furthermore, in any comparison of the metal–metal bonds steric aspects have to be considered, because repulsive interactions between bulky ligands can also lead to an elongation of M–M bonds.

Just how sensitive the metal–metal distance in bimetallic compounds is to geometric or electronic changes is demonstrated by the recently described digallane **5**, which is stabilized



5

by divalent 2,4-bis(trimethylsilyl)-2,4-dicarba-*nido*-hexaborate-(2 −) ligands:[73] The very short Ga–Ga distance of only 234 pm corresponds to that of the radical anion $[R_2Ga–GaR_2]^{\bullet-}$ (R = 2,4,6-$iPr_3C_6H_2$) (Table 2).

To reliably evaluate the effect of electronic and geometric factors, quantum chemical calculations ought to be made as a matter of principle, at least for simple model compounds. Calculations for the parent compound $H_2Al–AlH_2$ give an Al–Al

distance of about 262 pm.[74] Steric effects thus have hardly any influence on the bonding parameters of the compounds of the type $[R_2Al-AlR_2]$ listed in Table 2.

The synthesis of "AlX" solutions already described can be applied to "GaX" systems without any problem. The analytical data of the "GaX" solutions agree with the oxidation state one for gallium, and the thermal stability of the similarly dark red solutions is greater than that of the corresponding AlX system.[50, 51] For this reason, in contrast to the "AlBr" system, no formation of a divalent $[Ga_2X_4(Do)_2]$ side product is observed. As in the case of the "AlX" solutions, the isolation of defined GaX species is difficult, since conventional separation methods such as distillation or chromatographic techniques are not practicable. The experimental possibilities of fractional crystallization are also limited by the thermolability of the species and their high reactivity with respect to many solvents. In the GaCl/diethyl ether system it is possible to isolate $[Ga_5Cl_7(OEt_2)_5]$ ($\equiv [\{(Et_2O)_2ClGa\}Ga\{GaCl_2(Et_2O)\}_3]$) **6** at about $-30\,^{\circ}C$ in a reproducible manner and in acceptable yields (ca. 30 % with respect to Ga). The structure of **6** is shown in Figure 4. The central Ga atom is surrounded by a further four Ga atoms in a distorted tetrahedral fashion. Three of these metal atoms are each bonded to two chlorine atoms and one diethyl ether molecule, whereas the fourth metal atom is surrounded by just one chlorine atom and two donor molecules. The gallium atoms thus display three different formal oxidation states: 0, 1 and 2;[75] the average oxidation state is 1.4.

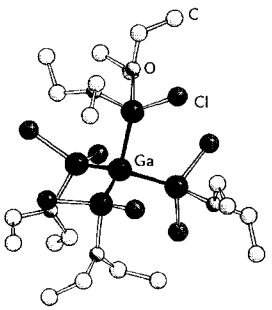


Fig. 4. Molecular structure of $[Ga_5Cl_7(OEt_2)_5]$ **6** in the solid state (H atoms not shown, d(Ga–Ga) = 242–245 pm).

The formation of **6** is possibly a result of the disproportionation of "GaCl", which slowly sets in at $-30\,^{\circ}C$ ($Ga^{I} \rightarrow Ga^{0} + Ga^{III}$ as well as $Ga^{I} \rightarrow Ga^{0} + Ga^{II}$), which under the existing conditions stops at the stage of the poorly soluble metastable intermediate $[Ga_5Cl_7(OEt_2)_5]$.

If $[Ga_2Cl_4(Do)_2]$ is considered as an ethane-analogue, **6** can be interpreted as being the neopentane counterpart in gallium chemistry. On the basis of this kind of analogy consideration, a large number of additional donor-stabilized gallium halides with metal–metal contacts can be envisaged. Their isolation will probably not be trivial, however, because based on the low decomposition temperature of **6** (0 °C), low thermal stabilities are also to be expected for these species.

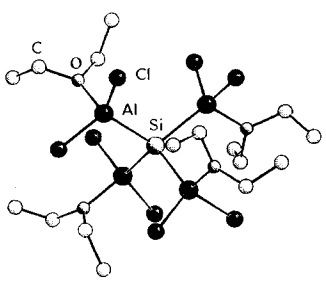

Fig. 5. Molecular structure of $[Si\{AlCl_2(OEt_2)\}_4]$ **7** in the solid state (H atoms not shown).

An Al compound corresponding to **6** is not known. The donor-stabilized ternary chloride $[Si\{AlCl_2(OEt_2)\}_4]$ **7** (Fig. 5) is closely related structurally to the hypothetical $[Al_5Cl_7(OEt_2)_5]$. It is formed rather unexpectedly from "AlCl" and $[SiCp^*_2]$.[76] The central Group 13 atom is replaced in **7** by an Si atom, which is surrounded by four $(AlCl_2 \cdot OEt_2)$ groups (isolobal with CH_3) in a distorted tetrahedral fashion. The Al–Si bond length is 243 pm. Compared with **6**, which disproportionates at about 0 °C, **7** is remarkably stable: it can be heated to 300 °C without decomposition.

X-ray structure analysis is an imperative tool in the unequivocal structural characterization of the compounds described in this section. Admittedly, this method only allows those compounds to be examined that can be obtained in the form of single crystal—and these single crystals do not necessarily represent the structures that are present in solution. Metal nucleus NMR spectroscopy is available as a complementary analytical method. The ^{27}Al NMR resonances of the solvated compounds **1** and **4** appear at about $\delta = 100-130$; thus, they lie in the region which is also typical for species with four-coordinate, trivalent aluminum.[77]

Examination of the solutions of "AlCl", "AlBr", and "AlI" in toluene/diethyl ether by ^{27}Al NMR spectroscopy reveals two signals at room temperature in each case: one very broad signal ($\omega_{1/2}$ ca. 3–4 kHz),[78] which lies at about $\delta = 100-130$, virtually regardless of the halogen, and one signal at higher field strength (AlCl: $\delta = +30$, AlBr: $\delta = +50$, AlI: $\delta = +80$), the intensity of which decreases when the sample is left to stand for prolonged periods at 25 °C. The first signal lies in the region mentioned above and has thus been assigned to donor-stabilized four-coordinate Al species. The assignment of the second signal is not yet possible. It is notable that, in contrast to AlX_3 compounds, the resonance field strength drops with increasing atomic number of the halogen. A possible explanation for this finding is provided by the shifts of non-donor-stabilized AlX (X = F, Cl) species as calculated by quantum chemical methods.[79] In this case too, the smaller chemical shift is determined for the lighter halide.[80] In addition to the donor-stabilized oligomeric AlX compounds, AlX species with different structures also seem to be present in the "AlX" solutions, particularly at low temperatures.

In spite of the diagnostic importance of ^{27}Al NMR spectroscopy, its value in structural elucidation is limited in this case. On the one hand the large full widths at half maximum of the signals prevents a differentiation between different species, on the other hand structural characteristics cannot yet be derived by using the fingerprint method, since only very few comparative data of subvalent compounds are available. This limitation applies to an even greater extent to $^{69/71}Ga$ NMR spectroscopy. The signal widths here are, as a rule, even larger, so that reliable statements regarding structures have only been possible in the case of a few compounds (see Section 3).

As already mentioned in Section 2.2, due to improvements in the technical possibilities, Raman spectroscopy coupled with quantum chemical calculations could prove to be a promising addition to structural analysis techniques in the future, in particular with regards to species in solution.

In addition to the preparation and structural characterization of further more or less donor-stabilized AlX and GaX oligomers, in future the investigation of the properties of these compounds will be of particular interest. Moreover, these species could well provide access to unusual solid-state compounds, which due to their metastable nature are not accessible by high-

temperature methods. Preliminary orientating investigations regarding this topic are currently being carried out in our group. An alternative route to donor-free Al^I and Ga^I halides could be provided by the decomposition of thermally labile MH_2X species ($MH_2X \rightarrow H_2 + MX$).[3b]

2.4. Syntheses with Al and Ga Monohalides

The temperature dependence of the equilibrium $3\,AlCl(g) \rightleftharpoons 2\,Al(s) + AlCl_3(g)$ can be used for the preparation of high purity aluminum or for the formation of thin Al layers by the CVD method.[81] Moreover, the monohalides are of importance for synthetic purposes, because they can be used as synthetic building blocks for new compounds of the trivalent elements.

Reactions that take place in solid noble gases were introduced in Section 2.2; however, monohalides can also be used for preparative syntheses. For this purpose a gas mixture made up of the AlX species prepared at high temperatures, the reaction partner, and an inert solvent are condensed onto a surface cooled with liquid nitrogen. This is subsequently heated slowly. The course of the reaction and the apparatus used correspond to the procedure described in Section 2.3; in this case the stabilizing donor is replaced by the reaction partner. In this way, a dimeric 1,4-dialumina-2,5-cyclohexadiene **8** results from AlCl and 2-butyne [Eq. (5)].[82]

$$4\ AlCl + 4\ Me{-}C{\equiv}C{-}Me \longrightarrow [ClAl\{\mu\text{-}(Me{-}C{=}C{-}Me)\}_2AlCl]_2 \quad (5)$$

8

The most interesting structural characteristic of **8** is the 2e3c bonds between the Al atoms and the C=C bonds (Fig. 6).[83] This unusual dimerization is preferred to the oligomerization

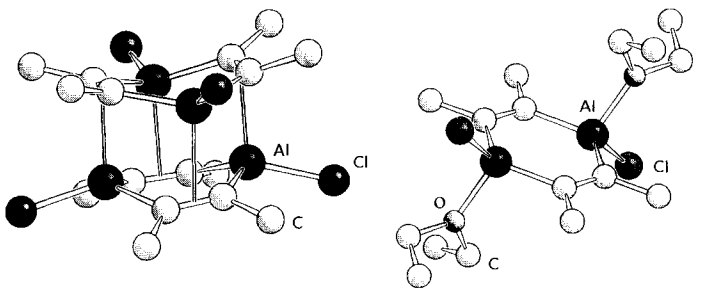

Fig. 6. Molecular structures of the 1,4-dialumina-2,5-cyclohexadienes **8** (left) and **9** (right) (H atoms not shown).

through bridging Cl atoms. The Al–C distances in the Al–olefin units are admittedly relatively long (ca. 235 pm), but all in all the four interactions lead to a remarkable stability of the dimer. The energy gained through each Al–olefin interaction is calculated to be about 25–40 kJ mol^{-1}.[83] As these quantum chemical investigations show, this value also contains small contributions from Al–Al interactions between the tetrahedrally arranged Al atoms. The high stability of the dimer is documented by the vaporization which occurs at about 140 °C without monomerization, and also by the occurrence of the molecular ion $[\mathbf{8}]^+$ in the EI mass spectrum.

If instead of butyne, hexyne is condensed with AlCl, the analogous ethyl-substituted compound is obtained. The structure of this corresponds essentially with that of **8**.[84] In addition to the particular structural characteristics of the dimer, its decomposition in solution to give hexamethylbenzene and hexaethylbenzene is worthy of mention.[45, 85] The mechanism of this decomposition is the subject of current investigation.

The Al–olefin bonds in **8** can be cleaved by ether, leading to the donor-stabilized dialuminahexadiene **9** (Fig. 6),[45, 85] in which the C=C bond is only slightly shorter: d(C=C) = 136.7 pm (**8**), 135 pm (**9**).[85, 86]

If instead of an alkyne, 2,3-dimethyl-1,3-butadiene is used as the organic component, in addition to polymeric products, the cyclic oligomer **10** is obtained [Eq. (6)], the structure of which is

$$6\ AlCl + 6\ H_2C{=}CMe{-}CMe{=}CH_2 \longrightarrow [Al_6\{\mu\text{-}Cl\}_6\{\mu\text{-}(H_2C{-}CMe{=}CMe{-}CH_2)\}_6] \quad (6)$$

10

shown in Figure 7.[87] The neighboring Al atoms of the central twelve-membered Al_6Cl_6 ring are bridged by butenediyl units, so that the coordination number four results for all Al atoms.

The reaction of AlF with bipyridine (bipy) was carried out under very similar conditions. Among others, a product was formed which could be detected by ESR spectroscopy and for which the formula $[FAl^{2+}(bipy^-)_2]_n$ was proposed.[88]

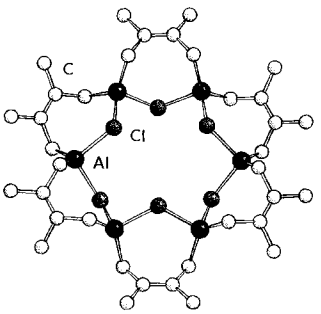

Fig. 7. Molecular structure of **10** in the crystal (H atoms not shown).

Corresponding reactions with GaX are not known to us. Although, GaI is assumed to be formed as an intermediate in the reaction of liquid Ga with I_2 in the presence of an alkyl iodide RI. The reaction is induced by ultrasound and leads to the formation of GaI_2R. In the absence of the alkyl iodide, a pale green product is formed that contains gallium and iodine in the ratio 1:1.[89]

In addition to the reactions introduced here in which Al^I and Ga^I species are oxidized to compounds of the trivalent elements, examples are also known in which the oxidation state I is retained. These metathesis reactions are treated in the following sections.

3. Organometallic Aluminum(I) and Gallium(I) Compounds

In the main, the synthesis of organometallic Al^I and Ga^I compounds has been achieved to date by two methods: a) by substitution of the halogen atoms of dissolved Al^I and Ga^I halides, and b) by reduction of a suitable Al^{III} or Ga^{III} precursor.[90] The former method has an advantage in that it can be carried out under very mild conditions, but also has a disadvantage in that

the preparation of the starting materials is coupled with considerable demands on the apparatus (see Section 2.3). The reductive method involves less demands on the apparatus, but higher temperatures are often required. Thus, this route is not frequently used to prepare temperature sensitive target compounds. In some cases readily accessible gallium dihalides (Ga_2X_4) can also be used in the preparation of Ga^I compounds; however, one equivalent of a Ga^{III} species is also formed. Corresponding reactions of donor-stabilized aluminum dihalides have not yet been investigated. Which of the methods of preparation is the most reasonable for a particular case has to be decided according to the target compound in question and the apparatus available.

3.1. Cyclopentadienyl Compounds of Monovalent Aluminum

Arenes with 6π electrons such as substituted cyclopentadienide anions are, as sterically demanding electron donors, very well suited for stabilizing metals in low oxidation states. For example, several years ago [$SiCp^*_2$] (Cp* = pentamethylcyclopentadienyl) became the first monomeric Si^{II} compound to be obtained which was stable at room temperature.[10] In the third main group of elements corresponding compounds of monovalent In and Tl are also known: [InCp] and [TlCp] were first prepared back in the 1950s.[91] Both of these compounds and their derivatives have been extensively studied and structurally characterized. The corresponding compounds of the lighter homologues were unknown until recently. In 1991 the first example of an Al^I compound stable under normal conditions,[92] namely $[Al_4Cp^*_4]$ (**11**),[93] was prepared from dissolved "AlCl" and $[MgCp^*_2]$ [Eq. (7)]. The compound **11** can be isolat-

$$4\ AlCl + 4\ [MgCp^*_2] \xrightarrow{\text{toluene/Et}_2O} [Al_4Cp^*_4] + 2\ [MgClCp^*(OEt_2)]_2 \quad (7)$$

11

ed in very high yields (85–90 %) in the form of yellow octahedral crystals. It sublimes at 140 °C and decomposes slowly as a solid at about 150 °C. Rather untypically for an Al compound, **11** crystallizes from the solvent mixture toluene/diethyl ether without additional donor molecules. The result of the X-ray crystal structure analysis is shown in Figure 8.

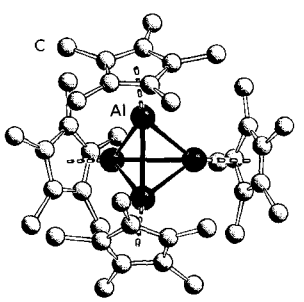

Fig. 8. Molecular structure of solid $[Al_4Cp^*_4]$ **11** (H atoms are not shown).

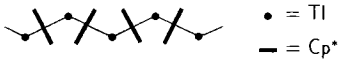
The most noticeable structural feature of the tetrameric compound is the central Al_4 tetrahedron, a structural element which finds its equivalent in boron chemistry, for example in B_4Cl_4 and B_4tBu_4. Apart from $K_2[Al_{12}iBu_{12}]$, which will be discussed in Section 3.3 in more detail, **11** is thus the only other polyhedral Al compound to date which has been characterized by diffraction methods.

The structure of **11** is not completely unexpected, because the solid structures of the corresponding In and Tl compounds indicate that in the case of the lighter elements of the third main group, decreasing ionic bonding contributions between the ligand and the metal, and stronger metal–metal interactions are to be expected. [TlCp*] thus forms a polymeric zigzag chain structure in the crystal, (Scheme 9) in which Tl atoms and Cp* rings alternate.[95]



Scheme 9. Schematic representation of the chain structure in solid [TlCp*].

The long and equidistant Tl–C distances (296 pm) to both the η^5-bonded Cp* rings suggest ionic bonding contributions. In contrast to this, the transition to a metal cluster structure is indicated in solid [InCp*], in which hexameric units are present containing an In_6 octahedron.[96] However, the In–In distances of about 395 pm herein are significantly longer than the shortest interatomic distances in In metal (325 pm) or in the diindane $[R_2In–InR_2]$ (R = $CH(SiMe_3)_2$) (282.8 pm)[68] and indicate very weak In–In interactions. In the nonpolar solvent cyclohexane the In_6 cluster dissociates fully into monomeric InCp* units.[96]

The Al–Al distance (276.9 pm) determined for **11** indicates immediately that the interactions between the Al atoms of the AlCp* units in **11** are stronger than those in Al metal, in which the distance is about 9 pm longer. Compared with the calculated bond lengths for other compounds with tetrahedral Al_4X_4 units (X = H, F, Cl; Table 3), however, the Al–Al distances are still relatively long.

Table 3. Calculated equilibrium distances d [pm] and tetramerization energies ΔE [kJ mol^{-1}] of selected Al_4X_4 compounds.

X	d(Al–Al)		ΔE		Ref.
	SCF	MP2	SCF	MP2	
H	261.7	258.3	−373	−569	[97, 98]
$SiiBu_3$	263.8	–	−430	−600 [a]	[99]
SiH_3	261.6	–	−397	−604	[99]
Cl	263.6	259.8	−185	−379	[97, 98]
F	264.0	260.5	−151	−322	[97, 98]
Cp	278.7	268.0	+27	−243	[97, 98]

[a] Estimated from the results found for X = SiH_3.

The ab initio calculation (MP2) for the model compound $[Al_4Cp_4]$ is quite consistent in delivering the rather small tetramerization energy of about −243 kJ mol^{-1}. In contrast, the tetramerization energy of −569 kJ mol^{-1} for a hypothetical Al_4H_4 molecule is very large.

What are the reasons for the relatively weak intermolecular interactions of the AlCp units? In a qualitative MO scheme[97, 99] (Fig. 9) it is possible to see how the framework orbitals of an Al_4X_4 molecule (T_d symmetry) are formed from the frontier orbitals of the monomeric species.[19] The orbitals of the lone pair of electrons (HOMOs) from four AlX molecules split on forming an Al_4X_4 molecule to give a strongly bonding a_1 orbital and three destabilized t_2 orbitals. The latter are further stabilized by interactions with the MOs formed from the p_π

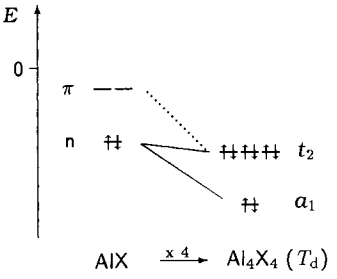


Fig. 9. Section of the qualitative MO diagram for the formation of the framework orbitals of an Al_4X_4 tetrahedron from the frontier orbitals of four AlX molecules [19,97,99].

orbitals of the AlX monomers, so that a bonding interaction results. The strength of the framework bonds in the tetrahedron depends decisively on the stabilization by the $t_2 - \pi$ interaction and thus on the energetic separation between the HOMO and LUMO (i.e. the more similar the energies of the frontier orbitals of the monomer, the more strongly the occupied t_2 orbital is stabilized).

The energies of the frontier orbitals of an AlX molecule are mainly influenced by two factors:[79] a) by the electronegativity of the ligand (high electronegativity on the part of X (e.g. X = F, Cl) leads to a higher positive charge density on the Al atom and thus to a decrease in the HOMO energy) and b) by the size of a possible delocalization of the electrons of filled ligand orbitals into the unoccupied p_π orbitals on the Al atom, which lead to a higher LUMO energy. In the case of [AlCp] the latter effect in particular leads to a large HOMO–LUMO separation and thus to a small tetramerization energy.

As similar bonding relationships are to be expected for [AlCp*], the question is posed as to whether **11** is tetrameric in solution or monomeric like [InCp*] and [TlCp*]. It was not possible to reliably determine the molar mass using cryoscopic methods to clarify this situation because of the poor solubility of **11**. The degree of association of dissolved **11** was finally determined by ^{27}Al NMR spectroscopy.[79] Figure 10 shows a

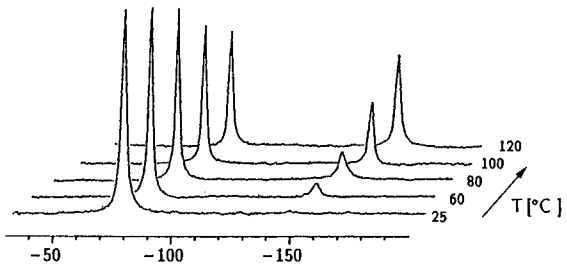

Fig. 10. ^{27}Al NMR spectra of $[Al_4Cp^*_4]$ in solution (C_7D_8).

series of ^{27}Al NMR spectra that were taken at various temperatures. Only one signal was detected at room temperature at $\delta = -80$ ($\omega_{1/2} = 140$ Hz). On raising the temperature a second resonance signal appears at $\delta = -150$ ($\omega_{1/2} = 180 \rightarrow 100$ Hz), the intensity of which increased with increasing temperature at the expense of the original signal. On subsequent cooling the original intensity ratios are restored. This process is thus in agreement with the equilibrium reaction given in Equation 8.

$$[Al_4Cp^*_4] \rightleftharpoons 4\,[AlCp^*] \qquad (8)$$

The assignment of the signals was made possible by calculating the signal positions using the GIAO method.[100] The theoretical shifts determined for the tetramer and monomer ($\delta = -85$ and -143, respectively) are in excellent agreement with the experimentally determined values. The tetramerization energy for [AlCp*] determined from the intensity ratios of the NMR signals is $-150(\pm 20)$ kJ mol^{-1}. As expected, this value is smaller than that calculated for [AlCp] (see Table 3), because repulsive interactions between the sterically more demanding Cp* ligands should additionally lower the tetramerization energy. The extremely effective shielding of the Al nuclei in **11** is mainly attributed to the influence of the Cp* ligands. First, the ring current induced in the π-electron system by the measurement takes effect and weakens the external magnetic field. Second, the η^5-Cp complexes of Al^{I} have large HOMO–LUMO separations due to the high degrees of π bonding between the ligand and aluminum, which then lead to high resonance field strengths due to the inverse proportionality of the chemical shift to the electronic excitation energy.[101, 102] As the extent of π bonding is lessened by the tetramerization in favor of the framework bonds, it is immediately apparent that a higher resonance field strength was found for the monomer than for the tetramer.

In view of the dissociation of **11** which was already detected in solution, it was to be expected that [AlCp*] does not exist in the tetrameric form in the gas phase. In spite of the low volatility and the limited thermal stability of the compound, it was possible to determine the structure of **11** in the gas phase by electron diffraction.[103] In analogy with the Cp* compounds of the heavier homologues, [AlCp*] exists in the gas phase in the monomeric [Al(η^5-Cp)] form with C_{5v} symmetry. The Al–C distance is 239 pm and is thus significantly longer than that in solid $[Al_4Cp^*_4]$ (233 pm). These values, having been determined by different methods of analysis, at different temperatures, and in different states of aggregation, are strictly speaking not comparable. The trend is unambiguous, however; the Al–C distance in the tetramer is shorter than in the monomer. The same change in distance also results from the ab initio (MP2) calculations for tetrameric and monomeric [AlCp] (d(Al–C) = 234.8 pm $[Al_4Cp_4]$; 236.3 pm [AlCp]).[98] An analysis of the molecular orbitals involved shows that these changes are due to a greater s character of the Al–C bond in the tetramer, or due to the dominant p character in the monomer.[79]

A second synthetic route to **11** was reported recently, according to which the compound is accessible by the reductive dehalogenation of $[AlCl_2Cp^*]_2$ [Eq. (9)].[104] This procedure places

$$2\,Al_2Cl_6 \xrightarrow[-4\,ClSiMe_3]{+4\,Cp^*SiMe_3} 2\,[AlCl_2Cp^*]_2 \xrightarrow[110°C]{+8K/-8KCl} [Al_4Cp^*_4]\ \mathbf{11} \qquad (9)$$

only minor demands on the apparatus required, but necessitates more synthetic steps than the first method of preparation. Because of the high thermal strain in the last reaction step the yield remains under 20 % and the target product is contaminated with small amounts of side products.[105] The reductive synthetic route is therefore hardly suitable for thermally less stable Al^{I} compounds.

What influence does the exchange of the methyl groups on the C_5 ring of **11** by other substituents have on the stability and on

the geometrical structure parameters of the cyclopentadienyl Al[I] compounds? Analogous to the preparation of [AlCp*], a yellow compound can be prepared from AlCl and [$MgCp_2$]—presumably oligomeric [AlCp] [Eq. (10)]. At about −60 °C the ex-

$$4\ AlCl + 4\ [MgCp_2] \xrightarrow{\text{toluene/}Et_2O} [Al_4Cp_4] + 2\ [MgClCp(OEt_2)]_2 \quad (10)$$

12

tremely thermolabile compound disproportionates within a few seconds and turns black due to the deposition of metallic aluminum.[79] It has not yet been possible to obtain single crystals of the "oligomer" and thus elucidate its structure by diffraction methods. It can be deduced from the ^{27}Al NMR spectrum obtained at −80 °C, however, that dissolved [AlCp]—like [AlCp*]—exists in the tetrameric form at this temperature.[79] The position of the ^{27}Al NMR signal measured ($\delta = -111$) agrees very well with the quantum chemical resonance calculated ($\delta = -105$) for tetrahedral [Al_4Cp_4] **12**. The full width at half maximum of the signal ($\omega_{1/2} = 1250$ Hz) is almost identical with that determined for the signal of [$Al_4Cp^*_4$] at this temperature. The stronger shielding of the Al nuclei in **12** in comparison to those in **11** is plausible, because the expected higher ionic bonding character between Al and the Cp ligand in the Cp compound leads to a larger HOMO–LUMO separation.

In an alternative synthetic strategy, attempts were made to synthesize **12** from **11**. With this aim in mind, Cp* ligands were to be substituted in a metal exchange reaction with [$MgCp_2$] [Eq. (11)]. As the rate of reaction was too slow even at 20 °C, the

$$[AlCp^*] + [MgCp_2] \longrightarrow [AlCp] + [MgCp^*Cp] \quad (11)$$

thermolabile **12** could not be prepared by this method. Nevertheless, a new yellow product was formed in the reaction mixture which was shown to be [$Al_4(\eta^5\text{-}Cp^*)_3(\eta^5\text{-}Cp)$] **13**,[94] by NMR spectroscopic analysis; thus one AlCp* unit of [$Al_4Cp^*_4$] was replaced by an AlCp fragment. The ^{27}Al NMR spectrum shows two signals in the ratio 3:1. The ^{27}Al NMR resonances for the AlCp* and AlCp partial structures are shifted slightly downfield compared with those for **11** and **12** ($\delta = -77$ and -108, respectively; $\omega_{1/2}$ 300 Hz in both cases).[106]

These experiments show that the substitution of the Cp* ring on [AlCp*] is possible in principle. For this reason [$Al_4Cp^*_4$] was treated analogously with pentabenzylcyclopentadienyllithium and tris(trimethylsilyl)cyclopentadienyllithium. The substitutions take place only slowly at room temperature, but they do go to completion and without disproportionation worthy of mention; however, reaction products [$Al\{C_5(CH_2Ph)_5\}$] (**14**) and [$Al\{C_5H_2(SiMe_3)_3\}$] (**15**) have not yet been isolated in crystalline form. According to the ^{27}Al NMR spectra, both compounds exist in the monomeric form in solution (δ(**14**) $= -155$ (1500 Hz); δ(**15**) $= -165$ (450 Hz)).[94] The isolation of these and other species is the subject of current investigations.

3.2. π Complexes of Monovalent Gallium

The π complexes of Ga^+ have been known for quite some time. Solutions of the mixed-valent gallium dihalides $Ga^+[GaCl_4]^-$ in aromatic solvents contain Ga[I] arene complexes,[107] which can be identified by Ga NMR spectroscopic techniques. The structural element of the 6π-electron arene coordinated η^6 to Ga^+ is also retained in the solid.[9] It is surprising, therefore, that Cp complexes of monovalent Ga were unknown until recently, although the gallium dihalides have long been available as starting materials, in which Ga occurs—at least partially—in the "correct" oxidation state.

The synthesis and identification of [GaCp] (**16**) was first achieved about 35 years after the characterization of [InCp]; its synthesis involves the treatment of dissolved "GaCl" with [$MgCp_2$] or [LiCp] under salt elimination [Eq. (12)]. Mass spec-

$$GaCl + [MCp] \xrightarrow{\text{toluene/}Et_2O} [GaCp] + MCl \quad (12)$$

(M = Li, CpMg) **16**

trometric and NMR techniques reveal that **16** exists in the monomeric form both in the gas phase and in solution. Ab initio calculations (MP2) on the structure and the ^{71}Ga NMR resonance were especially helpful in this respect.[108] According to these—and in analogy to [InCp] and [TlCp]—a C_{5v} symmetric structure with an η^5-coordinated Cp ring represents the minimum of the energy hypersurface for [GaCp] in the gas phase. The ^{71}Ga NMR shift calculated for this molecule is $\delta = -696$. The strong shielding of the metal nucleus seems reasonable in light of the behavior discussed for the Al compounds. In very good agreement with the calculated value, a signal is detected experimentally at $\delta = -714$ ($\omega_{1/2} = 250$ Hz), which indicates that the [Ga(η^5-Cp)] structure can be inferred in solution too.

The unexpectedly high volatility of **16** is quite remarkable. When dissolved in toluene/Et_2O, [GaCp] can be identified by mass spectroscopy in the gas phase using a feed cooled to −78 °C. There are problems associated with this property in trying to isolate pure [GaCp]. It is very easy to separate the product together with the solvent from the other reaction products,[109] but the preparation of solvent-free **16** has not yet been successful. The isolation is made additionally more difficult in that **16** is only stable in dilute form at room temperature and already starts to disproportionate at −70 °C at concentrations greater than 0.2 mol L^{-1}.[51] Small amounts of solid colorless [GaCp] can be precipitated by lowering the solubility through the addition of pentane. Compound **16** is more thermally stable and considerably less volatile as a solid than in solution. An exact determination of the decomposition temperature and the vapor pressure could not yet be carried out due to the problem of isolation.

In analogy with **16**, a series of further ring-substituted cyclopentadienyl compounds of Ga[I] have been prepared.[110] Ga_2Cl_4 can be used as an alternative to "GaCl", but in this case additional products of trivalent Ga are formed that make it more difficult to separate the target compounds. All in all, the isolation of the substituted compounds is considerably easier than that of the parent compound **16** thanks to greater thermal

stability and lower volatility. [GaCp*] (**17**) for example, can be isolated free from solvent by fractional distillation.[110] The ^{71}Ga NMR resonance of **17** appears at $\delta = -653$ ($\omega_{1/2} = 700$ Hz), and compared with that of **16**, it is only slightly shifted downfield. This tends to indicate that **17** also exists in the monomeric [Ga(η^5-Cp)] form in solution. Neither increases nor decreases in the temperature lead to changes in the ^{71}Ga NMR resonances of **16** or **17**, which indicates that neither compound is involved in association equilibria. An oligomerization involving the lone pair of electrons on gallium would thus appear to be less favorable than in the case of the analogous Al compounds, which seems reasonable in view of the larger inert pair effect expected for gallium.

The structure of [GaCp*] in the gas phase was determined by electron diffraction experiments (Fig. 11).[111] [GaCp*] has a pentagonal pyramidal structure with an η^5-coordinated C_5 ring. The Ga–C distance of 240.5 pm, is somewhat shorter than that calculated for **16** (242.0 pm). It is interesting to compare the gaseous molecules [AlCp*] and **17**. The Ga–C distance in **17** is about 0.7% (1.7 pm) longer than the Al–C bond in monomeric [AlCp*]. If the bond lengths of the gaseous compounds GaH, GaCl, and GaF are compared with those of the corresponding Al compounds,[16] it can be seen that here too, the Ga–X bonds are longer. Whereas this difference for the relatively nonpolar hydrides approximately corresponds with that of the Cp* compounds (0.6%), in the case of the polar halides the difference is considerably larger (Cl: 3.3%; F: 7.3%). The nonpolar character of the compounds **11** and **17** already deduced from their physical properties is thus also reflected in their bond lengths.

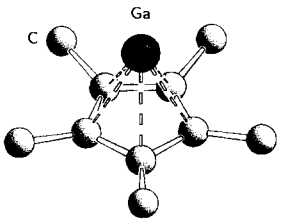

Fig. 11. Molecular structure of [GaCp*] **17** in the gas phase (H atoms not shown).

In addition to [GaCp] and [GaCp*], it was also possible to prepare [Ga(C_5H_4tBu)], [Ga{C_5(CH_2Ph)$_5$}], and [Ga{C_5H_2-($SiMe_3$)$_3$}].[110] According to the spectroscopic data, all of these compounds have, like [GaCp*], a half-sandwich structure and exist in the monomeric form in aromatic solvents. The question as to how the GaCp derivatives are constructed in the solid remains unclear. Do they—like the Al compounds—prefer polyhedral structures, or—like the heavier homologues—polymeric structures with weaker intermolecular interactions? The properties of the dissolved species (e.g. solubility, NMR shifts) would seem to indicate the latter.

3.3. Alkyl and Silyl Compounds of Al^I and Ga^I

As already suggested (see Table 3), alkyl and silyl compounds of Al and Ga should tend to oligomerize to a considerably greater extent than the Cp complexes in which the monomeric units are stabilized by π bonds between the ligand and the metal atom. Prerequisites for the synthesis of AlR and GaR compounds with R = alkyl and silyl are that the ligands R are bulky and kinetically stabilizing and as such prevent the thermodynamically preferred disproportionation from taking place.

Compounds of this type have long been known in boron chemistry.[112] B_4tBu$_4$ recently became the first example of just such an electron-deficient compound to be characterized by X-ray structure analysis.[113] In the meantime, similar species for Al, Ga, and In are also known: the first concrete spectroscopic indications came in 1991. Like [$Al_4Cp^*_4$] (**11**), [Al_4(SitBu$_3$)$_4$] (**18**) can be synthesized by metathesis, in this case by reacting "AlCl" with NaSitBu$_3$ in dibutyl ether.[114] The thermally very stable compound **18** can be separated from the other reaction products by sublimation at 180 °C [115] and characterized as tetrameric [Al(SitBu$_3$)] by mass spectrometry. Unfortunately it has not yet been possible to obtain a solid suitable for X-ray structure analysis. However, quantum chemical calculations (SCF) confirm the tetrahedral structure of **18** (Fig. 12).[99] Compound **18** is characterized by a relatively high tetramerization energy which is a result of the small HOMO–LUMO separation both in the monomeric and in the tetrameric species. Its value corresponds approximately with that of Al_4H_4 and [Al_4(SiH_3)$_4$] and is considerably larger than that of the Cp compounds **11** and [AlCp] (**12**) (see Table 3). In a comparison of **18** with **11** and **12**, this is noticeable not only in the significantly shorter Al–Al bond (263.8 pm in **18**, compared with 276.9 pm in **11** and 278.7 pm (SCF) in **12**), but also in the color: the Cp compounds are yellow, whereas the smaller frontier orbital separation in **18** leads to a blue-violet color. The Al–Al bond in **18** is only insignificantly longer than those calculated in the same manner for Al_4H_4 and [Al_4(SiH_3)$_4$], and it is assumed, therefore, that there are no steric strains of great significance due to interactions between the ligands.

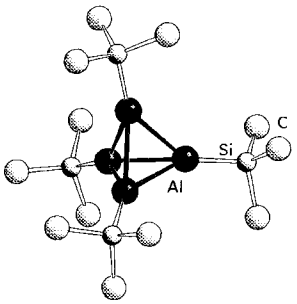

Fig. 12. Calculated structure for [Al_4(SitBu$_3$)$_4$] **18** (Me groups not shown).

A further Al^I compound is accessible by the reduction of di(neopentyl)aluminum chloride with K [Eq. (13)].[116] The results of the molecular mass determination indicates that the compound is the tetrameric [Al_4{$CH_2C(CH_3)_3$}$_4$] **19**. The sluggishness of **19** in entering into reactions leads to the assumption that it has a tetrahedral structure, because in this case the reactive Al_4 core is well shielded by a hydrocarbon shell.

$$2\ AlCl[CH_2C(CH_3)_3]_2 + 8\ K \xrightarrow{-2KCl} 1/4\ [Al_4\{CH_2C(CH_3)_3\}_4] + Al[CH_2C(CH_3)_3]_3 \quad (13)$$

19

As yet there have been no reports of an Al_4R_4 compound with alkyl or silyl ligands that has been characterized by diffraction methods. In contrast, the preparation and characterization of compounds of this type in gallium chemistry has been more successful. Red [Ga_4{$C(SiMe_3)_3$}$_4$] (**20**) was synthesized from the dioxane adduct of Ga_2Br_4 and Li[$C(SiMe_3)_3$] and was the first example found belonging to this class of compounds [Eq. (14)].[117]

$$[Ga_2Br_4(O_2C_4H_8)_2] + 3\ Li[C(SiMe_3)_3] \xrightarrow{-3\,LiBr}$$
$$1/4\ [Ga_4\{C(SiMe_3)_3\}_4] + \text{"}GaBr[C(SiMe_3)_3]_2\text{"} \quad (14)$$
$$\mathbf{20}$$

The structure of this surprisingly stable compound (decomposition > 255 °C) comprises a central tetragallatetrahedrane framework. It corresponds to the structure of **18** shown in Figure 12 when the Al atoms are replaced by Ga atoms and the *t*Bu$_3$Si ligands are replaced by (Me$_3$Si)$_3$C (trisyl) groups. The most interesting structural parameter is almost certainly the Ga–Ga distance of 268.8 pm, which is about 15 pm longer than that in the digallane [R$_2$Ga–GaR$_2$] (R = CH(SiMe$_3$)$_2$).[68] The long Ga–Ga distances are probably due to the repulsive interactions between the bulky trisyl ligands. The relatively facile dissociation of the tetrahedron also tends to indicate that the bonds between the Ga atoms are to be classified as weak. Cryoscopic studies in benzene show an increasing degree of dissociation with increasing dilution. At a concentration of 0.0014 mol L^{-1}, **20** is fully dissociated into monomeric units. In the gas phase too, only monomeric [GaC(SiMe$_3$)$_3$] is observed. The molecular structure of this gallanediyl was determined by electron diffraction experiments.[118]

The dark violet compound [Ga$_4${Si(SiMe$_3$)$_3$}$_4$] **21**, a compound related to **20**, can be prepared from [Ga$_2$Cl$_4$(O$_2$C$_4$H$_8$)$_2$] and Li[Si(SiMe$_3$)$_3$]·3THF.[119] The X-ray structure analysis of **21** shows that the exchange of the tertiary C atoms by Si atoms has a drastic effect on the size of the central Ga$_4$ tetrahedron. The Ga–Si bonds are longer than the Ga–C bonds and lead to considerably longer distances between the ligands, thus allowing the Ga atoms to approach each other to within 259.1 pm. This distance is only slightly longer than the Ga–Ga bond lengths calculated by quantum chemical methods (MP2) for simple tetragallatetrahedranes Ga$_4$X$_4$ (X = H (253 pm), Cl (257 pm), F (259 pm)).[98] Compound **21** should thus be relatively free of steric strain.

Although the tendency to form homonuclear bonds decreases with increasing atomic number in the Group 13 elements, the In compound analogous to **20**, [In$_4${C(SiMe$_3$)$_3$}$_4$] (**22**), also has a tetrahedrane structure in the solid state. The difference to the analogous Ga compound is that the tetrameric structure is retained even in solution. This observation is reasonable, since lower steric strain is to be expected between the substituents of **22** due to the larger M$_4$ tetrahedron. The red-violet compound **22** can be synthesized starting from In$_2$Br$_4$·2tmeda [2, 120] or from InCl on treatment with Li[C(SiMe$_3$)$_3$].[121] The average In–In bond length is 300 pm.[120] This is thus considerably shorter than that in the octahedral "cluster" [In$_6$Cp$^*_6$] (395 pm).[96] A more sensible value for making a comparison is the bond length in the diindane [R$_2$In–InR$_2$] (R = CH(SiMe$_3$)$_2$),[68] which is approximately 20 pm (about 7%) shorter than that in the tetrahedral compound **22**.

If the dimetallic compounds [R$_2$Ga–GaR$_2$] and [R$_2$Al–AlR$_2$] are compared in an analogous manner with the "strain free" tetrahedranes **18** and **21**, the metal–metal bonds in the M$_4$ frameworks are only 2.5% longer for gallium, and in the case of aluminum even about 2.5% shorter, than in the corresponding dimetallic compounds. This finding further reflects the lower tendency of the MR monomers of the heavier elements to tetramerize.

The compounds described in this section up till now give the impression that tetrameric M$_n$R$_n$ compounds are formed preferentially. This collection of tetrahedral oligomers may be due in the first instance to the fact that to date mainly those compounds with very bulky ligands have been studied. The tetrahedron, that is the smallest polyhedron, provides the greatest possible amount of space for the ligands and thus permits the metal atoms to approach one another most closely. In the case of smaller substituents, whose lesser spatial demands would permit the formation of larger polyhedra, it would be expected that the kinetic stabilization would become too small, and that the disproportionation of the compound would come to the fore.

In addition to these steric constraints, the electronic influences should also be of importance for the formation of a particular oligomer. According to Wade's rules,[122] *closo*-polyhedra attain their greatest stability when they have $n + 1$ electron pairs for the framework (n = number of corners on the polyhedron), that is when they are dianions. A large number of compounds are known from boron chemistry and from other fields of chemistry of the main group elements which adhere to this rule. To our knowledge, however, doubly reduced tetrameric M$_4$R$_4$ species of the Group 13 elements are not known. This finding can be explained by use of the MO diagram for tetrahedral MR compounds (Fig. 9). This shows that the four electron pairs from the HOMOs of the monomers already lead to a closed shell occupancy in the tetramer ($a_1 + t_2$).[99] The singly reduced radical anions [B$_4$*t*Bu$_4$]$^{\bullet -}$,[123] [Ga$_4${C(SiMe$_3$)$_3$}$_4$]$^{\bullet -}$,[124] and [In$_4${C(SiMe$_3$)$_3$}$_4$]$^{\bullet -}$ [124] can be identified, but little is known about their structures, for which Jahn–Teller distortion is expected. In the case of [B$_4$*t*Bu$_4$]$^{\bullet -}$, ESR spectroscopic studies lead to the conclusion that this has a butterfly structure.[123] In conclusion, small ligands and reductive reaction conditions that are as mild as possible should be advantageous for the synthesis of large polyhedra.

Polyhedral structural elements have long been known in the field of intermetallic phases—including for the heavy Group 13 elements. At this point only one example of this rather extensive and fascinating field will be mentioned. In Na$_x$Mg$_{5-x}$Ga$_9$ a three-dimensional Ga network is found which contains a Ga$_{12}$ icosahedron; this network is the result of partial reduction of Ga.[125] These structural elements can be treated using Wade's rules in the same way as for dianions of a *closo*-polyhedron, such as [B$_{12}$H$_{12}$]$^{2-}$, when performing an electron count. The role of the ligands is assumed by other atoms of the Ga network. The Ga–Ga distance in the slightly distorted Ga$_{12}^{2-}$ units lies between 269 and 273 pm.

Confirmation of an Al$_{12}$ icosahedron in a molecular compound was a long time in coming. Admittedly, back in 1976 a highly reduced polymeric Al compound was identified in the distillation residue in the reaction of diisobutylaluminum chloride with potassium,[126] but the elucidation of the course of the reaction and the characterization of the products was first achieved in 1991.[127] Dark red K$_2$[Al$_{12}$*i*Bu$_{12}$] (**23**) is made in small but reproducible yields [Eq. (15)]. The X-ray structure

$$AliBu_2Cl + K \xrightarrow[25°C]{hexane}$$
$$K_2[Al_{12}iBu_{12}] + K[AliBu_2Cl_2] + K[AliBuCl_3] \quad (15)$$
$$\mathbf{23}$$

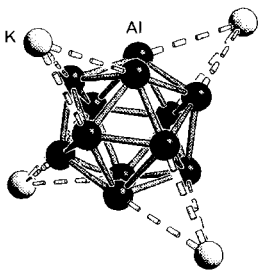

Fig. 13. Depiction of the Al_{12} unit and the surrounding K atoms in $K_2[Al_{12}iBu_{12}]$ **23** (*i*Bu groups not shown).

analysis of **23** confirms the presence of an almost undistorted icosahedral Al_{12} unit (Fig. 13). The Al–Al distance of 268.5 pm is somewhat longer than that in the neutral tetrameric Al_4R_4 (R = H, $SiMe_3$, $SitBu_3$, see Table 3). Compound **23** is rather unstable in solution, but in the solid state it first decomposes above about 150 °C. The redox behavior of the Al_{12} cluster is interesting. As in the case of similar boron compounds, cyclovoltammetric studies show a reversible single-electron oxidation and an irreversible second oxidation step.[2]

The second anionic Al cluster known to date is also formed under reductive conditions. A dark red compound of high thermal stability is formed from AlCl and Li*t*Bu; presumably Al_ntBu_n [Eq. (16)]. If the substance is reduced at 4 °C with Na/K alloy, a compound containing the radical anion $[Al_6tBu_6]^{\bullet -}$ **24** is formed, which has been identified by ESR spectroscopy, but unfortunately not yet been isolated.[128]

$$AlCl + LitBu \xrightarrow{-LiCl} Al_ntBu_n \xrightarrow{Na/K} \underset{\mathbf{24}}{[Al_6tBu_6]^{\bullet -}} \qquad (16)$$

According to SCF calculations, a distorted octahedral structure (D_{3d} symmetry, squashed along the three-fold axis) is expected for the radical anion, with six magnetically equivalent Al atoms (Fig. 14).[129] The singly occupied MO is localized to about 99% on the Al cluster, so that a coupling of the unpaired electron with the Al nuclei can occur, but a coupling with the alkyl groups should not be possible. The hyperfine structure of the ESR spectra obtained from solutions (31 lines) and the small hyperfine coupling constant ($a(^{27}Al) = 8.2$ G) are in agreement with the structure suggested by quantum chemical calculations. According to this, the Al–Al distances are 261.7 and 275.2 pm for the energetically most favorable conformation. Compared with six monomeric Al*t*Bu molecules, the neutral hexamer is already about 540 kJ mol^{-1} more stable on the SCF level.[130] The reduction to the monoanion stabilizes the entity by a further 140 kJ mol^{-1}. Electrochemical studies on this system, for example, the reduction to the dianion, have not yet been carried out.

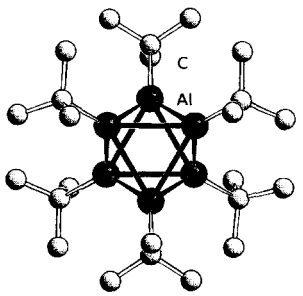

Fig. 14. Calculated structure of the radical anion $[Al_6tBu_6]^{\bullet -}$ **24** (H atoms not shown).

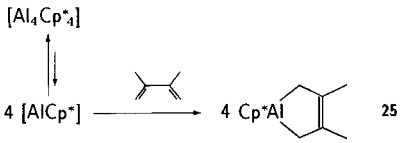
In conclusion, it remains to be mentioned that a mixture of different oligomers of neopentylgallium(I) are accessible by the reduction of di(neopentyl)gallium chloride. The average degree of association of these lies between 8.9 and 10.5.[131]

4. Chemical Properties of $[Al_4Cp^*_4]$

As already mentioned in Section 3, $[Al_4Cp^*_4]$ (**11**) differs from most of the compounds described therein with regard to its tendency to readily dissociate into monomers. This behavior should have an effect on the chemical properties of the compound, because it is to be expected that monomeric alanediyls, like the analogous boranediyls (borylenes),[132] are very reactive. However, the reactivity of [AlCp*] should be lowered by the good donor properties of the Cp* ligands. The previously studied reactions of **11** in solution confirm that indeed a "tamed", but as a result in most cases a very selective alanediyl is present. Compound **11** thus reacts quantitatively with 2,3-dimethyl-1,3-butadiene in toluene at 50 °C [Eq. (17)].[133]



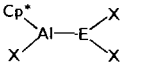
25 (17)

In the solid state **11** is even relatively inert with respect to air, since the aluminum atoms in the tetrameric unit are well shielded by the ligands. Compound **11** is even stable for prolonged periods in water and other polar solvents in which it does not dissolve. In water the surfaces of the crystals are first attacked after about 20 minutes. On the other hand, when in solution, **11** is readily oxidized by air. If a saturated solution of **11** in benzene is brought into contact with air the compound decomposes completely after just 20 minutes.

Rather unexpectedly, solutions of **11** are thermally stable. A solution of **11** in toluene disproportionates fully only after about 20 days at 100 °C, forming Al metal, a considerable amount of pentamethylcyclopentadiene (Cp*H), and an Al^{III} compound.[134] According to the results of spectroscopic studies this is not $AlCp^*_3$, but rather a product arising from this by the elimination of Cp*H.[135]

4.1. Reactions with Lewis Acids

[AlCp*] could function as a base which forms adducts with Lewis acids such as aluminum trihalides or boron trihalides. This type of behavior is known for [InCp], which reacts for example with BF_3 to give the donor–acceptor complex $[CpIn \rightarrow BF_3]$.[136] Furthermore, an insertion into element–halogen bonds is feasible by which, for example, species such as the type represented by **26** could arise.



26 (E = B, Al)

In the presence of $AlCl_3$, solutions of **11** in toluene start to disproportionate slowly at 25 °C. If the reaction solution is left at room temperature, Al metal and the aluminum sesquichloride $[Al_2Cl_3Cp^*_3]$ are obtained as the main products. The course of this reaction could be the result of an insertion of [AlCp*] into an Al–Cl bond, by which thermolabile Al subhalides of the type represented by **26** are formed. Their disproportionation would subsequently lead to the products observed.

However, intermediate products of this reaction have not yet been identified.

If this reaction is carried out at higher temperatures, a colorless compound is formed that is extremely sensitive with respect to hydrolysis [Eq. (18)]. The results of the X-ray structure analysis show the compound to be $[AlCp^*_2][AlCl_3Cp^*]$; an ionic isomer of $[Al_2Cl_3Cp^*_3]$.[137]

$$3\,[AlCp^*] + AlCl_3 \xrightarrow[-2\,Al]{\text{toluene/25°C}} [Al_2Cl_3Cp^*_3] \xrightarrow{\Delta} [AlCp^*_2][AlCl_3Cp^*] \quad (18)$$

The $[Al(\eta^5\text{-}Cp^*)_2]^+$ ion **27** of this compound (Fig. 15) is the first ferrocene analogue of a Group 13 element. Since $[BCp^*_2]^+$[138] and $[BeCp_2]$[139] each have just one η^5-coordinated Cp* or Cp ligand, **27** is possibly the smallest metallocene of any main group element.[140] The Al–C bond length is 215.5 pm. Decamethylmagnesocene is isoelectronic with **27**, but due to the smaller positive charge on the central atom it has considerably longer metal–C distances (234.8 pm).[141] The same is also valid for the bis(η^5-dicarbollide)aluminum anion $[Al(\eta^5\text{-}C_2B_9H_{11})_2]^-$ (d(Al–C) = 224–230 pm),[142] which is closely related to **27** from a structural point of view; however, the bonding situation is not exactly comparable with that in **27** (see below). The extremely high ^{27}Al NMR resonance field strength of the cation **27** at $\delta = -114.5$ is quite remarkable and completely untypical for diamagnetic Al^{III} compounds. The calculated ^{27}Al NMR shift (GIAO) for $[Al(\eta^5\text{-}Cp^*)_2]^+$ in D_{5d} symmetry is $\delta = -119.8$ and thus confirms that this structure is also retained in solution.[137] The strong shielding of the Al nuclei, as is the case in the π complexes of Ga^I and Al^I, is mainly attributed to the effect of the ring current. Interestingly, a considerably smaller resonance field strength ($\delta = +54$) is calculated for the Al atom in the bis(η^5-dicarbollide)aluminum anion, which is also surrounded in a sandwich fashion.[143] According to this finding, diamagnetic ring current effects have virtually no effect, that is the bonding differs from that in **27** although according to the usual bonding considerations Cp and dicarbollide ligands should behave similarly.[144, 145]

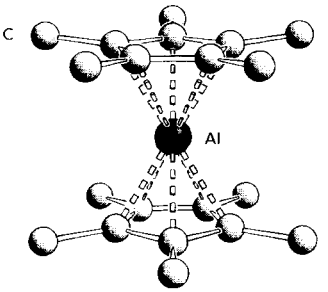


Fig. 15. Structure of the $[Al(\eta^5\text{-}Cp^*)_2]^+$ ion **27** in the crystal (H atoms not shown).

The possibility of insertion of [AlCp*] into element–halogen bonds mentioned at the beginning of this section was reason enough for us to also treat **11** with boron trihalides. In contrast to the reaction of **11** with $AlCl_3$, no Al deposition is observed. In the reactions that we studied no uniform products were obtained, as was the case in reactions of the carbene homologue $[SiCp^*_2]$ with boron trihalides for example.[146] Even at −78 °C, the reaction with BCl_3 in toluene rapidly led to a complicated mixture of products. According to the findings of NMR spectroscopic studies, the carbon framework of the Cp* ligand is also attacked.[147]

Boron tribromide reacts somewhat more selectively. In this case the reaction in toluene first gets underway at higher temperatures and leads to presumably three main products. About 30% of the aluminum used is found in the form of the ionic compound $[BBrCp^*][AlBr_4]$ (**28**), which was identified by its characteristic NMR spectra and by crystal structure analysis. The cation of this compound was already prepared by Jutzi et al. in 1977 in the form of $[BBrCp^*][BBr_4]$ and characterized by NMR spectroscopy in solution as a *nido*-carborane having a pentagonal pyramidal structure.[148] The X-ray structure analysis recently carried out on **28** confirms that this structure type also exists in the solid (Fig. 16). The CH_3 substituents of the Cp* ring are slightly bent towards the boron atom—in agreement with a theoretical prediction.[149, 150] Since both Al and B have the oxidation state III in this compound, but at the same time no aluminum is formed by disproportionation, **28** can be considered as indirect evidence for the (intermediate) occurrence of subvalent boron species. The direct characterization of these intermediates or their consecutive products has still to be made.

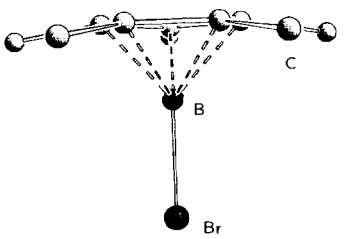

Fig. 16. Structure of the $[BBrCp^*]^+$ ion of **28** in the crystal (H atoms not shown).

The reduction of a suitable B^{III} precursor to make [BCp*] is particularly appealing, and according to the results shown here should also be feasible. This is the last missing member in the series of MCp* compounds (M = B, Al, ... Tl).

[AlCp*] first reacts with the weaker Lewis acid SiF_2Ph_2 at higher temperatures (ca. 110 °C) [Eq. (19)]. It is apparent that in

$$4\,[AlCp^*] + 2\,SiF_2Ph_2 \xrightarrow[3\,d]{\text{toluene/110°C}} [\{Si(AlCp^*F)_2Ph_2\}_2] \quad (19)$$

29

order to cleave the strong Si–F bonds a considerably high activation energy is required. In spite of this $[\{Si(AlCp^*F)_2Ph_2\}_2]$ (**29**) is formed in good yields (88 %) (Fig. 17).[151] Compound **29** can be considered as a dimer of an insertion product of [AlCp*] into the Si–F bonds of SiF_2Ph_2. The Cp* ligands are aprroximately η^2-coordinated. The Al–Si bond length (245.1 pm) corresponds well with the value found for $[Si\{AlCl_2(OEt_2)\}_4]$ (**7**) (see Section 2.3).

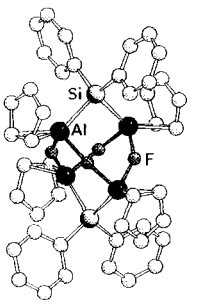

Fig. 17. Structure of $[\{Si(AlCp^*F)_2Ph_2\}_2]$ **29** in the crystal (H atoms not shown).

4.2. Reactions with Elements of the Fifth and Sixth Main Groups

Compound **11** can be oxidized with the elements P, Se, and Te to give interesting products in very good yields. If **11** is treated with white phosphorus in toluene at 25 °C, the unusual cage com-

pound $[(Cp^*Al)_6P_4]$ **30** [Eq. (20); Fig. 18] is obtained in just one synthetic step.[153] Six Al and four P atoms form an Al_6P_4 cage

$$6\ [AlCp^*] + P_4 \xrightarrow[25°C]{\text{toluene}} [(Cp^*Al)_6P_4]\quad \mathbf{30} \qquad (20)$$

with alternating occupancies. This cage can be described as consisting of two face-sharing heterocubanes, the opposite corners of which are missing (Scheme 10). The unexpected bonding in this compound is particularly remarkable. For the formation of two-electron–two-center bonds for the fourteen Al–P contacts in the framework, 28 electrons would be necessary. As can be shown by quantum chemical methods, however, one lone pair of electrons can be attributed to each P atom. As these lone pairs are not delocalized over the cage, only 24 electrons are available for the framework bonds (two from each AlCp* fragment and three from each P atom). Thus, **30** must be regarded as an electron-deficient compound in which 14 bonds are formed by 12 occupied MOs.

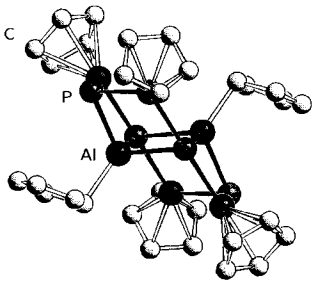

Fig. 18. Molecular structure of $[(Cp^*Al)_6P_4]$ **30** in the solid state (Me groups not shown).

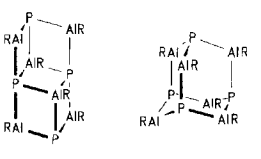
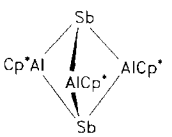
The insertion of one AlCp* unit into each of the six P–P bonds of the P_4 tetrahedron is a feasible mechanism for the formation of **30**. Initially a heteroadamantane (**31**) would be formed, built up from Al and P, which would then rearrange to give the isomer **30**. Quantum chemical studies on the model compound $[(CpAl)_6P_4]$ confirm that isomer **30** is about 30–80 kJ mol^{-1} more stable than isomer **31**. The stabilization is attributed to additional Al–P contacts as well as to significant Al–Al bonding contributions. The structure determined for **30** (Fig. 18) represents a new structural variation of M_6E_4 compounds, in which an additional possibility of stabilization exists due to an electron deficiency.



Scheme 10. Schematic representation of the cage compounds **30** and **31**; R = Cp*.

The structures of compounds with other element combinations from the Groups 13 (M) and 15 (E) of the Periodic Table would therefore also be very interesting. A M_3E_2 compound results from the reaction of [AlCp*] with $[Sb_4tBu_4]$ under elimination of the *t*Bu groups. Unfortunately the structure of the product could not be clarified unequivocally. The structure shown in Scheme 11 has been proposed, although it has not been possible to make an exact statement on the Al–Sb and Al–Al interactions as yet.[151] An analogous M_3E_2 framework exists in the compound $[(iPr_2NB)_3P_2]$.[152]



Scheme 11. Propose d structure for $[(Cp^*Al)_3Sb_2]$.

Heterocubanes are formed in high yields by the oxidation of [AlCp*] with Se and Te, in which both the Al atoms and the chalcogen atoms are able to realize their preferred oxidation states and coordination numbers [Eq. (21); Fig. 19].[104]

$$4\ [AlCp^*] + 4\ E \xrightarrow[25°C]{\text{toluene}} [(Cp^*Al)_4E_4] \qquad (21)$$
$$(E = Se\ (\mathbf{32}),\ Te\ (\mathbf{33}))$$

The Cp* ligands on both compounds are η^5-coordinated to the Al atoms; the Al–C bond lengths (as is also the case for the η^5-coordinated Cp* rings in **30**) are about 4–6 pm shorter than those in tetrameric [AlCp*]. The Ga compound analogous to **33** is accessible by silyl halide elimination from $[GaCl_2Cp^*]$ and $Te(SiMe_3)_2$.[154] Unlike in **33**, the Cp* ligands of the Ga–Te heterocubane are η^1-coordinated to the Ga atoms. This finding may be attributed to the lower Lewis acidity of the Ga atoms, and it clearly shows quite impressively the ability of the Cp* ligand to adjust itself to the electronic needs of the particular metal in question.

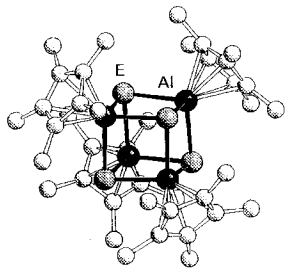


Fig. 19. Molecular structure of the isostructural compounds **32** and **33** (H atoms not shown).

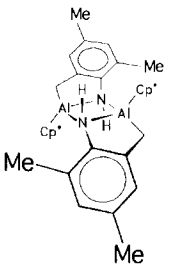
4.3. Reactions with Azides

Because of the isolobal relationship between atoms of the sixth main group and nitrenes (NR), it is not surprising that RAlE (E = chalcogen) and RAlNR′ oligomers have very similar structures. Analogous to the chalcogen compounds described in the previous section, the iminoalanes $(RAlNR')_n$ usually form three-dimensional cross-linked oligomers in which the Al and N atoms are arranged in an alternating fashion and are four-coordinate.[155] Only with very sterically demanding groups does it become possible to stabilize oligomers with $n<4$ and three-coordinate Al centers.[156] The oxidation of [AlCp*] with bulky azides ought, therefore, to be a promising synthetic route for this type of compound.

In the reaction of [AlCp*] with mesitylazide, however, the dimeric aminoalane $[Cp^*Al\{\mu\text{-}NH(C_6H_2\text{-}4,6\text{-}Me_2\text{-}2\text{-}CH_2)\}]_2$ **34** [Eq. (22)] is formed under N_2 elimination instead of an

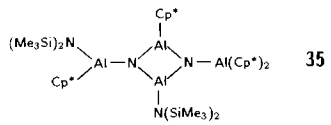
$$2\ [AlCp^*] + MesN_3 \xrightarrow[-N_2]{\text{toluene / 40°C}} \mathbf{34} \qquad (22)$$



iminoalane.[157] As in an analogous B-N system,[158] the Al atoms here extend their sphere of coordination by the activation of one of the C–H bonds on the mesityl ligand.

If trimethylsilylazide is used instead of mesitylazide, the dimeric iminoalane **35** is obtained in 34% yield, as a result of the unexpected migration of silyl and Cp* groups [Eq. (23)].[157]

$$4\,[AlCp^*] + 4\,Me_3SiN_3 \xrightarrow[-4\,N_2]{\text{toluene / 70°C}} \mathbf{35} \qquad (23)$$



In spite of the fact that all of the Al centers are three-coordinate, the Cp* rings are only bound η^1 or η^2 (Fig. 20). The N atoms thus appear to be able to compete with the Cp* ligands as π donors for the Al atoms. Quantum chemical studies that might shed some light on this interesting bonding situation have sill to be carried out. The very short Al–Al distance in the central four-membered Al_2N_2 ring is also remarkable (ca. 242 pm). A similarly short Al–Al distance has also been calculated for the four-membered Al_2O_2 ring in dimeric OAlF (238.2 pm).[29] A bonding interaction should not be interpreted in either case, however, as the bonding parameters ought to be largely dominated by ionic interactions.

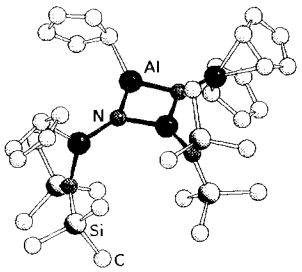


Fig. 20. Molecular structure of **35** in the crystal (Me groups of the Cp* rings and H atoms not shown).

4.4. Reaction with [NiCp$_2$]

Compounds with direct bonds between aluminum and a transition metal have been little studied as yet, although they could play a considerable role in many important catalytic processes.[159] The reaction of [AlCp*] with [NiCp$_2$] provides a simple route to this type of compound. [(NiCp)$_2$(AlCp*)$_2$] (**36**) is formed in good yields (72%) in accordance with Equation (24).[161] It has the butterfly structure shown in Figure 21, in

$$3\,[AlCp^*] + 2\,[NiCp_2] \xrightarrow{\text{toluene, 50°C}} [(NiCp)_2(AlCp^*)_2] + \text{"}[AlCp_2Cp^*]\text{"} \qquad (24)$$

36

which two AlCp* ligands bridge a CpNi–NiCp unit. Ni compounds of this type are also known with numerous other ligands such as CO (isolobal with [AlCp*]).[162] Compound **36** contains the first Ni–Al bond length determined in a molecular compound; the average length is about 228 pm.[160] It is somewhat shorter than the Co–Al distance (233 pm) in the recently reported [{CoCp*(η^2-C_2H_4)}$_2${AlEt}$_2$], which has a planar four-membered Co_2Al_2 ring in which the Al atoms are also three-coordinate.[164] The formation of **36** could be initiated by the intial attack of the alanediyl on the Lewis acidic Ni atom. This type of mechanism is supported, for example, by the reaction of germylenes and stannylenes with [NiCp$_2$], for which insertion products of the carbene analogues into the Cp–Ni bond have been characterized.[165]

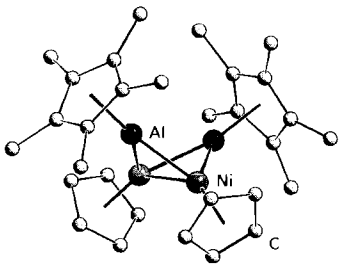

Fig. 21. Molecular structure of [(NiCp)$_2$(AlCp*)$_2$] **36** in the solid state (H atoms not shown).

4.5. Summary

The reactions of [AlCp*] described here show quite clearly that a rather simple route to novel products is frequently possible using this compound; these products are often very interesting from a theoretical standpoint with regards to the bonding aspects.

^{27}Al NMR spectroscopy is a very valuable tool for the characterization of the structures of cyclopentadienylaluminum compounds. Previous studies show that relatively clean signals occur, the resonance field strengths of which permit conclusions to be drawn as to the bonding mode of the Cp ligands. η^1-Cp complexes, for example, have shifts which correspond to those of comparable alkylaluminum compounds, whereas the ^{27}Al NMR resonance frequencies of π-Cp-aluminum compounds are shifted to considerably higher field strengths by anisotropic effects.[166] The well-known relationship between the coordination number and chemical shift in ^{27}Al NMR spectroscopy[77] still appears to be valid, however, although the entire shift region of the π-Cp-Al complexes is found at higher field strengths. The number of the compounds studied to date is still too small to be able to reliably attribute limited frequency regions to certain Al coordinations. Since [AlCp*] may well find wider use as a synthetic building block, extensive data might soon become available.

5. Outlook

Beginning with the matrix isolation technique, the consistent pursuit of an elaborate synthetic method with regards to the demands placed on the apparatus, preparative cryochemistry with reactive high-temperature molecules such as AlCl has led to the development of a new area of main group organometallic chemistry which opens a wide variety of possibilities for theoretical, synthetic, and applied chemistry. It is now expected that other, experimentally less elaborate, routes will increasingly be found for the synthesis of such compounds. In this way the rapid development of this field of research, which has already been manifest in the last few years, will continue to accelerate so that numerous surprising results can be anticipated in the near future.

A particularly interesting aspect is provided by the studies on novel cluster species, on molecular compounds with multiple bonds, and on the preparation of solid materials with metal–metal interactions. The question as to how far the singularly structural and bonding theoretical peculiarities from boron

chemistry, for example in the case of the boranes and carboranes, can be applied to the heavier homologues aluminum and gallium is particularly appealing.[167]

We would like to thank all of the colleagues in our research group for their contributions to this article. In addition we would like to thank Prof. R. Ahlrichs, Dr. J. Gauss, Dr. U. Schneider, F. Kurth, and Dr. R. Köppe for valuable discussions and theoretical studies. Prof. W. Uhl and Dr. G. Linti provided us with as yet unpublished results, for which we are extremely grateful. We thank the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for their financial support, the latter in particular for awarding a post-doctoral grant (D. L.).

[15] The listed energetic relationships in the third main group are no exception. They are valid for all homologous main group element compounds for example, also for the difluorides of the elements of the fourth main group. Admittedly, PbF_2 is unstable with regard to disproportionation in the gas phase, but this reaction path is not taken as the formation of a PbF_2 ionic crystal is even more favorable. This stabilization possibility does not exist for the lightest homologue. Covalent metastable CF_2 oligomers and polymers are formed instead, some of which demonstrate considerable thermal stability (e.g. Teflon).

[22] In principle, a higher monomer concentration ought to favor the formation of larger oligomers as well. However, a poorer "matrix isolation" is also coupled with this which leads to a broadening of bands and thus under certain circumstances the weak absorptions cannot be detected.
[23] In the matrix investigation of SiO (isoelectronic with AlF), considerable proportions of the trimeric ring are observed under certain conditions (J. S. Anderson, J. S. Ogden, *J. Chem. Phys.* **1969**, *51*, 4189; J. W. Hastie, R. H. Hauge, J. L. Margrave, *Inorg. Chim. Acta* **1969**, *3*, 601). Exclusively trimeric products are obtained in the deposition of PN, which is also isoelectronic with AlF. This experimental finding is in agreement with quantum chemical calculations, according to which the dimerization of PN is endothermic with 19 kJ mol^{-1}, but the trimerization is exothermic with 334 kJ mol^{-1} [3 PN → $(PN)_3$] (R. Ahlrichs, M. Bär, H. S. Plitt, H. Schnöckel, *Chem. Phys. Lett.* **1989**, *161*, 179).

[40] For all reactions the ratio MX(g) to MX_3(g) is determined by the thermodynamics of the equilibrium $2M(l) + MX_3(g) \rightleftharpoons 3MX(g)$; the influence of entropy increasingly favors the formation of the gaseous monohalides with increasing temperature.
[41] See for example: P. L. Timms, *J. Am. Chem. Soc.* **1967**, *89*, 1629; *ibid.* **1968**, *90*, 4585.

[52] Until now, dipropyl ether, *tert*-butylmethyl ether, 1,4-dioxane, anisole, dimethoxyethane, diethyleneglycoldimethyl ether, and triethylamine have been investigated [48].

[53] The role of the arene in the stabilization has not yet been determined. In connection with this, one is reminded of the arene complexes of Ga^+ which are formed on dissolving Ga_2X_4 in aromatic solvents [9]. It is also worth mentioning the complex of "quasi atomic" magnesium with THF and anthracene (Mg atoms can—like AlCl molecules—be regarded as carbenoid species); L. M. Engelhardt, S. Harvey, C. L. Raston, A. H. White, *J. Organomet. Chem.* **1988**, *341*, 39; H. Bönnemann, B. Bogdanović, R. Brinkmann, D.-W. He, B. Spliethoff, *Angew. Chem.* **1983**, *95*, 749; *Angew. Chem. Int. Ed. Engl.* **1983**, *22*, 728.

[58] M. Mocker, C. Robl, H. Schnöckel, *Angew. Chem.* **1994**, *106*, 946; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 862.

[59] The results from an earlier work (G. A. Olah, O. Farooq, S. Morteza, F. Farnia, M. R. Bruce, F. L. Clouet, P. R. Morton, G. K. Surya Prakash, R. C. Stevens, R. Bau, K. Lammertsma, S. Suzer, L. Andrews, *J. Am. Chem. Soc.* **1988**, *110*, 3231) concerning the synthesis of donor-free $AlCl_2$ and $AlBr_2$ at higher temperatures would appear doubtful on the basis of thermodynamic considerations [58].

[60] No $AlCl_3$-etherate can be identified by ^{27}Al NMR spectroscopic methods in an "AlCl" solution even at $-80\,^{\circ}C$. It has to be assumed, therefore, that the $AlCl_3$ formed in the synthesis reacts with "AlCl" at an even lower temperature.

[61] It should be possible to prepare compound **4**, which is only formed as a side product in the synthesis of donor-stabilized "AlBr", in a deliberate manner by slightly altering the reaction conditions. If reaction (4a) is carried out at lower temperatures, in addition to AlBr, more $AlBr_3$ is also formed (see Section 1). At about 600 °C and otherwise unchanged conditions, an equilibrium mixture is obtained that contains roughly equal amounts of AlBr and $AlBr_3$. After the cocondensation of this mixture with a suitable donor, it should be possible to prepare the dihalide in higher yields according to the equation $[M_nX_n(Do)_m] + n\,MX_3 \cdot Do \rightarrow n\,M_2X_4 \cdot 2\,Do$.

[62] The Al–Al distance in $[Al_2I_4(PEt_3)_2]$ is 256 pm, A. Ecker, H. Schnöckel, unpublished results.

[65] For example $B_2Cl_4 \cdot 2\,NMe_3$: N. N. Greenwood in *Comprehensive Inorganic Chemistry, Vol. 1* (Ed.: A. F. Trotman-Dickenson), Pergamon, Oxford, **1973**, p. 928; $Ga_2Cl_4 \cdot 2$ dioxane: J. C. Beamish, R. W. H. Small, I. J. Worrall, *Inorg. Chem.* **1979**, *18*, 220; $In_2Br_3I \cdot 2\,TMEDA$: M. A. Khan, C. Peppe, D. G. Tuck, *Can. J. Chem.* **1984**, *62*, 601.

[66] See for example: M. J. Taylor, P. J. Brothers in ref. [4], p. 198; D. G. Tuck in ref. [4], p. 468.

[67] According to the information currently available, similar stability relationships are also found in solvated donor-stabilized monohalides. This finding would agree with a mechanism proposed for the disproportionation of InX compounds, in which both monovalent and divalent species occur. The disproportionation mechanisms for $M_2X_4 \cdot 2\,Do$ and $[M_nX_n(Do)_m]$ would thus be directly connected with one another: $[M_nX_n(Do)_m] \rightarrow M^0 + MX_3 \cdot Do$ and $[M_nX_n(Do)_m] + n\,MX_3 \cdot Do \rightleftarrows n\,M_2X_4 \cdot 2\,Do$ (see D. G. Tuck, *Polyhedron*, **1990**, *9*, 377 and ref. [57]).

[74] The energies of the two isomers of Al_2H_4 with a nonbridging Al–Al bond ($H_2Al-AlH_2$ in D_{2d} and D_{2h} symmetry, respectively) represent local minima of the potential hypersurface, but the saltlike isomer $Al^+[AlH_4]^-$ is about 45 $kJ\,mol^{-1}$ more stable (K. Lammertsma, O. F. Güner, R. M. Drewes, A. E. Reed, P. von R. Schleyer, *Inorg. Chem.* **1989**, *28*, 313).

[75] D. Loos, H. Schnöckel, D. Fenske, *Angew. Chem.* **1993**, *105*, 1124; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1059.

[76] C. Dohmeier, H. Krautscheid, R. Köppe, P. Jutzi, H. Schnöckel, unpublished results. In this reaction $[AlCl_2Cp^* \cdot Et_2O]$ is also formed, as well as further Al–Si compounds which are currently under investigation.

[77] See for example R. Benn, A. Rufińska, *Angew. Chem.* **1986**, *98*, 851; *Angew. Chem. Int. Ed. Engl.* **1986**, *25*, 861, and references therein.

[78] The large signal width is possibly due to overlap of several individual signals.

[79] J. Gauss, U. Schneider, R. Ahlrichs, C. Dohmeier, H. Schnöckel, *J. Am. Chem. Soc.* **1993**, *115*, 2402.

[80] The reason for this finding can be easily explained by using an isolated AlX molecule as an example: more electronegative ligands increase, as in the case of AlX_3 species, the effective nuclear charge on the metal atom. This means for AlX molecules that the highest occupied molecular orbital (HOMO) with the lone pair of electrons is lowered energetically. Since the LUMO remains practically unaffected, the electronic excitation energy becomes larger, and the paramagnetic proportion of the chemical shift is thus reduced. The smallest resonance field strength in the series of the AlX species was therefore calculated for AlF [79]. The quantum chemical investigations show that this influence can also be expected in oligomeric AlX species, albeit to a slightly weaker extent.

[81] See for example: T. T. Kodas, M. J. Hampden-Smith, *The Chemistry of Metall CVD*, VCH, Weinheim, **1994**, p. 91; J.-O. Carlsson, U. Jansson, *Progr. Solid State Chem.* **1993**, *22*, 237.

[88] The AlF is not prepared from Al metal and HF, which is not easy to handle experimentally at higher temperatures, but rather by heating a pellet made from AlF_3 and excess Al (W. N. Rowlands, A. D. Willson, P. L. Timms, B. Mile, J. H. Bernard Chenier, J. A. Howard, H. A. Holy, *Inorg. Chim. Acta* **1991**, *189*, 189). Since this reaction takes place spontaneously (solid/liquid), according to our own matrix investigations gaseous AlF_3 is also formed.

[89] M. L. H. Green, P. Mountford, G. J. Smout, S. R. Speel, *Polyhedron* **1990**, *9*, 2763; S. R. Speel, Dissertation, Oxford, **1992**.

[90] MR_2X species (M = Al, Ga) proved to be suitable here. A divalent intermediate is presumably formed in the reduction, the disproportionation of which leads to M^{III} compounds in addition to the desired M^I product.

[101] The paramagnetic shielding term σ_{para} is generally the decisive factor in determining the position of the chemical shift of a metal nucleus, whereas the diamagnetic proportion varies little. As σ_{para} is inversely proportional to the electronic excitation energy, the energetic separation of HOMO and LUMO represents a crude but visual measure for the chemical shift: see ref. [102] and references therein, for example J. A. Pople, *Mol. Phys.* **1964**, *7*, 301; C. J. Jameson, H. S. Gutowsky, *J. Chem. Phys.* **1964**, *40*, 1714).

[102] This effect is also observed in the η^5-Cp complexes of other low-valent main group elements (e.g. Si^{II} or Sn^{II}) (B. Wrackmeyer in *Unkonventionelle Wechselwirkungen in der Chemie metallischer Elemente (DFG Forschungsbericht)* (Ed.: B. Krebs), VCH, Weinheim, **1992**, p. 111). The effect is less pronounced in the case of normally valent compounds such as [LiCp], $[MgCp_2]$, and $[Al(Cp^*)_2]^+$.

[104] S. Schulz, H. W. Roesky, H. J. Koch, G. M. Sheldrick, D. Stalke, A. Kuhn, *Angew. Chem.* **1993**, *105*, 1828; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1729.

[105] The recently determined differences [104] as regards the physical and chemical properties of the products obtained by the various routes are attributed to this impurity. If the compound prepared by the reduction with K is freed from impurities by crystal selection, the properties are identical with those of the product prepared by metathesis. As was unequivocally shown in a recent investigation (S. Schulz, H. W. Roesky, C. Dohmeier, H. Schnöckel, unpublished results), the ^{27}Al NMR spectroscopic results and the behavior on hydrolysis are particularly affected by the foreign substance.

[106] It is remarkable that although **13** is formed relatively quickly, it then reacts under disproportionation only very slowly with $[MgCp_2]$, even when this is added in excess. It is apparent that **13** has a lower tendency toward dissociation into monomers than does **11**; thus only a few AlCp* monomers are available for the reaction with $[MgCp_2]$. Both the observed downfield shift of the ^{27}Al NMR resonances, which as mentioned above is to be expected for a stronger framework bond in the tetramer, and the finding that neither monomeric [AlCp] nor monomeric [AlCp*] can be identified in solutions of **13** even at higher temperatures, are in agreement with this hypothesis.

[107] A review article concerning this class of compounds can be found in ref. [9].

Electronegativity and Molecular Properties

D. Bergmann and Juergen Hinze

The paradigm that the properties of the atoms determine the properties of the molecules that they form is systematically presented. To this end, three types of atomic properties are differentiated: a) those that can be determined directly by spectroscopy, b) those based on theoretical concepts, and c) those that can be assigned to the atoms interacting in molecules. On the basis of the electronegativity values of the atoms, which can be determined from spectroscopic data together with the assumption that the electronegativities are equalized in bonds, partial charges of the atoms in molecules are determined. These partial charges are correlated with ESCA data and proton affinities. In addition, simple expressions are given for the reliable estimation of bond lengths, bond energies, and force constants.

Keywords: electronegativity · molecular properties · theoretical chemistry

1. Introduction

The paradigm that the properties of the constituent atoms determine the characteristics of the molecules formed is exceptionally useful in chemistry. It can be founded solidly within quantum mechanics, within the framework of valence-bond (VB) theory for molecular structure.[1, 2] In the VB approach, the molecular wave function is written as a product of the state functions of the constituent atoms. In this description the atomic characteristics, which determine the molecular properties, are readily identified. This makes models based on the VB approximation intuitively appealing, as exemplified by the wide acceptance of Pauling's "Nature of the Chemical Bond"[3, 4] and by the extreme usefulness of Lewis structures and the VSEPR rules[5, 6] based on these structures. Unfortunately, the VB approach becomes unwieldy if the tight binding approximation cannot be maintained, and with its nonorthogonal atomic state functions and localized orbitals, it does not lend itself readily to detailed calculations of molecular wave functions.[7] Therefore theorists generally favor the molecular-orbital (MO) method, where the molecular wave function is composed of orthonormal delocalized orbitals and bears a direct relation to the electronic spectra of the molecules.

On the basis of the MO approach enormous progress has been made in the ab initio characterization of molecular properties,[8–10] and due to rapid computer evolution, which makes increasing computational power more readily available, valuable new programs (for example, GAUSSIAN,[11] GAMESS,[12] or MOLPRO[13]) have been provided to the practical chemist to further his research through the detailed quantum mechanical characterization of the molecules under investigation. Ab initio computations for larger molecules are indeed feasible; however, at present unless undue computational effort is invested, reliable results are possible only for small molecules. Thus, useful, empirical, interpretive models are still needed to further our understanding of chemistry. Within the MO picture many such models have been devised,[14] for example, Hückel theory, the Walsh rules,[15] and the frontier orbital picture of reactivity[16] leading to the Woodward–Hoffmann rules.[17, 18] However, the atomic characteristics that determine the molecular properties are difficult to uncover within MO theory with its delocalized molecular orbitals. Here the VB approach complements the picture, because it provides additional insight and the potential for enormous data reduction when well-defined atomic properties are used to derive the characteristics of the molecules formed. A predictive understanding of molecular properties such as structure, binding energies, charge distribution, electrophilicity, reactivity, and many more can be obtained on the basis of the atomic properties.

Atomic properties that are useful in this context are the atomic state term values and ionization potentials with the corresponding atomic configurations, orbitals and orbital energies, electronegativity and hardness, as well as covalent and van der Waals radii. To be sure, of these only the energies of the atomic term values and the ionization potentials can be measured directly, by spectroscopy, for the free atoms. The association of these with electronic configurations and orbitals requires the independent particle approximation, that is, the theory of atomic structure.[19, 20] Moreover, the electron configurations of the free atoms in their ground states are not those of the atoms in a molecule. For an atom in a molecule the valence-state configuration is required, which depends on the molecular environment of the atom and is thus not strictly an atomic property. Fortunately the valence states of an atom can be determined

readily in many cases and are related directly to the spectroscopic term values of the free atom.[21-23] The situation is different for the covalent radii of the atoms. They cannot be determined for the atoms directly; here recourse to a large amount of molecular structure data is necessary. Thus covalent radii of atoms should be considered as an atomic property derived from molecules for data reduction, which facilitates the prediction and understanding of molecular structure.

From this discussion it becomes clear that in the effort to derive molecular information from atomic properties in order to achieve data reduction and an understanding of chemistry, three types of atomic properties should be differentiated:

1. Primary atomic properties can be determined experimentally for the free atoms. These are the ionization potentials, electron affinities, and the spectroscopic term values of the free atoms.
2. Secondary atomic properties require, in addition to the experimentally determined quantities for the free atoms, theoretical concepts generally based on approximations within the quantum mechanical description of the electronic structure of atoms. These are the atomic shell structure, the orbitals, the valence shell, hybridization, the valence state, and the energy required to excite the isolated atom to the valence state (promotion energy).
3. Tertiary atomic properties can not be determined for the free atoms, but are assignable to the atoms in their interaction in gases, solids and molecules. These are van der Waals, ionic, and covalent radii, and the energy of the covalent bond, which require for their determination the analysis of a large database of properties of molecules or of the solid state.

Obviously, primary and, since theoretical concepts will generally be required, secondary atomic properties are to be preferred over tertiary properties, when molecular characteristics are to be derived qualitatively and semiquantitatively from the properties of the constituent atoms.

In the light of these considerations, the concept of electronegativity will be reviewed, with no attempt to be exhaustive. We will rather focus primarily on the concept of orbital electronegativity, which has its origin in Mulliken's original definition of absolute electronegativities.[24] On this aspect we will also present new results to demonstrate how this concept, based on primary and secondary atomic properties, can yield useful and practical correlations and predictions of molecular properties like charge distribution, bond length, and bond energies. To be sure, the secondary properties implied in these considerations, like valence states, atomic orbitals, and localized two-electron bonding valence structures (akin to Lewis structures), entail approximate theoretical models most closely related to the tight binding approximation of VB theory.[1, 2]

2. Electronegativity Scales

2.1. Pauling's Definition

The concept of electronegativity was recognized as a useful ordering principle in chemistry more than 150 years ago.[25] With the definition given by Pauling[3, 4] of electronegativity as "the power of an atom in a molecule to attract electrons to itself" and the electronegativity scale of the elements derived by him from thermochemical data, the concept of electronegativity has become one of the most widely used ordering principles in chemistry. The atomic configuration energy, related to electronegativity,[26] has been considered a necessary supplement to the two-dimensional arrangement of the Periodic Table, providing a third dimension, namely energy,[27] superimposed upon the ordering of the elements according to increasing nuclear charge Z (electron number), in such a way that the columns (groups) correspond to equal valence shell configurations with increasing shell quantum numbers. The apparent dependence of many physical and chemical properties of atoms and molecules on electronegativity has led to many correlations,[28, 29] and thus various different electronegativity scales have been suggested.[30] Thus, the concept of electronegativity has become increasingly ambiguous, to the point that its value has been criticized,[31, 32] because the electronegativity of an atom or of a functional group is neither directly measurable nor has it been uniquely defined.

Jürgen A. M. Hinze, born in Berlin in 1937, studied chemistry at the Technical University of Stuttgart from 1957–1960. From there he went to the University of Cincinnati, Ohio, where he wrote his thesis on electronegativity under the guidance of Professor H. H. Jaffé, in 1962. From 1962–1964 he was postdoctoral fellow with Professor K. S. Pitzer at Rice University in Houston, Texas. Till the beginning of 1966 he worked with T. Förster as assistant at the Institut für Physikalische Chemie der Technische Universität Stuttgart, after which he transferred to the University of Chicago to the Laboratory of Molecular Structure and Spectroscopy, chaired at that time by R. S. Mulliken and C. C. J. Roothaan. In 1967 he became professor at the department of chemistry of the University of Chicago, where he stayed till 1975. During this period he spent half a year's sabbatical at the Max-Planck-Institut für Astrophysik in München in 1973. In 1975 he was appointed professor at the Department of Theoretical Chemistry of the University of Bielefeld. His scientific activities in theoretical chemistry range from the exact quantum mechanical treatment of the three-body problem and electron/atom collision processes to the qualitative theoretical description of chemical phenomena. This is documented in a great number of scientific publications and six books that he has edited.

Pauling proposed originally the thermochemical scale, based on the relation (1).[33, 34] He had observed that the dissociation

$$D_{AB} = \left(\frac{D_{AA}+D_{BB}}{2}\right)+\Delta_{AB} = \left(\frac{D_{AA}+D_{BB}}{2}\right)+23(\chi_A-\chi_B)^2 \quad (1)$$

energy of the heteronuclear bond, D_{AB} between the atoms A and B could be expressed as the arithmetic mean of the corresponding homonuclear bond energies D_{AA} and D_{BB} plus the extra ionic resonance energy Δ_{AB} and that the extra ionic resonance energy was proportional to the square of the difference of two atomic quantities, which he associated with the electronegativity χ_A and χ_B of the atoms A and B. Originally Pauling used the units eV for the dissociation energies and a proportionality constant of 1.[34] Later, when Pauling used kcal mol^{-1} for the dissociation energies in Equation (1), he chose the proportionality constant 23,[3, 4] in order to convert the extra ionic resonance energy $(\chi_A - \chi_B)^2$, thought to be in units of eV, into kcal mol^{-1}. Today the value of the proportionality constant should be 100 with bond energies in kJ mol^{-1}.

By using a large set of thermochemical data with Equation (1), which relates bond dissociation energies and electronegativity, a relative electronegativity scale could be derived. The scale was made absolute by choosing the electronegativity of hydrogen χ_H to be 2.1, the value from Mulliken's publication.[24] Pauling's electronegativity values for the elements were readily accepted by the chemistry community, because a vast amount of chemical information could be correlated and rationalized in terms of electronegativities. The electronegativity values increased from left to right in the periodic table and generally decreased a little from top to bottom within a group. The values obtained by Pauling, in particular for the first row elements ($\chi_{Li} = 1.0$, $\chi_{Be} = 1.5$, $\chi_B = 2.0$, $\chi_C = 2.5$, $\chi_N = 3.0$, $\chi_O = 3.5$, and $\chi_F = 4.0$), were so appealingly simple that Pauling's original scale and "Pauling units" remained the reference for electronegativity, even though the dimension and units seem unnatural. With a dimensionless proportionality constant in Equation (1), the dimension of Pauling electronegativity is square root of energy and "Pauling units" would be $\sqrt{\text{eV}}$. As there is no reason why the proportionality constant must be dimensionless, other units could equally well be justified. It should also be mentioned that Pauling later suggested the use of the geometric rather than the arithmetic mean in Equation (1),[35] in order to overcome the problem of negative extra ionic resonance energies for the alkali hydrides. However, this suggestion has not been used in the extensive determination of electronegativities on the thermochemical scale.

2.2. Mulliken's Definition

Only few years after Pauling's original introduction of the electronegativity concept, Mulliken[24] proposed an absolute scale, in which the electronegativity of an atom was given as the arithmetic mean of the ionization potential IP and the electron affinity EA of an atom, quantities which can be determined experimentally and unambiguously for any atom [Eq. (2)].

$$\chi = \frac{(IP+EA)}{2} \quad (2)$$

Mulliken's definition of electronegativity is based on the consideration of the bond between the atoms (species) A and B in the frame of VB theory as a resonance hybrid of covalent and ionic structures (Scheme 1). The energy required to go from the covalent structure A–B to the ionic structure A^+B^- is the difference between IP_A and EA_B plus the covalent binding energy minus the ionic Coulomb attraction between oppositely charged particles. Similarly, the energy required to go from A–B to A^-B^+ is $IP_B - EA_A$. If the electronegativities of A and B are equal, the two ionic structures A^+B^- and A^-B^+ should have equal weights [Eqs. (3) and (4)].

$$A^+B^- \leftrightarrow A\text{–}B \leftrightarrow A^-B^+$$

Scheme 1. Resonance hybrids as basis for Mulliken's definition of electronegativity.

$$IP_A - EA_B = IP_B - EA_A \quad (3)$$

$$IP_A + EA_A = IP_B + EA_B \quad (4)$$

On the other hand if A were more electronegative than B, the structure A^-B^+ would dominate over the structure A^+B^- [Eqs. (5) and (6)]. Clearly, the ionization potentials and electron

$$IP_A - EA_B > IP_B - EA_A \quad (5)$$

$$IP_A + EA_A > IP_B + EA_B \quad (6)$$

affinities required in Equation (2) are not those of the ground states of atoms, but those of the valence state, that is, those of the orbitals used for bond formation. This was recognized already by Mulliken when he originally proposed his absolute electronegativity scale. This fact, however, has advantages and disadvantages. The disadvantage is that these ionization potentials and electron affinities cannot be measured directly; they can, nevertheless, be derived from the corresponding, experimentally accessible ground-state values and the atomic spectroscopic term values[21–23] within the frame of Slater's theory of atomic structure.[19, 20] Thus electronegativity becomes a derived atomic property, which depends on the valence state of the atom. As this is not a stationary state of the atom, it is not experimentally accessible, but depends on the bonding of the atom in a molecule. This, however, is also the advantage of Mulliken's definition of electronegativity: it permits different electronegativity values for the same atom, depending on the valence state the atom assumes in a molecule. The need for such a dependence was recognized early in the example of carbon, which was known to have a higher electronegativity in the ethynyl group (sp hybridization) than in the methyl group (sp^3 hybridization).[37]

Unfortunately, Mulliken's definition of electronegativity, which is well founded in the quantum theory of the electronic structure of molecules, did not receive the early wide acceptance in chemistry it deserves. This is in part because the experimental determination of electron affinities became reliable only recently.[38] Also the calculation of the required valence-state promotion energies from atomic term values has become possible only after the latter had been determined more completely.[39]

2.3. Comparison Between the Methods To Determine Electronegativity

In their excellent review on the concept of electronegativity, Pritchard and Skinner[40] critically evaluate different suggestions made for the determination of electronegativity values for atoms, most of them based on empirical correlations between atomic and molecular properties and Pauling electronegativity values. Pritchard and Skinner favor Mulliken's scale, as it is based on directly observable spectroscopic data of the atoms. They also succeeded in computing Mulliken electronegativity values for most of the atoms, in some cases even for different valence states, from ionization potentials, electron affinities, and atomic term values as they were known then.

It seems worthwhile here to recall some of the early suggestions made for the determination of electronegativities from molecular properties, as these could be useful when, vice versa, molecular properties are to be determined from known atomic electronegativities.

Malone[41] suggested using "bond" dipole moments μ_{AB} and relating them to the electronegativity difference for the bond A–B by the equation $\mu_{AB} = |\chi_A - \chi_B|$. This correlation, even though it seems obvious, was found not to be very good, and the relation was not used extensively to determine electronegativity values. That such a simple correlation between electronegativity and dipole moment cannot hold is well understood today. There is no reason why first the "ionicity" of a bond should be simply proportional to the electronegativity difference; second, the bond dipole moment should be determined only by the partial charges and not also by the bond distance; and third, the electric moments of lone pairs should be negligible when determining the dipole moment of a molecule from bond moments.

Another early empirical relation was found by Gordy[42,43] between electronegativity and force constants [Eq. (7)], where

$$k_{AB} = \left[1.67N\left(\frac{\chi_A\chi_B}{r_{AB}}\right)^{0.75} + 0.3\right] 10^{-3} \qquad (7)$$

k_{AB} is the stretching force constant of the bond between A and B in dyn Å^{-1} and N is the bond order. As we will see later, a relation like this is useful in determining bond distances and estimating force constants from electronegativities.

The electronegativity of the atoms played an increasingly important role in the qualitative arguments about chemical bonding, since a large amount of chemical information about molecule formation could be systemized and understood with the concept. The need to have reliable electronegativity values available for all of the atoms of the periodic system therefore became urgent. Unfortunately the lack of thermochemical data prevented an extensive use of Pauling's original relation to obtain a complete list of atomic electronegativity values, even though extensive efforts were made by Haissinsky[44,45] and Huggins.[46] A similar situation prevailed with Mulliken's absolute electronegativity values. In particular the electron affinity values of the atoms were not known then, and the definition and calculation of valence states and their promotion energies provided difficulties.

These difficulties in obtaining electronegativity values for the atoms appeared to be resolved by the suggestion of Allred and Rochow[47] that the electronegativity of an atom can be calculated from the empirical relation (8). Here Z_{eff} is the effective

$$\chi = 0.359\,\frac{Z_{eff}}{r^2} + 0.744 \qquad (8)$$

charge of the nucleus screened by the electrons of the atom as estimated by Slater's rules,[48] and r is the covalent radius of the atom as tabulated by Pauling.[49] With this relation electronegativity is given by the radial force an electron would experience one covalent radius from the nucleus of the atom (the "covalent boundary").

The numerical coefficients were determined by fitting the force formula [Eq. (8)] to the then known Pauling electronegativity values. The most significant difference is that in the Allred and Rochow scale the electronegativity value for Ge is larger than that for Si. Allred and Rochow pointed out[50] that this reversal is consistent with chemical evidence and was noted earlier by Sanderson,[51] who attributed it to the d-shell contraction. As the values of Z_{eff}, and apparently also the values for the covalent radii of the atoms, were readily available, it was easy to use Equation (8) and determine the electronegativity values for most of the atoms without the difficulties that afflicted such a determination with Pauling's or Mulliken's definition. Thus, the electronegativity values of Allred and Rochow were readily accepted, to the extent that these values are listed in most explicit periodic charts, where in general also the covalent radii of the atoms are given. That the covalent radius of an atom depends on the valence state of the atom is frequently recognized, but not reflected in the electronegativity values given, even though Allred and Rochow had emphasized it in their original article.

The various atomic and molecular properties that can be correlated with electronegativity have led to many different suggestions[26,28,29,52–71] for the definition and determination of electronegativity values. This has generated some confusion, and we will not discuss these different suggestions here in detail, even though some new insight can be gained from these suggestions if they are derived using an extensive data base and if they have a solid theoretical foundation. It should be mentioned here that in a number of theoretical investigations, using MO as well as VB approaches, connections have been derived between the electronegativity values determined using Mulliken's suggestion [Eq. (2)] and the extra ionic energy as defined in Equation (1).[28,36,72–74]

3. Electronegativity as Electrical Potential

A seemingly rigorous derivation of atomic and molecular electronegativity has been presented on the basis of the density functional theory.[75] Electronegativity is identified as the chemical potential and defined as the partial derivative of the total energy of a system with respect to the total number of electrons, that is, the trace of the charge density. This definition, restricted to the ground state, yields Equation (9) and, therefore, the same

$$\chi = -\left(\frac{\partial E}{\partial N}\right) \qquad (9)$$

electronegativity everywhere for the entire system, atom, or molecule. This electronegativity equalization throughout a

molecule does not seem to be useful and runs counter to chemical intuition and the observation of electro- or nucleophilic centers in a molecule. This global equalization of the electronegativity results because the partial derivative of the energy with respect to the total charge of the system is used; it would even obtain for a system composed of noninteracting subsystems. If the partial derivative were taken with respect to a change of the charge at a particular volume element or locus in the molecule, a space-dependent electronegativity would result for molecules, yielding the electro- and nucleophilic centers required for chemistry. This spatial dependence, desired in chemistry, is recovered through the definition of the Fukui function $f(r)$[76, 77] [Eq. (10)], where $\rho(r)$ is the electron density of the molecule

$$f(r) = \frac{\partial \rho(r)}{\partial N} \tag{10}$$

considered. The Fukui function indicates those regions in a molecule where the charge density changes during a reaction. As numerical approximation for the partial derivatives in Equation (10), the forward difference is used for a nucleophilic attack, while for an electrophilic attack the backward difference is employed. For radical reactions the central difference is recommended. This function is akin to the use of HOMOs (highest occupied MOs) and LUMOs (lowest unoccupied MOs) in the frontier orbital theory of reactivity,[16–18] with the advantage that, because the definition is in terms of the physically real charge density, no recourse to the concept of orbitals is needed. However, as a result the effect of orbital phase relations on reactivity is lost.

The definitions for atoms and molecules, of electronegativity according to Equation (9), and of hardness[78] according to Equation (11), in conjunction with the introduction of the

$$\eta = \frac{1}{2}\left(\frac{\partial^2 E}{\partial N^2}\right) \tag{11}$$

Fukui function [Eq. (10)] within the framework of density functional theory, have the appeal of rigor, as there seems to be no need for the concept of orbitals. However, for the practical use of these definitions, a knowledge of the atomic and molecular electron density functions is required. As this is difficult to obtain experimentally, if at all, recourse to detailed wave function or density functional calculations of these systems becomes necessary. Equations (9) and (11) can be approximated using finite differences instead of differentials, ionization energies, and electron affinities. These aspects have been reviewed recently.[30]

The density functional definition of electronegativity [Eq. (9)] is akin to the earlier definition of atomic electronegativity by Iczkowski and Margrave[79] and to the localized orbital-electronegativity concept introduced by Hinze et al.[80] We will focus here on the latter, since the combination of the localized orbital picture, in the frame of the tight binding approximation of valence-bond theory,[1, 2] with the idea of electronegativity as an electrical potential proves to be rather fruitful, as we hope to show in the following sections. With this definition, the original absolute electronegativity scale introduced by Mulliken[24] is retained and put on a solid theoretical foundation (see appendix A of Ref. [81]). In addition, by using the orbital concept the flexibility required to yield electro- and nucleophilic centers within a molecule is obtained immediately. Furthermore, the extension to a localized "hardness"[78] through the second derivative of the energy with respect to the charge localized in an orbital is retained.

The orbital electronegativity of an atomic orbital, say orbital i, is defined as (12),[80] where n_i is the occupation and q_i the charge in orbital i.

$$\chi_i = -\left(\frac{\partial E}{\partial n_i}\right) = \left(\frac{\partial E}{\partial q_i}\right) \tag{12}$$

This definition makes the electronegativity concept for atoms more complex, yielding more than one electronegativity value for a given atom. Nevertheless, this complexity is desirable if, for instance, the electron shell structure of atoms is to be reflected in the electronegativity values (for example, for a given atom $E(N)$ shows clear discontinuities at $N = 2$, $N = 4$, $N = 10$ etc.) leading to difficulties with the use of Equation (9).

More important for chemistry is the possibility of different electronegativity values for an atom, dependent on its valence state, or, which is more flexible, dependent on the s, p, or d character of the bond-forming hybrid orbital of the atom. Such a valence-state dependence of the electronegativity has been requested on chemical grounds,[37] and the need was recognized already by Mulliken[24] in his original definition of the "absolute" electronegativity scale. Thus, although the electronegativity concept is complicated by orbital electronegativities, the latter definition reflects more realistically the versatility, depending on the different chemical surroundings, of an atom in a molecule. This is particularly apparent in the case of carbon, which has a tetrahedral environment with sp^3 hybrid orbitals in saturated compounds, whereas the environment is trigonal (sp^2 hybrid orbital) or digonal (sp hybrid orbital) in unsaturated compounds. Here large differences in the electronegativity are expected. For most other atoms the variability and therefore the complexity is not so pronounced. Significant differences are also to be expected for the chalcogens, which may be di-, tetra-, or hexavalent and for the elements in the fifth main group, which may be tri- or pentavalent. In addition, as will be shown below, the concept of orbital electronegativities provides a consistent extension to group electronegativities and to the determination of partial charges in molecules.

To use the definition of orbital electronegativity [Eq. (12)] it is necessary to display the energy $E(q_i)$ of an atom as a continuous function of the charge q_i in the i-th spatial valence orbital. It is reasonable to use a quadratic polynomial [Eq. (13)] on empirical as well as theoretical grounds. The orbital electronegativity is then given by Equation (14), and depends on the charge (occupation) of the orbital considered. However, electronegativity should represent the potential for attracting electrons before bond formation, thus the values for empty, singly, or doubly occupied orbitals (that is, for $q_i = 0$, -1, or -2) will be of special significance.

$$E(q_i) = a + bq_i + cq_i^2 \tag{13}$$

$$\chi_i(q_i) = b + 2cq_i \tag{14}$$

Defining the valence-state ionization energy IP_i and electron affinity EA_i for the i-th orbital according to Equa-

tions (15) and (16) yields, on using Equation (13) with the

$$IP_i = E(q_i=0) - E(q_i=-1) \quad (15)$$

$$EA_i = E(q_i=-1) - E(q_i=-2) \quad (16)$$

orbital index i dropped, the relations (17) and (18) for the coefficients b and c.

$$b = \frac{(3IP-EA)}{2} \quad (17)$$

$$c = \frac{(IP-EA)}{2} \quad (18)$$

Substituting these values into Equation (14) results in the electronegativity for a singly occupied orbital, corresponding to the standard electronegativity (19) in accord with the original

$$\chi(-1) = \frac{(IP+EA)}{2} \quad (19)$$

definition of Mulliken.[24] In addition the electronegativity values for empty and doubly occupied orbitals are obtained according to Equations (20) and (21), respectively, which enables

$$\chi(0) = \frac{(3IP-EA)}{2} \quad (20)$$

$$\chi(-2) = \frac{(3EA-IP)}{2} \quad (21)$$

the orbital-electronegativity concept to be used for dative bonds, too. As the orbital occupation can be no smaller than 0 and no larger than 2, $\chi(0)$ is the potential of an empty orbital to attract electrons, while $\chi(-2)$ is the potential to withhold electrons, and only $\chi(-1)$ has both meanings.

The orbital electronegativities obtained in this way have the dimension of an electrical potential, and with the ionization energy and electron affinity in eV, the units for χ will be volts. To convert the results to "Pauling units", more familiar to chemists, the empirical relation (22) may be used, where χ_P is the

$$\chi_P = 0.303\chi_M \quad (22)$$

electronegativity in "Pauling units", while χ_M (Mulliken) is the orbital electronegativity in volts. The proportionality constant in (22) has been obtained by a least squares fit of the computed orbital electronegativities to the generally accepted values of Allred and Rochow.[47] The fit is excellent, and a possible constant term in the fit was found to be statistically insignificant. If ground-state ionization energies and electron affinities are used to determine the χ_M values, such a fit is much less satisfactory, and some inconsistencies arise.[26]

Within the framework of the concepts developed above, a "hardness" parameter η_i akin to the hardness introduced by Pearson[78] may be defined for an orbital according to Equation (23). It has the dimension of energy per square of charge or

$$\eta_i = \frac{1}{2}\frac{\partial^2 E(q_i)}{\partial q_i^2} = \frac{1}{2}\frac{\partial \chi_i(q_i)}{\partial q_i} = c_i \quad (23)$$

potential per charge, which is the same as reciprocal capacitance; if the energy (as used here) is in eV, the units for the hardness will be Ve^{-1}. The concept of "hardness" has been reviewed recently.[82]

In Scheme 2 the standard electronegativity values in "Pauling units" and hardness parameters in Ve^{-1} for the elements are

H χ = 2.17 η = 6.42							He χ = 2.93 η = 14.92

Schema 2. Electronegativity values and hardness parameters for the elements.

presented. These values have been obtained from Equations (19) and (23). The necessary valence-state ionization energies and electron affinities were obtained earlier[83, 84] by combining the corresponding ground-state values with the valence-state promotion energies computed from the atomic term values. Somewhat more detailed information, with the atomic electronegativity parameters required for the determination of the charge distribution in molecules, is presented in Table 1. All the parameters presented here have been reevaluated in the light of the most recent spectroscopic data (more detailed information is given in Refs. [81, 83, 84]); they thus supersede similar data of earlier compilations of Mulliken electronegativity values.[40, 85–88]

The values presented are derived directly from spectroscopic data of atoms and the definition of the atomic valence states that are reasonable on chemical grounds. For the elements of the main groups 1 through 4, the hybrid orbitals s, di (= sp), tr (= sp^2), and te (= sp^3) have been used for the standard values reported. In the case of carbon the orbital electronegativity of the π orbital ($\chi_\pi = 1.73$) is of interest, as well as the values $\chi_{di} = 3.17$ and $\chi_{tr} = 2.69$ obtained for the sp and sp^2 hybrid orbitals, respectively. This demonstrates that the electronegativity of carbon can be quite different, depending on the type of bonding. The situation is not as extreme for most other elements.

The standard electronegativity values reported for the elements of the main groups 5 through 7 have been computed with 15%, 10%, and 5% s character for the bonding orbitals, respectively. For the computation of these values, the parameters b and c were interpolated with a quadratic least squares fit for the experimental data. Although on chemical grounds it is expected that the s character in the bonding orbitals decreases on going to the heavier elements in these groups, the effect on the corre-

Table 1. Atomic electronegativity parameters. The parameters b^0, b^1 (in V), and c (in Ve^{-1}) are defined in Equation (34). In the last two columns the Mulliken and Pauling electronegativity values, χ_M and χ_P, are given.

[a] In each case the type of hybrid orbital is given in parentheses. s = s orbital, di = sp, tr = sp^2, te = sp^3, π = p orbital available for π bonding. [b] For the inert gases, the electronegativity values given are those for doubly occupied orbitals.

sponding electronegativity values would be minimal. This changes when these elements are not three-, two-, or one-connected, respectively, as was assumed for the standard values reported in Scheme 1. For example, if one would use sp^3d(pe) hybrid orbitals, the electronegativity for pentavalent phosphorus becomes $\chi_{pe} = 3.07$, significantly higher than the standard value. A similar situation obtains for tetra- or hexavalent sulfur; for pentagonal (pe) or octahedral (oh) hybrid orbitals, respectively, the electronegativity values obtained are $\chi_{pe} = 3.22$ and $\chi_{oh} = 3.19$. However, it is not clear at all whether the expansion of the valence shell in these atoms can be attributed to d orbital participation, or whether it is due to three-center bonds. This point will not be considered further here. Thus, by using the standard values for electronegativity as reported above, extended by a few extra values for common valence states, most relevant chemical structures can be accounted for, and it will be necessary only in rare cases to use the more extensive list of possible valence states reported earlier for completeness—for example, more than 40 valence states for sulfur.[81]

The electronegativity values reported in "Pauling units" are converted from the original results obtained in V with the empirical relation (22). They should be adequate for most qualitative considerations. The values given with three significant figures have an uncertainty of ± 0.04 (95% confidence level and interval) due to the conversion from V to "Pauling units" and due to the uncertainty of the s, p, or d character of the bonding orbitals. The latter uncertainty, as well as the lack of atomic spectroscopic data, is even larger for the transition metals and for the last rows of the periodic table; the values for these elements are therefore given with only two significant figures with an implied uncertainty of ± 0.1. Many of these values could not be obtained from spectroscopic data of atoms. For these elements the hardness parameter η is not specified, and the electronegativity values given are those of Allred.[89] The electronegativities for the lanthanides and actinides, not given explicitly, can be obtained only approximately from atomic data. For these elements electronegativity values of 1 or 1.1 are recommended, increasing slightly from left to right in the corresponding row.

The electronegativity values reported in Scheme 2 and Table 1 for the inert gases are the values for doubly occupied orbitals $\chi(-2)$ [see Eq. (21)]. Except for helium, where the s orbital is used, p orbitals are considered.

4. Charge Distribution in Molecules

If it were limited to the determination of the atomic electronegativity values presented in Table 1, the concept of orbital electronegativity would offer little new insight. The electronegativity values determined directly from spectroscopic data differ insignificantly from conventional values, as evidenced by the good correlation between the orbital-electronegativity scale in V, and the conventional Pauling scale obtained in a much less direct way. The few extra values obtained, corresponding to some common valence states of carbon, phosphorus, or sulfur etc., would not justify a new electronegativity concept. The new concept, however, leads to insights into the process of bond formation and the concomitant charge transfer, resulting in the possibility of determining the charge distribution in a molecule without extensive quantum mechanical calculations, and finally to a better understanding of molecular properties, derived from the electronegativity values of the atoms.

The definition of orbital electronegativity as an electric potential [Eq. (12)] provides an immediate rationalization of the electronegativity equalization between two orbitals forming a two electron bond, as suggested by Sanderson.[54, 90, 91] If orbital i on atom A forms a bond with orbital j on atom B, a transfer of charge Δq will occur from the less electronegative orbital to the more electronegative one, until the two electronegativities have become equal, as described in Equation (24). Here q^0 is the

$$\chi_{iA}(q^0_{iA}+\Delta q) = \chi_{jB}(q^0_{jB}-\Delta q) \qquad (24)$$

reference charge in the orbitals before bond formation, and Δq is the charge transferred from the bonding orbital j_B to the orbital i_A. This charge transfer corresponds to an energy lowering in the bond until the two electronegativities are equal,

provided no other energetic effects are connected with this charge transfer process. Such energetic effects have been investigated and discussed extensively. Fortunately, the main two effects—an additional energy lowering due to the coulomb attraction of the partially negative and positive centers A and B formed, and an energy increase due to the weakening of the covalent bond—tend to cancel in the case of bonds formed between singly occupied orbitals. The situation is expected to be different in the case of dative bonds, where both effects are energy lowering.

Using the full electronegativity equalization in a bond as working hypothesis immediately yields the charge transferred from orbital j to orbital i by combining Equations (14) and (24) to give (25).[80, 92]

$$\Delta q = \frac{\chi_j(q_j^0)-\chi_i(q_i^0)}{2(c_j+c_i)} \tag{25}$$

The net energy change due to such a charge transfer is obtained as (26).[28, 92]

$$\Delta E = -\frac{[\chi_j(q_j^0)-\chi_i(q_i^0)]^2}{4(c_j+c_i)} \tag{26}$$

The resulting reduction in energy due to the charge transfer is reminiscent of the extra ionic resonance energy [Eq. (1)] used by Pauling originally in establishing his relative electronegativity scale.[33] Some more recent investigations of the concept of electronegativity equalization,[93] as well as some earlier MO derivations of this concept,[28] seem to indicate that Equations (25) and (26) should also contain the coulomb attraction of the induced partial charges. As these terms would be distance-dependent, their inclusion would require molecular structure information in addition to the simple connectivity for the determination of the partial charges. We therefore proceed here with the simple model that neglects these terms. To what extent the inclusion of these terms will improve the correlations of electronegativity and partial charges with molecular properties remains a topic for future research.

The ideas developed above are adequate for the calculation of the charge transfer in a single two-electron bond. To deal with molecules in general, where the same atom may have several different ligands, an extension of these concepts is required. Consider an atom that uses m orbitals to form m localized two-electron bonds. Due to the orbital-electronegativity equalization, it will have the charge Δq_k transferred into each of the bond forming orbitals, that is, for $k = 1$ through m. The net total charge of the atom is expressed by Equation (27). The orbital

$$Q = \sum_{k=1}^{m} \Delta q_k \tag{27}$$

electronegativities of this atom will presumably depend on the charge transferred in all the other orbitals of the atom. The electronegativity χ_i of a particular orbital i will be a function of $q_i = q_i^0 + \Delta q_i$ [Equation (14)], but it will depend also on the residual charge r_i [Eq. (28)] from all the other bonds of the atom

$$r_i = \sum_{k \neq i} \Delta q_k = Q - \Delta q_i \tag{28}$$

considered. Thus Equation (14) needs to be generalized to (29),

$$\chi_i(r_i,q_i) = b_i(r_i)+2c_i(r_i)q_i \tag{29}$$

in which the parameters b and c depend on the residual charge r_i. Fortunately, the residual charge will be small in general ($|r| < 1$) and the parameter $c = (\mathrm{IP} - \mathrm{EA})/2$, which depends only weakly on the residual charge, can be treated as a constant, while for the parameter b, a linear approximation is adequate [Eq. (30)]. The relation (31) gives b^0 according to (32) and b^1 according to (33). The parameters b^1 can be evaluated from

$$b(r) = b^0 + b^1 r \tag{30}$$

$$b = (3IP - EA)/2 = IP + c \tag{31}$$

$$b^0 = IP^0 + c \tag{32}$$

$$b^1 = \frac{\partial IP}{\partial r} \tag{33}$$

atomic spectroscopic data from for various valence orbitals, just like the parameters b_0 and c. Slightly different b^1 values would be obtained, depending on the orbitals from which the residual charge results. As this dependence would unduly complicate the concept, and since this dependence is weak, b^1 values have been suitably averaged for the main group elements.[83, 84] With these values, the orbital electronegativity can be evaluated from the charge q in the orbital and the residual charge r due to charge transfer in other orbitals of the same atom. This orbital electronegativity [Eq. (34)] for an orbital i can now be used to calcu-

$$\chi_i(r_i,q_i) = b_i^0 + b_i^1 r_i + 2c_{iq_i} \tag{34}$$

late the charge shift Δq_i, using the concept of electronegativity equalization, when orbital i forms a localized two-electron bond with an orbital j of another atom. Since, in this case, $\Delta q_i = -\Delta q_j$, an equation of the form of (35) is obtained for each bond within a molecule. For a molecule with N bonds, N equations of type (35) result, one for each bond. Substituting Equation (34) into Equation (35) and replacing the r_i values by the Δq's [Equations (27) and (28)] yields for a molecule with N

$$\chi_i(r_i,q_i^0+\Delta q_i) = \chi_j(r_j,q_j^0-\Delta q_i) \tag{35}$$

bonds N linear equations (for details see Ref. [18]), which may be solved readily for the N unknowns (the charge shifts Δq in the bonds). This provides an easy method of determining the partial charges Q given by Equation (27) in a molecule, from just the orbital-electronegativity data, the coefficients b and c for the atomic valence orbitals (given in Table 1 and more detailed in Refs. [81, 83, 84]), and the Lewis structure of the molecule. No data on the geometrical structure of the molecule is required, and the determination of the charge distribution is much easier than an analogous quantum chemical calculation; just a set of linear equations containing as many equations as number of bonds needs to be solved. Even small computers (PCs) can handle the solution for large molecules. Not only the charge distribution, which should correlate with a number of experimentally accessible data and which is essential for more detailed molecular mechanics calculations, can be obtained in this way. It is just as easy to determine orbital electronegativities for free radicals or for doubly occupied or empty orbitals. To obtain these values, it is necessary to use Equation (34) together with the r_i value computed in a charge distribution calculation for the group.

It is also possible to determine the orbital hardness parameters [Eq. (9)] for molecular groups. However, here it will not be sufficient to use the c_i value of the corresponding atomic orbital directly, since in the group the residual charge r_i of the orbital considered will have a significant effect on the hardness. To this end it is necessary to use a finite difference approximation to obtain the partial derivative of the corresponding orbital electronegativity in the group. The hardness parameter is thus obtained as Equation (36). Thus two charge distribution calcula-

$$\eta_i = \frac{1}{2}\frac{\partial \chi_i\,(r_i,q_i)}{\partial q_i} \approx \frac{1}{4}\frac{\chi_i\,(r_i^+,\ q_i^0+\Delta q_i)-\chi_i\,(r_i^-,\ q_i^0-\Delta q_i)}{\Delta q_i} \qquad (36)$$

tions are necessary for the group, one with the orbital charge $q_i^0 + \Delta q_i$ to determine r_i^+ and another with $q_i^0 - \Delta q_i$ to determine r_i^-. We have found $\Delta q = 0.1$ to be adequate for the determination of the hardness of a free orbital of a molecular group.

Two problems with the charge distribution calculations should be mentioned. 1) When double or triple bonds are considered, σ and π bonds must be treated together as a localized four or six electron bond with the suitably averaged corresponding b and c parameters, otherwise σ donation and concomitant π back donation become unreasonably amplified. 2) When for the molecules under consideration two or more energetically equal or nearly equal Lewis resonance structures can be drawn, a charge distribution calculation should be performed for each of the resonance structures, and the results suitably averaged. This enables conjugation to be included in a localized orbital description; however, it introduces the ambiguity of the relative weights of these structures in the case of energetically nonequal resonance structures. We have found that for different, reasonably chosen weights, the results are not significantly different.

The theoretical development of the concept of orbital-electronegativity and of electronegativity equalization in a bond can be closed at this point. There are a number of other suggestions in the literature for the determination of partial charges in a molecule through partial[94] or complete[91, 95–100] electronegativity equalization in a molecule. The extent to which these empirical concepts, based on the paradigm that atomic properties (here spectroscopic data to which these of atoms) determine the properties of the molecules formed from these atoms, are useful remains to be demonstrated. To this end it is necessary to find reliable correlations of the computed orbital electronegativities and charge distributions with other results, preferably with molecular properties that can be determined experimentally.

5. Prediction of Molecular Properties

In this section we report some of our results using the concepts and atomic data presented in Sections 3 and 4. Obviously, the correlations we have found between the computed results and experimental data can be used in turn to predict as yet unknown data. Our main interest has been to obtain molecular structure data to use in the parameterization of molecular mechanics models,[101–108] with the aim of reducing the number of seemingly independent parameters in these models. We are sure that a number of additional useful correlations can and will be found in the future.

5.1. Charge Distribution in Molecules

Solving Equation (35) for electronegativity equalization in localized bonds for all the bonds in a molecule, in conjunction with Equations (27), (28), and (34), yields partial atomic charges for all the atoms in the molecule. The procedure is simple, and only primary and secondary atomic data are required together with the Lewis structure of the molecule. In addition, group electronegativity and hardness parameters can be obtained for molecular fragments. Unfortunately, the values for the partial charges in a molecule cannot be determined directly by experiment in order to validate these empirical concepts. The distribution of partial charges in a molecule is related to the uniquely defined charge distribution function $\rho(\boldsymbol{r})$, the first-order reduced electron-density function that is given for an n-electron system by Equation (37) in terms of the elec-

$$\rho(\boldsymbol{r}) = n\int d\sigma_1\, d\tau_2 \ldots d\tau_n\, |\,\Psi(\tau_1 \ldots \tau_n)\,|^2 \qquad (37)$$

tronic wave function of the specific state of the system. Here the integration is over the spin coordinate σ_1 of one electron and the space-spin coordinates τ_i of all the other electrons. To obtain the density function in this way, a full quantum-mechanical electron-structure calculation or a density-functional calculation for the molecule is required. In principle, the charge-distribution function of a molecule could also be determined experimentally with X-ray or electron scattering; however, the resolution obtained today with these methods is not yet satisfactory. Moments of the charge distribution (dipole or quadrupole moments of molecules) are more readily accessible.

But even if the full charge distribution function $\rho(\boldsymbol{r})$ is known, there seems to be no unique way yet to partition the charge distribution into its atomic contributions and thus obtain partial charges, so useful in the interpretation of molecular properties. The problem lies in the difficulty of assigning regions of space to the constituent atoms in a molecule. Several suggestions have been made for such a partition.[109–120] Most, with the exception of that made by Bader[121, 122] (its physical significance has not been established yet), are not unique. All these procedures require initially a full quantum mechanical characterization of the molecule, after which a charge distribution analysis seems to be of limited additional value.

Because of these difficulties, a comparison of the partial charges obtained simply and empirically (using atomic properties and the concepts outlined above) with results from ab initio calculations provides only limited validation of the empirical concepts used. Though a correlation between the partial charges obtained by us and by the more strictly "ab initio" methods is, in general, satisfactory,[81] the absolute values are frequently quite different. It seems more useful to compare molecular properties that can be determined directly by experiment, and which are expected to be related to partial charges, with the data obtained simply from the atomic properties. If the concepts can then be validated, they can be considered to be a useful operational definition of the partial charges in a molecule. In addition, relations are obtained that permit the prediction of observable molecular properties from atomic data.

5.2. ESCA Chemical Shifts

The observed ESCA chemical shifts ΔE relative to some reference compound are, according to the potential model, expected to correlate with partial atomic charges Q according to Equation (38),[124] where R_{AB} is the distance between nucleus A, the

$$\Delta E = c_1 Q_A + c_2 \sum_{B \neq A} \frac{Q_B}{R_{AB}} + c_3 \quad (38)$$

K-shell energy of which is observed, and the other nuclei in the molecule. The coefficients c are global adjustable parameters, and the value of c_3 is determined by the reference used.

We have used Equation (38) to fit 37 observed chemical shifts relative to methane for the carbon atoms of a number of molecules to partial charges computed as outlined above. In the data presented in Table 2, the carbon atoms giving rise to the reported K-shell shift are underlined. In the case of hexafluoro-

Table 2. ESCA C_{1s} shifts in eV, relative to CH_4.

cyclobutene the four connected carbon is signified by the symbol te and the three-connected one by tr. The resulting fit with a correlation coefficient of $r = 0.984$ and a standard deviation of $s = 0.56$ eV, is quite satisfactory (Fig. 1). The parameters obtained are $c_1 = 20.4$ V, $c_2 = -5.6$ VÅ, and $c_3 = 1.77$ eV. These, together with the partial charges computed simply from atomic data, can thus be used in Equation (38) to predict quite reliably carbon chemical shifts relative to methane. Similar results from fewer data have been obtained earlier by Gasteiger and Marsili,[94] who also used partial electronegativity equalization in the bonds to compute the partial charges.

5.3. Proton Affinities

The proton affinity PA of a species M in the gas phase is defined as the enthalpy of the reaction (39), which is difficult to measure directly for most systems. However, relative proton

$$MH^+ \rightleftharpoons M + H^+ \quad (39)$$

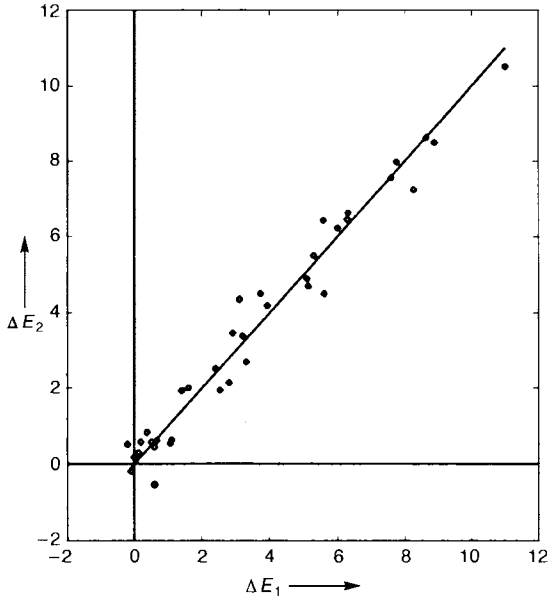

Fig. 1. Correlation of the experimentally determined ESCA C_{1s} shifts (ΔE_1) in eV with computed values (ΔE_2).

affinities are more readily accessible, and based on some absolute measurements Lias et al.[124] have compiled "absolute" values for more than 700 compounds. As the enthalpy of the reaction (39) represents the energy of association between a proton and a Lewis base—in the case of amines the nonbonding electron pair on nitrogen—we expect a correlation with the computed orbital electronegativities $\chi(-2)$ [Eq. (40)] of the corre-

$$PA = a + b\chi(-2) \quad (40)$$

sponding doubly occupied lone pair orbitals. We have fitted this equation to the experimental proton affinities (PA) of those species that have as basic center a lone electron pair on nitrogen and the computed orbital electronegativities of this doubly occupied lone pair ($\chi(-2)$). The simple correlation found from the data reported in Table 3 is reasonably good (correlation coefficient of $r = 0.93$ and a standard deviation $s = 27$ kJ mol^{-1}). The parameters for the nitrogen-containing bases are $a = 966$ kJ mol^{-1} and $b = -59$ kJ mol^{-1} V^{-1}. An earlier attempt at a correlation with the partial charges on nitrogen was not as good,[84] which indicates the important effect of the hybrid character of the lone pair orbital on nitrogen on its basicity. Clearly the parameters a and b would be different for the basicity on atomic centers other than nitrogen.

5.4. Bond Distances

Fundamental to the understanding of the behavior of molecules is their structure, for which internuclear distances and in particular bond lengths are of prime importance. Several suggestions have been made for predicting such bond lengths from atomic data. In one of the earliest, simplest proposals, Pauling and Huggins[126] suggested that the bond length d_{AB} can be computed as the sum of the corresponding covalent radii r_A and r_B [Eq. (41)]. Since the covalent radius of an atom is defined by

$$d_{AB} = r_A + r_B \quad (41)$$

means of this tertiary atomic property, the corresponding values can be determined by fitting Eq. (41) to many molecular bond lengths. An improvement in the predicted bond lengths was obtained through the suggestion by Shomaker and Stevenson[127] [Eq. (42)] of including the bond contraction (due to the

$$d_{AB} = r_A + r_B - \beta \mid \chi_A - \chi_B \mid \tag{42}$$

ionic contribution in heteronuclear bonds) as the difference of the electronegativity of the bonded atoms, multiplied by one extra global parameter β. This suggestion has been explored in detail by Polansky and Derflinger.[128] They suggest different values for the parameter β, depending on the type of bond. More recently Sanderson[54] stipulated using radii that are adjusted for the partial charges on the respective atoms in Equation (40). He proposed that the atomic radii be expressed as a function of atomic charges by a truncated Taylor expansion [Eq. (43)]. Sanderson has obtained remarkably good results

$$r = r^0 + b\,Q = r^0 + \left(\frac{\partial r}{\partial Q}\right)_{Q=0} Q \tag{43}$$

with this approach; however, in addition to the covalent radii, it requires the derivatives (that is, the parameters b) as tertiary parameters for each atom. To avoid this doubling of the tertiary atomic parameters we introduce the notion that the parameters b, the partial derivative of the atomic radius with respect to the atomic charge, should be proportional to the softness, the inverse of the atomic hardness parameter. This yields Equation (44), in which c_0 and c_1 are two global parameters that are

$$\left(\frac{\partial r}{\partial Q}\right)_{Q=0} = c_0 + c_1 \frac{1}{\eta} \tag{44}$$

the same for all atoms. In addition, we found it important to use different radii for different hybrid orbitals on the atoms; thus for the orbital radii to be used in Equation (41), we obtain Equation (45) in which the index A_i signifies the hybrid orbital i

$$r_{A_i} = r^0_{A_i} + \left(c_0 + \frac{c_1}{\eta_{A_i}}\right) Q_A \tag{45}$$

on atom A. Using these radii in Equation (41), together with an additional term that accounts for the influence of the Coulomb attraction or repulsion of the partial charges on the bond length, yields the model (46) for bond lengths. The relevant radii and

$$d_{AB} = r^0_A + r^0_B + c_0\,(Q_A + Q_B) + c_1\left(\frac{Q_A}{\eta_A} + \frac{Q_B}{\eta_B}\right) + c_2\,\frac{Q_A Q_B}{(\eta_a + \eta_B)\,d_{AB}} \tag{46}$$

hardness parameters are those for the bond-forming orbitals. The last term, which accounts for the Coulomb interaction effect, introduces another global parameter c_2, as well as a nonlinearity. Fortunately, as this term, in general, is small though significant, it is sufficient to use merely the sum of the two covalent radii, as given by Equation (45), for d_{AB} in the denominator.

Equation (46) was fitted to bond-length data of 543 bonds[83] to determine the parameters, namely, the 51 covalent radii and the three parameters c_0, c_1, and c_2. The data was taken only from structures determined by spectroscopy in the gas phase,[129–132] because X-ray structures would include also packing effects, which are not part of this model. The bond lengths of the homonuclear diatomic molecules H_2 and F_2 and of the alkali metals were eliminated from the regression, as they deviate significantly from the sum of the covalent radii, probably due to a larger Coulomb repulsion of the atomic cores or lone pairs not included in Equation (46). The regression (Fig. 2) is excellent, with a correlation coefficient of $r = 0.997$, a standard error of $\sigma = 0.028$ Å, and a relative standard error of 1.3%.

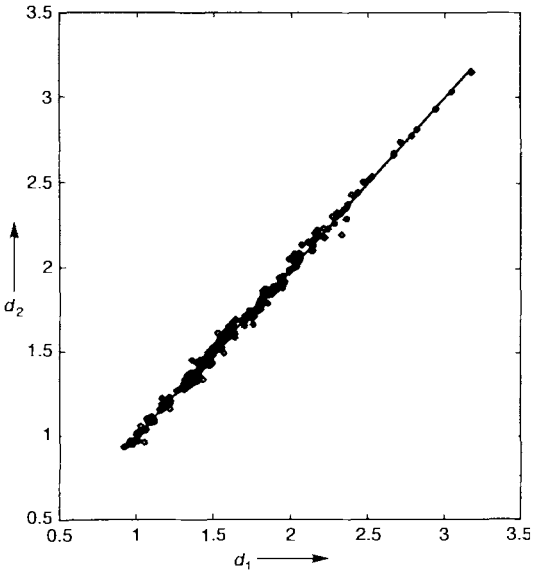

Fig. 2. Correlation between bond lengths in Å determined by experiment (d_1) and those computed with Equation (46) (d_2).

The calculated covalent radii of the orbitals and the three c parameters are compiled in Table 4. Note the different covalent radii for the same atom, depending on the hybrid used in bond formation, as well as on double or triple bonds formed. The data of this table, together with the orbital hardness and the partial charges, can be used in Equation (46) to predict bond length with an error of less than 2%. If just the sum of the covalent radii of the appropriate orbitals were employed, the error would be about 5%.

5.5. Force Constants for Stretching Vibrations

The last, nonlinear term in Equation (46) for the bond lengths has its origin in the VB analysis presented by Polansky and Derflinger.[128] Their analysis led to the suggestion that the sum of the covalent radii should be corrected by a term dependent on the force constant. The bond length is then approximated by Equation (47) in which f_{AB} is the force constant for the stretching vibration. We obtained the last term in Equation (46) by identifying $-\lambda^2 e^2$ with the product of the partial charges $Q_A Q_B$, and by relating the force constants to the orbital hardness parameters as in Equation (48), where c is again a global parameter.

$$d_{AB} = r_A^0 + r_B^0 - \frac{\lambda^2 e^2}{f_{AB} d_{AB}^2} \quad (47)$$

$$f_{AB} = c\frac{\eta_A + \eta_B}{d_{AB}} \quad (48)$$

The correlation between experimental force constants for 65 bonds[128] and those determined with Equation (48) from the orbital hardness parameters of the appropriate atomic orbitals is displayed in Figure 3. The correlation coefficient of $r = 0.98$ is resonably good. The global parameter in Equation (48) is determined to be $c = 0.5$ mdyn e V^{-1} if the force constants are given in mdyn Å^{-1}. In view of the difficulties and uncertainties in the experimental determination of force constants for stretching vibrations the relation (48) can be used effectively in the interpretation of IR spectra, as well as a basis in molecular mechanics force fields.[83]

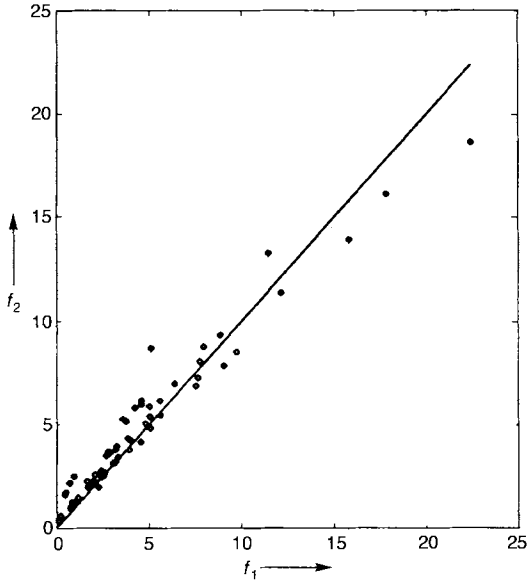

Fig. 3. Correlation between the measured (f_1) and calculated force constants (f_2) in mdyn Å^{-1} for the bond A–B.

5.6. Bond Dissociation Energies

A relation between bond dissociation energies and electronegativity is to be expected on the basis of Pauling's original definition of electronegativity involving the extra ionic resonance energy.[33] As the orbital electronegativity values can be determined directly from spectroscopic data of atoms, it seems natural to use these values for the prediction of bond dissociation energies. Thus, using relation (26) for the extra ionic resonance energy, we have obtained a good fit for the relation (49),

$$D_{AB} = \tfrac{1}{2}(D_{AA} + D_{BB}) + c_3\frac{(\chi_A - \chi_B)^2}{4(\eta_A + \eta_B)} + c_4\frac{Q_A Q_B}{d_{AB}} \quad (49)$$

which is in close accord with Pauling's original suggestion except for the last term, which accounts for the contribution of the Coulomb attraction or repulsion to the bond energy. In the various models tested,[83] this term was found to be essential, particularly in those cases where the bond is between two identical groups, for example the N–N bond or the O–O bond in molecules like N_2H_4 or H_2O_2. In those cases the extra ionic resonance energy would be zero, whereas the Coulomb term can be quite large.

The correlation between the experimentally determined[133] bond dissociation energies and those obtained with Equation (49) is displayd in Figure 4. The correlation (coefficient $r = 0.987$) is quite good. The standard error $\sigma = 5$ kcal mol^{-1} is satisfactory for such a simple relation. The covalent bond dissociation energies determined in this fit, which are tertiary atomic data, are presented in Table 5, together with the values for the global parameters c_3 and c_4. The covalent bond dissociation

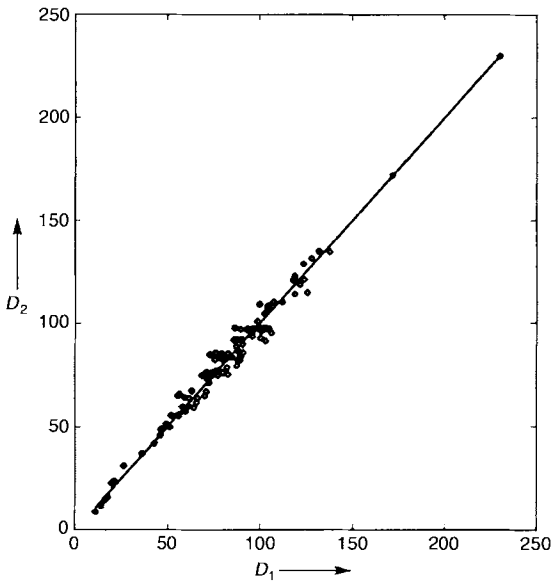

Fig. 4. Correlation between the experimental (D_1) and calculated bond dissociation energies (D_2) in kcal mol^{-1} for the bond A–B.

Table 5. Bond dissociation energies for homonuclear bonds in kcal mol^{-1} and the parameters c_3 and c_4 [Eq. (49)].

Atom	Type of hybrid orbital	D_{AA}	Atom	Type of hybrid orbital	D_{AA}	Atom	Type of hybrid orbital	D_{AA}

I	p	37.1						
$c_3\left(\frac{\text{kcal}}{\text{mol}\cdot\text{eV}}\right)$		18.51	$c_4\left(\frac{\text{kcal}\cdot\text{A}}{\text{mol}\cdot\text{e}^2}\right)$		−451.4			

energies given are again specific for the type of atomic hybrid orbital used in bond formation. The uncertainty in the values presented is about 4 kcal mol^{-1}, except for C(tr) where the statistical fit yielded $D_{AA} = 75.455$, which is unreasonably low. The reason for this discrepancy can be traced to the fact that the data set available contained only four C–H bonds of this type and three were aldehydes for which a rather low C–H bond energy is given. It is important to realize that, in general, the correction terms accounting for the ionic contributions to the bonds and containing the partial charges in Equation (49) for the dissociation energies and in Equation (46) for the bond length are small, unless the bonding is rather ionic. It is therefore frequently adequate to estimate these corrections for the partial charges on chemical grounds, alleviating the need for their detailed calculation.

6. Conclusion

We have reviewed the concept of orbital electronegativity and hardness, so widely used in the qualitative description of chemistry, and shown how the electronegativity and hardness values for most atoms of interest can be obtained from primary atomic data (spectroscopic data of atoms) provided the concept of atomic orbitals and valence states is used. On the assumption of electronegativity equalization in a bond, it has been possible to determine partial charges on the atoms in a molecule. Reasonable correlations have been obtained between these partial charges and molecular properties such as ESCA data and proton affinities. We anticipate that more such correlations that will be useful for the prediction of molecular properties can be found.

With the additional introduction of tertiary atomic properties such as covalent radii and bond energies, simple models were obtained which are remarkably reliable for the prediction of bond distances, force constants, and bond dissociation energies. In these models the atomic electronegativity and hardness parameters are used in conjunction with the partial charges computed from these values. It is surprising and encouraging how well the experimental data are represented by these simple, zeroth-order models, even though lone pair repulsions and van der Waals and Coulomb interactions of next nearest neighbors are not yet included. This can be done in calculations of molecular mechanics type in which the force field parameters can be derived by and large from the concepts based on the atomic properties presented in this review. Such an effort promises to yield a reliable force field, even though it contains many fewer parameters than the force fields in use today, and what is equally important, most of these parameters are based on atomic properties that can be ascertained experimentally for the free atoms. Thus it appears that to a large extent the molecular properties are determined by the properties of the constituent atoms—the relations have merely to be found. It can be hoped that extensive studies along these lines in the future, with much larger data bases, will yield not only more such relations, but also refinement of the models presented, without complicating them unduly.

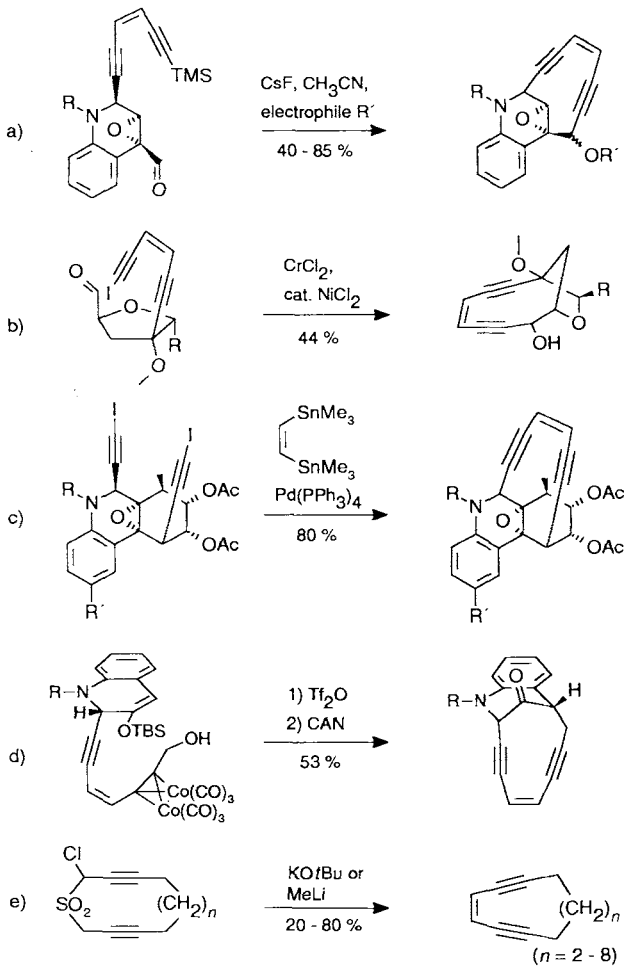
New, Efficient Routes to Cyclic Enediynes

Burkhard König*

The special fascination of strained cyclic enediynes lies in their intrinsic tendency to undergo thermal cyclization. This aspect has been stimulating the research on enediynes since its beginnings more than 20 years ago,[1] and it is this reactivity of the enediyne structure that brings about the pharmacological effectiveness of natural products like dynemicin A.[2]

The synthesis of an enediyne parent system calls for mild conditions with, at the same time, a strong driving force for the ring closure reaction. Various approaches have been taken to generate strained cyclic enediynes. Scheme 1 summarizes the major ones: Most often, an acetylide carbonyl addition is used as the ring closure reaction (Scheme 1, routes a and b).[3] Danishefsky et al., however, efficiently obtained highly substituted, 10-membered enediyne cycles by two-fold palladium-catalyzed coupling of iodoacetylene with *cis*-1,2-bis(trimethylstannyl-ethylene) (route c).[4] Substitution reactions can yield 10-membered enediyne cycles as well, though only after the ring strain has been reduced (route d).[5] In contrast to ring closure, Nicolaou et al. employed a ring contraction of cyclic sulfones to synthesize strained cyclic enediynes (route e).[6]



Scheme 1. CAN = cerium ammonium nitrate

Jones, Huber, and Mathews now could demonstrate that strained cyclic enediynes are accessible via carbenoid intermediates, too.[7] Their method is based on a sequence of tandem carbenoid coupling and elimination of two propynylic bromide units, a strategy published last year by the same group:[8] Here the synthesis of the acyclic enediyne bis(trimethylsilyl)hexadiyne (**3**) was achieved by reaction of trimethylsilylpropynylic bromide (**1**) with lithium hexamethyldisilazide (LiHMDS) in THF/HMPT (HMPT = hexamethylphosphoric triamide) at $-85\,^{\circ}C$. A *cis*–*trans* selectivity of about 2:1 was attained with good yields. Probably, a propynylic carbene is formed, which can insert intermolecularly into the C–H bond of another propynylic bromide. The E2 elimination of HBr from the intermediate bromide **2** then leads to the product. As this method proved to be broadly applicable for substituted propynylic substrates, Jones et al. even had it patented.[9] Recently still more highly substituted acyclic enediynes like **4** and **5** were obtained with this approach.[10]

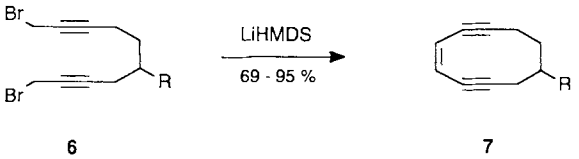
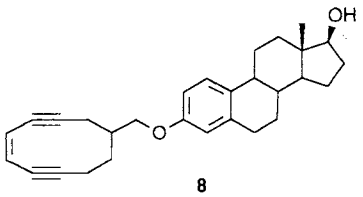
The intramolecular variant of this synthesis renders cyclic enediynes. Ten-membered functionalized enediyne cycles (**7**) were generated in yields of up to 95% using slightly altered reaction conditions. Since the starting materials are easily accessible, a synthesis of enediynes in multigram scale can be achieved. Thus, it should be possible to use these functionalized enediyne components to build libraries of enediyne diversomers by the approach of Nicolaou and others.[11] As Jones et al. stated, enediyne steroid conjugates like **8** have been synthesized already.[10]



6 **7**



8

Starting from the propynylic bromide **9**, Hopf, Werner, et al. successfully synthesized an only 8-membered cyclic aryl-1,2-diyne (**10**).[12] The remarkably stable molecule was obtained by cyclization with $Bu_3SnSiMe_3/CsF$[13] in 60% yield.

9 **10**

With the mechanistically interesting new approaches described here, the spectrum of methods for the synthesis of strained cyclic enediynes could be enlarged markedly. It is to be expected that the search for simple pharmacologically active enediyne derivatives will benefit accordingly.

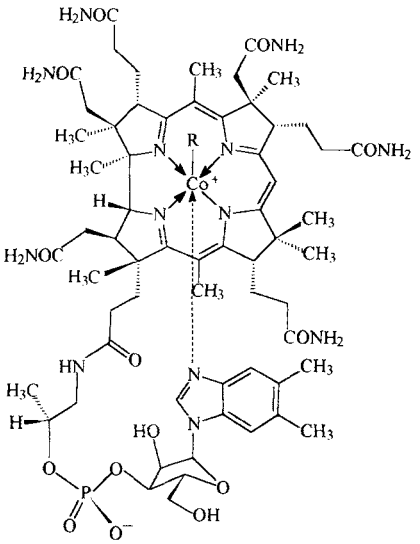
Vitamin B_{12}: The Haze Clears**

Bernhard Kräutler* and Christoph Kratky*

Dedicated to Professor Albert Eschenmoser on the occasion of his 70th birthday

First isolated nearly 50 years ago, the corrinoid cobalt complex vitamin B_{12} (Scheme 1) continues to be an extraordinarily fascinating compound to chemists, biologists, and physicians. Particularly striking among the several hundred proteins whose



Scheme 1. Structural formulas of vitamin B_{12} derivatives. R = CN: vitamin B_{12}; R = CH_3: methylcob(III)alamin; R = 5'-deoxy-5'-adenosyl: coenzyme B_{12}; R = e^-: cob(II)alamin.

three-dimensional structures were elucidated to atomic resolution last year was the X-ray structure analysis of the B_{12}-binding domain of the (cobalamin-dependent) methionine synthase (a methyl transferase) of *Escherichia coli*.[1, 2] It provided insight into the structure of a B_{12}-binding protein for the first time and revealed quite an unexpected facet of B_{12} chemistry: In this particular protein, a histidine imidazole provided by the peptide chain substitutes the nucleotide function of B_{12}, which coordinates in axial position in solution (see Fig. 3). The dramatic constitutional difference between isolated B_{12} and protein-bound B_{12} casts new light upon the importance of the typical and unique benzimidazole function of the nucleotide-containing B_{12} derivatives. Besides the corrin ligand, it is indeed the nucleotide function that gives the B_{12} derivatives their outstanding position among the porphinoid cofactors.[3]

The pseudo-nucleotide function attached covalently at the periphery of the "complete" corrinoids like that of vitamin B_{12} and other cobalamins always coordinates intramolecularly and in a structurally regular pattern. The intramolecularly coordinating and bulky nucleotide function has recently been shown to cause an increased upward folding of the corrin ligand,[4, 5] a finding of particular interest with regard to the still enigmatic enzymatic activation of coenzyme B_{12} (see, for example, Ref. [6]). Nowadays, a distinct acceleration of the homolysis of the organometallic bond of the protein-bound coenzyme B_{12} is generally considered a crucial prerequisite for the B_{12}-catalyzed enzymatic radical reactions (reviewed in, for example, Refs. [6,7], Fig. 1).

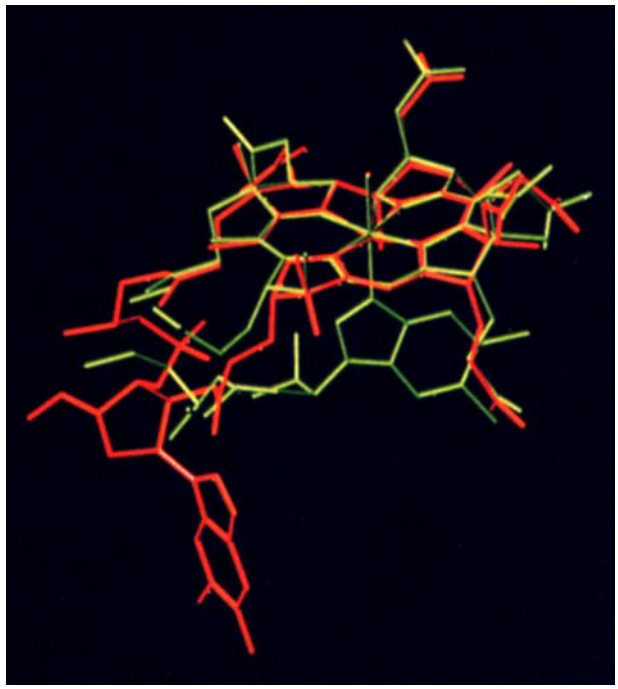


Fig. 1. Superposition of the structures of methylcob(III)alamin in the single crystal ("base-on", green) and in the B_{12}-binding domain of the methionine synthase of *Escherichia coli* ("base-off", red).

On account of the X-ray analysis of the structure of the cobalamin-binding domain of the methionine synthase of *Escherichia coli*[1, 2] published by Drennan, Huang, Drummond, Matthews, and Ludwig, all previous views on the biological role of the intramolecularly binding benzimidazole functions in "complete" vitamin B_{12} derivatives had suddenly to be reconsidered: The investigated 27 kDA segment of the 136 kDa methionine synthase is not able to catalyze the methyl transfer by itself, but

it does bind methylcob(III)alamin. This organometallic corrinoid cofactor is not bound in its "base-on" constitution known from investigations in solution and in single crystals.[8] Instead, and with the help of an external (protein-based) imidazole function as an axial ligand, methylcob(III)alamin is bound in a previously unknown "base-off" form (Fig. 1). In the methionine synthase the imidazole substitute mimics the electronic properties of the coordinating nucleotide function so well that this particular constitutional change was not recognized in earlier ESR and UV/Vis spectra of the holoenzyme.[9]

The methionine synthase of *Escherichia coli* catalyzes the formation of tetrahydrofolate and methionine from N^5-methyltetrahydrofolate and homocysteine. It therefore catalyzes the transfer of a methyl group, which (formally!) occurs by transfer of a methyl cation. This methyl group transfer most probably takes place as a sequence of two nucleophilic substitution steps (Fig. 2), since an overall stereochemical retention (corresponding to a twofold stereochemical inversion) has been established in investigations with isotopically labeled N^5-(HDT)methyltetrahydrofolate (see, for example, Ref. [9]).

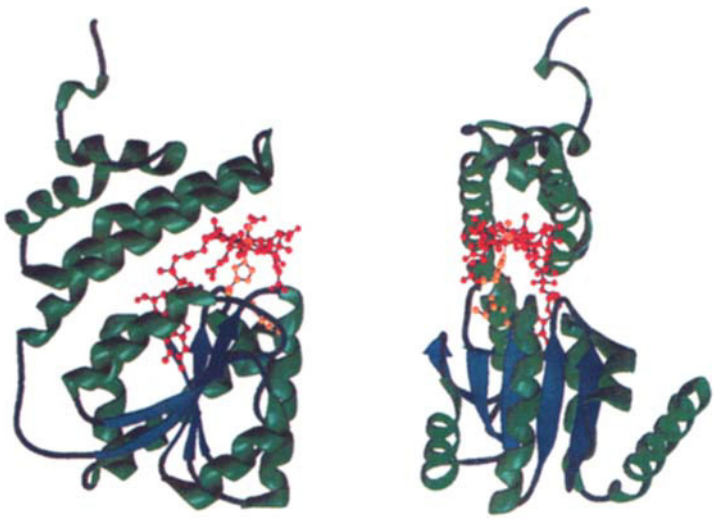

Fig. 3. The cobalamin-binding domain of the methionine synthase of *Escherichia coli* according to Drennan et al. [1, 2]: Ribbons diagrams of the protein part highlighting the amino acid triade His-759, Asp-757, and Ser-810, and the methyl-Co^{III} center (yellow) of the bound methylcob(III)alamin in the "base-off" form (red).

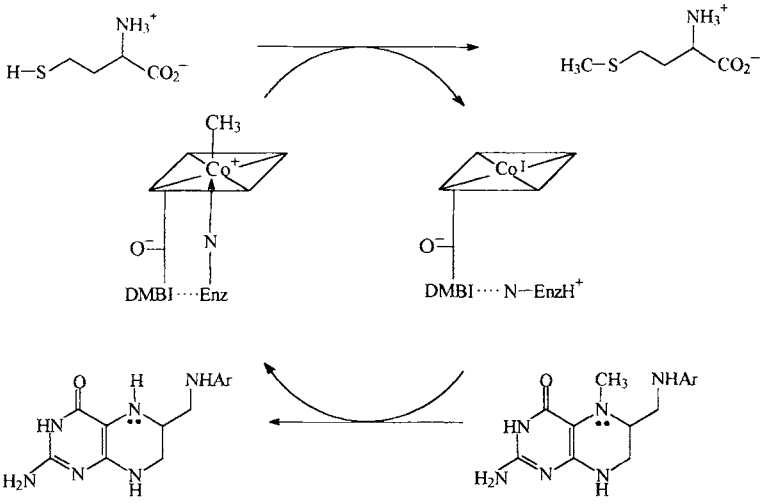

Fig. 2. Schematic representation of the cobalamin-dependent biosynthesis of methionine in *Escherichia coli*: methyl group transfer from N^5-methyl-tetrahydrofolate to homocysteine via enzyme-bound methylcobalamin and cob(I)alamin (DMBI = 5,6-dimethylbenzimidazole).

In the catalytic cycle, the protein-bound corrinoid occurs either as the (now) structurally known, enzyme-bound methylcob(III)alamin or as the oxidation-susceptible and highly nucleophilic cob(I)alamin. Although there is yet little known about the structure of the latter (even in solution), there is evidence that the metal center of cob(I)alamin does not carry any axial ligands. As a consequence, the transition between cob(I)alamin and methylcob(III)alamin (with a hexacoordinate Co^{III} center) implies considerable reorientation at the site of the axial ligand, which allows the enzyme environment to influence the reactivity of the cobalt corrin.[10]

The peptide moiety of the cobalamin-binding fragment of the methionine synthase is essentially composed of two domains (Fig. 3): a "helix bundle" consisting of four antiparallel helices covering the methylated "upper side" of the protein-bound corrinoid, and an α/β-domain, consisting of six α-helices and β-sheets, whose tertiary structure resembles the so-called "Rossmann fold" of nucleotide-binding proteins.[1, 2] The nucleotide function of the protein-bound cobalamin is anchored in a pocket of the α/β-domain. This domain also provides the cobalt-coordinating histidine (His-759), the functional substitute for the nucleotide. His-759 is linked by a hydrogen bond *syn* to an adjacent aspartate (Asp-757) which, in turn, is linked to a serine (Ser-810) by an *anti* hydrogen bond (Fig. 4)

The methionine synthase of *Escherichia coli* contains the new catalytically active tetrade composed of cobalt corrin, histidine, aspartate, and serine (cf. Figs. 3 and 4).[1, 2] Its catalytic activity is mainly due to the reactivity of the cobalt corrin. However, the contribution of the three H-bonded amino acids to the catalysis of the methyl group transfer is not insignificant, considering the important role the axial imidazole ligand plays in methylation equilibria with methyl corrinoids:[11] The stabilization the enzyme experiences in the methylated state (or in the Co^{II} state) on account of the cobalt coordination of His-759 counteracts the tendency to demethylate or reduce to the Co^{I} state.[10] According to electrochemical investigations on intact methionine synthase, the Co^{II}/Co^{I} reduction of the enzyme-bound corrinoid occurs at a potential that is more than 100 mV less negative (relative to the corresponding redox step in aqueous solution) and involves the net uptake of a proton. This indicates a destabilization of the Co^{II} state of the methyl transferase with respect to its Co^{I} state and relative to the redox pair cob(II)alamin/cob(I)alamin in solution. Build-up of strain accompanying the axial histidine coordination might result in loss of the imidazole ligand during demethylation (or reduction) to cob(I)alamin and might be one plausible explanation for the susceptibility to reduction of the protein-bound Co^{II} corrinoid. The actual evidence (deviation from the geometrically ideal bonding of histidine to cobalt and of the two bridging protons to Asp-757) is, however, not conclusive on account of the low nominal resolution of the structure analysis of the B_{12}-binding domain of the methionine synthase.

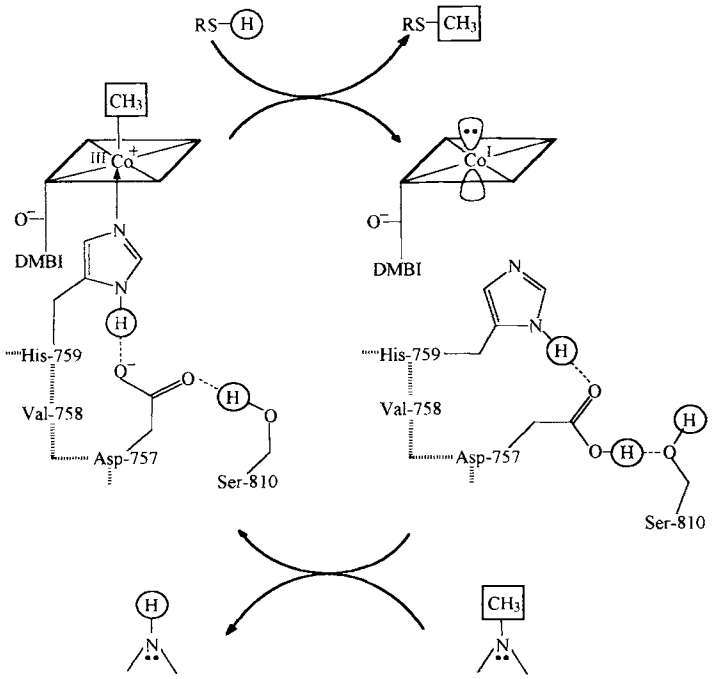

Fig. 4. The catalytically active tetrade of the methionine synthase, enzyme substrates, and products of the methyl transfer steps in a schematic representation, emphasizing potentially relevant stereoelectronic preferences for the formation of hydrogen bonds.

As suggested by Drennan et al., the enzyme-catalyzed methylation of homocysteine to methionine, which implies the demethylation of the protein-bound cofactor from methylcob(III)alamin to cob(I)alamin, involves uptake of a proton by the enzyme.[1, 2] In reverse, the enzyme-catalyzed demethylation of N^5-methyl-tetrahydrofolate to tetrahydrofolate occurs with net release of a proton from the enzyme, whose cofactor is methylated from cob(I)alamin to methylcob(III)alamin during this step. According to Drennan et al. these (hypothetical) protonation and deprotonation steps of the enzyme take place through the amino acid triade His-759, Asp-757, and Ser-810, which stretches from the cobalt center of the protein-bound cofactor to the surface of the B_{12}-domain.

No doubt, the assumed effect of the amino acid triade His-759, Asp-757, Ser-810 on the methyl transfer[12] has to do with the critical axial coordination of the protein-based imidazole ligand (of His-759), and with the structural reorganization occurring during its (de)coordination. However, the ability of His-759 to coordinate depends decisively on the state of protonation:[13] If the protonation of the His-759/Asp^--757 pair leads to $HisH^+$-759/Asp^--757, it completely eliminates the ability of His-759 to coordinate. The nucleophilicity of the imidazole ligand is also reduced when the protonation leads to neutral residues at His-759/Asp-757, as suggested by Drennan et al.[1, 2] Besides, the protonation of the His-759/Asp^--757 pair may lead to a substantial reorientation of the amino acids involved and may therefore indirectly influence the ability of His-759 to coordinate at the cobalt corrin. Indeed, the stereoelectronic preference for the protonation of aspartate at its more basic *syn* lone pair cannot be taken into account unless a change of conformation is postulated, if two hydrogen bonds are to be maintained to His-759 and to Ser-810 (cf. Fig. 4). The role of the H-bonded amino acid triade of the methionine synthase of *Escherichia coli* is therefore potentially that of a "switch" controlled by the degree of protonation and regulating, electronically and conformationally, the "base-on" or "base-off" states of coordination at the cobalt center.

The methionine synthase contains, in the α/β domain, two central amino acids (His-759 and Asp-757) among several other "conserved" amino acids and shows sequence homologies with B_{12}-binding proteins, even with some that use coenzyme B_{12} (adenosylcob(III)alamin) instead of methylcob(III)alamin as cofactor.[14, 15] The expectation that the cofactor of coenzyme B_{12}-binding enzymes might also be bound in a "base-off" form has actually been confirmed for the coenzyme B_{12}-dependent methylmalonyl-CoA-mutase of *Propionibacterium shermanii*.[16, 17] The publication by Phil Evans's group[17] of an X-ray analysis of this enzyme is anticipated in the near future.

The first evidence for cobalt coordination of histidine at a protein-bound "complete" corrinoid was supplied by ESR-spectroscopic data of Stupperich et al.[18] for preparations of the acetogenic bacterium *Sporomusa ovata*, which, however, produces a *p*-cresolylcobamide whose pseudo-nucleotide function is not able to coordinate at cobalt. A *p*-cresolylcobamide-binding protein from *Sporomusa ovata* could be crystallized, and an X-ray structure analysis is presently under way.[19]

Coenzyme B_{12} and the less complex methylcob(III)alamin were the first and only well-documented organometallic coenzymes to be discovered. Their biological functions are closely connected with their organometallic bond. The control and catalysis by the protein of the homolytic cleavage and formation of this bond are relevant for coenzyme B_{12},[20] whereas activation of the corresponding heterolytic reactions are important for methylcob(III)alamin. According to the present state of knowledge, the enzymatic acceleration of the homolysis of the organometallic bond of coenzyme B_{12} can be traced to mechanical steric factors,[6, 7] and the enzyme-catalyzed heterolysis of methylcob(III)alamin to electronic factors.[10]

In spite of the knowledge on the structure of the cobalt complex vitamin B_{12}, the biological function of the corrinoids remained an enigma until the organometallic bond of coenzyme B_{12} was discovered. Similarly, only the X-ray structure analysis of the methionine synthase led to a fundamental broadening of the views on the B_{12} derivatives. Earlier information on the structure of nucleotide-containing B_{12} derivatives obviously concerns molecular transport and storage forms of these unique cofactors, which possess a remarkable potential for self-constitution and have thermodynamically propitious structural properties.[3] Particularly striking among the latter is the structure of the unique nucleotide "loop" which, interestingly enough, plays no functional role in the methionine synthase of *Escherichia coli*. In this particular enzyme the cobalamin cofactor occurs as a special "dinucleotide", which contains, besides a catalytically active moiety of the molecule, a second nucleotide portion that is relevant for the bonding to the apoenzyme. This portion is characterized by an α-configurated pseudo-nucleotide base, but in a B_{12}-specific way. The results presented above cast new light on the question of the biological functions of the intramolecular coordinating benzimidazole function.

$[(AsOH)_3(MoO_3)_3(AsMo_9O_{33})]^{7-}$ and $[(AsOH)_6(MoO_3)_2(O_2Mo\text{-}O\text{-}MoO_2)_2\text{-}(AsMo_9O_{33})_2]^{10-}$: Coupling of Highly Negatively Charged Building Blocks**

Achim Müller,* Erich Krickemeyer, Stephan Dillinger, Jochen Meyer, Hartmut Bögge, and Anja Stammler

Dedicated to Professor C. N. R. Rao on the occasion of his 60th birthday

The design of syntheses in the field of inorganic and supramolecular inorganic chemistry combined with the control of the fundamental reaction pathways would enable the targeted synthesis of complex mesoscopic structures—even with predetermined material properties—on the basis of economical reactions. The realization of this still utopian dream demands the elucidation of formerly largely unknown reaction mechanisms that are fundamental for the formation of large molecular species (for example metal clusters) within conservative self-organization processes and that, for example in the field of polyoxometalate chemistry, have provided an enormous structural diversity, which yields a variety of properties.[1–3] A fundamentally promising route appears to be the strategy of generating large, highly negatively charged (and therefore soluble) intermediates as transferable units in the reaction solution,[4] which can be trapped and stabilized or (!) coupled to each other by progressive condensation reactions by electrophilic protecting groups (for example, As^{3+} [4a] or *fac*-$\{MoO_3\}$ "anti-Lipscomb" units[4b, 5]). We have now succeeded in isolating the mixed-valent, diamagnetic cluster anions **1a** and **2a**, which are the first molybdoarsenates(III) with facial trioxomolybdenum units.

$[(AsOH)_3(MoO_3)_3(AsMo_9O_{33})]^{7-}$ **1a**

$[(AsOH)_6(MoO_3)_2(O_2Mo\text{-}O\text{-}MoO_2)_2(AsMo_9O_{33})_2]^{10-}$ **2a**

The dark blue, mixed-valent salts **1** and **2** were characterized by elemental analysis (including manganometric titration of Mo^V), thermogravimetric analysis (to determine the content of water of crystallization), spectroscopic methods (ESR, IR, UV/Vis, and NIR spectroscopy), and single crystal X-ray structure analysis.[6] The cluster anion **1a** consists of a highly negatively charged $\{AsMo_9O_{33}\}^{13-}$ Keggin fragment (Fig. 1) that is capped by a six-membered ring comprising three electrophilic $\{AsOH\}^{2+}$ and three facial $\{MoO_3\}^0$ units. These units are arranged alternately and linked together as well as to the Mo atoms of the nucleophilic, lacunary $\{AsMo_9O_{33}\}^{13-}$ unit through μ_3-O atoms. The indicated protonation of the terminal oxygen atoms bound in **1a** (and **2a**; see below) to the As^{III} centers is unequivocal from their bond valence sums,[7] the conditions of the synthesis (acidic reaction milieu), and the approximately equally long As-OH and As-μ-O bonds (Figs. 1 and 2).

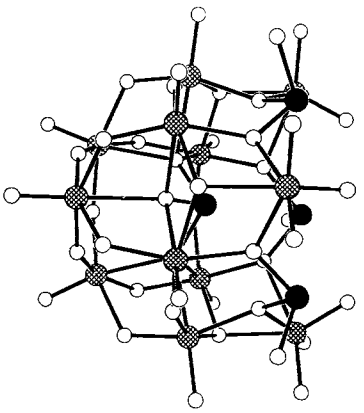

Fig. 1. Structure of the anion **1a** in crystals of **1** (Mo cross-hatched, As black, O white). Selected distances [pm]: Mo···Mo (edge-sharing) 333.7–343.5, Mo···Mo (corner-sharing) 365.6–367.0, Mo–O_{term} ($\{MoO_3\}^0$ units) 173.1–176.0, Mo–O_{term} ($\{AsMo_9O_{33}\}^{13-}$ unit) 167.1–170.3, As-OH 177.4, As-(μ_3-O)($\{AsOH\}^{2+}$ centers) 178.2–179.3, As–(μ_4-O) (central AsO_3 pyramid) 179.4.

Compound **1a** forms in aqueous solution at a pH value of about 4.5. However, if the same reaction is performed at a pH value of 3.0, the highly nucleophilic $\{AsMo_9O_{33}\}^{13-}$ groups react as their stable (trapped) product **1a** to give the "dimeric" cluster ion **2a** (see Fig. 2 and the reaction scheme in Fig. 3).

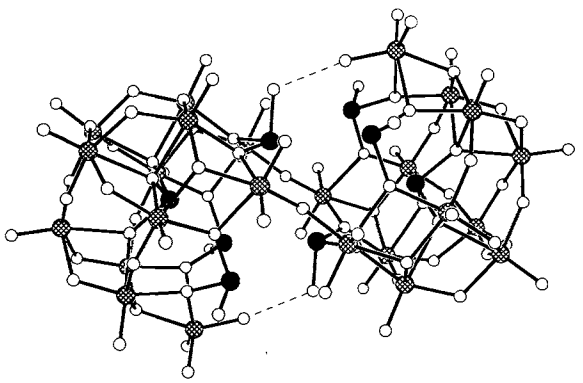

Fig. 2. Structure of the anion **2a** in crystals of **2** (Mo cross-hatched, As black, O white). The two *intramolecular* As^{III}-OH···O=$Mo^{VI}O_2$ hydrogen bonds are depicted as broken lines. Selected distances [pm]: Mo···Mo (edge-sharing) 329.6–347.0, Mo···Mo (corner-sharing) 364.4–368.1, Mo–O_{term} ($\{MoO_3\}^0$ units) 171.0–176.0, Mo–O_{term} ($O_2Mo\text{-}O\text{-}MoO_2$ bridges) 168.5–170.7, Mo–O_{term} ($\{AsMo_9O_{33}\}^{13-}$ unit) 167.4–170.1, As-OH 176.2–179.1, As-(μ_3-O)($\{AsOH\}^{2+}$ centers) 177.2–179.8, As–(μ_4-O) (central AsO_3 pyramid) 178.1–180.0.

According to this scheme, a condensation of four $\{Mo^{VI}O_3\}$ units takes place after protonation, and H_2O is evolved from **1a** on the formation of two $O_2Mo\text{-}O\text{-}MoO_2$ bridges. The two six-membered rings of **2a** therefore have only two facial $\{Mo^{VI}O_3\}$ groups. If at the same pH value a larger amount of As_2O_3 is added to the reaction solution, a further reaction of the remain-

$K_7[(AsOH)_3(MoO_3)_3(AsMo_9O_{33})]\cdot 15H_2O$ **1**

$K_{10}[(AsOH)_6(MoO_3)_2(O_2Mo\text{-}O\text{-}MoO_2)_2(AsMo_9O_{33})_2]\cdot 12H_2O$ **2**

ing trioxomolybdenum units of **2a** in the presence of trimethylammonium ions yields the cluster anion **3a** (cf. the reaction scheme in Fig. 3).[8] Cluster anion **3a** displays four links be-

$[(AsOH)_4(AsO)_2(HOAs\text{-}O\text{-}MoO_2)_2(O_2Mo\text{-}O\text{-}MoO_2)_2(AsMo_9O_{33})_2]^{8-}$ **3a**

tween the two $\{(AsOH)_3(MoO_3)_3(AsMo_9O_{33})\}^{7-}$ units, namely the Mo-O-Mo bridges familiar from **2a** and another two O_2Mo^{VI}-O-$As(OH)_{term}$-O-As bridges (Fig. 3).

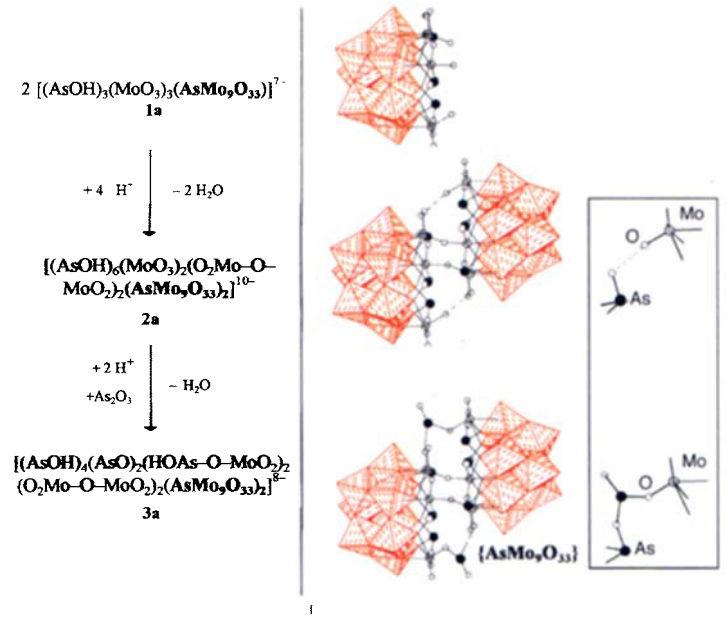

Fig. 3. Reaction scheme depicting the preparation of anions **1a**–**3a** and the linking of the fragments with emphasis on the identical $\{AsMo_9O_{33}\}^{13-}$ unit in each through polyhedral representation.

An important feature is the lone electron pair at the As^{III} center of $\{AsMo_9O_{33}\}^{13-}$ group in compounds **1**–**3** that prevents the adoption of a spherical structure, which can be formed on oxidation of this As^{III} center to an As^{V} center with concomitant rearrangement of the whole cluster framework and would lead to anions of the α-Keggin type with a central AsO_4^{3-} tetrahedron (cf. Ref. [8]).

The facial MoO_3 groups of the cluster anions **1a** and **2a** (that is, at exactly those positions at which further coupling and condensation reactions are possible after protonation) are stabilized by one hydrogen bond each between one of their terminal oxygen atoms and the OH function of the opposite $\{AsOH\}^{2+}$ unit (As^{III}-OH···O=$Mo^{VI}O_2$ distances of 264 pm for **1** and 257 pm for **2**). Whereas in cluster anion **2a** only two *intramolecular* As^{III}-OH···O=$Mo^{VI}O_2$ hydrogen bonds are present, in accordance with its low number of facial trioxomolybdenum units (cf. Fig. 2), every cluster anion in the crystal structure of **1** forms two *intermolecular* As^{III}-OH···O=$Mo^{VI}O_2$ hydrogen bonds to each of its three adjacent ions and therefore the maximal number (six) of such hydrogen bonds. The individual "monomeric" $[(AsOH)_3(MoO_3)_3(AsMo_9O_{33})]^{7-}$ units form a slightly distorted hexagonal closest packing in the crystal lattice and are arranged in such a way that the opening of a cluster anion, whose structure resembles a half-cleaved sphere with a central $As^{III}O_3$ group, points in the direction of the crystallographic *c* axis, while the corresponding openings of its three neighboring cluster anion spheres face in the opposite direction. This type of arrangement of the cluster anions **1a** in the crystal lattice gives rise to a two-dimensional double-layer structure.[9]

According to the results of titrimetric studies and bond valence sum considerations, the $\{AsMo_9O_{33}\}^{13-}$ groups of the cluster compounds **1**, **2**, and **3** have the same electron population (formally four Mo^{V} and five Mo^{VI} centers of type III according to Robin–Day): the number of electrons in 4d states per $\{AsMo_9O_{33}\}^{13-}$ fragment of the anions **1a**, **2a**, and **3a**[8] is always four, and the electrons are delocalized at room temperature[7] over all nine Mo centers of the $O{=}MoO_5$ octahedra that make up the $\{AsMo_9O_{33}\}^{13-}$ unit.

As conclusion the following is important: For otherwise identical reaction conditions, the selection of the reaction routes leading to **1** and **2** is determined exclusively by the different pH values of the reaction solution (**1**: 4.5; **2**: 3.0). One can therefore speak of a new synthesis principle in polyoxometalate chemistry, because ephemeral, highly reactive and otherwise inaccessible reduced, highly negatively charged clusters can be trapped by electrophilic protecting groups like $\{MoO_3\}$ and stabilized.[4b] The protecting groups can themselves cause further coupling of fundamental inorganic units under changed reaction conditions in the context of simple condensation reactions (after protonation at the oxygen atoms with high electron density). The assembly of these preorganized, transferable fundamental inorganic units that exist in aqueous solution to form higher nuclear molybdoarsenates like **2a**, which can be considered successful with respect to the deliberately selected reaction conditions (adjustment of the desired pH value) can be extended to other fields of polyoxometalate chemistry.[4] The interesting question arises whether the disorder (partial linking of units) is the trigger for the crystallization at the nucleation phase of **1**.

Experimental Procedure

1: $K_2MoO_4 \cdot 5H_2O$ (11.2 g, 34.1 mmol; Johnson Matthey), As_2O_3 (6.0 g, 30.3 mmol), and KSCN (20.0 g, 205.8 mmol) were dissolved in H_2O (400 mL) at 95 °C with stirring in a 500 mL Erlenmeyer flask (pH value of the clear solution about 6.2–6.5). After cooling to 85 °C, adjustment of the pH value to about 5.3 with 10% H_2SO_4, and subsequent addition of $N_2H_6SO_4$ (3.2 g, 24.6 mmol), the mixture was stirred for 4 min at this temperature. The pH value of the now deep blue solution was adjusted to about 4.5 with 10% H_2SO_4 (or 10% KOH depending on the resulting pH value) solution, and the reaction mixture rapidly cooled to 25 °C in a water bath. As_2O_3 that again precipitated was filtered off. Slowly, dark blue hexagonal crystals of **1** precipitate from the filtrate in a closed 500 mL round-bottomed flask at 5–7 °C. The As_2O_3 that also precipitates was suspended in the mother liquor by shaking and decanted from the crystals. This purification step was repeated with the filtered mother liquor until all the As_2O_3 had been removed. Yield: 5.8 g (77.7% based on $K_2MoO_4 \cdot 5H_2O$). Some characteristic IR bands (KBr disk; preparation under argon): $\tilde{\nu}$ [cm^{-1}] = 950(vs), 900(m) (Mo–O_{term}), 855(s), 840(s), 750(m), 625(s), 570(s), 540(sh) (As–(OH), As-O-Mo, Mo-O-Mo); UV/Vis (solid-state reflection spectrum with cellulose as white standard): λ [nm] = 315, 650, 790; NIR (KBr pellet, in transmission mode): λ [nm] = 1000, 1500.

2: As for **1** with one decisive difference: the pH value was adjusted to about 3.0 with 10% H_2SO_4 after the reduction with $N_2H_6SO_4$. Yield: 6.6 g (88% based on $K_2MoO_4 \cdot 5H_2O$). Some characteristic IR bands (KBr, preparation under argon): $\tilde{\nu}$ [cm^{-1}] = 950(vs), 910(w) (Mo–O_{term}), 845(m), 750(m), 740(sh), 700(w), 640(m), 560(s–m), 530(sh) (As–(OH), As-O-Mo, Mo-O-Mo); UV/Vis (solid-state reflection spectrum with cellulose as white standard): λ [nm] = 315, 620, 785; NIR (KBr pellet, in transmission mode): λ [nm] = 980, 1540.

[5] An important working hypothesis of polyoxometalate chemistry is that, in general, metal atoms bearing three or more terminal oxygen atoms in MO_6 octahedra do not occur. For this "Lipscomb rule" see W. N. Lipscomb, *Inorg. Chem.* **1965**, *4*, 132.

[6] Crystal data of **1**: space group $P\bar{3}$, $a = 1432.8(2)$, $c = 1829.8(3)$ pm, $V = 3253(1) \times 10^6$ pm^3, $Z = 2$, $\rho_{calcd} = 2.78$ g cm^{-3}, $T = 188$ K, $R = 0.083$ for 4533 independent reflections ($F > 4.0\sigma(F)$). Crystal data of **2**: space group $P\bar{1}$, $a = 1282.0(4)$, $b = 1380.3(4)$, $c = 1531.5(5)$ pm, $\alpha = 83.46(2)$, $\beta = 77.37(2)$, $\gamma = 68.92(2)$°, $V = 2466(1) \times 10^6$ pm^3, $Z = 1$, $\rho_{calcd} = 3.32$ g cm^{-3}, $T = 294$ K, $R = 0.067$ for 6614 independent reflections ($F > 4.0\sigma(F)$). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-59227. The cluster anion **2a** was also obtained as ammonium salt $(NH_4)_8[H_2(AsOH)_6(MoO_3)_2(O_2Mo\text{-}O\text{-}MoO_2)_2(AsMo_9O_{33})_2] \cdot 12H_2O$ (**4**).

[7] Calculated bond valence sums (according to I. D. Brown in *Structure and Bondings in Crystals, Vol. II* (Eds.: M. O'Keeffe, A. Navrotsky), Academic Press, New York, **1981**): **1a**: As 3.0, Mo ($\{AsMo_9O_{33}\}$ unit) 5.5, Mo ($\{MoO_3\}^0$ groups) 5.8, O (As-O-H) 1.0; **2a**: As 3.0, Mo ($\{AsMo_9O_{33}\}$ unit) 5.6, Mo ($\{MoO_3\}^0$ groups) 5.9, Mo ($\{O_2Mo\text{-}O\text{-}MoO_2\}$ groups) 5.85, O (As-O-H) 1.0.

[8] A. Müller, E. Krickemeyer, M. Penk, V. Wittneben, J. Döring, *Angew. Chem.* **1990**, *102*, 85; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 88.

[9] A precise examination of the structure of an individual crystal of **1** reveals the following disorder: One obtains a maximum of electron density "refinable" as 1/10 As between the oxygen atoms of the opposite $\{AsOH\}^{2+}$ and $\{MoO_3\}^0$ groups within a double layer. This can be interpreted as follows: in the statistical average, about every tenth of the $As^{III}\text{-}OH \cdots O{=}Mo^{VI}O_2$ hydrogen bonds is replaced by a covalent $As^{III}OAs(OH)_{term}\text{-}O\text{-}Mo^{VI}O_2$ bridge. These correspond to the $As^{III}OAs(OH)_{term}\text{-}O\text{-}Mo^{VI}O_2$ bridges in **3**; merely the relative position of the $\{(AsOH)_3(MoO_3)_3(AsMo_9O_{33})\}^{7-}$ units linked thereby is different. The oxygen atom of the terminal $(OH)_{term}$ group bound to this additional arsenic atom was also localized (found disorder: with water of crystallization and potassium ions). The mentioned disorder is more or less pronounced in different crystals of **1**, or not present at all. (We have performed X-ray crystal structure analyses on several single crystals of **1**.)

Synthesis of Chiral 1,1′-Iminodicarboxylic Acid Derivatives from α-Amino Acids, Aldehydes, Isocyanides, and Alcohols by the Diastereoselective Five-Center–Four-Component Reaction

Anton Demharter, Werner Hörl, Eberhardt Herdtweck, and Ivar Ugi*

Dedicated to Professor Paul von Ragué Schleyer

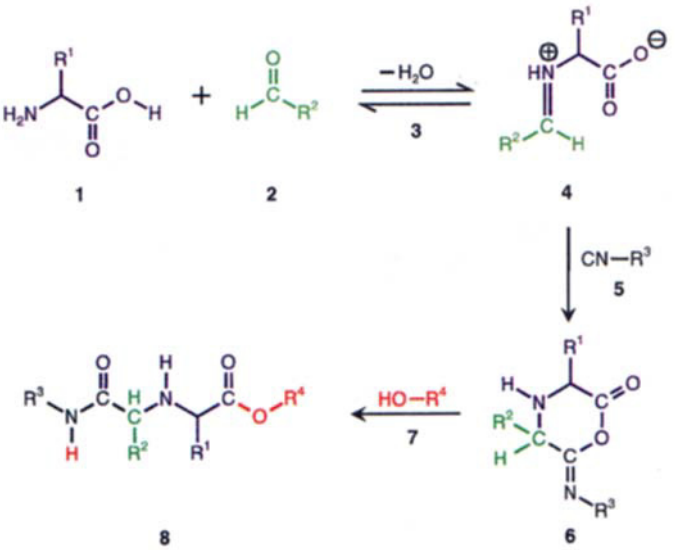
Chemical compounds are usually synthesized in several reaction steps. The intermediates must be separated and purified before they are used as starting materials in the next reaction. The total yield of such an iterative synthesis decreases sharply with the number of steps. Many compounds can also be prepared much faster and with higher yields by one-pot multicomponent reactions (MCR).[1] The scope of the four-component reaction (U-4CR)[2] was only recognized in 1958, shortly after isocyanides had become easily accessible.

A very effective variation of the U-4CR is the five-center–four-component reaction (U-5C-4CR). It combines very high yields (usually more than 95%) and excellent stereoselectivity (de ≈ 80%) with simple preparative procedures.

α-amino acids serve as bifunctional starting materials in the U-5C-4CR instead of the amine and acid components in the familiar U-4CR. They react with equimolar amounts of aldehyde and isocyanide as well as with the alcohol that also serves as a solvent. After one to two days the product, a 1,1′-iminodicarboxylic acid derivative, is obtained in almost quantitative yield.

1,1′-Iminodicarboxylic acids and their derivatives constitute an interesting and thoroughly investigated group of natural substances. They can be isolated from several types of poisonous mushrooms.[3] Opines,[4] such as octopine and nepaline, which have been isolated from crown gall tumors, also belong to this class of compounds. 1,1′-Iminodicarboxylic acid derivatives are also pharmaceutically active as ACE inhibitors.[5] The preparative simplicity and the high yield of the U-5C-4CR make it an ideal approach to this interesting group of compounds.

The postulated reaction mechanism[6] of the U-5C-4CR is given in Scheme 1. First, the amino function of the α-amino acid



Scheme 1. Postulated reaction mechanism for the U-5C-4CR.

1 condenses with the aldehyde compound **2**, losing water (**3**) to form the imine **4**. After α-addition of the isocyanide **5**, an O-acylamide (**6**) is formed. By the nucleophilic attack of the fourth component (alcohol **7**, the fifth reacting center) at the carboxylic carbon atom and the subsequent rearrangement the U-5C-4CR product, the 1,1′-iminodicarboxylic acid derivative **8** is formed. This is achieved by the esterification of the acid function of the α-amino acid with the alcohol. As in the U-4CR, a secondary amide is formed by the isocyanide. A new stereocenter is created at the initially quaternary carbon atom of the aldehyde. Its prefered absolute configuration is induced by the chiral amino acid employed.

Out of the large number of compounds that have already been synthesized by the U-5C-4CR, three representative examples (for physical data see Table 1) are given in Scheme 2. In accordance with the postulated mechanism, the X-ray structural analysis[7] of **9** (Fig. 1) shows that the new stereocenter has the same absolute configuration (*S*) as the amino acid employed. The assignment of the absolute configuration at the new stereocenter C7 can be unambiguously determined with the help of the second stereocenter C3, which is not affected by the reaction. In the crystal two crystallographically distinct molecules A and B are associated into dimers through weak hydrogen bonds ($N2_A\text{–}H2_A \cdots O2_B$: 297 pm and 174°; $N2_B\text{–}H2_B \cdots O2_A$: 305 pm and 170°). The geometry of the two molecules A and B is marginally different.[7]

multicomponent reactions, the U-5C-4CR is extremely suitable for generating combinatorial chemical libraries.[9] These findings confirm the authors' opinion that multicomponent reactions in general, and especially the U-4CR, will play a prominent part in research, development, and applications.

Experimental Procedure

The α-amino acid (10 mmol) in methanol (100 mL) was cooled to −30 °C. Then aldehyde and isocyanide (each 10 mmol dissolved in 5 mL methanol) were added. After 3 h the mixture was allowed to warm to room temperature. When the reaction was complete (clear solution, between three hours and two days), the solvent was removed in vacuo. The crude product was virtually free of by-products and often needed no further purification. Small amounts of starting materials could be removed by washing a solution in ether with water. The mixtures of diastereomers were viscous oils or sticky solids. The diastereomers were separated by flash chromatography.

Structure and Dynamics of Methanol in a Zeolite**

Ernst Nusterer, Peter E. Blöchl* and Karlheinz Schwarz*

The petrochemical industry relies heavily on zeolite catalysts for petroleum refinement and production of fine chemicals. About 80% of the gasoline currently produced has been in contact with zeolites in the refinement process. Furthermore, zeolites are used during the industrial production of gasoline from methanol, a process by which, for example, about 30% of New Zealand's gas supply is produced. Zeolites are a class of aluminum silicates with large cavities (cages) linked by pores. Only small molecules with certain structural properties can pass through these pores. Acid sites distributed over the large internal surface activate chemical bonds and thus are responsible for zeolites' catalytic function. The acid sites in zeolites typically are AlOH groups that replace SiO fragments in the crystal lattice. The interaction of molecules such as methanol with acid sites is little understood, although it is the key to the catalytic function of most zeolites.

The most direct experimental clues to the mechanisms on a microscopic level come from IR spectroscopy.[1, 2] The interpretation of the IR spectra measured for methanol in a zeolite[2-4] is, however, still a subject of hot debate. Proposals range from absorption of methanol through a weak hydrogen bond with an acid site to fully protonated methanol in the zeolite. The most direct way to correlate measured IR spectra with atomic structures is to compare the experimental results with the results of quantum mechanical simulations. So far, however, the latter are in clear disagreement with the experimental spectra.[5-8] One of the major deficiencies of previous quantum chemical calculations has been the limitation to fairly small fragments of the zeolite crystal.

For this reason we have undertaken dynamic ab initio electronic structure simulations to elucidate the structures and vibrational spectra of methanol trapped in sodalite (Fig. 1). We considered the entire periodic zeolite crystal as it interacts at finite temperature with an adsorbed methanol molecule. Thus we determined the adsorption structures and calculated vibrational spectra, which reproduce the measured IR spectra.

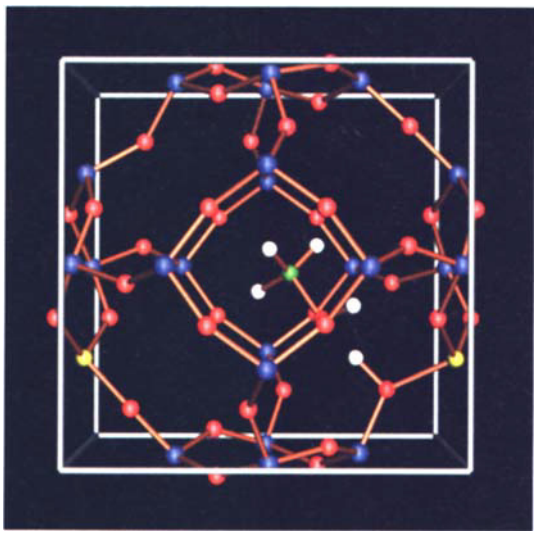

Fig. 1. One unit cell of the silica-rich sodalite (Si = blue, O = red, Al = yellow, H = white) used for the present study is included in the silver box. To complete the sodalite cage, periodic representations of the atoms located near the border of the unit cell are also shown.

Our calculations are based on the density functional theory,[9] including gradient corrections for exchange and correlation,[10, 11] on the ab initio molecular dynamics approach of Car and Parrinello,[12] and on the projector augmented-wave (PAW) method.[13, 14] The accuracy of this approach is comparable to that of correlated quantum mechanical MP2 calculations, but it also takes dynamic effects and finite temperatures into account.

First we examined an isolated acid site (periodically repeated in every other sodalite cage, Fig. 1) in a silicon-rich sodalite[15] as it interacts with methanol. This aluminum-poor zeolite has a silicon-to-aluminum ratio of 11:1. The internal surface is covered with one methanol molecule per acid site. Later we will describe how the resulting picture changes for aluminum-rich zeolites.

For this aluminum-poor sodalite we performed a molecular dyamics simulation for 11 ps at 400 K. The methanol molecule assumes a series of configurations, which we optimized separately to obtain the ground-state structures. Two structure types, **A** and **B** in Figure 2, were observed. In both structures one very strong hydrogen bond exists between the methanol oxygen atom O_m and the proton H_a of the acid site. This hydro-

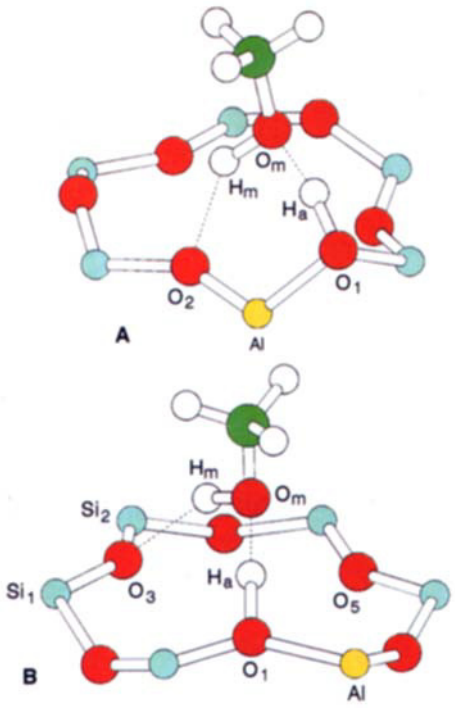

Fig. 2. Schematic drawing of structures **A** (top) and **B** (bottom) showing the adsorption of methanol in sodalite. Only a fragment of sodalite is shown: a ring containing one aluminum and five silicon atoms as well as the corresponding oxygen bridges. The dashed lines indicate hydrogen bonds. For further explanations see text.

gen bond with an O–O distance of 2.4 Å is substantially shorter than a typical hydrogen bond in water (O–O distance = 2.9 Å). It remained intact during our entire simulation. A second hydrogen bond with an O–O distance of 2.7 Å in **A** and 2.9 Å in **B**, similar to the hydrogen bond in water, is formed between the methanol hydrogen atom H_m and various framework oxygen atoms leading to the structures **A** and **B**. At finite temperatures this hydrogen bond breaks and forms again with different framework oxygen atoms. Structure type **B**, of which two virtually identical versions exist, is proposed here for the first time. In previous calculations the zeolite fragments were too small to include this structure, in which the weaker hydrogen bond forms with a framework oxygen atom that is—though located close to the acid site—several bonds away from the acid site. We find that structure **B** is slightly ($\approx 10\ kJ\,mol^{-1}$) more stable than structure **A**.

The crucial test of our structural models is whether our simulation also reproduces the measured IR spectra. The difference vibrational spectra (with and without methanol adsorbed on various zeolites) exhibit four broad characteristic peaks at about 3500, 2900, 2400, and 1700 cm^{-1}.[4] Our simulated spectra are obtained from a histogram of the instantaneous hydrogen stretching vibrations. This instantaneous frequency is obtained directly as $\omega = \pi/\tau$ from the period τ between two consecutive zeros of the hydrogen bond stretching velocity. We have chosen this approach to account for anharmonicities of the system, which result in relatively short lifetimes of the vibrational modes. It should be kept in mind that this procedure works well only for hydrogen stretching vibrations having frequencies clearly separated from those of other modes. This approach predicts the O–H stretching frequency of the isolated acid site (3570 cm^{-1}), in good agreement with experiment (3620 cm^{-1}), while the O–H stretching frequency of isolated methanol is underestimated by 3%.

Our simulated vibrational spectra of methanol in sodalite are shown in Figure 3. Our assignment presented below is consistent with experimental evidence.

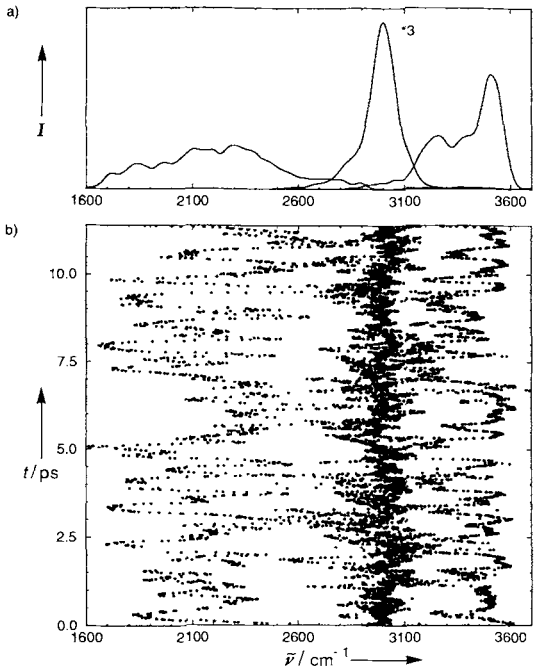

Fig. 3 a) Density of vibrational states I obtained by monitoring the proton stretching frequencies $\tilde{\nu}$ and b) their time evolution $\tilde{\nu}(t)$ during the simulation. In the upper panel the peak at 3500 cm^{-1} corresponds to the O–H stretch of the methanol proton H_m; the band at 3000 cm^{-1} is due to the C–H stretching vibrations of the methyl group; and the lowest band between 2600 cm^{-1} and 1600 cm^{-1} is caused by the O–H stretching vibrations of the acid-site proton H_a.

1) We assign the simulated peak at 3500 cm^{-1} to the methanol O–H stretching vibration (O_m–H_m) at 3300–3600 cm^{-1} in contrast to other assignments involving acid site protons.[4] This peak has also been observed in alkali forms of zeolites,[1] which lack acid sites. There only "normal" hydrogen bonds between the methanol hydrogen and framework oxygens are possible, which are similar to our "weak" hydrogen bond. Hence, our findings conclusively exclude any major contribution from the acid-site proton to this peak.

2) The C–H stretching vibrations are located in the simulated spectrum at 2800–3100 cm^{-1} and are broadened to a width of 200–300 cm^{-1} by weak interactions with the zeolite framework. As shown by recent experiments of Eder-Mirth, they disappear when the methyl group is deuterated. Hence these modes must be C–H vibrations, which are shifted towards lower frequencies when deuterated.

3) The O–H stretching vibration predicted for the acid-site hydrogen forms a very broad band from 1600 to 2600 cm^{-1} and corresponds to the measured broad peaks at about 2400 cm^{-1} and 1690 cm^{-1}. The latter peaks are not found in the alkali forms of the zeolites,[1] in accordance with our interpretation that these modes originate from vibrations of the acid-site proton interacting with the adsorbed methanol. A band for a combination mode of the zeolite lattice near 2000 cm^{-1} decreases upon adsorption and thus may suppress the center of the simulated broad peak and lead to a pseudo double peak in the experimental difference spectra.

In our simulations we observed a correlation between the O–H stretching frequency and the length of the hydrogen bond,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0176 $ 10.00+.25/0

which allows structural information to be deduced from a measured vibrational spectrum. Strong hydrogen bonds with short O–O distances correlate with long, weakened O–H covalent bonds and low hydrogen stretching vibrations. If the O–O distance is increased, the length of the covalent bond approaches its unperturbed value approximately exponentially; the O–H stretching vibration increases almost linearly as the length of the covalent bond decreases. Aluminum-rich zeolites differ from their aluminum-poor counterparts both in their IR spectra and in their reactivity.[4, 16] In particular, the highest peak at 3500 cm^{-1} seems to vanish as the Si:Al ratio approaches its lower limit of 1:1. Therefore we investigated the interaction of methanol with two acid sites simultaneously. We find that the hydrogen bond between the methanol proton H_m and an oxygen adjacent to another aluminum atom is shortened by about 5% and is therefore stronger than the hydrogen bond formed with an isolated acid site. Preliminary molecular dynamics simulations of 1 ps reveal a downward shift of the H_m–O vibration (located at 3500 cm^{-1} for the methanol hydroxyl group adsorbed on an isolated acid site) of roughly 400 cm^{-1}, which could explain the disappearance of the former absorption band. However, it should be noted that aluminum-rich zeolites exhibit a substantially richer variety of structures for acid-site centers and adsorption complexes than aluminum-poor zeolites, a fact that has not yet been explored exhaustively.

We studied sodalite to unravel processes that should also be relevant for the more complex zeolites actually used in technologically relevant processes. Therefore we should discuss to what extent our results apply to zeolites other than sodalite. We expect that the essential features of structure **A** are rather independent of the zeolite, as the tetrahedral angle on the Si and Al atoms is largely conserved. Structure **B**, however, depends strongly on the local structure. Since it depends on the proximity of distant oxygen atoms, this structure can only occur in sufficiently small or highly deformed larger rings. Rings consisting of four atoms with tetrahedral coordination cannot be bridged, because the acid-site protons point outward. Since the structures **A** and **B** have similar vibrational patterns, we expect only quantitative changes in the IR spectra for zeolites that cannot form structure **B**. The largest deviations in the IR spectra will occur in the lower part (see Fig. 3), because this part is most sensitive to the strength of bond of the acid-site proton.

Our computer experiments predicted adsorption structures of methanol in zeolites which, for the first time, are consistent with the available experimental data. This information forms the basis for the understanding of a large class of zeolite-catalyzed reactions. We have applied a theoretical approach to zeolite chemistry, which allows us to study with a high level of accuracy dynamic behavior of molecules in zeolites at finite temperatures without the limitation of small zeolite fragments. Real-time simulations of chemical reactions in zeolites are currently in progress.

Single-Chain Polyprenyl Phosphates Form "Primitive" Membranes

Gianluca Pozzi, Véronique Birault, Birgit Werner, Olivier Dannenmuller, Yoichi Nakatani, Guy Ourisson,* and Susumu Terakawa*

Terpenoid components are ubiquitous and very varied in biological membranes (archeal lipids, hopanoids, carotenoids, sterols, dolichols, ubiquinones, etc.). We showed that the structures of various molecular fossils (sedimentary biomarkers), considered along with known biosynthetic mechanisms, permit the deduction of the structures of their precusors, which often appear to be still undiscovered membrane terpenoid lipids. We have thus been led to the conclusion that the universal role of this class of natural products in all living organisms has been in membrane formation or reinforcement.[1]

We also showed that all these demonstrated or postulated membrane terpenoids can be arranged in a hypothetical evolutionary sequence and proposed that the most primitive members of such a group of substances involved in one common biological function should be sought among those accessible by the simplest possible "azymatic" reactions, that is, reactions not requiring enzymes.[2] This led us to postulate that the most primitive membrane constituents may have been some acyclic polyprenoid phosphates, whose chains are an adequate length

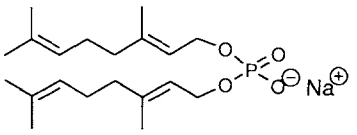
to achieve the amphipathic ratio required for spontaneous vesicle formation: these phosphates could have been formed by essentially one synthetic reaction, of the general type (a).

$$C^+ + C{=}C \longrightarrow C{-}C{-}C^+ \qquad (a)$$

We had synthesized a series of dipolyprenyl phosphates and had shown that their salts indeed formed vesicles (revealed by electron microscopy and encapsulation of dyes); this was the case for sodium digeranylphosphate (**1**) and its higher isoprenologs with two C_{15} or C_{20} chains.[3] On water, the same dipolyprenyl phosphates give monolayers, which, like those of di-*n*-acylphospholipids, become denser on the addition of cholesterol or of hopanoids.[4] It has also been shown that addition of diphytanyl phosphate (mixture of (*R*,*S*) diastereomers) improves the barrier properties of vesicles of dipalmitoylphosphatidylcholine.[5]



1

We wondered whether, like some fatty acids[6] and many other single-chain amphiphiles,[7] monopolyprenyl phosphates and/or pyrophosphates would not also be able to self-assemble into bilayer structures, in particular closed vesicles. These phosphates and the corresponding pyrophosphates have been described as intermediates in the biosynthesis of polyterpenoids,[8] but their phase behavior has not been studied, except for the brief mention that (uncharacterized) "micelles" might be formed in slightly acidic water dispersions of ammonium salts of monofarnesyl phosphate.[9] It has also been shown that phytanyltrimethylammonium phytanylphosphate (**7**) did form stable vesicles, albeit of a particular type in which cationic and anionic head-groups are located on identical lipophilic chains.[10] If the sodium salts of monopolyprenyl phosphates were to form vesicles, this would not only enable us to go one step backwards towards simpler, potentially more primitive membranes than the dipolyprenyl phosphates, but it would also be an experimental confirmation of part of the hypotheses presented by Wächtershäuser, in the completely different framework of his theory of a "pyrite-pulled" chemoautotrophic origin of life, for the formation of polyterpenoid membranes.[11] That these phosphates could indeed have interesting phase properties was suggested by the well-known uses of long-chain alkyl phosphates as industrial surfactants, though they have mostly been described as forming micelles, not closed vesicles.[12]

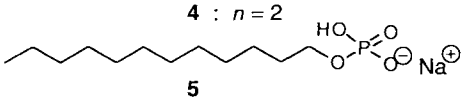
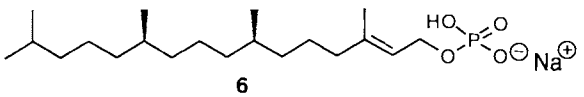
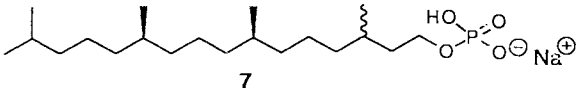
3 : $n = 1$
4 : $n = 2$



5



6



7

For the preparation of the phosphates derived from the unsaturated polyprenyl chains, one can, of course, not use hydrogenolysis of diphenyl phosphates, as had been described for the first clean preparation of long-chain *n*-alkyl phosphates.[13] We have now synthesized a series of monopolyprenyl phosphates—those of geraniol (**2**), farnesol (**3**), geranylgeraniol (**4**), dodecanol (**5**, for comparison), phytol (**6**), and (3*R*,3*S*)-phytanol (**7**)—as their sodium or ammonium salts, by the Cramer phosphorylation procedure adapted by Danilov et al.,[14] and isolated the products from the reaction mixture as the cyclohexylammonium salts, as reported by Julia et al.[15] For the pyrophosphates of geraniol (**8**), farnesol (**9**), geranylgeraniol (**10**), phytol (**11**), and phytanol (**12**), we used the fast synthetic

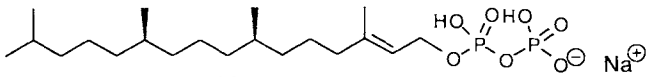
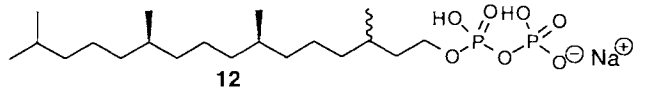
9 : $n = 1$
10 : $n = 2$



11



12

method of Keller and Thompson.[16] These pyrophosphates could again be used to obtain the phosphates by controlled hydrolysis. After cation exchange to obtain the sodium or ammonium salts, the products, visualized as single spots on TLC, were characterized by their potentiometric curves (pK_{a_1} 3.2–3.3, pK_{a_2} 6.6–6.7 for the phosphates; for the pyrophosphates, hydrolysis occurred during titration, and the pK_a's observed corresponded to the phosphate) and their ^1H and ^{31}P NMR spectra. Suspensions in water were examined by electron microscopy (cryomicroscopy), and their formation from the solid phosphates in the presence of a series of buffers was followed by two types of optical microscopy: by differential interference contrast microscopy, or by confocal microscopy, both of which can only reveal "giant" vesicles.

Table 1 summarizes the results obtained. Compounds **2** and **8**, with only the C_{10} chain of geraniol, were apparently completely

soluble in water across the whole pH range. No giant vesicle of farnesyl phosphate could be seen by optical microscopy, though electron microscopy did show the presence of small vesicles. All the other phosphates and pyrophosphates formed giant vesicles (diameter larger than 10 μm, Fig. 1) on simple contact of the

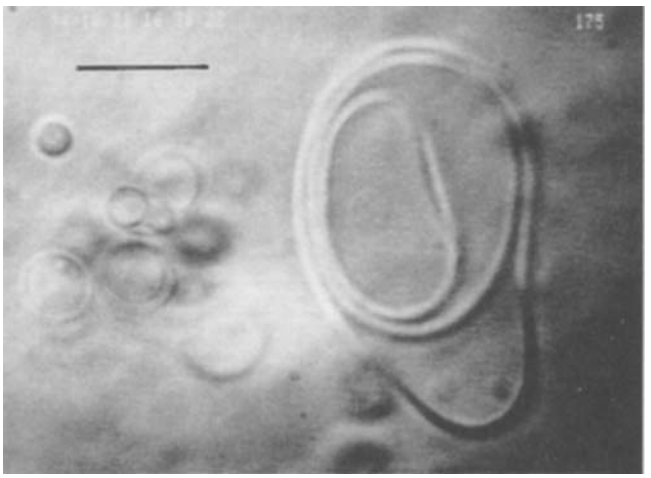

Fig. 1. Copy of a video frame of the differential interference contrast image of a multivesicular structure of sodium geranylgeranylphosphate in a buffer at pH 4.1 and 23 °C. The bar represents 5 μm.

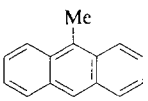
solid with an appropriate buffer. They were observed to bud from the solid by a variety of processes: formation of warts, growing until they detached as closed vesicles from the surface of the solid, or formation of tubules, the distal end of which progressively grew into an intumescence, then into a bubble, and finally into a free vesicle. The best conditions for observation of the giant vesicles were at about pH 4 in an acetate or phthalate buffer. Hydrolysis of the pyrophosphates, however, appeared to occur within a few minutes. We must also note that our setups do not allow us to vary the temperature, which was in all cases about 23 °C. This appears to be above the transition temperature of these polyprenylphosphates anyway; it should be remembered that branchings on the lipophilic chains appear to lower the phase transition temperature enough to make it impossible to measure, if one generalizes from the case of archeal lipids.[17]



13

We also added 5% of the fluorescent hydrocarbon 9-methylanthracene (**13**, Nile Red) to the vesicle preparation and used the laser equipment of the confocal microscope to observe the fluorescence of the vesicle preparation after excitation at $\lambda = 485$ and 551 nm in the *xz* and *xy* planes (Fig. 2). This demonstrated that at least some of the vesicles were quasi-spherical, and formed by one lipophilic layer (emitting in the green in the first case and in the red in the second); furthermore it established directly that lipophilic molecules are selectively extracted into the vesicle bilayer, as expected, a fact of some importance in the discussion of the establishment of increasing complexity in self-organized systems.[2]

It is obvious that **2**–**4** (or **8**–**10**) are much more plausible primitive membrane constituents than the *n*-alkyl amphiphiles or the meteoritic mixtures of aromatic acids previously postulated for that role.[18] We are presently studying the properties of these novel vesicles (in particular to elucidate the importance of

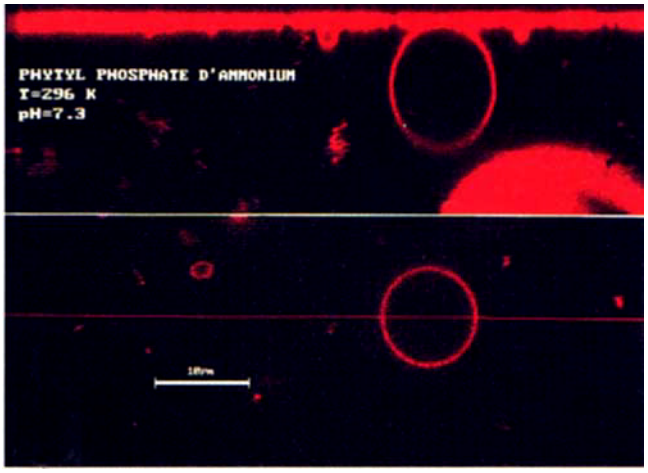


Fig. 2. Confocal fluorescence images of a vesicle of ammonium phytylphosphate containing 5% Nile Red (**13**) grown from the solid, in a buffer at pH 7.3 and 23 °C. Wavelength of excitation light: 551 nm. The same vesicle is seen in two orthogonal sections, the *xy* and *xz* planes. The bar represents 10 μm.

the chain-branchings and unsaturation, which are not yet clear at all), as well as their formation under the prebiomimetic conditions suggested earlier.[2, 11]

Experimental Procedure

Differential interference contrast microscopy: Inverted microscope (Axiovert 135, 63x/1.40 Plan Achromat Oil DIC objective, × 2.5 insertion lens, Carl Zeiss), charge-coupled device (CCD) camera (C2400-75i, Hamamatsu Photonics), image processor (Argus-20, Hamamatsu Photonics), S-VHS video recorder (SVO-9500MDP, Sony), video monitor (PVM-1443, Sony), and video printer VP-1500, Seikosha).

Confocal microscopy: Inverted confocal microscope (LSM Invert 410, Plan Apo X63 objective, Carl Zeiss), laser sources Ar (488 nm, bandpass 515–565 filter) and He/Ne (543 nm, Longpass 595 filter), image processor (Matrox 4MW), PC 486-488PX microcomputer, color monitor (FT 3420 ETKL, Mitsubishi), printer (VP-1800 EPM, Sony), and digital image recorder (Focus).

Observations: A typical procedure was as follows: the phosphate (3 mg) was dissolved in 300 mL of a 2:1 mixture of chloroform and methanol. An aliquot (1.5 mL) of the solution was dropped on a coverglass (0.17 mm thick). After 10 min of drying, the lamellar solid remaining on the slide was brought into focus and 4.5 mL of a buffer (for example an acetate buffer, pH 4.1) at 25 °C was added. Vesicles were observed to grow from the edges of the solid. Besides multilamellar structures shown in the figure, unilamellar vesicles and tubules were also observed. The membranes appear to be thick because of the diffraction-limited resolution of the optical system.

Shape-Selective Catalysis with Microporous Amorphous Mixed Oxides**

Wilhelm F. Maier,* Johan A. Martens, Stephan Klein, Jens Heilmann, Rudy Parton, Karen Vercruysse, and Pierre A. Jacobs

The increasing demand on new chemical processes has led to a growing need for more selective catalysts. Selectivity based on the hindered diffusion of larger molecules in micropores, so-called shape selectivity, is the key to the success of zeolites;[1] however, fundamental limitations restrict the general applicability of these highly porous crystalline solids. The stable isomorphic substitution of elements other than alumina in the silica matrix of catalytically active zeolite structures is limited to a few elements and small contents. The pore size and pore architecture are not variable and can only be selected from the many known structures. Thus, there is a demand for alternative materials with shape-selective catalytic properties.

We have shown recently that amorphous microporous silica, titania, zirconia, and alumina with a narrow pore size distribution can be synthesized in the absence of organic templating agents by a specific sol–gel process.[2] These microporous materials form only under acid-catalyzed sol–gel conditions. Rheological studies show a simultaneous increase in the elasticity and viscosity under these sol–gel conditions, indicative of a linear chain growth in the polycondensation process.[3] We are convinced that the release of organic products during the slow and careful drying on these glasses is responsible for the pore size and porosity of the final products. We have now succeeded with this sol–gel process in synthesizing homogeneous microporous amorphous mixed metal oxides with narrow pore size distribution and high porosity.[4] These materials will be denoted in the following as amorphous microporous mixed oxides AMM-M_xSi, in which Si stands for silica as a base oxide and x for the atom% of the additional oxide M.

The porosity of the calcined materials was characterized by nitrogen and argon adsorption/desorption isotherms. All glasses show type I isotherms,[5] characteristic of purely microporous materials (Fig. 1). Table 1 shows the BET surface and pore diameter of the materials. The micropore distribution, determined by using the Horvath–Kawazoe method,[6] is monomodal and very narrow, comparable with the pore size distribution of zeolites. The effective pore diameters are between 0.65 and 0.77 nm, which is the range also found for large-pore 12-ring zeolites. The amorphous state of the AMM materials was identified by temperature-dependent X-ray diffraction, high-resolution transmission electron microscopy (TEM), and electron diffraction. X-ray analysis of selected areas of various sizes (from 1 μm to 2 nm) revealed that the materials have a homogeneous mixed oxide composition and that domain formation is absent. Figure 2 shows a representative micrograph of the AMM-$Ti_{17}Si$ glass. IR studies of the AMM-Ti_xSi materials by diffuse reflectance exhibit the Si-O-Ti band at 960 cm^{-1}, which is indicative of isomorphic Ti substitution in the TS zeolites. The observation of this band is only meaningful, when the presence of surface SiOH vibrations in the investigated spectral region has been excluded by in situ temperature treatment of the mixed oxides.

Transmission IR spectra of adsorbed pyridine show similar intensities for the V- and Ti-containing glasses at 1540 cm^{-1}, indicative of Brønsted acidity. With increasing Ti or V content the absorption signals associated with Lewis and Brønsted acidity increase. A similar correlation between acidity and titanium content was observed in other amorphous titanium silicates,

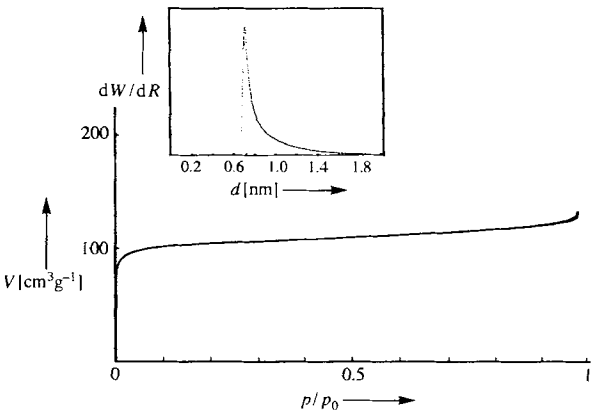

Fig. 1. N_2 adsorption isotherm at 77 K of AMMTi_3Si. V = adsorbed volume; insert: pore size distribution, d = effective pore diameter.

Table 1. BET surface and pore diameter of the AMM glasses. The pore diameters have been calculated by the HK method [a].

Mixed metal oxide	BET surface [$m^2 g^{-1}$]	Pore diameter [nm]
AMM-Ti_3Si	523	0.73
AMM-$Ti_{17}Si$	395	0.76
AMM-$V_{10}Si$	480	0.62

[a] The standard parameters of the Omnisorb-software have been used for the pore size calculation. In our tests these parameters reproduced the trend and pore sizes of H-ZSM5 and HY zeolites correctly.

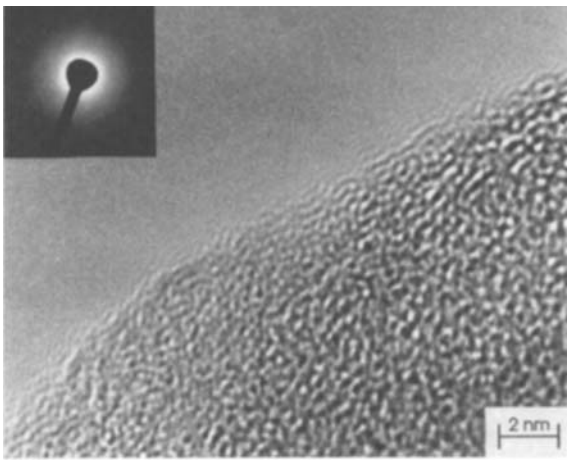

Fig. 2. Representative high-resolution TEM image of AMM-$Ti_{17}Si$ (electron optical magnification 1.5×10^6); the insert shows the electron diffraction at an amplification of 2×10^5 and a camera length of 0.2 m.

and attributed to Ti atoms in octahedral environments linked to silica tetrahedra, the hydroxyl ligands of which have Brønsted acidic properties.[7]

Crystalline mircoporous titanium silicates catalyze the epoxidation of olefins.[8, 9] Amorphous mesoporous Ti-containing aerogels also show good epoxidation properties, however, only with organic hydroperoxides as oxidation agent.[10] The AMM-Ti_xSi materials are comparable epoxidation catalysts with *tert*-butylhydroperoxide (TBHP) as oxidizing agent. In contrast to crystalline TS-1, the AMM-Ti_xSi materials show no epoxidation activity with H_2O_2 as the oxidizing agent. With linear and cyclic olefins, the rate of epoxidation with the AMM-Ti_3Si catalyst decreases rapidly with increasing number of carbon atoms (Fig. 3). This behavior is unexpected, as the reactivity of terminal alkenes is barely affected by chain length. A similar decrease of the rate of epoxidation with increasing number of carbon atoms in the epoxidation of alkenes with TS-1 was ascribed to molecular shape selectivity.[11] On TS-1, however, the epoxidation of hex-1-ene is much quicker than that of cyclohexene,

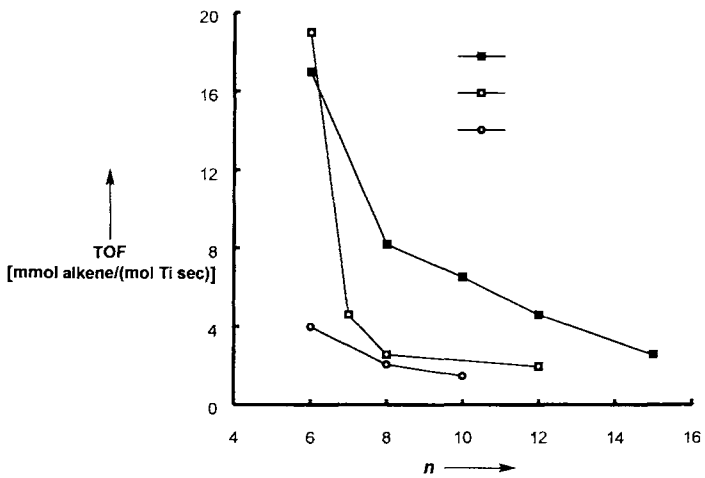

Fig. 3. Relative rate of epoxidation (TOF = turnover frequency) of 1-alkenes and cycloalkenes with AMM-Ti_3Si. Reaction conditions: batch reactor 353 K, 15.8 mmol alkene, 3 mmol TBHP (3 M in isooctane), 50 mg catalyst. The data on Ti-β (at 333 K) are taken from reference [11a]. n = number of carbon atoms of the alkene. ■ = 1-alkene (AMM-Ti_3Si), □ = cycloalkene (AMM-Ti_3Si), ○ = 1-alkene (Ti-β).

whereas on AMM-Ti_3Si the two alkenes are converted at comparable rates, confirming the presence of larger pores in the AMM catalyst. Compared to the zeolite Ti-β, the Ti atoms in the AMM catalyst are also much more efficiently used.[11a] The yield of peroxide relative to TBHP is nearly quantitative. These data indicate that with the preparation of a purely microporous Ti-Si glass with narrow pore size distribution a new, shape-selective epoxidation catalyst with pores in the range of the large-pore 12-ring zeolites with high epoxidation activity has been developed.

Since significant shape selectivity has only been observed with crystalline zeolites, this indication of shape selectivity with a purely amorphous material seems of special importance. The presence of Brønsted acidic centers in AMM-Ti_xSi and AMM-V_x-Si materials allows, besides the mentioned redox catalysis, the investigation of acid-catalyzed reactions. The hydrocracking of decane is of special value for the characterization of the pore architecture of crystalline zeolites. This established test reaction[12] allows a precise assignment of pore structure on the basis of product distribution by comparison with the data bank of known zeolites. The hydrocracking of decane was carried out under standardized reaction conditions, after the AMM materials had been impregnated with 0.5 wt% Pt. Table 2 summarizes the obtained indices of the AMM materials together with the data from the zeolites H-Y and ZSM-5. The position of the AMM materials relative to known zeolites with regard to the ethyloctane criterion is shown in Figure 4.[13]

Table 2. Characterization of the microporous materials by the hydrocracking test of decane [a].

Microporous material	CI*	EC8	PC7	3EC8/4EC8	DBiC10	iC5	DI
USY	1.5	12.5	1.9	0.6	–	50	–
AMM-Ti_3Si	1.5	10.3	0.9	0.7	30	30.5	–
AMM-$Ti_{17}Si$	1.7	11.8	1.1	0.7	–	–	15
AMM-$V_{10}Si$	3.4	3.8	0.9	1.0	17.3	13.3	12
ZSM5	6.6	0	0	–	–	11	–

[a] CI* = content of 2-methylnonane/5-methylnonane at 5% conversion; EC8 = content of ethyloctanes/methylnonanes; PC7 = content of 4-propylheptane in monobranched isomers at 75% conversion; 3-EC8/4-EC8 = content of 3-ethyloctane/4-ethyloctane; DBiC10 = content of dibranched isodecanes at maximal isomerization; iC5 = mol isopentane per 100 mol cracked decane; DI = molar yields of (C3–C7) + (C4–C6) (expressed as mol per 100 mol cracked) at 35% cracking.

The refined constraint index (CI*)[12a] of AMM-Ti_3Si (CI* = 1.5) and of AMM-$Ti_{17}Si$ (CI* = 1.7) positions the pore size of the materials in the range of large-pore 12-ring zeolites ($1 < CI^* < 2.2$). In such large-pore zeolites the extent of the rather bulky ethyl isomers correlates with pore size (Fig. 4). This confirms the assignment of the AMM-Ti materials in the family of large-pore zeolites based on the pore diameter of 0.73 nm from the adsorption isotherm. The decane test further identifies the AMM-Ti_xSi materials as tubular pore systems lacking additional larger cavities and pore intersections, as derived from the high dimensionality index (DI) values ($DI > 5$).[12d] The slightly larger pore size of AMM-Ti_3Si compared to AMM-$Ti_{17}Si$ is confirmed by both the argon adsorption (Table 1) and the decane test (Fig. 4).

The V-containing AMM-$V_{10}Si$ with a CI* of 3.4 is positioned in the zeolite-free range between the medium-pore 10-ring and the large-pore 12-ring zeolites. The high DI of 12 identifies the material as a system of unconnected tubular pores without inner cages like the Ti-containing AMM. The results of the argon

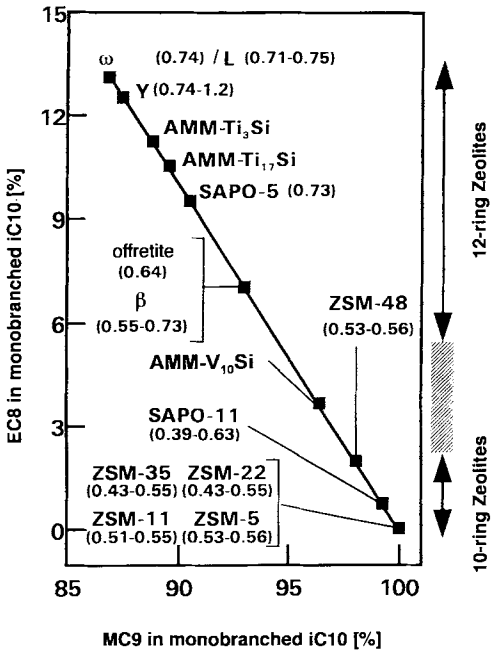

Fig. 4. Comparison of the amorphous AMM glasses with known zeolites, based on the ethyl octane criterion from the decane test [13]. Minimum and maximum diameters of pore cross sections given in brackets. The zeolite data were taken from reference [12]. EC8 = ethyloctanes, MC9 = methylnonanes, iC10 = isodecane.

adsorption (Table 1) and the decane test (Fig. 4) revealed that the pores of the AMM-V_{10}Si are slightly smaller than those of the AMM-Ti_xSi. HR-TEM studies of the materials after the decane test show that the amorphous nature of the AMM materials is stable at high temperatures. However, a slight reduction of the overall surface by about 20% was found with the catalysts used (heated to 550 °C). The temperature-dependent X-ray diffraction exhibits no detectable crystallinity up to 800 °C. The stability of the AMM materials was confirmed by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC), which showed no change in the range of 200 to 600 °C, while in the range below 200 °C the expected weight loss due to drying was observed.

These results show that microporous amorphous glasses have shape-selective properties in redox and hydrocracking catalysis, a property up to now only observed with crystalline zeolites. There are no known zeolites with the pore architecture and pore sizes of the AMM glasses, thus, these glasses supplement the known zeolites. These studies also confirm that the shape-selective catalytic properties of microporous materials like zeolites are not associated with the crystallinity but with the narrow pore size distribution and small pore size of these materials. The preparation of purely microporous glasses with shape-selective catalytic properties opens the door for the synthesis of new shape-selective catalysts. Compared to traditional zeolite synthesis, the sol–gel route avoids the use of organic templating agents that have to be eliminated through calcination and does not require hydrothermal synthesis conditions. In contrast to zeolites, the chemical composition and pore size of these materials is not limited. The sol–gel process also opens new possibilities for the manufacture of inorganic permselective catalytic membranes and monolithic materials. Thus with the preparation of microporous amorphous mixed oxides it may be possible to overcome many of the limitations of traditional zeolite chemistry.

[13] Content of ethyloctanes plotted against methylnonanes in the monobranched isomerization products at 5% isomerization yield in the hydrocrack test of decane. The AMM-Ti_xSi materials are compared to 10-ring and 12-ring zeolites. Reaction conditions: continuous-flow, fixed-bed reactor with a total pressure of 0.45 MPa, a decane and water partial pressure of 1.2 kPa; a space time of decane of 1.7 kg s $mmol^{-1}$; a temperature range of 473 to 673 K. AMM-Ti_xSi samples were loaded with 0.1 wt% Pt metal by impregnation with an aqueous $[Pt(NH_3)_4Cl_2]$ solution, calcination in oxygen, and reduction in hydrogen at 673 K.

Asymmetric Dihydroxylation Enables Rapid Construction of Chiral Dendrimers Based on 1,2-Diols**

Han-Ting Chang, Chien-Tien Chen, Teruyuki Kondo, Gary Siuzdak, and K. Barry Sharpless*

Research in dendrimers is a rapidly expanding area at the interface between conventional organic chemistry and polymer science.[1] These macromolecules consist of a polyfunctional central core covalently linked to layers of repeating units bearing functionalized branches, leading to structures with a discrete number of generations and functional end groups. The main quest in dendrimer research has been to find reliable strategies for their efficient construction, especially regarding control of homogeneity, branching patterns, interior cavity size, topology,

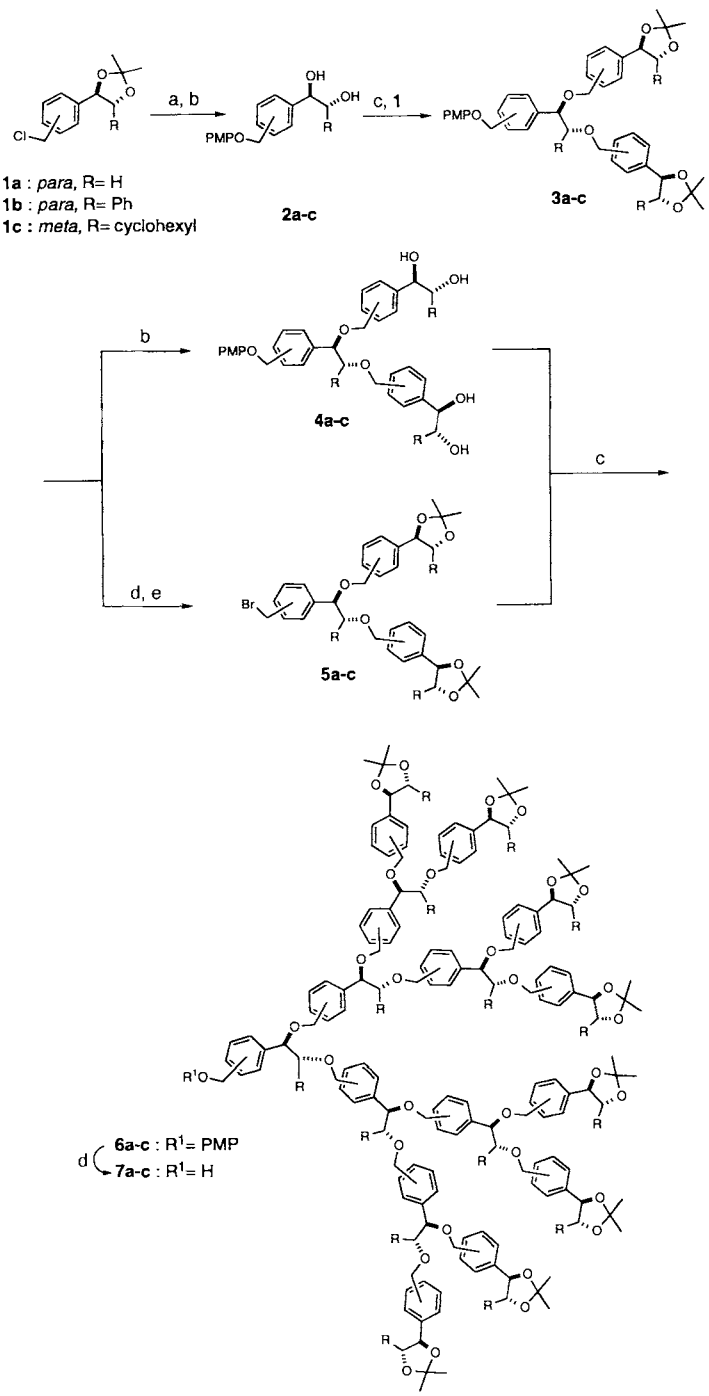
and surface functionality. More recently, following success in the aforementioned areas, the emphasis has shifted toward the elaboration of components with specific functions in both the peripheral and interior domains of the dendrimer.[2] Nevertheless, relatively few studies have focused on chiral dendrimers. Most of those cases involve the use and derivatization of chiral pool materials such as nucleotides, amino acids, and tartaric acid as building blocks or as terminal groups for the construction of biopolymers[3] and abiotic cascade molecules.[4, 5] The Seebach group has done the pioneering work in the synthesis of chiral starburst dendrimers.[6]

Interest in applications of the asymmetric dihydroxylation process attracted us to this field. The primary goal was to introduce chiral cavities into these materials, creating the potential for asymmetric catalysis, chiral recognition, and resolution. Since two stereogenic centers can be created in the asymmetric dihydroxylation (AD) of prochiral olefins,[7] we sought to utilize these readily available 1,2-diols as branch units for the construction of chiral dendrimers, in which the hydroxyl groups provide the covalent linkage points. Here we describe our initial results on the assembly of chiral polyether dendrimers by a "double exponential dendrimer growth" approach.[8]

On the basis of several considerations, three functionalized acetonides **1a–c** with various R substituents in the acetonide and the chloromethyl group in different positions on the aromatic ring were chosen as chiral monomer units. First, these chiral isopropylidene ketals can be readily prepared in enantiomerically pure form by the AD of appropriate 3- or 4-chloromethylphenyl alkenes. Second, the acetonide protecting group can be removed under mildly acidic conditions and also greatly simplifies spectroscopic analysis. Third, the aromatic spacer reduces steric congestion, enabling propagation to higher generations, and also bears the functionality for anchoring to the central core. Of special importance in this latter role is the benzylic activation facilitating the Williamson ether couplings.

To efficiently employ the alternative double exponential approach, judicious selection of a focal protective group compatible with both stages of propagation was essential. We chose the *p*-methoxyphenyl (PMP) ether group due to its stability under both basic (etherification) and acidic (hydrolysis) reaction conditions. The PMP ether functionality was installed at the focal site of **1a–c** by reaction with 4-hydroxyanisole in the presence of K_2CO_3 and a catalytic amount of Bu_4NI under reflux in 2-butanone;[9] quantitative yields were obtained in all cases. The masked diol functionality of the resulting PMP ether was released by exposure to 3 N hydrochloric acid in acetonitrile at ambient temperature.[10] The corresponding 1,2-diols **2a–c**, each prepared in greater than 95% yield, were then subjected to double etherification with the individual benzylic chlorides **1a–c**. Instead of the commonly employed Williamson etherification conditions (NaH/THF or DMF), we took advantage of a KOH/toluene-based benzylation technique for the propagation step. Virtually quantitative formation of the bis(acetonides) **3a–c** can be accomplished by simply refluxing the requisite diol and benzylic chloride in toluene in the presence of KOH pellets with concomitant azeotropic removal of water.[11, 12]

The double exponential dendrimer growth process[13] pioneered by Moore and co-workers[8] comprises the repetitive use of a three-reaction sequence for a doubly protected subunit: 1) selective deprotection of the peripheral groups (acetonides), 2) selective unmasking and functionalization of the focal group (PMP), and 3) coupling of these two components. Hydrolysis of the common intermediates **3a–c** under conditions similar to those described previously provided tetraols **4a–c** in yields



Scheme 1. a) $CH_3OC_6H_4OH$, K_2CO_3, Bu_4NI (5%), 2-butanone, reflux; b) 3 N HCl/CH_3CN (1/10 or 1/3 v/v), room temperature; c) KOH pellets (1.3–3 equiv), toluene, Dean–Stark; d) CAN (2.2–3 equiv), CH_3CN or C_2H_5CN/H_2O (2/1 v/v), −10 °C or 0 °C; e) PPh_3 (1.1 equiv), NBS (1.1–1.8 equiv), CH_2Cl_2, 0 °C.

ranging from 70% (R = cyclohexyl) to 97% (R = H, Ph). The PMP group in **3b** (R = Ph) was cleaved oxidatively by cerium ammonium nitrate (CAN) in CH_3CN/H_2O at 0 °C providing the corresponding benzylic alcohol in 93% yield.[14] However, for ether **4a** removal of the PMP group (95% yield) must be carried out at −10 °C to prevent concomitant hydrolysis of the peripheral acetonides, which are more sensitive in this less substituted series. To overcome the problem associated with the low solubility of **3c** (R = cyclohexyl) in the solvent system employed, propionitrile was ultimately found to be the best substi-

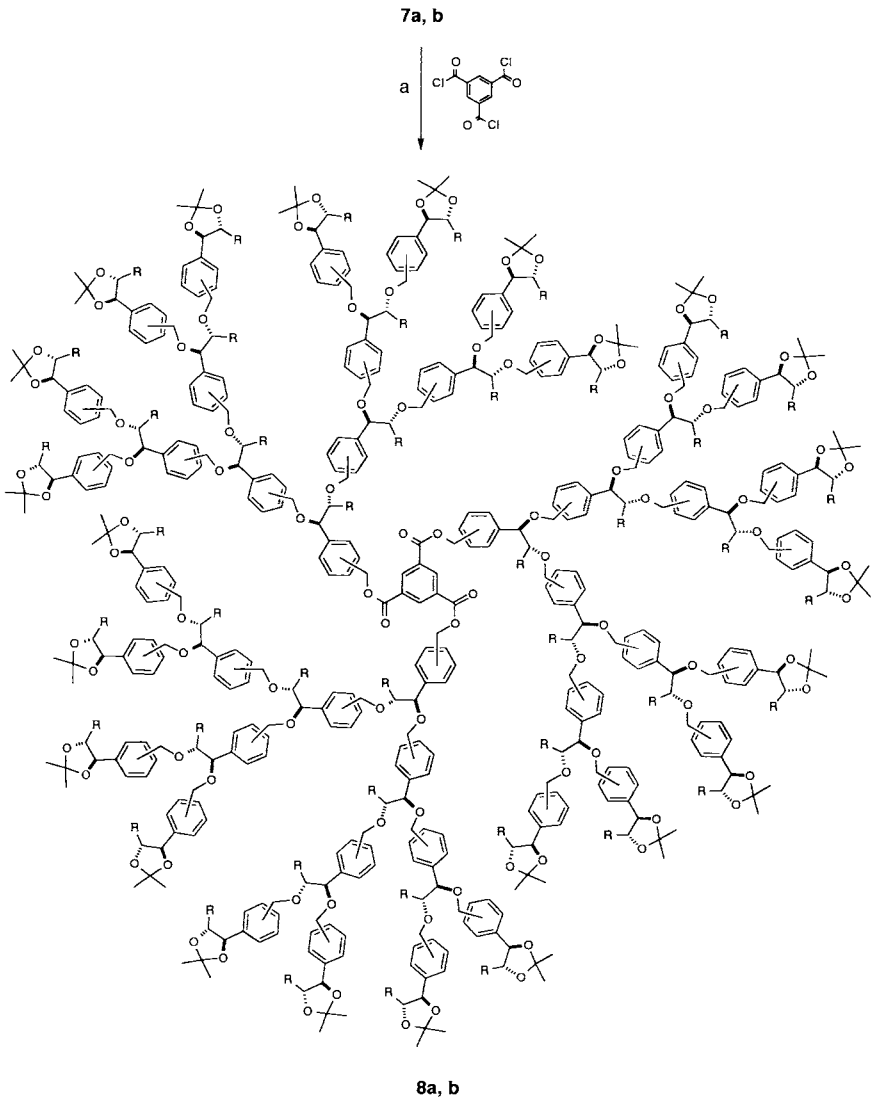
tute for CH_3CN (yield increased from 78 to 92%). Conversion of the resulting benzylic alcohols to the bromides **5a–c** (88–93%) proceeded smoothly upon treatment with PPh_3 and *N*-bromosuccinimide in CH_2Cl_2 at 0 °C.[15] In the final stage, the second-generation tetraols **4a–c** were propagated to the fourth-generation monodendrons **6a–c** by the KOH/toluene-mediated coupling with the respective benzylic bromides **5a–c**. These exhaustive, fourfold etherifications provided **6a–c**, which have eight end groups, in good yields ranging from 88 to 93%. Electrospray and/or FAB mass spectral analyses of these monodendrons exhibited no signs of products with defects that would arise from incomplete branches, thus demonstrating the overall efficiency of this approach.

After the final coupling the PMP group was removed by our modified oxidative cleavage conditions without overoxidation of the resulting alcohol.[16] The fourth-generation benzylic alcohols **7a–c** were thus obtained in yields of 84 to 89%. A variety of chiral dendrimers can be constructed by anchoring these chiral dendritic components onto a polyfunctional molecular core. As a model for the synthesis of C_3-symmetric dendrimers, 1,3,5-benzenetricarbonyl trichloride was coupled directly with benzylic alcohols **7a** (R = H) and **7b** (R = Ph) in the presence of 4-dimethylaminopyridine in benzene (Scheme 2). The fourth-generation dendrimer **8a** with 45 monomer units, 45 stereogenic centers, and a molecular weight of 7929 Da was synthesized in 75% yield (101 mg) at ambient temperature. In contrast, for the couplings with **7b**, which has more steric congestion, heating to reflux was required. The corresponding fourth-generation dendrimer **8b** possessing 45 monomer units, 90 stereogenic centers, and a molecular weight of 11 354 Da was obtained in 67% yield (130 mg). Important features allowing us to confirm unambiguously the structural integrity and identity of this type of dendrimer are the characteristic ^1H NMR shifts of the aromatic hydrogens in the core unit and the benzylic hydrogens at the focal point. For example, in **8b** these two signals appear as sharp singlets at $\delta = 8.9$ and 5.3, respectively, in a ratio of 1 to 2 (Fig. 1a). Further confirmation of structure and purity was obtained by size exclusion chromatography (Fig. 1b) and MALDI-TOF mass spectroscopy (Fig. 1c).

We have developed an efficient approach to chiral polyether dendrimers. The examples described here are C_3-symmetric dendrimers consisting of 45 chiral monomers and bearing 24 acetonide groups in the periphery. Nature uses α-amino acids as the fundamental repeat units for protein synthesis; this asymmetric dihydroxylation methodology for dendrimers may offer an abiotic counterpart, holding promise for the construction of chiral macromolecules of either antipode and with a vast array of spacer functionality, directionality (branching patterns), and surface chemistry by simple permutations of the 1,2-diol monomer units. In current research we are exploring the properties of this class of dendrimers in chiral recognition[17] and for the preparation of C_3-symmetric dendritic phosphanes as potential ligands for transition metal catalyzed asymmetric transformations.



Scheme 2. a) DMAP (3 equiv), PhH, room temperature or reflux.

Experimental Procedure

6a: A single-necked flask fitted with a Dean–Stark apparatus and a magnetic stir bar was charged under a nitrogen atmosphere with tetraol **4a** (746 mg, 1.3 mmol), benzyl bromide **5a** (3.8 g, 6.25 mmol), and 60 mL of toluene. This stirred solution was heated to reflux for 0.5 h, followed by addition of three pellets of KOH (these contain 15 wt.% H_2O, ca. 410 mg, 6.5 mmol). The reaction was monitored by thin-layer chromatography until intermediates were no longer observed; if the reaction seemed too slow in reaching completion, more KOH was added, and the reaction mixture was refluxed an additional hour (approximately 12 h total). After solvent removal in vacuo, the residue was dissolved in 25 mL of CH_2Cl_2, filtered through Celite, and purified by flash chromatography (3.10 g, 88% yield; $R_f = 0.13$, 2/3 EtOAc/hexane).

8b: A two-necked flask fitted with a Dean–Stark trap (filled with molecular sieves) and a condenser was charged with **7b** (211 mg, 0.057 mmol), DMAP (19 mg, 0.15 mmol), and 20 mL of benzene. The resulting solution was stirred and refluxed for 2 h, then cooled to room temperature. 1,3,5-Benzenetricarbonyl trichloride (4.52 mg, 0.017 mmol) was added and the solution refluxed an additional 4 h. Following removal of the solvent in vacuo, flash chromatography gave 130 mg of **8b** (67% yield; $R_f = 0.63$, 2/3 EtOAc/hexane). (An additional 33 mg (25% yield) of a product ($R_f = 0.13$, 2/3 EtOAc/hexane) resulting from incomplete esterification, the diester carboxylic acid, was recovered—presumably a consequence of trace amounts of water.) ^1H NMR (400 MHz, $CDCl_3$): $\delta = 8.90$ (s, 3H, $C_6H_3(CO_2CH_2Ar)_3$), 7.27–7.05 (m, 405H, $45 \times C_6H_4 + 45 \times C_6H_5$), 5.32 (s, 6H, $C_6H_3(CO_2CH_2Ar)_3$), 4.70 (s, 48H, methine protons of

[11] This unusual process harkens back to the old days of sugar chemistry in Germany [12]. However, its use here requires comment since the best modern conditions for ether formation (NaH, DMF, cat. R_4NI) fail in these systems due to formation of insoluble alkoxides. Furthermore, for the perbenzylation of smaller, less oxygenated polyols (e.g. pentaerythritol and methyl glycosides) the present Zemplén conditions [12a] are much poorer (i.e. deliver a lot of the expected $ArCH_2OCH_2Ar$ by-product) than the NaH/DMF conditions (H.-T. Chang, K. B. Sharpless, unpublished results). We believe that the large polyether polyols in this study cover the surface of the solid KOH and serve as solid/liquid phase-transfer catalysts, such that the $ArCH_2X$ species is denied access to hydroxide ion. Whatever the explanation, the Zemplén etherification procedure is uniquely effective for construction of these polyether dendrimers.

[17] Since this type of dendrimer has unsymmetrical branch cells leading to surfaces with higher fractal dimensions [1a, 3a, 17a–c], it could possibly provide a chiral environment. a) B. B. Mandelbrot, *Fractals: Form, Chance and Dimensions*, Freeman, New York, **1977**; *The Fractal Geometry of Nature*, Freeman, New York, **1982**; b) B. H. Kaye: *A Random Walk Through Fractal Dimensions*, VCH, Weinheim, New York, **1989**; c) A. B. Blumen, H. Schnörer, *Angew. Chem.* **1990**, *102*, 158; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 113. One preliminary investigation of these dendrimers' properties examined the relationship of the optical rotation with generation numbers on the styrene-based dendrons and of dendrimer **8a**. We found that the molar optical rotation is approximately proportional to the number of repeat units. Hence, the molar optical rotation of the PMP/acetonide-protected dendrons per repeat unit is as follows: 1st generation, $-143°$ (molar rotation, $-143°$; 1 unit; $[\alpha]_D^{25}$ $-45.6°$ ($c = 3.0$ in $CHCl_3$)); 2nd generation, $-165°$ (molar rotation, $-495°$; 3 units; $[\alpha]_D^{25}$ $-75.6°$ ($c = 1.0$ in $CHCl_3$)); 3rd generation, $-156°$ (molar rotation, $-1095°$; 7 units; $[\alpha]_D^{25}$ $-82.0°$ ($c = 13.6$ in $CHCl_3$)); 4th generation, $-189°$ (molar rotation, $-2836°$; 15 units; $[\alpha]_D^{25}$ $-105.2°$ ($c = 4.25$ in $CHCl_3$)) and dendrimer **8a**, $-163°$ (molar rotation, $-7345°$; 45 units; $[\alpha]_D^{25}$ $-92.7°$ ($c = 0.8$ in $CHCl_3$)).

A Novel Lithocenophane Derivative of a Trisgermole Dianion: [Li(thf)(tmeda)][2,3,4,5-Et_4-*Ge*,*Ge*-{Li(2,3,4,5-$Et_4C_4Ge)_2$}C_4Ge]**

Jang-Hwan Hong, Youlin Pan, and Philip Boudjouk*

Only two lithocenes, $[Cp_2Li]^-$ and $[(isodicyclopentadiene)_2Li]^-$, have been reported to date.[1] Studies on lithium cyclopentadienide ions show that they are in a monomer–dimer equilibrium.[2] Group 14 "heterole" anions are of particular interest because they are potentially aromatic[3, 4] and offer the promise of a rich and varied chemistry similar to their carbon congeners. In the case of silole anions, the ^{29}Si and ^{13}C NMR chemical shifts led to the conclusion that the degree of aromaticity was significant in these species.[5, 6] Recent high-level calculations support this conclusion.[7] The novel transition metal complexes $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4SiSi(SiMe_3)_3\}]$ and $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$, in which the heterole rings appear highly delocalized, have been prepared and characterized.[8, 9] Germole anions, on the other hand, once considered resonance stabilized based on pK_a data,[10] do not have NMR characteristics consistent with extensive delocalization.[11] In contrast, a NMR study of the unique 2,3,4,5-tetraphenylgermole dianion $[Ph_4C_4Ge]^{2-}$ provided evidence that this species exhibits significant π delocalization.[12]

To our knowledge, there are no examples of lithocene-type complexes of Group 14 heteroles. Herein, we report the synthesis and characterization of a novel trisgermole complex of lithium (**3**). X-ray analysis of a single crystal reveals that this species

[Li(thf)(tmeda)][2,3,4,5-Et_4*Ge*,*Ge*-{Li(2,3,4,5-$Et_4C_4Ge)_2$}C_4Ge] **3**

has a sandwich structure in the solid state. NMR studies indicate that the dianion is in dynamic equilibrium in solution but that the sandwich structure is maintained.

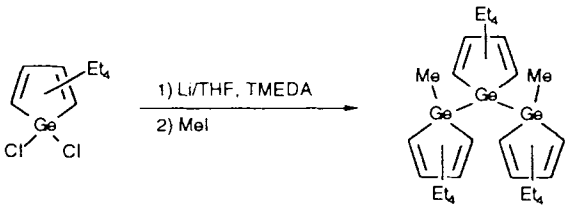
Sonication of 1,1-dichloro-2,3,4,5-tetraethylgermole (**1**) with excess Li in THF in the presence of tetramethylethylenediamine (TMEDA) gives a red solution (**3**) which, upon addition of MeI, leads to the trigermole **2** in high yield [Eq. (a)]. The intermediate



(a)

1 **2**

salt **3** was isolated as crystals and analyzed by X-ray diffraction. The essential structural features of **3** (Fig. 1)[13] are: 1) two differently π-complexed rings, one with only π bonding to the Li center, the other with π bonding to the Li center plus a σ Ge–Li bond; 2) apparent η^5 and η^4 bonding to the Li(1) center; 3) two terminal rings, the germanium atoms in which tilt away from the

π complexed lithium (the angle between the two least-squares planes Ge(1), C(25), C(26), C(27), C(28) and Ge(3), C(13), C(14), C(15), C(16) is 10.7°); and, 4) ring to Li bond lengths close to those in lithocenes.[1] Other noteworthy structural features are that the Ge–Ge bonds are longer than typical Ge–Ge bonds (2.41–2.46 Å) in trigermanes,[14] but shorter than typical Ge–Ge bonds (2.53–2.59 Å) in cyclotrigermanes.[15] The Ge(2)–Li(1) distance of 2.794 Å indicates the absence of a significant bonding interaction between Ge(2) and Li(1).[16]

The structure of **3** consists of three rings, the middle ring (C_4Ge(2)) of which bridges the other two rings by Ge–Ge

bonds. This middle ring is a typical germole.[17] The germanium atoms of the two terminal rings are slightly out of the ring's plane. For example, the deviations from the least-squares planes are 0.072 Å for $C_4Ge(1)$, and 0.082 Å for $C_4Ge(3)$. Li(1) is positioned close to the center of the two planes defined by $C_4Ge(1)$ and $C_4Ge(3)$, similar to the situation in lithocene or ferrocenophane derivatives.[18] Li(2) is tetrahedrally coordinated by the two nitrogen atoms of the TMEDA molecule, the oxygen atom of the THF molecule and Ge(1). The Ge(1)–Ge(2) bond (2.527(2) Å) is longer than the Ge(2)–Ge(3) bond (2.508(2) Å).

Delocalization in the $C_4Ge(1)$ and $C_4Ge(3)$ rings is not as complete as in lithocene derivatives[1] and $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$.[9] (See the values of $C_\beta C_\beta$–$C_\alpha C_\beta$ and the bond lengths in Table 1.) These intra-ring bond lengths notwithstanding, the Li(1)–$C_4Ge(3)_{centroid}$ distance of 1.918 Å compares favorably to the Li–$C_{5centroid}$ distance of 1.987–2.008 Å in the lithocene anion.[1] In contrast, the Li(1)–$C_4Ge(1)_{centroid}$ distance of 2.046 Å is a little out of that range, which is attributed to the significant bonding interaction[16] between Ge(1) and Li(2) (Table 1). Thus, Li(1) is η^5 coordinated to the $C_4Ge(3)$ ring but Ge(1) is sp^3 hybridized, and Li(1) is η^4 coordinated to the $C_4Ge(1)$ ring.

The NMR spectra of **3** indicate that the sandwich structure is preserved in solution even at room temperature; one Li cation is in a highly anisotropic environment as in lithocene, while the other Li cation is in an environment similar to that in common organolithium compounds. The two terminal rings can be distinguished by low-temperature ^1H NMR spectroscopy (Table 2). At 25 °C, two broad peaks are observed in the ^7Li NMR spectrum which, upon cooling to −50 °C, form two sharp resonances at $\delta = -4.98$ and $\delta = -0.93$ (Table 2). The former is consistent with π bonding in cyclopentadienyllithium derivatives ($\delta = -8.2$ to -12.5),[19] while the latter is typical of coordinated lithium ions.[20] In the ^1H NMR spectrum only two sets of two ethyl peaks in the ratio of 1:2 are observed, consistent with C_2 symmetry, over the temperature range +50 to +10 °C. Upon cooling from +50 to −50 °C, the two broad quartets of methylene absorptions become four well-defined quartets, indicating the coordination of the second lithium ion to a germanium atom (Table 2).

[a] ^7Li NMR (155 MHz, $[D_8]$THF, external LiBr (1 M/THF)). [b] AB system.

These observations can be explained by a simple process in which the σ-bound lithium ion becomes solvated and is reattached to the ring, as shown in Figure 2. The NMR spectroscopic data do not rule out a more complex bimolecular process in which lithium atoms are passed between rings without the intermediacy of a solvated lithium ion.

^{13}C NMR data for **3** at 25 °C (Tables 3 and 4) show that the chemical shifts assigned to the $C_4Ge(2)$ ring are typical of a conventional neutral germole. The signals of the α and β carbon atoms in the $C_4Ge(1)$ and $C_4Ge(3)$ rings, however, appear much further downfield than those in other neutral germoles, including the $C_4Ge(2)$ ring in **3**. These downfield shifts are in contrast to the upfield shifts in shifts in silole anions which possess signif-

icant π delocalization,[5-7] instead, they are similar to the downfield shifts for the ring carbon atoms in 1-lithio-2,3,4,5-tetramethyl-1-1-phenylgermacyclopentadienide [$\Delta\delta(C\alpha) = 10.5$ ppm and $\Delta\delta(C\beta) = 2.6$ ppm], in which the negative charge is localized on the germanium atom.[11] We attribute the downfield shifts of the signals in **3** to a field effect induced by the incompletely delocalized negative charges on Ge(1) and Ge(3).

Experimental Procedure

All reactions and manipulations were performed under an inert nitrogen or argon atmosphere and anhydrous conditions. NMR spectra were recorded on JEOL GSX270 and GSX400 spectrometers. GC-MS and solid sample MS data were obtained on a Hewlett-Packard 5988A GC-MS system equipped with a methyl silicon capillary column. Elemental analyses were performed by Desert Analytics, Tucson, Arizona. All ^{13}C NMR data are given in Table 2 [21].

1: A mixture of Mg (4.86 g, 200 mmol) and $HgCl_2$ (5.43 g, 20 mmol) in THF (70 mL) was stirred for 40 min. To this was added a solution of $[Cp_2ZrCl_2]$ (14.62 g, 50 mmol) and 3-hexyne (11.34 mL, 8.20 g, 100 mmol) in THF (200 mL) with stirring at room temperature [22]. The mixture was stirred overnight to give a dark red solution which was decanted into a 500 mL flask and cooled to −78 °C. To this was added $GeCl_4$ (5.70 mL, 10.72 g, 50 mmol) with stirring. The mixture was warmed to room temperature and stirred overnight to produce a clear, light orange solution [23]. After solvent was removed under reduced pressure, the residue was extracted with pentane. Removal of solvents under reduced pressure gave **1** as a colorless liquid. Yield: 9.84 g (64%, 99% pure by GC), b.p. 87–89° C/0.1 mm Hg, correct elemental analysis for $C_{12}H_{20}Ge_2Cl_2$; ^1H NMR (270 MHz, $CDCl_3$, ext. TMS), $\delta = 1.04$ (q, $^3J(H,H) = 7.3$ Hz, 6H; Me), 1.23 (q, $^3J(H,H) = 7.3$ Hz, 6H; Me), 2.33 (t, $^3J(H,H) = 7.3$ Hz, 4H; CH_2), 2.45 (t, $^3J(H,H) = 7.3$ Hz, 4H; CH_2); MS (70 eV): *m/z* (%): 312 (1.2) [$M^+ + 4$], 311 (0.7) [$M^+ + 3$], 310 (4.2) [$M^+ + 2$], 309 (1.4) [$M^+ + 1$], 308 (7) [M^+, 7], 306 (5.40) [$M^+ - 2$], 304 (2.4) [$M^+ - 4$], 164 (32) [$C_4Et_4^+$], 149 (100) [$C_4Et_4^+ - 15$], 135 (86), 107 (79), 91 (43).

2: Crystals of **3** (1.0 g) were dissolved in THF (30 mL) and slowly added to an excess of methyl iodide at 0 °C. Additional stirring at room temperature for 4 h produced a colorless solution and a white solid. Removal of all volatiles, extraction with hexane, followed by column chromatography gave a colorless oil which solidified slowly at room temperature. The yield of **2** was quantitative as determined by GC and ^1H NMR. Correct elemental analysis for $C_{38}H_{66}Ge_3$; ^1H NMR (270 MHz, $CDCl_3$, ext. TMS), $\delta = 0.64$ (s, 6H; $GeCH_3$), 0.87–1.03 (overlapped t, 36H; CH_3), 2.15–2.48 (brd m, 24H; CH_2).

3: Sonication of **1** (6.30 g, 20.5 mmol) in an ultrasonic cleaning bath [24] with excess Li (0.68 g, 97.14 mmol) in THF (70 mL) and TMEDA (6.5 mL, 5.01 g, 43 mmol) for 10 h gave a red-orange solution. After the unconverted lithium was filtered, all volatiles were removed under vacuum. The residue was extracted with hexane. The resulting solution produced orange-red crystals of **3**. ^1H NMR (270 MHz, [D$_8$]THF, 25 °C, solvent: $\delta = 1.73$), $\delta = 0.94$ (t, $^3J(H,H) = 7.3$ Hz, 12H; CH_3 of Ge(1,3)), 1.07 (t, $^3J(H,H) = 7.3$ Hz, 6H; CH_3 of Ge(2)), 1.12 (t, $^3J(H,H) = 7.3$ Hz, 12H; CH_3 of Ge(1,3)), 1.24 (t, $^3J(H,H) = 7.3$ Hz, 6H; CH_3 of Ge(2)), 2.29 (brd s, 8H; CH_2 of G(1,3)), 2.34 (q, $^3J(H,H) = 7.3$ Hz, 4H; CH_2 of Ge(2)), 2.72 (q, $^3J(H,H) = 7.3$ Hz, 4H; CH_2 of Ge(2)), 2.88 (brd s, 8H; CH_2 of Ge(1,3)). All peak assignments are based on proton homo decoupling, INEPT ^{13}C, and ^{13}C-^1H correlation 2D experiments.

Patterns of Multiple Additions to Fullerene C_{70}: Isolation and Structural Characterization of $[C_{70}\{Pt(PPh_3)_2\}_4]$**

Alan L. Balch,* Leijun Hao, and Marilyn M. Olmstead

Fullerenes provide the chemist with a rich framework for the assembly of large molecules with remarkably complex and frequently aesthetically pleasing structures.[1-4] Since the fullerenes contain a multiplicity of similar carbon–carbon bonds that appear to be only weakly interconnected electronically, the pat-

[**] This work was supported by the U.S. National Science Foundation (Grant CHE 9321257). We thank Johnson Matthey, Inc. for a loan of platinum salts.

terns of reactivity, which frequently involve multiple addition reactions, require experimental exploration. Single and multiple additions to C_{60} have been studied in detail, and some factors leading to regiospecific multiple additions have been identified.[5] However, comparable information relevant to the patterns of additions to the higher fullerenes such as C_{70} is limited. Here we report on the results of addition reactions of $Pt(PPh_3)_2$ units to C_{70} which involves the successive formation of adducts **1**–**4** with the eventual addition of four platinum atoms in a plane about the fullerene.

$[C_{70}\{Pt(PPh_3)_2\}]$ **1** $[C_{70}\{Pt(PPh_3)_2\}_2]$ **2**

$[C_{70}\{Pt(PPh_3)_2\}_3]$ **3** $[C_{70}\{Pt(PPh_3)_2\}_4]$ **4**

The structure of C_{70}, which is shown in Figure 1, contains five types of carbon atoms in layers, a–e, and eight types of carbon–carbon bonds. Additions to C_{70} are governed by considerations of both π-bond order and the fullerene curvature. Of the four C–C bonds at 6-6 ring junctions, those at the C_c–C_c and C_a–C_b bonds have the highest π-bond orders, 1.74 and 1.66, respectively.[6] The curvature of C_{70} is greatest at the poles so that the C_a–C_b bonds are the most pyramidalized.[7–9] Formation of organometallic complexes of C_{70} by addition of one or two molecules of Vaska's complex $[Ir(CO)Cl(PR_3)_2]$ has been shown to involve addition to the C_a–C_b bonds, the most pyramidalized bonds in this fullerene.[7, 8] In this case the only double addition product that crystallizes has isomeric structure **B**.[8] Osmylation of C_{70} produces two isomeric monoaddition products that involve addition to the C_a–C_b and C_c–C_c bonds.[9] Diels–Alder adducts of C_{70} have been obtained in which addition has occurred at three of the possible 6-6 ring junctions to produce adducts involving the C_a–C_b, C_c–C_c, and C_d–C_e bonds.[10, 11] Three biscyclopropanation adducts of C_{70} have been observed to form; the isomeric form **B** is predominant (relative ratio of isomers: **A**, 0.19; **B** 0.68; **C**, 0.13).[12]

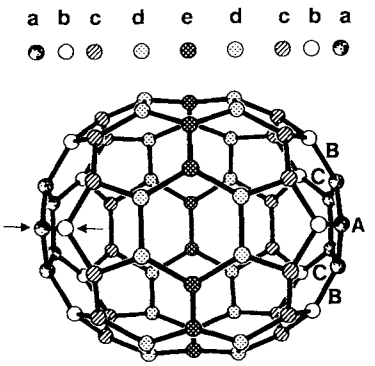

Fig. 1. Structure of C_{70} emphasizing the layers of five types (C_a–C_e) of carbon atoms. For double addition to C_{70}, in which the first addition occurs at the bond denoted by the arrows, three isomeric products are possible. Addition at bonds A, B, and C produce isomers **A**, **B**, and **C**, respectively.

Addition of four molar equivalents of $[Pt(C_2H_4)(PPh_3)_2]$ to a solution of C_{70} in benzene produces a deep brown solution from which **4** can be obtained by evaporation. The complex can be recrystallized from benzene by the slow diffusion of diethyl ether/methanol. The results of a single-crystal X-ray diffraction study of **4** · 6.5 benzene · 0.5 methanol are shown in Figure 2.[13] The adduct **4** has no crystallographically imposed symmetry, but the $C_{70}Pt_4P_8$ unit does have effective C_{2v} symmetry with the twofold axis passing through the centers of the C36–C37 and C31–C32 bonds. The four platinum atoms reside in a single plane (maximum deviation: ±0.051 Å for Pt3 and Pt4). Two of the platinum atoms, Pt1 and Pt2, are coordinated to C_a–C_b bonds and thus are in sites that are analogous to those utilized in the binding of Vaska's compound to C_{70}. However,

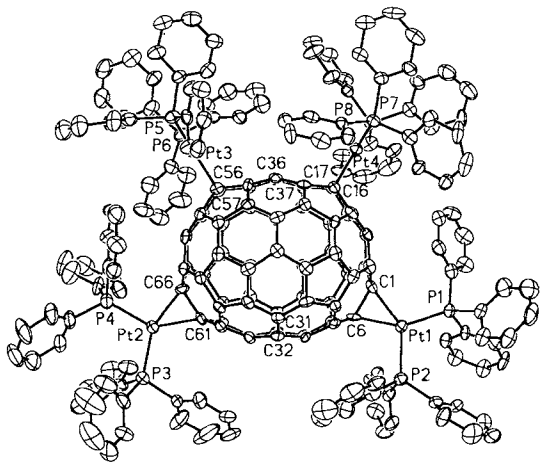

Fig. 2. A perspective drawing of the structure of **4** (50% thermal contours for all non-hydrogen atoms). Selected bond lengths [Å]: Pt(1)-C(1) 2.122(12), Pt(1)-C(6) 2.092(12), Pt(2)-C(61) 2.146(11), Pt(2)-C(66) 2.092(12), Pt(3)-C(56) 2.140(11), Pt(3)-C(57) 2.112(12), Pt(4)-C(16) 2.086(11), Pt(4)-C(17) 2.136(11), Pt(1)-P(1) 2.280(3), Pt(1)-P(2) 2.295(3), Pt(2)-P(3) 2.280(3), Pt(2)-P(4) 2.282(3), Pt(3)-P(5) 2.267(3), Pt(3)-P(6) 2.297(3), Pt(4)-P(7) 2.286(3), Pt(4)-P(8) 2.258(3), C(1)-C(6) 1.51(2), C(16)-C(17) 1.48(2), C(56)-C(57) 1.495(14), C(61)-C(66) 1.51(2).

the other two platinum atoms, Pt3 and Pt4, are attached to C_c–C_c bonds. This compound represents the first case in which direct attachment of a metal center to a C_c–C_c bond in C_{70} has been observed and is currently the highest adduct of C_{70} to be fully characterized. As Figure 3 shows, this arrangement of platinum bearing addends results in effective coverage of the two

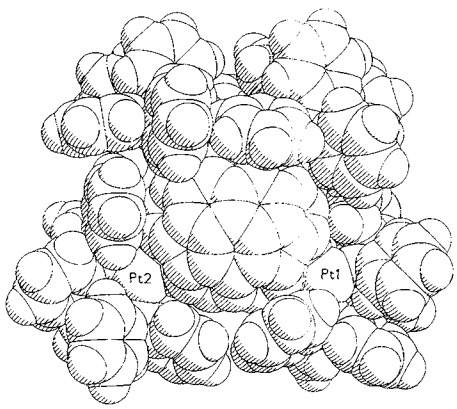

Fig. 3. Van der Waals surfaces of **4**.

poles of the fullerene by phenyl groups of the phosphane ligands. As seen previously for $[C_{70}Ir(CO)Cl(PPh_3)_2]$ and $[C_{70}\{Ir(CO)Cl(PPhMe_2)_2\}_2]$,[7, 8] two of the phenyl groups addends attached to the C_a–C_b bonds make face-to-face π–π contact with the fullerene, but there is no contact of this sort by the ligands attached to the C_c–C_c bonds. In contrast to the situation at the poles, the central portion of the C_{70} moiety, especially the C_e–C_e bonds, is exposed and accessible for chemical reaction. Consequently steric factors, symmetry considerations, and solubility play major roles in determining the pattern of addition seen in the formation of **4**.[14] Notice that the placement of the platinum complexes on the specific C_c–C_c bonds, C16–C17 and C56–C57, places these as far as possible from the platinum complexes at the C_a–C_b bonds, C1–C6 and C61–C66. The resulting arrangement of four groups about

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0189 $ 10.00+.25/0

the C_{70} core has the highest possible symmetry for such a tetraaddition product.

It is important to note that information obtained about the favored geometry of bisaddition products cannot be used to predict the pattern of higher addition products of C_{70} at least in the case of relatively labile addenda. From the structural study of $[C_{70}\{Ir(CO)Cl(PPhMe_2)_2\}_2]$[8] and work on the biscyclopropanation of C_{70},[12] it may be concluded that isomer **B** is the favored geometry for double addition. However, the arrangement of $Pt(PPh_3)_2$ groups at the C_a-C_b bonds of **4** does not correspond to isomer **B** of a double addition product. Rather it corresponds to isomer **A**, the statistically least favored isomer.

Attempts to add more than four $Pt(PPh_3)_2$ groups to C_{70} by increasing the $[Pt(C_2H_4)(PPh_3)_2]/C_{70}$ ratio have not been successful, but it has been possible to observe the formation of the lower adducts **1**–**3**. When C_{70} is treated with $[Pt(C_2H_4)(PPh_3)_2]$ in benzene in ratios of 1:1, 1:2, and 1:3, brown solids are obtained upon evaporation of the solvent. Analysis by ^{31}P NMR spectroscopy shows that each sample contains a spectroscopically discrete species. The 1:1 adduct **1** has been briefly described and identified as having the platinum bound to a C_a-C_b bond.[15] Our ^{31}P NMR data ($\delta = 28.0$ [d, 1P, $^1J(Pt,P) = 4038$ Hz, $^2J(P,P) = 24$ Hz], 25.3 [d, 1P, $^1J(Pt,P) = 3866$ Hz, $^2J(P,P) = 24$ Hz] in C_6D_6) are consistent with this interpretation. Additionally we have X-ray crystallographic data that shows that the related complex $[C_{70}Pd(PPh_3)_2]$ has the palladium center coordinated to a C_a-C_b bond.[16] The ^{31}P NMR data obtained for **2** ($\delta = 28.5$ [d, 2P, $^1J(Pt,P) = 4032$ Hz, $^2J(P,P) = 29$ Hz], 26.3 [d, 2P, $^1J(Pt,P) = 3868$ Hz, $^2J(P,P) = 29$ Hz] in C_6D_6) are similar to those for **1** and are consistent with addition to the C_a-C_b bonds at opposite poles of C_{70}. Three isomers of **2**, **A** with C_{2v} symmetry and **B** and **C** with C_2 symmetry,[8] are possible and further structural characterization will have to await a crystalline sample suitable for X-ray diffraction. For **3**, the ^{31}P NMR data ($\delta = 30.0$ [s, 2P, $^1J(Pt,P) = 4000$ Hz], 29.6 [d, 1P, $^1J(Pt,P) = 3932$ Hz, $^2J(P,P) = 41$ Hz], 28.9 [d, 1P, $^1J(Pt,P) = 4002$ Hz, $^2J(P,P) = 34$ Hz], 27.8 [d, 1P, $^1J(Pt,P) = 3876$ Hz, $^2J(P,P) = 41$ Hz], 27.0 [d, 1P, $^1J(Pt,P) = 3889$ Hz, $^2J(P,P) = 34$ Hz] in C_6D_6) suggest that two of the $Pt(PPh_3)_2$ groups (those with $\delta = 28.9$ and 27.0) are bound to C_a-C_b bonds, while the third ($\delta = 30.0$) is attached to a C_c-C_c bond. These spectroscopic data combined with the X-ray crystallographic structure for **4** indicate that binding of the platinum centers preferentially occurs at the C_a-C_b bonds and only after the two poles are blocked with addends, does binding to the less pyramidalized C_c-C_c bonds occur. As a result of steric considerations and the low reactivity of the exposed C_e-C_e bonds, addition of $Pt(PPh_3)_2$ groups to C_{70} stops after the formation of the tetraadduct **4**. In contrast, up to six $Pt(PR_3)_2$ groups have been added to the smaller fullerene C_{60}.[2, 3]

Experimental Procedure

All reactions were carried out under a N_2 atmosphere using Schlenk techniques. The solvents were dried and freshly distilled. $[Pt(C_2H_4)(PPh_3)_2]$ was prepared by a literature method [17].

4: Solid $[Pt(C_2H_4)(PPh_3)_2]$ (57 mg, 0.076 mmol) was added to a solution of C_{70} (16 mg, 0.019 mmol) in benzene (20 mL). The red-brown solution of C_{70} darkened immediately. The mixture was stirred for 20 min. The solvent was then removed under vacuum to give the product as a dark brown solid in 85% yield. Well-shaped black crystals of **4** · 6.5 benzene · 0.5 methanol that were suitable for X-ray diffraction were obtained by diffusion of diethyl ether/methanol (10/1, v/v) into a solution of **4** in benzene. IR (KBr pellet): $\tilde{\nu} = 1478$ (m), 1433 (s), 1094 (s), 742 (s), 692 (vs), 674 (m), 534 (m), 517 (s), 507 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (in C_6D_6): $\delta = 29.9$ [s, 4P, $^1J(Pt,P) = 4000$ Hz], 28.7 [d, 2P, $^1J(Pt,P) = 3923$ Hz, $^2J(P,P) = 41$ Hz], 27.9 [d, 2P, $^1J(Pt,P) = 3901$ Hz, $^2J(P,P) = 41$ Hz].

Samples of the other addition products **1**–**3** were obtained similarly as dark brown solids. These were examined by ^{31}P NMR spectroscopy but so far have not produced crystals suitable for single crystal X-ray diffraction.

Acyclic Stereocontrol in Radical Reactions: ρ-Selectivity with Oxazolidinone Auxiliaries**

Mukund P. Sibi* and Jianguo Ji

Stereocontrol in reactions of acyclic radicals is a subject of considerable interest.[1] ρ-Diastereoselective radical reactions mediated by chiral auxiliaries[2] have been investigated by the research groups of Curran,[3] Porter,[4] Giese,[5] Garner,[6] and others.[7] However, the use of oxazolidinone auxiliaries[8] in radical reactions has been hampered because the reactive rotomer is not available in the absence of Lewis acid additives.

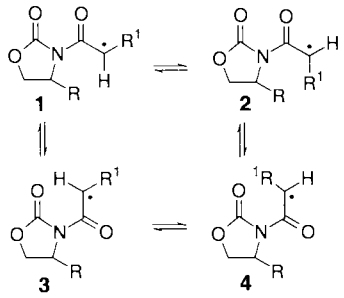
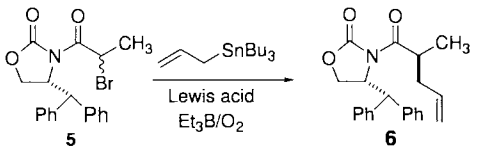
[**] This work was supported in part by the NSF (OSR-9108770). We thank Prof. Craig Jasperse for helpful discussions.

Until recently, the application of Lewis acids in radical reactions has been rather sparse.[9] We surmised that a proper combination of a chelating Lewis acid and the R substituent in the chiral auxiliary would allow for highly diastereoselective radical reactions if the radical were to react from a single rotamer. Of the several possible rotamers (**1**–**4**), type **1** is attainable when a Lewis acid chelates the two carbonyls, and steric interaction orients R^1 *syn* to the carbonyl group.[10] The rotamer population having been thus controlled, radical addition to the substrate should occur from the least hindered face opposite to the 4-substituent of the oxazolidinone. This communication describes outstanding levels of *p*-diastereoselectivity in Lewis acid mediated radical allylation with a simple, readily available, and easily removable oxazolidinone chiral auxiliary. Additionally, the first examples of the successful use of $Sc(OTf)_3$ in radical reactions are described.



The reaction we chose to test the *p*-diastereoselectivity when oxazolidinone auxiliaries are used was the transfer of an allyl group with allyl stannane [Eq. (a)].[11] The starting material **5**



(a)

was prepared by standard acylation of our new oxazolidinone, derived from diphenylalaninol,[12] with racemic α-bromopropionic acid. The reaction of **5** with allyltributylstannane and triethylborane/oxygen[13] as the radical initiator produced **6** as a 1:1.8 diastereomeric mixture in 93% chemical yield (Table 1, entry 1). The absolute configuration of the newly formed stereocenter for the major diastereomer was established as (*R*).

Table 1. The results of allylations according to Equation (a) [a].

Entry	Lewis Acid	Reaction Conditions	% Yield[b]	Ratio (*RS*:*RR*) [c]
1	None	−78 °C, CH_2Cl_2, 3 h	93	1:1.8
2	$BF_3 \cdot OEt_2$	−78 °C, CH_2Cl_2, 2.5 h	85	1:1.4
3	Et_2AlCl	−78 °C, CH_2Cl_2, 3 h	44	1.8:1
4	$ZnCl_2$	−78 °C, CH_2Cl_2, 2 h	95	6:1
5	$Zn(OTf)_2$	−78 °C, CH_2Cl_2/THF (1:1), 2 h	86	7.6:1
6	MgI_2	−78 °C, CH_2Cl_2, 2 h	57(39)	≥100:1
7	$MgBr_2$	−78 °C, CH_2Cl_2, 2 h	94	≥100:1
8	$MgBr_2$	25 °C, CH_2Cl_2, 2 h	94	30:1
9	$Yb(OTf)_3$ [d]	−78 °C, CH_2Cl_2/THF (1:1), 2 h	64(14)	5:1

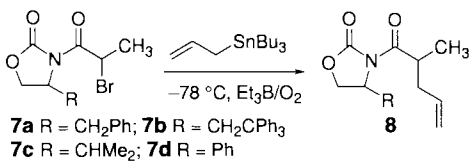
11	$Yb(OTf)_3$ [d]	−78 °C, Et_2O, 2 h	91	16:1
12	$Yb(OTf)_3$ [d]	−78 °C, Et_2O, H_2O (10 eq.), 2 h	77(3)	9:1
13	$Sm(OTf)_3$ [d]	−78 °C, Et_2O, 2 h	90	7:1
14	$Sc(OTf)_3$ [d]	−78 °C, Et_2O, 2 h	94	≥100:1

[a] 2 equiv of Lewis acid was used in all reactions unless otherwise noted. [b] Yield of isolated product; yield of the reduction product in parentheses. [c] Diastereomer ratios were determined by ^1H NMR spectroscopy (400 MHz). [d] 1 equiv of the Lewis acid was used.

The next series of experiments involved the screening of several mono- and multidentate Lewis acid additives of varying strength. Several entries in Table 1 are noteworthy. Outstanding levels of diastereoselectivity and high chemical yields were obtained with several Lewis acids (entries 6–8 and 14). The scandium and magnesium Lewis acids gave the highest selectivity.[14] *These experiments provide the first examples of the use of scandium triflate in radical reactions.* Lewis acids capable of chelation gave higher selectivities than those which give only single point coordination (compare entries 6–8 and 14 with 2). Increasing the temperature from −78 °C to room temperature led to a reduction in diastereoselectivity (compare entries 7 and 8). The absolute stereochemistry of **6** obtained with Lewis acid additives was (*S*), opposite to that obtained in the absence of a Lewis acid.[15] The sense of stereoinduction in Lewis acid mediated radical allylation was the same as that of enolate allylation, and these two reactions provide comparable diastereoselectivity.[16]

We have also examined the effect of the oxazolidinone ring's 4-substituent on diastereoselectivity in the allylation reaction [Eq. (b), Table 2]. Some trends are discernible from the data.



(b)

7a R = CH_2Ph; **7b** R = CH_2CPh_3
7c R = $CHMe_2$; **7d** R = Ph

Table 2. Effect of the chiral auxiliary's substituent on the diastereoselectivity of reaction (b).

Entry	Auxiliary[b]	Reaction Conditions	% Yield	Ratio [b]
1	**5** (*R*)	$MgBr_2$ (2 equiv), −78 °C, CH_2Cl_2, 2 h	94	≥100:1 (1:1.8) (*S*)
2	**5** (*R*)	$Sc(OTf)_3$ (1 equiv), −78 °C, Et_2O, 2 h	94	≥100:1 (1:1.8) (*S*)

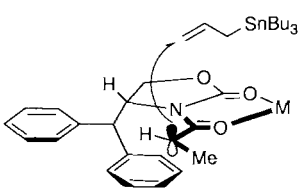
8	**7d** (*S*)	$MgBr_2$ (2 equiv), −78 °C, CH_2Cl_2, 2 h	92	3:1 (1.5:1)[c]

[a] The absolute configuration of the auxiliary is indicated in parentheses. [b] The ratio for reactions without Lewis acid additive and the absolute configuration of the newly formed stereocenter are given in parentheses. Diastereomer ratios were determined by ^1H NMR spectroscopy (400 MHz). [c] The absolute configuration of the products was not determined.

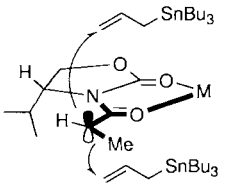
Oxazolidinones with aromatic substituents (**5**, **7a**, **7b**, entries 1–6) gave higher diastereoselectivities than those with the isopropyl substituent (**7c**, entry 7). Of all the oxazolidinones examined in this study, the auxiliary derived from diphenylalaninol and the tritylmethyl-substituted auxiliary gave highest selectivity. It is interesting to note that allylation with the valinol auxiliary (**7c**) under radical conditions gave **8c** with lower diastereoselectivity than enolate allylation.[17] Substrate **7d** with an auxiliary derived from phenylglycine gave poor selectivity.

We present here a working hypothesis for the stereoselectivities observed for the Lewis acid mediated allylations with different auxiliaries [Eq. (a) and (b)]. For reactions with **5**, coordination with a bidentate Lewis acid leads to the chelated intermediate **9** with an s-(*Z*) orientation of the C–CH_3 group.

Addition of the allyltin occurs from the face opposite to the large diphenylmethyl substituent, leading to **6** with the observed (*S*) stereochemistry. The low selectivity observed for **7c** with an isopropyl substituent (see **10**) relative to that for **5** and **7a** with



9



10

diphenylmethyl and benzyl substituents suggests that other factors in conjunction with steric effects may be responsible for the high selectivities observed with these auxiliaries.[18]

In conclusion we have shown that the versatile oxazolidinone auxiliaries can be used in conjunction with Lewis acids to provide outstanding levels of ρ-selectivities. The first use of scandium triflate in radical reactions was also illustrated. The extension of these studies to more complex systems and reactions with other radical acceptors is underway.

Experimental Procedure

Allylation of **5**: To a flask containing **5** (194 mg, 0.5 mmol), $MgBr_2 \cdot Et_2O$ (258 mg, 1.0 mmol), and CH_2Cl_2 (5 mL) under N_2 was added allyl tributylstannane (333 mg, 1 mmol) at $-78\,^{\circ}C$. Triethylborane (1 M in hexane, 1.0 mL, 1 mmol) and finally oxygen (5 mL, over 2 min) were added by syringe. The reaction mixture was stirred at $-78\,^{\circ}C$ for 2 h. After the reaction was complete, the mixture was diluted with CH_2Cl_2 (20 mL), washed with brine (3 × 3 mL), and the organic layer dried over $MgSO_4$. The product was purified by chromatography on silica gel (eluent: hexane/ethyl acetate 9/1). Yield 164 mg (94%).

6: M.p. 98–100 °C; $R_f = 0.6$ (80/20 hexane/ethyl acetate); ^1H NMR (400 MHz, $CDCl_3$): δ = 7.08–7.33 (m, 10H), 5.6 (m, 1H), 5.29 (m, 1H), 5.01 (m, 2H), 4.66 (d, J = 6.6 Hz, 1H), 4.35 (d, J = 5.1 Hz, 2H), 3.62 (m, 1H), 2.28 (m, 1H), 1.89 (m, 1H), 1.05 (d, J = 6.6 Hz, 3H); ^{13}C NMR (65 MHz, $CDCl_3$): δ = 176.1, 153.0, 139.5, 138.1, 135.5, 129.2, 128.9, 128.6, 128.4, 128.3, 127.8, 127.0, 117.0, 64.9, 56.5, 51.2, 37.3, 16.0; $[\alpha]_D^{26} = -111.93$ (c = 0.352, CH_2Cl_2); C,H,N analysis: calcd for $C_{22}H_{23}NO_3$: C 75.62, H 6.63, N 4.01; found: C 75.34, H 6.82, N 4.24.

[18] The higher selectivity with aryl-containing auxiliaries indicates that some π-stacking may be operative with these systems. Experiments are underway to understand these results.

A Sustainable Catalyst for the Partial Oxidation of Methane to Syngas: $Ni/Ca_{1-x}Sr_xTiO_3$, Prepared In Situ from Perovskite Precursors

Takashi Hayakawa,* Hideaki Harihara, Arnfinn G. Andersen, Andrew P. E. York, Kunio Suzuki, Hiroyuki Yasuda, and Katsuomi Takehira*

The catalytic partial oxidation of methane to syngas has been intensively studied.[1–4] This process has advantages over the conventional steam reforming of methane to make syngas, since this process is highly endothermic and produces syngas with a H_2/CO ratio ≥ 3. The partial oxidation of CH_4, expected to afford syngas with a H_2/CO ratio of about 2, makes methanol synthesis an ideal follow-up process. Precious metals such as

Ru, Rh, Pd, Ir, and Pt, supported on alumina,[1] or platinum and rhodium surfaces in a metal-coated ceramic monolith[3] were suitable as catalysts for this oxidation. Interestingly, some transition metal oxides combined with alkaline earth or rare earth oxides were found to be catalytically active at low temperatures (300 °C);[4] however, hot spots have been observed in the catalyst bed where the actual temperature was up to 370 K higher than the temperature measured by a thermocouple.[5] Ni/Al_2O_3, a typical catalyst for the steam reforming process, was tested with regard to its suitability for the partial oxidation of CH_4 at temperatures above 700 °C.[2] This process was thought to involve the initial oxidation of some of the CH_4 to H_2O and CO_2, followed by the reforming reactions of CH_4 with H_2O and CO_2.

In the production of syngas from CH_4, coke formation over the catalyst frequently takes place, resulting in catalyst deactivation. However, coke formation has been largely ignored,[2-5] except by Claridge et al.,[6] who observed that the relative rate of coke formation follows the order Ni > Pd > Rh > Ir.[6] We recently reported on the activity of a (Ca,Sr)(Ti,Ni) oxide in the oxidation of CH_4 to syngas; the Ni catalyst was prepared by in situ reduction of perovskite-like precursors.[7] The $Ca_{1-x}Sr_xTiO_3$ perovskite probably has an important role as the carrier of the Ni catalyst. We report herein the details of the activity of the (Ca,Sr)(Ti,Ni) oxide catalyst and its sustainability against coke formation in the partial oxidation of CH_4 to syngas.

To confirm that the perovskite carrier influences the efficiency of the catalyst, the Ni catalysts were prepared by three methods, that is, the citrate method ($Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit)), the impregnation method ($Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp)), and the mixing method ($Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$). The results of the CH_4 oxidation over these catalysts are shown in Figure 1. The most

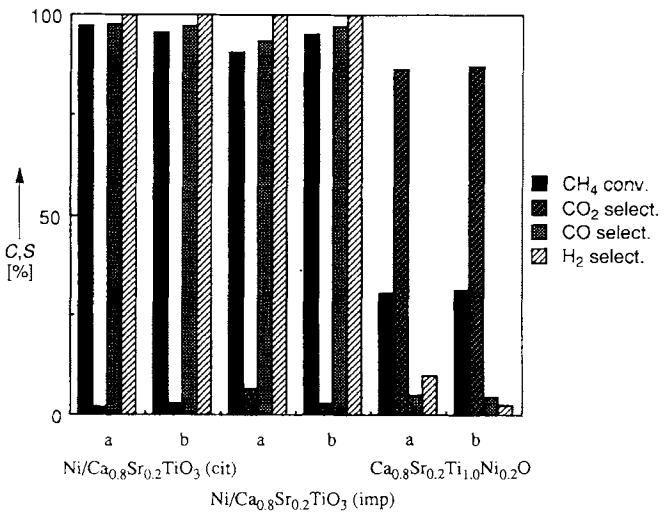

Fig. 1. CH_4 oxidation over the Ni catalyst. a: Directly after increase to 800 °C; b: After reduction with CH_4 (1.0 L h^{-1}) for 2 h. C = conversion, S = selectivity.

active catalyst was $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit), followed by $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp). After reduction with CH_4 (1.0 L h^{-1}) for 2 h, the activity of the $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) catalyst increased to almost the same value as the $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) catalyst. $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$ showed a very low activity for syngas production and gave small amounts of C_2 compounds as the by-products. In all reactions, the total amount of carbon in the effluent gas, ΣC, was almost constant.

X-ray diffraction (XRD) measurements revealed that both $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) are composed of orthorhombic $Ca_{0.8}Sr_{0.2}TiO_3$ perovskite and NiO. NiO was reduced to Ni metal after the testing. $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$ contains CaO, TiO_2 (rutile), and NiO together with small amounts of $CaTiO_3$. In this case, after the catalytic testing, NiO was only partly reduced to Ni metal, which helps to explain the marked contrast to the results obtained with $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp), where NiO was almost completely reduced to Ni metal.

The particle sizes of Ni metal in the catalysts after the catalytic testing, determined from X-ray line broadening measurements based on the most intense reflection, that is the (111) reflection for Ni, were as follows: citrate, 20 nm; impregnation, 33 nm, and mixing, 40 nm. X-ray photoelectron spectra (Ni 2d) of the catalysts revealed peaks at 852.7 eV (Ni^0) and around 855.5 eV (Ni^{2+} and Ni^{3+}); the former peak was clearly enhanced after the studies on the catalytic activity, showing that NiO had reduced to Ni metal during the CH_4 oxidation. The composition of the catalyst after the tests on the catalytic activity was calculated from the X-ray photoelectron spectra[8] (Fig. 2). The amount of Ni present was obtained by summing

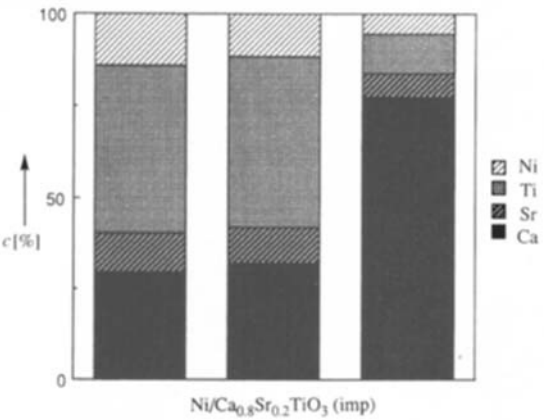

Fig. 2. Composition of the surface of the Ni catalyst. c = relative concentration.

the amounts of Ni^0, Ni^{2+} and Ni^{3+}. Similar metal distributions were observed for $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp), except that a higher Ni content was obtained for the former catalyst, contrary to our expectations. In $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$ the Ca content increased, whereas the Ti and Ni contents decreased.

Scanning electron microscopic images of $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) showed that the particle size of 10 μm prior to testing the catalytic activity decreased to 1 μm after the testing, suggesting that the catalyst particles were pulverized during the CH_4 oxidation. This may be due to the reduction of NiO to Ni metal: NiO was separated from the perovskite structure and may be located at the grain boundaries in the catalyst particles prior to the testing. The catalyst particles may be pulverized to fine particles as the "binder" NiO is no longer present after the testing. Thus nickel probably appears on the catalyst surface. On the other hand, the $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$ catalyst showed particles of tight agglomerates, which may be formed by sintering of small metal oxide particles; these agglomerates were not decomposed during the reaction. Only the surface morphology changed after the catalytic testing. These observations, and the low nickel concentration on the surface of $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$ (Fig. 2)

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0193 $ 10.00+.25/0

were consistent with the partial reduction of NiO to Ni metal observed in the XRD analyses of the catalysts. In $Ca_{0.8}Sr_{0.2}Ti_{1.0}Ni_{0.2}O$, the NiO in the catalyst bulk cannot be easily reduced and does not appear on the catalyst surface. Only NiO species on the surface of the catalyst particles were reduced to Ni metal. Interestingly, among the methods of preparation tested, the citrate method gave both the most active catalyst and that with the highest Ni content.

To test the lifetime of the catalysts, $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) were used for the CH_4 oxidation for 150 h at 800 °C. The activity of both these catalysts remained constant; the $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) catalyst gave higher selectivities to syngas than $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) (Fig. 3).

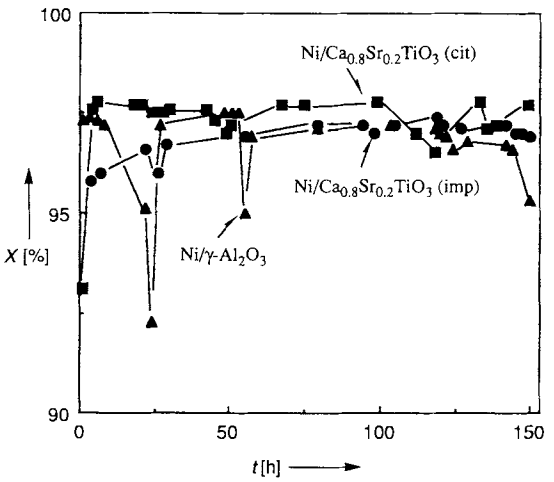

Fig. 3. CH_4 oxidation over the Ni catalysts. Dependence of the CO selectivity X on the reaction time t. Conditions: CH_4 1 Lh^{-1} (41.6 $mmol\,h^{-1}$); air: 2.4 Lh^{-1} (O_2: 21.0 $mmol\,h^{-1}$; N_2: 78.9 $mmol\,h^{-1}$); catalyst: 0.3 g; reaction temperature 800 °C.

$Ni/\gamma\text{-}Al_2O_3$ was used for comparison. Its activity varied, and both the selectivity and the conversion oscillated periodically (with a considerable time interval between the oscillations). At each oscillation the selectivity for syngas decreased, while the complete oxidation to CO_2 was accelerated. This is also evident from Figure 4, in which a sudden decrease in the value of ΣC is

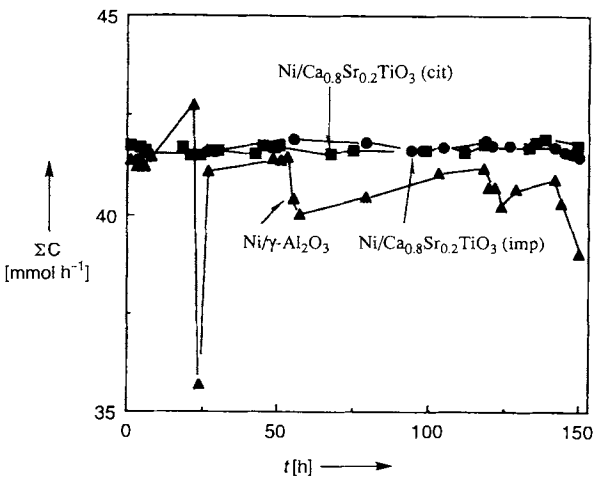

Fig. 4. CH_4 oxidation over the Ni catalysts. Dependence of the total carbon content ΣC in the effluent gas on the reaction time t. Conditions: CH_4 1 Lh^{-1} (41.6 $mmol\,h^{-1}$); air: 2.4 Lh^{-1} (O_2: 21.0 $mmol\,h^{-1}$; N_2: 78.9 $mmol\,h^{-1}$); catalyst: 0.3 g; amount of Ni: 11.5 wt% on $\gamma\text{-}Al_2O_3$ or 8.1 wt% on $Ca_{0.8}Sr_{0.2}TiO_3$ ($Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit)); reaction temperature 800 °C.

observed at each oscillation point, while both $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp) showed constant ΣC values in the effluent gas, close to the theoretical value of 42 $mmol\,h^{-1}$. This oscillation may be caused by the progressive build-up of a carbon layer over the catalyst, finally resulting in a blockage in the reactor. Since CH_4 and air were controlled by separate mass flow controllers with an entrance pressure of 1 and 3 $kg\,cm^{-2}$, respectively, the back pressure resulting from the reactor blockage would lead to a preferential decrease in the CH_4 flow rate. A decrease in the CH_4 partial pressure in the reactor would result in a more favorable composition of the reaction mixture for the formation of CO_2 and, more importantly, to the combustion of some of the deposited carbon to CO_2 and the recovery of the original steady state conditions. Furthermore, since the partial oxidation of CH_4 to syngas over the $Ni/\gamma\text{-}Al_2O_3$ catalyst proceeds by the complete oxidation followed by the reforming reactions, and the catalyst bed consists of two zones (the first zone comprises NiO under the oxygen-rich atmosphere, while the second comprises Ni metal under the reducing atmosphere[2]), the oscillation can probably also be related to a balance between the zones in the catalyst and thus to a balance between the complete oxidation and the reforming equilibria. After 150 h, the reactor was cooled to room temperature in N_2 gas flow. The catalyst was then treated in air (1.5 Lh^{-1}) by increasing the temperature at 2.5 $K\,min^{-1}$ to measure the amount of coke formed over the catalyst during the CH_4 oxidation. The coke over the catalyst was oxidized to CO_2; the rate of its formation was plotted against temperature as shown in Figure 5. CO_2 formation was evident above 250 °C; the main peaks

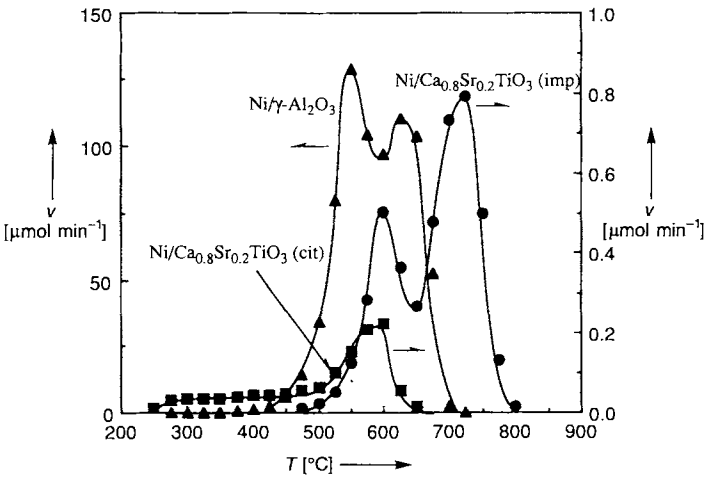

Fig. 5. Carbon deposition over the Ni catalysts. Dependence of the rate of formation of CO_2 (v) on the temperature T. After the reactions for 150 h, the catalysts were treated in air (1.5 Lh^{-1}) by increasing the temperature at 2.5 $K\,min^{-1}$. The arrows indicate which scale for the rate of formation of CO_2 is applicable to a particular catalyst.

were observed between 500–800 °C. Integration of the rate gave the total amount of CO_2, from which the amount of coke formed over the catalyst was calculated. The following values were obtained: 29.3 wt% on $Ni/\gamma\text{-}Al_2O_3$, 0.17 wt% on $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (imp), and 0.05 wt% on $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit).

Transmission electron microscopic studies of the surface of $Ni/\gamma\text{-}Al_2O_3$ after the reaction for 150 h showed that in the coke formation, the typical tubular carbon filaments (whisker carbon) formed with a small nickel particle at the end.[9] On the other hand, no coke formation was observed on the surface of $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit); the size of the nickel particles increased

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0194 $ 10.00+.25/0

after the reaction. Prior to the reaction, NiO particles were evenly dispersed on $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) and their average sizes were below 5 nm, while after the reaction they had grown to about 50 nm diameter.

Ni catalysts supported on $(Ca,Sr)TiO_3$ oxidize CH_4 to syngas. The most active of these catalysts is $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) prepared by the citrate method from the perovskite precursor. Coke formation over $Ni/Ca_{0.8}Sr_{0.2}TiO_3$ (cit) was negligible, even after reaction for 150 h. Thus, nickel, which is abundant and cheap, can now be used in place of the expensive platinum group metals as a component of catalysts for the production of syngas.

Experimental Procedure

The catalysts were prepared by the citrate, impregnation, and mixing methods. In the citrate process [10], nickel nitrate, alkaline earth carbonates, and tetraisopropoxidotitanium were treated and heated with citric acid and ethylene glycol to make a sol. This was subsequently decomposed in two steps by heating to 200 °C for 5 h and then to 500 °C for 5 h, and finally calcined at 850 °C in air for 10 h. In the impregnation process, nickel nitrate, citric acid, and ethylene glycol were added to an aqueous suspension of the perovskite $Ca_{0.8}Sr_{0.2}TiO_3$, which had previously been prepared by the citrate method. The suspension was evaporated and calcined at 850 °C in air for 5 h. In the mixing method, a mixture of metal oxides was ground and calcined at 850 °C in air for 5 h. The Ni metal content was fixed at 8.1 wt% in all three catalysts. The Ni/γ-Al_2O_3 catalyst, used for comparison, was prepared by the impregnation method with γ-Al_2O_3 (Sumitomo Chemical Co., NK-124). The Ni metal content was 11.5 wt%.

The structure of the catalysts was studied by powder X-ray diffractometry (MAC Science MXP-18 diffractometer with $Cu_{K\alpha}$ radiation) and X-ray photoelectron spectroscopy (PHI-5000 spectrometer employing $Al_{K\alpha}$ radiation and an electron flood gun). The surface areas of the catalysts ($1\ m^2 g^{-1}$) used were almost identical, as measured by the N_2-BET method with a Micromeritics model 2200.

All the catalysts were tested at 800 °C in a mixture of air ($2.4\ L h^{-1}$) and CH_4 ($1.0\ L h^{-1}$) using a quartz reactor. 300 mg of catalyst was dispersed in 2 mL of quartz wool to avoid sintering and clogging of the reactor. Product gases were sampled immediately after the reactor and injected into a gas chromatograph for analysis. The selectivities for C_2 compounds, CO_2, CO, and H_2 were calculated based on the numbers of carbon and hydrogen atoms in CH_4.

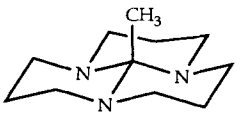
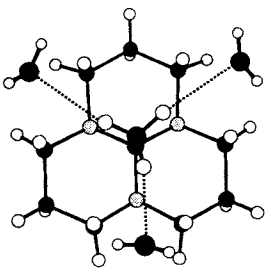
Resolving the Puzzling Eclipsed Conformation of the Methyl Group in a Tricyclic Orthoamide Trihydrate**

Ito Chao* and Jye-Chan Chen

It is well known that a staggered conformation around a $C_{sp^3}-CH_3$ bond is preferred over an eclipsed one. Nevertheless, the striking crystal structure of the trihydrate of tricyclic orthoamide **1** ($\mathbf{1}\cdot 3H_2O$) was pointed out by Seiler et al.[1] as the first example of a nearly eclipsed arrangement for a $C_{sp^3}-CH_3$ bond (N-C-C-H dihedral angle is 8°). In this unusual crystal structure, each C–H bond of the methyl group seemed to be engaged in C–H···O hydrogen bonding[2] with a H_2O molecule surrounding the orthoamide molecule, according to the intermolecular C–H···O distance (2.67 Å) and angle (170°). Because a staggered $C_{sp^3}-CH_3$ conformation was found in the crystal structure of *anhydrous* **1**, Seiler et al. carried out ab initio calculations on $CH_3-C(NH_2)_3$, $CH_4\cdots OH_2$, and $CH_4\cdots OH_2\cdots NH_3$[3] as models to study the magnitude of the torsional barrier for the rotation of the methyl group (ΔE_{rot}) in **1** and the strength of C–H···O interactions in the $\mathbf{1}\cdot 3H_2O$ crystal. Their results were in line with the assumption that the eclipsed conformation in $\mathbf{1}\cdot 3H_2O$ originated from C–H···O H-bonding (about 2 kcal mol^{-1} for each C–H···O interaction), which is higher for the three hydrogen bonds than the estimated ΔE_{rot} of $C_{sp^3}-CH_3$ (about 5.5 kcal mol^{-1} at the RHF/6-31G* level).[1a] An important implication of their finding was that the conformation of aliphatic moieties of molecules next to clusters of H_2O molecules may be different from that in non-aqueous environments.



1



$\mathbf{1}\cdot 3H_2O$

However, the conclusion by Seiler et al. based on theoretical results was later questioned by Novoa et al.[4] They pointed out that a large part of the C–H···O stabilization energy reported by Seiler et al. came from basis set superposition errors (BSSEs). The BSSE-corrected $CH_4\cdots OH_2$ binding energy was calculated to be 0.59 kcal mol^{-1} based on MP2 calculations with a near Hartree–Fock (HF) limit basis set.[5] To reexamine the problem, Novoa et al. calculated ΔE_{rot} for the model compounds $CH_3-C(NH_2)_3$ and $CH_3-C[N(CH_3)_2]_3$ with a larger basis set, 6-31 + + G**. Furthermore, to model C–H···O interactions

in $1\cdot 3H_2O$, they carried out MP2/6-31 + + G** calculations on $CH_4\cdots OH_2$, $CH_4\cdots(OH_2)_2$, $CH_4\cdots(OH_2)_3$, and $CH_4\cdots OH_2\cdots NH_3$, AM1 calculations on **1** and $1\cdot 3H_2O$, and atom–atom potential calculations on crystalline $1\cdot 3H_2O$. The ab initio HF/6-31 + + G** calculations for $CH_3-C(NH_2)_3$ and $CH_3-C[N(CH_3)_2]_3$ still supported a ΔE_{rot} value of about 5.5 kcal mol^{-1} for **1**. However, the total stabilization energy provided by the three C–H···O contacts was estimated to be about 2.5 kcal mol^{-1} by the ab initio method and less than 3 kcal mol^{-1} by all methods used. Therefore, Novoa et al. did not agree that the C–H···O H-bonds resulted in the eclipsed arrangement of the methyl group in the $1\cdot 3H_2O$ crystal and suggested that the observed structure of $1\cdot 3H_2O$ may be a local energy minimum.[4]

Since computing resources are limited, it is often imperative to use small model systems to solve chemical problems in the real world. However, it is not trivial to assess the validity of models. It has been shown that the H-accepting ability of a H-bond acceptor can be estimated by the most negative value (V_{min}) of its molecular electrostatic potential (MEP).[6] Likewise, the H-donating ability of a H-bond donor can be estimated by the most positive value (V_{max}) on a MEP surface defined by the 0.002 e bohr^{-3} contour of the electron density (ρ) of the molecule.[7] Therefore, we calculated the MEP at the RHF/6-31G* level to assess dependence of the H-bond forming ability on the size of model systems.[8a] Figure 1a and b show that the V_{min} of H_2O (−62.1 kcal mol^{-1}) is smaller than that of $H_2O\cdots NH_3$ (−78.6 kcal mol^{-1}). This is in agreement with the finding that polarization of H_2O by NH_3 increases the strength of C–H···O H-bonding.[1a, 4] In fact, in the $1\cdot 3H_2O$ crystal each H_2O molecule is not only H-bonded to an N atom and a C–H bond of **1**, but also to two nearby H_2O molecules. Overall, six water molecules form a chairlike cluster, which is sandwiched by two molecules of **1** with their N sides facing the H_2O cluster. The V_{min} value shown in Figure 1c reveals that adding two more H_2O molecules to the $H_2O\cdots NH_3$ model reduces the C–H···O H-bonding ability of H_2O. However, if all heteroatoms in the H-bonded cluster are accounted for in the model (Fig. 1d), the V_{min} value is more negative than that of the $H_2O\cdots NH_3$ model.[9] Because many-body effects in the solid state are expected to enhance electronic polarization of heterobonds, H_2O in $1\cdot 3H_2O$ crystal should be a better H-bond acceptor than isolated H_2O or $H_2O\cdots NH_3$. On the other hand,

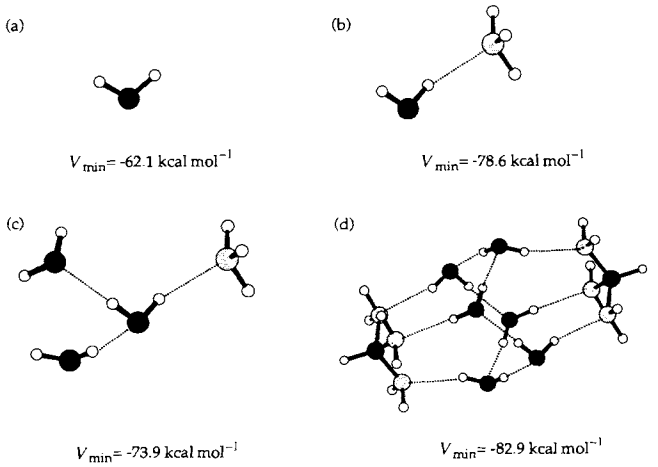

Fig. 1. V_{min} of a) an isolated H_2O molecule, b) H_2O H-bonded to NH_3, c) H_2O H-bonded to one NH_3 and two H_2O, and d) H_2O in the presence of the complete network of O–H···O and O–H···N bonds. All geometries are taken directly from X-ray coordinates.

V_{max} values of CH_4 and **1** are 11.7 and 12.5 kcal mol^{-1}, respectively. If the V_{max} of a good H-donor CHF_3 (V_{max} = 42.3 kcal mol^{-1}) is taken as reference, the H-donating ability of **1** is slightly larger than CH_4.[10] Based on above analyses, we believe models studied by Novoa et al. provide the lower limit of the strength of C–H···O bonds in the $1\cdot 3H_2O$ crystal.[11]

We evaluated ΔE_{rot} of **1** by carrying out ab initio HF and density functional theory (DFT) calculations on the molecule itself, rather than on a simplified model.[8] Since ΔE_{rot} values for ethane calculated at HF/6-31G* and HF/6-31 + + G**[4] levels (both afforded 2.98 kcal mol^{-1}) agreed well with experiment (2.88 kcal mol^{-1}),[12] the same theory levels were used to calculate **1**. The calculated ΔE_{rot} barriers were 1.96 and 2.00 kcal mol^{-1} at 6-31G* and 6-31 + + G** levels, respectively. These energy barriers are more than 3 kcal mol^{-1} lower than that of model compounds calculated at the same theory level. More importantly, these low energy barriers make it possible for C–H···O interactions to induce the nearly eclipsed conformation in $1\cdot 3H_2O$. Results from DFT calculations also support the above conclusion. The ΔE_{rot} of **1** is 1.56 kcal mol^{-1} at the BLYP/6-31G* level and 1.04 kcal mol^{-1} at the BLYP/6-31 + + G**//BLYP/6-31G* level.[13]

One may wonder what the reason is for this significant difference between the ΔE_{rot} of **1** and that of $CH_3-C(NH_2)_3$. On examining the RHF/6-31 + + G** optimized geometry of **1** we found that the distances between H_a and H_b in **1** are smaller than the sum of the van der Waal radius of the H atom (2.4 Å) in both the eclipsed and the staggered forms (Fig. 2), whereas this type of short contact is absent in $CH_3-C(NH_2)_3$. The crowdedness around the methyl group generated by the axial H atom of **1** explains why the values of the $H_a\cdots N$ distances and H-C_1-C_2 angles of **1** are larger than those of the corresponding conformations of $CH_3-C(NH_2)_3$ (Fig. 2). However, it was not apparent why the eclipsed **1** and $CH_3-C(NH_2)_3$ have similar C_1-C_2 bond lengths, whereas the staggered **1** has a longer C_1-C_2 bond than $CH_3-C(NH_2)_3$. We sought insights by looking into molecular orbitals (MOs) of **1** and $CH_3-C(NH_2)_3$. We found that the orbital energies of two thirds of the occupied MOs of staggered **1** are reduced upon rotation to the eclipsed conformation. Although the energies of most MOs decrease by a small amount upon rotation, some of them decrease by a significant amount. For example, rotating **1** from the staggered conformation to the eclipsed, the orbital energy of degenerate orbitals 47 and 48 decreases by 2.58 kcal mol^{-1} (Fig. 3). For $CH_3-C(NH_2)_3$ the orbital energies of most occupied orbitals of the staggered form increase upon rotation to the eclipsed conformation. For orbitals whose energies decrease upon rotation, the magnitudes of the energy decrease are less significant than in **1** (the largest energy decrease is 1.04 kcal mol^{-1}). In other words, the absence of the axial H atom in $CH_3-C(NH_2)_3$ makes it a poor model for estimating ΔE_{rot} of **1**. Similarly, fully optimized

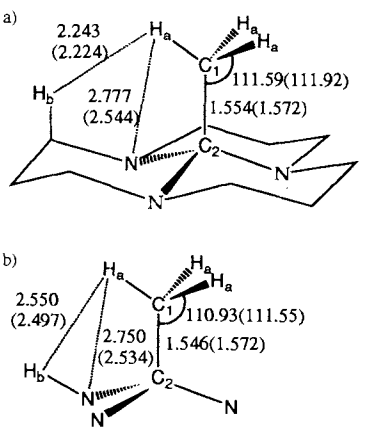

Fig. 2. Selected bond lengths [Å] and bond angle [°] of RHF/6-31 + + G** optimized **1** (a) and CH_3-$C(NH_2)_3$ (b). Numbers in parentheses are for the eclipsed conformer. The rest are for the staggered conformer.

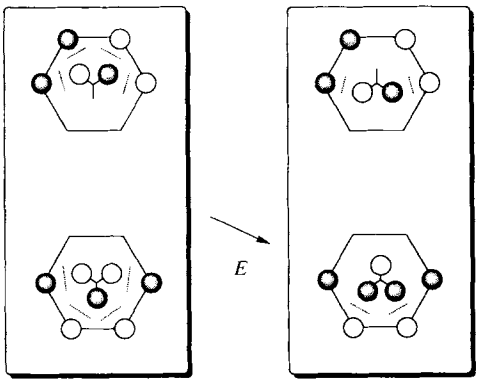

Fig. 3. Simplified representation of (47th and 48th) degenerate orbitals of the staggered and the eclipsed **1**. Only positions of axial and methyl H are shown. Nodal planes between H in close contact are shown by dashed lines. The orbital energy of the eclipsed conformer is lower than that of the staggered conformer by 2.58 kcal mol^{-1}, because it has fewer nodal planes.

CH_3-$C[N(CH_3)_2]_3$[4] is not a good model of **1** either. This is because the H atom of the $-N(CH_3)_2$ groups will not occupy the corresponding axial positions in **1**, in order to avoid strong repulsion between neighboring H atoms (Fig. 4). Finally, it should be noted that MM3[14] molecular mechanical calculations, without any MO concept in the underlying principles, afford 3.98 and 4.38 kcal mol^{-1} for the ΔE_{rot} of **1** and CH_3-$C(NH_2)_3$, respectively.

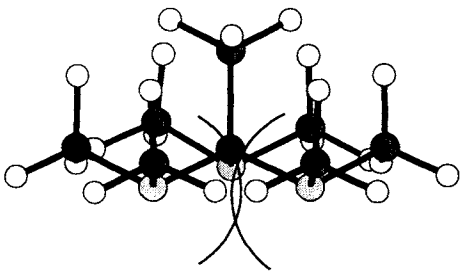

Fig. 4. Unfavorable contacts between H of CH_3-$C[N(CH_3)_2]_3$.

In summary, we found that 1) the strength of the three C-H···O H-bonds in **1**·3H_2O estimated by Novoa et al. (2.5 kcal mol^{-1}) is the lower limit of these interactions and 2) ΔE_{rot} of **1** is equal to or less than 2 kcal mol^{-1} because of the existence of proximal axial H atoms. Therefore, our results lead to the conclusion that the unique crystal structure of **1**·3H_2O is a result of the C-H···O interactions that overcome the low rotational barrier of **1**. Furthermore, these results demonstrate the danger of relying on small model systems for solving delicate problems of large molecules.

[9] Since a C-H···O H-bond is significantly weaker than O···H···O and O-H···N bonds, we did not include any C-H···O bond in any model shown in Figure 1.

[10] At the RHF/6-31G* level, the BSSE-uncorrected C-H···O binding energies of CH_4···H_2O and CHF_3···H_2O are −0.56 (Ref. [5]) and −4.05 kcal mol^{-1}, respectively.

[11] When using MEP as a measure of H-bond donor/acceptor ability, we overlooked the dispersion energy contribution to nonbonded interactions. However, due to the attractive nature of dispersion energy and because more dispersion forces are present in the crystal than in the models, our conclusion that model systems provide the lower limit of the strength of C-H···O interactions remains unchanged.

AIDS (Acquired Immunodeficiency Syndrome) is a vicious retroviral disease characterized by immunosupression associated with opportunistic infections, secondary neoplasms, and neurological manifestations. Despite an extensive international research effort, the viral infection caused by the human immunodeficiency virus (HIV) remains incurable. In the United States it is presently the fourth leading cause of mortality for men between the age of 15 and 54.[1]

The heavily glycosylated surface glycoprotein gp120 plays a critical role for HIV infection of cells. Gp120 is responsible not only for the attachment and penetration of target cells, but also for the antiviral immune response. There is evidence that the

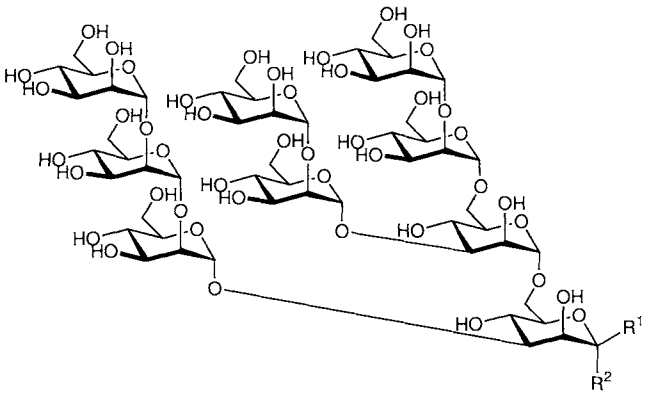
[**] Cyclohexane-1,2-diacetals in Synthesis. Part 4. This work was supported by the BP Research Endowment (to S. V. L.), the Zeneca Strategic Research Fund, the Deutsche Forschungsgemeinschaft (postdoctoral fellowship to J. P.), and Schering Agrochemicals Ltd, now AgrEvo, (Schering Fellowship in Bioorganic Chemistry to H. W. M. P). Parts 1-3: Ref. [7a-c]

glycans of the viral envelope are possible targets for immunotherapy and/or vaccine development.[2] No less than 29 N-linked oligosaccharides have been identified, the main fraction being of the high mannose type, for example **1**,[3] a ubiquitous undecasaccharide.[4] In view of the remarkable activity of antibodies directed against the mannose residues of HIV-1 glycoprotein gp120 in vitro,[5] the mannan moiety of this glycoprotein is a very attractive synthetic target.[6] In this paper we describe the preparation of the model nonasaccharide **2** with our CDA methodology (CDA = cyclohexane-1,2-diacetal) for oligosaccharide assembly.[7]

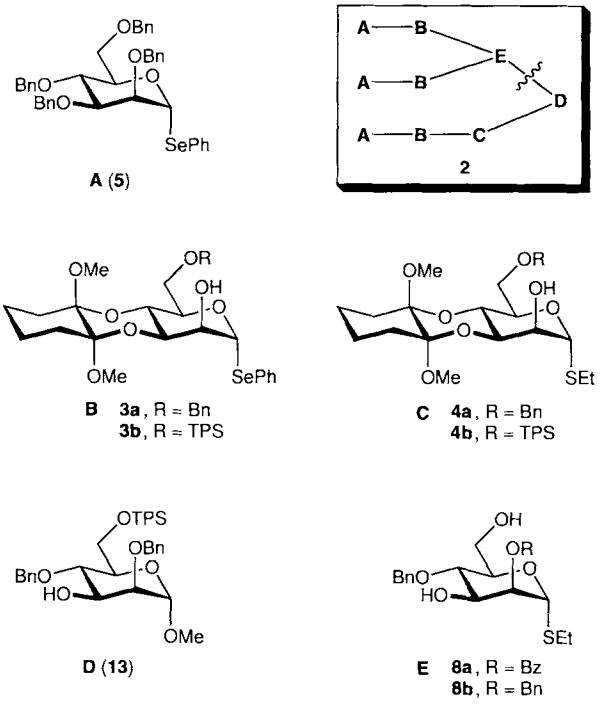


1, R^1 =  , R^2 = H

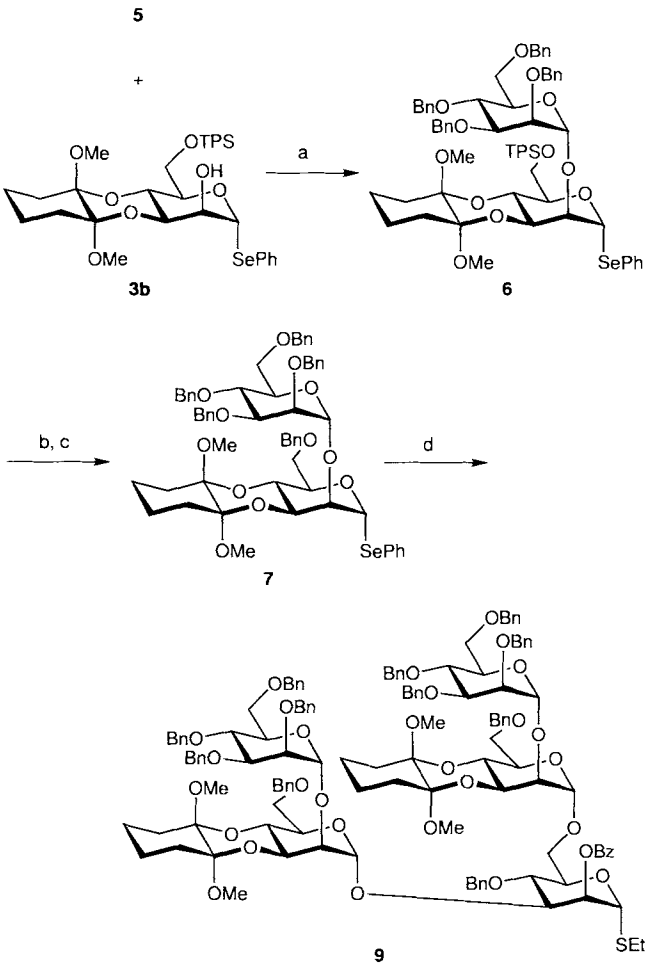
2, R^1 = H, R^2 = OMe

Recently we reported that the reactivity of glycosyl donors can be tuned by the selective introduction of different protecting and leaving groups, thus enabling highly efficient oligosaccharide synthesis.[7] Four levels of reactivity are provided by these methods. This led us to propose a synthetic plan for **2** including the five building blocks **A**–**E** (Scheme 1).[8] We anticipated that the final step for assembling the nonasaccharide would be the coupling between an ethylthio pentasaccharide donor and a tetrasaccharide acceptor unit. The preparation of the two segments should be straightforward, since the CDA group decreases the reactivity of glycosyl donors relative to the per-O-benzylated compounds (reactivity **A** > **B**).[7] In addition, phenylseleno glycosides are more reactive than the ethylthio analogues (reactivity **B** > **C**,**E**), whereas the O-glycoside **D** is virtually unreactive in the presence of iodonium sources.[9]

Unfortunately it was not possible to selectively benzylate the 6-position of CDA-protected mannose donors, which would have led directly to **3a** (**B**) and **4a** (**C**).[8] Instead we began with the TPS-protected (TPS = 6-*O*-*tert*-butyldiphenylsilyl) analogues **3b** and **4b** and performed appropriate deprotections and reprotections at later stages. First we synthesized the "common" disaccharide **6** from **5** (**A**) and **3b** in 55% yield (Scheme 2), by a fast reaction (reaction time less than ten minutes) that is selective towards activation with *N*-iodosuccinimide/triflic acid (NIS/TfOH). Subsequent protecting group manipulation (desilylation/benzylation) furnished **7** in 84% yield. Two equivalents of **7** then reacted selectively with **8a** (**E**) to form the pentasaccharide **9** (80%). The benzoyl group in the 2-position of **8a** is essential not only for high α-selectivity in the following coupling reaction, but also for the successful formation of **9**, since the 2-O-benzyl compound **8b** reacted with NIS faster than disaccharide **7**.



Scheme 1. Building blocks **A**–**E** for the synthesis of **2** (schematic representation at the top right).



Scheme 2. a) NIS/TfOH(cat.), dichloroethane/Et_2O (1/1), 4 Å molecular sieves, 55%; b) TBAF/AcOH (3%), THF; c) NaH, BnBr (Bn = $PhCH_2$), DMF, 84% over two steps. d) **8a** (0.4 equiv), NIS/TfOH(cat.), dichloroethane/Et_2O (1:1), 4 Å molecular sieves, 80%.

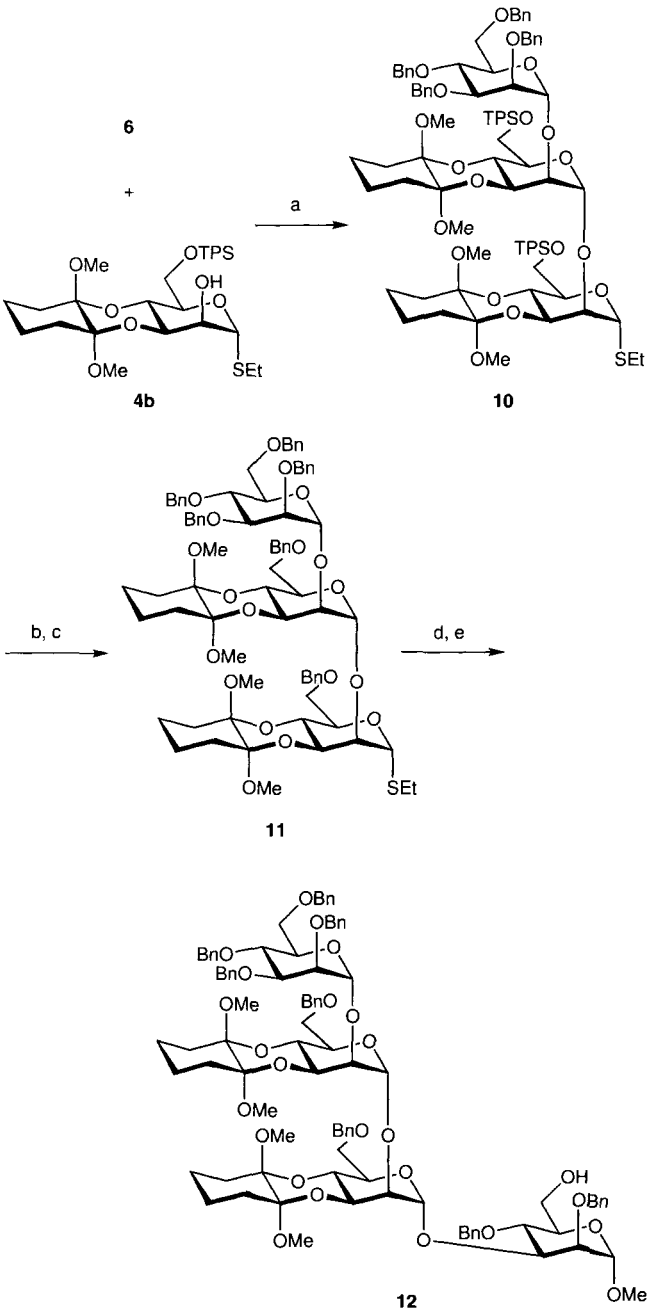
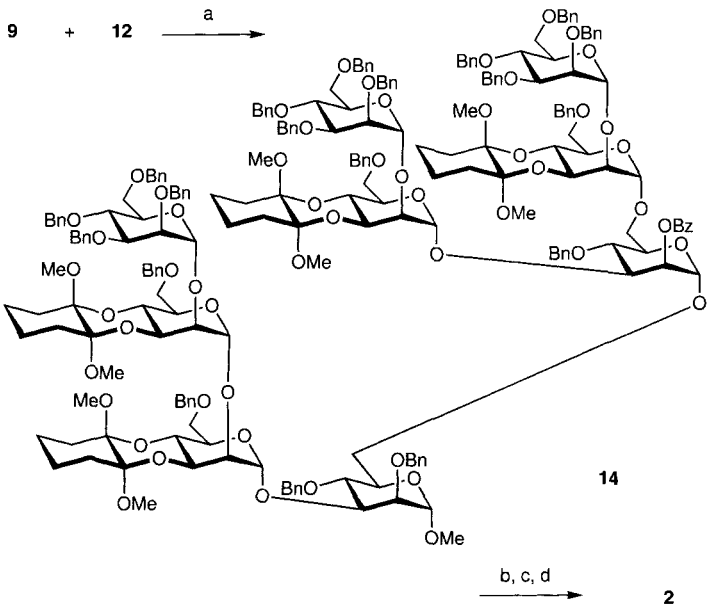
Next we focused on the synthesis of the trisaccharide **10** for further elaboration to the tetrasaccharide **11** (Scheme 3). For the formation of disaccharide **6** the difference in glycosyl reactivity originated from the choice of protecting groups. For the formation of trisaccharide **10**, however, the difference in glycosyl reactivity could be exclusively controlled by changing from the phenylselenoglycoside **3b** to the ethylthioglycoside **4b** without changing the protecting groups. The desired trisaccharide **10** was thus formed in an excellent yield (80%); after protecting group manipulation **12** was obtained in 70% yield over two steps. Finally, tetrasaccharide **11** was formed by activation of **12** in the presence of acceptor **13** with NIS/TfOH and desilylation with tetrabutylammonium fluoride (TBAF)/acetic acid (66% over two steps, Scheme 3).



Scheme 3. a) NIS/TfOH(cat.), dichloroethane/Et_2O (1/1), 4 Å molecular sieves, 80%; b) TBAF/AcOH (3%), THF; c) NaH, BnBr, DMF, 70% over two steps; d) **12** (1.1 equiv), NIS/TfOH(cat.), dichloroethane/Et_2O (1/1), 4 Å molecular sieves; e) TBAF/AcOH (3%) in THF, 66% over two steps.

The final glycosidation step—activation of **9** in the presence of **11**—provided the desired nonasaccharide **14** (Scheme 4). However, the low 30% yield of this reaction was disappointing. More successful preliminary results with other tetrasaccharide



Scheme 4. a) NIS/TfOH(cat.), dichloroethane/Et_2O (1/1), 4 Å molecular sieves, 30%; b) CF_3CO_2H/H_2O (20/1), 5 min, (43%); c) $NaOCH_3$ in MeOH, Amberlite IR 120, (55%); d) $Pd(OH)_2$ on activated charcoal, MeOH, quantitative.

acceptors indicate that this may be due to a steric mismatch of the two partners, a phenomenon which has been previously noted.[10] Deprotection of **14** to yield the target molecule **2** was straightforward. The global cleavage of the CDA groups was achieved with trifluoroacetic acid/water (20/1) in an acceptable 43% yield (81% per CDA unit). Debenzoylation mediated by sodium methoxide in methanol at 55 °C (no reaction at room temperature) followed by removal of the benzyl groups by catalytic hydrogenation occurred smoothly to afford **2**.[11]

In summary, we have achieved a short synthesis of the mannan residue of a high mannose type oligosaccharide present on the viral coat of HIV-1. We efficiently assembled the protected nonasaccharide **14** from monosaccharide building blocks using only one promotor system (NIS/TfOH) to activate the different glycosyl donors and only minor protecting group manipulation. Furthermore, this synthesis demonstrates that the strategy of tuning the reactivity of glycosides is a powerful tool for the concise and rapid preparation of complex oligosaccharides. The synthesis of a nonasaccharide with a β-O-linker (instead of the α-O-methyl group) that would permit binding of the glycan to a protein (hence providing us with a tool for further biological/medical testing) is currently under investigation.

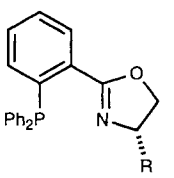
Chiral Phosphanyldihydrooxazoles in Asymmetric Catalysis: Enantioselective Heck Reactions**

Olivier Loiseleur, Peter Meier, and Andreas Pfaltz*

The development of enantioselective variants of the Heck reaction has added a new dimension to this important method for C–C bond formation.[1, 2] Excellent enantioselectivities have been achieved and several remarkable applications in the synthesis of complex natural products have been reported. So far, the most effective ligand for these reactions has been BINAP.[1–3] However, the application range of Pd(BINAP) catalysts seems limited to certain classes of substrates and their activity is often low. In addition, these catalysts promote C=C bond migration which sometimes leads to useful products but unfortunately often results in mixtures of isomers. Therefore, it is necessary to search for other ligands and catalysts to enhance the scope of enantioselective Heck reactions.

In the course of our work on phosphanyldihydrooxazoles **1**,[4–6] which have proven to be effective ligands for enantioselective Pd-[4a, 5] and W-catalyzed[6] allylic substitution, we have



1a R = CH_3
1b R = $CH(CH_3)_2$
1c R = $C(CH_3)_3$
1d R = C_6H_5
1e R = $CH_2(C_6H_5)$
1f R = $CH_2CH(CH_3)_2$
1g R = $CH_2C(CH_3)_3$

tested these ligands in intermolecular Heck reactions of cyclic olefins. The reaction between 2,3-dihydrofuran and 1-cyclohexenyl triflate, previously reported by Ozawa, Hayashi et al.,[2b] was chosen to screen different ligands and catalyst precursors and to optimize the reaction conditions (Table 1). The best enantioselectivity and also the highest catalyst activity was observed with the *tert*-butyldihydrooxazole derivative **1c**. With 3 mol% of catalyst, prepared in situ from [Pd(dba)$_2$][7] and 1.5–2 equivalents of ligand **1c**, the 2,5-dihydrofuran derivative **2** was formed in high yield and with excellent enantioselectivity [Eq. (a), Table 1]. The corresponding 2,3-dihydrofuran derivative was not detected, in contrast to the Pd(BINAP)-catalyzed reaction[2b] which yields the thermodynamically more stable 2,3-dihydro isomer as the main product with 58% yield and 87% *ee*. With Pd(BINAP) catalysts, 1,8-bis(dimethylamino)-naphthalene (proton sponge) has to be used as base for optimum results, whereas in our case simpler bases such as triethylamine or *N*,*N*-diisopropylethylamine are equally effective. Catalysts derived from analogous ligands with less bulky substituents at the stereogenic center are significantly less reactive and the resulting *ee* values are slightly lower [% conversion/% *ee*: 97/98 for **1c**, 24/90 for **1e**, 18/95 for **1f**; proton sponge, 50 °C, other conditions, see Equation (a)].

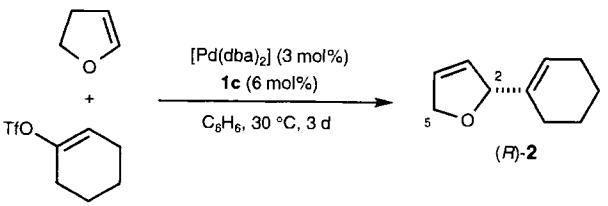


Table 1. Enantioselective Heck reaction of 2,3-dihydrofuran to give (*R*)-**2** [Eq. (a)].

Base	*ee* [%]	Yield [%] [a]
1,8-bis(dimethylamino)naphthalene	98	95
2,2,6,6-tetramethylpiperidine	99	95
triethylamine	>99	78
N,*N*-diisopropylamine	>99	92
N,*N*-diisopropylethylamine	99	98 [b]
sodium carbonate	98	34
sodium acetate	98	50

[a] Determined by GC with *n*-tridecane as internal standard. [b] Yield of purified product: 92%.

Similar results were obtained with phenyl and 1-cyclopentenyl triflate (Scheme 1). Arylation of 4,7-dihydro-1,3-dioxepin, which leads to a masked hydroxyaldehyde, also proceeds with good enantioselectivity and satisfactory yield. The corresponding Pd(BINAP)-catalyzed process[2d] was reported to give 72% *ee* and 84% yield.

The reaction was found to be highly sensitive to traces of chloride ions and chloroform. No reaction was observed in the presence of Et_4NCl or with [(**1c**)$PdCl_2$]/BuLi as catalyst precur-

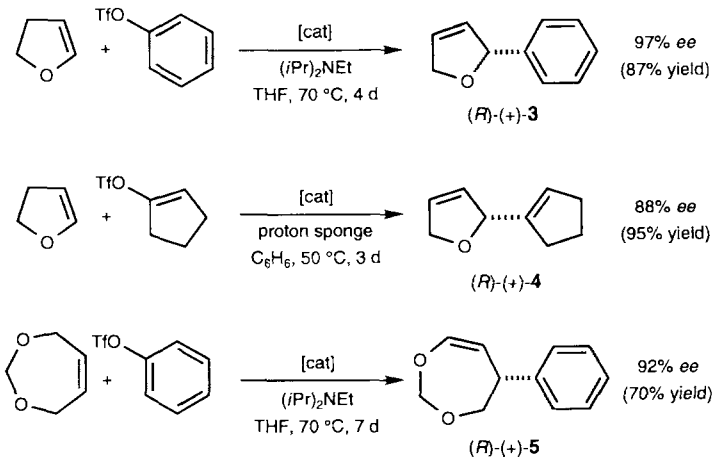


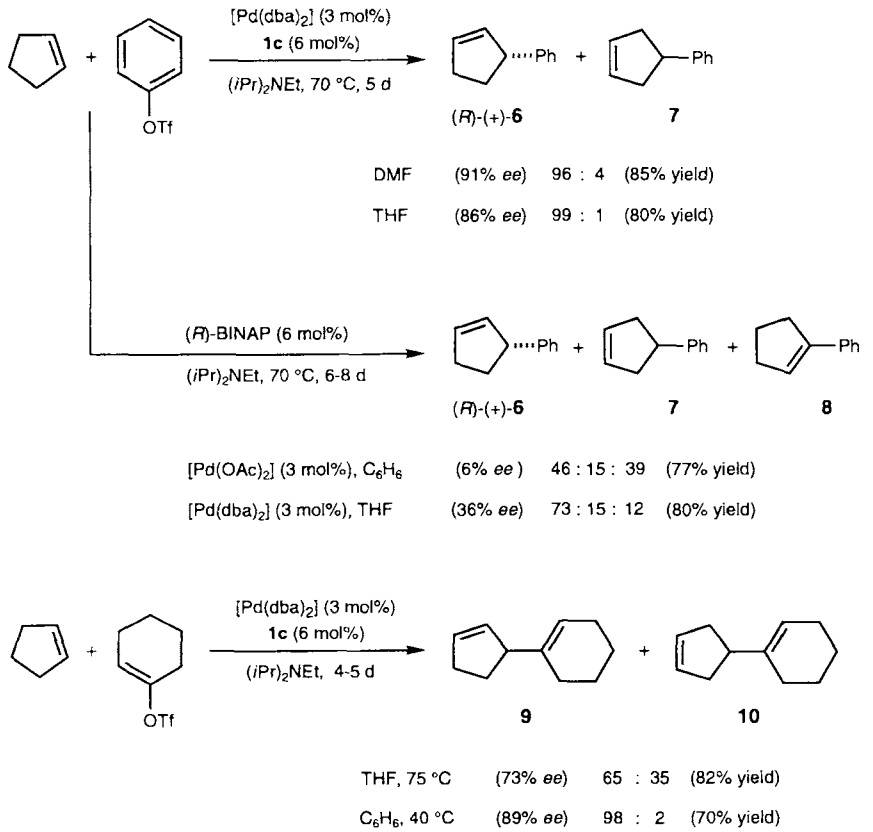
Scheme 1. [cat] = [Pd(dba)$_2$] (3 mol%), **1c** (6 mol%).

sor. [$Pd_2(dba)_3 \cdot CHCl_3$] as catalyst precursor gave lower conversion than [$Pd_2(dba)_3 \cdot dba$], and large fluctuations in yields and enantiomeric excesses were observed.[8]

The low tendency of (phosphanyldihydrooxazole)palladium catalysts to promote C=C bond migration allows the use of substrates such as cyclopentene, which are converted to mixtures of isomers with Pd(BINAP) catalysts (Scheme 2). The product distributions are strongly dependent on the solvent and the base. However, under optimized conditions, the desired chiral 3-substituted cyclopentene derivatives **6** and **9** are formed in good yield and with high preference over the corresponding achiral isomers **7** and **10**. Other isomers are formed only in trace amounts under these conditions, in contrast to the corresponding Pd(BINAP)-catalyzed reactions which give complex mixtures of isomers and low *ee* values due to extensive double bond migration in the five-membered ring.

A mechanistic interpretation of the observed selectivities will have to wait until more is known about the structure, relative stability, and reactivity of the intermediates in the catalytic cycle.[1] Unless we can distinguish between two possible pathways, one involving *cis* the other *trans* coordination of the olefin and the P atom, no meaningful mechanism of enantioselection can be proposed.

The remarkable selectivities obtained with phosphanyldihydrooxazoles point to a considerable potential of P,N ligands of this type for enantioselective Heck reactions. Because of the low extent of C=C bond migration, the product distribution can differ substantially from analogous Pd(BINAP)-catalyzed reactions. Phosphanyldihydrooxazoles are attractive ligands because they are readily synthesized from simple precursors[4, 5] and because their modular structure allows extensive and independent variation of the backbone, the dihydrooxazole ring, and the phosphane group. Thus it should be possible to improve the catalysts described here still further by optimizing the steric and electronic properties of the ligand.



Scheme 2. Heck reactions with cyclopentene. Comparison of ligand **1c** with BINAP.

Experimental Procedure

[$Pd_2(dba)_3 \cdot dba$] (77.5 mg, 0.135 mmol) and (−)-(*S*)-**1c** (104.6 mg, 0.270 mmol) were placed under Ar in an ampoule equipped with a magnetic stirring bar and a Young valve and treated with a solution of 1-cyclohexenyl triflate (1.048 g, 4.55 mmol) and *n*-tridecane (424 mg, 2.30 mmol) as internal GC standard in Ar-saturated benzene (10 mL), followed by 2,3-dihydrofuran (1.35 mL, 17.9 mmol), *N,N*-diisopropylethylamine (1.57 mL, 9.17 mmol), and Ar-saturated benzene (40 mL). The ampoule was sealed under argon and the mixture stirred at 24 °C (red solution, precipitation of *N,N*-diisopropylethylammonium triflate) until the reaction was complete according to GC analysis (65 h; MN Permabond OV 1701; 50 m, 90–210 °C, 0.7 °C min^{-1}, 120 kPa: t_R = 21.7 min (*n*-tridecane), 22.3 min (**2**)). The reaction mixture was diluted with pentane (ca. 150 mL) and the resulting red suspension was filtered through a 2 cm layer of silica gel (∅ = 7 cm). Further elution with Et_2O and concentration gave a red oil which was purified by flash chromatography (silica gel, 4 × 25 cm; *n*-pentane/CH_2Cl_2 1:1) followed by Kugelrohr distillation (125 °C, 12 kPa) to afford (*R*)-(+)-**2** (629 mg, 92%) as a colorless oil [9]. $[\alpha]_D$ = + 201 (*c* = 1.06, $CHCl_3$, 24 °C, 99% *ee* by GC). GC (Chiraldex γ-CD-TFA; 30 m, 80–140 °C, 0.3 °C min^{-1}, 60 kPa): 29.3 min (*S*), 30.4 min (*R*).

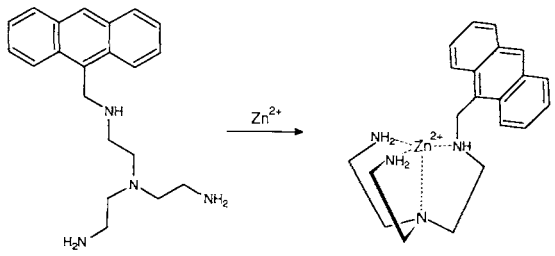
Molecular Recognition of Carboxylate Ions Based on the Metal–Ligand Interaction and Signaled through Fluorescence Quenching**

Giancarlo De Santis, Luigi Fabbrizzi,* Maurizio Licchelli, Antonio Poggi, and Angelo Taglietti

Molecular recognition of a given substrate can be signaled in a number of ways: the change in the the potential of an electrode, the shift of an NMR signal, an abrupt color change. However, the most spectacular and easily detectable signaling effect is probably a change in fluorescence. Fluorescent sensing procedures have been developed over the last decade for several metal ions.[1] Usually the recognition of the metal center is communicated to the outside through the quenching (for transition metal ions)[2] or the revival (for alkali and alkaline earth metal cations)[3] of the fluorescence of a light-emitting unit linked to the receptor. In any case, the variation of the fluorescence emission is related to an intramolecular electron transfer process, which directly involves the metal center. On the other hand, fluorescence sensing of anions is a much less developed field, which may be due to the low energy of the receptor–substrate interactions (hydrogen bonding, electrostatic effects). A successful case is the binding of hydrogen phosphate to a polyammonium unit, to which an anthracene subunit is appended as a fluorescent group.[4]

We considered that the metal–ligand interaction, which can be significantly stronger than hydrogen bonding and other van der Waals interactions, could be conveniently used for anion recognition. In this connection, we first appended a 9-anthracenyl group to a peripheral nitrogen atom of tris(2-aminoethyl)amine (tren). The resulting anthrylamine **1** was reacted with Zn^{II} to give the corresponding complex. In the two-component system $[Zn^{II}(\mathbf{1})]^{2+}$, the four-coordinate metal center has a



1 $[Zn^{II}(\mathbf{1})]^{2+}$

vacant site for coordination of a solvent molecule or for an anion to give a trigonal-bipyramidal arrangement. The proximate luminescent unit is in a favorable position to signal the occurrence of the anion recognition. In methanolic solutions $[Zn^{II}(\mathbf{1})]^{2+}$ shows a strong affinity towards anions bearing a carboxylate group. In particular, a stable 1:1 adduct is formed with the benzoate ion, as shown by spectrophotometric titrations. However, parallel titration experiments carried out in the spectrofluorimetric cuvette indicate that anion binding does not interfere with the photophysical activity of the proximate anthracene group, whose emission spectrum was not altered even after the addition of several equivalents of the anion. Thus, in this case the anthracene subunit is only a "silent witness" of the anion binding to the Zn^{II} center.

However, when a solution of $[Zn^{II}(\mathbf{1})]^{2+}$ was titrated with the 4-*N*,*N*-dimethylaminobenzoate ion (X^-), the fluorescence intensity progressively decreased until complete quenching (Fig. 1). The plot of fluorescence intensity (I_F) versus equiva-

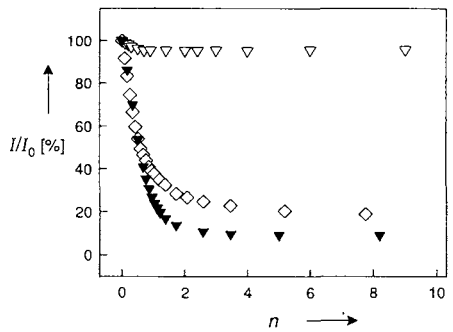


Fig. 1. Spectrofluorimetric titrations of the $[Zn^{II}(\mathbf{1})]^{2+}$ receptor in methanolic solution (10^{-4} M) with standard methanolic solutions of *N*,*N*-dimethylaminobenzoate (▾), acetate (▿); *N*,*N*-dimethylaminobenzoate + acetate (○); n = equivalents of anion/equivalents of complex.

lents of anion added indicates that the 1:1 adduct $[Zn^{II}(\mathbf{1})X]^+$ is formed, and least-squares treatment of the curve gave a $\lg K$ value of 5.45 ± 0.03 for the equilibrium $[Zn^{II}(\mathbf{1})]^{2+} + X^- \rightleftharpoons [Zn^{II}(\mathbf{1})X]^+$.[5] It is suggested that fluorescence quenching is due to an intramolecular electron transfer (ET) process within the $[Zn^{II}(\mathbf{1})X]^+$ adduct, in particular from the Zn^{II}-bound dimethylaminobenzoate subunit D to the photo-excited anthracene unit *An. The electron donor tendencies of *N*,*N*-dimethylaniline

and its derivatives are well recognized.[6] Moreover, the D → *An ET process is thermodynamically feasible, as indicated by the distinctly negative value of $\Delta G^{\circ}_{ET} = E_{0-0} - \Delta G_{D^+/D} + \Delta G_{An/An^-} = (-3.1 + 0.3 + 2.4)\,eV = -0.4\,eV$. The ET nature of *An quenching has been confirmed by spectrofluorimetric studies at 77 K. It is known that immobilization of the solvent molecules in a frozen matrix prevents charge separation and strongly disfavors the ET process, thus restoring fluorescence.[7] Indeed, when an ethanolic solution containing $[Zn^{II}(\mathbf{1})]^{2+}$ and an excess of 4-*N*,*N*-dimethylaminobenzoate, which does not emit at room temperature, was frozen at 77 K, fluorescence of the anthracene subunit was restored, demonstrating the ET nature of the quenching at room temperature.

To verify the selectivity of the $[Zn^{II}(\mathbf{1})]^{2+}$ receptor, spectrofluorimetric titration experiments were carried out with the following inorganic anions: NO_3^-, NCS^-, and Cl^-. The anthracene emission was not altered or showed an intensity decrease of less than than 5% (Cl^-). Competitive titration experiments were also conducted. A 5×10^{-5} M solution of $[Zn^{II}(\mathbf{1})]^{2+}$ in methanol was titrated with a solution containing equimolecular amounts of 4-*N*,*N*-dimethylaminobenzoate and the particular anion. The I_F titration curves obtained with NO_3^- and NCS^- were identical to that with 4-*N*,*N*-dimethylaminobenzoate alone, indicating no competition for the binding to the metal center. However, in the presence of Cl^-, I_F was not fully quenched, but decreased to about 80% of the value observed in the titration with 4-*N*,*N*-dimethylaminobenzoate alone. This indicates that the chloride ions compete successfully with the X^- ions, binding about 20% of the available $[Zn^{II}(\mathbf{1})]^{2+}$ complex cations. The acetate ion behaved in a similar way. The acetate alone does not exert any quenching effect on the anthracene unit of the $[Zn^{II}(\mathbf{1})]^{2+}$ receptor; however, in a competitive titration experiment (CH_3COO^-, X^-), fluorescence quenching was not complete, but corresponded to about 85% of that observed in the titration with 4-*N*,*N*-dimethylaminobenzoate alone (see Fig. 1). This would imply a ratio of the equilibrium constants for the adduct formation $K_{benzoate}/K_{acetate} \approx 6$. The distinctly higher value of the binding constant observed for the 4-*N*,*N*-dimethylaminobenzoate anion may suggest that a $\pi-\pi$ interaction between the Zn^{II}-bound benzoate group and the anthracene subunit provides an additional contribution to the solution stability of the $[Zn^{II}(\mathbf{1})X]^+$ adduct.

In this context, it should be noted that the occurrence of the intramolecular ET process in the $[Zn^{II}(\mathbf{1})X]^+$ supramolecular system requires that the fluorophore and the acceptor are close enough for the appropriate orbitals to overlap. Stacking of benzoate and anthracene fragments may favor electron transfer and induce the nonradiative deactivation of the *An state. A pictorial representation of the intramolecular ET process is sketched in Figure 2. A similar stereochemical arrangement has been proposed for the 1:1 adduct between the benzoate anion and a Zn^{II}-cyclen complex with an acridine pendant.[8] Noticeably, interaction of the thymine anion with the Zn^{II} center of the same complex induced a distinct decrease of the intensity of acridine fluorescence emission.[9]

In any case, fluorescence quenching of the excited anthracene unit of the $[Zn^{II}(\mathbf{1})]^{2+}$ receptor should not be limited to 4-*N*,*N*-dimethylaminobenzoate, but should be feasible for any benzoate anion bearing either a donor or an acceptor group, provided that the thermodynamic requirements for the transfer of an electron to or from the photo-excited fluorophore are fulfilled. In fact, titration of $[Zn^{II}(\mathbf{1})]^{2+}$ with 4-nitrobenzoate ion in methanolic solution induced the decrease and quenching of the fluorescence, according to a profile analogous to that displayed in Figure 1. Nitrobenzene and its derivatives are

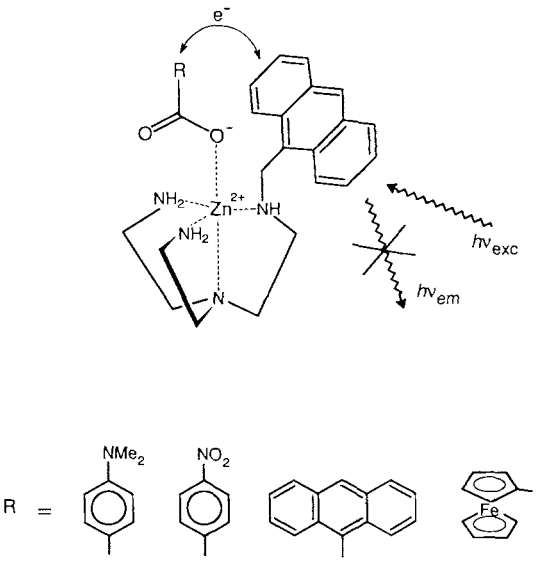

Fig. 2. Representation of the electron transfer mechanism responsible for the fluorescence quenching of the excited anthracene unit *An, which signals the binding of a carboxylate anion by the Zn^{II} center.

classical acceptors. Thus, fluorescence quenching has to be ascribed to an intramolecular ET process from *An to the metal-bound 4-nitrobenzoate ion A. The negative value of $\Delta G^{\circ}_{ET}[= E_{0-0} + \Delta G_{A/A^-} - \Delta G_{An^+/An} = (-3.1 + 1.3 + 0.8)\,eV = -1.0\,eV]$ accounts for its thermodynamic feasibility. Quite interestingly, decrease and almost complete quenching of the fluorescence was observed also when $[Zn^{II}(\mathbf{1})]^{2+}$ was titrated with 9-anthracenoate ion, which itself is fluorescent. Fluorescence quenching should arise from the "disproportionation" process involving an electron transfer between the two anthracene subunits of the supramolecular adduct: $*An + An \rightleftharpoons An^- + An^+$. Both the anthracenoate-to-anthracene and anthracene-to-anthracenoate electron transfer processes exhibit a slightly negative ΔG°_{ET} value (−0.2 eV). In any case, the observed revival of the fluorescence emission in an ethanolic solution frozen at 77 K demonstrates also for the present system that electron transfer is responsible for the quenching of the photo-excited aromatic subunit.

The $[Zn^{II}(\mathbf{1})]^{2+}$ system is able to signal the binding of carboxylate ions other than benzoates, provided that they have definite donor or acceptor properties in a photophysical sense. For instance, fluorescence quenching is observed also on titration of $[Zn^{II}(\mathbf{1})]^{2+}$ with 1-ferrocenecarboxylate (Fcc^-). Ferrocene (Fc) and its derivatives are quite strong donors, and the $Fcc^- \rightarrow *An$ electron transfer is thermodynamically favored: $\Delta G^{\circ}_{ET} = E_{0-0} + \Delta G_{An/An^-} - \Delta G_{Fcc^+/Fcc^-} = (-3.1 + 2.4 + 0.3)\,eV = -0.4\,eV$. In this case, too, the electron transfer nature of the quenching process was confirmed by the fluorescence revival observed at 77 K.

The Zn^{II} ion was deliberately chosen as a Lewis acid for carboxylate binding owing in part to its photophysical innocuosness. Transition metal ions bind to the tren framework to form even more stable adducts with inorganic and organic anions, but tend to complicate the photophysical response. This is the case with the $[Cu^{II}(\mathbf{1})]^{2+}$ system, which, even in absence of any coordinating anion, displays a much less intense emission spectrum (about 15% of that observed for $[Zn^{II}(\mathbf{1})]^{2+}$). This partial fluorescence quenching has to be ascribed to a direct interaction between the Cu^{II} center and the *An fragment. We note that freezing an ethanolic solution of $[Cu^{II}(\mathbf{1})]^{2+}$ at 77 K did not induce any

fluorescence revival. This may suggest that quenching takes place through an *An-to-Cu^{II} energy transfer process, although the occurrence of a very fast electron transfer process cannot be excluded in principle. The Cu^{II} ion (d^9) is well inclined to undergo an energy transfer process, as it has a half-filled d level of low energy ($x^2 - y^2$), which is available for a double electron exchange process (Dexter mechanism).[10] In any case, titration of $[Cu^{II}(\mathbf{1})]^{2+}$ with 4-nitrobenzoate or 4-*N*,*N*-dimethylaminobenzoate caused complete quenching of the residual fluorescence emission.

This work has demonstrated that metal–ligand interactions can be conveniently used for anion binding and recognition. The coordination environment provided by the tren ligand leaves one binding site of the metal center free for the approach of anions of various sizes and shapes: the selectivity is essentially determined by the energy of the metal–anion coordinative interaction. Then, the appended fluorescent unit signals the occurrence of the recognition. A further element of selectivity is introduced by the signal transduction mechanism: only the interactions with anions displaying distinctive electron donor or electron acceptor tendencies will be signaled and sensed. The Zn^{II}-containing system described is well suited for carboxylate anions. Following a similar approach, more sophisticated systems can be designed for the recognition and sensing of anions of various types and complexities.

Experimental Procedure

1: Anthracene-9-carbaldehyde (2.0 mmol) was allowed to react with an excess of tren (6.0 mmol) in 30 mL of a 1:1 EtOH/MeCN mixture at room temperature for 36 h. The solvent and most of the excess tren were distilled off at reduced pressure. The remaining oil was dissolved in 30 mL of EtOH and the resulting solution was treated with 0.7 g of $NaBH_4$, in small portions, then heated at 50 °C for 4 h. On concentration at reduced pressure, a sticky solid was obtained, to which 25 mL of water was added. The suspension that formed was extracted with three 25 mL portions of CH_2Cl_2. The organic layer was dried over $MgSO_4$ and the solvent removed on a rotary evaporator to give **1** as a bright orange oil. Yield 75%. MS (ESI): *m/z* (%) 337 (100) ($M^+ + H$). The corresponding Zn^{II} complex was obtained as the salt $[Zn^{II}(\mathbf{1})](ClO_4)_2$ in the form of a pale yellow solid, through reaction of equimolar amounts of **1** and $Zn(ClO_4)_2 \cdot 6H_2O$ in ethanol. The salt gave a satisfactory C,H,N analysis.

Emission spectra were recorded on a Perkin-Elmer LS-50 luminescence spectrometer and were not corrected for instrument response. Emission spectra at 77 K were measured in dry ethanol by using quartz sample tubes and the same luminescence spectrometer equipped with a low-temperature luminescence accessory (Perkin-Elmer). Pertinent electrode potentials (of the A/A^- and D^+/D redox couples) for the relevant acceptor and donor units (4-nitrobenzoate, 4-*N*,*N*-dimethylaminobenzoate, 9-anthracenecarboxylate, and 1-ferrocenecarboxylate as sodium salts) were determined through differential pulse voltammetry experiments (vs. the Fc^+/Fc internal reference couple, MeCN, 0.1 M Bu_4NClO_4). A platinum microsphere was used as the working electrode. The calculated ΔG°_{ET} values refer to the MeCN medium, as $\Delta G^\circ_{Ox/Red}$ values ($= -FE^\circ_{Ox/Red}$) were obtained in MeCN solutions. Corresponding δG°_{ET} values in MeOH solution should be even more negative, and the ET process more favorable, due to the higher solvent polarity.

$[S(NtBu)_3]^{2-}$—A Cap-Shaped Dianion, Isoelectronic with the Sulfite Ion and Oxidizable to a Stable Radical Anion**

Roland Fleischer, Stefanie Freitag, Frank Pauer, and Dietmar Stalke*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

Recently we have been interested in the synthesis of new ligands with main group elements in low oxidation states as central atoms. These tripodal ligands, as a result of the lone pair on the central atom, have potentially Lewis base character; metal atoms are coordinated by nitrogen atoms in the substituents on the ligands and not by the central atom. Tripodal ligands of this kind include, in particular, compounds with structural units such as $E(NR)_3^-$ (E = Ge, Sn, Pb),[1] as well as polypyrazolylgermanates and -stannates;[2] trislithium tris(trimethylsilylamino)silanes $[(LiNSiMe_3)_3SiR]_2$, R = Me, *t*Bu, Ph;[3] R = H[4] and $[\{(thf)LiNSiMe_2tBu\}_3SiPh]$ [5] are described as trianionic tripodal ligands.

Our aim was to extend this range of mono- and trianionic ligands by synthesizing a dianionic ligand system, to make homoleptic complexes of low-coordinate bivalent metals accessible. Here we report on the tris(*tert*-butyl)triazasulfite ligand, which is formally derived from the dianionic SO_3^{2-} ion in that the three oxygen atoms were substituted by isoelectronic *t*BuN groups. Together with bivalent metals this ligand could lead to interesting organometallic precursors for II/VI semiconducting materials.

In analogy to the addition of organo alkali metal compounds to sulfurdiimines, which leads to aminoiminosulfinates,[6] we have added alkali metal amides to sulfurdiimides. Although equimolar amounts of the starting materials were used, the equimolar addition of lithium *tert*-butylamide to di(*tert*-butyl)sulfurdiimide did not occur, but two equivalents of the sulfurdiimide react with four equivalents of lithium *tert*-butylamide to give the dimeric bislithium tris(*tert*-butyl)triazasulfite **1** [Eq. (a)].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. D. Marsh, Max-Planck-Institut für Biophysikalische Chemie, Göttingen, for recording the ESR spectra.

The crystal structure analysis[7] shows a dimer, comprising two cap-shaped dianions, the concave sides of which face each other. Between these caps, there are four lithium atoms each coordinated by three nitrogen atoms (Fig. 1). The lengths of the three crystallographically independent S–N bonds (av 165.0 pm) do not differ significantly. Thus, the negative charge is completely delocalized over the whole ligand. The average N-S-N angle of 102.1° reveals that the central sulfur(IV) atom has trigonal-pyramidal coordination.

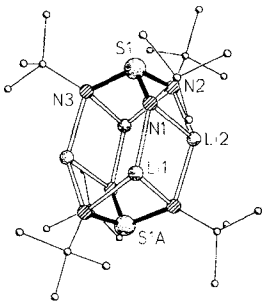

Fig. 1. Structure of **1** in the crystal. Selected bond lengths [pm] and angles [°]: S1–N1 164.8(2), S1–N2 165.8(1), S1–N3 164.4(1), av Li–N 200.6(4); N1-S1-N2 100.08(7) N1-S1-N3 105.34(7) N2-S1-N3 100.85(7) av S1-N-C 116.3(1).

To date there are only two structurally characterized derivatives of triazasulfite compounds. In the solid state both are solvent-separated ion pairs with N-bonded sulfonyl groups. In $S(NR)_3^{2-}$, with R = $S(O)C_6H_4Me$, the S–N distance is 164.3 pm and the N-S-N angle is 101.7°;[8] in the derivative with R = $S(O)C_6H_5$, these values are 162 pm and 103.2°, respectively.[9]

Pure **1** is a white pyrophoric solid. Both as a solid and in solution, **1** turns dark blue if it is handled in an inert gas atmosphere (Ar 5.0) without an additional oxygen absorber. On the other hand, by using an oxygen absorber, both can be handled for a short time with Schlenk techniques. This phenomenon suggests that a radical is formed in the reaction with oxygen. Indeed, a dark blue solution of oxidized **1** in hexane shows an ESR signal even at room temperature. The hyperfine splitting of the signal to give a septet (intensity ratio 1:3:6:7:6:3:1) with a coupling constant of a = 8 G confirms that the unpaired electron interacts with three equivalent ^{14}N atoms (I = 1/2) (Fig. 2). An additional septet (intensity ratio 1:2:3:4:3:2:1) with a coupling constant of a = 0.8 G can be resolved, which might indicate further interaction of the unpaired electron with two equivalent ^{7}Li atoms (I = 3/2).

The radical anion is not only generated by exposure to oxygen but also by reaction with elemental iodine. The final product of the oxidation with iodine is the triiminosulfur(VI) compound $S(NtBu)_3$.[10] Dark blue crystals can be grown from the blue solution. The structure analysis of these crystals provides almost identical structural parameters to those of **1**. The only noticeable difference between the parameters of the blue compound and those of the white one is that for the blue compound the amplitude of the anisotropic displacement parameters of the lithium atoms is marginally higher. This may indicate that not all metal atom positions are occupied in the crystal. The blue crystals probably comprise two compounds—a radical monoanion coordinated by one lithium atom, and a dianion coordinated by two lithium atoms—that together form a dimer. The unoccupied lithium atom position is thus disordered over the two crystallographically independent positions. The ESR spectrum of the blue solid shows no hyperfine splitting.

$[\{Li_2(tBuN)_3S\}_2(thf)]$ **2** is obtained, if the triazasulfite is synthesized in THF. Like in **1**, the concave sides of the cap-shaped dianions face each other. However, in contrast to **1**, only three lithium atoms are located between the staggered *t*BuN groups. The fourth, Li4 (Fig. 3), is only coordinated to two nitrogen atoms (N2 and N3) of the dianion **A** and to a single thf molecule. While the nitrogen atoms N2–N6 are coordinated to two lithium atoms each, N1 is exclusively coordinated to Li1.

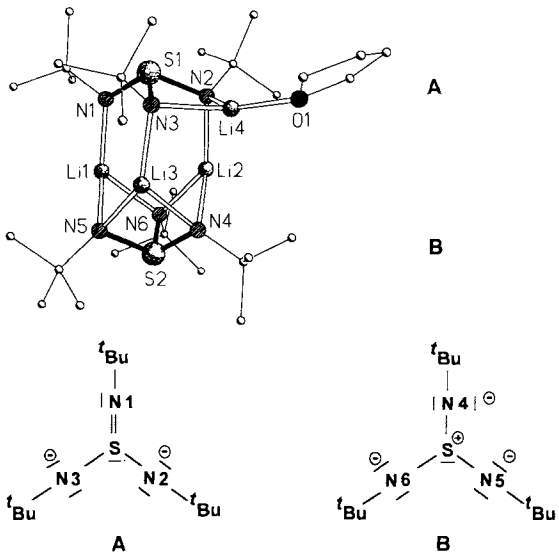

Fig. 3. The structure of **2** in the crystal (top) and the related mesomeric forms (bottom). **A**: S1–N1 160.7(2), S1–N2 168.0(2), S1–N3 168.1(2) pm; N1-S1-N2 108.0(1), N1-S1-N3 108.5(1), N2-S1-N3 93.0(1)°. **B**: S2–N4 163.2(3), S2–N5 164.2(3), S2–N6 164.1(3) pm; N4-S2-N5 100.5(2), N4-S2-N6 100.4(2), N5-S2-N6 98.8(2)

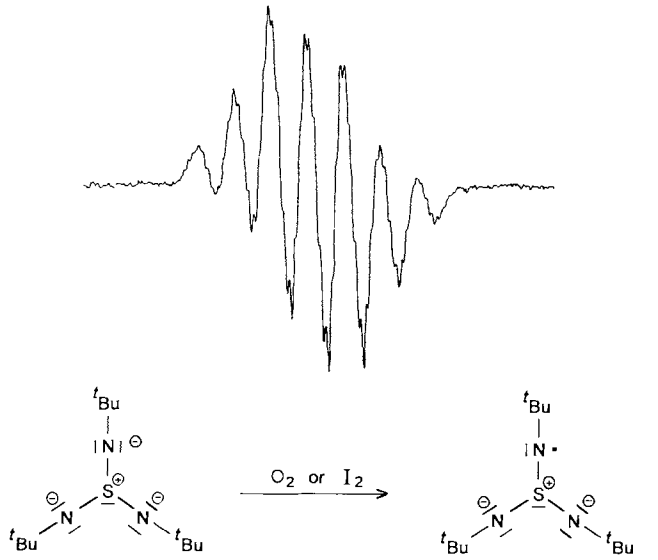

Fig. 2. Oxidation of **1** in hexane at 20 °C. The unpaired electron is delocalized over the three nitrogen atoms.

The significantly different coordination of the metals in **2** compared to **1** gives rise to completely different structural parameters in the two dianionic caps. Cap **A** is described more adequately by a mesomeric form in which one of the three nitrogen atoms (N1) is double-bonded to the central sulfur atom. In cap **B**, all three S–N bonds are approximately the same length. The S1–N1 bond (160.7 pm) is more than 7 pm shorter than the two remaining S–N bonds. Hence this bond can be assigned more double bond character.

The central sulfur atom in the triiminosulfur(VI) compound is coordinated in a trigonal-planar arrangement by three double-bonded imino groups.[10] The S=N distances in this compound are, depending on the substiuents, 12–14 pm shorter than those in the triazasulfite molecules, the S=N distances in the solid-state structures of sulfurdiimides $S(NR)_2$ a further 7–8 pm

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0205 $ 10.00+.25 0

shorter.[11] Hence, the distance between S1 and N1 in **2** indicates only partial double bond character. The N-S-N angle opposite this partial double bond is about 15° smaller than the other two N-S-N angles, since a double bond is more sterically demanding than a single bond and the nitrogen atoms N2 and N3 are bridged by Li4. The cap **B** adopts almost ideal local threefold symmetry. The S–N bonds are identical within their estimated standard deviations. The N-S-N angles in **B** are on average more acute than in **A**, because all nitrogen atoms are μ_2 bridged by a lithium atom.

Tris(*tert*-butyl)triazasulfite, which is isoelectronic to the SO_3^{2-} ion, is a promising ligand that can be oxidized to a stable radical monoanion.[15] The structural motif with only three lithium atoms between the two caps also seems to be favored for steric reasons, as demonstrated in the conversion of **1** to **2**: in the presence of a donor molecule, one of the four lithium atoms (Li4, Fig. 3) leaves the sterically crowded inner region between the caps to take up a less congested position on the periphery.

Experimental Procedure

1: *tert*-Butylamine (30 mmol, 0.69 mL) was added dropwise to a solution of *n*-butyllithium (30 mmol, 20 mL of a 1.52 M solution in hexane) at −78 °C and the mixture was subsequently stirred for 30 min at room temperature. Di(*tert*-butyl)sulfurdiimide (2.61 g, 15 mmol) was added dropwise to the resulting suspension of lithium *tert*-butylamine at room temperature. After all volatile components had been removed in vacuum, the solid was dissolved in toluene to give a red solution from which colorless crystals of **1** (2.9 g, 75%) were obtained after one day at 0 °C. The pyrophoric product melted at 260 °C (decomp.); satisfactory elemental analysis. ^{1}H NMR (250 MHz, [D$_8$]toluene, 25 °C): $\delta = 1.31$ (s, 54H, *t*Bu); ^{7}Li NMR (155 MHz, [D$_8$]toluene, 25 °C): $\delta = 2.88$ (s); ^{13}C NMR (400 MHz, [D$_8$]toluene, 25 °C): $\delta = 33.88$ (s; $C(CH_3)_3$), 53.66 (s; $C(CH_3)_3$); MS(EI): *m/z* (%): 518 (11), M^+; 266 (56), $S(NtBu)_3Li_3$; 103 (59), $SNtBu$; 58 (100), SNC.

2: **2** (3.0 g, 68%) was obtained after recrystallization of **1** from THF/hexane (1:1). The product decomposed at temperatures slightly higher than 100 °C; satisfactory elemental analysis. ^{1}H NMR (250 MHz, [D$_8$] toluene, 25 °C): $\delta = 1.39$ (s, 9H, N-*t*Bu); 1.45, 3.56 (8H, thf); ^{7}Li NMR (155 MHz, [D$_8$]toluene, 25 °C): $\delta = 4.75$ (s); ^{13}C NMR (400 MHz, [D$_8$]toluene, 25 °C): $\delta = 25.67$ (s; $O(CH_2)_2(CH_2)_2$), 34.02 (s; $C(CH_3)_3$), 53.61 (s; $C(CH_3)_3$), 68.16 (s; $O(CH_2)_2(CH_2)_2$); MS(EI): *m/z* (%): 518 (4), $M^+ - THF$; 266 (25), $[(tBuN)_3S]Li_3$; 103 (50), $SNtBu$; 58 (100), SNC.

[15] Note in proof (Dec. 20, 1995): Recently the structure of $[Li_2(NtBu)_3Te]_2$ analogous to that of **1** was described (T. Chivers, X. Gao, M. Parvez, *Angew. Chem.* **1995**, *107*, 2756; *Angew. Chem.* **1995**, *34*, 2549). It would be interesting to determine whether this compound can also be oxidized to a stable radical.

Epoxidation of Electron-Deficient Olefins by a Nucleophilic Iron(III) Peroxo Porphyrinato Complex, Peroxo(tetramesitylporphyrinato)ferrate(1 −)**

Marlene F. Sisemore, Judith N. Burstyn, and Joan S. Valentine*

Heme complexes in which a peroxo ligand is bound to an iron center are probable intermediates in reactions of cytochromes P-450 and related enzymes. Peroxo(porphyrinato)iron(III) complexes have been synthesized as models for such intermediates and characterized with respect to their physical and chemical properties.[1, 2] The reactivities of peroxo transition metal complexes have been classified in the past as either electrophilic or nucleophilic on the following basis:[3] electrophilic peroxo complexes react readily with normal (that is, electron-rich) olefins to give epoxides, while some nucleophilic peroxo complexes such as $[Pt(O_2)(PPh_3)_2]$ react with very electron-poor olefins, for example tetracyanoethylene.[4] Likewise, only electrophilic peroxo complexes oxidize the butyl anion to butoxide.[5] The oxo(diperoxo)rhenium(VII) complex $[ReO(O_2)_2(CH_3)(H_2O)]$, however, is

an exception in that it epoxidizes both electron-rich and electron-poor substrates.[6] Previous studies of peroxo(porphyrinato)iron(III) complexes demonstrated that they did not display strongly electrophilic reactivities such as direct hydroxylation of hydrocarbons or epoxidation of electron-rich olefins.[7, 8] Such complexes instead have been shown to be nucleophilic; for example, manganese[9] and iron peroxo porphyrinato complexes[10] react with acyl halides, and iron(III) peroxo porphyrinato complexes react with aldehydes[11] and with carbon dioxide.[12] We recently realized that it might be possible to transfer an oxygen atom directly to an olefin from a bound peroxo ligand by a nucleophilic pathway if we used an electron-deficient olefin. We report here that peroxo complexes of iron(III) porphyrins do indeed react cleanly with electron-deficient olefins, such as enones and quinones, to give the corresponding epoxides. To our knowledge, this is the first time that a peroxo(porphyrinato)iron(III) complex has been shown to insert oxygen directly into an olefinic bond.

In order to investigate further the electronic character of peroxo(porphyrinato)iron(III) complexes, we prepared $[Fe(O_2)TPP]^-$[7, 13] in situ by stirring [FeTPPCl] (1.85 mM) with an excess of tetramethylammonium superoxide[14] in THF[13] for six hours, followed by filtration to remove the excess superoxide salt.[15] Two equivalents of superoxide are required to form the peroxo(porphyrinato)iron(III) complex (Scheme 1).[1]

$$[Fe^{III}Cl(TPP)] + TMA^+O_2^- \longrightarrow [Fe^{II}(TPP)] + O_2 + TMA^+Cl^-$$

$$[Fe^{II}(TPP)] + TMA^+O_2^- \longrightarrow TMA^+[Fe^{III}(O_2)(TPP)]^-$$

Scheme 1. Stepwise reaction of $[Fe^{III}Cl(TPP)]$ with superoxide to give $[Fe^{III}(O_2)(TPP)]^-$.

Formation of $[Fe(O_2)TPP]^-$ was confirmed by the characteristic visible spectrum.[1, 2] Following the procedure described by Regen and Whitesides,[5] butyllithium (1.5 M in hexane) was added to $[Fe(O_2)TPP]^-$, and the resulting solution was stirred for between 5 and 60 min. An excess of acetic anhydride was added, and the solution stirred for another hour to trap and convert any butoxide that might be formed into the acetate. The reaction mixture was analyzed by gas chromatography; no butyl acetate was detected. As a control, $[MoO_5(HMPA)]$,[13, 16] which is known to be an electrophilic Mo^{VI} peroxo complex, was subjected to the same treatment; in this case 1.0 equiv of butyl acetate per peroxo ligand was detected. These results confirmed our earlier conclusion,[7] based on its lack of reactivity with electron-rich olefins, that the peroxo(porphyrinato)iron(III) complex is not electrophilic.

Reactions of the tetraphenyl- and tetramesitylporphyrinato peroxo complexes with electron-deficient olefins were carried out in a similar fashion.[15] An aliquot of the peroxo(porphyrinato)iron(III) solution was removed prior to substrate addition, in order to confirm spectrophotometrically the presence of the metalloperoxide complex.[17] Two equivalents of either 2-methyl-1,4-naphthoquinone (menadione), or 2-cyclohexen-1-one was then added to aliquots of the peroxo(porphyrinato)iron(III) solution. The solutions were stirred vigorously, and aliquots of the reaction mixture were removed after between 2 and 15 minutes for analysis.[18] The results of these reactions are summarized in Table 1.

Reaction of $[Fe(O_2)TMP]^-$ with two equivalents of menadione produced menadione epoxide in $(76\pm8)\%$ yield. Reaction with $[Fe(O_2)TPP]^-$ afforded menadione epoxide in $(52\pm10)\%$ yield. The control reactions with KO_2[19] resulted in $(8\pm1)\%$ epoxide formation. Reaction of $[Fe(O_2)TMP]^-$[20] with two equivalents of 2-cyclohexen-1-one resulted in a $(23\pm2)\%$ yield of epoxide. Addition of a large excess of 2-cyclohexen-1-one (80 equiv) did not increase the epoxide yield. The control reaction with KO_2 alone gave less than 3% epoxide by GC-MS.

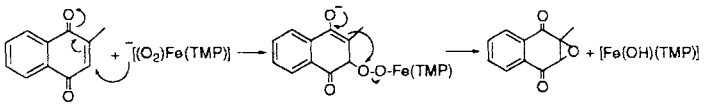
Table 1. Reactions of peroxo(tetramesitylporphyrinato)ferrate(1−) with electron-deficient olefins.

Substrate	c ([FeCl-(TMP)]) [mM]	Time [min]	c (Epoxide) [mM]	Yield [a]
menadione	0.10	10–15	0.076 ± 0.008	$76\pm8\%$
KO_2 (0.10 mM control)	0.00	10–15	0.008 ± 0.001	$8\pm1\%$
$H_2O_2/KHCO_3$ (0.10 mM control)	0.00	10–15	0.005 ± 0.001	$5\pm1\%$
2-cyclohexen-1-one	3.44	2–4	0.78 ± 0.06	$23\pm8\%$
KO_2 (3.44 mM control)	0.00	2–4	<0.10	<3%

[a] Yields are based on the starting concentration of [FeCl(TMP)] or of the oxidant in control reactions.

Titration of $[Fe(O_2)TMP]^-$ with aliquots (0.25 equiv) of menadione was monitored by visible absorption spectroscopy. The intensity of the Soret band of $[Fe(O_2)TMP]^-$ (at 434 nm) decreased by approximately 25% upon each addition of menadione. The clean isosbestic points obtained at 424 and 543 nm indicates that $[FeTMP]^-$ reacted directly with the olefin to give the product epoxide. The best results were obtained when the successive aliquots were all added within five minutes, which implies that $[Fe(O_2)TMP]^-$ might react slowly with the epoxide product; this conclusion was confirmed in separate experiments by the observation of the disappearance of the EPR signal due to the peroxo complex and of the loss of epoxide detected by HPLC when the two were mixed.

The mechanism that we propose for this reaction (Scheme 2) is analogous to that proposed for the reaction of electron-deficient olefins with basic hydrogen peroxide, HO_2^-:[21, 22]



Scheme 2. The epoxidation of menadione (or 2-cyclohexen-1-one) by $[Fe(O_2)TMP]^-$ probably proceeds through a peroxy intermediate, which rearranges to give the epoxide.

$[Fe(O_2)TMP]^-$ attacks menadione (or cyclohexenone) to form a peroxy intermediate, which then rearranges to give menadione epoxide and a porphyrin product whose UV-Vis absorption spectrum resembles that of [Fe(OH)(TMP)].[23] The organic products obtained from reaction with $[Fe(O_2)TMP]^-$ are identical to those resulting from reaction with HO_2^-, which suggests that the mechanisms are analogous. It is conceivable that HO_2^- could dissociate from the peroxoporphyrin complex to epoxidize the olefin. However, since control reactions (Table 1) with HO_2^-, prepared from 0.10 mM $H_2O_2/KHCO_3$, produced only $(5\pm1)\%$ menadione epoxide after 10–15 minutes (Table 1), we conclude that the high yields of epoxide obtained with $[Fe(O_2)TMP]^-$ are due to reactions of the iron(III) complex itself and not to free HO_2^-.

Our results indicate that peroxo(porphyrinato)iron(III) complexes behave as nucleophiles toward electron-deficient olefins, a finding that lends further support to the studies carried out with acyl halides,[9, 10] aldehydes,[11] and carbon dioxide.[12] Similar nucleophilic peroxo heme species are proposed as reac-

tive intermediates in a series of reactions with cytochrome P-450 aromatase,[24] an enzyme that converts androgens into estrogens (which is implicated in breast cancer), with cytochrome P-450 2B4 (which aromatizes the bicyclic steroid analog, 3-oxodecalin-4-ene-10-carboxaldehyde[25]), and with NO synthase[26] (which converts arginine to citrulline and nitric oxide gas; NO gas is important in neurotransmission, vascular dilation, and macrophage toxicity to name but a few of its biological functions). The nucleophilic chemistry of the peroxo(porphyrinato)iron(III) complex described here may be a good model for such enzymatic intermediates.

Synthesis and Structure of the Bis(imido)gold Complex $[Au^{I}_5(NtBu)_2(PPh_3)_4]^+Cl^- \cdot 2C_6H_5CH_3$; a Higher Homologue of the Organotris-(triphenylphosphaneaurio)ammonium Ions**

Robert E. Allan, Michael A. Beswick, Michael A. Paver, Paul R. Raithby, Alexander Steiner, and Dominic S. Wright*

Recently we investigated the syntheses and structures of main group metal imido compounds generated from the reactions of the dimethylamido metal complexes with primary amines (RNH_2) or metalated primary amines (RNHLi).[1] Of particular interest has been the development of Group 15 (Sb and Bi) metal imido anions,[1c,d] which are novel ligands for transition metals. Hence, the transmetalation reaction of $[\{Sb_2(Ncy)_4\}_2Li_4]$ with CuCl gives $[\{Sb_2(Ncy)_4\}_2Cu_4]$ (cy = cyclohexyl), in which a Cu_4 square-planar core is stabilized by $[Sb_2(Ncy)_4]^{2-}$ dianions.[2] Our most recent studies have focused on the applications of $[Sn(NMe_2)_x]$ ($x = 2$ or 4) in the syntheses of anionic Sn^{II} and Sn^{IV} ligands.[1e]

In an attempt to generate in situ a mixed-metal Sn^{IV}/Au^{I} complex containing a $[Sn(NtBu)_4]^{4-}$ tetraanion, [*t*BuNHLi] was treated with $[Sn(NMe_2)_4]$ in the molar ratio 4:1. However, addition of $[AuCl(PPh_3)]$ (4 equiv) to this mixture affords the bis(imido)gold(I) complex **1**, in which imido group transfer

$[Au_5(NtBu)_2(PPh_3)_4]^+Cl^- \cdot 2C_6H_5CH_3$ **1** $\cdot 2C_6H_5CH_3$

has occurred, rather than formation of the mixed-metal aggregate which was sought. Evidently, $[Sn(NMe_2)_4]$ functions simply as a base in this reaction. This became clear when **1** was also formed when [*t*BuNHLi] was treated directly with $[AuCl(PPh_3)]$ (1 equiv), the excess [*t*BuNHLi] now acting as the base. Compound **1** is most conveniently prepared by this latter route (see Experimental Procedure).

The synthetic strategies used to date to generate imidogold(I) cations $[Au_3(\mu_3\text{-}NR)(PPh_3)_3]^+$ have involved reactions of RNH_2 or RNCO with $[(AuPPh_3)_3O]^+BF_4^-$ and resulted in the formation of the organotris(triaurio)ammonium salts and H_2O or CO_2, respectively.[3] Although the exact mechanism of formation of **1** is uncertain, we assume that the cation of **1** finally results from the interaction of $[Au_2(\mu\text{-}N\text{-}tBu)(PPh_3)_2]$, formed during the reaction, with $[AuCl(PPh_3)]$ (Scheme 1).

The low-temperature X-ray structure of **1**[4] shows that it is an ion-separated species consisting of a bis(imido)-Au_5 cation and a Cl^- anion (Fig. 1). Additionally, two lattice-bound

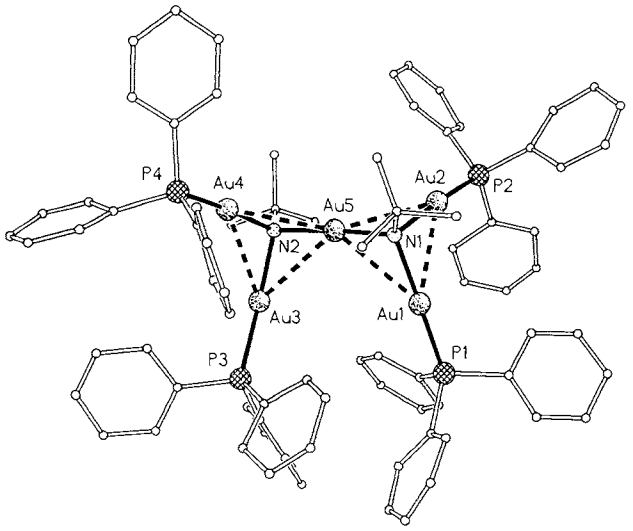

Fig. 1. Molecular structure of **1** in the crystal. Hydrogen atoms and the lattice-bound toluene molecules have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Au1–N1 2.03(4), Au2–N1 2.11(3), Au5–N1 2.00(3), Au5–N2 2.07(3), Au3–N2 2.05(4), Au4–N2 2.09(3), Au1···Au2 2.945(3), Au5···Au1 3.110(2), Au5···Au2 3.005(2), Au5···Au3 3.016(2), Au5···Au4 3.033(2); N1-Au5-N2 176(2), av N-Au-P 173.6, av Au-N-Au 94.0.

toluene molecules are present for each formula unit of **1**. The two triangular Au_3 moieties of the "bowtie-shaped" core of the cation are interlocked by the central Au5 atom; the planes of these Au_3 units are inclined at an angle of about 43° to each other. The Au···Au distances between the central Au5 atom and the four terminal, phosphane-complexed Au centers (av 3.04 Å) are considerably longer than those formed between the terminal metal atoms of the "bowtie" (av 2.94 Å). These Au···Au distances correspond to those found in the few structurally characterized imidogold(I) complexes (in the $[Au_3(\mu_3\text{-}NR)(PPh_3)_3]^+$ ions: 2.93–3.30 Å).[3] The two Au_3 rings are capped by μ_3-N*t*Bu ligands at opposite faces of the Au_5 core, resulting in an overall transoid conformation for the cation. The cation of **1** can be regarded as a "naked" Au^I center which has been complexed by two neutral $[Au_2(\mu_2\text{-}NtBu)(PPh_3)_2]$ units. Interestingly, both the terminal Au atoms (av P-Au-N 174°) and the central Au (N-Au-N 176°) atom all have essentially linear ligand coordination geometries.

Although there has been considerable fundamental interest in the nature and influence of the "aurophilic" interaction spurred by the recent structural characterizations of the $[(PPh_3)_4Au_4(\mu_4\text{-}N)]^+$[5] and $[(PPh_3)_5Au_5(\mu_5\text{-}N)]^{2+}$[6] nitridogold(I) cations, all the imido complexes that have been structurally elucidated are cations of the type $[Au_3(\mu_3\text{-}NR)(PPh_3)_3]^+$.[3] The Au_5 cation of **1** is composed of similar $Au_3(\mu_3\text{-}N)$ units and can be regarded as the next homologue of a potential series of cations, constructed from interlocked Au_3 units, of the general formula $[Au_{(3+2n)}(\mu_3\text{-}NR)_{(1+n)}(PR'_3)_{(3+n)}]^+$. As such, **1** is the largest imidogold(I) complex to be structurally characterized so far. Several mixed-metal cluster compounds have been structurally characterized in which "bowtie-shaped" Au_5 units akin to that in the cation of **1** are capped by another transition metal center[7] (e.g. in the cation $[Rh(C\text{-}NC_8H_9)_3(AuPPh_3)_5]^{2+}$).[7b] The cation of **1** is a potential precursor for the formation of analogous mixed-metal species. We are currently investigating the reactions of transition metal anions with **1** with a view to synthesizing bimetallic complexes in a targeted way.

Experimental Procedure

1: *n*BuLi (0.31 mL, 1.6 M in hexanes, 0.5 mmol) was added to a solution of $[tBuNH_2]$ (0.5 mL, 0.5 mmol) in toluene (5 mL). After the mixture had been heated to reflux for 5 min, a pale yellow solution was formed. This was subsequently cooled to −78 °C, $[AuCl(PPh_3)]$ (0.25 g, 0.5 mmol) was added, and the mixture stirred for 30 min at −78 °C. The reaction mixture was allowed to warm to room temperature; most of the solid that had formed dissolved. The solution was filtered through Celite. Reduction of the volume of the filtrate under vacuum (ca. 2 mL) gave a white solid, which redissolved when the solution was warmed gently; hexagonal, colorless crystals grew at room temperature (24 h). Although two lattice-bound toluene molecules are present per molecular unit of **1** in the crystal, placing **1** under vacuum (ca. 15 min, 10^{-1} Torr) leads to unsolvated, amorphous samples in which all the lattice solvent is apparently removed. The following analytical and spectroscopic investigations were carried out on the dry amorphous material: yield 0.18 g (80%); decomposition to give a black solid at about 145 °C; elemental analyses for $(C_{80}H_{78}Au_5ClN_2P_4)_n$, found: C 42.1, H 3.5, N 1.2, P 5.4; calcd: C 43.4, H 3.5, N 1.3, P 5.6; IR (Nujol), $\tilde{\nu}$ [cm^{-1}] = ca. 3040 (aryl C-H stretching vibration), 1435 (P-Ph stretching vibration), 743, 691 (aryl bending vibration); ^1H NMR (250 MHz, +25 °C, $CDCl_3$), δ = 7.50–7.15 (10H, br., m, C_6H_5-), 1.34 (3H, s, *t*Bu); ^{31}P NMR (101.25 MHz, +25 °C, $CDCl_3$), δ = −113.2 (s, PPh_3); ^{13}C NMR (100.61 MHz, +25 °C, $CDCl_3$), 134.1–128.9 (PPh_3), 42.8 (*t*Bu).

[4] Crystal data for **1**: $C_{94}H_{94}Au_5ClN_2P_4$, M_r = 2395.87, space group, monoclinic, $P2_1/c$, a = 19.892(8), b = 11.052(3), c = 39.16(2) Å, β = 90.35(5)°, V = 8609(6) Å^3, Z = 4, λ = 0.71073 Å, ρ_{calcd} = 1.849 M gm^{-3}, $\mu(Mo_{K\alpha})$ = 8.642 mm^{-1}. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated [8] crystal of dimensions 0.15 × 0.13 × 0.12 mm by the θ/ω method ($8.0 \le 2\theta \le 45.0°$). Of a total of 12347 reflections collected, 11135 were independent. A semiempirical absorption correction was applied (max. and min. transmission, 0.536 and 0.188, respectively). The structure was solved by direct methods [9] and refined by full-matrix least-squares on F^2 [10] to final values of $R1$ ($F > 4\sigma F$) = 0.092 and $wR2$ = 0.320 (all data) [$R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/\Sigma wF_o^4\}^{0.5}$, $w = 1/[\sigma^2(F_o^2) + (xP)^2 + yP]$, $P = (F_o^2 + 2F_c^2/3)$. Largest features in the final difference map, 2.093 and −1.841 e Å^{-3}. The crystal used in the experiment was irregularly shaped and gave a weak diffraction pattern even at 153 K. When restraints were applied to the light atoms, a chemically sensible structure was obtained with an R value of less than 0.10. However, as pointed out by one of the referees, this refinement procedure leads to large estimated standard deviations. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full citation.

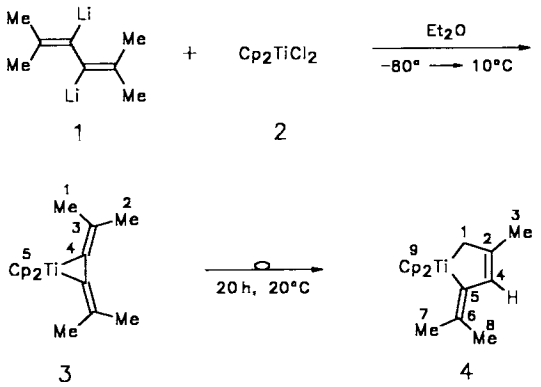
Synthesis of the First Titana[3]radialene and Its Ring Enlargement to a Titanacyclopentene**

Adalbert Maercker* and Andreas Groos

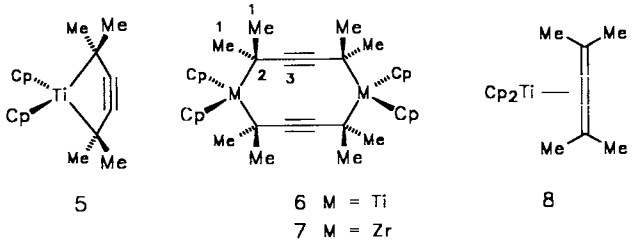
Dedicated to Professor Harald Günther on the occasion of his 60th birthday

The ready availability of 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**1**)[1] and its conversion into heteroradialenes[2] with boron,[3] silicon,[4] tin,[5] and phosphorus[6] as heteroatoms challenged us to investigate the existence of transition metal derivatives.

Indeed, the reaction of **1** with titanocene dichloride (**2**) led to the expected titana[3]radialene **3**, which underwent a fast rearrangement with ring enlargement to give titanacyclopentene **4**.



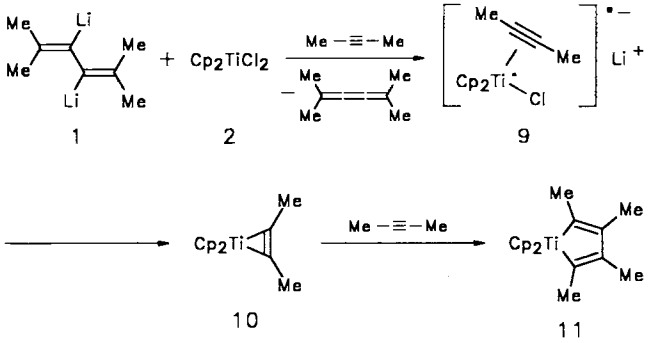
Intermediate **3** could not be isolated. The structures of both titanium compounds **3** and **4** were determined unequivocally by their NMR spectra, and data for derivatives of **4**, compounds **12** and **13**, lent further support (Table 1). Even just the ^{13}C chemical shifts of the carbon atoms C-3 ($\delta = 121.24$) and C-4 ($\delta = 191.63$) indicate that the proposed structure of the initial product is **3** and not, for example, **5** or **6**. Compound **7**, the zirconium analogue of **6** obtained from the reaction of **1** and zirconocene dichloride,[7] shows totally different ^{13}C chemical shifts ([D_6]benzene: $\delta = 60.57$ (C-2), 103.97 (C-3)). The number of methyl signals in the ^1H and ^{13}C NMR spectra also indicate that **5** and **6** are not the initial products; like **7** these compounds should give rise to only one methyl signal, whereas



the initial product **3** gives rise to two methyl signals (cf. also: butadiyne–zirconocene complexes of Rosenthal et al.[8] and Erker et al.,[9] which have two more electrons, and also the butadiyne–titanocene complexes of Rosenthal et al.[10]).

Furthermore, the number of NMR signals excludes an unsymmetrical structure. Due to the integration of the ^1H NMR signals one can also exclude a butatriene-bridged dimer structure. The question whether **3** is a titanium(IV) or titanium(II) compound is only a formal one. The actual structure must be between that of **3** and **8**.[11] It has been proposed, however, that the mesomeric resonance structure **8** is only a minor contributor, since the ^1H NMR chemical shift of the cyclopentadienyl signal of titanium(II) compounds should be shifted upfield by up to 2 ppm;[12] here this signal is observed at low field (([D_8]THF): $\delta = 6.38$).

When **1** is allowed to react with **2** in the presence of 2-butyne, the titanacyclopentadiene **11**[13] is formed, possibly via **9** and certainly via the titanacyclopropene intermediate **10**[14], together with **3** and **4**. A reaction of titana[3]radialene **3** with 2-butyne did not occur.



In contrast, the titanacyclopentene **4** reacts slowly with 2-butyne and titanacyclopentene **12** is formed by insertion (Table 1). With 1-hexyne a fast and strictly regioselective reaction leads to **13**, in which the butyl group of hexyne is directly adjacent to the titanium center (Table 1). This can be explained by assuming

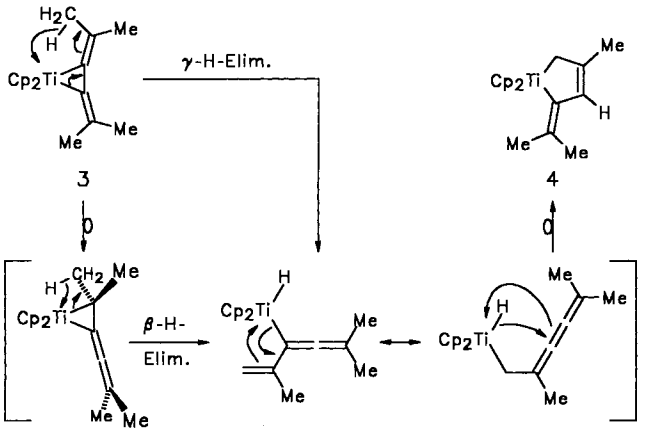
13: ^{1}H NMR [a, c] (200 MHz, [D$_8$]THF): δ = 0.75 (3H-6), 0.87 (3H-14), 0.8–1.5 (6H-11–H-13), 1.26 (3H-7), 1.70 (3H-10), 3.23 (1H-3), 4.58 (1H-9), 4.67 (1H-9), 4.84 (1H-2), 6.22 (5H-15), 6.28 (5H-15); ^{13}C NMR (50 MHz, [D$_8$]THF): δ = 14.55 (C-14), 20.86 (C-10), 22.60 (C-7), 23.82 (C-13), 24.69 (C-6), 32.18 (C-12), 38.90 (C-11), 55.51 (C-3), 109.29 (C-9), 114.79 (C-15), 115.07 (C-15), 118.69 (C-2), 129.27 (C-5), 151.31 (C-8), 186.53 (C-4), 201.05 (C-1)

[a] Only broad singlets were observed due to the presence of paramagnetic impurities. Thus coupling constants could not be determined. [b] Assignment by inverse C,H shift correlation. [c] Assignment by C,H shift correlation.

that when complex **4** coordinates the alkyne initially, the bulky butyl group avoids the triene ligand. A direct insertion of the alkyne into **4** by formation of a titanacycloheptadiene was not observed. Compounds **4**, **12**, and **13** show some unique structural features similar to those of compounds described by Doxsee et al.[15]

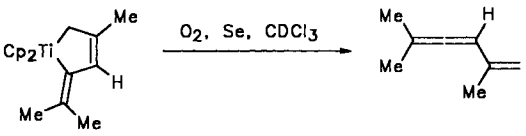
Since *no* intermediates were detected during the rearrangement **3** → **4**, the mechanism can only be speculative. The reaction may follow the path shown in Scheme 1. When the rearrangement was monitored by NMR spectroscopy no further hydrocarbons or titanium compounds could be found.



Scheme 1.

The five-membered ring compound **4** reacts with oxygen, with selenium, and with $CDCl_3$ giving 2,5-dimethyl-1,3,4-hexatriene (**14**), which was identified by comparison of the NMR and MS data with reported values.[16] No deuterium from $CDCl_3$ was incorporated into **14**. The titanacyclopentene **4** can be stored at ambient temperature in [D$_8$]THF under argon for some days without noticeable decomposition.

The reaction of 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**1**) with zirconocene dichloride (instead of titanocene dichloride



(**2**)) led to other types of products. Neither a zircona[3]radialene nor a compound like **4** could be detected. The ten-membered ring compound **7** was obtained in addition to other compounds.[7]

Experimental Procedure

3 and **4**: To a stirred solution of **1** in diethyl ether (30 mL of a 1 M solution, 30 mmol) diluted with 280 mL of diethyl ether was added **2** (7.47 g, 30 mmol; Merck) in one portion at −80 °C. The mixture was allowed to warm up to 10 °C within 1 h and then filtered through a G3 glass sinter frit under argon. The solvent was removed in vacuo and 100 mL of pentane was added to the residue. The mixture was stirred for 30 min and filtered again through a G3 glass sinter frit under argon. The solvent was removed in vacuo. The crude product (6.7 g) consisted of **3** (50%) together with **4** (^{1}H NMR). Pentane (100 mL) was added to the crude product and after sedimentation of some solid, the solution was transferred into another Schlenk flask. Then the solution was concentrated to a volume of 20 mL, and after one week at −25 °C solid **4** formed (2.5 g, 29%). After the mother liquor was removed by pipette, the solid was dried under high vacuum.

14: Black selenium (0.8 g, 10 mmol; Merck) was added to a solution of **4** (1.4 g, 5 mmol) in 30 mL of pentane at room temperature, and the mixture was stirred for 48 h. The mixture was filtered through a G3 glass sinter frit under argon and the solvent removed in vacuo. The residue contained **4** and **14** in a molar ratio of 2:1 (^{1}H NMR). When oxygen was introduced into a benzene solution of **4**, or **4** was added to $CDCl_3$, **14** formed as main product.

12: At ambient temperature 2-butyne (1.6 g, 30 mmol) was added in two portions with an interval of 1 h to a stirred solution of **4** (7.3 g, 25.5 mmol) in 150 mL of pentane. The mixture was stirred for another 5 h then filtered through a G3 glass sinter frit under argon. The solvent was removed in vacuo and 40 mL pentane was added to the residue (7.8 g; **12** and **4** ca. 1:1.3). After one week at −25 °C pure **12** (1.92 g, 22%) had precipitated. The mother liquor was removed by pipette and **12** was dried at high vacuum. **13** was synthesized in the same way.

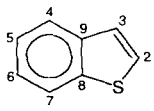
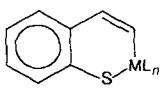
Model Compounds for the Homogeneous Hydrodesulfurization of Benzothiophene: Insertion of Manganese into the S–C(aryl) Bond**

Conor A. Dullaghan, Shouheng Sun, Gene B. Carpenter, Brandon Weldon, and Dwight A. Sweigart*

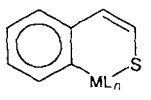
The great importance of heterogeneous hydrodesulfurization (HDS)[1] has spawned numerous studies with homogeneous model systems.[2] Of particular interest has been the activation of derivatives of thiophene (T), benzothiophene (BT), and dibenzothiophene (DBT). While all three of these sulfur-containing molecules are relevant to HDS, the latter two are especially so because they are more difficult to desulfurize and thus are much more abundant in fossil fuels. The key step in HDS is cleavage of the S–C bonds, and a reasonable way for this to occur is by initial coordination to a metal followed by insertion into the S–C bond. In particular, precoordination of the metal to the sulfur atom of the thiophene unit is thought to be crucial to S–C bond cleavage.[3–5] In the case of BT (**1**), several examples of the insertion of metal fragments ML_n into the S–C(vinyl) bond to give **2** (M = Fe, Ru, Rh, Ir, Pt[3b, 5, 6]) have been reported; however, there have been no reports of S–C(aryl) bond cleavage to give **3**. The X-ray structure[4] of [(BT)Re(CO)$_2$Cp*] (Cp* = C_5Me_5), in which the rhenium



1



2



3

atom is η^1-bonded to the sulfur atom, suggests that η^1-S coordination selectively weakens the S–C(vinyl) bond but not the S–C(aryl) bond, thus providing an explanation[6e] for why **2**, and not **3**, is formed. Herein we demonstrate that the insertion of a metal atom into the S–C(aryl) bond of BT to give complexes of type **3** can, in fact, be readily accomplished.

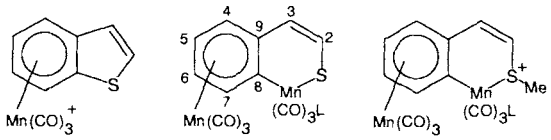
$[(\eta^6\text{-polyarene})Mn(CO)_3]^+$ ions, in which the polyarene is a naphthalene-type ligand, are converted by one equivalent of reducing agent to *syn*-facial bimetallic $[(\eta^4,\eta^6\text{-polyarene})Mn_2(CO)_5]$ complexes containing a Mn–Mn bond.[7] In analogy to this, it was anticipated that reduction of the readily available[8] $[(\eta^6\text{-BT})Mn(CO)_3]^+$ ion **4** would yield a bimetallic η^4,η^5-BT complex. However, reduction of **4** with cobaltocene under an atmosphere of CO produced a high yield of the bimetallic complex **5a**, which contains a $Mn(CO)_4$ moiety inserted into the S–C(aryl) bond of BT. When the reduction of **4** was carried out under N_2 and in the presence of one equivalent of $P(OR)_3$, the analogous bimetallic products **5b** and **5c**



4 **5a-c** **6a,b**

a: L = CO, **b**: L = $P(OMe)_3$
c: L = $P(OEt)_3$

were obtained, in which $Mn(CO)_3P(OR)_3$ is inserted into the S–C(aryl) bond. Complexes **5b** and **5c** could also be synthesized in comparable yield directly from **5a** by the thermal displacement of a CO ligand with one equivalent of $P(OR)_3$. Both synthetic methods produced **5b** (as well as **5c**) as a mixture of two isomers in a ratio of ten or more to one. The red-purple isomers, which were easily separated by chromatographic techniques, give *very* similar but perceptibly different IR and NMR spectra, indicating that the $P(OR)_3$ ligand is bonded to the same manganese atom in the two isomers (see Experimental Procedure).

Complexes **5a–c** are stable under N_2 in the solid state and suffer no detectable decomposition over 24 h in CH_2Cl_2 or CH_3CN. They are reversibly oxidized at a platinum electrode in CH_2Cl_2/Bu_4NPF_6 at potentials only moderately more positive than the ferrocenium/ferrocene couple.[9] The results of X-ray structural analysis of **5a** and **5c** are given in Figures 1 and 2, respectively.[10] The neutral molecules are, in effect, zwitterions in which the $Mn(CO)_3$ unit bears a formal +1 charge, while the inserted manganese atom formally carries a −1 charge. The Mn–S bond length in **5a** is 2.369(2) Å, a value similar to that reported for $[(C_6H_6)Mn(CO)_2SPh]$ (2.35 Å).[11] The most significant structural feature of **5a**, however, is the nonplanarity of the metallacyclic ring (Fig. 1 bottom). Mn2 and C3 are essentially coplanar with the highly planar C4–C9 carbocyclic ring. However, C2 and S1 are 0.53 Å and 1.05 Å, respectively, above this plane. Complex **5c** also has a highly nonplanar metallacyclic ring and is structurally very similar to **5a** except that an "axial" CO is replaced by $P(OEt)_3$ to give a *facial* ligand arrangement about Mn2 (Fig. 2).[12] The position of the sulfur atom in **5a** and **5c** is particularly interesting as it is seemingly rather exposed and may therefore be susceptible to electrophilic extraction; the formal negative charge on the adjacent manganese atom would serve to enhance such behavior.

The nucleophilicity of the sulfur atom in **5a** (and **5b**) was tested by treating a solution of the complex in CH_2Cl_2 with methyl triflate. The initially red-purple solution turned yellow within minutes and the product was isolated in high yield as a triflate salt by the addition of diethyl ether. Examination of the spectra indicated that methylation occurred cleanly at the sulfur to afford **6a,b**.[13] Thus, the IR spectra of **5a,b** and **6a,b** in the

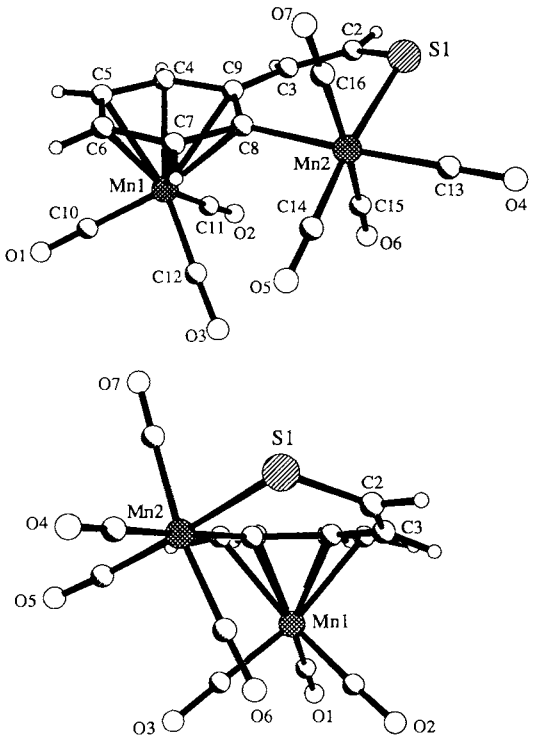


Fig. 1. Crystal structure of **5a**. Top: View showing the atom numbering scheme. Bottom: A side-on view parallel to the carbocyclic ring. Selected bond lengths [Å]: S1–C2 1.720(7), C2–C3 1.324(9), C3–C9 1.455(9), Mn1–C4 2.179(6), Mn1–C5 2.172(6), Mn1–C6 2.175(6), Mn1–C7 2.184(6), Mn1–C8 2.312(5), Mn1–C9 2.301(5), Mn2–S1 2.369(2), Mn2–C8 2.091(6), Mn2–C13 1.835(8), Mn2–C14 1.804(7), Mn2–C15 1.863(7), Mn2–C16 1.868(7).

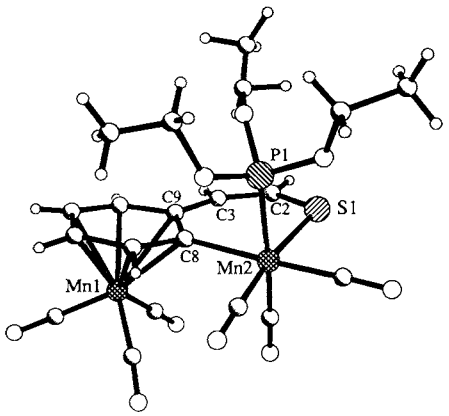

Fig. 2. Crystal structure of **5c**. Selected bond lengths [Å]: S1–C2 1.69(2), C2–C3 1.34(2), C3–C9 1.43(2), Mn2–S1 2.344(5), Mn2–C8 2.10(1), Mn2–P1 2.268(6).

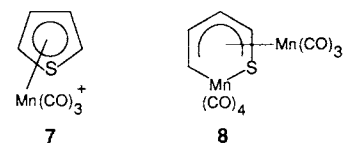
ν_{CO} region are very similar except for the expected shift of the peaks of the latter to higher wavenumbers. The NMR chemical shifts of the hydrogen atoms of the SMe group in **6a,b** are similar to those reported for methyl thioethers coordinated to manganese carbonyl units,[11, 14] and are inconsistent with the presence of a Mn–Me linkage. Furthermore, the reaction of **5a,b** in CH_2Cl_2 with methyl triflate to give **6a,b** occurred in comparable yield whether the reaction was performed under CO or under N_2. This shows that Mn–S (or Mn–C) bond cleavage does not accompany methylation, since such cleavage would generate a free coordination site at which CO would bind. The sulfur center in **6a,b** is chiral and the methyl group can be in an *exo* or *endo* orientation. ^{1}H NMR spectroscopic studies showed that on the timescale of the reaction, **6a** was formed as a single diastereomer. However, **6b** was formed as a diastereomeric mixture in a ratio of about 2:1. Over a period of hours in solution, or days in the solid state, the diastereomeric mixture of **6b** transformed cleanly into a single diastereomer.[15]

In conclusion, the S–C(aryl) bond in benzothiophene can be activated by reduction of the $[(\eta^6\text{-BT})Mn(CO)_3]^+$ ion, leading to the bimetallic complexes **5a–c**. That the S–C(aryl) bond can be readily cleaved means that this mode of activation should be considered in HDS reactions. The mechanism of formation of **5a–c** is currently under investigation with an emphasis on the probable influence of the first manganese on the insertion of the second metal. Possibly, S–C(aryl) bond cleavage requires initial η^6-coordination of a metal to the carbocyclic ring, suggesting that this type of precoordination should not be discounted[4, 16] in heterogeneous HDS reactions. Indeed, one pathway for the catalytic desulfurization of BT may involve simultaneous coordination of the carbocyclic and the thiophene rings prior to insertion into a S–C bond. The sulfur atom in the nonplanar metallacyclic ring in **5a–c** is nucleophilic and, accordingly, can be methylated to give **6**. The reaction of **5a–c** with other electrophilic reagents, as well as dihydrogen, is under investigation.

In analogy with the behavior of the $[(\eta^6\text{-BT})Mn(CO)_3]^+$ ion, the $[(\eta^5\text{-thiophene})Mn(CO)_3]^+$ ion **7** also undergoes insertion of manganese into a S–C bond when reduced with cobaltocene. The bimetallic product **8** has the metallacyclic ring π-bonded (η^5) through C2-C3-C4-C5-S to a $[Mn(CO)_3]$ moiety (Fig. 3).[17] As a consequence of this π bonding, and in sharp contrast to the situation with **5a**, the C_4S segment of the metallacyclic ring is highly planar (mean deviation = 0.030 Å) and the sulfur atom in **8** is not nucleophilic towards HBF_4 or MeOTf.[18] Reduction of the $[(\eta^5\text{-}2,5\text{-}Me_2T)Mn(CO)_3]^+$ ion was found to afford a bimetallic complex completely analogous to **8**. A thorough study of manganese insertion into these thiophene complexes is underway.



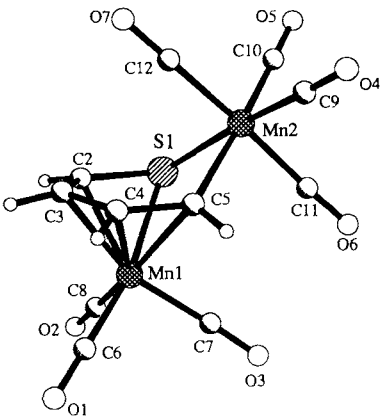


Fig. 3. Crystal structure of **8**. Selected bond lengths [Å]: S1–C2 1.718(6), C2–C3 1.370(7), C3–C4, 1.442(8), C4–C5 1.362(7), Mn1–S1 2.379(2), Mn1–C2 2.117(5), Mn1–C3 2.149(5), Mn1–C4 2.174(5), Mn1–C5 2.403(4), Mn2–S1 2.346(2), Mn2–C5 2.109(5), Mn2–C9 1.806(6), Mn2–C10 1.821(6), Mn2–C11 1.855(6), Mn2–C12 1.846(6).

Experimental Procedure

5a: Cobaltocene (0.31 mmol) and **4**-BF_4 (0.30 mmol) were combined in CH_2Cl_2 (5 mL), and the mixture was stirred under CO at room temperature for 20 min and then passed through deactivated neutral alumina (10% water) with CH_2Cl_2 as eluant. After the solvent had been removed under vacuum, the resulting red-purple solid was washed with pentane and dried. Yield 80%; IR (CH_2Cl_2): ν_{CO}

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0213 $ 10.00+.25/0

$[cm^{-1}]$ = 2074(m), 2049(s), 1995(s), 1980(s), 1932(m); IR (hexanes): ν_{CO} $[cm^{-1}]$ = 2076(m), 2050(s), 2000(s), 1995(s), 1979(s), 1939(m); ^1H NMR (CD_2Cl_2): δ = 7.55 (d, J = 9.6 Hz, H2), 6.85 (d, J = 5.5 Hz, H7), 6.18 (d, J = 9.4 Hz, H3), 6.04 (t, J = 5.6 Hz, H6), 5.49–5.41 (m, H4,5); anal. calcd: C 40.91, H 1.36; found: C 41.00, H 1.36. Crystals suitable for X-ray studies were grown by slow evaporation of a pentane solution at −20 °C.

5b: To a mixture of cobaltocene (0.61 mmol) and $P(OMe)_3$ (48 μL, 0.41 mmol) in CH_2Cl_2 (10 mL) under N_2 was added **4**-BF_4 (0.41 mmol), and the solution was stirred for 20 min. After concentration and filtration through a short deactivated neutral alumina column, purification was completed by TLC on silica gel with Et_2O/hexanes (1/1). The first band contained traces of a red-purple minor isomer, which separated cleanly from the red-purple major isomer. Complex **5c** was prepared similarly. **5b**: yield of major isomer 85%; IR (hexanes): ν_{CO} $[cm^{-1}]$ = 2052(vs), 2012(s), 1996(s), 1975(s), 1950(s), 1914(m); ^1H NMR ($CDCl_3$): δ = 7.63 (d, J = 9.7 Hz, H2), 7.05 (d, J = 6.6 Hz, H7), 6.09 (d, J = 9.7 Hz, H3), 5.88 (t, J = 6.0 Hz, H6), 5.20–5.35 (m, H4,5), 3.57 (d, J = 10.3 Hz, OMe); yield of minor isomer <5%; IR (hexanes): ν_{CO} $[cm^{-1}]$ = 2052(vs), 2025(m), 1995(s), 1975(s), 1946(s), 1917(m); ^1H NMR ($CDCl_3$): δ = 3.74 (d, J = 11 Hz, OMe), otherwise identical to major isomer. **5c**: yield of major isomer 76%; IR (hexanes): ν_{CO} $[cm^{-1}]$ = 2052(vs), 2010(s), 1996(s), 1975(s), 1946(s), 1912(m); ^1H NMR (CD_3COCD_3): δ = 7.44 (d, J = 9.6 Hz, H2), 7.12 (d, J = 6.4 Hz, H7), 6.43 (t, J = 6.0 Hz, H6), 6.17 (d, J = 9.7 Hz, H3), 5.76 (t, J = 6.1 Hz, H5), 5.68 (d, J = 6.8 Hz, H4), 3.91 (q, J = 7.0 Hz, OCH_2), 1.16 (t, J = 7.0 Hz, Me); anal. calcd: C 41.53, H 3.67; found: C 41.73, H 3.69. Complex **5b** was also synthesized in about the same yield by the following alternative procedure: **5a** (0.10 mmol) and $P(OMe)_3$ (0.20 mmol) were mixed in CH_2Cl_2 (3 mL) under N_2. After the mixture had been stirred for 1 h, the solvent was removed and the residue chromatographed on neutral alumina. Impurities, as well as the minor isomer, were eluted with Et_2O/hexanes (1/1) and the major isomer was eluted with Et_2O/hexanes (4/1). Complex **5c** was also made by this method except that the elution solvents were Et_2O/hexanes (1/5 and 1/3, respectively). Small single crystals of **5c** were grown by slow evaporation of a pentane solution at −20 °C.

6a: Methyl triflate (0.30 mmol) was added to complex **5a** (0.10 mmol) in CH_2Cl_2 (5 mL) under CO or N_2, and the solution stirred for 30 min during which time the color changed from red-purple to yellow. After concentration to 2 mL, Et_2O was added to precipitate the product as fine yellow microcrystals. Yield 81%; IR (CH_2Cl_2): ν_{CO} $[cm^{-1}]$ = 2097(m), 2066(vs), 2020(vs), 1979(m); ^1H NMR (CD_3COCD_3): δ = 7.18 (d, J = 9.9 Hz, H2), 7.10 (d, J = 6.4 Hz, H7), 7.03 (d, J = 9.9 Hz, H3), 6.81 (t, J = 6.3 Hz, H6), 6.61 (d, J = 6.6 Hz, H4), 6.51 (t, J = 6.1 Hz, H5), 2.98 (s, Me).

6b: Methyl triflate (0.30 mmol) was added to **5b** (0.10 mmol) in CH_2Cl_2 (10 mL) under CO or N_2. After the mixture had been stirred for 30 min, the solution was concentrated and transferred to a dry acidic alumina column, washed with CH_2Cl_2 and eluted with acetone. Yield 79%; IR (CH_2Cl_2): ν_{CO} $[cm^{-1}]$ = 2067(s), 2030(s), 2010(s), 1963(ms), 1940(ms); ^1H NMR (CD_3COCD_3): δ = 7.08–7.04 (m, H2,7), 6.88 (d, J = 10.1 Hz, H3), 6.73 (t, J = 6.3 Hz, H6), 6.48 (d, J = 6.4 Hz, H4), 6.37 (t, J = 6.3 Hz, H5), 3.74 (d, J = 10.5 Hz, OMe), 2.84 (s, Me).

8: Cobaltocene (0.24 mmol) and **7**-BF_4 (0.22 mmol) [19] were combined in CH_2Cl_2 (8 mL) under an atmosphere of CO. After the reaction mixture had been stirred for 20 min, it was concentrated and eluted through a column of deactivated neutral alumina with CH_2Cl_2 to yield the product as a microcrystalline orange solid. Yield 71%; IR (hexanes): ν_{CO} $[cm^{-1}]$ = 2081(m), 2039(s), 1999(sh,s), 1994(s), 1979(m/s), 1962(s); ^1H NMR ($CDCl_3$): δ = 6.94 (t, J = 6 Hz, 1H), 6.09 (d, J = 6 Hz, 1H), 6.04 (dd, J = 10.5, 5.5 Hz, 1H), 5.09 (d, J = 10 Hz, 1H). Large crystals of **8** were easily grown from pentane solutions at −20 °C.

[9] $E_{1/2}$ is +0.35 for **5a** and +0.04 V for **5c** (relative to the Fc^+/Fc couple).

[10] a) The crystal structures of **5a** and **5c** were determined with a Siemens P4 diffractometer. Data was collected at 25 °C with $Mo_{K\alpha}$ radiation, and refinements based on F^2 were carried out with the SHELXL 93 package. For **5a**: triclinic, space group $P\bar{1}$, a = 7.469(2), b = 8.4800(10), c = 13.444(2) Å, α = 78.190(10), β = 86.840(10), γ = 72.63(2)°, V = 795.5(3) Å^3, Z = 2, ρ_{calcd} = 1.838 g cm^{-3}, μ = 1.754 mm^{-1}, θ range 2.57–25.00°, 226 variables refined with 2762 independent reflections ($I > 2\sigma(I)$) to R = 0.0668, $wR2$ = 0.1669, and GOF = 1.040. X-ray data for **5c** were of rather low quality due to the small size of the crystal. Because of this only about 1500 reflections were collected with $I > 2\sigma(I)$ and only the S, P, and Mn atoms were refined anisotropically. In spite of the resultant large standard deviations, the data were sufficient to unambigously define the structure. The unit cell contains two independent molecules of **5c**, which differ insignificantly. Crystal data for **5c**: monoclinic, space group $P2_1/c$, a = 15.346(3), b = 10.877(2), c = 30.688(5) Å, β = 103.101(14)°, V = 4988.9(14) Å^3, Z = 8, ρ_{calcd} = 1.540 g cm^{-3}, μ = 1.206 mm^{-1}, θ range 1.99–22.50°, 306 variables refined with 1480 independent reflections ($I > 2\sigma(I)$) to R = 0.0744, $wR2$ = 0.1607, and GOF = 0.773. b) Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

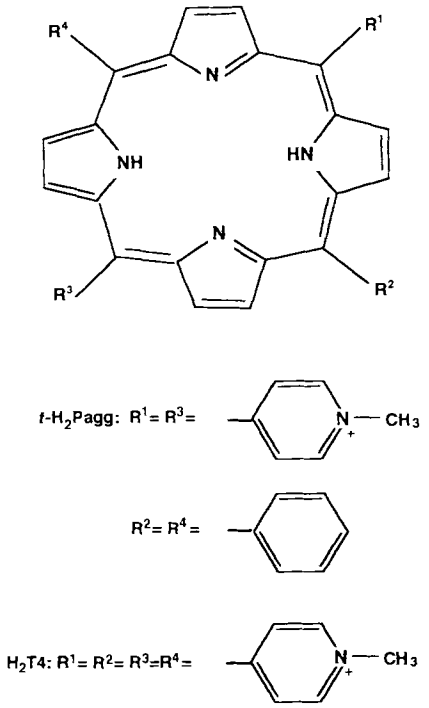
Poly(A·A·U) Triple Helix Formation Promoted by Porphyrin Assembly**

Rosaria Lauceri, Tiziana Campagna, Annalinda Contino, and Roberto Purrello*

Porphyrins are aromatic molecules whose properties (planarity, large molar absorption coefficients, tunable absorption and emission properties) make them ideal building blocks in supramolecular complexes that are models for molecular devices that store electronic[1] or solar energy.[2].

Porphyrins having polar groups in the *meso* position are water-soluble. Some of them (like *trans*-bis(N-methylpyridinium-4-yl)diphenylporphine (*t*-H_2Pagg), Scheme 1) have a pronounced tendency to self-stack in aqueous solution even at micromolar concentrations and low ionic strengths ($I = 0.02$ M), both in the absence and in the presence of charged matrices (DNA, poly-L/D-glutamate).[3,4] Furthermore, the interaction of cationic porphyrins with DNA or RNA could be relevant for medical and biological applications.[5]



Scheme 1. Counterion Cl^-.

Recently tetrakis(*N*-methylpyridinium-4-yl)porphine (H_2T4, Scheme 1), which does not have any tendency to self-associate, was also found to form extended aggregates on single-stranded (*ss*) poly(A) but not on *ss* poly(dA),[4] poly(C), poly(G), and poly(U).[6] These findings demonstrate that aggregation of porphyrins on matrices of opposite charge is not necessarily correlated to their tendency to self-aggregate but also involves molecular recognition processes. Aggregation of porphyrins on chiral matrices can be detected easily by means of circular dichroism (CD) measurements; it leads to an induced CD band in the Soret region having a characteristic shape (conservative) and unusually large intensity ($|\Delta\varepsilon| > 100\ M^{-1}cm^{-1}$).[7]

The specificity of the interaction of H_2T4 with *ss* poly(A) encouraged us to study the poly(A)–poly(U) system in the presence of this free-base porphyrin. Poly(A) and poly(U) can form three types of complexes: the double-stranded (*ds*) helix poly(A·U) and the three-stranded helices poly(U·A·U)[8] and poly(A·A·U).[9] The latter helix forms in the presence of 0.15 M NaCl and 5 mM $MgCl_2$ after one week of incubation at 4 °C.[9] Fresco and co-workers have also shown that the complex forms only when the degree of polymerization (dp) of poly(A) is between 28 and 150, whereas the length of poly(U) does not affect the triple helix formation.[9]

Because of coulombic repulsions between the negative arrays of phosphate groups, most triple helices form at high salt concentrations or in the presence of divalent cations in millimolar concentrations. Here we report evidence that the presence of cationic porphyrins in micromolar concentrations "induces" the formation of the poly(A·A·U) triple helix also under unfavorable conditions, for example with poly(A) strands having an average dp higher than 400 base residues. We anticipate that the "catalytic" action of porphyrins occurs through specific molecular recognition processes on the "external" poly(A) strand. Figure 1 shows the absorbance mixing curves monitored at

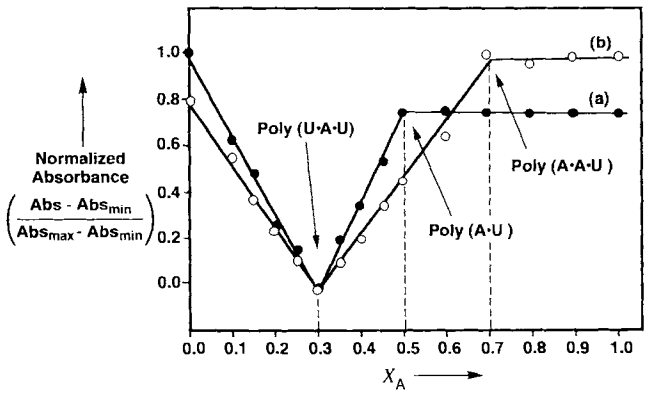


Fig. 1. Absorbance mixing curves of poly(A)–poly(U) mixtures (total concentration = 100 μM) in the absence (a) and in the presence (b) of H_2T4 (4 μM). Poly(A) dp > 400. $I = 0.1$ M (NaCl). X_A = mole fraction of adenine residues.

280 nm[10] for poly(A)–poly(U) mixtures incubated for one hour at room temperature in the absence and in the presence of H_2T4 at $I = 0.1$ M (NaCl).[11] As expected, when no porphyrin is added (Fig. 1a) the curve shows two clear endpoints at $X_A = 0.3$ and $X_A = 0.5$, corresponding to the three-stranded helix poly(U·A·U) and the double helix poly(A·U), respectively.[8,9] In the presence of porphyrin (Fig. 1b) the endpoint at $X_A = 0.5$ is absent,[12] but an additional endpoint at $X_A \approx 0.7$ is present. This corresponds to a helix with A_2U stoichiometry and shows that H_2T4 is an effective "catalyst" for the formation of a poly(A·A·U) triple helix.

CD spectra of the poly(A)–poly(U) mixtures containing H_2T4 were recorded soon after the absorption spectra. The intensity of bands in the Soret region are plotted in Figure 2 as

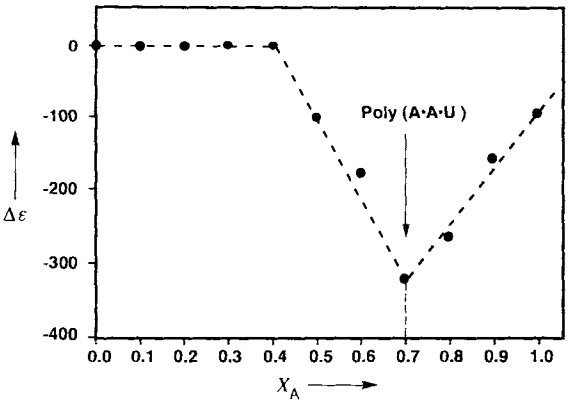

Fig. 2. Plot of the intensity of the CD bands ($\Delta\varepsilon$ [$M^{-1}cm^{-1}$)] at 450 nm of poly(A)–poly(U) mixtures in the presence of H_2T4 vs. mole fraction of adenine residues.

a function of the mole fraction of adenine residues (X_A). For $X_A < 0.5$[12] the CD spectra do not show any induced features, implying that porphyrins are essentially monodispersed on the surface of the polynucleotide (as indicated by hypochromism and the frequency shift of the Soret band observed in the absorption experiments). In contrast, for $X_A \geq 0.5$ the intensity of the induced CD bands increases with the mole fraction of A, reaches a maximum ($\Delta\varepsilon = -320\ M^{-1}cm^{-1}$) at $X_A = 0.7$, and then decreases. The unusually large intensity and the nonconservative shape of the CD signals indicate that for $X_A \geq 0.5$ porphyrins are assembled on polynucleotides. Thus, UV and CD data show that 1) under our experimental conditions the poly(A·A·U) helix forms only in the presence of H_2T4, and 2) CD intensities maximize at $X_A = 0.7$, suggesting that specific aggregation of H_2T4 is a key step in the formation of the triple helix.

To further investigate this last point we conducted the same experiments with copper(II) and zinc(II) derivatives of H_2T4. CuT4 (which also aggregates on *ss* poly(A)[4] and not on poly(U)[6]) behaves in the same way as the free-base porphyrin, showing clear endpoints at $X_A = 0.7$ in the absorption and CD titrations. In contrast, absorption titration curves obtained in the presence of ZnT4 are identical to those obtained when no porphyrin is added and show only the endpoints at $X_A = 0.3$ and $X_A = 0.5$. Moreover, the CD spectra measured in the presence of ZnT4 do not show any features in the Soret region over the entire mole fraction range. We would like to recall that ZnT4 aggregation is severely limited by the presence of a water molecule axially coordinated to the Zn^{II} center.[4] These results underline that aggregation is crucial for the whole assembly process.

The following experimental findings obtained for *t*-H_2Pagg show that, to "catalyze" poly(A·A·U) formation, porphyrin aggregation must be specific on *ss* poly(A). *t*-H_2Pagg has a very strong tendency to aggregate on DNA and RNA polymers[3a, b, 4b] and therefore lacks specificity. We noted, in fact, aggregation on both *ss* poly(U) and poly(A).[6] However, absorbance and CD titrations performed on poly(A)–poly(U) mixtures in the presence of *t*-H_2Pagg do not show clear endpoints. Most likely, indiscriminate aggregation on all the constituents of the mixtures hinders not only the formation of the triple-stranded helix but also the formation of poly(A·U) and poly(U·A·U) helices, confirming that the interactions of porphyrins on single strands can strongly affect the formation of double and triple helices.[4a] The results obtained with ZnT4 and *t*-H_2Pagg indicate that 1) the formation of the poly(A·A·U) triple helix is fostered only by porphyrins that recognize (through aggregation) *ss* poly(A), and 2) the recognition process involves the "external" poly(A) because we noted aggregation only for solutions having $X_A \geq 0.5$.

A possible explanation for this behavior is that aggregation of cationic porphyrins occurs on a single strand of poly(A); this leads to a partial "neutralization" of the phosphate negative charges thus facilitating the approach of the third strand to an already formed poly(A·U) double helix. We also hypothesize that porphyrins aggregate in a "face-on" fashion (i.e. with the porphyrin plane parallel to the helix axis) because this arrangement may allow a more efficent "contact" (neutralization) between porphyrins and phosphate groups. Studies on the dependence of the system on ionic strength and concentration are currently in progress.

Experimental Procedure

Poly(U) and poly(A) were obtained both from Sigma and Pharmacia. The average dp for poly(A) was certified to be higher than 400 bases. Tetrakis(*N*-methylpyridinium-4-yl)porphine and *trans*-bis(*N*-methylpyridinium-4-yl)diphenylporphine were purchased from Mid-Century. The porphyrin were metalated as described in the literature [13]. Circular dichroism spectra were recorded on a JASCO J-600 spectrometer. Absorption spectra were measured on an HP-8462A spectrometer. Porphyrin-containing solutions were always kept in the dark. Doubly distilled water was used throughout.

[7] Porphyrins are D_{4h}-symmetric and therefore they show an "induced" CD spectrum in the Soret region only when they interact with chiral molecules [3] or when they form chiral superstructures [2b]. The interaction of porphyrins with polynucleotides leads to modest negative CD signals when intercalation occurs. In contrast, external binding is associated with at most low positive bands [3].

[10] Absorbance mixing curves are plots of absorbances vs. the fractional composition of the mixtures at constant total concentration [8b]. In analogy to Fresco et al. [9], we monitored the absorbances at 280 nm.

[11] Mixtures with porphyrin were prepared adding H_2T4 as the last component shortly after the polynucleotides.

[12] We hypothesize that the endpoint at $X_A = 0.5$ is obscured by the disproportionation reaction (a), which disfavors formation of the double helix. Our

$$2\,\text{poly(A·U)} + n\,H_2T4 \rightleftharpoons \text{poly(U·A·A)}\cdot n\,H_2T4 + \text{poly(U)} \quad \text{(a)}$$

hypothesis is confirmed by the CD data which show that 1) H_2T4 does not aggregate up to $X_A = 0.5$ (which means that H_2T4 does not aggregate on *ds* poly(A·U), because it is not conceivable that poly(A·U) is not present at $X_A = 0.4$), and 2) H_2T4 is suddenly extensively aggregated ($\Delta\varepsilon = 120\ M^{-1}cm^{-1}$) at $X_A = 0.5$, where triple helix formation begins.

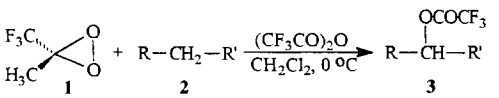
A General and Efficient Method for the Monohydroxylation of Alkanes**

Gregorio Asensio,* Rossella Mello, María Elena González-Núñez, Gloria Castellano, and Julia Corral

The selective functionalization of alkanes is an important challenge in synthetic organic chemistry. In this context, several methodologies have been developed to oxidize hydrocarbons.[1] The cyclic peroxide methyl(trifluoromethyl)dioxirane (**1**) has been revealed as a selective and very efficient oxidant for alkanes under very mild conditions.[2] Dioxirane **1** discriminates tertiary C–H bonds in the presence of methylene and methyl groups to give tertiary alcohols with a remarkably high selectivity. However, methylene groups are oxidized to ketones, since the secondary alcohol produced in the first oxygen transfer step reacts with **1** faster than the starting alkane.[1–3] Analogously, in the few examples reported of oxidation of methyl groups,[4] carboxylic acids are the reaction products.

During our studies on the factors influencing the selectivity of the O-atom insertion into C–H bonds by dioxiranes, we found that acylated primary and secondary alcohols are protected against oxidation by **1**. This result prompted us to study the control of the oxidation of methyl and methylene groups at the alcohol stage. Now we report that unactivated primary and secondary C–H bonds are selectively monohydroxylated by **1** with excellent yields when reactions are carried out in the presence of a tenfold excess of trifluoroacetic anhydride [Eq. (a)].



(a)

R= alkyl, aryl
R'= H, alkyl, aryl

The reaction products were the trifluoroacetates **3** in all cases. Overoxidation to carboxylic acids or ketones was not observed in any case under our reaction conditions. The yields of monohydroxylation products decreased with the use of a threefold excess of trifluoroacetic anhydride; the resulting trifluoroacetic acid esters were stable under the reaction conditions. The results are shown in Table 1.

The formation of the trifluoroacetic acid esters **3** is easily understood if we consider that the alcohols formed initially by oxidation of a C–H bond undergo acylation by trifluoroacetic anhydride, present in excess, faster than any further oxidation by **1**. The oxygen transfer is nearly quantitative in all cases to give only monohydroxylated products; moreover, no product resulting from the radical chain decomposition of **1** is detected.[5] A model of concerted electrophilic O-atom insertion[6] into C–H bonds best accommodates the above observations. Our results parallel those reported in the oxidation of methylene groups to ketones by **1**; the presence of trifluoroacetic anhydride in the medium has obviously no any significant influence on the course of the oxygen transfer process.

Table 1. Reaction of alkanes **2** with **1** in the presence of trifluoroacetic anhydride [a].

Substrate	Reaction time	Product(s) (Yield [%]) [b]
2a	60 h	**3a** (>99)
2b	40 min	(±)-**3b** (58) (±)-**3b'** (42)
2c	10 min	 **3c** (>99)
2d	2 min	 **3d** (50) (±)-**3d'** (50)
 **2e**	40 min	 (±)-**3e** (5) (±)-**3e'** (95)
 **2f**	20 min	 (±)-**3f** (75)[c]
 **2g**	1 h	 (±)-**3g** (>99)[d]

[a] Substrate concentration (in CH_2Cl_2) about 0.1 M in all cases; initial molar ratio of **2**/**1** = 1/1.2. The substrate conversion was quantitative except where otherwise indicated (see [c, d]). [b] Determined by GC analysis; all values are within 1% error limits. [c] Substrate conversion 12%. [d] Substrate conversion 75%.

2,2,3,3-Tetramethylbutane (**2a**) was selected for the study of the oxidation of methyl groups (Table 1). The stoichiometric reaction takes 60 hours to afford monoester **3a**, which reveals the low reactivity of primary C–H bonds. *n*-Hexane (**2b**) reacts in 40 min to give a mixture of secondary esters **3b**, and **3b'** in a nearly statistical ratio. Cyclohexane (**2c**) reacts much faster (in only 10 min) to afford cyclohexyltrifluoroacetate (**3c**) as the only product.

Bicyclo[2.2.2]octane (**3d**) is monohydroxylated in the tertiary and secondary positions in a 1:1 ratio in accord with the known preference of **1** to react with tertiary C–H bonds. Norbornane (**2e**)[2, 7] is hydroxylated at C2 with high *exo*-selectivity (*exo*/*endo* ratio 95/5). Benzylic positions are also monohydroxylated by this process. In this case, an important side reaction, the oxidation of the activated aromatic ring, causes lower yields (for instance, of monoester **3f**). If the aromatic ring carries an electron-withdrawing trifluoromethyl group as in **2g**, this side reaction does not take place, but the rate of O-atom insertion into the benzylic C–H bond decreases (see **2f** and **2g** in Table 1).

In conclusion, the methodology reported for oxidation with **1** enables highly selective monohydroxylation of alkanes.

Experimental Procedure

General procedure: A 1.2-fold excess of **1** (0.37 M) in ketone-free [5] CH_2Cl_2 was added to a solution of alkane **2** (0.5–1.0 mmol, 0.13–0.15 M) in CH_2Cl_2 containing a tenfold excess of trifluoroacetic anhydride at 0 °C. The progress of the reactions

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3502-0217 $ 10.00+.25/0

was monitored by iodometric titration [8] until the iodometric titer was constant. Then the solutions were treated with solid sodium carbonate at 0 °C for 1 h with stirring and subsequently filtered; the volatile products were removed under vacuum at 0 °C to yield the trifluoroacetate esters **3**. Yields were determined by GC analysis of the crude reaction mixture (internal standard p-$ClC_6H_4CO_2CH_3$) after neutralization. All the products were isolated and identified by comparison (^1H and ^{13}C NMR, and GC-MS) with authentic samples.

Preparation of 1,3-Dizinc Compounds by a Boron–Zinc Exchange**

Holger Eick and Paul Knochel*

1,3-Dimetallic reagents are interesting building blocks that have proved to be especially useful for the preparation of metallacyclic transition metal complexes.[1] However, applications of these dimetallic reagents in organic synthesis have been hampered by their difficult preparation. Thus, treatment of 1,3-dibromopropane with metals such as Li, Mg, and Zn affords cyclopropanes as major products, but 1,3-dimetallic compounds can only be obtained in modest yields.[2] Alternatively, the transmetalation of 1,3-dimercury compounds[1, 2] constitutes a satisfactory approach to 1,3-dimagnesio-[1, 2] and 1,3-dilithiopropanes;[1] however, the high toxicity of mercury compounds precludes broad synthetic applications of this chemistry. Recently we developed an efficient synthesis of polyfunctional dialkylzinc compounds by a boron–zinc exchange reaction.[3] Herein, we report an application of this reaction to the preparation of 1,3-dizinc compounds **1a,b** (Scheme 1).

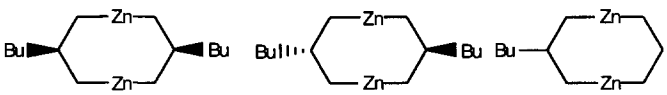
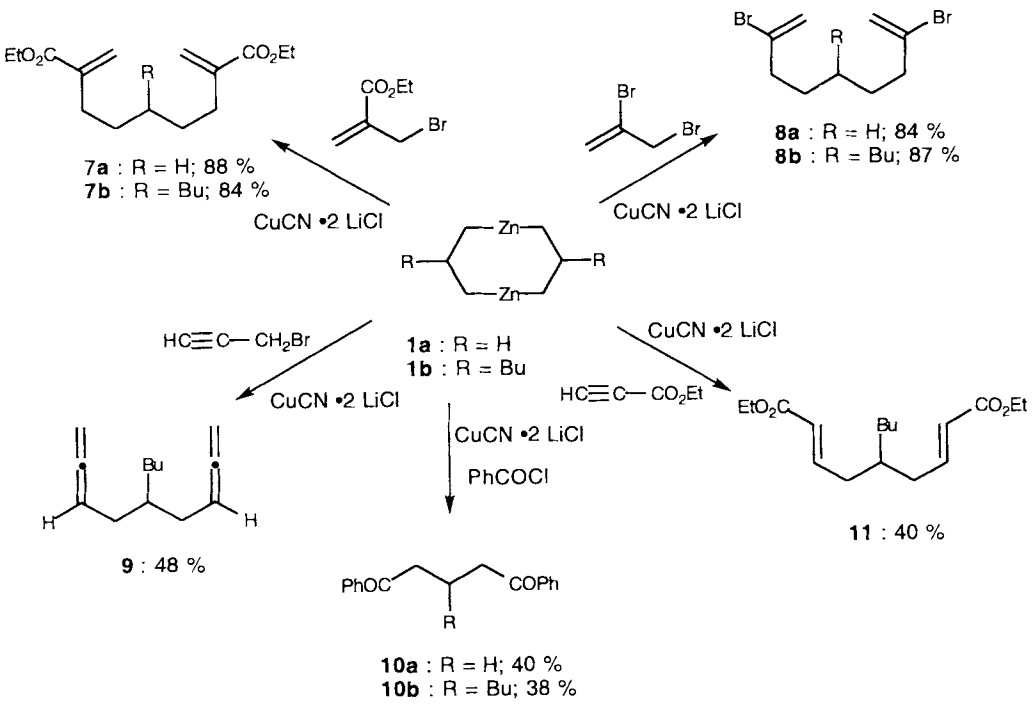
Thus, treatment of the allylic zinc bromides **2a,b**[4] with diethylthiophenylborane **3**[5] affords the corresponding allylic diethylboranes **4a,b**. These air-sensitive organoboranes can be isolated in pure form by distillation under reduced pressure (53–67% yield). The hydroboration of **4a,b** with diethylborane/methyl sulfide complex[3, 6] (25 °C, ca. 2 h) affords the 1,3-bis(diethylboryl)propanes **5a,b** in 82–85% yield as clear oils. Treatment of **5a,b** with diethylzinc (4 equiv, neat, 0 °C, 0.5 h) leads as expected to a fast boron–zinc exchange. After removal of the excess diethylzinc by application of vacuum, the crude 1,3-dizinc species **1a,b** are obtained as sole products (ca. 90% yield) as shown by ^1H and ^{13}C NMR analysis.[7] NMR experiments and a comparison with the pioneering work by F. Bickelhaupt et al. on the structures of 1,4-, 1,5- and 1,6-dizinc compounds[8] led us to propose an eight-membered cyclic structure for **1a,b** rather than an open-chain polymeric structure $[(ZnCH_2CH_2CH_2)_n]$. The ^{13}C NMR spectrum of the 2-butyl-substituted 1,3-dizinc derivative **1b**[7] shows two sharp signals each for C(1), C(2), and the CH_2 group attached to C(2), suggesting the formation of a 1:1 *cis*/*trans* mixture for **1b**. The reaction of an equimolar mixture of **5a** and **5b** with diethylzinc gives a mixture of products. The ^{13}C NMR signals are broader and of unequal intensity for C(1), C(2), and the CH_2 group attached to C(2), which can be explained by the additional formation of the 1,5-dizincacyclooctane **6**.[9]



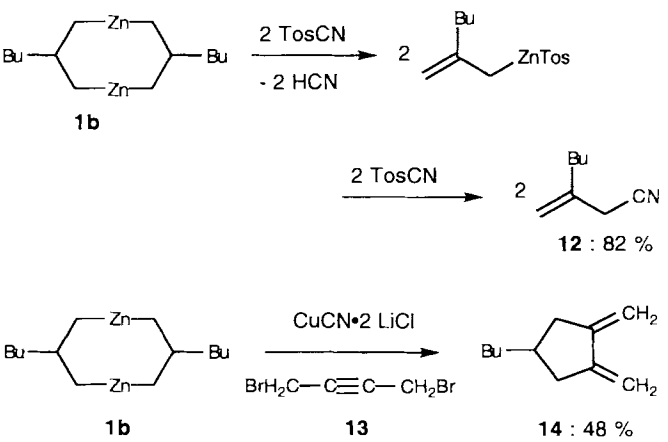
cis-**1b** *trans*-**1b** **6**

The dimetallic reagents **1a,b** do not react directly with electrophiles;[10] however, in the presence of copper(I) salts like $CuCN \cdot 2LiCl$,[11] allylic halides and propargyl bromide are converted at −60 °C to the bisallyl products **7a,b** and **8a,b**, and the bisallene **9**, respectively, in excellent yields (84–89%) (Scheme 2). With less reactive electrophiles, higher temperatures are required. The intermediate 1,3-dicopper reagents are significantly less stable than the 1,3-dizinc precursors, and some decomposition of these compounds occurs under the reaction conditions required for performing an acylation (−10 °C, 10 h) or an addition to ethyl propiolate (−15 °C, 3 h), leading to lower yields (ca. 40%) of the respective products **10a,b** and **11**.



Scheme 2.

An allylated, reduction side product (1-phenyl-3-buten-1-yl benzoate) is formed during the reaction of **1a** with benzoyl chloride. Similarly, Bickelhaupt has observed that 1,3-dimagnesium compounds can play the role of a hydride donor. This reaction pathway is observed when **1b** is treated with tosyl cyanide.[12] In this case, the unsaturated cyanide **12** is obtained as sole product in 82% yield (Scheme 3). Finally, the reaction of



Scheme 3.

1b with a bis-electrophile like 1,4-dibromo-2-butyne (**13**)[13] allows a short one-step synthesis of the 1,2-bis(exomethylene)-cyclopentane **14** in 48% yield (Scheme 3).

In summary, we have developed a new simple synthesis of 1,3-dizinc derivatives using the boron–zinc exchange reaction and have shown that these reagents can be allylated and allenylated in excellent yield. Furthermore, we have reported a new cyclization reaction. Further investigations into the synthesis, structure, and reactivity of 1,3-dizinc compounds are currently underway in our laboratories.

Experimental Procedure

Diethyl(2-butylallyl)borane **4b**: A solution of 2-butylallyl bromide (16.29 g, 92 mmol) in THF (90 mL) was added dropwise to pieces of zinc foil (6.9 g, 92 mmol) in THF (2 mL) in such a way that the temperature of the solution did not rise above 10 °C [4]. The reaction was complete after stirring 2 h at 25 °C and gave the corresponding zinc reagent **2b** (ca. 70% yield according to GC analysis of an iodolyzed reaction mixture aliquot). Diethylthiophenylborane **3** [3] (11.40 g, 64 mmol) was added. The crude reaction mixture was purified by distillation (b. p. 31 °C/0.2 mmHg) to give **4b** (8.15 g, 49 mmol, 53% yield) as a colorless liquid.

1,3-Bis(diethylboryl)-2-butylpropane **5b**: The allylic borane **4b** (2.15 g, 12.9 mmol) prepared as described above was treated with diethylborane methyl sulfide complex [3] (1.17 g, 12.9 mmol) for 2 h at 25 °C. The unconverted diethylborane and methyl sulfide was distilled off to leave crude **5b** (2.49 g, 10.6 mmol, 82% yield) which was used directly in the next step.

5-Butyl-1,2,7,8-nonatetraene **9**: A 50 mL two-necked flask equipped with an argon inlet and a rubber septum was charged with **5b** (1.2 g, 5 mmol) and diethylzinc (2.0 mL, 20 mmol) at 0 °C. After 0.5 h at 0 °C the excess diethylzinc and resulting triethylborane were removed under vacuum (0 °C, 3 h, then 25 °C, 1 h at 0.1 mmHg) to give the crude 3,7-dibutyl-1,5-dizincacyclooctane **1b** as a gray oil. Satisfactory ^{1}H and ^{13}C NMR spectra were obtained. The zinc compound **1b** is stable for at least 1 day at 0 °C in the dark (no appreciable change of the NMR spectra was detected). The crude **1b** was diluted with THF (8 mL), cooled to −60 °C, and CuCN·2LiCl [10] (10 mmol) in THF (12 mL) was added by syringe. Subsequently, propargyl bromide (2.60 g, 17.5 mmol) was added, and the reaction mixture was slowly allowed to warm up to 25 °C and stirred for 0.5 h. After the usual workup [10], the crude oil obtained after evaporation of the solvents was purified by flash chromatography (hexane) to give **9** (760 mg, 4.35 mmol; 89% yield) as a yellow oil.

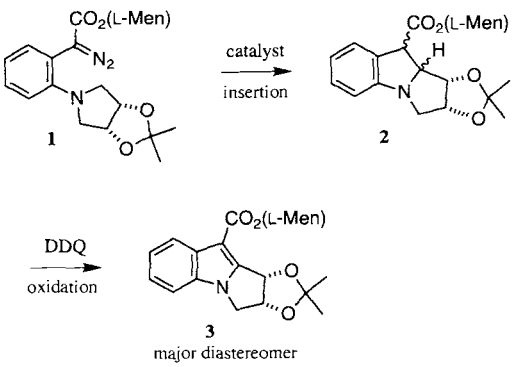
New Catalysts and Conditions for a C–H Insertion Reaction Identified by High Throughput Catalyst Screening**

Kevin Burgess,* Hee-Jong Lim, Alexander M. Porte, and Gary A. Sulikowski

Diazo compounds with suitably oriented substituents can undergo intramolecular cyclizations by metal-promoted reactions that presumably involve insertion of metallocarbenes into C–H bonds.[1, 2] Most of the known reactions of this type involve rhodium complexes,[3] typically bearing optically pure ligands from amino acids,[4] but two of us recently reported that optically active copper catalysts seemed to be superior for the reaction shown in Scheme 1.[5] In the best case, the product **3** was isolated in 64% yield as a 2.3:1.0 mixture of diastereomers. The object of the current study was to use high throughput catalyst screening to improve these results.



Scheme 1. L-Men = L-menthyl.

Our strategy was based on examining 96 potential systems for the transformation of diazo compound **1** into **2**, using a microtitre plate format. Solvents and reagents were mixed in the plate, which was then gently agitated under an inert atmosphere for 18 h at ambient temperature. The plate was then brought into the air, and the product was oxidized by adding 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) into each well. Each reaction mixture was then filtered through a silica gel plug, an internal standard (naphthalene) was added to each, and their compositions were analyzed by using an HPLC equipped with an autosampler. In this way, 96 sets of approximate yield and stereoselectivity data could be obtained in less than a week. Finally, the most promising leads would be reinvestigated in the standard way, that is sequentially.

Table 1 shows the ligand/metal/solvent combinations that were used and the data that was obtained from the high throughput screen. In summary, three different bis(oxazolidine) ligands,[6–8] a salen-type ligand,[9] and sparteine were used in combination with seven different metal salts (although not for each ligand), and four different solvents. Copper(1+) and rhodium(1+) ions were combined with the following, less well investigated, metal candidates: silver(1+), scandium(3+), gold(1+), lanthanum(3+), and ytterbium(3+) ions. Silver(1+) and scandium(3+) ions were used in more wells than the other metals of the latter category.

The original study had demonstrated that the influence of the menthyl group on the diastereomeric ratio was negligible: all the stereoselectivity could be attributed to the catalyst.[5] Inclusion of the menthyl group gives diastereomers of product **3** which can be separated by using analytical HPLC on a silica column.[5] Convenient analyses are a prerequisite for high throughput screening, hence the menthyl ester **1** was chosen for this work, in preference to esters of any achiral alcohols.

There are two main reasons for uncertainties in the screening process. First, small quantities are involved in the reactions performed in microtitre plates (ca. 10 mg of **1**, 0.6–1.4 mg of ligand, and 0.63–1.5 mg of metal salt) hence there can be significant weighing errors. Second, the agitation process may also effect the results obtained from this type of screen. Consequently, the procedure can only be considered to render leads for further investigations. To further explore the most encouraging results from the screening process, several of the reactions from the plate therefore were repeated on a larger scale (10 mol% of catalyst, throughout) with stirring, under more carefully controlled conditions. Under those conditions the following systems gave relatively poor yields of product as judged by HPLC: sparteine (ligand **7**) with $(CuOTf)_2 \cdot C_6H_6$ (THF, 25 °C, 12 h), with $Sc(OTf)_3$ (THF, 25 °C, 12 h), with $[Rh(nbd)]BPh_4$ (MePh, 10 °C, 24 h); and ligand **8**[9] with $(CuOTf)_2 \cdot C_6H_6$ (MePh, 10 °C, 24 h). Moreover, the diastereomeric ratio of product **3** formed in all these reactions was no greater than 1.3:1. Discrepancies between the latter data and that from the screen can be attributed mainly to the factors outlined above. Two sets of conditions, however, did give very interesting results. Ligand **5**[10] with $(CuOTf)_2 \cdot C_6H_6$ (THF, 10 °C, 12 h), and with $AgSbF_6$ (THF, 25 °C, 24 h), gave diastereomeric ratios for product **3** of 3.9:1 and 3.5:1, respectively. HPLC traces and isolated yields for the copper- and silver-based processes indicated that the product yield was better in the latter case (61% and 75%, respectively).

The results of the screening process suggest that ligand **5** was superior to many others, as inferred in the original study.[5] However, THF seems to be a better solvent than chloroform (the solvent originally reported), and when the reaction was repeated at a slightly reduced temperature using

Table 1. Diastereomeric ratios and yields [%] for the 96 different systems that were screened for efficacy in the reaction shown in Scheme 1.

Ligand [a]	Metal salt [b]	Diastereomic ratio (yield [%]) [c]

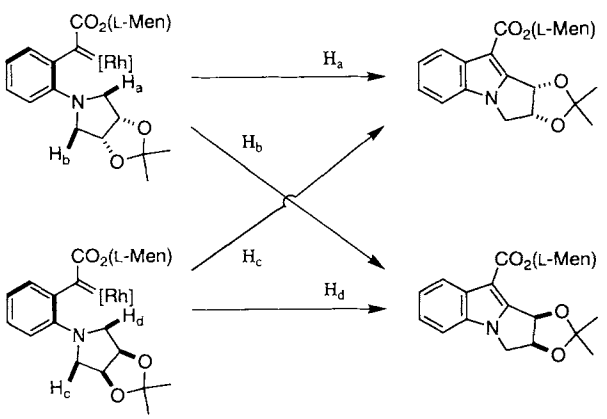
[a] Substrate **1**:ligand:salt ratio is 1:0.1:0.1 throughout. [b] Tf = trifluoromethanesulfonyl, nbd = norbornadiene. [c] After DDQ oxidation, accessed by HPLC. Throughout, the first value quoted in the ratios refers to the isomer shown in the reaction shown in Scheme 1 [11]. [d] Where no data is quoted, insufficient product was obtained for analysis.

$(CuOTf)_2 \cdot C_6H_6$, the diastereomeric ratio was improved from the value of 2.3:1 (CH_2Cl_2, 25 °C) as reported in the original work, to 3.9:1 (THF, 10 °C). With respect to yield, the combination of ligand **5** with $AgSbF_6$ was better than the copper-based system, and the stereoselectivity for this catalyst was almost as good as for the best copper system identified. Use of silver complexes in C–H insertion reactions is at least extremely rare, and perhaps unprecedented.

Stereoselective processes of the type depicted in Scheme 1 are difficult to control since there are two possible pathways to each of the diastereomeric products. Scheme 2 shows the four different processes by which the two diastereomers of **3** may form. Any catalyst that is intended to favor production of one of these



Scheme 2. The origin of both diastereomers in the reaction shown in Scheme 1.

isomers has to selectively reduce a specific combination of two of the four activation energies involved. Consequently, it may be difficult to obtain high diastereoselectivities in this transformation.

We have shown how 96 different catalyst systems were screened for their potential to mediate a challenging asymmetric C–H insertion reaction. The best stereoselectivity was observed with a copper catalyst, but comparable diastereoselectivities and superior yields were obtained with a silver-based catalyst. Use of silver complexes in these reactions may be unique.

In general, high throughput catalyst screening can have several advantages over the usual approach wherein experimentalists perform only a limited number of test reactions simultaneously. First, the plate format is much more efficient when many catalysts are to be screened. Second, parallel screening encourages the researcher to try a wide variety of systems, some of which would otherwise have been regarded as too unusual to warrant testing in a sequential fashion. In this respect, the concept of high throughput screening encourages creativity. Moreover, given a model reaction, high throughput catalyst screening with incremental changes could be very useful for optimization situations commonly encountered in industrial process development.

There are obvious parallels with this research and the concept of "combinatorial catalysis" wherein extremely large numbers of catalysts (many more than 96) might be generated by combining reagents, and screened in parallel. Experimentally, that idea is likely to be extremely difficult to put into practice. We strongly advocate a "one catalyst per well" strategy until a truly combinatorial method is devised for screening varied catalysts for a range of different reaction types.

Experimental Procedure

Screening in microtitre plates: All operations preceding the DDQ oxidation were performed in a glove box. Weighed amounts of metal salts (10 mol%) and then ligands (10 mol%) were introduced into the wells of a microtitre plate. A solvent (100 μL), then 100 μL of a 10 mg/100 μL solution of substrate **1** in the same solvent, were added by using a micropipetter. The plate was gently agitated for 18 h at 25 °C. The plate was brought out into the air, and DDQ (20 mg) was added as a solid to each well. The plate was agitated for 1 h at 25 °C. The solvents were allowed to evaporate. The contents of each well were passed through a short column of silica eluted with 1.5 mL of 2:3 EtOAc/hexanes, then 50 μL of a 1 mg mL^{-1} solution of naphthalene (internal standard) in 2:3 EtOAc/hexanes was microsyringed into each reaction mixture. Finally, an autosampler was used to input each sample into an HPLC (10 × 250 mm Dynamax, 60 Å pore size, silica gel column; isocratic 3 mL min^{-1} solvent flow of 9:1 hexanes/EtOAc; UV detection at 290 nm).

3: The following procedure is illustrative of the larger scale reactions. Silver hexafluoroantimonate (1.4 mg, 0.0057 mmol) and ligand **5** (1.9 mg, 0.0057 mmol) were weighed into a reaction flask in a glove box. THF (1 mL) was added to generate the catalyst system. A solution of substrate **1** (25 mg, 0.057 mmol) in THF (0.5 mL) was then added to the catalyst and stirred at 25 °C for 24 h. Solid DDQ (0.086 mmol) was added to the mixture, and it was then stirred for 1 h. An aliquot of the reaction mixture was taken for HPLC analysis. Solvent was removed form the reaction mixture and the product redissolved in ether (10 mL). Subsequent washes with $NaHCO_3$ (3 × 5 mL) and brine (5 mL) and drying of the organic layer over $MgSO_4$ followed by flash chromatography produced **3**.

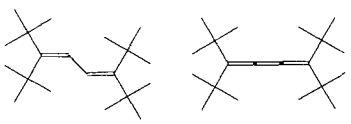
Correction of "1,1-Di-, 1,2,3-Tri- and 1,1,4,4-Tetra-*tert*-butyl-1,3-butadiene"

Henning Hopf,* Ralf Hänel, Peter G. Jones, and Peter Bubenitschek

We recently reported the preparation and crystal structure of 1,1,4,4-tetra-***tert*-butyl-1,3-butadiene** (**1** in this note, compound **8** of the original publication[1]). The structure displayed unusual aspects such as a very wide C1-C2-C2′ angle [142.2(2)°] and equal bond lengths in the butadiene chain (C1–C2 134.6(2), C2–C2′ 135.3(4) pm). For this reason a referee requested us to check the structure carefully for possible errors. However, we could find no obvious signs of serious basic errors: low temperature measurements had led to a conventional *R*-value of 0.061; there were no regions of significant residual electron density (max. 267 e nm^{-3}) and no unusually large displacement parameters (e.g., U_{eq} 456 pm^2 for C2; see footnote [4] in Ref. [1]).



1 **2**

Since the appearance of our article, many colleagues have again asked us whether the structure analysis is reliable. In retrospect the equal bond lengths did indeed appear suspicious to us, although the wide angles could conceivably have been the result of steric effects. We therefore decided to repeat the structure with a new sample of **1**.[2]

The new structure (Fig. 1) displays the expected alternating bond lengths in the butadiene chain [C1–C2 134.9(2), C2–C2′ 145.8(3) pm], and the angle C1-C2-C2′ is at 131.1(2)° not as markedly widened. It is therefore clear that the original structure determination was incorrect. The probable cause is the contamination of the first crystal (which unfortunately was not preserved and thus could not be subjected to spectroscopic checks) by a significant amount of the cumulene **2** (compound **9** in the original), which was formed as a by-product in all preparations of **1**. The new crystal was taken from a sample that had been scrupulously checked for purity. In addition, no traces of impurity could be detected in the measured crystal by NMR spectroscopy and gas chromatography.

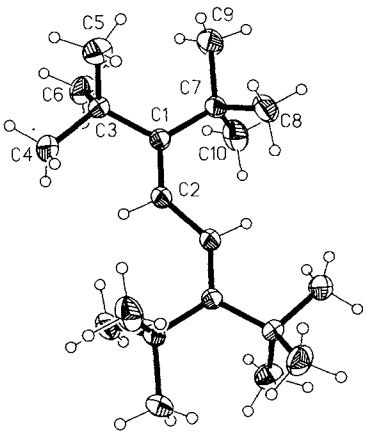


Fig. 1. The revised structure of **1** in the crystal. Ellipsoids correspond to 50% probability levels. Hydrogen radii are arbitrary. Only the asymmetric unit is numbered.

This case shows that unsuspected disorder phenomena can lead to totally incorrect results even when a structure determination appears satisfactory.

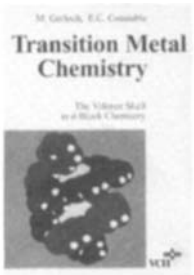
Once Exotic, Now Essential

Transition Metal Chemistry. By *M. Gerloch* and *E. C. Constable*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1994. 211 pp., hardcover DM 128.00/XI $ 75.00; paperback DM 58.00/$ 35.00.—ISBN 3-527-29218-7/1-56081-885-9

Brief, concise, and yet fundamental introductions to scientific fields are welcomed not only in education, but also in research, because it has become increasingly interdisciplinary. Although abundant in the periodic system, the transition metals have frequently been regarded as rather "exotic" elements; however, increasing knowledge of their chemistry has turned out to be very useful for furthering progress in the areas of organic chemistry (synthetic methodology, supramolecular compounds), chemical technology (catalysis), biochemistry ("bioinorganic" chemistry) as well as physical chemistry and physics (optical and magnetic properties).



The book by *Gerloch* and *Constable* contains a well readable and succinct description of the structural and electronic properties of transition metal complexes, the theoretical–mathematical treatment being kept to a minimum. As the authors admit, the actual "chemistry" (e.g. reactivity) receives less consideration in comparison to spectroscopic and structural aspects, and for the training of chemists the book will have to be supplemented accordingly. The text is, however, well suited for interested researchers from other areas.

The problem of starting with highly symmetrical compounds as primary, "simple" examples without completely losing the relation to the more complex everyday systems has been adequately solved by the authors. Unfortunately, compounds of the 4d and 5d transition metals are mentioned only sporadically. Yet these compounds have received more attention in recent research than the lighter (3d) transition metals which are predominantly featured in this book.

After an elementary introduction (including the notorious 3d/4s problem) the following 55 pages contain a well-presented description of crystal field theory and the correlation of optical spectra with d-electron configurations. After what is probably the best chapter, "Spin and Magnetism", ligand field theory and the concept of back-bonding are introduced by using the molecular orbital approach. Correlations between structure and d^n configuration as rationalized by perturbation theory are described in a further chapter in which square-planar d^8 systems and the Jahn–Teller effect receive comprehensive treatment.

The next chapter concerns thermodynamic properties such as complex stabilities (including a nonkinetic representation of the chelate effect) and the classical manifestations of crystal field stabilization energy. The penultimate chapter introduces less stringent but unavoidable concepts like the 18-electron rule, the "hard/soft" concept, and the stability of oxidation states, followed by a rather short section on the reactivity of simple complexes. The last, brief chapter is dedicated to the lanthanoid elements.

When a directly accessible albeit comprehensive description is attempted within a limited space, it is inevitable that many questions remain open and alternative examples come to mind. The charge transfer phenomenon, for example, is described on page 114 in such an abstract way that the nonexpert cannot understand why Mn^{VII} compounds are colored. On page 168 it could have been easily explained *why* Co^{II} tends to form tetrahedral complexes. The lanthanoid element chapter could have profited if ground and excited states of NMR shift reagents had been used as examples and, more generally, practical aspects are hardly covered. Neither the repeatedly emphasized use of the model by *Kepert* to explain structural preferences nor the strict classification of low, intermediate, and high oxidation states with different functions of the d electrons and binding characteristics seem to be compelling to this reviewer.

Factual errors and misprints in the text are rare ("Frank–Condon", p. 32; "coordninates", p. 69) but unfortunately the first citation of one of the author's (M. G.) articles in the preface is incorrect (p. 117 instead of p. "199"). Other errors concern the Laporte rule (transitions between orbitals or states of different parity are *allowed* and not "forbidden", p. 64), and $Ru(bpy)_3^{3+}$ is certainly not a "labile" complex (p. 190).

Two aspects of the book warrant more severe critism: Several figures are of low quality, e.g. absorption spectra and functions drawn by shaky hand on pages 22, 143, or 199. Secondly, the few references are of little help: In addition to citing their own previous books and articles (which, for a considerable part, serve as components of this book), the authors have restricted themselves largely to the classical literature from their own impressionable years; about half of the "further reading" material is more than 25 years old!

Despite these two irritating aspects, the book is excellently suited as an introduction to the realm of transition metal complexes. Its strong point is the step-by-step approach in the interpretation of spectra, magnetism, and structure which does not overburden the reader with mathematical equations and formalisms. Considering the price of this text, students as well as interested researchers from neighboring fields will be able to use it for increasing their knowledge in an enjoyable way.

Stereocontrol in Organic Synthesis Using the Diphenylphosphoryl Group

Jonathan Clayden* and Stuart Warren

In 1959, Horner showed that metalated alkyldiphenylphosphane oxides react with aldehydes or ketones to give alkenes. With this reaction, the diphenylphosphoryl (Ph_2PO) group made its entrance into synthetic organic chemistry. In the thirty-six years since that date, extensive research has shown that this olefination, the Horner–Wittig reaction, has unique properties that make it much more than simply the phosphane oxide cousin of the more famous phosphorus-based olefinations—the Wittig reaction (based on phosphonium salts) and the Wadsworth–Emmons reaction (based on phosphonate esters). Early work on the Horner–Wittig reaction concentrated on the reactivity of phosphane oxides and the regioselectivity of their reactions, but more recently the power of the Ph_2PO group to control the stereochemistry of alkenes, and to produce "on demand" either stereoisomer in high stereochemical purity, has emerged. From the study of these stereocontrolled Horner–Wittig reactions arose the realization that the Ph_2PO group is useful not only for the control of the two-dimensional stereochemistry of alkenes, but also of three-dimensional stereochemistry in general.

After a brief introduction to phosphane oxide chemistry, this review will examine the Horner–Wittig reaction, in both its original and "stereocontrolled" varieties. From there, we will move on to an account of the stereoselective construction of molecules containing the Ph_2PO group, concentrating on the stereochemical directing effects of the Ph_2PO group and on the role of its unique combination of attributes—steric bulk, electronegativity, and Lewis basicity—in controlling these reactions. Finally, we will present what is intended as a practical guide to this chemistry, covering the type of functionalized alkenes that have been made with the help of the Ph_2PO group and giving guidelines that we hope will help the organic chemist to make the most of the chemistry the Ph_2PO group has to offer.

Keywords: alkenes · asymmetric syntheses · Horner–Wittig reactions · phosphane oxides · synthetic methods

1. Introduction

Horner's first olefinations with phosphane oxides[1–3] were carried out by metalating benzyldiphenylphosphane oxides **1** (R^1 = Ar) with a potassium base (KO*t*Bu) and then adding an aldehyde or a ketone to give an alkene in one step (Scheme 1).

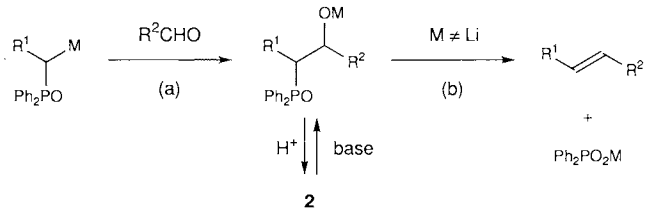
With lithium bases, however, the reaction did not give the alkene, but stopped at an intermediate adduct **2**.[1–4] These β-hydroxy phosphane oxide intermediates are generally quite stable even at 20 °C, and it is their existence as normal, isolable, and usually crystalline compounds that underlies the degree of control the chemist can exert over the Horner–Wittig reaction when compared with its Wittig[5–7] and Wadsworth–Emmons[7, 8] analogues. As we shall see, our ability to reach right into the center of the Horner–Wittig reaction, adjusting stereochemistry and conditions to favor the required stereoisomer, compares with the fine adjustments a mechanic might make to the engine of a car. In contrast, stereochemical control in the Wittig or Wadsworth–Emmons reactions seems more like pressing buttons on the dashboard or choosing what is to be put in the fuel tank.

We will refer only rarely to the Horner–Wittig *reaction*, but rather more often to its two synthetically separable mechanistic components, the Horner–Wittig *addition* of a lithiated alkyldiphenylphosphane oxide to an aldehyde, and the Horner–Wittig *elimination*, the concerted extrusion of diphenylphosphinic acid from a β-hydroxy phosphane oxide (Scheme 2). Many Horner–Wittig eliminations we will discuss will not be from β-hydroxy phosphane oxides made directly by Horner–Wittig additions. Any reaction sequence leading to an alcohol

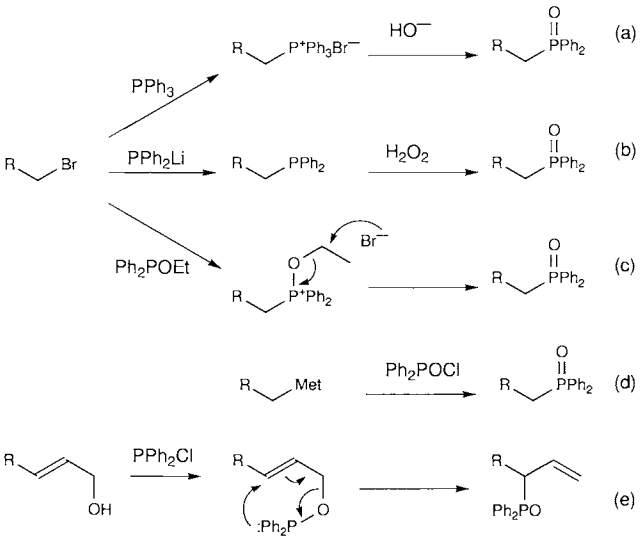


Scheme 2. The Horner–Wittig reaction; a) Horner–Wittig addition, b) Horner–Wittig elimination.

bearing a β-Ph_2PO group can be used to make a Horner–Wittig intermediate, and it is on the stereochemical control inherent in these reactions, often directed by the unique properties of the Ph_2PO group, that we will concentrate.

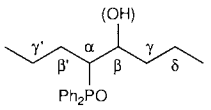
The usefulness of the Ph_2PO group in synthesis derives not just from the stereoselectivity of the reactions of phosphane oxides. Compounds containing the Ph_2PO group are very often crystalline. This property is important for the synthetic application of stereoselective reactions because it allows the separation and purification of stereoisomers by crystallization.[9] Because of the electronegativity of the Ph_2PO group, its stereochemical disposition relative to other polar groups in a molecule dominates the overall polarity of the molecule. This aids greatly the separation of diastereomers by flash chromatography.[9]

The anion-stabilizing ability of the Ph_2PO group makes compounds containing it easy to build. Complicated structures can be built up rapidly by metalation and alkylation, hydroxyalkylation, or acylation of simple alkyldiphenylphosphane oxides. The most common methods for making the starting materials for such a sequence are shown in Equations (a)–(e) in Scheme 3: a) nucleophilic displacement with triphenylphosphane followed by hydrolysis of the phosphonium salt,[9] b) nucleophilic displacement with lithium diphenylphosphanide followed by oxidation of the phosphane,[10–12] c) the Arbuzov reaction,[13, 14] d) phosphorylation of an organometallic compound by Ph_2POCl, and e) (for allylic phosphane oxides) the Arbuzov rearrangement.[15] They have also been made by addition of a phosphorus nucleophile to aldehydes[16] and by Wittig reaction of cyclic phosphonium salts.[17–22] Clearly these methods can also be used at a later stage in a synthesis to introduce the Ph_2PO group to a well-developed carbon skeleton.[11, 23, 24]



Scheme 3. Methods for making simple phosphane oxides.

Structure **3** illustrates the way we will refer to the chiral centers and substituents in an elaborated phosphane oxide. The two chains on the carbon atom bearing the Ph_2PO group are distinguished by the presence of the hydroxyl group that will ultimately undergo Horner–Wittig elimination, and the Greek letters denote the positions relative to the phosphorus atom.



3

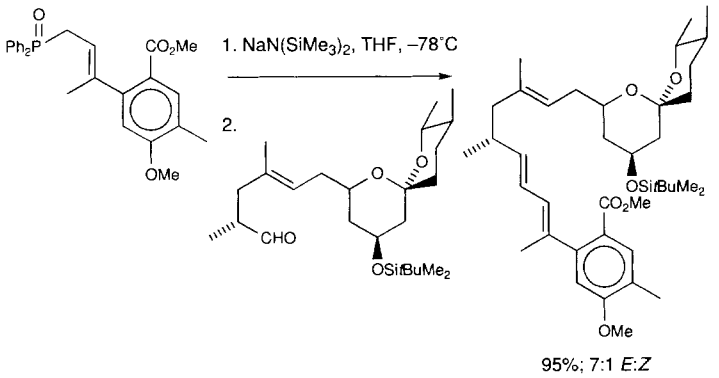
2. Two-Dimensional Stereocontrol with the Ph_2PO Group: The Horner–Wittig Reaction

The chemistry of the diphenylphosphoryl group is well suited for syntheses of molecules containing C=C bonds. Early work in this area concentrated on the connective and regioselective aspects of such syntheses, but more recently the power of the Ph_2PO group to control the two-dimensional stereochemistry of alkenes, and to produce either stereoisomer in high geometrical purity, has emerged. The stereochemical control offered by the Ph_2PO group is in fact only a special case of the three-dimensional stereocontrol we will examine in detail Section 3.

Jonathan Clayden was born in 1968 in Kampala, Uganda, and brought up in Bradwell-on-sea on the east coast of Essex (UK). In 1989 he gained a degree in chemistry from the University of Cambridge. He remained in Cambridge to carry out research on phosphane oxides under the direction of Dr. Stuart Warren, leading to a Ph.D. in 1992. He then moved to Paris, spending 18 months in the laboratories of Prof. Marc Julia at the École Normale Supérieure, where he worked on transition metal catalyzed reactions of sulfones. In 1994 he was appointed as a Lecturer in the Department of Chemistry of the University of Manchester. His research interests include stereoselectivity in organic reactions and organo-main group chemistry. He lives in Manchester with his wife and son.

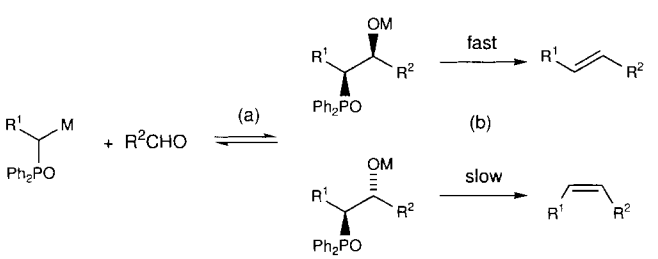
2.1 The One-Step Horner–Wittig Reaction

Metalated alkyldiphenylphosphane oxides **1** bearing certain functional groups in the α position (R^1 = benzyl,[4, 25] allyl,[10, 12, 26–31] CN,[32] isoxazole,[33] NR_2,[14] OR,[34, 35] SR[36]), can undergo a "one-step" Horner–Wittig reaction with aldehydes or ketones like that shown in Scheme 1. Horner–Wittig elimination follows directly after Horner–Wittig addition without isolation of an intermediate. These reactions have been widely used by Lythgoe et al.[10, 26, 37] and others[29–31] in syntheses of vitamin D and its analogues. The penultimate step of the synthesis of milbemycin β_3 by Smith et al.[38] is an important recent example (Scheme 4).



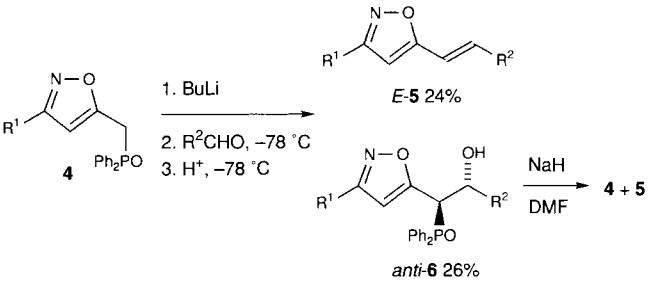
Scheme 4. Part of the synthesis of milbemycin β_3 by Smith et al.

One-step Horner–Wittig reactions are usually (*E*)-selective, like the corresponding Wadsworth–Emmons reactions (Scheme 5).[7] The metalated Horner–Wittig adduct decomposes easily in these one-step reactions because R^1 provides conjugation or stabilization of the negative charge and lowers the activation energy for the elimination. The (*E*) stereoselectivity is almost certainly a result of the reversibility of the addition to a carbonyl group of an alkyldiphenylphosphane oxide bearing an additional anion-stabilizing group. This reversibility allows interconversion of the two diastereomers of the adducts, and faster elimination from the *syn* adduct means that the (*E*) isomer of the product alkene is formed selectively (Scheme 5). Vedejs[5] has challenged an analogous explanation for the (*E*) selectivity of Wittig olefinations of stabilized phosphonium ylides, as he doubts the existence of the intermediate betaines. In the Horner–Wittig reaction the "betaines" are formed—they can



Scheme 5. The (*E*)-selective one-step Horner–Wittig reaction; a) reversible when R^1 is anion-stabilizing, b) reaction rates increase when R^1 is anion-stabilizing or conjugating. In this and all subsequent schemes only relative configurations will be shown (except in Sections 3.3.2, 3.3.3, and 4.5).

be isolated—so there is no reason to rule out this explanation. Indeed, treatment of the Horner–Wittig adduct *anti*-**6** with NaH/DMF gave a mixture of starting phosphane oxide **4** and alkene (*E*)-**5**, proving that equilibration can occur during the elimination: stereospecific elimination directly from *anti*-**6** would give (*Z*)-**5**.[33]

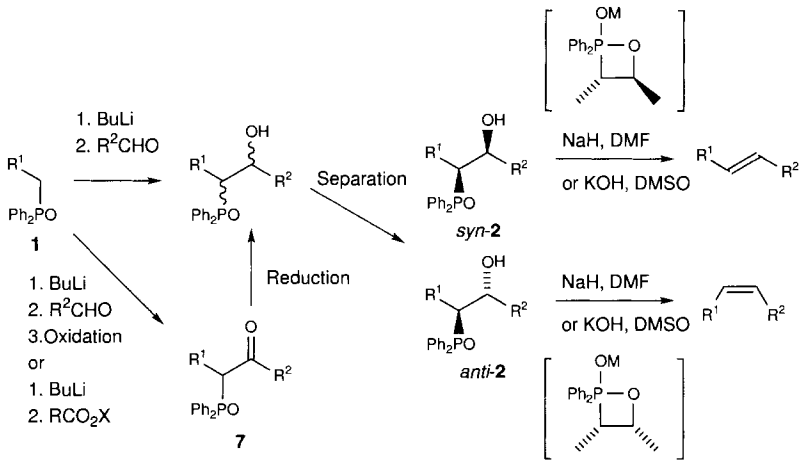


Many of these one-step reactions have direct analogues in the Wittig and Wadsworth–Emmons series, and do not specifically make use of some of the properties more particular to the Ph_2PO group. In many of the cases in which the one-step Horner–Wittig reaction has been used in a synthetic route, the phosphane oxide variant was chosen simply because it performed better than the alternatives.[35, 37, 39] An advantage that the Horner–Wittig reaction shares with the Wadsworth–Emmons is the water-solubility of the elimination by-product, a diphenylphosphinate salt. A common practical problem with the Wittig reaction is the removal of its elimination by-product, triphenylphosphane oxide, from the desired alkenes. With the Horner–Wittig reaction a simple aqueous wash suffices.

2.2. The Two-Step Horner–Wittig Reaction

For the reactions described in Section 2.1 and summarized in Scheme 5, both Horner–Wittig addition of the lithiated phosphane oxide to the aldehyde and the reverse reaction are fast, as is the sterically preferred Horner–Wittig elimination of lithium diphenylphosphinate from the *syn* adduct to give an (*E*) alkene. For simple, "unstabilized" lithiated phosphane oxides, however, this is not the case. Neither the reverse reaction nor the elimination takes place when R^1 = alkyl or H, and aqueous quenching of a Horner–Wittig reaction mixture at 0 or at 20 °C gives not an alkene but a stable, often crystalline, β-hydroxy phosphane oxide.[9] Even the Horner–Wittig adducts from stabilized lithium derivatives of phosphane oxides **1** (R^1 = benzyl,[9, 25] allyl,[40–42] isoxazole,[33] NR_2,[39, 43] OR,[44, 45] SR[46]) can be isolated before elimination if conditions are adjusted carefully (e.g. adducts **2** of benzyldiphenylphosphane oxide **1** (R^1 = Ph) must be quenched below −50 °C).[25] Crucial to this control is the use of a lithium base: the lithium counterion binds strongly to the oxyanion formed in the reaction and prevents it from attacking the electrophilic Ph_2PO group. This unique attribute of the phosphane oxides, which distinguishes them from their phosphonium and phosphonate analogues, permits the synthesis of alkenes of very high stereochemical purity. The diastereomers of the Horner–Wittig adduct **2** (typically formed

in a ratio of 85:15 *anti*:*syn*) are usually easily separated by flash chromatography or by crystallization.[9] Treatment of each pure diastereomer with a sodium or potassium base in a dipolar aprotic solvent (usually NaH in dimethylformamide (DMF), or KOH in dimethyl sulfoxide (DMSO)),[47] which generates a much more nucleophilic oxyanion, then leads stereospecifically[47] to a single stereoisomer by *syn* elimination of sodium or potassium diphenylphosphinate.[9, 20, 48, 49] We call this stepwise sequence (Horner–Wittig addition, purification of the intermediate, and Horner–Wittig elimination) the "stereocontrolled Horner–Wittig Reaction"[9] (Scheme 6).



Scheme 6. The stereocontrolled Horner–Wittig reaction.

Because of the *anti* selectivity of the Horner–Wittig addition (the diastereomers *anti*-**2** can usually be isolated in pure form in 60–80% yield) this route is usually suitable only for the synthesis of (*Z*) alkenes. The practical synthesis of (*E*) alkenes by the Horner–Wittig elimination requires a high-yielding route to the *syn* diastereomer *syn*-**2**.[50] The usual approach[9, 13, 51] makes use of a β-oxo phosphane oxide **7**, easily prepared by acylation of an alkyldiphenylphosphane oxide or by oxidation of the mixture of diastereomers of the adduct **2** obtained from a Horner–Wittig addition. Reduction of the ketone **7** with $NaBH_4$ followed by purification generally returns the *syn* diastereomer of the adduct **2** in a yield of 80–95%.[9, 51]

The Horner–Wittig elimination from either *syn* or *anti* β-hydroxy phosphane oxides **2** is usually carried out with NaH/DMF or KOH/DMSO. During the reaction with NaH/DMF a thick, feathery precipitate of sodium diphenylphosphinate is usually formed. Recent results suggest that KOH/DMSO is marginally preferable in some cases, as it can reduce the formation of by-products (e.g. from fragmentation reactions[52]) and increase the stereospecificity of the elimination.[42]

The relative stereochemistry of the Horner–Wittig adducts **2**, and hence the *syn* specificity of the elimination, has been confirmed by X-ray crystallography. Clear differences in the NMR spectra of the *syn* and *anti* diastereomers of **2** allow reliable stereochemical assignments to be made by inspection of the NMR spectra of other compounds.[47] The elimination is, in general, 100% stereospecific, giving pure (*Z*) alkenes from pure *anti* β-hydroxy phosphane oxides, and pure (*E*) alkenes from pure *syn* β-hydroxy phosphane oxides. This stereospecificity is compromised only if R^1 of **2** is a conjugating or anion-stabilizing group, in which case the increased rate of Horner–Wittig reverse reaction of *anti*-**2** may allow "stereochemical leakage" to produce some of the more rapidly eliminating *syn* diastereomer, and hence the (*E*) alkene.[9, 25]

3. Three-Dimensional Stereocontrol with the Ph_2PO Group

We have already seen that β-hydroxy phosphane oxides are stable, often crystalline, compounds. This fact, along with the stereospecificity of the Horner–Wittig elimination, means that any stereoselective route to a β-hydroxy phosphane oxide can lead to a pure stereochemically defined alkene. With this in mind, a wide variety of reactions have been examined in which the Ph_2PO group directs the stereoselective construction of an adjacent hydroxyl-carrying center, often over several steps of a synthesis. This work led to the idea that the Ph_2PO group is useful not just for the control of the stereochemistry of double bonds, but also in the stereoselective construction of chiral centers in general. Section 3 will expand this idea, and demonstrate that the stereochemical influence of the Ph_2PO group in a molecule can reach far beyond just an adjacent hydroxyl-carrying carbon atom, and that Ph_2PO chemistry can therefore form the basis for the stereoselective synthesis of molecules in which three-dimensional as well as two-dimensional stereocontrol is required.

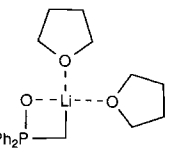
The stereochemical control exerted by the Ph_2PO group can be rationalized in terms of its three important attributes: its size, its electronegativity, and its ability to participate in hydrogen bonds and Lewis acid/base complexes.

3.1. Addition Reactions of Lithiated Alkyldiphenylphosphane Oxides

The anion-stabilizing ability of the Ph_2PO group permits easy α metalations, and the reaction of an α-lithiated alkyldiphenylphosphane oxide with a carbonyl electrophile is often stereoselective, making it a valuable method for the construction of molecules containing the Ph_2PO group.

3.1.1. The Structure of Lithiated Alkyldiphenylphosphane Oxides

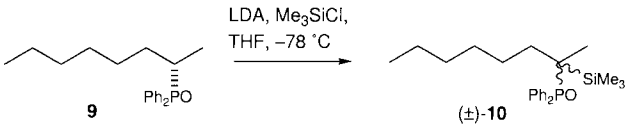
To explain the reactions of lithiated phosphane oxides, we need to consider their structure. Ab initio calculations suggest that, in THF solution, lithiated alkyldiphenylphosphane oxides contain four-membered P-C-Li-O rings as the monomeric unit, complexed with one or two THF molecules: structure **8** is proposed for the lithiated methyldiphenylphosphane oxide.[53]



8

Recent work[54a] has shown that lithiated phosphane oxides are not configurationally stable about a stereogenic carbon atom bearing phosphorus and lithium.

For example, when enantiomerically pure (>95% *ee*) phosphane oxide **9** was treated with BuLi or lithium diisopropylamide (LDA) at −78 °C and quenched with a variety of electrophiles under Grignard or Barbier conditions, the products **10** were all racemic. Vedejs and Garcia-Rivas[55] have reported that benzylic phosphane oxides **11** can be lithiated and then quenched with chiral proton sources to return the starting phosphane oxides with very high enantiomeric excesses.



9 (±)-**10**

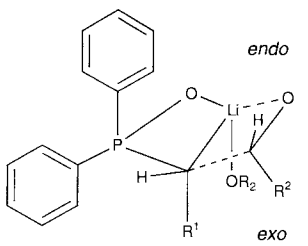
11

3.1.2. Additions to Aldehydes and Ketones: The Horner–Wittig Addition

As we mentioned in Section 2.2, the Horner–Wittig addition usually produces preferentially the *anti* diastereomer of the product alcohol. Table 1 lists the stereoselectivities obtained in some representative Horner–Wittig additions of phosphane oxides **12** to aldehydes and ketones. If we take the selectivity shown in entries 1–5 (about 85:15) as the standard, we can say that the *anti* selectivity is 1) fairly independent of R^2, but reduced slightly if R^2 is very large (entry 6) or very small (entries 7, 8), 2) reduced significantly if R^1 is large (entries 9–12), 3) reduced significantly if R^1 carries a functional group capable of complexing lithium (entries 13–18), and, in a special case of this situation, 4) inverted, giving excellent *syn* selectivity, if the complexing group contains a lithiated nitrogen atom (entry 19).

Secondary phosphane oxides **12** ($R^3 \neq H$) react with low stereoselectivity (entry 20); similarly, additions to ketones ($R^4 \neq H$) are unselective (entry 21) unless there is a very large size difference between the two groups R^2 and R^4 (entry 22).

The model we now favor for the transition state of the Horner–Wittig reaction helps understand these observations. Ab initio calculations on the reactive complex formed between uncomplexed $LiCH_2P(O)H_2$ and H_2CO, coupled with the understanding we have gained from structural studies on lithiated alkyldiphenylphosphane oxides, suggest that the reaction passes through a butterfly-shaped transition state structure **14**.[53] Both R^1 and R^2 occupy the less sterically demanding *exo* positions, hence the *anti* selectivity. Increasing the bulk of R^1 increases the steric interaction between R^1 and R^2, and between R^1 and the *exo* phenyl ring. R^1 then tends to flip to the pseudoequatorial *endo* position, leading to the observed drop in *anti* selectivity with branched R^1 substituents. For R^2 the pseudoequatorial *exo* position and the pseudoaxial *endo* position



14 R_2O = THF

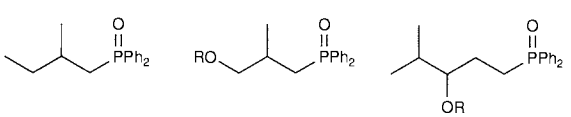
[a] Cyclohexyl.

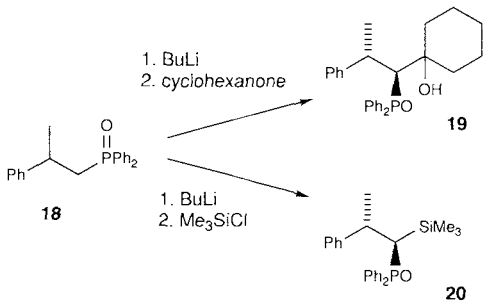
(which suffers from strong 1,3-diaxial interactions with the *endo* phenyl ring) are much more clearly differentiated, and, in almost every case, R^2 will prefer the *exo* face. Only very small R^2 groups can occupy the *endo* position, lowering the *anti* selectivity. Very large R^2 groups may lower *anti* selectivity by forcing R^1 to take the *endo* position. The low selectivity with unsymmetrical ketones and secondary alkyldiphenylphosphane oxides results because at least one alkyl group must be *endo*. The decrease in selectivity in the presence of coordinating functional groups is harder to explain quantitatively: clearly coordination of these groups to the lithium atom in the reacting complex changes the structure of the complex and therefore necessarily the stereochemical outcome of the reaction.

With a few notable exceptions, preexisting chiral centers in either the phosphane oxide or the aldehyde exert little chiral induction over the formation of the new C–C bond and the two new chiral centers. For example, additions of lithiated **15**,[42] **16**,[56, 57] **17**,[58] and **18**[57] to aldehydes generally give all four

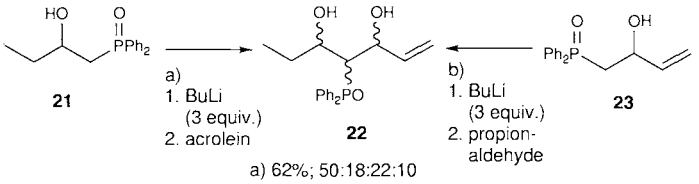


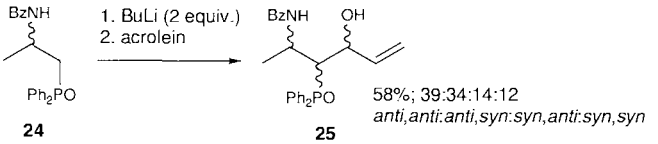
15 **16** **17**

possible diastereomers in more or less equal quantities. On the other hand, **18** gives only one diastereomer of the products **19** and **20** on lithiation and addition to cyclohexanone and Me_3SiCl, respectively.[58, 59] A β-LiO group induces weak *anti*

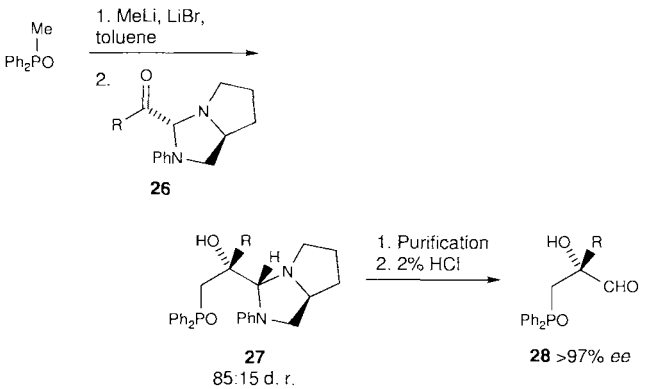


selectivity across the existing C–C bond and reduces the *anti* selectivity in the formation of the new C–C bond to about 70:30. As an example, lithiated **21** reacts with acrolein, and lithiated **23** with propionaldehyde, to give products **22** with about the same diastereomeric distribution.[42] A β-amido group has a similar effect;[60] addition of lithiated **24** to acrolein gives predominantly the *anti* diastereomers of **25**.[52] Control of this chiral center in the β' position is achieved more reliably by acyl transfer (Section 3.1.4) or by alkylation of Ph_2PO-lactones (Section 3.3.5).



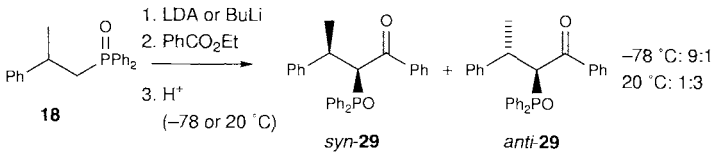


Ketones bearing chiral auxiliaries have been used to prepare optically active functionalized phosphane oxides.[54b] For example, lithiation of methyldiphenylphosphane oxide with MeLi/LiBr in toluene and addition to the chiral ketones **26** (R = Me, Ph) gave the adducts **27** as an 85:15 mixture of diastereomers. Separation and hydrolysis yielded **28** with >97% *ee*. An alternative procedure with THF as the solvent gave a 35:65 mixture of diastereomers; here the sense of the induction is reversed by disruption of the chelation presumed responsible for the selectivity in toluene.



3.1.3. Acylation with Esters, Lactones, Acyl Chlorides, and Acid Anhydrides

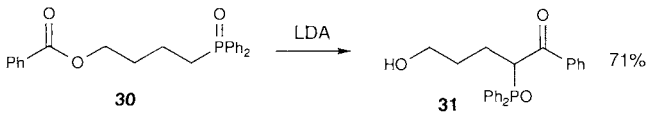
The β-oxo phosphane oxides **7**, which are formed by acylation of an alkyldiphenylphosphane oxide, are important starting materials for the stereoselective additions and reductions described in Section 3.2. The cleanest acylations are achieved by reacting the lithiated phosphane oxide with an acid anhydride, an ester,[61] or a lactone,[40, 58, 62, 63] or by reacting a copper derivative with an acid chloride.[64] As only one chiral center is formed in these reactions, the question of stereocontrol does not usually arise. Interestingly, however, phosphane oxide **18** can be acylated stereoselectively with ethyl benzoate;[58] the major diastereomer of the product **29** is dependent on the temperature



at which the reaction is quenched.[58, 65] Low-temperature quenching returns the kinetic product, while, at higher temperatures the thermodynamic product is produced.

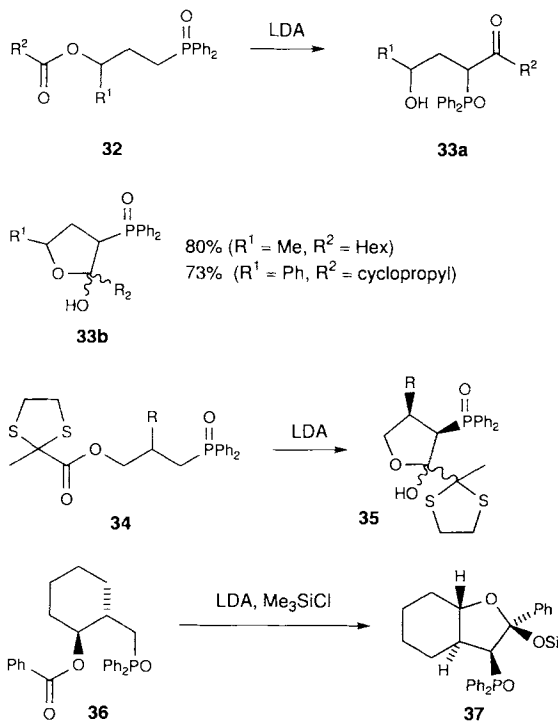
3.1.4. Intramolecular Acylation: The Acyl Transfer Reaction

Phosphane oxides can also be acylated intramolecularly. For example, treatment of the ester **30** with LDA gives the hydroxy ketone **31** in high yield.[66, 67] The reaction has been used as a



method for ring expansion,[68] but its stereoselective aspects are more important. In contrast to its intermolecular counterpart, intramolecular acylation is stereoselective for a range of substrates,[9, 58, 67, 69] allowing control of up to three chiral centers in one step. The cyclic transition state of the reaction means that preexisting chiral centers within the molecule have a powerful influence over the stereochemistry at the new carbon–carbon bond α to Ph_2PO, and the construction of chiral centers quite distant from the Ph_2PO group can be controlled.

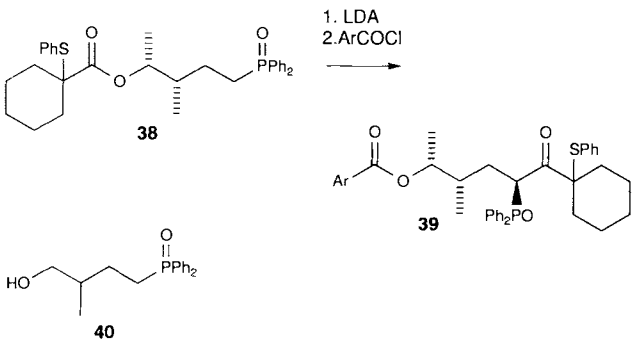
Compounds **32**[66, 67] and **34**,[58] with chiral centers γ and β to phosphorus, respectively, undergo stereoselective 1,4 O→C acyl transfers to give only one diastereomer at the newly formed C–C bond (**33a**). In both cases the products exist partly as a mixture of the anomers of hemiacetals **33b** and **35**, respectively. In the analogous acyl transfer reaction of **36** internal trapping of the reaction's tetrahedral intermediate as **37** showed that it ex-



32 **33a** **33b** **34** **35** **36** **37**

ists as only one diastereomer, even at the anomeric center.[70] Thermodynamic equilibration to the mixture of hemiacetals (such as **33b** and **35**) must occur only later.

1,5 O → C Acyl transfer is also stereoselective for **38**, which has chiral centers γ and δ to phosphorus, but not for esters of **40**, with only a γ chiral center.[58] Conveniently, the acyl transfer product could be trapped as the oxo ester **39** by acylation with



38 **39** **40**

2,4-dinitrobenzoyl chloride. Other attempts to avoid hemiacetal formation by protection of the hydroxyl group have not always been so successful.[71]

Acyl transfers are best with unenolizable esters and are low-yielding with α,β-unsaturated esters.[58, 72]

3.1.5. *Additions to Epoxides*

Lithiated alkyldiphenylphosphane oxides can be added to epoxides to give γ-hydroxy phosphane oxides in good yield. Thus, lithiated methyldiphenylphosphane oxide gives the adduct **41** in a reaction in which the stereochemistry is merely a consequence of the necessary inversion at the electrophilic center.[67] A new chiral center α to Ph_2PO may nonetheless also be introduced with excellent selectivity. While lithiated ethyldiphenylphosphane oxide gives a 50:50 mixture of the two diastereomers of **42**, reaction of lithiated ethyl- and propyldiphenylphosphane oxide with styrene oxide yields the diastereomers of **43** in ratios of 91:9 and >96:4, respectively.[67] High stereoselectivity is also obtained when ethyldiphenylphosphane oxide reacts with cyclic epoxides to give **44** and **45**.[73, 74]

3.2. Ph_2PO-Directed Addition to a Carbonyl Group

Section 3.1 concentrated on the stereocontrolled formation of carbon–carbon bonds where the Ph_2PO group was initially not at a chiral center. The new carbon–carbon bond was formed by using the anion-stabilizing ability of the Ph_2PO group, and the stereoselectivity derived from the size of the Ph_2PO group and from its ability to coordinate to a lithium atom through its oxygen atom. The next two sections will turn to the formation of new chiral centers directed by a preexisting chiral center bearing a Ph_2PO group. Section 3.2 will deal with stereocontrolled nucleophilic additions to carbonyl groups and Section 3.3 with stereocontrolled electrophilic additions to alkenes.

3.2.1. *Reduction of β-Oxo Phosphane Oxides*

As we saw in Section 2.2, the reduction of β-oxo phosphane oxides **46** (R^3 = H) by sodium borohydride is usually stereoselective, favoring formation of the *syn* isomer. Table 2 gives an outline of the dependence of this selectivity on the substitution pattern of the ketone. This selectivity is often higher, and less

dependent on the size or type of the substituents, than the complementary *anti* selectivity obtained in the Horner–Wittig addition. With unfunctionalized alkyl or aryl substituents at R^1 and R^2 the *syn* selectivity is usually of the order of 85:15 to 90:10 (entries 1–5), but the selectivity is reduced slightly if R^1 is very large (entries 6–9), particularly if R^2 is also small. The selectivity is also reduced if R^1 or R^2 contains a Lewis-basic functional group (other than hydroxyl) anywhere along the chain (entries 10–17). If R^1 contains a hydroxyl (or carboxyl) group, the *syn* selectivity is usually reduced (entries 18, 19), and the effect *increases* when the hydroxyl group is further from the Ph_2PO group (entries 20–23). For certain R^1 the selectivity may even be enhanced if the hydroxyl or carboxyl group is close (γ) to Ph_2PO (entries 18, 19). If R^2 contains a hydroxyl group, the *syn* selectivity is also reduced (entries 24–26). For ketones **46** derived from secondary phosphane oxides ($R^3 \neq H$), the selectivity is also lower (entry 28), though a γ-hydroxyl group can improve it significantly (entry 29).

Higher selectivities (practically 100%) are obtained by hydrogenation over PtO_2 or with some bulky hydrides, though the conversion is low.[9] Most other reducing agents tried (e.g. $Zn(BH_4)_2$, $LiBHEt_3$, $LiAlH_4$, and B_2H_6)[9, 69, 75] give products in lower yields or with lower selectivities.

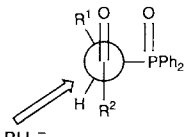
[a] Cyclohexyl.

The *syn* selectivity of the borohydride reduction is easily explained by a Felkin–Anh[76, 77] transition state structure **48**,[51] in which the large, electronegative Ph_2PO group occupies a position perpendicular to the carbonyl group; the larger of the two remaining groups, R^1, adopts the position furthest from R^2. Larger R^2 groups increase this preference, though larger R^1 groups have little effect unless, like *i*Pr, they rival Ph_2PO in angular bulk. Complexing functional groups can clearly modify the selectivity by favoring small changes in the structure of the transition state, but these effects (like those in the Horner–Wittig addition) are difficult to quantify.[62]

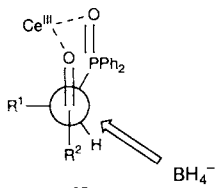


48

3.2.2. *Luche Reduction of β-Oxo Phosphane Oxides*

The presence of $CeCl_3$[78–80] can have dramatic and unexpected effects on the stereoselectivity of these reductions. Table 3 outlines the selectivities obtained in $NaBH_4/CeCl_3$ reductions of β-oxo phosphane oxides **7** and compares them with the selectivities for $NaBH_4$ reductions of the same compounds. In most cases, except those in which a further coordinating hydroxyl group in the molecule complicates the situation, the addition of $CeCl_3$ shifts the stereoselectivity towards the *anti* diastereomer of the product. When R^1 is a simple, unbranched alkyl group, this effect is weak, and the selectivity of the reaction is either weakly *syn* or just reversed to weakly *anti* (entries 1–3). However, when R^1 is β'-branched, the stereoselectivity swings dramatically towards the *anti* diastereomer. These compounds are reduced by $NaBH_4/CeCl_3$ to give *anti* β-hydroxy phosphane oxides *anti*-**2**, often with no trace of the *syn* isomers (entries 4–14).

The shift in selectivity toward the *anti* product, which is enhanced greatly by β'-branched substituents, can be rationalized by assuming that the cerium ions can be chelated by the carbonyl group and the Ph_2PO group, distorting the transition state structure for the reduction from **48** towards **49**.[81, 82] If R^1 is large and β'-branched (in which case structure **49** will be more favorable than **48**, as interactions between R^1 and both R^2 and the complexed carbonyl oxygen atom are minimized), the left-hand side of the carbonyl group in **49** is more shielded than the right, so the predominant isomer of the product will be *anti*. Otherwise, with small R^1, chelation simply serves to lift the blocking Ph_2PO group partly out of the way of the incoming nucleophile, lessening the group's *syn* directing effect. For *anti*-selective $NaBH_4/CeCl_3$ reduction of compounds with unbranched R^1, we have to turn to a modified analogue of the Ph_2PO function, the dibenzophosphole group,[83] but discussion of this is beyond the scope of this review.



49

As an exception to these principles, compounds with a free γ'-hydroxyl group, which are reduced in the presence of cerium chloride with excellent *syn* selectivity, whether they are β'-branched or not, in complete reversal of the effect described above (Table 3, entries 15–17). The free γ'-hydroxyl group is

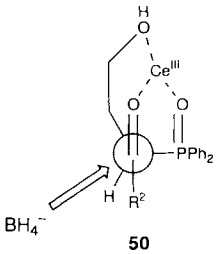
[a] Cyclohexyl.

essential for this stereochemical reversal: compounds with more distant OH groups (entries 18–20), with OH groups in R^2 (entries 21, 22), or with OH groups protected as ethers (entries 23, 24) are reduced with weakened *syn* selectivity, like the compounds in entries 1–3. Again, chelation effects appear to be responsible. By chelating the γ-OH group, cerium ion can now pull R^1 away from its blocking position on the left-hand side of the carbonyl group in **49** and allow attack *anti* to Ph_2PO, as shown in **50**, giving a product with a *syn* hydroxyl group.[81]



50

3.2.3. *Pinacol Cross-Coupling of α-Ph_2PO Aldehydes*

Vanadium(II)-promoted coupling of the two aldehydes **51** and R^3CHO gives diols **52** in excellent yields (Table 4).[84] When $R^1 \neq R^2$ the stereochemistry of the third chiral center, α to Ph_2PO, is remarkably well controlled, even for pairs of usually

Table 4. Pinacol coupling of **51** [84].

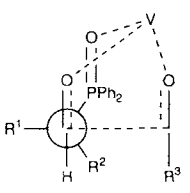
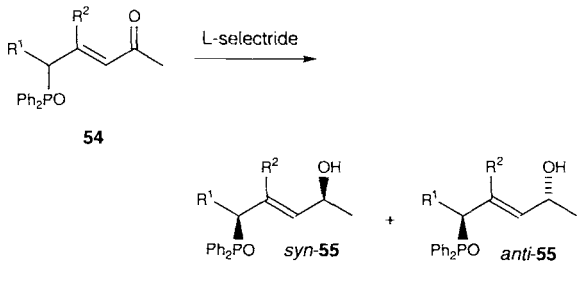
only weakly contrasting groups such as Et and Me (entry 2) or Et and *i*Pr (entry 5). As with the $CeCl_3$-catalyzed reductions, a chelated transition state structure **53** explains the sense of the chiral induction, in which R^3CHO approaches from the same side as the smaller of the two substituents R^1 and R^2.



53

3.2.4. A Vinylogous Cram Rule—Reduction of γ-Ph_2PO Enones

The stereodirecting effect of the Ph_2PO is not limited only to nearby chiral centers. An impressive demonstration of the size of the sphere of influence of the Ph_2PO group in a molecule is provided by the remarkably stereoselective reductions of the enones **54** to give *syn* δ-hydroxy phosphine oxides **55**.[85] The



55a (R^1 = *n*-C_5H_{11}; R^2 = Me): >85:15 *syn*:*anti*
55b (R^1 = *n*-C_5H_{11}; R^2 = H): 72:28 *syn*:*anti*
55c (R^1 = *i*Pr; R^2 = H): 87:13 *syn*:*anti*

bulky reducing agent L-selectride performs better than $NaBH_4$ in this reaction, in which the bulk of the Ph_2PO group directs not only the stereoselectivity but also the regioselectivity of the reduction by crowding the enone. This inductive effect, exerted over the full length of a *trans* double bond, follows the "vinylogous Cram rule" discussed and sought by Fleming et al.[86] The reaction is even more remarkable in the light of evidence from IR studies that both the s-*cis* and s-*trans* conformations of enones **54** (R^2 = Me) are populated.[87]

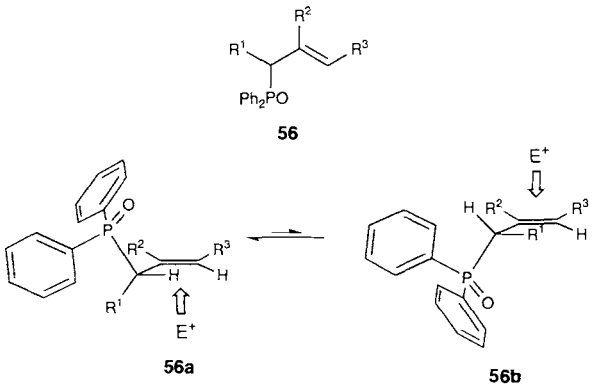
In Section 3.2 we have seen that the Ph_2PO group is capable of directing highly stereoselective nucleophilic attack at a carbonyl group. Important characteristics of the Ph_2PO group are 1) its size, strikingly demonstrated by the reductions in Section 3.2.4; 2) its electronegativity, which helps fix the reactive conformation in the Felkin-style additions described in Section 3.2.1; and 3) its ability to coordinate to metal cations, which controls the reductions in Section 3.2.2 and the couplings in Section 3.2.3. The $NaBH_4/CeCl_3$ reductions of bulky ketones in Section 3.2.2 show how, in some cases, these attributes of the Ph_2PO group can have opposing effects, and by choosing which we want to be important, we can determine the stereochemical outcome of a reaction.

In Section 3.3 we will go on to consider stereocontrolled reactions of carbon–carbon double bonds directed by the Ph_2PO group, and we will see that the same themes will emerge. In Section 3.3.1 another nice example of the complementarity of the Ph_2PO group's steric and coordinating effects will be presented.

3.3. Ph_2PO-Directed Additions to C–C Double Bonds

The reactions of alkenes with an allylic chiral center have been well studied and form the basis of some of the most effective methods for the stereocontrolled introduction of new chiral centers into a molecule. When the allylic chiral center carries a Ph_2PO group, some remarkable examples of allylic stereocontrol can be observed.

In Sections 3.3.1 to 3.3.4 we will discuss the stereochemistry of electrophilic additions to allylic phosphane oxides. We will rationalize these reactions in terms of the transition state conformations for electrophilic attack on chiral alkenes proposed by Houk et al.[88] and recently clarified by Fleming et al.[89, 90] The lowest energy conformation for reactions of allylic phosphane oxide **56** will be considered to be **56a**, in which H (the

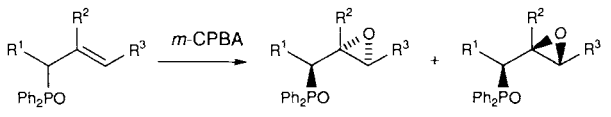


smallest group) more or less eclipses the double bond. We will see that the major diastereomeric product in each reaction can usually be explained by a reaction of this conformation; the electrophile E^+ approaches the double bond *anti* to the bulky Ph_2PO group. However, if R^1 is small (e.g. R^1 = Me) the next lowest energy reactive conformation **56b** may also become important. This conformation is strongly disfavored only when a large R^1 group generates too much 1,3-allylic strain with the *cis* vinylic hydrogen atom of the double bond. Electrophilic attack on the less hindered face of the double bond in this conformation reverses the stereochemical result of the reaction. We will see that the transition state structure **56b** also becomes significant if the electrophile is bulky and interacts strongly with R^1 in **56a**. As with the examples discussed in Section 3.2, we will also see that this fundamental selectivity pattern can be altered significantly by coordination effects involving the phosphoryl oxygen atom.

3.3.1. Epoxidation with Peracids

Epoxidation of allylic phosphane oxides **56** with *m*-chloroperbenzoic acid (*m*CPBA) is *anti* selective (Table 5); the major diastereomer of the product **57** is formed via transition state

Table 5. Epoxidation of **56**.

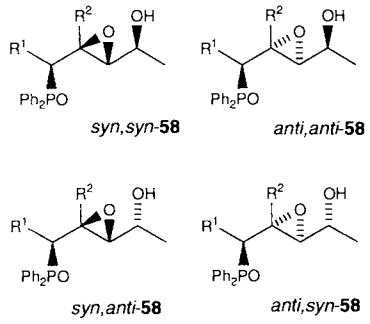


Entry	R^1	R^2	R^3	*anti*-**57**:*syn*-**57**	Ref.
1	Me	H	Me	66:34	[92]
2	Pr	H	Me	85:15	[92]
3	*i*Pr	H	CH_2OSi*t*$BuMe_2$	86:14	[92, 127]

56a, and a selectivity of about 6:1 is obtained when $R^1 > Me$ (entries 2, 3). When $R^1 = Me$ the reaction is less *anti* selective (entry 1), probably because the alternative conformation **56b** is then low enough in energy to lead to a significant amount of *syn* product. Magnesium monoperoxyphthalate (MMPP) also epoxidizes allylic phosphane oxides with *anti* selectivity.[91]

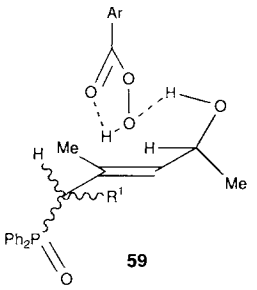
If the allylic phosphane oxide also contains a δ-hydroxyl group, some interesting and unusual effects arise (Table 6).[92] Hydroxyl groups are strong directors of peracid epoxidations,

Table 6. Epoxidation of *syn*-**55** and *anti*-**55** with *m*CPBA [92].



Entry	Starting cmpd.	R^1	R^2	Epoxidation of *syn*-**55**: *syn,syn*-**58**:*anti,anti*-**58**	Epoxidation of *anti*-**55**: *anti,syn*-**58**:*syn,anti*-**58**
1	**55a**	n-C_5H_{11}	Me	93:7	100:0
2	**55b**	n-C_5H_{11}	H	73:27	56:44
3	**55c**	*i*Pr	H	81:29	53:47

encouraging a *syn* attack on the double bond by hydrogen bonding to the epoxidizing agent.[93] As expected, therefore, *syn*-**55a** and *anti*-**55a** are both epoxidized *syn* to the hydroxyl group with high stereoselectivity (entry 1). Any effect arising from the chiral center α to phosphorus is completely dominated by the chiral center carrying the hydroxyl group in the δ position, because the methyl group (R^2 = Me) *cis* to this hydroxyl group firmly fixes the reactive conformation **59** at this center.



The epoxidations of *syn*- and *anti*-**55b** and *syn*- and *anti*-**55c** show that removal of this methyl group allows both chiral centers to play a role in directing the epoxidation. For these compounds matched and mismatched diastereomers exist in which the effects of the two chiral centers are engaged in cooperation and in competition, respectively (entries 2, 3). Unexpectedly, the matched diastereomer is that in which epoxidation occurs *syn* to the OH group and *syn* to the Ph_2PO group, and not *anti* to the Ph_2PO group as would be expected from the results with simpler allylic phosphane oxides (Table 5).

This effect persists even when the hydroxyl group is not attached to a chiral center, but disappears if it is protected. Thus, **60** is epoxidized with 73:27 *syn* selectivity, while **61** is epoxidized with 86:14 *anti* selectivity [Eqs. (f), (g)]. Reducing the size of the group R^1 of **62** reduces this *syn* selectivity, and with R^1 = Me the *anti* epoxide product dominates (Table 7).[92]

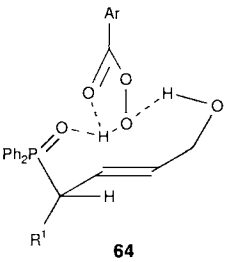
[a] Cyclohexyl.

The *syn* selectivity in the presence of an allylic hydroxyl group probably arises from a hydrogen bond between the Ph_2PO group and the acidic hydrogen atom of the peracid, favoring the reactive conformation **64**.[92] This is another example of the opposition of the Ph_2PO group's coordinating ability to its steric effects. Why the free hydroxyl group should encourage formation of this cyclic structure is not clear, though a similar effect has been noted by Johnson and Kishi in the epoxidation of benzyl ethers.[94] In any case, the stereoselectivity of the epoxidation of **60**, though remarkable, is low enough for us to deduce that a significant amount of reaction still takes place without hydrogen bonding to the Ph_2PO group, on the *anti* face of the double bond. For compounds **62** with smaller R^1 groups, population of the eclipsed conformation **56b** increases the amount of *anti* epoxide produced.



The Ph_2PO group can also have an influence over the epoxidation of a more distant double bond. For example, while the

allylic alcohol *anti*-**65** is epoxidized very cleanly to give an *anti* product [Eq. (h)], its diastereomer *syn*-**65** is epoxidized with only 75:25 selectivity in favor of the *anti* diastereomer [Eq. (i)].[57] A kind of match/mismatch effect involving the two

chiral centers is evidently in operation, though in fact the selectivities of both diastereomers are remarkable considering that allylic alcohols with this substitution pattern are usually epoxidized with almost no selectivity.[93] The lactones **66**, with their hydroxyl groups protected and conformational mobility restricted, are epoxidized with *syn* selectivity (85:15 to 90:10) [Eq. (j)].[95]

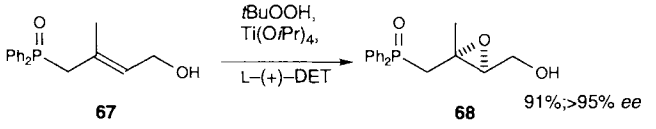
3.3.2. *Asymmetric Epoxidation*

Sharpless's asymmetric epoxidation[96–99] is an important way of functionalizing an alkene enantioselectively. Allylic phosphane oxides can be epoxidized with this method if they are also allylic alcohols: epoxidation of **67** under the standard stoichiometric conditions of Sharpless's asymmetric epoxidation (*t*BuOOH, $Ti(OiPr)_4$, L- or D-diethyl tartrate)[96] gives **68** in high yield and enantiomeric excess.[100] Under these conditions similar compounds are kinetically resolved if they have a chiral center α to the hydroxyl group. Kinetic resolution of **69** gives only one (*anti*) epoxide **70** with high *ee* at 50% completion; the allylic alcohol starting material **69** is also returned in high enantiomeric excess.[100] Interestingly, and contrary to precedent,[97] these kinetic resolutions are significantly affected by a second chiral center carrying a Ph_2PO group located *trans* to the allylic hydroxyl group. As with the peracid epoxidations described in Section 3.3.1, **55c** demonstrates cooperation and competition between the two chiral centers of its diastereomers. In this case the matched diastereomer *syn*-**55c** is epoxidized (this time with



67 **68** 91%;>95% *ee*

70 >95% *ee* (*R*)-**69** 95% *ee*

L-(+)-diisopropyl tartrate) *anti* to both the OH and Ph_2PO groups, and at 52% completion the kinetic resolution yields starting material *syn*-**55c** and a single epoxide product *anti,anti*-**58** with excellent enantiomeric excesses. Epoxidation of the mismatched diastereomer *anti*-**55c** results in poor conversion, low selectivies, and the appearance of ketones as by-products.

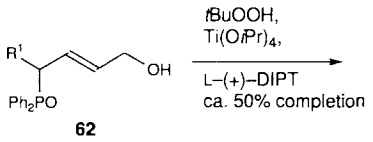
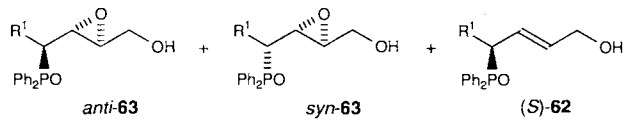
A single chiral center α to phosphorus is sufficient to drive a kinetic resolution as long as one of the other two groups at this chiral center is also large (Table 8).[100] When $R^1 = iPr$ or cyclohexyl, **62** can be kinetically resolved with efficiency, giving high selectivity for the *anti* epoxide *anti*-**63**, and returning enantiomerically enriched starting material (entries 1, 2). However, with small R^1 groups the kinetic resolutions are not so efficient.

Again, the transition states **56a** and **56b** can be used to explain these selectivities. In this case the added complication of the enantiomerically pure epoxidizing agent means that epoxidation is possible only on the bottom face of the double bond, as

Table 8. Kinetic resolution of **62** [100].





Entry	R^1	*anti*-**63**:*syn*-**63**	*ee*(*anti*-**63**)[%]	*ee*(**62**, recovered)[%]
1	*i*Pr	90:10	75	63

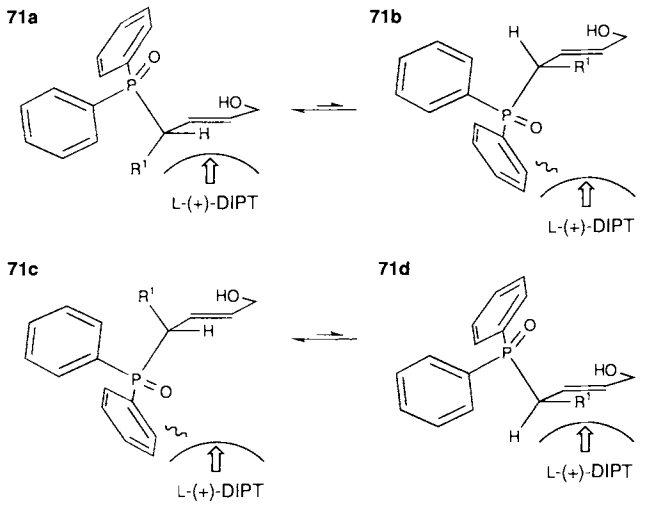
5	Me	54:46	[b]	10

[a] Cyclohexyl. [b] Not determined.

shown in **71a–d**. For the conformation and configuration shown in **71a**, this means approach of the bulky titanium–tartrate–peroxide reagent alongside R^1, while for the configuration shown in **71c**, the catalyst must approach alongside the much larger Ph_2PO group. When conformations **71b** and **71d** are unpopulated (i.e.

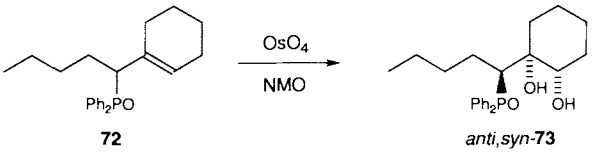


when R^1 is large), the outcome of this interplay of effects is that the epoxidation of the enantiomer of **62** in **71a** is much faster than epoxidation of the enantiomer of **62** in **71c**, and an efficient kinetic resolution results. By this model the faster reacting enantiomer of **62** gives the observed *anti* epoxide *anti*-**63**.

If R^1 is smaller than *i*Pr or cyclohexyl, the conformation of **62** depicted in **71b** and **71d** can be populated to some extent. The relative rates of epoxidation of the two enantiomers of **62** in these conformations are reversed: for the configuration in **71b**, the titanium–tartrate–peroxide reagent must approach alongside the bulky Ph_2PO group, while for the configuration in **71d** it is hindered only by a hydrogen atom. So, the more **71b** and **71d** are populated, the less efficient is the kinetic resolution. This also fits our observed trend in the decrease in efficiency for resolution of **62** with R^1 groups in the series *sec*-alkyl > *n*-alkyl > Me (Table 8).

3.3.3. *Dihydroxylation with Osmium Reagents*

Hydroxylations of allylic phosphane oxides with osmium reagents are *anti* selective: The reaction of **72** with OsO_4 and morpholine *N*-oxide gives mainly the *anti,syn* diastereomer of the diol **73**.[91] Recent results have shown that this *anti* selectivity is dependent on the solvent and reagent used for the reaction: with $OsCl_3/[K_3Fe(CN)_6]$, **73** was formed with only 60:40 selectivity.[101]



Asymmetric dihydroxylation (AD) of achiral phosphane oxides **74** with commercially available AD-mixes[102] produced optically active diols **75**; the enantiomeric excess of the product is highest with the largest, most hydrophobic groups R^1 and R^2 (Table 9).[103]

Table 9. Asymmetric dihydroxylation of **74** [103].

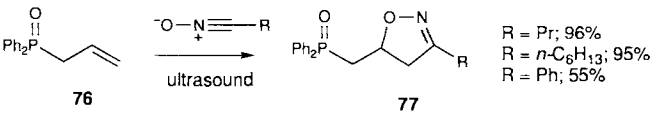
3.3.4. *[3 + 2]Cycloadditions with Nitrile Oxides*

Allyldiphenylphosphane oxide **76** reacts with nitrile oxides RCNO with aliphatic R groups under ultrasound sonication to give excellent yields of the isoxazolines **77**.[15, 104] The reaction



proceeds with 100% regioselectivity; a C–O bond is formed with the carbon atom β to Ph_2PO. Phosphane oxides **78** with a chiral center α to the Ph_2PO group give predominantly the *syn* diastereomer of the isoxazoline products **79** (Table 10),[15, 105] in contrast with the *anti* selectivity of the epoxidation reactions of similar compounds (Section 3.3.1). The stereoselectivity is relatively insensitive to the substitution pattern of either the nitrile oxide or the phosphane oxide component. However, increasing the size of R^1 marginally reduces the selectivity (entries 1–3), and very big R^1 groups stop the reaction (entry 4).

Table 10. Cycloadditions of nitrile oxides R^2CNO and **78**.

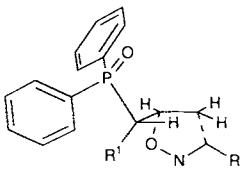
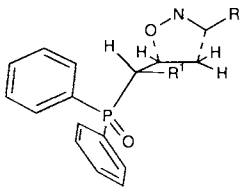
5	OMe	Ph	76:24	[105]
6	OEt	Ph	80:20	[105]

[a] No product formed.

The *syn* stereochemistry of the products is consistent with the results of Houk et al.[106] for nitrile oxide cycloadditions. It can be explained along the lines of transition states **56a** and **56b** if we consider the nitrile oxide to be a very large electrophile, which can therefore interact strongly with the allylic substituent R^1 in the transition states **80a** and **80b**. This interaction raises the energy of conformation **80a**, and favors reaction via **80b**, in which R^1 eclipses the double bond, but only a hydrogen atom is directed at the nitrile oxide. When R^1 is very large, reaction in neither conformation is possible.



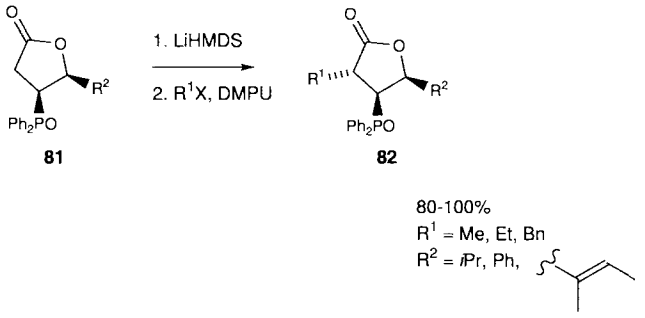


For allylic ethers the stereoselectivities of nitrile oxide cycloadditions are usually greater because of the electronic "inside alkoxy effect"—the double bond is most nucleophilic when the interaction between π and the σ^* orbitals of the C–O bond is least.[107] The absence of this effect in the reaction of **78** with R = OMe or OEt (entries 5, 6) is perhaps due to the presence of two electronegative groups at the chiral center.

Cycloadditions of allylic phosphane oxides to nitrones can also be carried out, but they are fairly unstereoselective.[108]

3.3.5. Alkylation of Ph_2PO-Substituted Lactones

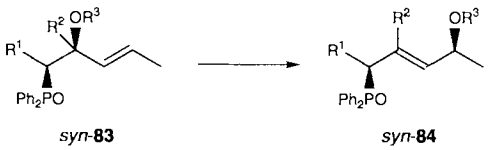
The power of the Ph_2PO group to direct stereoselective reactions is amplified when conformations are restricted by the presence of a ring. Alkylation of the enolates of lactones **81**, which were prepared by treatment with lithium hexamethyldisilazide (LiHMDS) in the presence of *N*,*N*′-dimethyl-*N*,*N*′-propylene urea (DMPU), gave single diastereomers of the products **82** (according to NMR spectra), with attack of the electrophile on the enolate occurring *anti* to the Ph_2PO group.[95]



3.3.6. Stereospecific Allylic Rearrangements

We have already seen, in the epoxidations of **65**, how a chiral center bearing a hydroxyl group can be used to "relay" chiral information further along a carbon chain. Another way of propagating chiral centers distant from the Ph_2PO group, yet with a defined stereochemistry relative to it, is to perform stereospecific allylic rearrangements of single diastereomers of unsaturated β-hydroxy phosphane oxides **83** (R^3 = H) to give the unsaturated δ-hydroxy phosphane oxides **84** (R^3 = H). Several methods, each demonstrating a different degree of stereocontrol, have been used to rearrange these compounds, usually via their esters (Table 11).

Table 11. Rearrangement of **83** to **84**.



a: R^1 = n-C_5H_{11}; R^2 = Me
b: R^1 = n-C_5H_{11}; R^2 = H

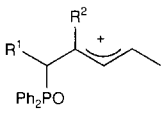
6	*anti*-**83b**	[a]	B	**84b**	[a]	7:93	[85]
7	*anti*-**83b**	Ac	C	**84c**	Ac	0:100	[111, 112]

[a] *p*-Nitrobenzoyl. [b] Methods: A: Ac_2O, AcOH, TsOH (cat.), 0 °C, 5 min.; B: PhCN, 190 °C, 1 h; C: $[PdCl_2(MeCN)_2]$ (5 mol%), 20 °C, 2 h.

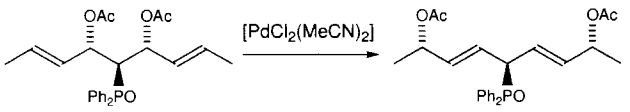
The acid-catalyzed rearrangements of **83** to give **84** (R^3 = Ac) probably via the acetates **83** (R^3 = Ac) are partially stereoselective (both diastereomers of the starting material form predominantly the *anti* diastereomer of the product) and partially stereospecific (the amount of *syn* product formed from *syn* starting material is greater than the amount of *syn* product formed from *anti* starting material) (entries 1, 2). This rearrangement passes through a cationic intermediate



85

85.[85] The cationic intermediate generated from compounds **83b,c** lacks one of the stabilizing methyl substituents and must therefore remain more tightly bound as an ion pair. A greater amount of suprafacial migration of the acetate group then takes place, and the reaction is more stereospecific (entries 3, 4).

The thermal rearrangement of the *p*-nitrobenzoates of **83** is even more stereospecific, since in the absence of acid the transition state is an ion pair (entries 5, 6). However, the best method makes use of Overman's Pd^{II}-catalyzed allylic ester transposition (entry 7).[109, 110] This method is also higher yielding and tolerates a wider range of substitution patterns than the acid-catalyzed or thermal rearrangements.[42, 111, 112] Some spectacular double transpositions have also been carried out by this method: starting from **86**, a 1,7-chiral relationship is controlled in the product **87**.[42]



86 **87**

The role of the Ph_2PO group in these reactions is twofold. Firstly, it makes possible the easy synthesis and separation of the diastereomerically pure starting materials for the rearrangements. Secondly, it acts as a driving force for the rearrangements, probably for steric reasons. For example, while the rearrangement of **83a** may be driven by the increase in substitution of the double bond, the rearrangements of **83b**, **83c**, and **90** must be driven by steric repulsion between the Ph_2PO group and the migrating acetate group, since both the starting material and the product are alkenes with equal numbers of substituents on their double bonds.

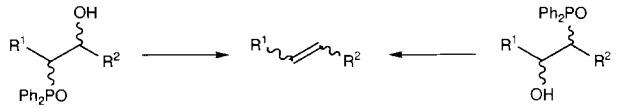
4. Stereochemically Controlled Organic Synthesis Using the Ph_2PO Group

The first three sections of this article have considered the reactions of compounds containing the Ph_2PO group, placing particular emphasis on stereoselective aspects. In this last section we shall examine these reactions in the context of a practical guide to making molecules, in particular alkenes, using Ph_2PO chemistry. We will highlight those compounds for which this chemistry is exceptionally appropriate.

The simplest alkenes containing no other functional groups will be considered first. Ph_2PO chemistry lends itself particularly well to the synthesis of certain types of alkenes, but we will show that careful consideration of the possible reaction sequences can enhance the chances of making any given alkene in good yield and stereochemical purity. Alkenes containing functional groups can be made by the same routes as those used for unfunctionalized alkenes. However, these functional groups often lower the stereoselectivity and stereospecificity of the classic Horner–Wittig reaction. Better results can be obtained by making these functional groups active participants in the construction of the molecules—in other words by making full use of the stereoselective reactions described in Section 3. This is particularly true for alkenes carrying two or more chiral centers or those that are required in optically active form.

4.1. Simple Alkenes

Except in the case of (*E*) alkenes bearing stabilizing substituents (e.g. polyenes, styrenes, vinyl sulfides, ethers; see Section 4.2), the two-step Horner–Wittig reaction (Section 2.2) is well-suited to making simple (*E*) or (*Z*) alkenes. As we have already discussed, the stereospecificity of the Horner–Wittig elimination usually means that the problem of producing pure (*E*) or (*Z*) alkenes is reduced to the much easier task of purifying *syn* or *anti* β-hydroxy phosphane oxides, and the best yields will be obtained if we can make the required diastereomer with high stereoselectivity. In addition, for a specific alkene there are usually two β-hydroxy phosphane oxide precursors, in which R^1 and R^2 are exchanged (Scheme 7). We need to consider firstly

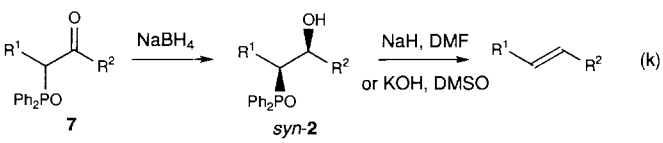


Scheme 7. Two routes to one alkene.

which route to each candidate β-hydroxy phosphane oxide would give the best yield, and then, on the basis of these yields, which of the two candidates we will use to make our alkene, bearing in mind that certain anion-stabilizing groups at R^1 lower the stereospecificity of elimination to give (*Z*) alkenes.[9] Sometimes, further considerations will also be important: for example, if pure samples of both the (*E*) and the (*Z*) isomer of an alkene are required, high yields for each isomer may be sacrificed for the convenience of using the same starting materials for each route. In this case, a particularly *un*selective Horner–Wittig addition might be chosen and the products would be separated to obtain both isomers.

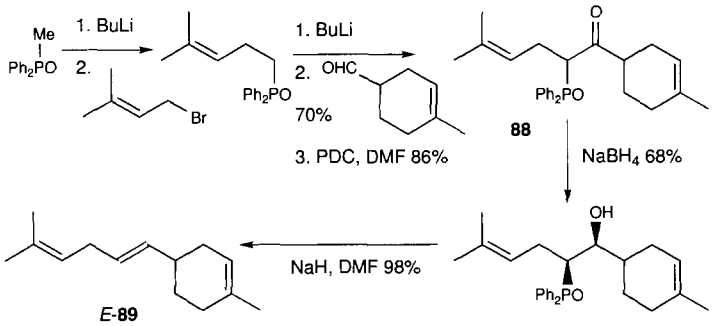
4.1.1. *Disubstituted (E) Alkenes*

The only reliable route to simple *syn* β-hydroxy phosphane oxides is reduction of a β-oxo phosphane oxide **7** with sodium borohydride. The selectivity for this reduction is usually of the order of 90:10 *syn*:*anti* unless R^1 is large [Eq. (k)]. Thus, the



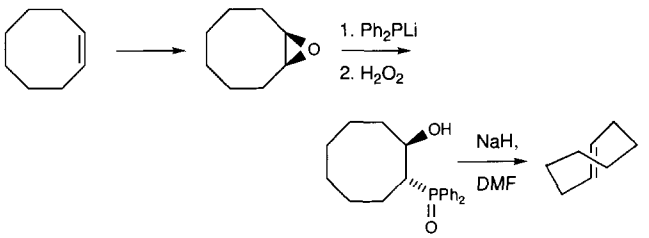
7 *syn*-**2** (k)

best yields will be obtained when R^1 is the smaller substituent. The reduction of **88**, in which R^1 = isoprenyl, led to pure (*E*)-**89** in high yield (Scheme 8).[9]



Scheme 8. Synthesis of the disubstituted alkene (*E*)-**89**; PDC = pyridinium dichromate.

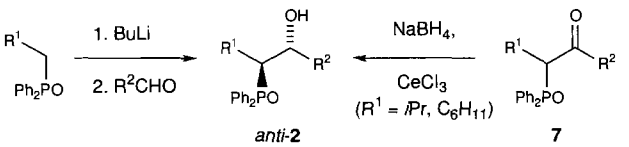
Bridges and Whitham used the stereospecific opening of *cis* epoxides by phosphorus nucleophiles as a route to *syn* β-hydroxy phosphane oxides. This method can be used to invert the stereochemistry of alkenes and is particularly suited to the control of double-bond stereochemistry in medium rings (Scheme 9).[113]



Scheme 9. Inversion of double-bond stereochemistry by Bridges and Whitham.

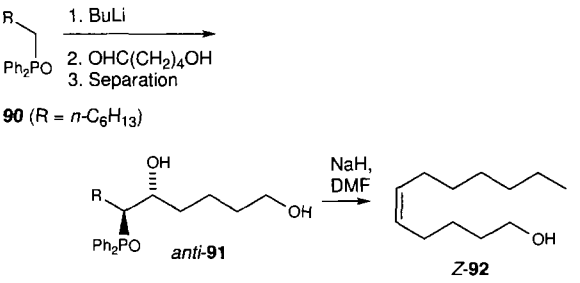
4.1.2. Disubstituted (*Z*) Alkenes

anti β-Hydroxy phosphane oxides *anti*-**2** can be made selectively by two routes: a) Horner–Wittig addition of a lithiated β-hydroxy phosphane oxide to an aldehyde, or b) Luche reduction ($NaBH_4/CeCl_3$) of β-oxo phosphane oxides **7** having a β′-branched R^1 group (Scheme 10). While Horner–Wittig addition is generally more useful since it tolerates most substituents R^1 and R^2, in those cases where the *anti*-selective Luche reduction is successful, it is spectacularly so, giving almost quantitative yields of the *anti* isomer.[82] We can therefore deduce two strategies: if one of the alkene substituents is α-branched (e.g. isopropyl or cyclohexyl), this should be specified as R^1 and route 2 used; otherwise, the smaller of the two substituents should be designated R^1 and a Horner–Wittig addition applied (as for the $NaBH_4$ reduction, the stereoselectivity is lowered by when R^1 is large).[9]



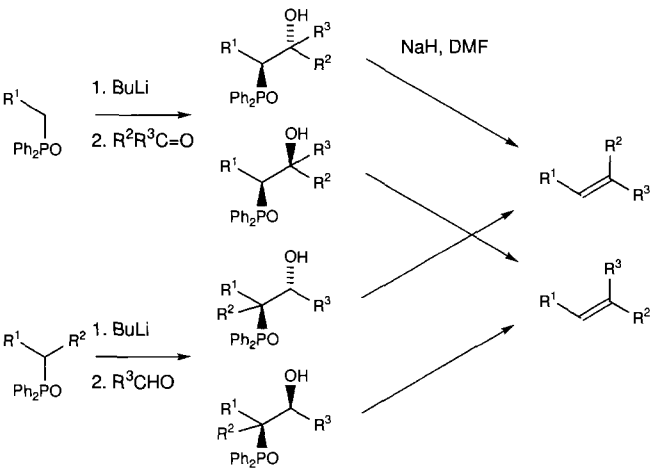
Scheme 10. Two routes to *anti* β-hydroxy phosphane oxides.

Van den Nieuwendijk and van der Gen needed the (*Z*) alkene (*Z*)-**92** for a synthesis of an unusual unsaturated fatty acid.[114] Addition of lithiated heptyldiphenylphosphane oxide **90** to 5-hydroxypentanal, followed by purification of the major diastereomer, gave the *anti* β-hydroxy phosphane oxide **91**, which underwent stereospecific elimination to give (*Z*)-**92**.

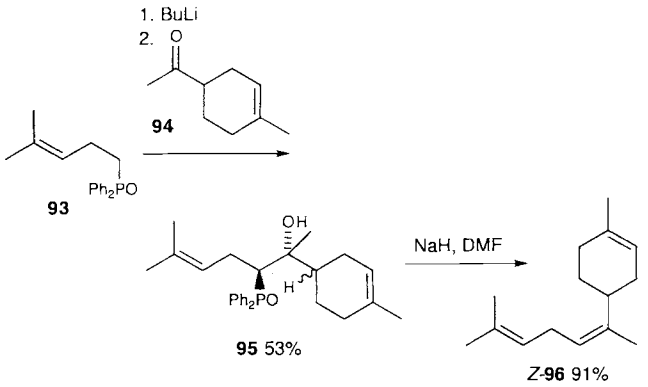


4.1.3. Trisubstituted Alkenes

Both (*E*) and (*Z*) trisubstituted alkenes can be made by the two-step Horner–Wittig route.[63] Two combinations of starting materials are possible: a lithiated primary alkyldiphenylphosphane oxide and a ketone, or a lithiated secondary alkyldiphenylphosphane oxide and an aldehyde (Scheme 11). In general, as neither addition proceeds with good stereoselectivity, overall yields tend to be low. In the elimination step, the additional complication of Horner–Wittig reversal can arise, but syntheses starting from secondary phosphane oxides are less prone to this problem. Nonetheless, elimination of the pure *anti* β-hydroxy phosphane oxide **95** isolated from the mixture of adducts of phosphane oxide **93** and ketone **94** gave the perfumery compound (*Z*)-α-bisabolene **96**. Interestingly, the second, unfunctionalized chiral center of **95** (γ-C) does not affect chromatographic separation of the mixture into a *syn* pair and an *anti* pair. Denmark and Amburgey have recently described the stereoselective contruction of trisubstituted double bonds using phosphoramidates.[115]



Scheme 11. Routes to trisubstituted alkenes.

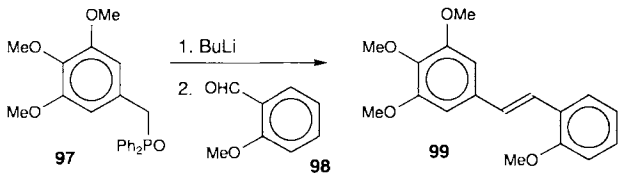


4.2. Functional Groups at Vinylic Positions

If the target alkene carries an anion-stabilizing or a conjugated aryl or alkenyl substituent, two further effects need to be taken into consideration in planning a synthesis. Firstly, the reversal of the Horner–Wittig addition step is accelerated by anion-stabilizing groups at R^1, leading to "stereochemical leakage" during the Horner–Wittig elimination and contamination of the alkene with its stereoisomer. In some cases, for example in the synthesis of alkenyl isoxazoles,[33] this reversal makes the two-step Horner–Wittig reaction almost unusable, as the driving force of the elimination is required for the Horner–Wittig addition to reach completion. Secondly, conjugating groups at R^1 or R^2 stabilize an incipient double bond and accelerate the Horner–Wittig elimination, making one-step reactions particularly successful. Deciding on the best strategy means comparing the relative importance of these two factors. If a pure (*E*) or (*Z*) alkene is required, and the two stereoisomers are separable only with difficulty, it would be important to avoid Horner–Wittig reversal; a two-step Horner–Wittig reaction would be more appropriate with R^2 as a conjugating group. If some contamination with a stereoisomer is not important, R^1 could be the conjugating group and the simplicity of a one-step Horner–Wittig reaction exploited.

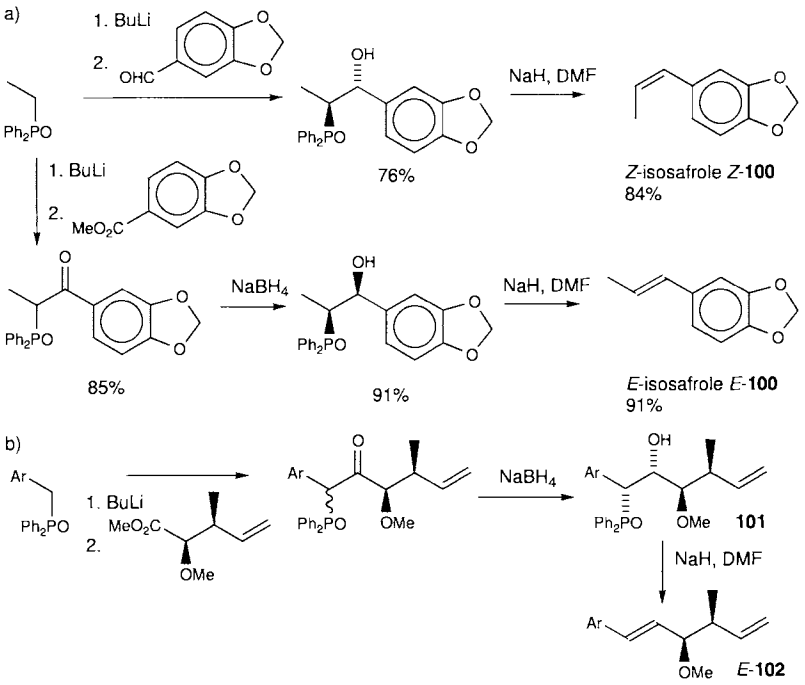
4.2.1. Stilbenes

Owing to the equilibration of Horner–Wittig adducts made from benzyldiphenylphosphane oxides, it is very difficult to make (*Z*)-stilbenes by the Horner–Wittig reaction.[25] (*E*)-Stilbenes have, however, been made by using one-step Horner–Wittig reactions.[1–3] For example, lithiation of phosphane oxide **97** and addition to aldehyde **98** gave (*E*)-stilbene **99**.[16]



4.2.2. Styrenes

Because of the danger of nonstereospecific eliminations of β-hydroxy phosphane oxides having R^1 = Ar, (*Z*)-styrenes must be made by two-step Horner–Wittig reactions with R^2 = Ar.[9, 25] Thus, both isomers of isosafrole **100** could be made from the same starting materials by a two-step Horner–Wittig sequence.[9] For (*E*)-styrenes, R^1 can be Ar, and Kallmerten and Wittman[13] obtained only the (*E*) product (*E*)-**102** from the *syn* β-hydroxy phosphane oxide **101** in their synthesis of the oudemansins (Scheme 12b).



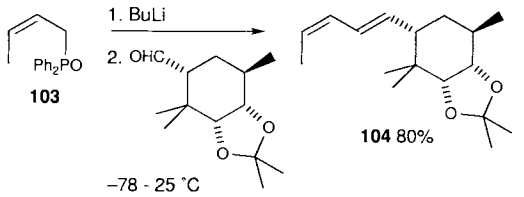
Scheme 12. Synthesis of (*Z*)- and (*E*)-isosafrole (a) and of the oudemansin precursor (*E*)-**102** (b).

4.2.3. Polyenes

4.2.3.1. One-Step Horner–Wittig Reactions

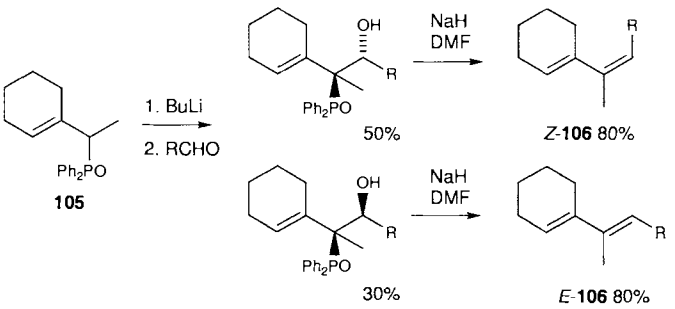
As discussed in Section 2.1, all-(*E*) polyenes are easily made by reacting the lithium, sodium, or potassium derivative of an allylic phosphane oxide with an aldehyde or ketone, and conditions of time and temperature can be used that allow the elimination to go to completion. Several examples exist, especially in vitamin D chemistry,[10, 26, 29–31, 37] but also in other fields,[12, 27, 28] of connective polyene syntheses in which allylic phosphane oxides perform better than their phosphonate or phosphonium salt analogues. Nearly all of these syntheses feature a one-step Horner–Wittig reaction. This variant is quite appropriate, since Horner–Wittig reversal, in conjunction with fast elimination, serves to increase the proportion of (*E*) product.

Polyenes containing a (*Z*) double bond can be made by a one-step Horner–Wittig reaction, by starting with a (*Z*) allylic phosphane oxide. Unlike allylic phosphonium salts, allylic phosphane oxides react stereospecifically, retaining their stereochemistry.[7] One example is the synthesis of (*E*,*Z*) diene **104** from the (*Z*) allylic phosphane oxide **103** described by Dolle and Nicolaou.[28]

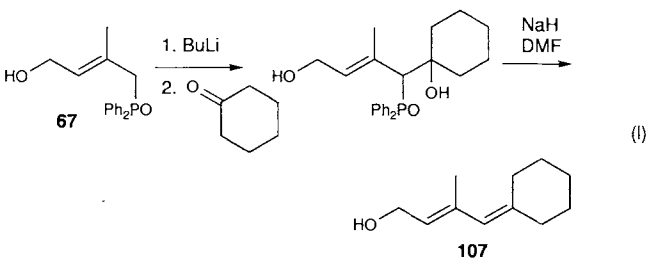


4.2.3.2. Two-Step Horner–Wittig Reactions

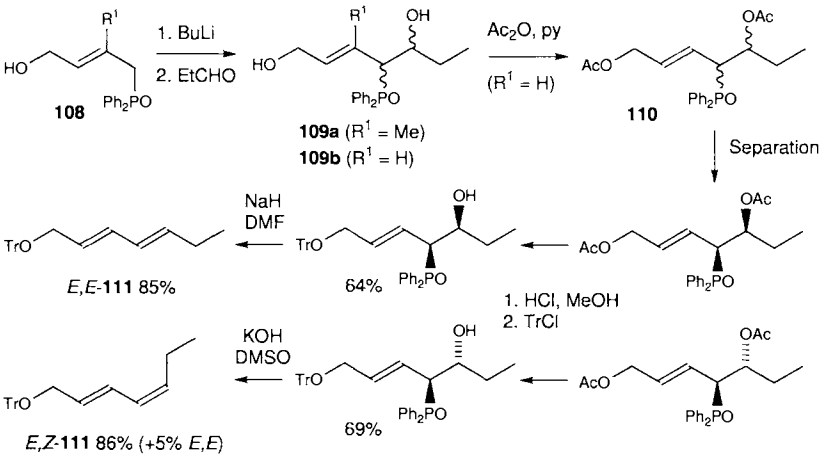
The stereoselectivities obtained in Horner–Wittig additions of allylic phosphane oxides to aldehydes or in reductions of ketones **7** (R^1 = allyl) are often poor.[42] Nonetheless, the two diastereomers are often separable, and elimination of the individual diastereomers can lead to pure (*E*,*E*) and (*E*,*Z*) dienes, albeit in low overall yield. The dienes (*Z*)- and (*E*)-**106** were made by this sort of two-step route.[41]



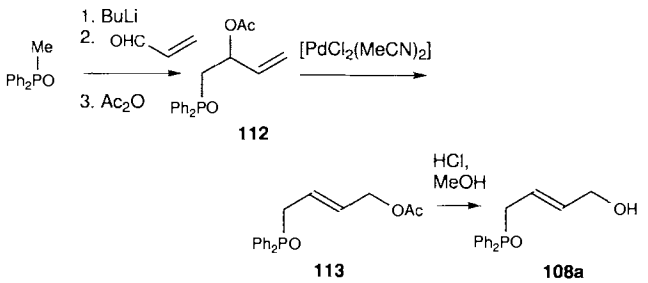
Stereochemically pure dienols are interesting because of their potential use in intramolecular Diels–Alder reactions. Addition of **67** to cyclohexanone, followed by Horner–Wittig elimination, gave dienol **107** [Eq. (l)].[40] Some attempted stereocontrolled syntheses of dienols have been frustrated by difficulty in separating the two diastereomers of the β-hydroxy phosphane oxides **109**.[40, 42] Diastereomeric mixtures of the diols, diacetates, and bis(trimethylsilyl) ethers of **109a** were inseparable, and separation of the diols **109b** was achieved only by converting them into the diacetates **110**.[42] Hydrolysis, protection, and elimination completed a synthesis of the protected (*E*,*E*) and (*E*,*Z*) dienols **111**, intermediates in the synthesis of some insect pheromones (Scheme 13). In this case KOH/DMSO was found to be more effective than NaH/DMF in promoting the stereospecific elimination leading to (*E*,*Z*)-**111**.

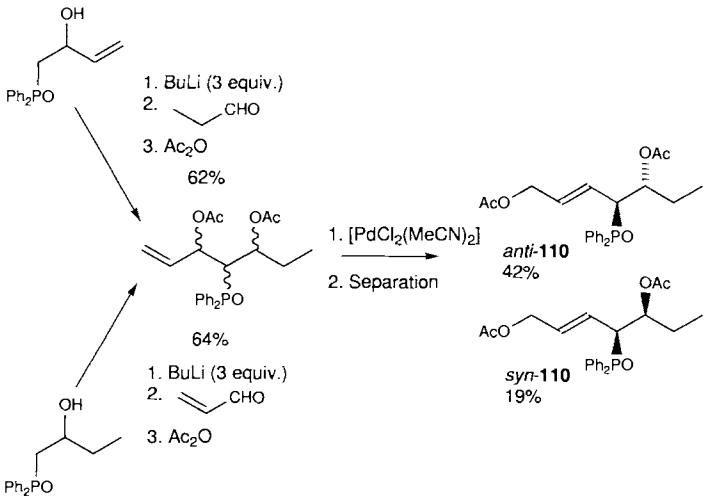


The allylic and hydroxyallylic phosphane oxide starting materials for these two examples of two-step Horner–Wittig routes to dienes were all made by rearrangement: the allylic phosphane oxides **105** by acid-catalyzed dehydration,[41] and the hydroxyallylic phosphane oxides **108** by acid-catalyzed,[40, 85] or, more generally, palladium-catalyzed[111] rearrangement of allylic acetate **112** to **113**. In the synthesis of **110** (Scheme 14) the addition and rearrangement steps may be successfully reversed by using the phosphane oxide version of Corey's SCOOPY reaction.[42]



Scheme 13. Synthesis of the dienes (*E*,*E*)- and (*E*,*Z*)-**111**; Py = pyridine, Tr = Ph_3C.

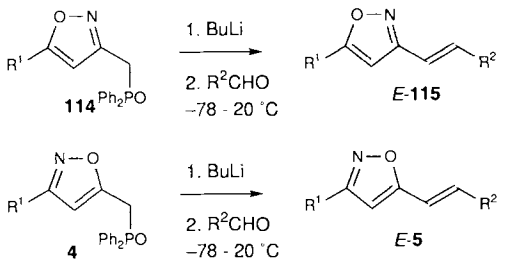




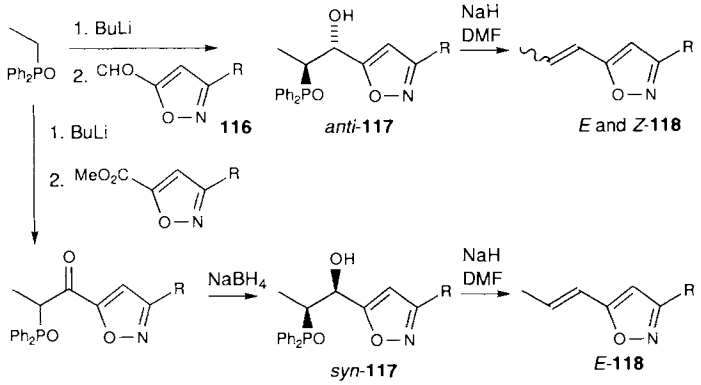
Scheme 14. Synthesis of the allylic phosphane oxides *anti*- and *syn*-**110** by a modified SCOOPY reaction [42].

4.2.4. Alkenyl Isoxazoles

(*E*) Alkenyl isoxazoles **115** and **5** are interesting as leukotriene analogues. They have been made in a one-step Horner–Wittig reaction from phosphane oxides **114** and **4**, which are easily synthesized by cycloaddition chemistry.[33] Two-step Horner–Wittig reactions of these phosphane oxides were unsuccessful due to Horner–Wittig reversal of the intermediate β-hydroxy



phosphane oxides (Section 2.1). The alternative addition of ethyldiphenylphosphane oxide to aldehydes **116** was unselective as well, and elimination of the pure *anti* isomer **117** gave mixtures of (*E*) and (*Z*) alkenes **118** (Scheme 15). Reduction of the corresponding ketone gave *syn*-**117**, which could be converted stereospecifically into (*E*) alkenes (*E*)-**118**, but none of these approaches was as good as the one-step route.



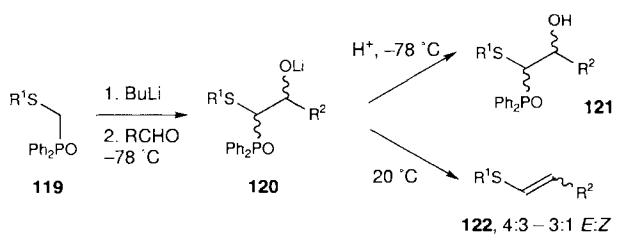
Scheme 15. Synthesis of the alkenyl isoxazoles (*E*)- and (*Z*)-**118**.

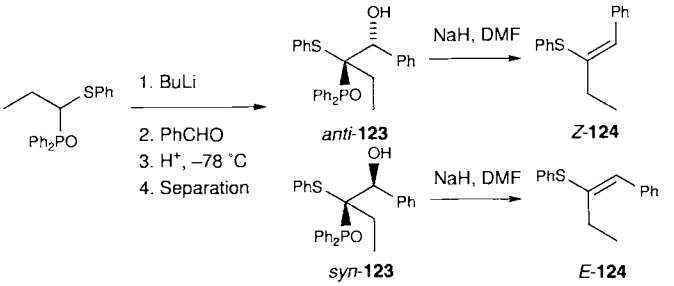
4.2.5. *Heteroatoms in Vinylic Positions*

Horner–Wittig routes to alkenes carrying heteroatoms in vinylic positions are successful, providing R^1 is the functional group containing the hetereoatom. Vinyl sulfides, ethers, and amines have all been made by stereocontrolled two-step Horner–Wittig routes, but in the case of the sulfides, completion of the elimination is rapid and special precautions must be taken to isolate the intermediates.

4.2.5.1. *Vinyl Sulfides*

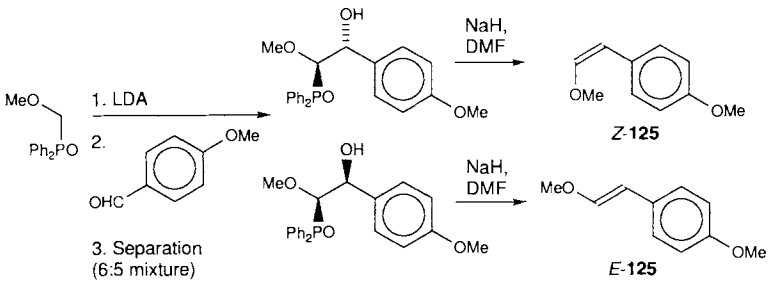
Lithiation of **119** and addition to an aldehyde gives a diastereomeric mixture of β-hydroxy phosphane oxide adducts **120**, which can be isolated as the alcohols **121** by quenching with acid at low temperature.[46] If the reaction mixture is instead warmed to room temperature, Horner–Wittig elimination takes place and a mixture of stereoisomers of the vinyl sulfide **122** is isolated.[36, 116] This one-step olefination is moderately (*E*) selective, and the selectivity is determined by the ratio of diastereomers formed in the addition step. Pure (*E*) and (*Z*) vinyl sulfides **124** have been prepared by elimination of single diastereomers of **123**, which are obtained from α-phenylthiopropyldiphenylphosphane oxide.[46]



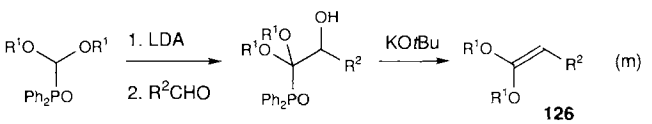


4.2.5.2. *Enol Ethers*

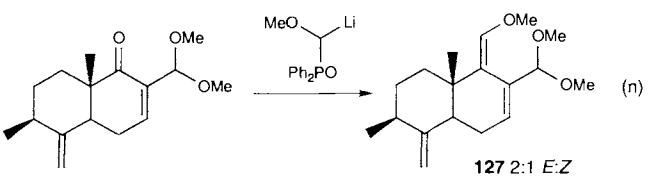
When alkoxyalkyldiphenylphosphane oxides are lithiated with LDA, they add successfully to aldehydes and ketones.[44] The C–C bond forming additions are unselective, but separation of the diastereomers and elimination allows stereospecific synthesis of (*E*) and (*Z*) enol ethers such as (*E*)- and (*Z*)-**125** (Scheme 16). Ketene acetals **126** have been made by a similar route [Eq. (m)].[45] In this case, there is no question of stereo-



Scheme 16. Synthesis of enol ethers (*Z*)- and (*E*)-**125**.



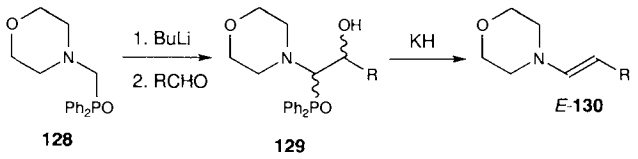
chemistry, and the olefination can be carried out as a one-step reaction if the addition reaction mixture is warmed. Bosch used a one-step Horner–Wittig addition to make enol ether **127** [Eq. (n)].[35] This elimination is presumably encouraged by conjugation.



Enol ethers bearing amino groups have been made using nitrile oxide cycloadditions (Section 4.3.4).[105]

4.2.5.3. Enamines

Van der Gen et al. have shown that although addition of lithiated amino phosphane oxides **128** to aldehydes gives a mixture of diastereomers **129**, which can be isolated, elimination of these mixtures with potassium bases leads exclusively to the (*E*) enamines **130**.[14, 39] They ascribe this to an isomerization of the enamine during the workup.



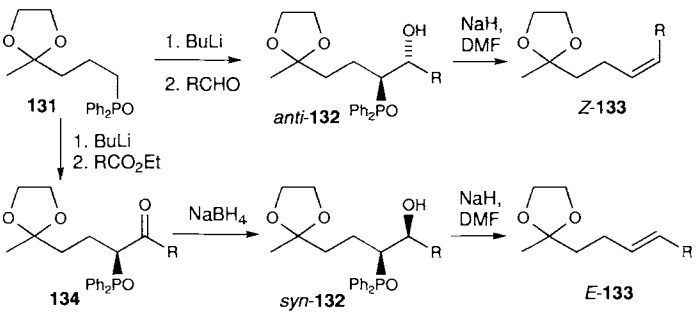
4.3. Functional Groups in Homoallylic and More Remote Positions

4.3.1. Unsaturated Ketones

4.3.1.1. γ,δ-Unsaturated Ketones

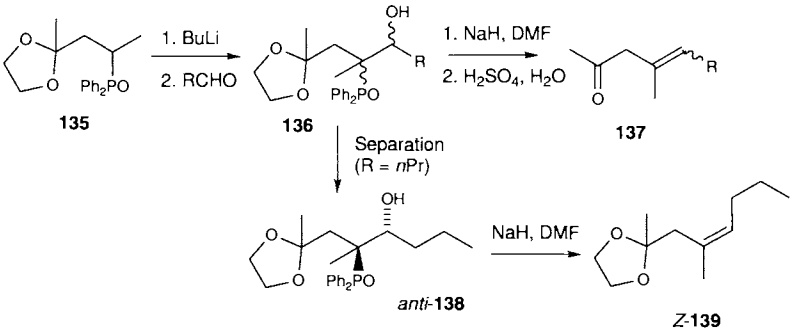
γ,δ-Unsaturated ketones can be made by the two-step Horner–Wittig reaction.[117] The carbonyl group is included in the alkyl phosphane oxide as an acetal **131**. In contrast with protected β-Ph_2PO ketones (see Section 4.3.1.2), these protected γ-Ph_2PO ketones undergo Horner–Wittig additions to aldehydes with good *anti* selectivity. Purification of the *anti* diastereomer *anti*-**132** and elimination with NaH/DMF gives the protected ketone (*Z*)-**133**.

(*E*)-γ,δ-Unsaturated ketones are made by stereoselective reduction of the ketones **134** with $NaBH_4$. Purification of the major *syn* isomer and elimination gives ketone (*E*)-**133**.



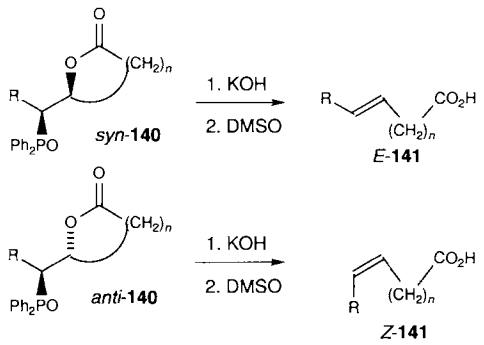
4.3.1.2. β,γ-Unsaturated Ketones

Horner–Wittig reactions of protected β-Ph_2PO ketones **135** can be used to make β,γ-unsaturated ketones **137**[118] in much the same way that γ-Ph_2PO ketones give γ,δ-unsaturated ketones. However, the stereoselectivity of the addition is poor, and the diastereomers of the intermediate hydroxy phosphane oxides **136** are hard to separate. In only one case (R = *n*Pr) was it possible to isolate the pure intermediate *anti*-**138**: as expected, elimination gave the (*Z*) alkene (*Z*)-**139**. Nonetheless, elimination of mixtures of diastereomers of **136** produced by the Horner–Wittig reaction gives good yields of mixtures of alkenes; the protecting acetal group can then be removed without shifting the double bond into conjugation. Protected β-Ph_2PO ketones therefore perform well as homenolate equivalents, provided single stereochemical isomers of the product alkenes are not required.



4.3.2. Unsaturated Carboxylic Acids

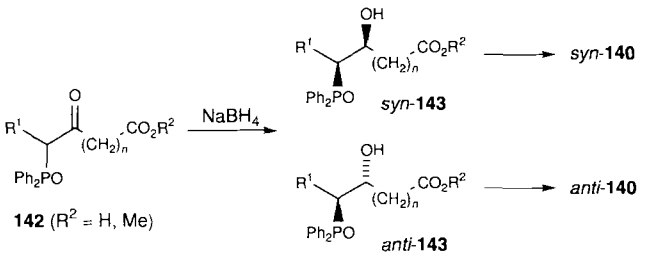
Horner–Wittig eliminations leading to carboxylic acids **141** are best carried out directly with the lactones **140**.[119] The lactones are hydrolyzed with an excess KOH in aqueous THF, and the solvents removed by freeze-drying to give a solid mixture of KOH and the potassium salt of the hydroxy carboxylic acid. The Horner–Wittig elimination takes place stereospecifically when the dried salt is dissolved in DMSO.



The problem of making single stereoisomers of unsaturated carboxylic acids is therefore reduced to making and separating the two diastereomeric lactones **140**. This has been achieved by two complementary routes: the first is more successful for (*E*) carboxylic acids, and the second for (*Z*), though each is applicable to both.

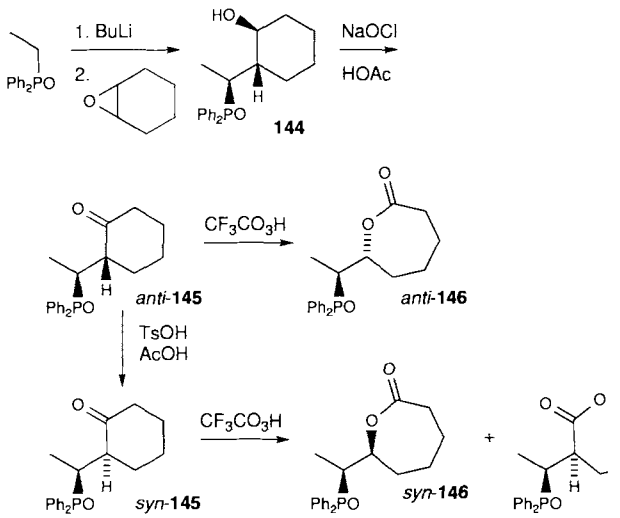
4.3.2.1. Route Recommended for (E) Unsaturated Carboxylic Acids

Diphenylphosphoryl carboxylic acids, even as polyanions, do not undergo Horner–Wittig addition reactions.[119] Reduction of the oxo carboxylic acids or oxo esters **142** with $NaBH_4$ is successful but only marginally stereoselective, and the diastereomeric products **143**, are difficult to separate. However, the lactones **140** are crystalline and easily separable. After lactonization of the mixture of esters **143** *syn*- and *anti*-**140** can be separated, and hence the (*E*) and (*Z*) unsaturated acids **141** prepared.



4.3.2.2. Route Recommended for (Z) Unsaturated Carboxylic Acids

An alternative approach uses the cyclic alcohols **144** (Scheme 17).[73] These compounds can be made with high stereoselectivity by addition of lithiated alkyldiphenylphosphane oxides to epoxides (Section 3.1.5). Oxidation of **144** gives pure *anti*-**145**, which is converted into the lactone *anti*-**146** by Baeyer–Villiger oxidation. Subsequent hydrolysis and elimination according to the procedure described above gives the pure (*Z*) carboxylic acid (*Z*)-**141**.



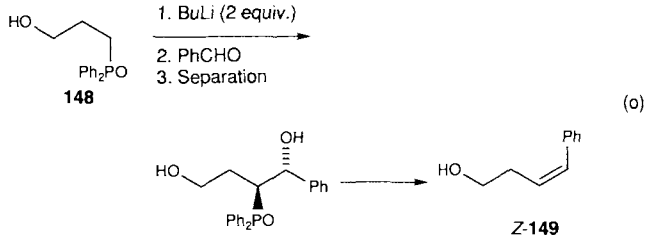
Scheme 17. Synthesis of a precursor for a (*Z*) unsaturated carboxylic acid; Ts = $H_3CC_6H_4SO_2$.

The *syn* ketone *syn*-**145** is made by epimerization of the ketone *anti*-**145**. Exposure to TsOH/AcOH for one week converts *anti*-**145** into 10:1 mixture of *syn*-**145** and *anti*-**145**, from which pure *syn*-**145** can be isolated in 81% yield. In this case, however, the Baeyer–Villiger reaction is not regiospecific, giving two inseparable lactones *syn*-**146** and **147**, and lowering the overall yield. After hydrolysis and elimination of the mixture, the (*E*) carboxylic acid can be separated from the by-products, as only one of the hydroxy carboxylic acids can undergo Horner–Wittig elimination.

4.3.3. Unsaturated Alcohols

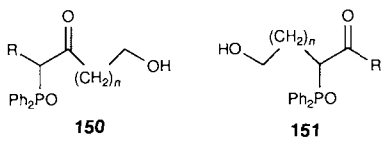
4.3.3.1. (Z) Unsaturated Alcohols

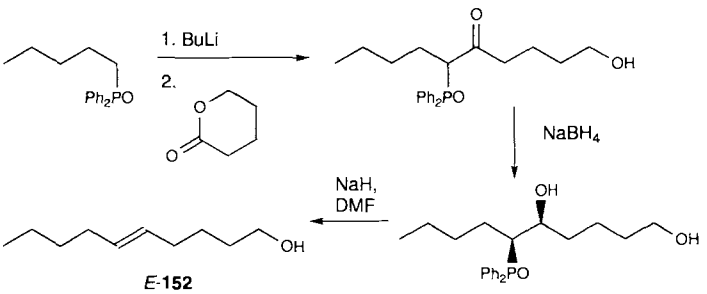
Although Horner–Wittig additions of alkyldiphenylphosphane oxides carrying hydroxy or silyloxy groups are usually rather unselective, giving the product as 50:50 to 70:30 mixtures of diastereomers in favor of the *anti* adduct, separation of the product alcohols and elimination can lead to pure (*E*) or (*Z*) unsaturated alcohols. The (*Z*) homoallylic alcohol (*Z*)-**149** was made from phosphane oxide **148** and benzaldehyde by this strategy [Eq. (o)].[75] Van den Nieuwendijk and van der Gen made the (*Z*) unsaturated alcohol (*Z*)-**92** by the alternative route, addition of a phosphane oxide to a hydroxy aldehyde.[114]



4.3.3.2. (E) Unsaturated Alcohols

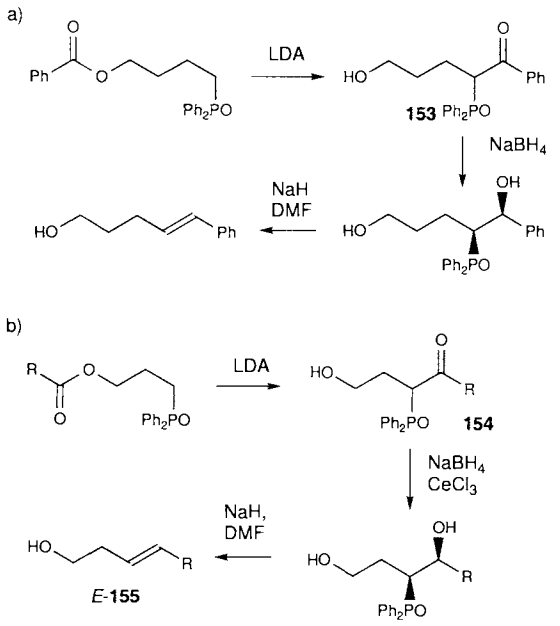
(*E*) Unsaturated alcohols can be made by *syn*-selective reduction of the oxo alcohols **150** or **151**. Oxo alcohols **150** are available by addition of lithiated phosphane oxides to lactones and are best reduced with $NaBH_4$.[63, 75] This route was used to make (*E*)-dec-5-en-1-ol (*E*)-**152**, a pheromone of the peach twig borer moth (Scheme 18).[63] Oxo alcohols **151** are available by





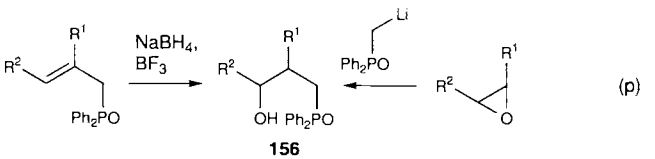
Scheme 18. Synthesis of the pheromone (*E*)-**152** from the peach tree borer moth.

intramolecular acyl transfer and can be *syn*-selectively reduced either with $NaBH_4$[67] (e.g. **153**) or, for **154** (≡**151**, $n = 1$), with $NaBH_4/CeCl_3$ (Luche conditions) (Scheme 19).[75] (*E*) Homoallylic alcohols are among the very best target compounds that can be prepared by phosphane oxide chemistry because Luche reduction of their precursor ketones is extremely (>95:5) *syn* selective.



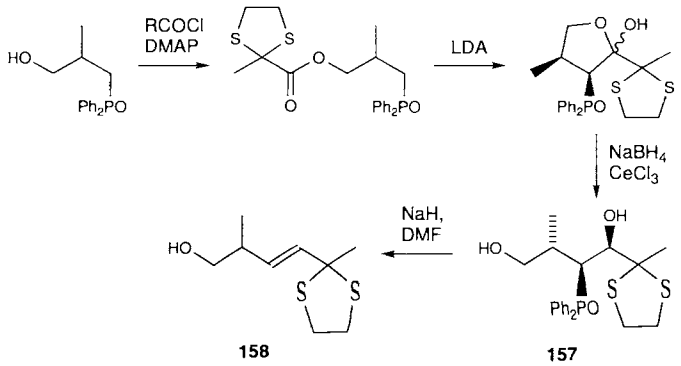
Scheme 19. Synthesis of the (*E*) unsaturated alcohols (*E*)-5-phenylpent-4-enol-1 (a) and (*E*)-**155** (b).

The starting materials for a synthesis of an (*E*) homoallylic alcohol by this route are the alcohols **156**, which are available either by addition of a lithiated phosphane oxide to an epoxide[67] or by hydroboration[58] of an allylic phosphane oxide [Eq. (p)]. When the starting alcohol contains a chiral center, the



(p)

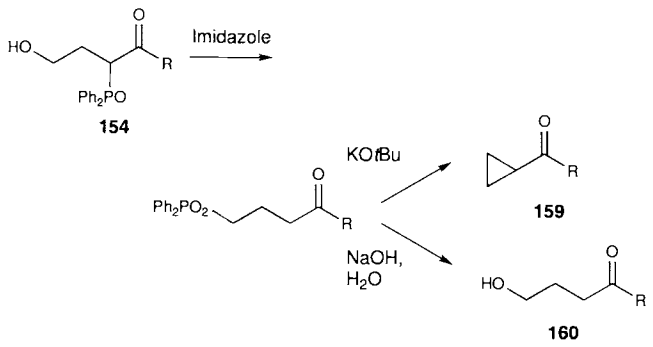
acyl transfer can be stereoselective, allowing the synthesis of homoallylic alcohols with chiral substituents such as **158** (Scheme 20).[58] Although simple Horner–Wittig additions have been used to make chiral alkenes (e.g. **96**), there is always the danger that a third chiral center could complicate the clean separation of diastereomers. The method describes here avoids this problem, since construction of all three chiral centers of **157** is controlled, though stereochemical information is lost in the elimination step.



Scheme 20. Synthesis of the homoallylic alcohol **158**; DMAP = 4-dimethylaminopyridine.

Interestingly, treatment of the oxo alcohols **154** with base can lead to phosphoryl migration and formation of cyclopropyl ketones **159** or γ-hydroxy ketones **160** (Scheme 21).[58, 67]

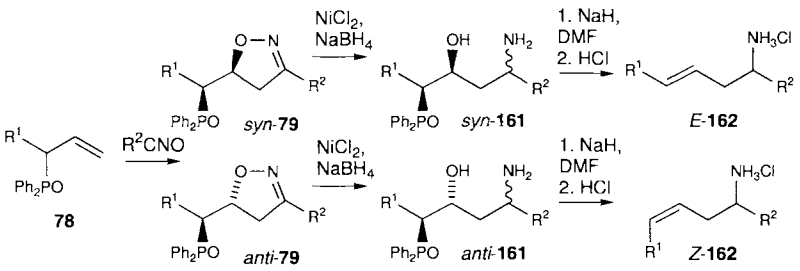
Certain branched (*E*) homoallylic alcohols can also be synthesized by opening epoxy phosphane oxides with carbon nucleophiles (Section 4.5).



Scheme 21. Base-catalyzed migration of the Ph_3PO group of **154** leading to **159** and **160**.

4.3.4. Homoallylic Amines

Cycloaddition of a nitrile oxide to an allylic phosphane oxide **78** is an effective way of stereoselectively introducing the hydroxyl and amino functional groups needed to make a homoallylic amine by Horner–Wittig elimination.[15] As discussed in Section 3.3.4, this reaction is regio- and stereoselective, giving mainly the *syn* isomer *syn*-**79**. The diastereomers of the cyclo-

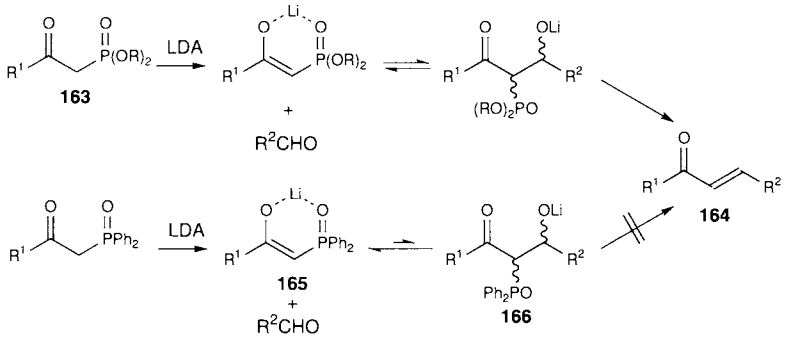


adduct are easily separated by chromatography. Reduction of the isoxazoline to reveal the alcohol needed for Horner–Wittig elimination is achieved with nickel boride. This reaction is moderately stereoselective too, though the diastereomers of the amino alcohols **161** are very difficult to separate. This is unimportant from a practical point of view, since, in the final step, both of these diastereomers give the same homoallylic amine (*E*) or (*Z*)-**162**. The *syn* and *anti* diastereomers of the cycloadducts **79** can be carried through to elimination separately, giving stereospecifically the (*E*) and (*Z*) homoallylic amines **162**, respectively. The amines are most easily isolated as their hydrochloride salts.

4.4. Functional Groups in Allylic Positions

4.4.1. α,β-Unsaturated Ketones

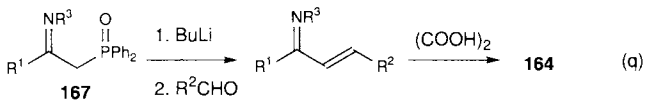
α,β-Unsaturated ketones **164** are very easily made by the Wadsworth–Emmons reaction of β-oxo phosphonates **163** (Scheme 22).[120, 121] However, the Horner–Wittig equivalent



Scheme 22. Synthesis of the α,β-unsaturated ketones **164**.

of this reaction fails.[122] Presumably the Wadsworth–Emmons reaction is driven to completion by spontaneous elimination of phosphate. In the Horner–Wittig reaction the equilibrium between the lithiated α-Ph_2PO ketone **165**[61] and the adducts **166** clearly lies on the side of the starting materials, and as elimination of phosphonate has to be a separate step, only starting materials can be recovered.

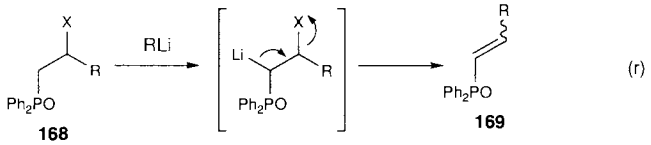
Azaenolates formed from imines **167** do, however, combine with aldehydes to give enones **164** [Eq. (q)].[123, 124] The lithiated Ph_2PO-imines were heated with the aldehydes to complete the elimination.



(q)

4.4.2. Allylic Amines and Amides

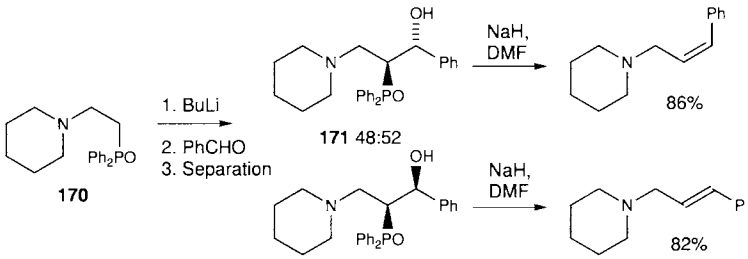
Lithiated alkyldiphenylphosphane oxides **168** with functional groups X in the β position are prone to fragmentation to give vinyl phosphane oxides **169** [Eq. (r)], and are therefore usually



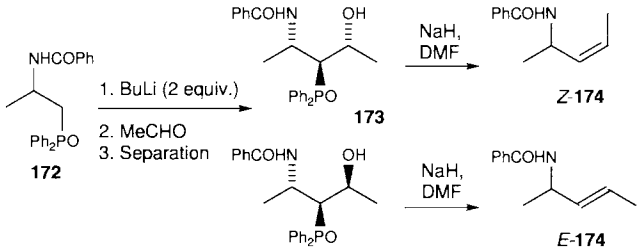
(r)

poor choices as starting materials for Horner–Wittig additions. It is for this reason that the more uncoventional routes to the β-hydroxy phosphane oxides, which are needed to make the allylic functionalized compounds discussed towards the end of this review, have been developed. However, when the β-substituent X is a poor leaving group, such as R_2N, RCONLi, or OLi, the lithiated compounds are stable, and Horner–Wittig additions are possible.

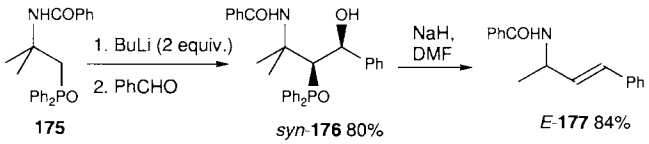
As usual for functionalized phosphane oxides capable of chelating Li^+, the stereoselectivity in the Horner–Wittig addition of the amines **170** is low, but the isomers of the product **171** could be separated and gave the (*E*) and (*Z*) allylic amines stereospecifically (Scheme 23).[60] (*E*) and (*Z*) amides **174** could be made by the same route, starting with bis-lithiation of phosphane oxides **172**. Separation of the two diastereomers **173** formed in the addition to acetaldehyde followed by elimination gave the (*E*) and (*Z*) amides **174** stereospecifically. Interestingly, only two diastereomers of **173** arise from this reaction, just as in the reaction of the **172** with symmetrical ketones. Both have the same (*anti*) relative stereochemistry at the third chiral center, though this is irrelevant to the stereochemistry of the allylic amides **174**.



Scheme 23. Synthesis of allylic amines.



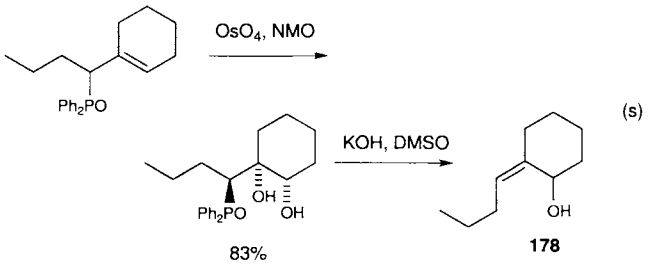
In additions of the amide **175** (doubly lithiated) to aldehydes high stereoselectivity was observed for the formation of the two new chiral centers. Moreover, the major isomer (formed almost exclusively in the reaction of **175** with benzaldehyde) was remarkably the *syn* diastereomer *syn*-**176**. Horner–Wittig elimination gave (*E*) allylic amide (*E*)-**177** in excellent overall yield



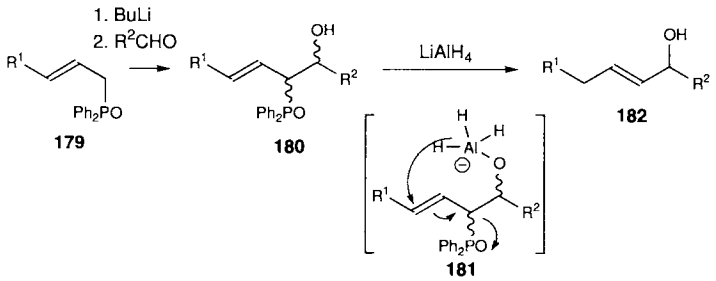
from **175**. Such unexpected results mean that although the Horner–Wittig route may not be the first choice in the synthesis of an allylic amide, in certain cases it may significantly outperform its competitors.

4.4.3. Allylic Alcohols

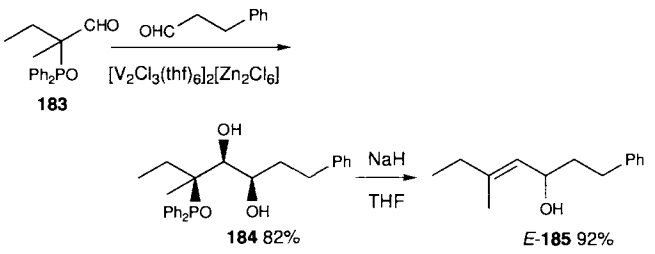
anti-Selective osmylation of allylic phosphane oxides gives *anti,syn* diols, which undergo Horner–Wittig elimination to give (*Z*) alkenes. The otherwise difficult to make exocyclic (*Z*) alkene **178** was made in this manner [Eq. (s)].[91]



An altogether different route makes use of a reduction step rather than a Horner–Wittig elimination to remove the Ph_2PO group used to construct the carbon skeleton of the alkene. Treatment of the alcohols **180**, prepared by Horner–Wittig addition of lithiated allylic phosphane oxides **179** to aldehydes, with $LiAlH_4$ gives (*E*) allylic alcohols **182**.[125] It is presumed that the hydroxyl group delivers the reducing agent to the allylic phosphane oxide (**181**). The (*E*) stereochemistry in this case is the result of stereoselective migration of a double bond rather than a stereospecific elimination.



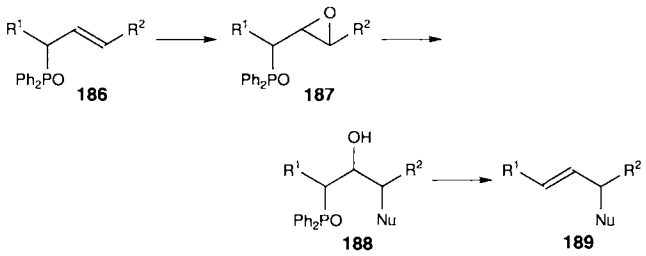
(*E*) allylic alcohols with trisubstituted double bonds can be made from the major diastereoisomer formed with excellent stereoselectivity in the vanadium(II)-promoted mixed pinacol reactions of aldehydes such as **183** and 3-phenylpropanal.[84] Crystallization of the diol **184** removes traces of the unwanted diastereomer, and elimination with NaH/THF gives excellent yields of the allylic alcohols **185**.



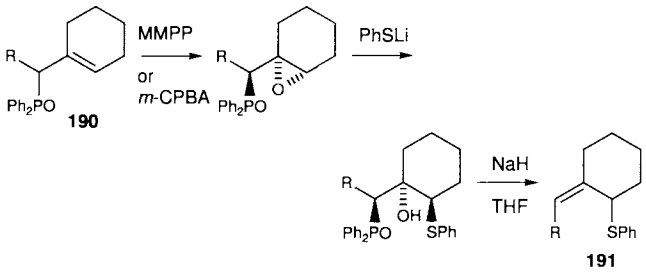
(*E*) and (*Z*) allylic alcohols bearing substituents in homoallylic position have been made from Ph_2PO epoxy alcohols (Section 4.5).

4.4.4. *Allylic Sulfides*

The epoxide **187** of an allylic phosphane oxide **186** is an excellent starting point for synthesizing a whole variety of compounds **189** functionalized in the allylic position. As discussed in Section 3.3, epoxidations can be *syn* or *anti* selective, and even



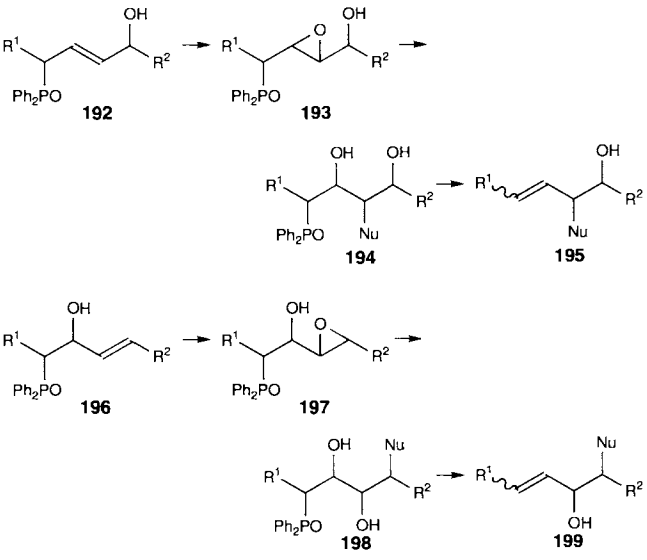
enantioselective, and through epoxide opening a range of functional groups can be introduced yielding products **188**. For example, the allylic sulfides **191** were made by epoxidation of the allylic phosphane oxide **190**, regioselective nucleophilic ring opening with a thiolate, and Horner–Wittig elimination (Scheme 24).[91, 126] Similar reactions form the basis of most of the chemistry discussed in the remainder of this review.



Scheme 24. Synthesis of the allylic sulfides **191**; MMPP = magnesium monoperoxyphthalate.

4.5. Functional Groups in Both Allylic and Homoallylic Positions

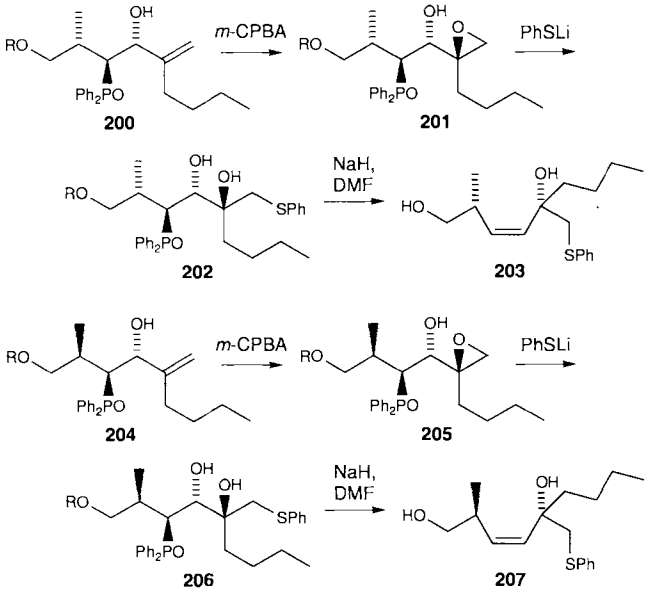
The compounds discussed in this section are the products of reactions of epoxy alcohols **193** and **197**. In Sections 3.3.1 and 3.3.2 we described how these compounds can be made from **192** and **196**, respectively, by diastereo- and enantioselective epoxidation reactions. A regioselective (and stereospecific) ring-opening reaction and Horner–Wittig elimination of the resulting alcohols **194** and **196** completes the stereocontrolled synthesis of alkenes **195** and **199**, which have functional groups



in allylic and homoallylic positions, respectively. By modifying reagents or route, either enantiomer of any diastereomer of the epoxy alcohol **193** can be made, and each enantiomer will stereospecifically produce an enantiomerically pure diastereomer of a substituted alkene **195**. The main problem encountered in using this strategy is the regioselectivity of the epoxide-opening step, and ways of synthesizing the required regioisomer selectively for are discussed for each of the classes of target compound.

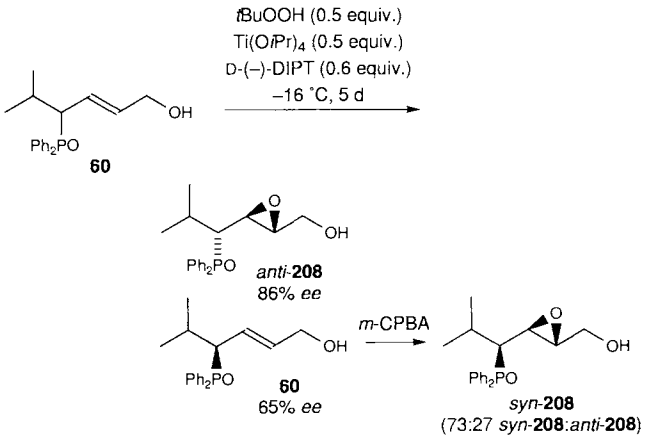
4.5.1. Unsaturated Hydroxy Sulfides

Epoxy alcohols **201** and **205**, which result from the cooperative epoxidation of the respective allylic alcohols **200** and **204** (Section 3.3.1), react with thiolate nucleophiles stereospecifically at their less hindered terminal carbon atoms to give sulfides **202** and **206**, respectively.[57] Horner–Wittig elimination of these sulfides gave the (*Z*) allylic alcohols **203** and **207**. Only the

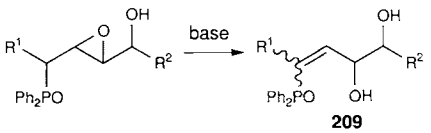


(*Z*) alkenes can be made in this way because only *anti* β-hydroxy phosphane oxides can be epoxidized stereoselectively. The stereoselectivity of the epoxidation is in fact important only because a fourth chiral center is present in the molecule. The 1,4-chiral relationship in these alkenes will be discussed further in Section 4.6.

Epoxy alcohols **193**, which are formally the Payne-rearranged analogues of epoxy alcohols **197**, are valuable as intermediates because they can be made enantioselectively by Sharpless asymmetric epoxidation and kinetic resolution.[100] By making use of the complementarity between the stereoselectivity of the kinetic resolution and of the *syn*-selective peracid epoxidation[92] it is in fact possible to make both diastereomers of the epoxides in each enantiomeric sequence from the same starting materials by choice of route.[127–129] For example, optically active *anti* epoxide *anti*-**208** is the main product of kinetic resolution of **60**. Treatment of the enantiomerically enriched remaining starting material with *m*CPBA gives optically active *syn* epoxide *syn*-**208**. Either enantiomer of each diastereomer of **208** is available

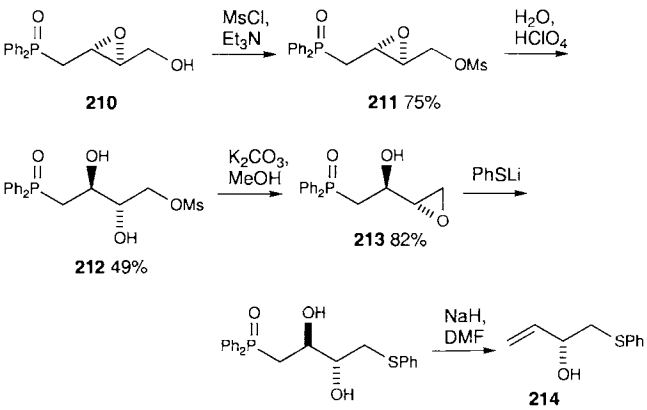


simply by using the appropriate enantiomer of tartrate ester in the kinetic resolution. Application of these epoxides in synthesis does, however, pose some problems, firstly because of the lack of regioselectivity in the reactions of 1,2-disubstituted epoxides, and secondly because they are prone to undergo base-catalyzed elimination reactions to give vinylic phosphine oxides **209** [Eq. (t)].



(t)

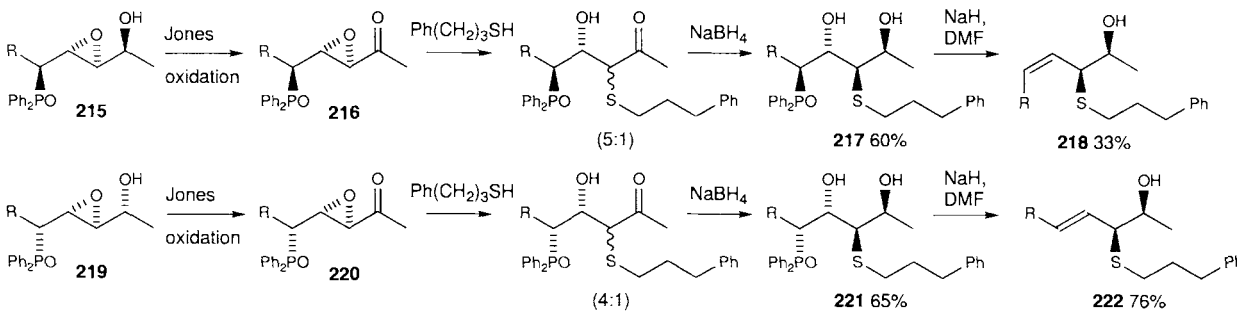
The asymmetric synthesis of the sulfides **214** from enantiomerically enriched epoxides **210** (Scheme 25) aimed to avoid the regioselectivity problem by using a Payne rearrangement to produce a terminal epoxide **213**, which would undergo regiose-



Scheme 25. Synthesis of the unsaturated hydroxysulfide **214**.

lective ring opening. The Payne rearrangement could not be carried out under basic conditions because of the problem of base-catalyzed elimination, so Sharpless's stepwise controlled Payne route[130] was used. Epoxide opening and Horner–Wittig elimination gave the allylic alcohol **214**. Unfortunately, regiocontrol still posed a problem because the nonregioselective addition of water to epoxide **211** resulted in reduced enantiomeric excess in the product diol **212**.[128]

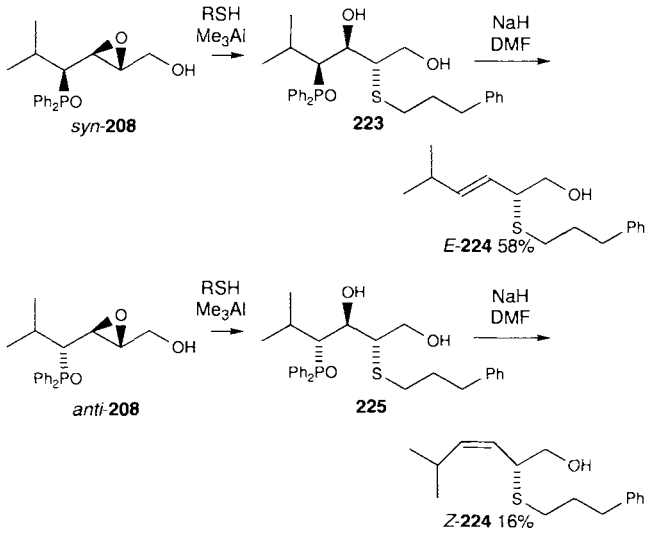
Lack of regioselectivity in the attack of thiolate nucleophiles on epoxy alcohols **215** and **219** was overcome by first oxidizing them to ketones **216** and **220** (Scheme 26).[128, 131] Nucleophilic



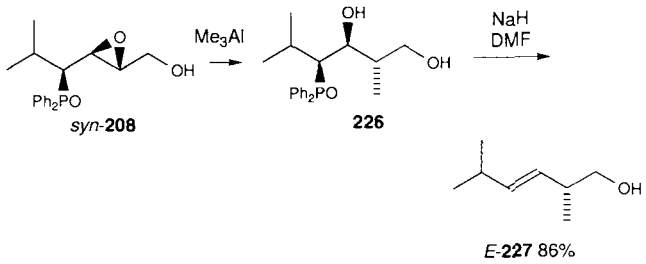
Scheme 26. Synthesis of the unsaturated hydroxysulfide **214**.

addition was then regioselective, though not completely stereospecific, and small quantities of epimerized sulfides were produced. Horner–Wittig eliminations of these compounds proved impossible because of a competing fragmentation. However, reduction to the alcohols **217** and **221** was stereoselective; the reaction was directed by the arylthio substituent and gave the diastereomer predicted by a Felkin–Anh transition state. Horner–Wittig elimination gave stereospecifically the (*E*) and (*Z*) allylic sulfides **218** and **222**.

The regioselectivity of the ring opening of the optically active epoxides **208** by thiolate nucleophiles was controlled by using a Lewis acidic reagent, trimethylaluminum.[128] The aluminum thiolate gave only one regioisomer of the products **223** and **225**, while lithium thiolates led to mixtures of regioisomers in low yield. Horner–Wittig eliminations gave the optically active allylic sulfides (*E*)- and (*Z*)-**224**. The low yield of (*Z*)-**224** illustrates a general problem with the synthesis of alkenes bearing groups that can stabilize anions (e.g. thio or acyl substituents). Often these groups encourage fragmentation rather than Horner–Wittig elimination. This problem is especially noticeable with slower eliminations leading to (*Z*) alkenes.

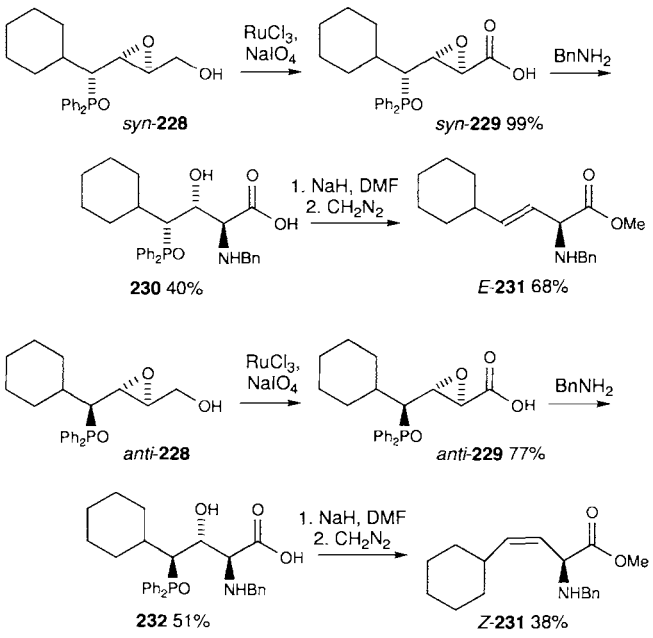


Lewis acid promoted regioselective epoxide opening was also used to introduce nitrogen and carbon nucleophiles. The reaction was surprisingly substrate dependent: *syn*-**208** was much more reactive than *anti*-**208**.[128] Horner–Wittig elimination of **226** gave the optically active (*E*) homoallylic alcohol (*E*)-**227**.



4.5.2. *Unsaturated Amino Acids*

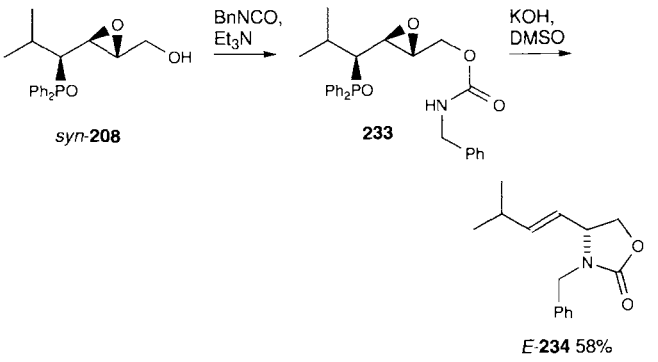
After the epoxy alcohols **228** were oxidized to the acids **229**, regioselective ring opening succeeded with benzylamine.[127, 128] The product of this reaction is a protected amino acid, and Horner–Wittig elimination of **230** and **232** led to the interesting unsaturated protected amino acids (*E*)- and (*Z*)-**231**. Choice of synthetic route and of chiral catalyst allowed access to either enantiomer of either (*E*)/(*Z*) isomer.[127]



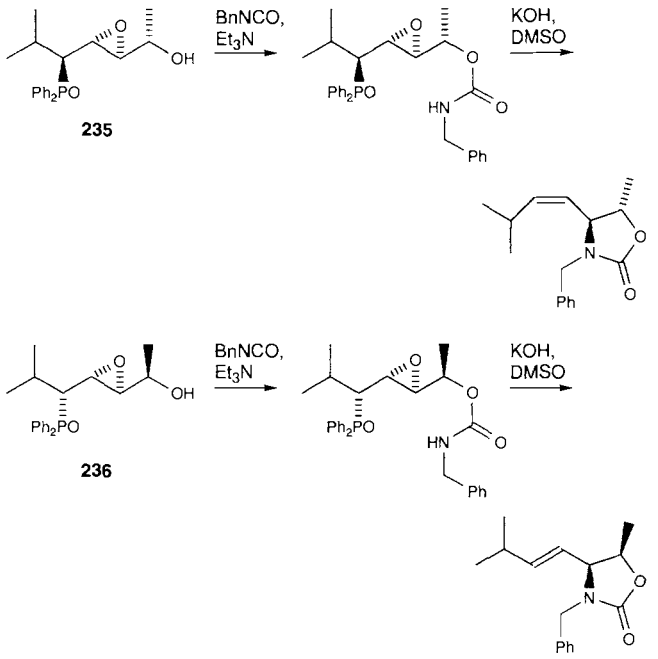
4.5.3. *Alkenyl Oxazolidinones*

A third strategy for ensuring regioselective ring opening was used to make single enantiomers and (*E*)/(*Z*) isomers of the

alkenyl oxazolidinones **234**.[129, 132] The nucleophile (a masked benzylamine equivalent) was tethered to the hydroxyl group of *syn*-**208** with formation of urethane **233**. Deprotonation with KOH in DMSO promoted attack of the nitrogen nucleophile on



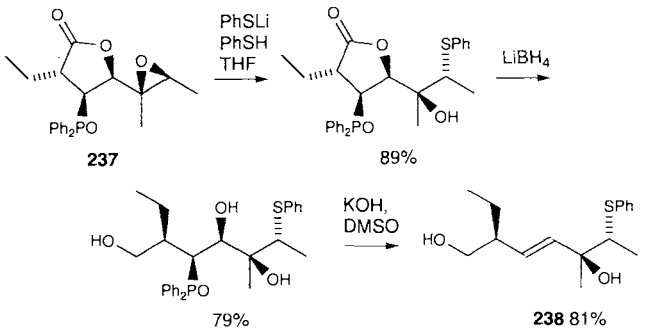
the nearer end of the epoxide to give a potassium oxyanion, which collapsed immediately in a Horner–Wittig elimination to give the alkenyl oxazolidinones **234**. Both enantiomers of both (*E*)/(*Z*) isomers could be made available in this way, and derivatives with further chiral centers could be prepared by starting with epoxides **235** and **236** (Scheme 27).



Scheme 27. Synthesis of alkenyloxazolidinones from epoxides **235** and **236**.

4.6. Remote Stereocontrol

Alkenes with chiral centers in the 1- and 4-positions have been synthesized by a number of strategies, most usually involving stereospecific allylic rearrangement of chiral centers from a 1,2- to a 1,4 relationship.[133–136] 1,4-Chiral relationships across (*Z*) double bonds are harder to control. Ph_2PO chemistry can be used to set up a sequence of four chiral centers, from which the middle two are converted by stereospecific elimination into a double bond of either stereochemistry. The diastereomeric pair of racemic (*Z*) alkenes **203** and **207** was made in this way (Section 4.4.4). Similar conversions may be used to control 1,4,5-related chiral centers across an (*E*) double bond. Stereoselective alkylation (Section 3.3.5) and stereoselective epoxidation (Section 3.3.1) gave epoxide **237**. Epoxide opening, reduction, and Horner–Wittig elimination gave a single diastereomer of the alkene **238** (Scheme 28).[95]

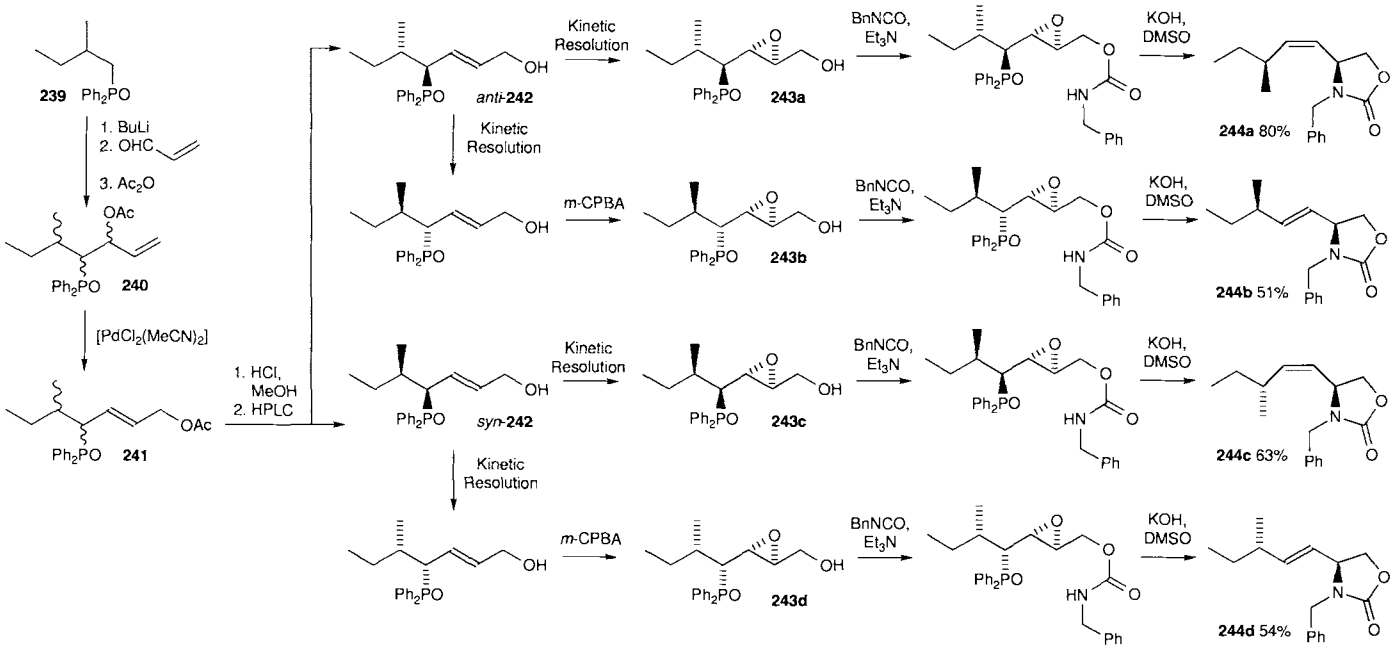


Scheme 28. Stereocontrolled synthesis of alkene **238**.

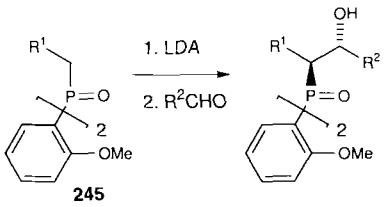
More recent work has extended this strategy to both (*E*) and (*Z*) alkenes in the homochiral series. Addition of lithiated **239** to acrolein gave a more or less random mixture of all four diastereomers of **240** (Scheme 29). Allylic rearrangement[111] converted these four into two diastereomers of **241**, which could be separated by HPLC after hydrolysis to give the alcohols *syn*- and *anti*-**242**. By using a combination of kinetic resolution[100] and peracid epoxidation,[92] all four diastereomers of the epoxides **243** were made, and each was elaborated with the tethered nucleophile employed to make alkenyl oxazolidinones. One-step ring opening of the epoxide and Horner–Wittig elimination then gave, stereospecifically, the four isomers **244**, one from each diastereomer of epoxide (Scheme 29).[129, 132] Although the other enantiomeric series was not made, it is clearly available just by using the other enantiomer of tartrate ester in the Sharpless kinetic resolution step.

5. Modifications and Improvements to the Ph_2PO Group

We have considered a large number of the reactions of compounds containing the Ph_2PO group, in which starting materials, reagents, and conditions were changed to achieve the level and sense of stereocontrol required. One thing we have not considered altering is the Ph_2PO group itself. Variations on the Ph_2PO group have nonetheless been used to great effect. It has been shown, for example, that Horner–Wittig additions of alkyl bis(*ortho*-anisyl)phosphane oxides **245** are significantly more stereoselective than Horner–Wittig additions of their Ph_2PO counterparts [Eq. (u)].[137] The result of altering the steric bulk of the Ph_2PO group by linking the two phenyl rings together as in a dibenzophosphole system has also been investigated: while

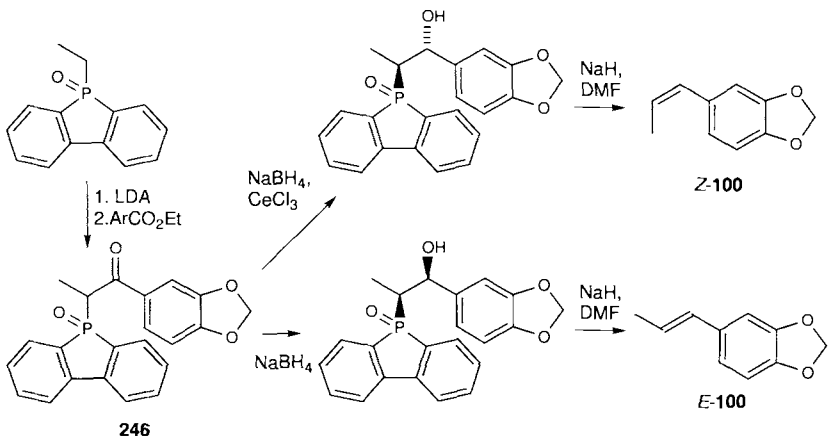


Scheme 29. Stereocontrolled synthesis of all four diastereomers of alkenyl oxazolidinone **244**.



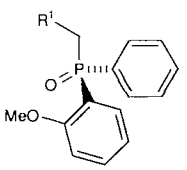
(u)

$NaBH_4$ reductions of α-dibenzophospholyl ketones such as **246** are *syn* selective, Luche reductions are invariably *anti* selective, in contrast with the strong substituent dependence of analogous reductions of Ph_2PO compounds. This result was applied to the synthesis of both (*E*)- and (*Z*)-isosafrole [(*E*)- and *Z*-**100**].

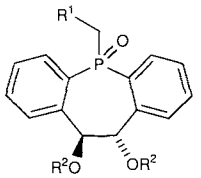


Scheme 30. Synthesis of (*Z*)- and (*E*)-**100** with a dibenzophosphole.

Asymmetric induction using chiral versions of the Ph_2PO group are currently under investigation: the anisylphenylphosphane oxide **247**[91] and the dihydrodibenzophosphepin oxide **248**[138] are being used to make individual (*E*) and (*Z*) isomers of homochiral compounds. Work is continuing in this area with the aim of developing new syntheses of enantiomerically pure alkenes with a recyclable phosphine oxide based chiral auxiliary.[138]



247



248

6. Summary

Chemists usually consider two chiral centers with a controlled three-dimensional relationship to be of greater "synthetic value" than a double bond with controlled stereochemistry in two dimensions: many synthetic strategies rely on the stereospecific transformation of a double bond into chiral centers with a three-dimensional chiral relationship. Transformations like the Horner–Wittig elimination that move in the other direction, sacrificing two controlled chiral centers for a double bond, therefore seem wasteful. This is particularly the case when the stereochemical information contained in a second controlled chiral relationship to a third chiral center is completely lost, as, for example, in the synthesis of racemic allylic alcohols by osmylation (Section 4.4.3). When that third chiral center is retained (as in the enantiomerically pure amino acids in Sec-

tion 4.5.2), or when two chiral centers and their controlled relationship are retained (e.g. **218** and **222**), such strategies seem more profitable. But in fact single (*E*)/(*Z*) isomers of alkenes are in general harder to make and purify than single diastereomers of chiral compounds, especially by connective methods. It is here that lies the greatest strength of the Horner–Wittig reaction, since it simplifies the production of stereochemically pure alkenes to the production of stereochemically pure diastereomers. Our aim in this review has been to demonstrate that the Ph_2PO group facilitates all three stages of this process: the stereoselective synthesis of these single diastereomers, their purification, and their stereospecific elimination to give pure alkenes.

Metallophosphaalkenes—from Exotics to Versatile Building Blocks in Preparative Chemistry

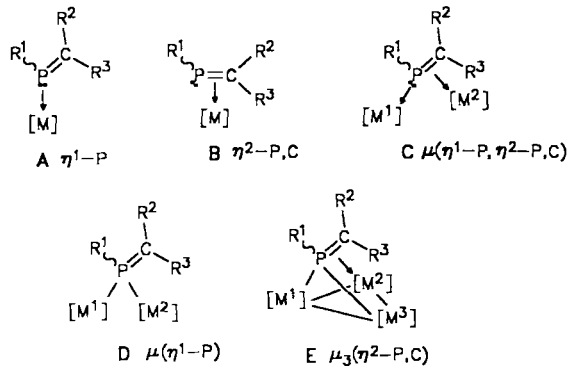
Lothar Weber

The chemistry of low-valent organophosphorus compounds such as phosphaalkenes and phosphaalkynes has undergone rapid development in the last two decades. This development also includes the coordination chemistry of these species, which can act as versatile ligands in metal complexes. Metallophosphaalkenes are compounds in which one or more of the organic substituents on the P=C unit is replaced by a transition metal complex fragment. Metallophosphaalkenes have emerged from an existence as laboratory curiosities to become a link between main group and organometallic complex chemistry. The great richness of their chemistry not only mirrors the specific properties of the individual building block, but also shows novel and individual traits. Particular examples are cycloadditions of these electron-rich heteroalkenes with electron-deficient alkenes, alkynes, azo, and diazo compounds. These often lead to novel types of reaction and compounds. Metallophosphaalkenes are also important as intermediates in all metal-assisted cyclooligomerizations of phosphaalkynes.

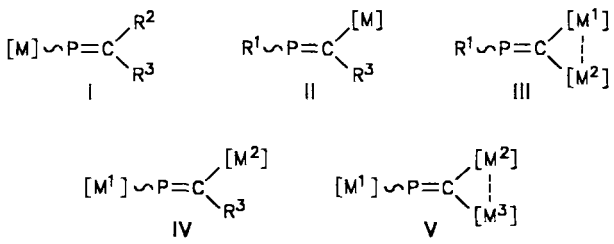
Keywords: metallophosphaalkenes · phosphaalkenes · transition metal compounds

1. Introduction

The rapid development in the chemistry of low-valent phosphorus compounds during the last twenty years includes their coordination chemistry.[1, 2] There are now five types of complexes known containing phosphaalkene ligands (**A**–**E**) (Scheme 1).[2] The structural integrity of the phosphaalkene ligand is largely retained in complexes **A**–**E**. In metallophosphaalkenes, on the other hand, one or more of the substituents R on the phosphaalkene is replaced by a transition metal complex fragment; thus five basically different types of compound (I–V) can be differentiated (Scheme 2). Like phosphaalkenes with purely organo substituents, the phosphorus atom as well as the P=C-π bond in compounds of type I–V are capable of acting as donors and are therefore, in principle, in the position to interact further as ligands with other metal centers. Moreover, since metallophosphaalkenes are polyfunctional molecules, they are valuable starting materials for a wide range of chemical transformations with both organic and inorganic partners.



Scheme 1. Basic types of phosphaalkene transition metal complexes.



Scheme 2. Basic types of metal-functionalized phosphaalkenes (metallophosphaalkenes).

This review provides an overview of metal-functionalized P=C systems with particular emphasis placed on the preparative and structural aspects of this chemistry.

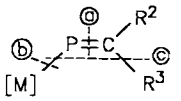
2. Synthetic Methods

2.1. *P*-Metallophosphaalkenes (Type I)

P-Metallophosphaalkenes [M]–P=R^2R^3 are now available by several synthetic routes; however, three general principles, a–c, are discernable (Scheme 3). In syntheses following route (a), the P=C bond is constructed from starting materials with [M]–P bonds such as metallophosphanes, in route (b), a M–P bond is formed between a P-functionalized phosphaalkene and a metal complex, and in route (c), phosphaalkynes are reduced within the coordination sphere of transition metal complexes.

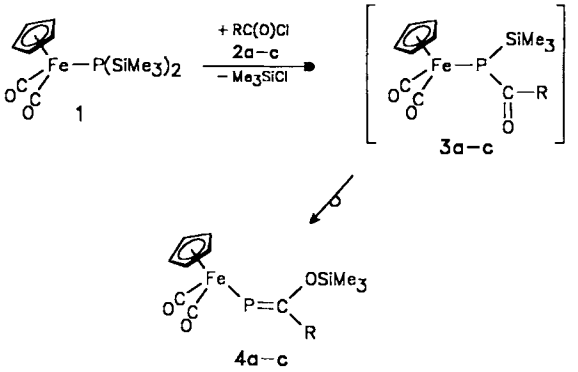


Scheme 3. Routes to metallophosphaalkenes of type I.

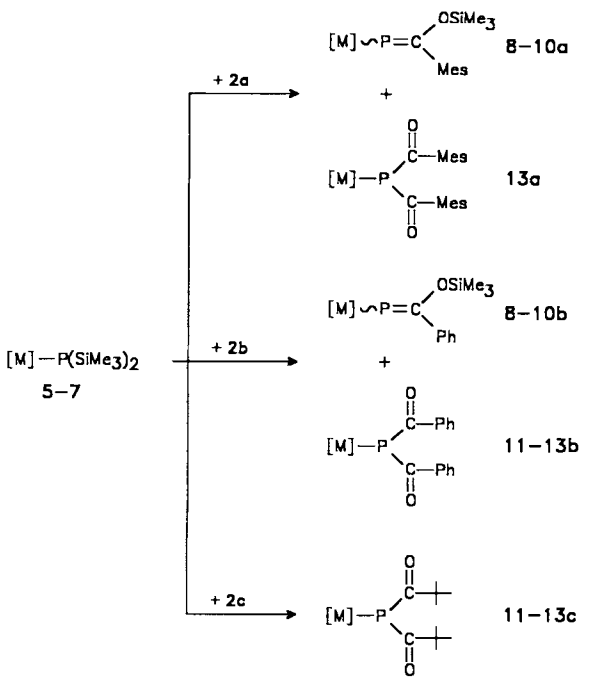
2.1.1. Syntheses by Route a

The first *P*-metallophosphaalkenes were obtained from the reaction of metallodisilylphosphane **1** with acid chlorides **2** (Scheme 4).[3] The reaction sequence of condensation and silyl migration resembles the synthesis of phosphaalkenes from acid chlorides and organodisilylphosphanes,[4] in which, in contrast to transient **3**, the primarily formed acyl(silyl)phosphanes were detectable by ^{31}P NMR spectroscopy.

The principle of the synthesis outlined in Scheme 4 cannot be subjected to unlimited generalization (Scheme 5). Thus, the reaction of pentamethylcyclopentadienyl (Cp*) derivatives [Cp*$(CO)_2$M–P$(SiMe_3)_2$] of iron (**5**)[5] and ruthenium (**6**)[6] with mesitoyl chloride (**2a**) leads cleanly to the metallophosphaalkenes **8a** and **9a**, respectively, whilst treatment with benzoyl chloride (**2b**) leads to mixtures of **8b** and **9b**, respectively, together with the dibenzoylphosphido complexes **11b** and **12b**, respectively. With pivaloyl chloride (**2c**) only the diacylphosphido complexes **11c** and **12c**, respectively, are formed. These limitations are even more valid for the osmium complex **7**, which, even with **2a**, produces mixtures of the osmiophosphaalkene **10a** and the dimesitoylphosphido complex **13a**.[7]

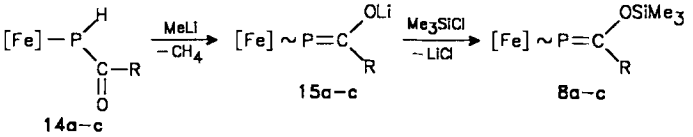


Scheme 4. Syntheses of the metallophosphaalkenes **4**. R = mesityl (Mes) (**a**), Ph (**b**), *t*Bu (**c**).



Scheme 5. Reaction of [Cp*$(CO)_2$M–P$(SiMe_3)_2$] with acid chlorides. M = Fe: **5**, **8**, **11**; Ru: **6**, **9**, **12**; Os: **7**, **10**, **13**; R = Mes (**a**), Ph (**b**), *t*Bu (**c**).

Another successful synthesis of ferriophosphaalkenes (such as **8**) following route (a) is based on the lithiation of the acyl(metallo)phosphanes **14a–c** and the subsequent treatment of the enolates **15a–c** with chlorotrimethylsilane. Compound **8c** is also accessible by this route (Scheme 6).

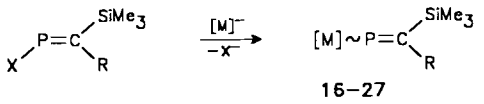


Scheme 6. Ferriophosphaalkenes from acylferriophosphanes. [Fe] = Cp*$(CO)_2$Fe; R = Mes (**a**), Ph (**b**), *t*Bu (**c**).

Lothar Weber was born in 1944 in Langenöls in Schlesien. He studied at the Universität Marburg and received his doctorate there under the supervision of Professor Günter Schmid in 1973. Thereafter, he carried out post-doctoral studies with Professor Barry M. Trost at the University of Wisconsin in Madison, USA. On his return to Marburg, he began the experimental work towards his Habilitation, which was completed in 1982 at the Universität Essen. His work centered on the coordination chemical aspects of sulfur ylides. In 1985, he became a C2 Professor, before he received the call to the Fakultät für Chemie der Universität Bielefeld. His research interests also include the chemistry of compounds with low-coordinate elements of the fifth main group, the synthesis of small homo- and heterocycles with heavy elements as well as metal complex catalyzed reactions of multiply bonded systems.

2.1.2. *Syntheses by Route b*

A particularly efficient method for the synthesis of the metallophosphaalkenes **16**–**27** utilizes the reaction of halogeno(methylene)phosphanes $XP{=}C(R)(SiMe_3)$ with carbonylmetalate ions. The products, with the exceptions of **16** and **20**, are obtained as stable solids in good yield (Scheme 7).[8–10]

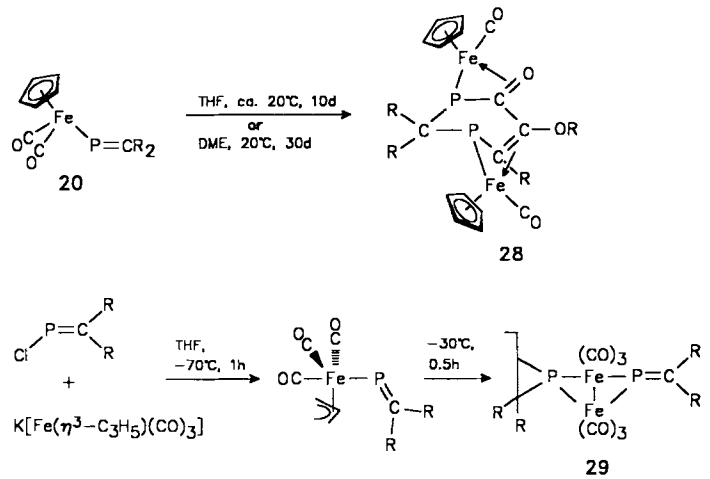


16–27

	[M]	R		[M]	R
16	$[Cp(CO)_3Mo]$	Me_3Si	**22**	$[Cp(CO)_3Mo]$	Ph
17	$[Cp^*(CO)_3Mo]$	Me_3Si	**23**	$[Cp^*(CO)_3Mo]$	Ph
18	$[Cp(CO)_3W]$	Me_3Si	**24**	$[Cp(CO)_3W]$	Ph
19	$[Cp^*(CO)_3W]$	Me_3Si	**25**	$[Cp^*(CO)_3W]$	Ph
20	$[Cp(CO)_2Fe]$	Me_3Si	**26**	$[Cp(CO)_2Fe]$	Ph
21	$[Cp^*(CO)_2Fe]$	Me_3Si	**27**	$[Cp^*(CO)_2Fe]$	Ph

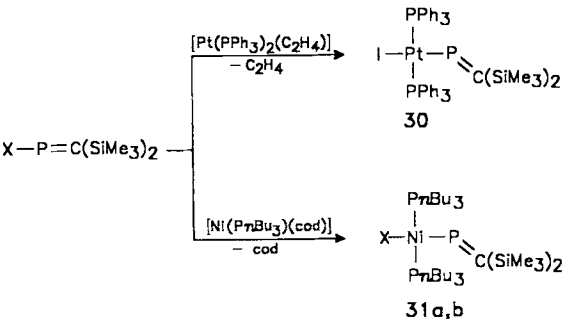
Scheme 7. Metallophosphaalkenes from carbonylmetalates and halogenophosphaalkenes. X = Cl, Br.

The thermal stability of these metallophosphaalkenes decreases with increasing electron density on the metal ($Mo(d^4) < Fe(d^6)$) as well as with decreasing steric demand of the π ligand ($C_3H_5 < Cp < Cp^*$). Thus, the thermolabile complexes **20** and $[(\eta^3\text{-}C_3H_5)(CO)_2FeP{=}C(SiMe_3)_2]$ readily undergo further reaction to **28** and **29**, respectively (Scheme 8).[11]



Scheme 8. Subsequent reactions of unstable metallophosphaalkenes **20** and $[(\eta^3\text{-}C_3H_5)(CO)_3Fe{-}P{=}CR_2]$. R = Me_3Si. DME = 1,2-dimethoxyethane. THF = tetrahydrofuran.

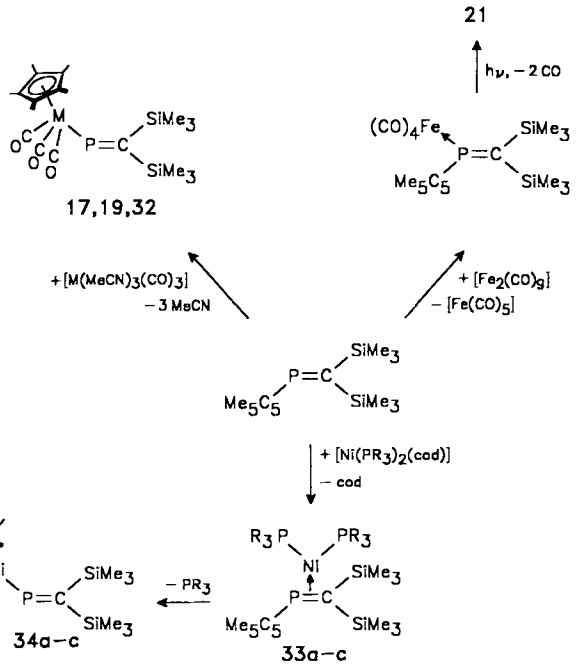
There have been some reports on the oxidative addition of P-halogenophosphaalkenes to low-valent nickel and platinum centers (Scheme 9). Whilst the platinum complex **30**, a cream-colored solid, is stable, the nickel compounds **31a** and **31b** rapidly decompose in solution.[12]



Scheme 9. *P*-Nickelio- and *P*-platiniophosphaalkenes by oxidative addition. X = Cl (**a**), I (**b**), cod = 1,5-cyclooctadiene.

Oxidative addition takes place in competition with η^1 and η^2 coordination of the halogenophosphaalkenes and is particularly favored for the reactive P–I bond (184 kJ mol^{-1}). In contrast, the phosphaalkene $F{-}P{=}C(SiMe_3)_2$ has a strong P–F bond (490 kJ mol^{-1}) and has only been observed so far as a η^1 and η^2 ligand for example in *trans*-$[Rh(PPh_3)_2(Cl)\{\eta^1\text{-}P(F){=}C(SiMe_3)_2\}]$ or $[Ni(PnBu_3)_2\{\eta^2\text{-}P(F){=}C(SiMe_3)_2\}]$.[13] The nature of the transition metal complex fragment clearly influences the reaction behavior of the corresponding chlorophosphaalkene [dissociation energy (P–Cl) = 319 kJ mol^{-1}]. Here, along with **31a**, η^1 complexes are known such as *trans*-$[RhCl(PPh_3)_2\{\eta^1\text{-}P(Cl){=}C(SiMe_3)_2\}]$[13] and η^2 complexes such as $[Pt(PPh_3)_2\{\eta^2\text{-}P(Cl){=}C(SiMe_3)_2\}]$.[12]

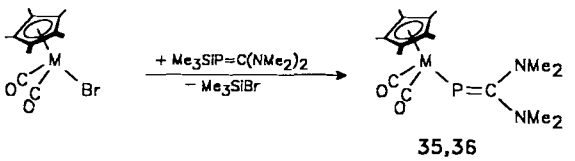
As an alternative to the methods described in Scheme 7, the pentamethylcyclopentadienyl metal derivatives **17** and **19** can be obtained from $Cp^*P{=}C(SiMe_3)_2$ and the kinetically labile complexes $[M(MeCN)_3(CO)_3]$ (M = Mo, W). Here, the metal complex fragment is inserted into the labile P–C(Cp*) bond (1.931(4) Å[14]) (Scheme 10).



Scheme 10. Oxidative additions with $Cp^*P{=}C(SiMe_3)_2$. M = Mo (**17**), W (**19**), Cr (**32**); R = Ph (**a**), Et (**b**), *n*Bu (**c**).

Complexes **17** and **19** are synthesized photochemically; however, the analogous chromiophosphaalkene **32** is produced by thermolysis. Formation of **21** from $Cp^*P{=}C(SiMe_3)_2$ and $[Fe_2(CO)_9]$ proceeds by the photolysis of the isolable complex $[\{\eta^1\text{-}Cp^*P{=}C(SiMe_3)_2\}Fe(CO)_4]$. The synthesis approach for **17**, **19**, and **21** based on $Cp^*P{=}C(SiMe_3)_2$ does not show any advantages over the method given in Scheme 7 (which generates greater yields), because the organophosphorus starting material has to be prepared from $Cl{-}P{=}C(SiMe_3)_2$ beforehand. No alternatives, however, exist for the synthesis of the chromium complex **32** and the nickeliophosphaalkenes **34a–c**.[10]

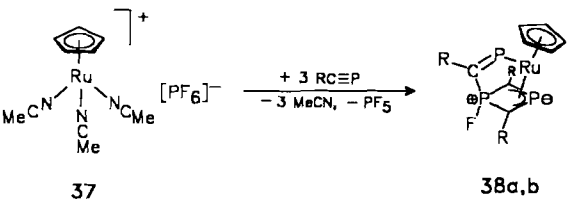
The particularly electron-rich metallophosphaalkenes **35** and **36** are obtained by condensation of the bromo complexes $[MCp^*(CO)_2Br]$ (M = Fe, Ru) with $Me_3Si{-}P{=}C(NMe_2)_2$ (Scheme 11).[15]



Scheme 11. Metallophosphaalkenes from $Me_3SiP{=}C(NMe_2)_2$ by condensation. M = Fe (**35**), Ru (**36**).

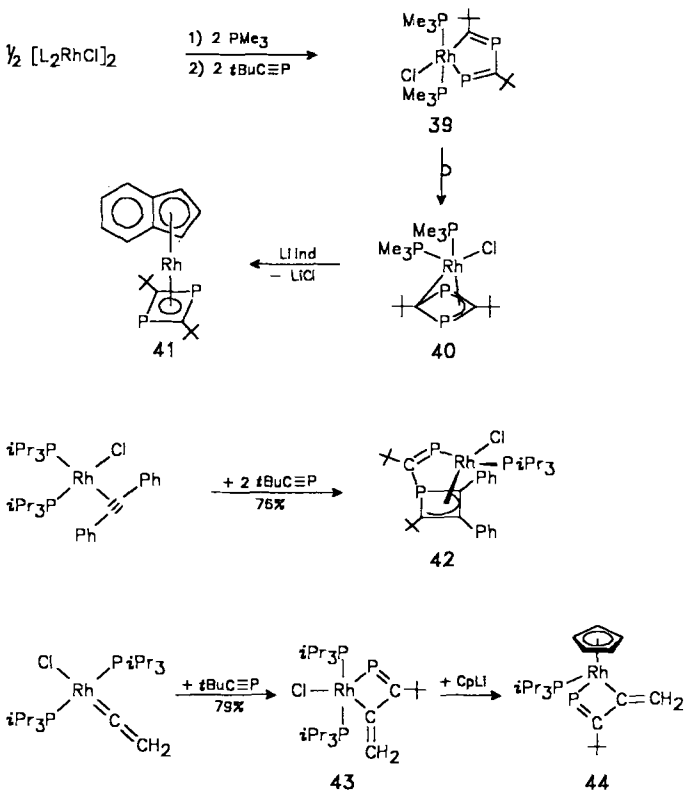
2.1.3. *Syntheses by Route c*

Phosphaalkynes oligomerize within the coordination sphere of transition metals to furnish a wide range of new compounds[1f, 2] some of which display the structural characteristics of *P*-metallophosphaalkenes. Thus, cyclotrimerization of *t*BuC≡P or 1-AdC≡P on the $[CpRu]^+$ fragment of **37** yields complexes **38a** and **38b**, respectively, in which all the acetonitrile ligands have been displaced by the phosphaalkyne. The fluorine atom in the products originates from the hexafluorophosphate ion (Scheme 12).[16]



Scheme 12. Synthesis of a *P*-rutheniophosphaalkene by cyclotrimerization of phosphaalkynes; R = *t*Bu (**a**), 1-adamantyl (1-Ad) (**b**).

Treatment of $[Rh(C_2H_4)_2Cl]_2$ with trimethylphosphane and *tert*-butylphosphaacetylene in the molar ratio of 1:4:4 produces a 1:2 mixture of the 1,4-diphospha-2-rhodacyclopentadiene **39** and the 1,3-diphosphacyclobutadiene derivative **40**. Reaction of **40** with indenyllithium cleanly yields the sandwich complex **41** (Scheme 13).[17] Rhodiophosphaalkene **39** is a model complex for an important intermediate product in metal-induced cyclooligomerizations of phosphaalkynes. On cobalt, rhodium,[1f] and iron[18] centers this usually leads to η^4-ligated 1,3-diphosphacyclobutadienes. On the other hand, cyclodimerization of *t*BuC≡P on $[Cp_2Zr]$ and $[Cp_2Hf]$ fragments yields complexes with 1,3-diphosphabicyclo[1.1.0]butanediyl ligands.[19] A highly efficient cyclotetramerization of the phosphaalkyne occurs on



Scheme 13. Synthesis of cyclic rhodiophosphaalkenes. Ind = indenyl.

the (η^8-cyclooctatetraene)zirconium fragment to give a (η^4-1,3,5,7-tetraphosphabarralene)zirconium complex, and here reactive metallophosphaalkynes are also postulated as intermediates.[20]

The tolanrhodium complex $[Rh(PiPr_3)_2(Cl)(\eta^2\text{-}PhC{\equiv}CPh]$ reacts with two equivalents of *t*BuC≡P, undergoing a cyclodimerization to yield **42**. One molecule of phosphaalkyne adds to the alkyne to generate a η^3-phosphacyclobutenyl ligand. The second molecule of phosphaalkyne bridges the P atom of the four-membered ring to the metal center, thus producing a rhodiophosphaalkene (Scheme 13).[21]

The cyclo-cooligomerization of alkynes with phosphaalkynes is sensitively dependent on the nature of the other ligands on the metal center. Thus, in the reaction of $[RhCp(PiPr_3)(\eta^2\text{-}PhC{\equiv}CPh)]$ with *t*BuC≡P only one molecule of the phosphaalkyne is incorporated to give the η^4-phosphacyclobutadiene-rhodium complex $[CpRh(\eta^4\text{-}\overline{PC(Ph)C(Ph)C}\,t\text{Bu})]$.[21]

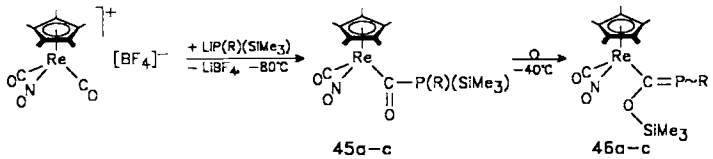
Another type of [2+2]cycloaddition occurs between the vinylidene complex $[(PiPr_3)_2(Cl)Rh{=}C{=}CH_2]$ and *t*BuC≡P. Here, the cyclic rhodiophosphaalkene **43** is produced, which subsequently reacts smoothly with cyclopentadienyllithium to yield **44** (Scheme 13).[21]

2.2. *C*-Metallophosphaalkenes (Type II)

2.2.1. *From Lithiosilylphosphanes and Carbonylmetal Cations*

The syntheses of the first *C*-metallophosphaalkenes **46a–c** were contrived by the addition of lithiosilylphosphanes to the carbonylrhenium cation $[Cp^*Re(CO)_2(NO)]^+$ in ether at

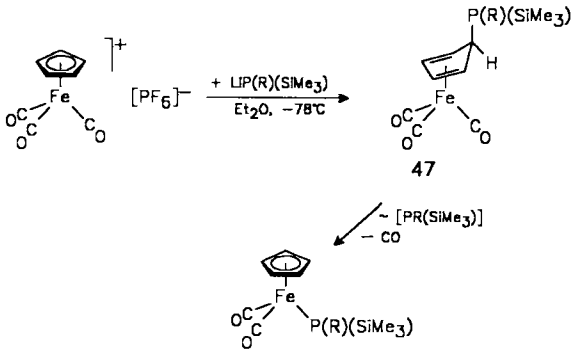
-80 °C (Scheme 14). The initially formed complexes **45a–c** can be detected by ^{31}P NMR spectroscopy, they rearrange above -40 °C to the products **46a–c**. Analogously, the extremely sensitive compound [Cp(CO)(NO)Re–C(OSiMe$_3$)=P*t*Bu] is obtained from the reaction of [CpRe(CO)$_2$(NO)]BF$_4$ with LiP(*t*Bu)(SiMe$_3$).[22]



Scheme 14. Synthesis of *C*-rheniophosphaalkenes. R = Me$_3$Si (**a**), *t*Bu (**b**), Ph (**c**).

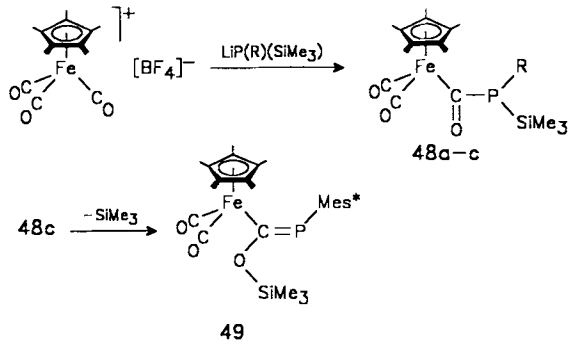
This type of synthesis, however, has only a limited range of application. Thus, treatment of the manganese complex cation [Cp*Mn(CO)$_2$(NO)]$^+$ with LiP(SiMe$_3$)$_2$ produces the complex [Cp*(CO)$_2$Mn–P(SiMe$_3$)$_2$] instead of a *C*-manganiophosphaalkene.[23]

The tendency of formation and stability of *C*-metallophosphaalkenes are also sensitively influenced by the spatial requirements of the other ligands in the complex and by the substituents on the P atom. This is particularly valid for the corresponding iron and ruthenium compounds. The cation [CpFe(CO)$_3$]$^+$ is attacked at the cyclopentadienyl ligand by LiP(R)(SiMe$_3$) (R = SiMe$_3$, *t*Bu) at -78 °C in ether. The *exo*-phosphinocyclopentadiene complexes **47** thus formed rearrange at room temperature to the metallophosphanes [Cp(CO)$_2$Fe–P(R)(SiMe$_3$)] (Scheme 15).[24]



Scheme 15. Reaction of [FeCp(CO)$_3$]$^+$ with lithiosilylphosphanes. R = Me$_3$Si (**a**), *t*Bu (**b**).

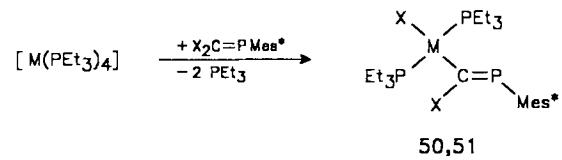
If the analogous pentamethylcyclopentadienyl cation [Cp*(CO)$_3$Fe]$^+$ is used, the attack by the phosphide on the ring ligand does not occur, however, the desired *C*-metallophosphaalkene **49** is only produced in the case of the bulky supermesityl group (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$) on the P atom (Scheme 16).[25] For R = SiMe$_3$ and *t*Bu the 1,3-silyl migration does not occur, and the phosphinocarbonyl complexes **48a** and **48b**, respectively, are isolated as the final products (Scheme 16).[26] Similar results are obtained in the chemistry of the ruthenium derivative [Cp*Ru(CO)$_3$]$^+$.[25, 27]



Scheme 16. Synthesis of (phosphino)carbonyl complexes **48a–c** and a *C*-ferriophosphaalkene **49**. R = Me$_3$Si (**a**), *t*Bu (**b**), Mes* (**c**).

2.2.2. *From C-Functionalized Phosphaalkenes*

Two research groups have succeeded in synthesizing *C*-metallophosphaalkenes from phosphaalkenes that have halogen functions on the methylene carbon atom.[28, 30] The *trans*-configured compounds **50a** and **51** result from the oxidative addition of equimolar amounts of Cl$_2$C=PMes* and [M(PEt$_3$)$_4$] in benzene or hexane at 20 °C (Scheme 17). Similarly, the bromoplatinum derivative **50b** is obtained from [Pt(PEt$_3$)$_4$] and Br$_2$C=PMes*. The analogous bromopalladium compound could not be isolated due to decomposition to *trans*-[Pd(PEt$_3$)$_2$Br$_2$] and Mes*C≡P.[28a, c]



Scheme 17. Synthesis of *C*-palladio- and *C*-platiniophosphaalkenes; M = Pt, X = Cl (**50a**), X = Br (**50b**); M = Pd, X = Cl (**51**).

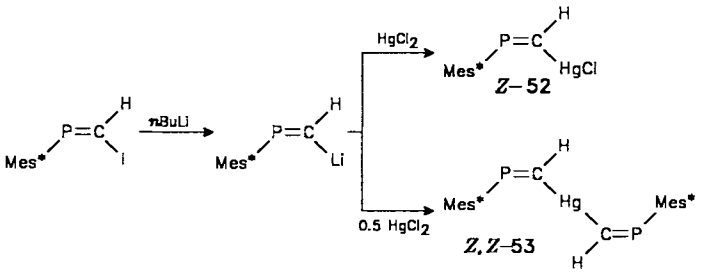
The *cis* isomer corresponding to **50a** is formed from Cl$_2$C=PMes* and [Pt(PEt$_3$)$_4$] in hexane at -50 °C and can be isolated as analytically pure crystals at this temperature. However, in solution *cis*-[(Et$_3$P)$_2$(Cl)Pt{C(Cl)=PMes*}] rearranges in the presence of PEt$_3$ and above -30 °C to the *trans* isomer.[28c] An alternative synthesis of **50a** utilizes a ligand exchange reaction between *trans*-[Pt(PEt$_3$)$_2$Cl$_2$] and LiC(Cl)=PMes*.[28c]

The principle of synthesis outlined in Scheme 17 is also subject to narrow limits: 1. To date there are only a few *C*-halogenomethylenephosphanes known, and these carry, with the exception of the 2,2,6,6-tetramethylpiperidino and bis(trimethylsilyl)amino substituents, the supermesityl group on phosphorus. 2. The stability of the products discussed here is as follows: Pt > Pd; Cl > Br; PEt$_3$ > PPh$_3$.

In agreement with this, the reaction of [Pt(η^2-C$_2$H$_4$)(PPh$_3$)$_2$][28c] or [Pd(PPh$_3$)$_4$][29] with Cl$_2$C=PMes* does not lead to stable *C*-metallophosphaalkenes, but only to the phosphaalkyne Mes*C≡P and to *cis*-[Pt(PPh$_3$)$_2$Cl$_2$] and *trans*-[Pd(PPh$_3$)$_2$Cl$_2$], respectively.

The organolithium compound (*Z*)-Mes*P=CHLi reacts with one equivalent of HgCl$_2$ to give the mercuriophosphaalkene

(*Z*)-**52**, whilst treatment with only 0.5 equiv of $HgCl_2$ generates the bis(phosphaalkenyl)mercury derivative (*Z*/*Z*)-**53** (Scheme 18).[30] If, instead of the single isomer of the lithium compound, the mixture (*E*/*Z*)-Mes*P=CHLi is used, as is produced from the lithiation of the phosphaalkene mixture (*E*/*Z*)-Mes*P=CHI (80:20), the mercury compound is also obtained as a mixture of (*E*/*E*)-**53** and (*Z*/*Z*)-**53**. The isomers can be separated by crystallization.[30]

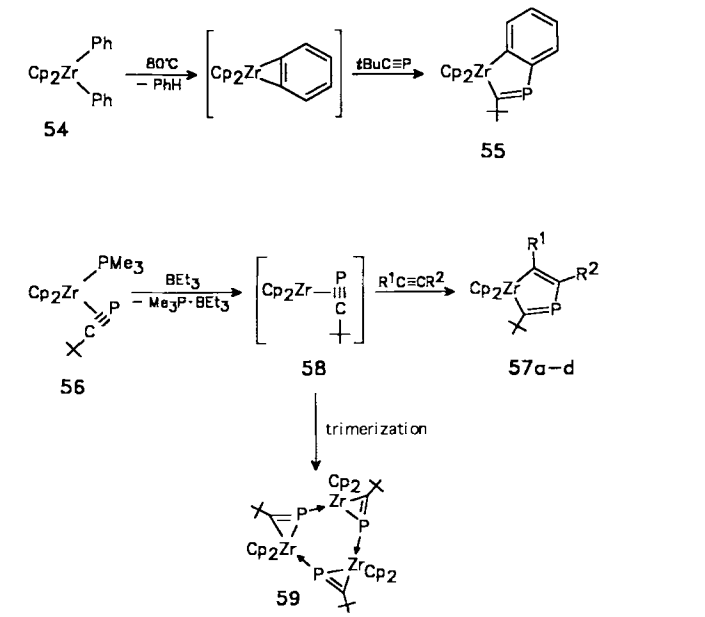


Scheme 18. Synthesis of *C*-mercuriophosphaalkenes **52** and **53**.

2.2.3. *From Phosphaalkynes or η^2-Phosphaalkyne Complexes*

Cyclo-codimerizations of *t*BuC≡P with alkenes and alkynes within the coordination sphere of titanocenes and zirconocenes lead to metallaheterocycles with structural features of *C*-metallophosphaalkenes. If, for example, a solution of **54** in *n*-heptane is heated with the phosphaalkyne for several hours at 80 °C, the zirconiophosphaalkene **55** is obtained as a red powder and a η^2-dehydrobenzene complex is postulated as an intermediate (Scheme 19). A titanium derivative analogous to **55** has also been reported.[31]

The *C*-metallophosphaalkenes **57a–d** are readily accessible from the phosphaalkyne complex **56** by reaction with the alkynes HC≡CH, MeC≡CMe, PhC≡CPh, and PhC≡CH, respectively, if the released phosphane is removed from the equilibrium by adduct formation with triethylborane (Scheme 19). However, codimerization fails with silylated alkynes such as $HC{\equiv}CSiMe_3$, $PhC{\equiv}CSiMe_3$, $Me_3SiC{\equiv}CSiMe_3$ as well as with dimethyl acetylenedicarboxylate. In the absence of trapping agents the coordinatively unsaturated complex **58**, formed from **56** by abstraction of phosphane, trimerizes to **59**.[32] The cyclic *C*-metallophosphaalkenes **55** and **57** are the first stable representatives of a class of compounds which are most probably intermediates playing an important role in all metal-induced cyclo-cooligomerizations, but which have, to date, evaded detection. This is true not only for the formation of (η^4-phosphacyclobutadiene)cobalt[33] and -rhodium[21] complexes but also for the synthesis of (1,3-diphosphinine)iron compounds.[18] A highly reactive nickeliophosphaalkene has been proposed as an intermediate in the synthesis of a tetraphosphatricyclooctadiene.[34]



Scheme 19. *C*-Zirconiophosphaalkenes from alkyne, phosphaalkyne, and zirconocene building blocks. $R^1 = R^2 = H$ (**a**), Me (**b**), Ph (**c**); $R^1 = H$, $R^2 = Ph$ (**d**).

The 1-phospha-3-zirconia[3.1.0]bicyclohex-1-enes **60a–e** can be synthesized from **58** and cyclopropene derivatives. If **58**, generated in situ, is treated with acetone, benzophenone, benzaldehyde, or isobutyraldehyde, metallaheterocycles **61** are obtained. Treatment of 1,1-dimethylallene or triphenylketeneimine with **58** produces complexes **62** and **63**, respectively (Scheme 20).[32] The titanium derivatives analogous to **60a–c** and **61c,d** have also been prepared.[32]

The insertion of a methylene group into the metal–phosphorus bond can be achieved when **56** or the trimer **59** is treated with the ylides $Ph_3P{=}CH_2$ or $Me_3P{=}CH_2$ as well as with the adduct $Ph_3P{=}CH_2 \cdot BEt_3$ (Scheme 21).[32]

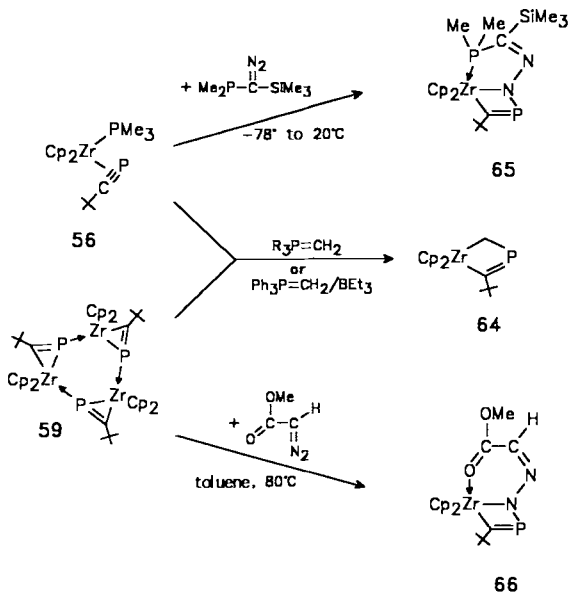
60a	Me	Me	H	H
60b	Ph	Ph	H	H
60c	Me	Ph	H	H
60d	Ph	Me	H	H
60e	H	H	Ph	Ph

	R^5	R^6
61a	Me	Me
61b	Ph	Ph
61c	Ph	H
61d	*i*Pr	H

Scheme 20. Synthesis of cyclic *C*-zirconiophosphaalkenes.

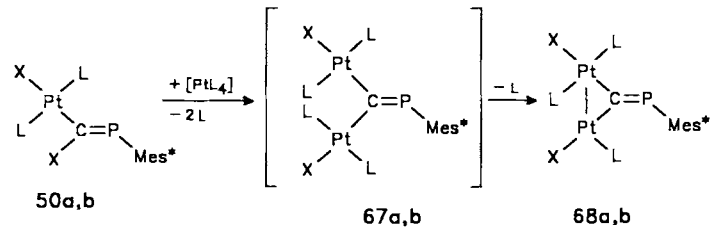


Scheme 21. Reaction of (η^2-phosphaalkyne)zirconocene complexes with ylides and diazo compounds. R = Me, Ph.

The reaction of **56** or **59** with diazo compounds does not lead to the expected loss of N_2 and insertion of the carbene fragment into the Zr–P bond. Instead, a cycloaddition reaction yields the 2-aza-1-phospha-3-zirconiacyclobut-4-enes **65** and **66**, respectively, which, like **64**, have the structural motif of a *C*-metallophosphaalkene in the heterocycle (Scheme 21).[32]

2.3. *C,C*-Dimetallophosphaalkenes (Type III)

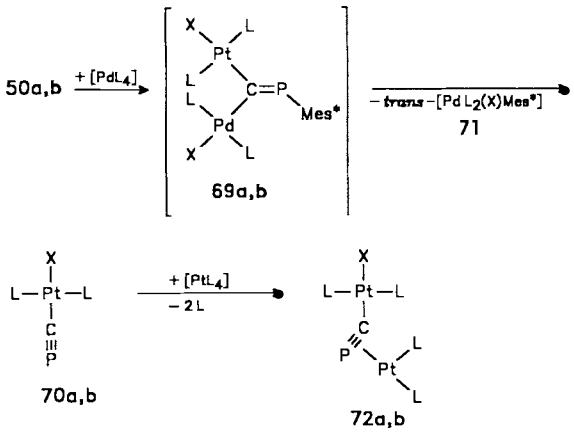
For compounds of this type, which can also be regarded as μ-isophosphaalkyne or phosphoisonitrile complexes, there are two methods of synthesis available so far. These complexes deserve particular attention, as the ligated isophosphaalkynes C≡P(aryl) are unknown as the free species, and all attempts to synthesize them up to now afforded only the already well known phosphaalkyne isomers (aryl)C≡P. The first complexes of this type, **68** (Scheme 22), are obtained by the oxidative addition of



Scheme 22. Synthesis of *C,C*-diplatiniophosphaalkenes. X = Cl (**a**), Br (**b**); L = PEt_3.

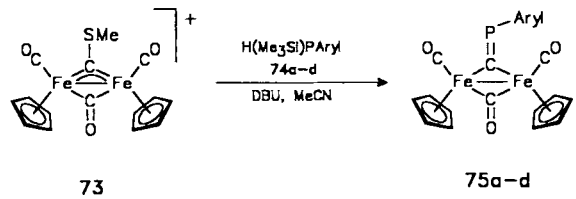
one equivalent of $[Pt(PEt_3)_4]$ to the *C*-metallophosphaalkenes **50**; the dinuclear complexes **67** are assumed to be the primary products.[28a–d]

Experiments to produce heterodimetallic complexes of type **68** with Pt and Pd proceed by a different route:[28d] The complexes **70** and **71** are the only organometallic products detectable following the reaction of **50** with $[Pd(PEt_3)_4]$ for 24 h; however, the metallophosphaalkynes **70** could not be isolated. Their subsequent treatment with $[Pt(PEt_3)_4]$ leads to **72** with the novel $\mu(\eta^1:\eta^2)$-phosphaethynyl ligand (Scheme 23).[28d]



Scheme 23. Synthesis of $\mu(\eta^1:\eta^2)$-phosphaethynyl complexes. X = Cl (**a**), Br (**b**); L = PEt_3.

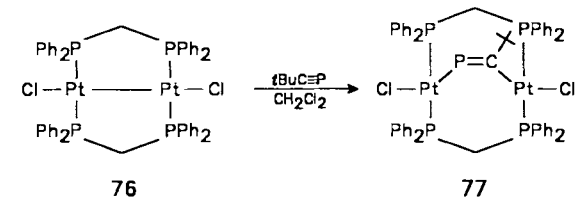
An alternative method for the synthesis of *C,C*-dimetallophosphaalkenes employs base-induced condensation of aryl(silyl)phosphanes **74a–d** with the μ-carbynediiron complex **73** (Scheme 24).[35,36] Compounds **75a–c** are obtained by column chromatography as dark red, air-stable, crystalline substances, whereas **75d** has not yet been isolated undecomposed. On the basis of findings to date, the condensation described above is limited to bulky aryl(silyl)phosphanes.



Scheme 24. Synthesis of *C,C*-diferriophosphaalkenes. Aryl = Mes (**a**), 2,4,6-$iPr_3C_6H_2$ (**b**), Mes* (**c**), 2,4,6-$(CF_3)_3C_6H_2$ (**d**); DBU = diazabicycloundecene.

2.4. *C,P*-Dimetallophosphaalkenes (Type IV)

The only compound with this type of structure known so far, **77**, is obtained by the addition of *t*BuC≡P to the Pt–Pt fragment of the diplatinum complex **76** (Scheme 25).[37]

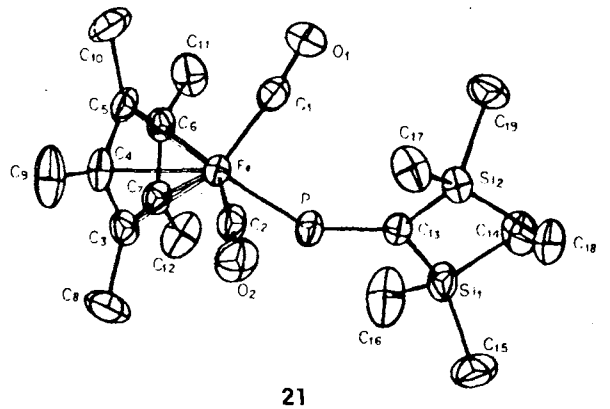


Scheme 25. Synthesis of a *C,P*-diplatiniophosphaalkene.

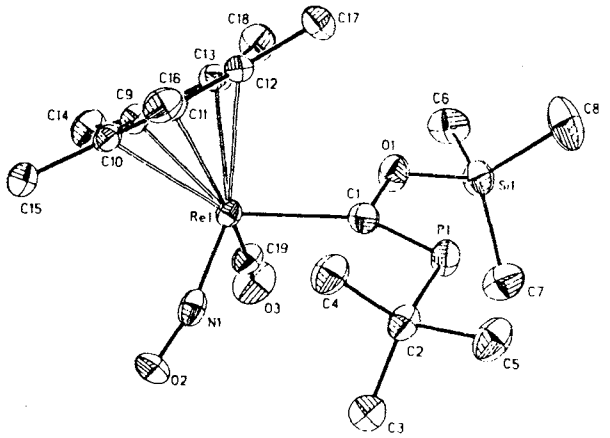
3. Structures and Bonding Properties

3.1. Molecular Structures of Metallophosphaalkenes

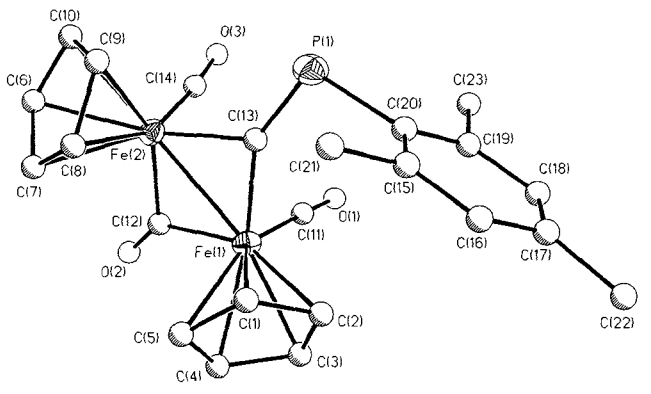
The most noticeable structural change that a classical phosphalkene undergoes on exchanging an organic substituent on the phosphorus atom for a transition metal complex fragment is the opening of the valence angle on the phosphorus atom. The angle M-P-C varies from 113.8(2)° in the [CpFe] complex **4c** (see Scheme 4)[3] to 126.2(3)° in the [Cp*Fe] complex **21**[9] (Fig. 1). In the parent compound $HP{=}CH_2$ the calculated value for the angle H-P-C is 97.4°,[38, 39] whilst in phosphaalkenes with organic substituents the value for this angle usually varies between 100–114° depending on the spatial requirements of the substituents.[40] The unusually large valence angle N-P-C in $Mes^*(Me_3Si)N{-}P{=}C(SiMe_3)_2$ (121.38(6)°) undoubtedly results from steric repulsion within the molecule.[41] The opening of the angle in metallophosphaalkenes is due not only to steric but also to electronic effects which arise from the low electronegativity of the metal substituent. In the parent compound, the orbital of the lone pair on the phosphorus has mainly 3s character. This changes in the metallophosphaalkenes: the p character of the lone pair increases. This causes an opening of the angle on phosphorus and a decrease in the ionization energy of the n orbital. In metallophosphaalkenes, this orbital then becomes energetically the HOMO, whilst the π orbital becomes HOMO − 1. All in all, the energy difference HOMO–LUMO (the latter is a π*-orbital) is smaller than that in $HP{=}CH_2$.[38, 39]



21



46b



75a

Fig. 1. Crystal structures of the metallophosphaalkenes **21**, **46b**, and **75a**. Selected bond lengths [Å] and angles [°]: **21**: P-C13 1.680(9), Fe-P 2.256(2); Fe-P-C13 126.2(3); **46b**: P1-C1 1.704(4), Re1-C1 2.138(4), C1-O1 1.399(5); C1-P1-C2 112.3(2); **75a**: P1-C13 1.683(12), C13-Fe1 1.903(16), C13-Fe2 1.927(16); C13-P1-C20 104.5(7).

In the *C*-rheniophosphaalkene **46b**[22] and in the *C*,*C*-diferriophosphaalkene **75a**,[35] C-P-C bond angles of 112.3(2)° and 104.5(7)°, respectively, have been measured (Fig. 1).

The molybdeniophosphaalkene **16** (see Scheme 7) has the shortest P=C distance observed to date for a *P*-metallophosphaalkene (1.665(3) Å;[8] calc.: 1.673 Å[38]). π-Conjugation with the lone pairs on oxygen or nitrogen atoms of heterosubstituents generally leads to a small elongation of the P=C bond (e.g. 1.701(4) Å in *t*Bu(OSiMe$_3$)C=P complex **4c**[3] or 1.709 Å in the $(NMe_2)_2C{=}P$ complex **35**[15]). The same is true of the P=C bond lengths in **46b** (1.704(4) Å) and **75a** (1.683(17) Å). The metal–phosphorus distances in *P*-metallophosphaalkenes are in agreement with single bonds with negligible π-bond contributions.

3.2. NMR Spectra

The characteristic ^{31}P and ^{13}C NMR shifts for selected compounds are summarized in Table 1.

The ^{31}P NMR chemical shifts of phosphaalkenes vary in the wide range between $\delta = -62.0$ for $(Me_2N)C{=}PH$[42] to $\delta = 740.5$ in the nickel complex **34b**.[9, 10] The ^{31}P NMR data of compounds containing low-coordinate phosphorus published up to 1987 are summarized in a review.[43] Inspite of the large problems associated with the theoretical collation and interpretation of these large differences in shift, which generally occur for compounds containing two-coordinate phosphorus, some trends can be discerned for metallophosphaalkenes.

In metallophosphaalkenes strong downfield shifts of the ^{31}P resonances relative to the signals of the analogous, purely organo-substituted compounds are typical, this points to a small HOMO–LUMO gap. The effect can be correlated to the σ-donor effect of the complex fragment which is dependent not only on the donor strength of the 3d metal (Cr in **32** ($\delta = 605.4$) < Fe in **21** ($\delta = 641.5$) < Ni in **34b** ($\delta = 740.5$)), but also on the ring ligand. Thus, the exchange of a Cp for a Cp* ligand causes a deshielding of $\Delta\delta(^{31}P)$ of 42.9 to 60.3.

Table 1. ^{13}C and ^{31}P NMR data of selected *P*-metallophosphaalkenes and phosphaalkenes[a]

[a] In C_6D_6; 85% H_3PO_4 as external standard for the ^{31}P NMR signals.

In contrast, the exchange of iron in **8b** for the heavier homologues Ru and Os causes upfield shifts ($\Delta\delta(^{31}P) = -23.0$ and -38.4, respectively). Similar results are observed in the CpMo and CpW complexes **16** and **18** ($\Delta\delta^{31}P = -23.2$) as well as in the Cp*Cr, Cp*Mo, and Cp*W complexes **32**, **17**, and **19** ($\Delta\delta^{31}P = -16.6$ and -24.5, respectively). As in nonmetalated phosphaalkenes, substituents on the heteroatom lead to an increased shielding of the phosphorus nucleus by conjugation of a lone pair with the P=C bond.

Up to now there are only a few examples known of (*E*/*Z*) isomerism of *P*-metallophosphaalkenes. In these compounds the more strongly sterically hindered (*E*) isomers absorb at somewhat lower field than the (*Z*) isomers (e.g. δ((*E*)-(**9a**)) $-\delta$((*Z*)-(**9a**)) = 24.8[6]).

Downfield shifts of the ^{31}P NMR signal are also observed for *C*-metallophosphaalkenes of type [RP=C[M](OSiMe$_3$)] when a *tert*-butyl group on the methylene carbon atom is exchanged for a carbonylcyclopentadienyl metal complex fragment. This is attributed essentially to changes in the paramagnetic shift contribution. Thus, the singlet in (*E*)-[Cp*(CO)(NO)Re–C(OSiMe$_3$)=PPh] ((*E*)-**46b**)[22] observed at δ = 194.4 is shifted downfield relative to that in (*E*)-PhP=C(OSiMe$_3$)(*t*Bu) (δ = 135.0[44]) by $\Delta\delta$ = 59.4. For the pair of compounds (*E*)-[Cp*(CO)(NO)ReC(OSiMe$_3$)=PSiMe$_3$] ((*E*)-**46a**) (δ = 214.4[22]) and (*E*)-Me$_3$SiP=C(OSiMe$_3$)(*t*Bu)[48] the corresponding downfield shift is $\Delta\delta$ = 99.4. The *P*-aryl-*C*,*C*-dimetallophosphaalkenes **68a**[28] and **75c**[35] give singlets at $\delta(^{31}P)$ = 151.3 and 258.0, respectively.

The ^{13}C NMR spectra of phosphaalkenes show characteristic doublets for methylene carbon atoms at δ = 170–210; the *P*-metallophosphaalkenes are found in the upper region of the range. As the electron density on the metal atom increases, the ^{13}C NMR chemical shift decreases. This also applies when the substitution pattern on the phosphaalkenyl fragment remains the same within a triad ((d^4): Cr > Mo > W; (d^6): Fe > Ru > Os) as well as for 3d metals with increasing atomic number (Cr(d^4) > Fe(d^6) > Ni(d^8)).

In *C*-metallophosphaalkenes **46**[22] and **49**,[25] the ^{13}C NMR resonances lie at noticeably lower field (δ = 210.0–252.5 (d), $^1J_{C,P}$ = 80.7–113.5 Hz). The corresponding signals in the ^{13}C NMR spectra of the *C*,*C*-dimetallophosphaalkenes **75a–c** are doublets at even lower field (δ = 338.8–345.8 (d), $^1J_{P,C}$ = 92–97 Hz)[35] and therefore within the range of signals observed for carbenium ions.[49]

4. Reactivity

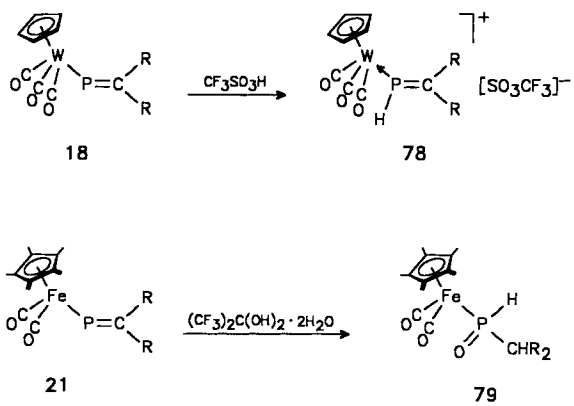
Metallophosphaalkenes of types I–IV are polyfunctional molecules with various reactive centers that can undergo chemical transformations. The reactivity of *P*-metallophosphaalkenes (type I) has been the most extensively investigated to date. These species react readily with electrophiles, and several types of reaction and products are often observed. The initial step is frequently a Lewis acid–base interaction, in which the phosphaalkene plays the part of the Lewis base through the lone pair of electrons on phosphorus. Therefore, it seems reasonable to organize this section according to the nature of the reaction partner. The subdivision of the metallophosphaalkenes, types I–IV, remains unchanged.

4.1. Reactivity of the *P*-Metallophosphaalkenes (Type I)

4.1.1. Protic Reagents

The tungstiophosphaalkene **18** is protonated at the P atom by trifluoromethanesulfonic acid in CH_2Cl_2 at $-78\,^\circ C$ to afford the cationic η^1-phosphaalkene complex **78** (Scheme 26).[8]

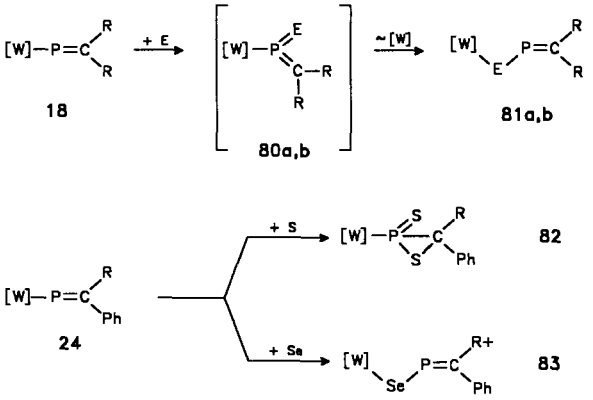
Equimolar amounts of **21** and 1,1,1,3,3,3-hexafluoropropane-2,2-diol dihydrate (hexafluoroacetone trihydrate) react in benzene to give the ferriophosphane oxide **79**, which can be isolated as pale yellow crystals in 30% yield.[50] The hydration is catalyzed by the fluoroorganic compound, a weak protic acid (pK_a = 6.58).[51]



Scheme 26. Reaction of metallophosphaalkenes **18** and **21** with protic reagents. R = Me$_3$Si.

4.1.2. *Chalcogens*

Reactions of **18** and **24** with sulfur and selenium follow an unexpected course. Instead of the anticipated oxidation to products of type **80**, the chalcogen is inserted into the phosphorus–metal bond to produce complexes **81** and **83**, respectively (Scheme 27). Double sulfurization of **24** gives the $1,2\lambda^5$-thiaphosphirane **82** with preservation of the P–W bond. Compounds **80a** and **80b**, respectively, are postulated as intermediates.[10]

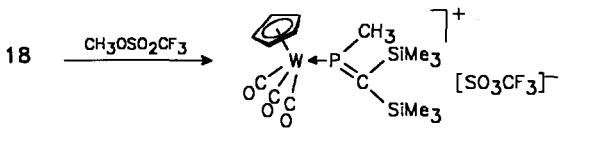


Scheme 27. Chalcogenation of tungstiophosphaalkenes; [W] = $Cp(CO)_3W$; E = S (**a**), Se (**b**); R = Me_3Si.

4.1.3. C_1 *Building Blocks*

4.1.3.1. *Alkylating Agents*

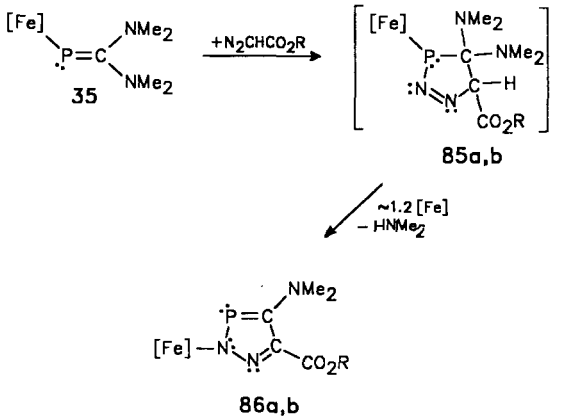
The cationic η^1-[bis(trimethylsilyl)methylene]methylphosphane complex **84** can be prepared by the alkylation of **18** with methyl trifluoromethanesulfonate (Scheme 28).[10]



Scheme 28. Methylation of $[Cp(CO)_3W–P=C(SiMe_3)_2]$ **18**.

4.1.3.2. *Diazoalkanes*

Diphosphenes react smoothly with diazoalkanes with the loss of N_2 to produce diphosphiranes.[1h] As yet there are no reports of a similar phosphirane synthesis from phosphaalkenes and diazo compounds. The first 1,2,3-diazaphospholes with metal functions on nitrogen (**86a,b**), are obtained unexpectedly from the treatment of **35** with equimolar amounts of diazoacetates (Scheme 29).[52] The reaction proceeds by a 1,3-dipolar cycloaddition, in which the P atom of **35** is negatively polarized.[52] 1,3-Dipolar cycloadditions between acyldiazoalkanes and phosphaalkenes such as $Me_3SiP=C(R)(OSiMe_3)$ or $ClP=C(R)(SiMe_3)$, which contain positively polarized phosphorus centers, usually lead to 1,2,4-diazaphospholes.[53] Intermediates such as **85** were not detectable.

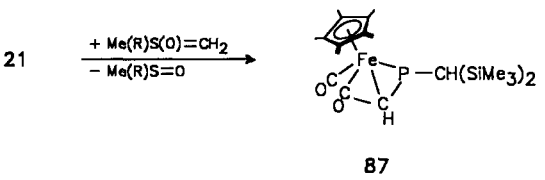


Scheme 29. [3+2]Cycloaddition between **35** and diazoacetates. [Fe] = $Cp^*(CO)_2Fe$, R = Et (**a**), *t*Bu (**b**).

Evidently, after cycloaddition of the starting materials to produce **85**, there is a subsequent rapid elimination of dimethylamine and a 1,2-metal migration (Scheme 29). Compound **35** and trimethylsilyldiazomethane do not react with one another.

4.1.3.3. *Sulfur Ylides*

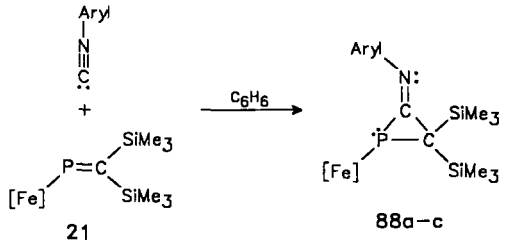
Sulfur ylides are known to be excellent alkylidene transfer reagents that readily convert diphosphenes to diphosphiranes.[1h] The reaction of **21** with $Me_2S(O)=CH_2$ or $Me(Me_2N)S(O)=CH_2$, however, does not lead to the expected *P*-metallophosphirane, but to the "butterfly" complex **87** (Scheme 30).[54]



Scheme 30. Reaction of **21** with sulfur ylides. R = Me, Me_2N.

4.1.3.4. *Isocyanides*

The red, crystalline 2-imino-*P*-metallophosphiranes **88a–c** result from a formal [2+1]cycloaddition of aryl isocyanides to **21** (Scheme 31).[55] A striking feature in the molecular structure of **88a** (Fig. 2) is the P(1)–C(14) bond which is markedly elongated relative to the P(1)–C(13) bond. The endocyclic angle on the phosphorus atom [45.3(3)°] is strongly compressed com-



Scheme 31. Reaction of **21** with aryl isocyanides. Aryl = Ph (**a**), *o*-MeC_6H_4 (**b**), 2,6-$Me_2C_6H_3$ (**c**); [Fe] = $Cp^*(CO)_2Fe$.

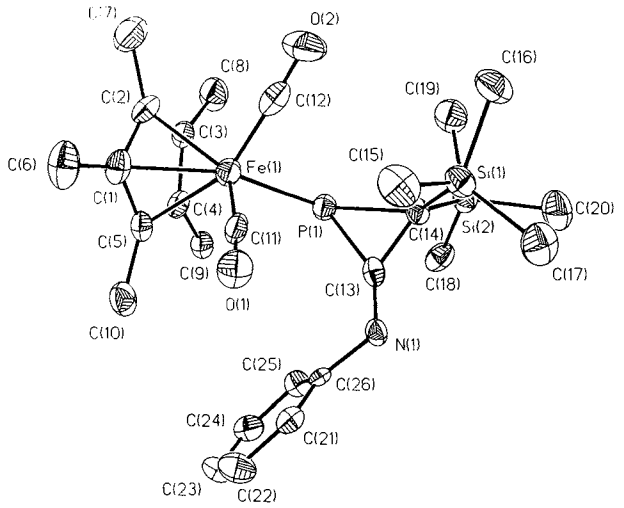


Fig. 2. Crystal Structure of **88a**. Selected bond lengths [Å] and angles [°]: Fe1-P1 2.279(2), P1-C13 1.799(7), P1-C14 1.990(7), C13-C14 1.469(8), N1-C13 1.273(7); C13-P1-C14 45.3(3), P1-C14-C13 60.9(3), P1-C13-C14 74.3(4).

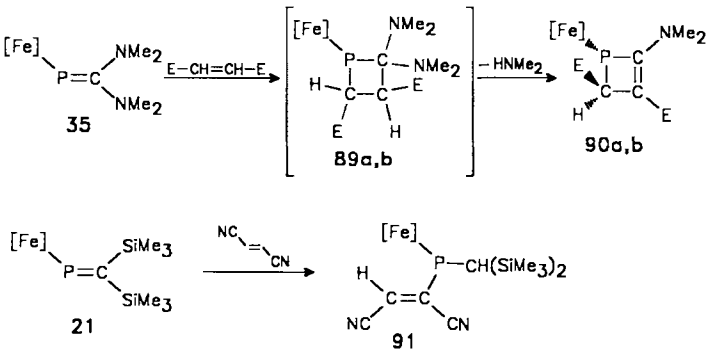
pared to that on the ring carbon atoms C(13) [74.3(4)°] and C(14) [60.5(3)°].[55]

In contrast, the ferriophosphaalkene **35** is not attacked by isocyanides on the P—C double bond under similar conditions, but reacts with CO substitution to afford [Cp*(CO)(RNC)-Fe—P=C(NMe$_2$)] (R = *t*Bu, *c*C$_6$H$_{11}$, 2,6-Me$_2$C$_6$H$_3$).[56a]

4.1.4. C_2 Building Blocks

4.1.4.1. Alkenes

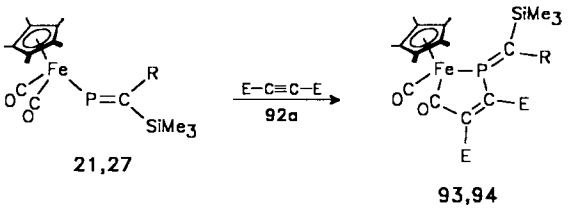
Since α,β-unsaturated carboxylic acid esters and nitriles are electrophilic, they are suitable partners for reaction with electron-rich metallophosphaalkenes. As a result of a two-step [2 + 2]cycloaddition, *P*-metallophosphetanes of type **89** are, a priori, the expected products (Scheme 32). However, treatment of **35** with fumarodinitrile and dimethyl fumarate lead instead to the *P*-metallo-1,2-dihydrophosphetes **90**; the initial products **89a,b** were not detectable by spectroscopy.[15] The reaction of ferriophosphaalkene **21** with fumarodinitrile proceeds completely differently and leads to the insertion product **91**. X-ray structure analysis of the deep violet phosphido complex **91** reveals that the two cyano groups occupy *cis* positions at the C=C bond (Scheme 32).[56b]



Scheme 32. Reactivity of ferriophosphaalkenes towards electron-deficient alkenes. [Fe] = Cp*(CO)$_2$Fe; E = CO$_2$Me (**a**), CN (**b**).

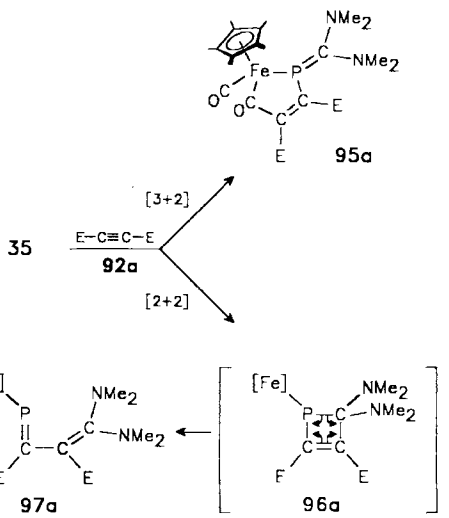
4.1.4.2. Alkynes

The reactivity of metallophosphaalkenes towards carbonyl-activated alkynes is determined largely by the substituents on the reaction partners concerned, as well as by the solvent and by the stoichiometry of the starting materials. There have been no cases of the isolation of *P*-metallo-1,2-dihydrophosphetes, which should result from a formal [2 + 2]cycloaddition. Thus, the reaction of *C*-silylated metallophosphaalkenes **21** or **27** with one equivalent of dimethyl acetylenedicarboxylate **92a** produced the [3 + 2]cycloadducts **93** and **94**, respectively (Scheme 33). In this case, the role of the 1,3-dipole is played by the OC-Fe-P fragment which is polarized negatively on the P atom and positively on the carbonyl carbon atom.[57]



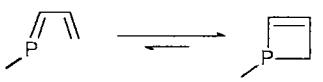
Scheme 33. Reaction of the ferriophosphaalkenes **21** and **27** with dimethyl acetylenedicarboxylate; E = CO$_2$Me; R = Ph: **27**, **94**; R = Me$_3$Si: **21**, **93**.

The metallaheterocycle **95a**, which is analogous to **93** and **94**, however, is only a minor product of the reaction between **35** and **92a**. The main product is the 1-metallo-1-phospha-1,3-butadiene **97a**, which is isolated as a stable, red-brown solid (Scheme 34).[58] The synthesis of **97a** from **35** and the alkyne is plausible if it is assumed that the initial reaction step is a non-concerted [2 + 2]cycloaddition to give 1,2-dihydrophosphete **96a**. The four-membered ring evades spectroscopic detection by spontaneous [2 + 2]cycloreversion to **97a** (Scheme 34).[58] This result is unusual because, as a rule, heterobutadienes with phosphorus fragments can only be isolated if the P=C bond is kinet-



Scheme 34. Reaction of **35** with dimethyl acetylenedicarboxylate. [Fe] = Cp*(CO)$_2$Fe; E = CO$_2$Me.

ically stabilized by bulky substituents.[1a, 59] If there is insufficient steric shielding, the 1-phosphabutadienes spontaneously cyclize to 1,2-dihydrophosphetes. Mathey et al. postulate an equilibrium between 1,2-dihydrophosphetes and 1-phosphabutadienes (Scheme 35). At high temperatures this equilibrium shifts towards the heterodiene, which can be detected by trapping reactions.[60]



Scheme 35. Equilibrium between 1-phosphabutadienes and 1,2-dihydrophosphetes.

In the synthesis of **97a**, however, the reverse reaction from a ring to an acyclic compound was accomplished for the first time, without the resulting heterodiene having particularly bulky substituents.

According to the X-ray structure analysis of **97a** (Fig. 3), the molecule has a cisoid conformation with a localized P=C bond. The C4–C5 and C4–C8 distances are similar and provide evidence for the pronounced delocalization of the C=C bond in the diene moiety of the molecule.

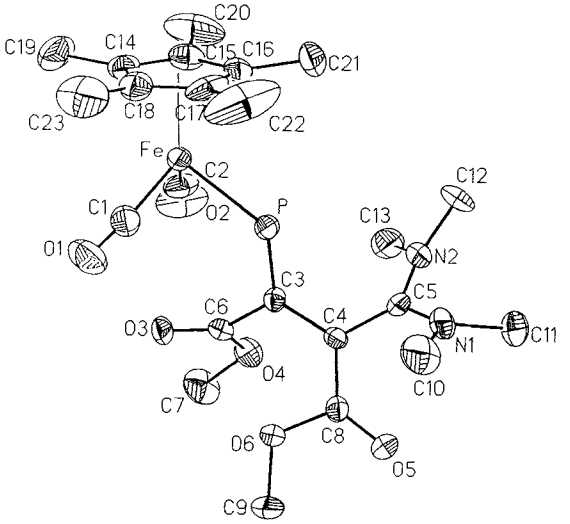


Fig. 3. Crystal Structure of **97a**. Selected bond lengths [Å] and angles [ ]: Fe-P 2.259(2), P-C3 1.688(7), C3-C4 1.451(9), C4-C5 1.427(10), C3-C6 1.513(11), C4-C8 1.428(10); Fe-P-C3 119.3(3).

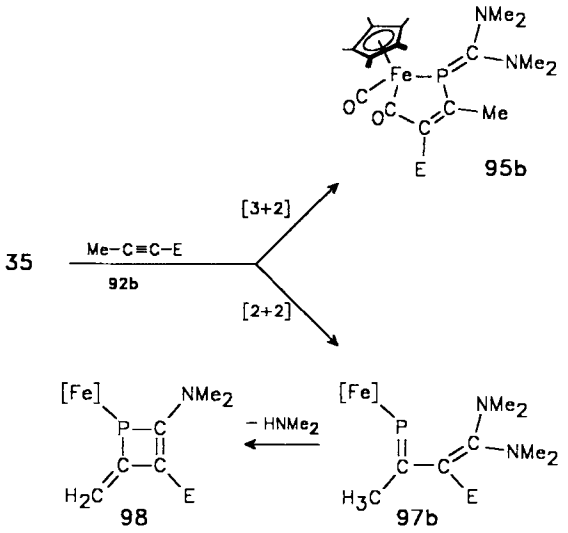
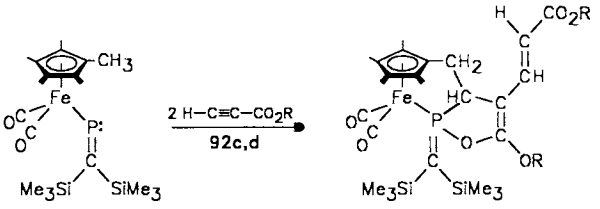
The ferriophosphaalkenes **21** and **27** are not attacked by methyl 2-butynoate (**92b**); however, if equimolar amounts of **35** and **92b** are allowed to react in *n*-pentane, the 1-phosphabutadiene **97b** precipitates as a red-brown solid (42% yield) (Scheme 36). Approximately equal amounts of **95b** and the 2-methylene-1,2-dihydrophosphete **98** can be detected in the mother liquor. In ether or benzene, **97b** cyclizes rapidly to **98** with release of dimethylamine. In keeping with this, treatment of **35** with the alkyne **92b** in ether leads directly to orange microcrystalline **98** as the main product (41% yield).[58]

On the other hand, alkyl propiolates $HC{\equiv}CCO_2R$ behave completely differently towards ferriophosphaalkenes. Compound **21** adds two equivalents of the alkyne in pentane to form the bicyclic, red, crystalline *P*-metallo-ylide **99** (Scheme 37); no intermediates were detected by ^{31}P NMR spectroscopy.[61] For-



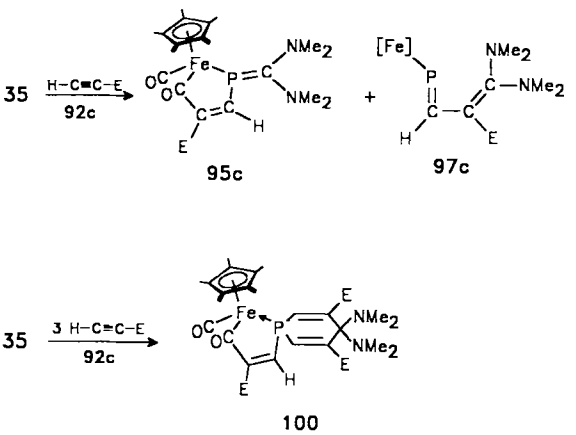
Scheme 36. Reaction of **35** with methyl 2-butynoate. E = CO_2Me. [Fe] = $Cp^*Fe(CO)_2$.



Scheme 37. Reaction of **21** with propiolates. R = Me (**92c**), Et (**92d**).

mation of the product is evidently preceded by the addition of two equivalents of the ester onto the P atom of **21** and a proton transfer from the ring methyl group to the end of the diene chain.[61]

Equimolar amounts of **35** and methyl propriolate (**92c**) react in *n*-pentane to a furnish a mixture of the metallaheterocycle **95c** and the 1-phosphabutadiene **97c** (Scheme 38). The reaction between the ferriophosphaalkene and three molar equivalents of alkyne is more straightforward, here the bicyclic compound **100**

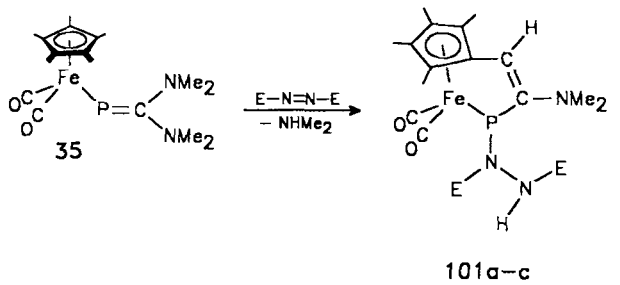


Scheme 38. Reactions of **35** with methyl propiolate. E = CO_2Me; [Fe] = $Cp^*(CO)_2Fe$.

is obtained as the sole product in good yield. It is conceivable that **97c** forms a reactive [4+2]cycloadduct with the second equivalent of **92c** and is then rapidly converted to the final product by the third equivalent of alkyne.[61]

4.1.5. *Azo Compounds*

Azodicarboxylates E–N=N–E induce the intramolecular condensation of a ring-methyl group with the P=C function in the metallophosphaalkene **35** to afford complexes **101a–c** in 48–54% yield (Scheme 39). This reaction is important because this was the first such condensation involving the η^5-C_5Me_5 ligand. An essential advantage of this ring ligand in its complexes, along with its donating ability and bulk, is its pronounced reluctance to chemical transformations.[62]



Scheme 39. Treatment of **35** with azodicarboxylates. E = CO_2Et (**a**), CO_2tBu (**b**), CO_2CH_2Ph (**c**).

The X-ray structure analysis of **101b** (Fig. 4) reveals that the η^5-ring ligand is additionally bonded to the metal atom by a

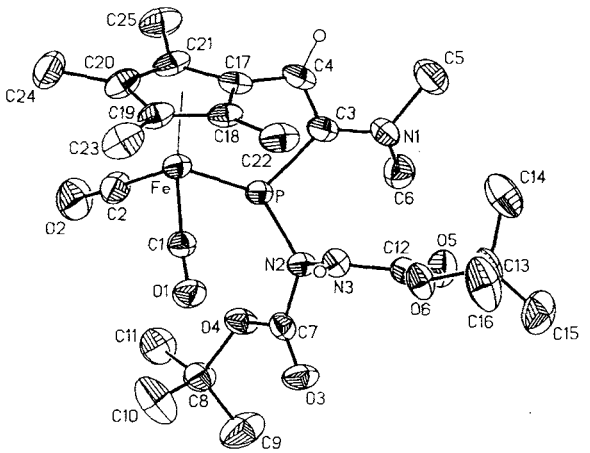


Fig. 4. Crystal Structure of **101b**. Selected bond lengths [Å] and angles [ ]: Fe-P 2.307(2), P-C3 1.843(5), P-N2 1.781(5), C3-C4 1.338(9); Fe-P-C3 102.1(2), P-C3-C4 113.3(4), P-C3-N1 121.4(5), N1-C3-C4 124.7(5).

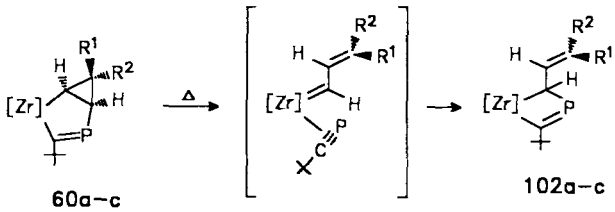
C=C–P chain. The C3–C4 distance of 1.338(9) Å corresponds to a double bond. The trigonal pyramidally surrounded phosphorus atom also bears a hydrazido substituent (N2–N3 1.399(6) Å).[62]

4.2. Reactivity of the Metallophosphaalkenes of Type II and III

4.2.1. *Rearrangement of Phosphametallabicyclohexenes*

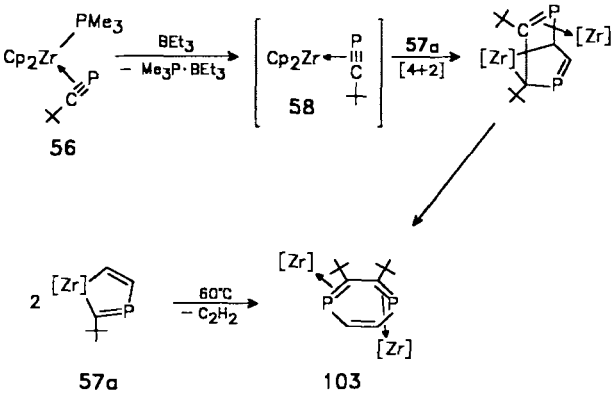
If the phosphazirconiabicyclic compounds **60a–c** are heated in toluene to 60 °C, they undergo ring opening to generate unstable vinylcarbene complexes. Subsequent "dimerization" of the carbene–metal fragment with the phosphaalkyne ligand produces four-membered rings of the type in compound **102**, which also show structural properties of C-metallophosphaalkenes (Scheme 40). The corresponding titanium derivatives are also accessible.[32]



Scheme 40. Thermal rearrangement of the bicyclic compounds **60a–c**. [Zr] = Cp_2Zr; **a**: $R^1 = R^2$ = Me (89%), **b**: $R^1 = R^2$ = Ph (97%), **c**: R^1 = Me, R^2 = Ph (64%).

4.2.2. *Thermolysis of the Phosphazirconiacyclopentadiene 57a*

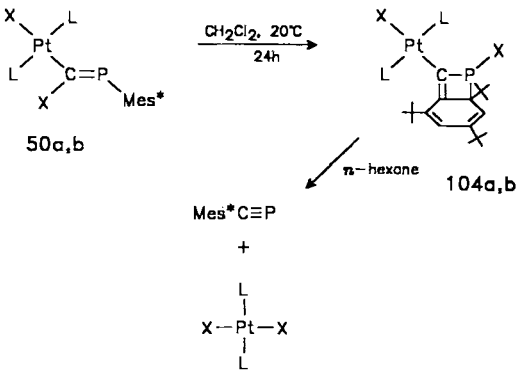
On warming a yellow solution of **57a** in toluene to 60 °C, it changes color to deep red over a period of 72 h with formation of the 1,4-diphosphinine complex **103** (92% yield) (Scheme 41).[32] The same product arises almost quantitatively from an equimolar mixture of **57a**, **56**, and BEt_3 on warming from −78 °C to 20 °C.[32]



Scheme 41. Synthesis of a (1,4-diphosphinine)dizirconium complex. [Zr] = Cp_2Zr.

4.2.3. *Thermolysis of C-Platiniophosphaalkenes*

The metallophosphaalkenes **50a,b** rearrange at 20 °C in dichloromethane within 24 h to the bicyclic compounds **104a,b** which can be isolated without decomposition from the polar solvent (Scheme 42). In *n*-hexane, however, the products rapidly decompose to Mes*C≡P and *trans*-$[Pt(PEt_3)_2X_2]$.[28c]

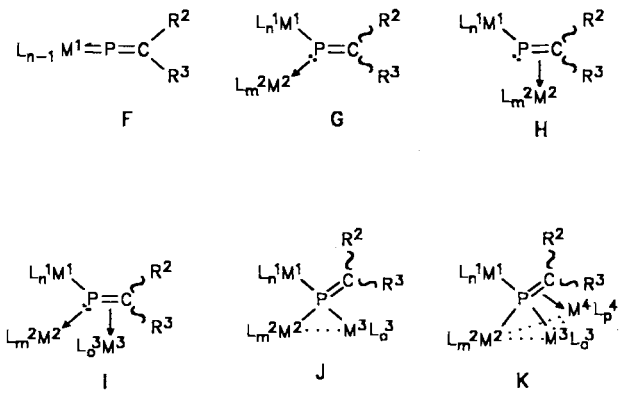


Scheme 42. Intramolecular cyclization of *C*-platiniophosphaalkenes **50a,b**. L = PEt_3; X = Cl (**a**), Br (**b**).

5. Coordination Chemistry of Metallophosphaalkenes

5.1. *P*-Metallophosphaalkenes as Ligands

Akin to their organo-substituted prototypes, the metallophosphaalkenes $L_nMP{=}CR^2R^3$ (type I) can also act as ligands in transition metal complexes. In principle, the coordination modes **G**–**K** are conceivable. (Scheme 43).

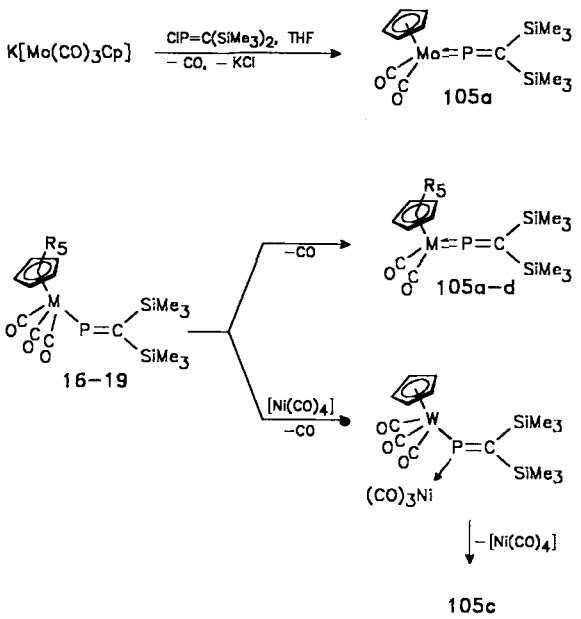


Scheme 43. Coordination modes of metallophosphaalkenes in transition metal complexes.

The metallophosphaalkenes of the four other structural types (II–V) should show comparable ligand properties. In contrast to the coordination behavior of conventional phosphaalkenes, it is possible for the lone pair of electrons on the phosphorus atom in *P*-metallophosphaalkenes to displace a loosely bound two-electron donor (2e donor) intramolecularly from the metal, so that the organophosphorus fragment becomes a 3e ligand. Similar behavior is known from phosphido and phosphenium ligands PR_2,[63] and, of course, from NO ligands. In the case discussed here, phosphavinylidene complexes **F** are formed.

5.1.1. Phosphavinylidene Complexes (Type F)

This type of complex is known with molybdenum, tungsten and nickel; the first, the complex **105a**, was obtained from the reaction of $K[Mo(CO)_3Cp]$ with $ClP{=}C(SiMe_3)_2$ in THF (Scheme 44).[64]

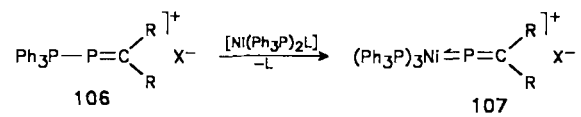


Scheme 44. Syntheses of phosphavinylidene complexes of molybdenum and tungsten. **a**: M = Mo, R = H; **b**: Mo, Me; **c**: W, H; **d**: W, Me.

The metallophosphaalkenes **16**–**19** undergo thermal decarbonylation in solution to give the phosphavinylidene complexes **105a**–**d** (Scheme 44). The reaction conditions required for the cleavage of the CO ligand depend on the stability of the metal–CO bond as well as on the substituents on the phosphaalkenyl fragment. Accordingly, cleavage of CO from the molybdeniophosphaalkenes **16** and **17** in nonpolar solvents commences at room temperature, whilst the formation of the tungsten derivatives **105c,d** requires several hours reflux in benzene. For the ferriophosphaalkene **21** as well as for the phenyl-substituted metallophosphaalkenes **22**–**27**, elimination of CO to form phosphavinylidene complexes is not observed under thermal nor under photochemical conditions.[10]

Abstraction of CO can also be carried out chemically. Thus, the adduct obtained from **18** and nickel tetracarbonyl at low temperatures rapidly decomposes in solution at 20 °C to afford **105c** and $[Ni(CO)_4]$ (Scheme 44).[10]

An interesting route to the (phosphavinylidene)nickel cation **107** is based on the treatment of $[Ni(PPh_3)_2(cod)]$ with triphenyl(phosphaalkenyl)phosphonium ion **106** (Scheme 45). No intermediates were detected by spectroscopy.[65]

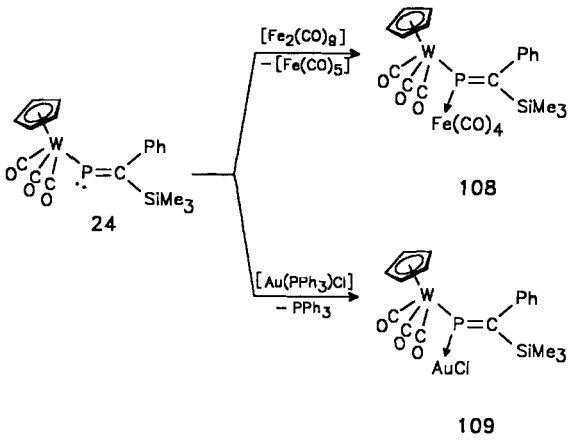


Scheme 45. Synthesis of a (phosphavinylidene)nickel complex. L = 1,5-cyclooctadiene, R = Me_3Si, X = $AlCl_4$.

5.1.2. Metallophosphaalkenes as η^1 Ligands (Type G)

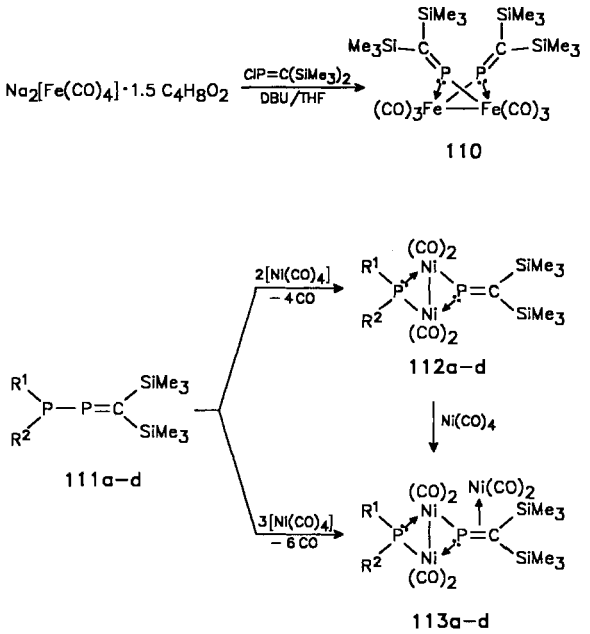
Transition metal complexes with η^1-metallophosphaalkene ligands of type **G** are formally divided into those without metal–metal interactions (e.g. **108** and **109**) and those with **M**–**M** bonding (e.g. **110** and **112**). The former usually arise from

the treatment of metallophosphaalkenes, for example **24**, with transition metal complexes containing labile ligands (Scheme 46).[110]



Scheme 46. *P*-Metallophosphaalkenes as η^1-ligands without M–M bonds.

The preparation of the dinuclear complex **110** with an Fe–Fe bond was carried out by the reaction of $ClP{=}C(SiMe_3)_2$ with excess $[Na_2Fe(CO)_4]\cdot 1.5$ dioxane in the presence of diazabicycloundecene (Scheme 47).[66]

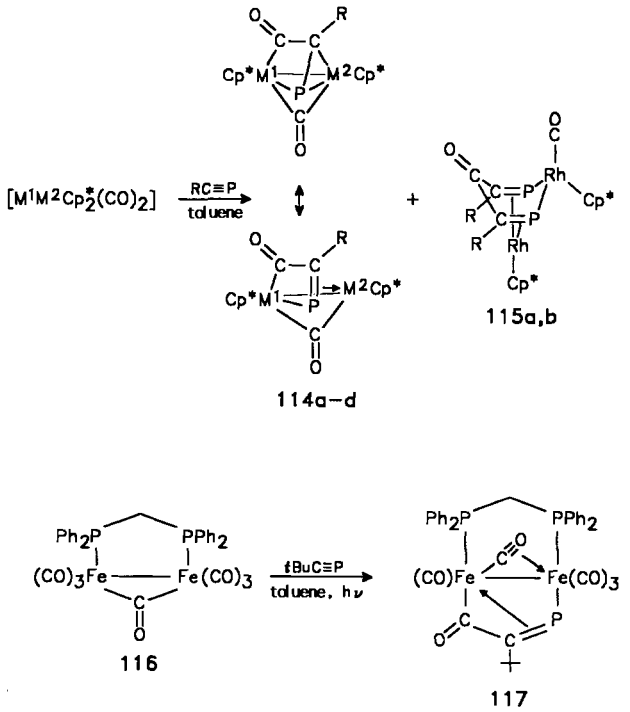


Scheme 47. *P*-Metallophosphaalkenes as η^1-ligands with M–M bonds. **a**: $R^1 = R^2 = c\text{-}C_6H_{11}$; **b**: *t*Bu; **c**: Me_3Si; **d**: $R^1 = t$Bu, $R^2 = Me_3Si$.

Dinuclear carbonylnickel complexes **112a–d** with μ-phosphaalkenyl and μ-phosphido ligands result from the treatment of 1,2-diphosphapropenes **111a–d** with two molar equivalents of $[Ni(CO)_4]$ (Scheme 47). If a larger excess of nickel carbonyl is added, the trinuclear species **113a–d** are formed in which the P=C bond also acts as a π donor. Compounds **112a–d** also react directly with $[Ni(CO)_4]$ to give **113a–d**.[67] Derivatives of type **112** are also known with iron and molybdenum centers.[67]

5.1.3. *P*-Metallophosphaalkenes as η^2 Ligands (Type H)

Compounds containing a metallophosphaalkene with this mode of coordination usually arise from peripheral reactions of phosphaalkynes with transition metal complexes. For example, the reaction of $[Cp^*_2(CO)_2Rh_2]$ or $[Cp^*_2(CO)_2CoRh]$ with *t*BuC≡P readily affords the complexes **114** (Scheme 48).[68, 69] Complex **115a** is formed as a side-product and can be regarded as a metallodiphosphadiene which is additionally π-bound through both C=P functions to a Cp*Rh fragment. The reaction of $[Cp^*_2(CO)_2Rh_2]$ with AdC≡P proceeds similarly.

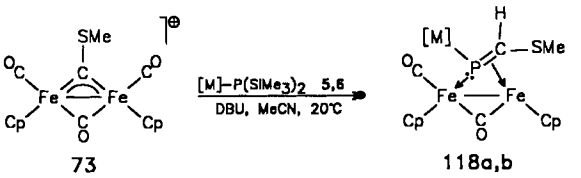


Scheme 48. Metallophosphaalkenes as η^2 ligands; **a**: $M^1 = M^2 = Rh$, R = *t*Bu; **b**: $M^1 = M^2 = Rh$, R = 1-adamantyl; **c**: $M^1 = Rh$, $M^2 = Co$, R = *t*Bu; **d**: $M^1 = Co$, $M^2 = Rh$, R = *t*Bu.

A mode of coordination similar to that present in **114** is encountered in the dinuclear iron complex **117**, which is produced by the photolysis of **116** in the presence of *t*BuC≡P (Scheme 48).[70]

5.1.4. Metallophosphaalkenes as η^1:η^2 Ligands (Type I)

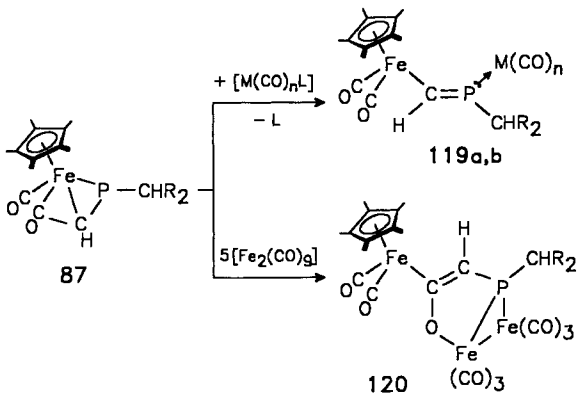
It appeared reasonable to extend the principle of synthesis for *C,C*-dimetallophosphaalkenes, outlined in Scheme 24, to the preparation of *C,C,P*-trimetallophosphaalkenes $[[M^1]{-}P{=}C{-}([M^2])[M^3]]$ (type V, Scheme 2). Condensation of the cation **73** with metallodisilylphosphanes **5** or **6** gave, instead of the expected threefold functionalized phosphaalkenes, the trinuclear complexes **118a** and **118b**, respectively, in which the η^1:η^2-metallophosphaalkene ligand bridges the $[Fe_2Cp_2(CO)(\mu\text{-}CO)]$ skeleton (Scheme 49). Compound **118a** can also be obtained from the reaction of $[FeCp^*(CO)_2(PH_2)]$ and **73** under analogous conditions.[71]



Scheme 49. Synthesis of complexes with η^1:η^2-metallophosphaalkene ligands; **a**: [M] = Cp*(CO)$_2$Fe; **b**: [M] = Cp*(CO)$_2$Ru.

5.2. Miscellaneous

Metallophosphaalkenes of type II and IV (Scheme 2) can also function as ligands in transition metal complexes. For example, the η^1 complexes **119** containing a *C*-metallophosphaalkene ligand are obtained from the action of thermolabile carbonylmetal complexes such as [Cr(cyclooctene)(CO)$_5$][72] or [Fe$_2$(CO)$_9$][73] on compound **87** (Scheme 50). However, if **87** or **119b** is treated with excess [Fe$_2$(CO)$_9$], the trinuclear complex **120** is isolated, which has a formal μ_3-1-oxa-4-phosphabutadiene ligand.[73]

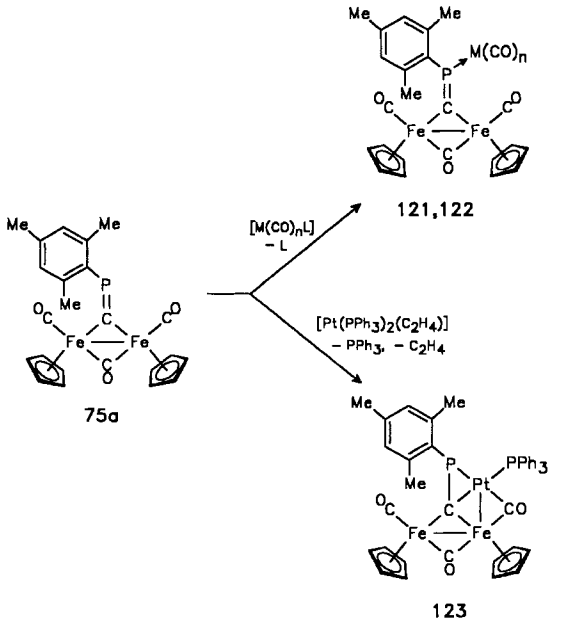


Scheme 50. Reaction of **87** with carbonylmetal complexes. R = Me$_3$Si; **a**: L = cyclooctene, M(CO)$_n$ = Cr(CO)$_5$; **b**: L = Fe(CO)$_5$, M(CO)$_n$ = Fe(CO)$_4$.

The coordination mode which the dimetallophosphaalkene **75a** displays towards transition metal fragments is controlled by the nature of the complex building unit. The reaction with equimolar amounts of [Cr{(*Z*)-cyclooctene}(CO)$_5$] or [Fe$_2$(CO)$_9$] leads to the black-brown microcrystalline compounds **121** and **122**, respectively (Scheme 51). In complex **123**, obtained from the treatment of **75a** with [Pt(PPh$_3$)$_2$(η^2-C$_2$H$_4$)], the dimetallophosphaalkene can be described as a η^3-1-phospha-3-ferraallyl ligand bound to a [Pt(PPh$_3$)] fragment.

The X-ray crystal structure analysis of **123** (Fig. 5) reveals that the molecular framework of **75a** has remained largely intact. The trigonal-planar surrounded donor site C(12) (sum of angles = 359.2°) symmetrically bridges the iron atoms. The P=C bond is elongated to 1.737(10) Å on account of π coordination to the Pt atom. In order to saturate its coordination, the platinum atom also bonds to Fe(1) and C(13). Alternatively, the framework can be regarded as an *arachno* cluster of atoms Pt(1), P(2), C(12), Fe(1), and C(13).[36]

The complex anions **125a–d**, which arise from the reaction of carbonylhydridometalates **124a–d** with equimolar amounts of *t*BuC≡P (Scheme 52), contain a μ_3-η^2-phosphaalkyne ligand,



Scheme 51. The *C*,*C*-Diferriophosphaalkene **75a** as a ligand in Cr, Fe, and Pt complexes. **121**: M(CO)$_n$ = Cr(CO)$_5$, L = cyclooctene; **122**: M(CO)$_n$ = Fe(CO)$_4$, L = Fe(CO)$_5$.

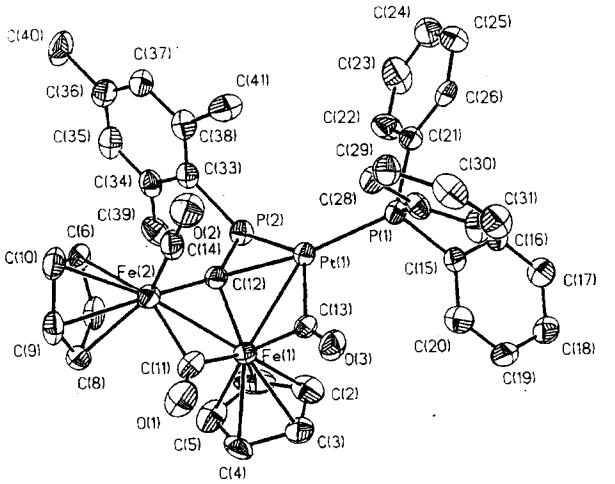


Fig. 5. Crystal Structure of **123**. Selected bond lengths [Å] and angles [°]: Pt1-Fe1 2.577(2), Pt1-P1 2.240(2), Pt1-P2 2.471(2), Pt1-C12 2.162(9), Pt1-C13 1.997(2), Fe1-C13 1.951(9), P2-C12 1.737(10), Fe1-Fe2 2.518(4); Fe1-C12-P2 130.6(5), Fe2-C12-P2 146.5(5), Fe1-C12-Fe2 82.1(4).

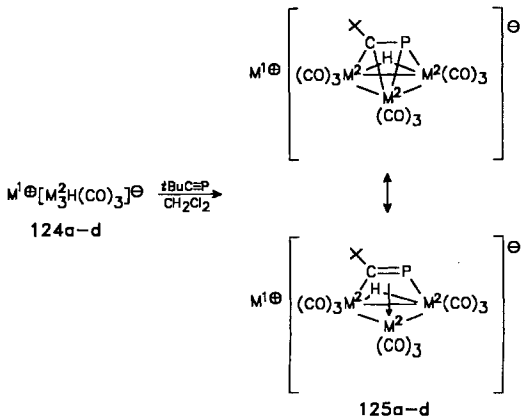
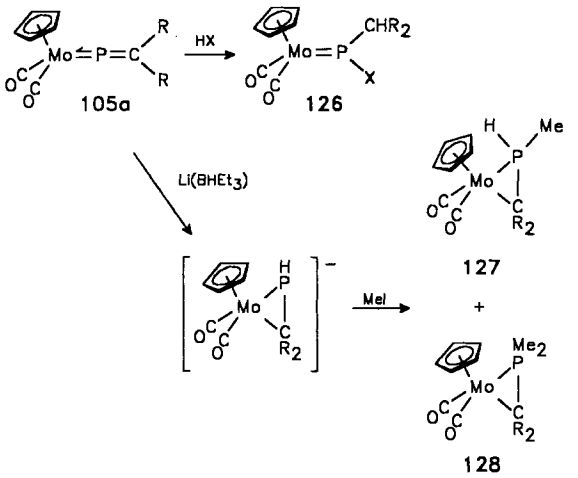


Scheme 52. Complex anions with a *C*,*P*-dimetallophosphaalkene as a η^2-ligand. **a**: M^1 = PPh$_4$, M^2 = Fe; **b**: M^1 = (Ph$_3$P)$_2$N, M^2 = Ru; **c**: M^1 = Na, M^2 = Ru; **d**: M^1 = NEt$_4$, M^2 = Ru.

which unsymmetrically spans the metal triangle. Alternatively, these anions may also be regarded as *C,P*-dimetallophosphaalkenes in which the C=P bond maintains a π interaction with a third metal atom.[74]

6. Chemical Properties of Phosphavinylidene Complexes

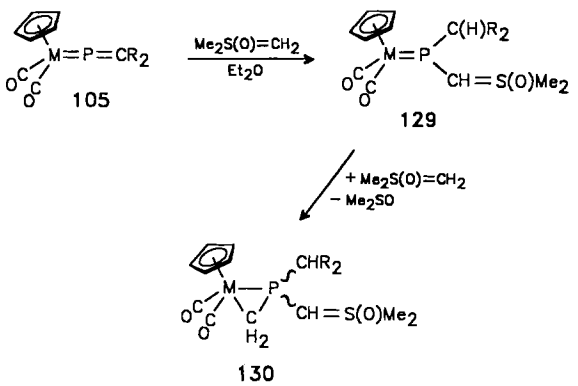
In agreement with the polarization $P^{\delta+}-C^{\delta-}$ of the P=C bond in the molybdenumphosphavinylidene complex **105a**, protic substances, HX, add regioselectively to the double bond to form the phosphenium complexes **126** (Scheme 53).[44b] The



Scheme 53. Reactions of **105a** with proton and hydride donors. R = Me_3Si; X = EtO, Me_2N, C_6F_5S.

behavior of **105a** towards the hydride donor $Li(BHEt_3)$ is explained similarly. If a solution of the phosphavinylidene complex is treated with one equivalent of $Li(HBEt_3)$ and subsequently with excess methyl iodide, heterocycles with three-membered rings, **127** and **128**, are produced. Here, hydride attack on the phosphorus atom of **105a** plays the key role.[75]

Equimolar amounts of the phosphavinylidene complexes **105a** or **105c** and the sulfur ylide $Me_2S(O)=CH_2$ in ether react to form the phosphenium complexes **129** (Scheme 54), which



Scheme 54. Reaction of phosphavinylidene complexes of molybdenum and tungsten with $Me_2S(O)=CH_2$. M = Mo, W.

are isolated as brick red solids in yields of about 70%. Evidently, the addition of the carbanionic ylide center onto the P atom is accompanied by a rapid transylidation. A second ylide molecule subsequently "cyclopropanizes" the M=P bond to yield the metallaheterocycle **130**.[76]

7. Summary and Future Prospects

This review demonstrates that the chemistry of metal-functionalized phosphaalkenes has developed rapidly in recent years. In the beginning the interest focused on the synthesis and structural elucidation of such complexes. Ever increasingly it has shifted towards the reactivity of these compounds which are to be found in the border regions of organophosphorus, organometallic, and complex chemistry.

The combination of electrophilic and nucleophilic centers on the P=C unit as well as on the organometallic fragment makes metallophosphaalkenes versatile reaction partners, and we have only just begun to explore the great richness of their chemistry.

The possibilities for the synthesis of metallophosphaalkenes with their structural variations are by no means exhausted. Novel reactive compounds, such as the recently discovered phosphane-stabilized methylenediylphosphenium salts ($(Ph_3P-P=CR_2)X$) continually lead to novel metallophosphaalkenes. Even phosphaalkynes, which are in the meantime so well-known, serve further as a valuable source for the synthesis of metallophosphaalkenes. Metallophosphaalkenes play a key role as intermediates in the metal-mediated oligomerization of phosphaalkynes to phosphorus–carbon heterocycles and cages. The understanding of the chemical properties of metallophosphaalkenes not only casts light onto such oligomerization processes, but also should be an aid in the planning of efficient syntheses.

In future, along with purely preparative considerations, physico-chemical investigations will make an important contribution to this field, in particular, electrochemical, kinetic, and mechanistic studies, as well as theoretical calculations. Application-orientated aspects such as polymerization and copolymerization of suitably substituted derivatives are also waiting to be discovered.

I would like to thank all my coworkers who have contributed with great commitment to the development of this field. Their names can be found in the literature citations. I owe many thanks to Professors E. Niecke (Bonn) and W. W. Schoeller (Bielefeld) for helpful discussions. I thank Mrs M. Schimmel for writing up the manuscript. Much of the cited work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the companies BASF AG, Ludwigshafen, and DEGUSSA AG, Hanau.

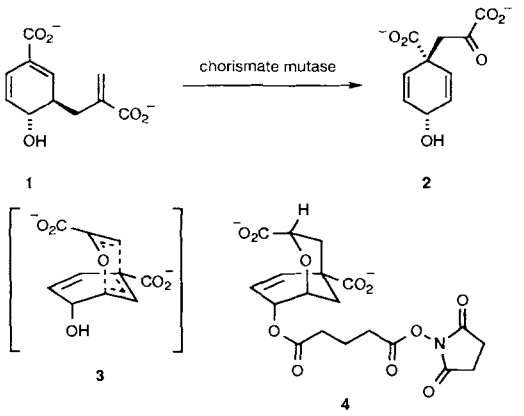
Pericyclic Reactions in Biological Systems—Does Nature Know About the Diels–Alder Reaction?

Sabine Laschat*

Pericyclic reactions, that is one-step processes that proceed through cyclic transition states under control of orbital symmetry, represent an import tool for the synthetic organic chemist. A large number of pericyclic key steps also occurs in biological systems.[1] The classical example, which led Woodward and Hoffmann to establish the rules of conservation of orbital symmetry, is the formation of vitamin D_3 from 7-dehydrocholesterol by a photochemically induced, conrotatory cycloreversion of the steroid B-ring, followed by a thermally allowed [1,7]sigmatropic H-shift. Claisen rearrangements are also found in natural systems. The [3,3]sigmatropic Claisen rearrangement of chorismic acid (**1**) to prephenic acid (**2**), which is catalyzed by the enzyme chorismate mutase, can be considered as the key step in the biosynthesis of aromatic compounds, that is the so-called shikimic acid pathway. The chairlike transition state geometry **3** was confirmed by double isotope labeling experiments.[2]



1 **2** **3** **4**

However, in the laboratory this particular reaction can be accelerated not only by enzymes but also by catalytic antibodies.[3] For the generation of such antibodies haptens such as **4** were used, that is, molecules whose structure is very similar to the transition state of the particular reaction and which at the same time are tightly bound by the antibody.

However, pericyclic reactions in natural systems do not necessarily require the participation of an enzyme. Several reactions proceed spontaneously, for example the above-mentioned 1,7-H shift in the biosynthesis of vitamin D_3. Recently Boland et al. reported that the ectocarpenes **6** and related substances, which were isolated from the brown algae *Ectocarpus siliculosus*, are not the sexual pheromones of the algae but that these cycloheptadienes **6** are formed from the actual pheromones, namely the thermolabile *cis*-divinylcyclopropanes **5**, by a spontaneous Cope rearrangement.[4] Thus, the Cope rearrangement of **6** resembles a deactivation pathway of the pheromones **5**.

5 R = H, Et, $CH=CH_2$ **6**

Diels–Alder reactions have been postulated as key steps in a number of biosynthetic conversions. The biosynthesis of the endiandric acids **13** and **14** is discussed below as an example for

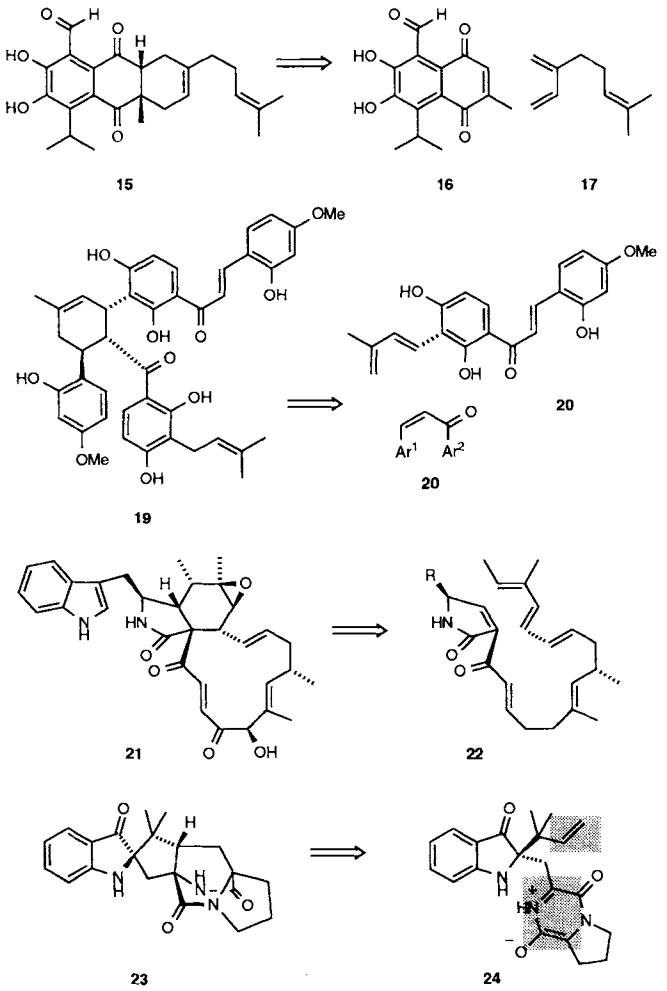
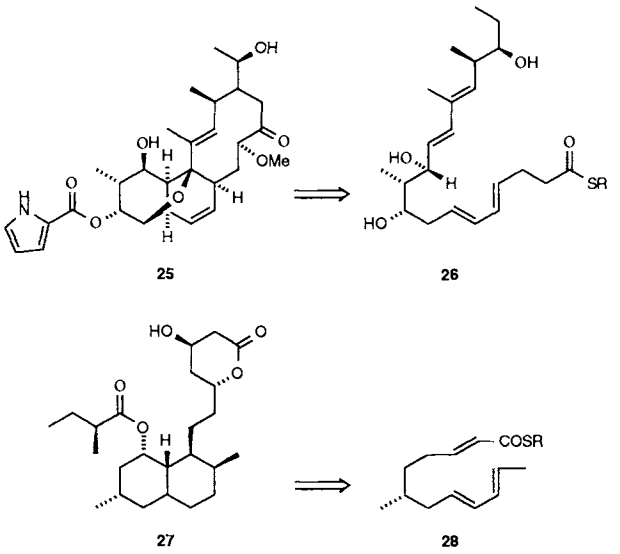
a spontaneous [4 + 2]cycloaddition. This class of compounds which is produced by the Australian plant *Endiandra introsa (Lauraceae)* is remarkable, because different constitutional isomers were formed simultaneously and in all cases racemic mixtures were synthesized by the plant. It was first postulated by Black et al.[5] and later confirmed by biomimetic total syntheses by Nicolaou et al.[6] that the endiandric acids A, B, and C (**13a**, **13b**, and **14**, respectively) are formed by a cascade of electrocyclic reactions. The cascade is initiated by a conrotatory 8π-electron ring closure of the polyene carboxylic acids **7** and **8** to the isomeric cyclooctatrienes **9** and **10**, respectively, which subsequently undergo a disrotatory 6π-electron cyclization to **11** and **12**, respectively. Termination of the cascade by an intramolecular Diels–Alder reaction yields either the tetracyclic endiandric acids **13a**,**b** or the bridged derivative **14**.

Besides those spontaneous processes a variety of [4 + 2]-cycloadditions exists for which it still remains unclear whether they are Diels–Alder reactions and if so, whether they proceed spontaneously or only in the presence of an enzyme.[7] In this respect the stereospecific synthesis of the sesterpenoid heliocide H_2 (**15**), an insecticide isolated from cotton wool, from hemigossypolon (**16**) and myrcene (**17**)[8, 9] should be mentioned. Other examples of biomolecules that are probably formed by Diels–Alder reactions include the chalcone kuwanon J (**19**) from the mulberry tree *Morus alba L.*, the mycotoxins chaetoglobosin A (**21**)[11] and brevianamide A (**23**),[12]





the polyketide nargenicin (**25**),[13] and mevinolin (**27**), a metabolite of the fungus *Aspergillus terreus* MF4845, which is used as a drug for reducing the blood cholesterol level.[14] However, until now there is no case known where the corresponding enzyme system, that is the Diels–Alder-ase, could be detected. Even in the biosynthesis of the iboga and aspidosperma alkaloids the final proof for a Diels–Alder reaction is still missing.[15] In 1970 Scott et al. were able to elucidate nearly the whole biosynthetic pathway by feeding experiments with plant seedlings.[16] According to Scott et al. isovincoside (**29**) is converted to stemmadenine (**30**) in several steps. Heterolytic ring opening and concomitant dehydration leads to the postulated intermediate dehydrosecodine **31**. Starting from the acrylic ester **31** two [4 + 2]cycloadditions are possible. If the 2-dehydropyridine system of **31** reacts as a dienophile, the aspidosperma alkaloid tabersonine (**32**) is formed, whereas participation of the 2-dihydropyridine moiety as a diene leads to the iboga alkaloid

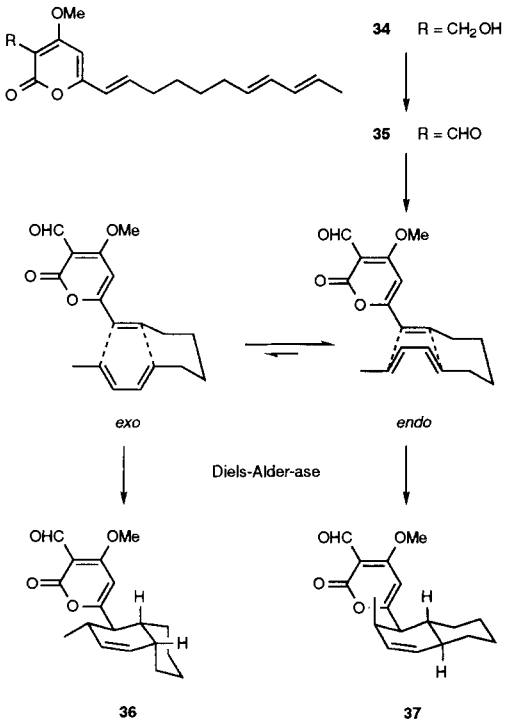
catharanthine (**33**). The reversibility of the reactions led the authors to assume stepwise Michael additions.

In view of the difficulties in detecting and isolating Diels–Alder-ases, one might assume that there are no enzyme-catalyzed [4 + 2]cycloadditions involved in natural systems. However, this assumption seems to be incorrect. Recently Oikawa, Ishihara et al. published experimental evidence that the solanapyrones **36** and **37**, two phytotoxins produced by the



pathogenic fungus *Alternaria solani*, are probably formed by enzyme-catalyzed [4 + 2]cycloadditions.[17] Treatment of prosolanapyrone III (**35**) with a cell-free extract of *A. solani* at 30 °C for 10 min yielded a mixture of **36** and **37** (25% conversion) with an *exo*/*endo* ratio of 53:47. In the absence of the cell-free extract under the same conditions the aldehyde **35** undergoes an uncatalyzed Diels–Alder reaction to **36** and **37** (15% conversion) with an *exo*/*endo* ratio of 3:97.[18] Treatment of **35** with the denatured cell-free extract yielded likewise an *exo*/*endo* ratio of 3:97 (10% conversion). Thus, the enzyme-related conversion is about 15% and the *exo*/*endo* ratio 87:13 (>92% *ee* for **36**). The high *exo* selectivity is remarkable, because it cannot be achieved by chemical methods. It should be emphasized, however, that in the above-mentioned investigations no isolated enzymes were used but a cell-free extract. Thus the postulated Diels–Alder mechanism needs to be further confirmed by characterization of the enzyme or enzyme complex. The biosynthesis of the solanapyrones **36** and **37** shows an additional feature worthy of mention. Whereas the alcohol prosolanapyrone II (**34**) does not form any cycloaddition products in aqueous medium without any catalyst, the presence of the cell-free extract induces the production of 19% of the solanapyrones **36** and **37** (*exo*/*endo* 85:15) and 6% of the aldehyde **35**. Apparently, the Diels–Alder-ase is accompanied by a dehydrogenase which catalyzes the oxidation of **34** to **35**. Further studies with isolated enzymes are required to investigate whether these are separated enzymes or coupled in an enzyme complex. However, in light of these results further biosynthetic pathways for which Diels-Alder reactions will be found and the isolation of the corresponding enzymes are eagerly awaited in the near future.

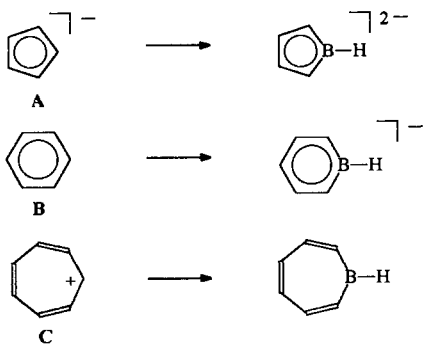
Boron-Substituted Heterocycles as π-Donors in Organometallic Chemistry—A Sandwich Complex with 1-*H*-Boratabenzene and Lithium

H. Nöth* and Martin Schmidt

Since the discovery of ferrocene, aromatic π-donor ligands have become an indispensible part of organometallic chemistry. In particular, complexes with cyclopentadienyl ions and benzene, as well as with the derivatives of these ligands, revolutionized the coordination chemistry of the transition metals.

Far less thoroughly studied is the chemistry of the heterocyclic, isoelectronic analogs of these compounds. If, for example, a CH fragment in a cyclopentadienyl ion **A** is replaced by an isoelectronic and isolobal BH^- group, the result is the borole(2−) anion (Scheme 1). Just like Cp^-, it is a 6-π electron



Scheme 1. The replacement of CH units by BH^- groups.

donor. Analogously, replacement of a CH fragment in benzene **B** by a BH^- group affords the boratabenzenes. An expansion of this substitution pattern leads to the formulation of the electroneutral borepine,[1] derived from the tropylium ion **C**, as an aromatic π-donor. Of course, this replacement need not be restricted to only one CH fragment, but can be extended in all cases.[2]

Metal complexes prepared with boron-substituted heterocycles containing a hydrogen substituent at the boron atom are in the minority. The most common examples contain amino or phenyl substituents in this positon. The examples **D**–**F** represent an arbitrary selection of the different sized heteroring systems.[3–5] As in the metal complexes of the congeners **A**–**C**, the aromatic character of the boron-substituted ligands is detected, inter alia, by the experimentally confirmed planarity of the rings.

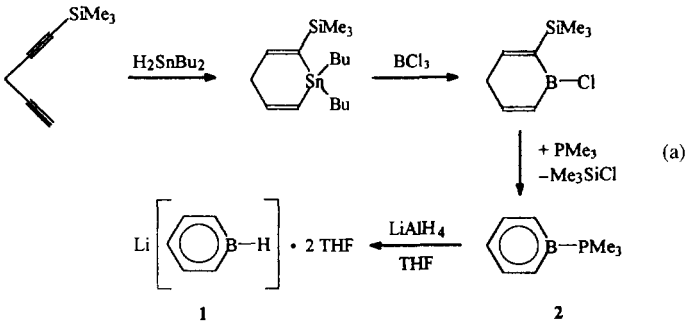
The replacement of a CH fragment by an isoelectronic BR^- group is accompanied by an increase in the electron density in the π-electron system of the ligands. Such electron-rich species should thus be particularly suitable for coordination to electron-poor metal centers of the transition metal elements, as well as to alkali or alkali earth metals. In contrast to cyclopentadienyl compounds of the alkali and alkali earth metals, several representatives of which have been characterized and structurally analyzed,[6,7] only a few complexes of these metals with benzene are known. Infrared spectroscopic studies by L. Andrews et al. on $Li(C_6H_6)$ and $Li(C_6H_6)_2$ in an argon matrix showed that the sandwich structure typical of the transition metal complexes with aromatic ligands is also adopted with alkali metals and, in particular, with lithium (Scheme 2).[8]

Scheme 2. The structures of $Li(C_6H_6)$ and $Li(C_6H_6)_2$ as determined by IR spectroscopy.

Fu et al. have now succeeded in synthesizing the boratabenzene compound $Li_2[H_5C_5BH]_2 \cdot 4THF$ (**1**), which besides $Fe[H_5C_5BH]_2$ prepared by Ashe et al.[9] is the second derivative of a boratabenzene containing a hydrogen substituent at the boron atom and the only example that has been characterized by X-ray crystallography.[10] The synthesis of **1** is based on a prescription by Paetzold et al. for the corresponding pyridine derivative.[11] Fu et al.'s route proceeded via the accessible PMe_3 adduct of borabenzene (**2**) according to Equation (a).



As the X-ray analysis indicates, **1** is a dimer incorporating four THF molecules (Fig. 1). Two boratabenzene ions coordinate to the lithium ion in a sandwich structure. The lithium ion lies on a crystallographic inversion center: the boron atoms of the ligands are therefore as far apart as possible. The second lithium ion, which compensates for the negative charge of the sandwich anion, is separated from the sandwich anion by four THF donor solvent molecules.

The lithium ion in the anion of **1** does not lie in the center above or below these two ring planes. The two boratabenzene anions are shifted relative to each other in such a way that the lithium ion is closest to the carbon atom *para* to the boron

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3503-0292 $ 10.00+.25/0

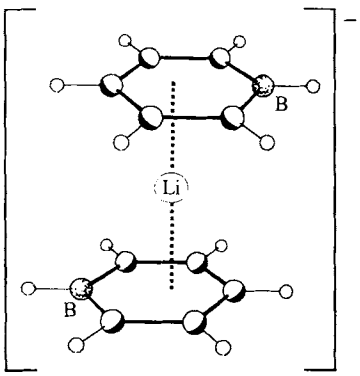


Fig. 1. Crystal structure of the anion in **1**.

atoms. This distance is 2.413(3) Å, whereas the B–Li distance is 2.474(4) Å. The B–Li distance is shorter than that in $[Li\{Me_2NC_2H_4NMe_2\}][H_5C_5B(NMe_2)]$, studied by Herberich et al.[12] In this compound the π-symmetric orbital at the boron atom interacts strongly with the lone electron pair of the N atom. This compound can therefore be better described as a η^5-cyclohexadienyl complex.

In **1** the distance between the lithium ion and the ring planes is comparable with those found in other lithocene derivatives; for example in $[Cp_2Li]^-PPh_4^+$ it is 1.98 Å.[13]

Fu et al. were recently also able to structurally analyze the PMe_3 adduct of borabenzene (**2**, Fig. 2).[14] As in the previously characterized pyridine adduct,[11] the boron-containing heterocycle is planar. Just as in the anionic boratabenzene and dictated by the different covalent radii of boron and carbon, the ring geometries cannot be described by a regular hexagon. The differences between corresponding bond parameters of **1** and **2** are, however, only slight.

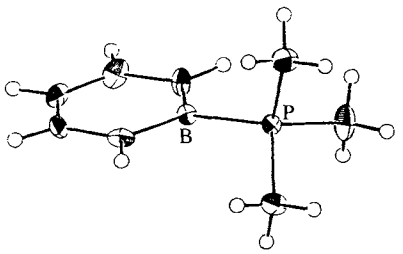

Fig. 2. Crystal structure of **2**.

With the synthesis of **1** Fu et al. advanced both the organometallic chemistry of the alkali metals and organoboron chemistry. This important contribution can give new impetus to both these fields of inorganic chemistry. Compound **1** will also be a challenge to theoreticians to study the coordination behavior of boron-substituted heterocycles theoretically.[15] Perhaps one day the stabilization of solvent-free borabenzene by coordination to metal centers, which has still not been accomplished, will also be achieved.

Synthesis and Structure of the First Cyclopentadienyl(halogeno)metal(VI) Complex of the Chromium Triad $[(\eta^5\text{-}C_5Me_5)WF_5]$**

Katrin Köhler, Axel Herzog, Alexander Steiner, and Herbert W. Roesky*

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

The development of transition metal complexes with one cyclopentadienyl ligand and halogeno ligands is of great interest, since these compounds can be used as readily accessible precursors in the synthesis of numerous organometallic compounds containing metals in both low and high oxidation states.[1] Since the discovery of the pentamethylcyclopentadienyl-substituted metal chlorides $[Cp^*MoCl_4]$[2] and $[Cp^*WCl_4]$[3] ($Cp^* = \eta^5\text{-}C_5Me_5$), many monocyclopentadienyl compounds of molybdenum and tungsten have been prepared in which the metal atoms are present in the formal oxidation states +III and +V. The synthesis of compounds containing molybdenum in the rarely observed +IV oxidation state was only achieved very recently.[4–6]

We report herein on the synthesis of the first fluorinated pentamethylcyclopentadienyltungsten complexes $[Cp^*WF_4]$ **1**, $[(\eta^5\text{-}C_5Me_4Et)WF_4]$ **2**, $[Cp^*WF_4(thf)]$ **3**, and $[Cp^*WF_5]$ **4**, as well as on the crystal structure of the tungsten(VI) fluoride.

Within the context of our investigations on cyclopentadienyl(fluoro) transition metal complexes, we have shown that by using trimethyltin fluoride[7] as a metathetically acting fluorinating reagent it is possible to prepare organometallic fluorides of Group 4 of the type $[Cp^*MF_3]$ (M = Ti, Zr, Hf) as well as main group element fluorides such as PF_3 and SOF_2.[8] Herein we report that these fluorinating reagents can be used to synthesize completely new cyclopentadienyl fluorides of Group 6.

The reaction of the tetrachloro complexes $[(\eta^5\text{-}C_5Me_4R)WCl_4]$ (R = Me,Et) with trimethyltin fluoride in the molar ratio 1:4 leads to the fluorides $[Cp^*WF_4]$ **1** and $[(\eta^5\text{-}C_5Me_4Et)WF_4]$ **2** [Eq. (a)]. The trimethyltin chloride formed during the reaction can be easily separated from the products by sublimation in vacuum and can be subsequently converted back into Me_3SnF by reaction with aqueous KF solution. Both compounds **1** and **2** are obtained from the reaction as beige solids with melting points above 300 °C.

1 R = Me
2 R = Et

The bands at 300–400 cm^{-1} characteristic for tungsten–chlorine vibrations are absent in the IR spectra of **1** and **2**. Instead, very strong absorption bands (576 cm^{-1} **1** and 572 cm^{-1} **2**) appear that may be assigned to tungsten–fluorine vibrations. The ESR signal of the solid **1**, detected at room temperature, has a *g* value of 1.82.[9] A comparable ESR signal was found for the analogous chlorine compound $[Cp^*WCl_4]_2$.[3] The color of complex **1**, atypical for a paramagnetic compound, indicates the presence of at least a dimer, which results in an intermolecular coupling of the unpaired electrons. The very low intensity peak in the EI mass spectrum (correct isotopic distribution) of **1** for $[M_2]^+$ minus four fluorine atoms may serve as an indication of this dimer formation. Further characterization by elemental analysis confirms the presence of both compounds.

Complexes **1** and **2** are insoluble in *n*-hexane and toluene, but can be recrystallized from THF as violet solids. The one obtained from **1** was characterized by mass spectrometry and elemental analysis as its THF adduct $[Cp^*WF_4(thf)]$ **3**. It may be assumed that **3** exists as a monomeric d^1 complex, and that its color originates through the uncoupled spin of the electron. The ESR spectrum of solid **3**, recorded at room temperature, exhibits a *g* value of 1.82.[9] In comparison, the complex $[Cp^*WCl_4(PMe_3)]$ shows, like the Lewis base free chloride, a *g* factor of about 1.9.[3]

To investigate the sensitivity of the complex to hydrolysis, a solution of **1** in THF was exposed to air. The deep violet solution changed to orange over a period of twelve hours. Slow evaporation of the solvent yielded orange crystals that were identified as the tungsten(VI) complex $[Cp^*WF_5]$ **4** by a single-crystal X-ray analysis (Fig. 1).[10]

Compound **4** crystallizes in the orthorhombic space group $Pna2_1$. The tungsten atom in the monomeric complex resides in

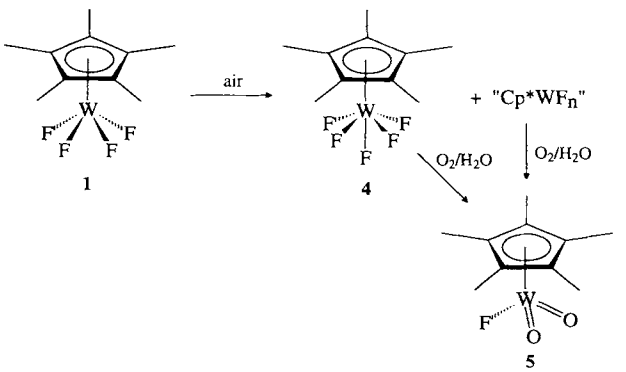
Fig. 1. Crystal structure of **4**. [**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Bundesministerium für Bildung und Forschung. We thank Dr. D. Marsh, MPI für Biophysikalische Chemie, Göttingen, for recording the ESR spectra.

a square-bipyramidal (distorted octahedral) environment, surrounded by a pentamethylcyclopentadienyl ligand and five fluorine atoms; the center of the Cp ligand is considered as one apex of the pyramid. The square basal plane around the metal center is formed by the four fluorine atoms F2, F3, F4, and F5. The angles between these atoms are on average 87.9°, that is, the deviation from the sum of angles (360°) in the square is only 8.4°. The bond angles between opposite fluorine atoms (F2-W1-F4 = 156.6° and F3-W1-F5 = 158.5°) show that the tungsten atom does not lie in the plane of the square base of the pyramid, but is somewhat projected out of this plane. In the ideal octahedron, the basal plane would be oriented perpendicular to the fifth fluorine atom F1. The average angle, however, is 75.6°, indicating a distortion of the octahedron. The average tungsten–fluorine distance is 189.5 pm and is thus in good agreement with the bond lengths in the compound $[F_4W\{NS(O)Me_2\}_2]$[11] (mean value of the W–F bonds is 190.5 pm).

After crystallization of **4** from THF, it was not possible to redissolve the compound in that solvent. However, **4** is readily soluble in acetone, and thus the NMR spectra were recorded in deuterated acetone or an acetone/acetonitrile mixture. The ^{19}F NMR spectrum of **4** confirms the existence of nonequivalent fluorine atoms. In contrast to $[Cp^*WMe_5]$, for which a rapid exchange of the methyl groups is observed at room temperature,[13] compound **4** at room temperature reveals a signal for the four equatorial fluorine atoms as a doublet at $\delta = 102.20$, and a corresponding signal for the axial fluorine atom as a quintet at $\delta = 90.80$. Thus, both signals lie in the range of chemical shifts expected for fluorine atoms terminally bonded to transition metals.[8] In the ^1H NMR spectrum of **4**, the signal for the protons of the pentamethylcyclopentadienyl ligand appears at $\delta = 2.99$. The occurrence of the signal as a doublet of quintets may be explained by the existence of H–F through-space coupling. The downfield shift of the signal is unusual compared to the proton resonance signals of other Cp*-substituted complexes. A corresponding deshielding of the hydrogen atoms can be ascribed to the strong electron-withdrawing effects of the WF_5 unit.

After filtration of the orange crystals and concentration of the THF solution, a yellow solid is obtained as the major product. The latter is characterized as the cyclopentadienyl-substituted oxofluoride $[Cp^*WO_2F]$ **5**. The singlet that appears at $\delta = -153.9$ in the ^{19}F NMR spectrum of **5** indicates the presence of a bridging fluorine atom. In addition to the molecular peak of **5**, even heavier fragments that are indicative of a polynuclear complex are also found in the mass spectrum of the compound. The IR spectrum of the compound shows in addition to a strong absorption band at 578 cm^{-1}, which can be ascribed to the tungsten–fluorine vibration, other absorptions in the region from 933 to 875 cm^{-1} that confirm the presence of W–O groups.

The disproportionation reaction that **1** undergoes upon contact with air may be understood as the first step in the hydrolysis of the tungsten(v) fluoride **1**. A simultaneously formed species in a low oxidation state could not be detected, since it is presumably immediately converted to the corresponding oxotungsten(VI) compound **5** in the presence of oxygen in the air. Compound **4** can be handled in air for only a limited time; it hydrolyzes further to **5**. This "hydrolysis start", which initially appeared not usual, has also been observed by us in other systems, for example, in the onset of hydrolysis of imidotungsten(v) complexes.[12]



Experimental Procedure

1 (Method a): $[Cp^*WCl_4]$ (5.35 g, 11.6 mmol) and freshly sublimed Me_3SnF (8.45 g, 46.4 mmol) were combined as solids. After addition of toluene (60 mL), the initially orange-colored suspension was stirred for five days at room temperature. During this time, the color changed to dark yellow. After the solid was filtered off, toluene and the Me_3SnCl resulting from the reaction were removed in vacuum. The solid was washed with *n*-hexane (3 × 30 mL). After removal of the *n*-hexane, the residue was dried in vacuum. Compound **1** (3.94 g, 86%) was obtained as a beige powder with a melting point above 300 °C.

1 (Method b): $[Cp^*WCl_4]$ (5.35 g, 11.6 mmol) and freshly sublimed Me_3SnF (8.45 g, 46.4 mmol) were combined as solids. After addition of dichloromethane (60 mL), the suspension was stirred for 8 h at room temperature. The solvent and the Me_3SnCl resulting from the reaction were removed in vacuum. The residue was washed with toluene (30 mL) and *n*-hexane (30 mL) and the remaining solid was dried in vacuum. Compound **1** (4.10 g) was obtained in 89.5% yield. IR (CsI): $\tilde{\nu}$ = 1261, 1192, 1078, 1021, 802, 650, 576 (W–F), 477 cm^{-1}. MS (70 eV): *m/z* (%): 702 (3) $[(M_2)^+ - 4F]$, 395 (18) $[M^+]$, 135 (100) $[C_5Me_5]$. Elemental analysis [16] of $C_{10}H_{15}WF_4$: calc. C 30.4, H 3.8, F 19.3; found C 31.1, H 3.9, F 19.6.

2: The preparation was carried out analogously to that of **1** (method a or b). $[(\eta^5\text{-}C_5Me_4Et)WCl_4]$ (3.20 g, 7.8 mmol) and Me_3SnF (5.73 g, 31.2 mmol) afforded **2** as a beige solid with a melting point above 300 °C in 80% (2.55 g) and 88% (2.82 g) yield, respectively. IR (CsI): $\tilde{\nu}$ = 1261, 1191, 1095, 1050, 1029, 801, 722, 572 (W–F) cm^{-1}. MS (70 eV): *m/z* (%): 409 (38) $[M^+]$, 149 (100) $[C_5Me_4Et]$. Elemental analysis [16] of $C_{11}H_{17}WF_4$: calc. C 32.3, H 4.2, F 18.6; found C 31.1, H 4.3, F 19.0.

3: **1** (2.0 g, 5.1 mmol) was dissolved in warm THF (40 mL). After the solution was allowed to cool to room temperature, it was concentrated, and **3** crystallized as violet crystals, which were filtered off and dried in vacuum. Yield 93% (2.2 g). M.p. 205 °C. IR (CsI): $\tilde{\nu}$ = 2610, 1074, 1026, 875, 573, 540 cm^{-1}. MS (70 eV): *m/z* (%): 395 (18) $[M^+]$, 357 (100) $[M^+ - 2F]$. Elemental analysis of $C_{14}H_{23}WF_4O$: calc. C 36.0, H 5.0, F 16.3; found C 35.3, H 5.0, F 16.1.

4: **1** (0.50 g, 1.2 mmol) was dissolved in THF (50 mL). The violet solution was exposed to air for 12 h during which time the solution turned orange. The clear orange solution was concentrated in vacuum to about 30 mL. At −20 °C, compound **4** (0.04 g, 15%) was obtained as an orange crystalline solid with a melting point of 212 °C. IR (CsI): $\tilde{\nu}$ = 1262, 1169, 1155, 1079, 966, 802, 655, 641, 584 (W–F), 544 cm^{-1}. MS (70 eV): *m/z* (%): 414 (2) $[M^+]$, 395 (100) $[M^+ - F]$. ^1H NMR ([D$_6$]acetone/CD_3CN, 250 MHz, TMS): δ = 2.99 (d quint, $J(H,F_{equatorial})$ = 1.1 Hz, $J(H,F_{axial})$ = 0.7 Hz, 15H; C_5Me_5). ^{19}F NMR ([D$_6$]acetone, 250 MHz, $CFCl_3$): δ = 102.20 (d quart, $^2J(F,F)$ = 140 Hz, $J(W,F)$ = 10 Hz, $J(H,F)$ = 4.5 Hz, 4F; $F_{equatorial}$), 90.80 (quint, $^2J(F,F)$ = 140 Hz, $J(W,F)$ = 62 Hz, 1F; F_{axial}). Elemental analysis of $C_{10}H_{15}WF_5$: calc. C 29.0, H 3.6, F 22.9; found C 28.9, H 3.7, F 22.7.

5: After the THF solution had been decanted from the orange crystals of **4**, the solution was further concentrated in vacuum. This led to the precipitation of **5** in the form of a pale yellow solid, which was separated by filtration and dried in vacuum. Compound **5** (0.15 g, 62%) was obtained as a pale yellow powder with a melting point of 168 °C. IR (CsI): $\tilde{\nu}$ = 1262, 1169, 1032, 933 (W=O), 875, 761, 578 (W–F), 481, 448, 423, 370, 312 cm^{-1}. MS (70 eV): *m/z* (%): 370 (100) $[M^+]$. ^1H NMR ($CDCl_3$, 250 MHz, TMS): δ = 2.16 (s 15H; C_5Me_5). ^{19}F NMR ($CDCl_3$, 250 MHz, $CFCl_3$): δ = −153.9 (s, 1F). Elemental analysis [16] of $C_{10}H_{15}WFO_2$: calc. C 32.4, H 4.0, F 5.1; found C 31.2, H 3.9, F 5.4.

[16] Satisfactory carbon values were not obtained because of incomplete combustion (tungsten carbide formation).

A Freely Hinged Macrotricycle with a Molecular Cavity**

Ziyan Wu and Jeffrey S. Moore*

We describe here the synthesis and characterization of the carbon-rich macrotricycle **1**, whose strands form the perimeter of a $36 \times 12 \times 12$ Å molecular cavity (Fig. 1a, b). The topology of **1** is analogous to that of the prototypical three-dimensional network of three-connected silicon atoms in the intermetallic compound α-$ThSi_2$ (Fig. 1c).[1] One of the simplest cyclic fragments of this network is an 18-membered tricycle in which four parallel central edges are joined in pairs to the four, three-connected bridgeheads. Closure of the tricycle is accomplished with a three-vertex chain that links the bridgehead pairs at each end. All edges of this quadruple-bridged tricycle are joined at angles of 120° (i.e. each vertex has trigonal-planar coordination). In other words, the 18-membered tricycle **1** is to α-$ThSi_2$, what adamantane is to diamond (Fig. 1c, d).

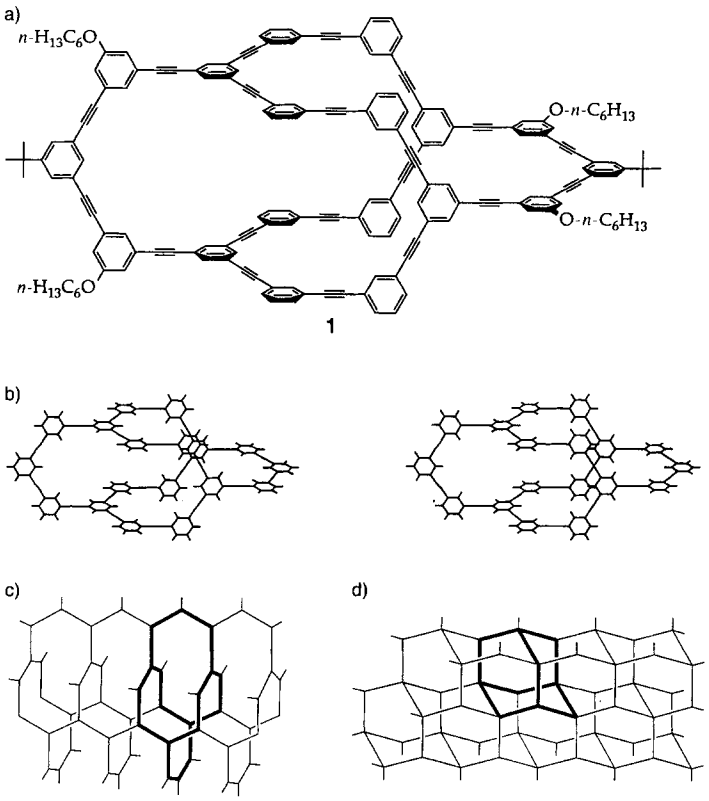

Fig. 1. a) The structural formula of macrotricycle **1**, b) stereoview of the carbon skeleton of **1** (computer-generated model; the pendant groups are removed for clarity), c) the silicon framework of α-$ThSi_2$, and d) the carbon framework of diamond. The bold lines in (c) and (d) denote the simplest cage motifs in these networks.

Many structural motifs based on the silicon network of α-$ThSi_2$ have received considerable attention of late. In 1983 Hoffmann et al. described a hypothetical carbon allotrope with the α-$ThSi_2$ topology as an alternative packing to graphite for trigonal-planar sp^2 carbon atoms.[2] Later, Diederich and Rubin postulated other carbon networks having the α-$ThSi_2$ connectivity.[3, 4] In 1993 a theoretical paper by Baughman and Galvão[5] showed how such a topology could give rise to materials with unusual mechanical (i.e. negative Poisson's ratio or auxetic[6] behavior) and thermal properties, provided that the network was expanded so as to retain a significant fraction of internal volume (the "uncrowded" hinged network phase). These hinged networks have the peculiar feature that the entire lattice can undergo reorganization by a nearly barrierless type of twisting motion around a set of parallel bonds that extends throughout the lattice.

Interestingly, supramolecular approaches to compounds of the expanded α-$ThSi_2$ structure type have recently been attempted. Single-crystal X-ray structures have shown that silver(I) salts complexed to certain tritopic, planar ligands give metal coordination networks possessing the α-$ThSi_2$ connectivity.[7, 8] Although these networks have the proper topology, they are heav-

ily interpenetrated[9] leaving behind no open space along a direction that would permit large-scale mechanical deformation. One approach to prevent the formation of interpenetrated networks in these supramolecular constructions might involve the use of cyclic building blocks.[10] Because of their covalent connectivity, such building blocks would be incapable of forming catenated networks during crystallization. Properly functionalized derivatives of macrotricycle **1** should be geometrically predisposed to organize into expanded α-$ThSi_2$ supramolecular networks.

Each of the 18 vertices of **1** is constructed from a 1,3-diconnected or a 1,3,5-triconnected aromatic ring. All of the arene units are linked by linear ethynyl bridges. As a result of these "expanded" vertices and edges, the framework of **1** possesses a large internal void (Fig. 1b). Molecular mechanics calculations[11] on **1** confirm that a compliant, hinge-like rotation about the $C_{sp}-C_{sp^2}$ single bonds is possible for lateral deformations. In contrast, the structure is relatively stiff along its longitudinal axis, both in compression and under tension. The hingelike lateral conformational change occurs as the result of a concerted torsional rotation around the eight parallel edges in **1**. This rotational motion is restricted only when the macrocycle has collapsed upon itself, leading to a nearly planar, folded structure. This motion is purely torsional, occurring without any significant change in bond lengths. The simulated mechanical response of this finite fragment is thus similar to that of the infinite lattice structures described by Baughman and Galvão.[5]

The synthesis of **1** involved back-to-back cyclization steps using preassembled branched sequences. We have previously described an efficient method for synthesizing branched phenylacetylene sequences[12, 13] and showed how these could be double-cyclized to three-dimensional macrobicycles.[14] The sequences were designed carefully and their connection planned to uniquely obtain the topology of macrotricycle **1**. Scheme 1 illustrates this point by showing three synthetic routes leading to two isomeric macrotricycles from a pair of branched sequences. Here A and B refer to functional groups capable of forming a new covalent bond, while A_p and B_p are corresponding protected versions of these groups. For all three routes shown in Scheme 1 the first cyclization step entails a tandem bimolecular coupling of two branched segments and subsequent intramolecular cyclization. The second step involves double-cyclization of the resulting branched sequence. The three routes differ with regard to the substitution pattern on the branched sequences. Only one of these routes leads unambiguously to the desired connectivity. Specifically, the desired macrotricycle is the only isomer obtained by combining one sequence that is symmetrically substituted across its branch junctures with another sequence that is unsymmetrically substituted across its branch junctures.

The preparation of the required sequences **2** and **3** followed from repetitive methods previously developed in our laboratory.[12-14] The first cyclization step [Eq. (a)] was most crucial since it involved tandem bimolecular coupling and unimolecular cyclization. Besides uncontrolled oligomerization, the desired

cross-coupling reactions also had to compete against oxidative dimerization, which is an important side reaction common to this chemistry producing diacetylene by-products. This side reaction is probably catalyzed by adventitious molecular oxygen. Extensive experimentation established that a catalyst to sequence molar ratio of 1:2 and a sequence concentration of 0.002 M (in dry triethylamine) gave the best yield of compound **4** [Eq. (a)]. Strict exclusion of oxygen and reaction at low temperature for extended times was optimal. Interestingly, the best mode of addition was to mix both sequences together at the start, rather than slowly add as solution of one sequence to a solution of the other. Product **4** was isolated by silica gel chromatography in 40% yield. Following removal of the triazene and trimethylsilyl groups, the resulting sequence was subjected to double cyclization [Eq. (b)] to afford macrotricycle **1** in 50% yield as a white powder.

Table 1. Assignments of the ^{1}H NMR signals of **1** in the aromatic region [a].

Aromatic ring	Spin system	Relative intensity	δ
1	A_2X	1	7.54, 7.48
2	ABX	2	7.34, 7.05, 7.02
3	A_2B	2	7.66 [b]
4	ABMX	4	7.52, 7.43, 7.36, 7.27

[a] 500 MHz, $CDBr_3$, 100 °C. [b] The chemical shifts of this ABC spin system are apparently equivalent.

Macrotricycle **1** has low solubility in common organic solvents, which hampered its characterization. The ^{1}H NMR spectrum of **1** ($CDBr_3$, 100 °C) was assigned from a two-dimensional ^{1}H,^{1}H-COSY experiment at 500 MHz (Table 1). The COSY spectrum (Fig. 2) shows the expected four aromatic spin systems A_2X, ABX, A_2B, and ABMX present in the intensity ratio 1:2:2:4. In addition, only one singlet resonance is observed for the *tert*-butyl groups, consistent with the D_{2d} symmetry of **1**. Size exclusion chromatography (SEC) showed only one narrow, symmetrical peak confirming the purity of macrotricycle **1**. The SEC retention time of **1** is slightly longer than that of the branched precursor **4**, as expected owing to its more compact size. The elemental composition of **1** was verified by silver chemical ionization, laser desorption FT mass spectrometry[15] (MS calcd for $C_{180}H_{132}O_4Ag$ 2465.9244, found 2465.9420).[16]

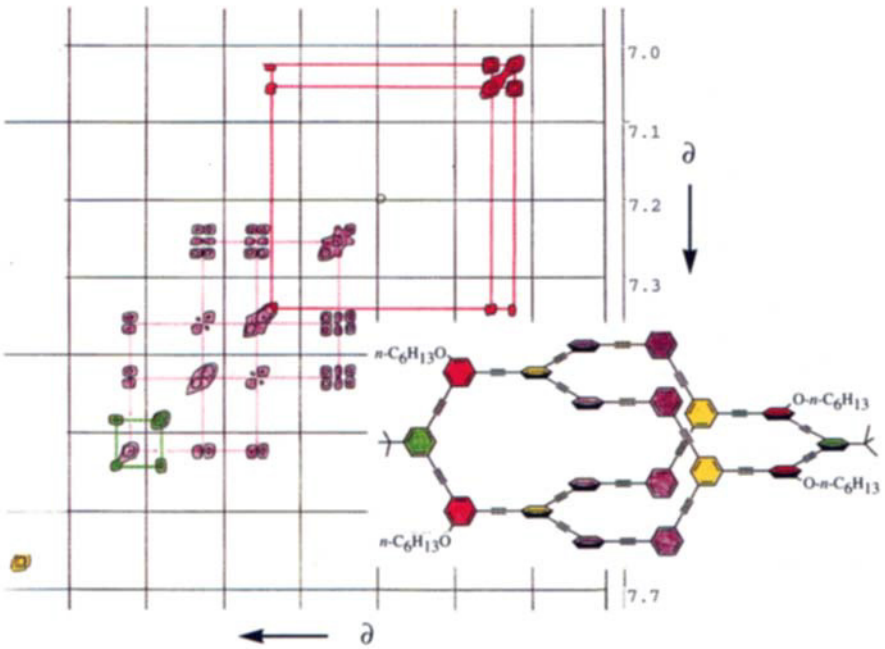

Fig. 2. Aromatic region of ^{1}H,^{1}H-COSY NMR spectrum of macrotricycle **1** (500 MHz, $CDBr_3$) at 100 °C. Color coding has been used to indicate the four unique spin systems.

In summary, a freely hinged macrocycle with a molecular cavity was prepared whose carbon-based skeleton represents a finite fragment of the α-ThSi_2 network. Properly functionalized derivatives of macrotricycle **1** might be useful as nanomechanical building blocks for constructing the noninterpenetrated, open networks required for the rational design of molecular-based auxetic materials.

Experimental Procedure

4: A single-neck flask with a side arm was charged with **3** (94.8 mg, 0.06 mmol), **2** (82.9 mg, 0.06 mmol), bis(dibenzylideneacetone)palladium(0) (31.4 mg, 0.03 mmol), triphenylphosphane (78.8 mg, 0.16 mmol), copper(I) iodide (5.2 mg, 0.015 mmol), and dry triethylamine (100 mL). The flask was stoppered, evacuated, and flushed with nitrogen three times, and the mixture was stirred at 45 °C for 24 h. The disappearance of the starting sequences was monitored by TLC. After the reaction was complete, the mixture was diluted with dichloromethane, washed three times with water and brine, dried over anhydrous magnesium sulfate, and filtered. The crude mixture was separated by column chromatography eluting with hexane/dichloromethane (1/1) to give the major product **4** as a clear, colorless glasslike material (70.1 mg, 40%): $R_f = 0.5$ (dichloromethane/hexane 1/1); ^{1}H NMR (360 MHz, C_6D_6): $\delta = 8.15$ (m, 2H), 7.95 (d, $J = 6.4$ Hz, 4H), 7.90 (d, $J = 8.7$ Hz, 2H), 7.80 (m, 3H), 7.76 (m, 1H), 7.71 (m, 5H), 7.67 (m, 3H), 7.65 (m, 2H), 7.64–7.60 (m, 10H), 7.41–7.29 (m, 14H), 7.22 (t, $J = 1.6$ Hz, 2H), 6.90 (td, $J = 7.7$, 1.6 Hz, 4H), 6.81 (t, $J = 7.7$ Hz, 2H), 3.55 (m, 8H), 3.35 (br s, 8H), 1.56 (m, 8H), 1.26–1.17 (m, 24H), 1.14 (s, 9H), 1.12 (s, 9H), 1.08–0.86 (m, 24H), 0.25 (s, 18H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 158.84$, 158.82, 151.64, 151.61, 151.14, 135.07, 134.95, 134.60, 134.22, 134.03, 133.98, 133.94, 132.12, 131.90, 131.82, 131.52, 131.39, 128.99, 128.95, 128.81, 128.57, 128.37, 128.18, 127.54, 127.22, 124.37, 124.33, 124.19, 124.03, 123.88, 123.83, 123.62, 123.54, 123.40, 123.35, 123.12, 123.05, 122.92, 121.29, 118.08, 117.89, 117.75, 117.28, 103.97, 95.13, 90.98, 89.98, 89.81, 89.79, 89.72, 89.60, 89.47, 89.45, 89.38, 89.19, 88.61, 88.57, 88.41, 88.39, 88.25, 88.19, 87.99, 87.94, 87.30, 68.29, 48.0 (br), 42.0 (br), 34.72, 31.54, 31.09, 29.10, 25.66, 22.61, 14.04, 12.0 (br), −0.11.

1: Procedures for transforming the triazene to the corresponding aryl iodide and the trimethylsilyl-protected alkyne to the corresponding terminal alkyne are similar to those previously described [12]. The double cyclization procedure is as follows: A septum-stoppered flask with a side arm charged with bis(dibenzylideneacetone)palladium(0) (37 mg, 0.031 mmol), copper(I) iodide (6.1 mg, 0.016 mmol), and triphenylphosphane (92.7 mg, 0.173 mmol) was evacuated and flushed with nitrogen. Dry triethylamine (10 mL) and toluene (20 mL) were added and the solution was stirred at 65 °C. The deprotected sequence (56 mg, 0.021 mmol) was dissolved in dry triethylamine (10 mL) and toluene (10 mL) and added to the flask by a syringe pump at a rate of 1.67 mL h^{-1}. White solid started to precipitate after the first half hour. At the end of the addition the mixture was heated at 70 °C for another 10 h and then the reaction mixture was cooled to room temperature. The solid was filtered and dissolved in large amount of chloroform. The solution was washed with 1 N aqueous HCl, water, and brine, and then dried over magnesium sulfate. After the solvent was removed, the residue was reprecipitated with chloroform and ether to afford a white powder (24.3 mg, 50% yield). Mass spectrometrie and ^{1}H NMR data for 1 are given in the text and Table 1.

Tris(chalcogenato)carbenium Ions $[C(XR)_3]^+$ (X = O, S, Se, Te): An Experimental and Quantum-Chemical Comparison**

Dietmar Ohlmann, Christina M. Marchand, Hansjörg Grützmacher,* Grace Shiahuy Chen, David Farmer, Rainer Glaser,* Antonio Currao, Reinhard Nesper, and Hans Pritzkow

Dedicated to Professor H. W. Roesky on the occasion of his 60th birthday

We have performed a systematic study of tris(chalcogenato)carbenium ions $[(RX)_3C]^+$ (X = S, Se, Te) to obtain a better understanding as to how donor atoms of the higher periods influence carbenium ion stability. Extensive experimental[1] and theoretical[2] studies have shown that carbenium ions $[H_{3-n}CY_n]^+$ can be stabilized by substituents Y (Y = NR_2, PR_2, OR, SR, and halogen) that contain electronegative heteroatoms with lone pairs that may engage in π donation as well as by substituents Y (Y = Li, Na, BeH) with electropositive elements which act as σ donors. In general, the stabilization energies (SE) can be quantified by the reaction energies of the hydride-transfer reactions [Eq. (a)] and the respective values for the cations $[H_{3-n}C(XH)_n]^+$ (X = O, S, Se, Te; $n = 1, 2, 3$) are listed in Table 1.

$$[H_{3-n}CY_n]^+ + n\,CH_4 \longrightarrow CH_3^+ + n\,H_3CY \qquad (a)$$

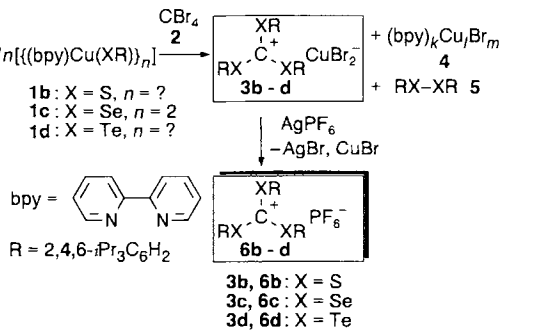
The oxocarbenium ion $[H_2C(OH)]^+$ (SE ≈ 64 kcal mol^{-1}; see also[1d, 2e-g]) has almost the same stabilization energy as the $[H_2C(XH)]^+$ ions (SE ≈ 64–68 kcal mol^{-1}; see also[1d, 2e-g]). The stabilization energies increase as the number of XH groups in the ions $[H_{3-n}C(XH)_n]^+$ increase. This increase is about the same for the thio-, seleno-, and telluro-substituted ions (average values: ΔSE(1 → 2) = 22.3 kcal mol^{-1}; ΔSE(1 → 3) = 33.3 kcal mol^{-1}; where ΔSE(1 → 2) = $SE[HC(XH)_2]^+ - SE[H_2C(XH)]^+$ and ΔSE(1 → 3) = $SE[C(XH)_3]^+ - SE[H_2C(XH)]^+$). The SE values increase particularly for the ions $[HC(OH)_2]^+$ and $[C(OH)_3]^+$ (ΔSE(1 → 2) = 40.7 kcal mol^{-1} and ΔSE(1 → 3) = 71.5 kcal mol^{-1}), and these ions are significantly more stabilized (by about 18 and 38 kcal mol^{-1}, respectively) than the homologous S, Se, and Te ions. These results are surprising in light of the decrease of the electronegativity χ_{spec}[3] in the order O ≫ S > Se > Te and of the concomitant increases of the σ- as well as of the π-donating ability of the heteroatom X.[2a,c] On the other hand, the χ_{spec} values of S, Se, and Te are relatively similar and we report herein experimental results that suggest that the bonding situations in the ions $[C(XR)_3]^+$ (X = S, Se, Te) also are comparable to each other, while they are clearly distinct from those in the $[C(OR)_3]^+$ ions.

Table 1. Stabilization energies (SE) [a] at the QCISD(T, full)/LANL1DZ + P′//MP2(full)/LANL1DZ + P′ level.

Molecule [b]	Element X: O	S	Se	Te
$[C(XH)_3]^+$	135.31	100.37	96.55	100.79
$[HC(XH)_2]^+$	104.56	89.00	86.01	89.61
$[H_2CXH]^+$ [c]	63.83	65.65	64.40	67.72

[a] SE calculated as the reaction energy ΔE_{HTR} of the hydride transfer reaction: $[H_{3-n}C(XH)_n]^+ + n CH_4 \rightarrow [H_3C]^+ + n H_3C(XH)$. [b] Trisubstituted cations in C_{3h} symmetry; di- and monosubstituted cations in C_s symmetry. All energies in kcal mol^{-1}. [c] In good agreement with results obtained at comparable levels and reported in ref. [2g].

Since the usual synthetic routes for the preparation of $[C(XR)_3]^+$ cations with X = O, S by protonation or alkylation of $(RX)_2C{=}X$ cannot be extended to the selenium and tellurium compounds, we have devised a new synthesis for these cations (Scheme 1). The copper complexes **1b, c** can be prepared in situ by addition of 2,2′-bipyridine to the copper chalcogenolates [Cu(XR)] (X = S,[4] Se;[5] R = 2,4,6-iPr$_3$C$_6$H$_2$) and **1d** can be obtained by reaction of $[\{(bpy)CuBr\}]_2$[6] with $[(thf)_2LiTeR]$.[7] The complexes **1b–d** react with CBr_4 (**2**) in CH_3CN (**1b, c**) or toluene (**1d**) to form the desired carbenium ions **3b–d** with dibromocuprate counterions. Exchange of the $CuBr_2^-$ ion by the PF_6^- ion yields the salts **6b–d** as yellow (**6b**), orange (**6c**), and pink (**6d**) solids, respectively. The corresponding oxocarbenium ion $[C(OR)_3]^+$ with R = 2,4,6-iPr$_3$C$_6$H$_2$ has not yet been prepared, but many such ions with other R groups were prepared by alkylation of carbonates and are well characterized. The salts **3b–d** and **6b–d** are remarkably soluble in apolar solvents such as benzene and Et_2O and can be handled in air.



Scheme 1. Synthesis of **3b–3d** and **6b–6d**.

The result of a single-crystal X-ray structure determination of **6d** is shown in Figure 1.[8] Selected average distances and angles of **6d** are listed in Table 2 together with the respective data for the cations of **3b, c**.[9] The central carbon atom in all of the cations of **3b, c** and **6d** is coordinated in a trigonal-planar fashion (sum of angles at the carbon center = 360°) and the X-C-X angles vary only marginally (119.0°–121.3°). The C-X-C angles decrease in the series S > Se > Te as expected (**3b**: 102.5°; **6c**: 97.8, **6d**: 93.6°). Remarkably, the X–C bond to the central carbon atom C1 is shortened by about the same percentage (3.4–4.3%) in all cations. For the calculation of these percentages, we employed the $X-C_{aryl}$ bonds as internal standard for the $X-C(sp^2)$ bond length. This indicates that the S–C, Se–C,

[**] This research was supported in part by NATO (CRG 940399), the Fonds der Chemischen Industrie, and the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. P. von R. Schleyer for making a preprint (ref. [2g]) available to us.

Table 2. Selected bond lengths [Å] and angles [°] for the cations of **3b,c**, **6d**, and **7a–d**. The Δ values specify the percentage shortening of the C1–X bond relative to the C_{aryl}–X bond. The calculated values (in italics) for **7a–d** were obtained at the MP2(full)/LANL1DZ+P′ level. The redox potentials for **6b–d** were measured in CH_3CN/nBu_4NPF_6 with a Pt electrode using a Ag electrode with ferrocene as standard. A reversible redox wave (ΔE = 0.85 mV) was observed in the cyclic voltammogram for **6b** at T = 298 K and for **6c,d** at T = 238 K.

[a] The calculated percent shortening Δ is based on a C_{aryl}–O distance of 1.370 Å[10]. [b] Ref. [11a]. [c] Refers to $[C(OMe)_3][BF_4]$[11b].

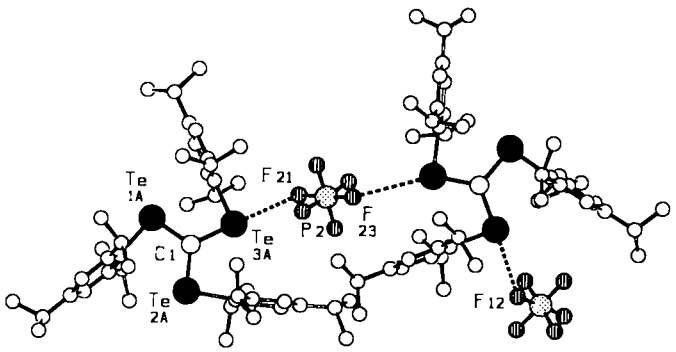

Fig. 1. SCHAKAL drawings of the two $[C(TeR)_3][PF_6]$ complexes (R = 2,4,6-iPr$_3$C$_6$H$_2$) in the asymmetric unit of **6d** which are connected through one shorter (3.061(15) Å) and one longer Te–F (3.637(15) Å) contact. Selected averaged distances and angles are given in Table 2.

and Te–C bonds are electronically rather similar in these cations. This expectation can be corroborated by experimental results: a) The chemical shifts of the central carbon atom C1 (Table 2) fall in the same range for all cations; b) cyclic voltammetry in acetonitrile/nBu$_4$NPF$_6$ electrolytes showed nearly identical peak potentials at about −0.66 V for the reductions of the cations. These observations suggest that the LUMO energies—which depend on the (p-p)π interactions between the donor atom X and the acceptor atom C1—deviate from each other only marginally in all cations of **6b–d**. On the other hand, the lowest energy absorptions in the UV/Vis spectra of the salts **6b–d** exhibit a bathochromic shift of 79 nm when S is replaced by Se and a further shift of 112 nm when Se is replaced by Te (Table 2). Evidently, an increasing destabilization of the HOMO is associated with varying the X atom in the series S, Se, and Te. In contrast, the ^{13}C NMR signal of protonated carbonic acid $[C(OH)_3]^+$ (**6a**) occurs at significantly higher field (Table 2), and no absorptions with wavelengths above 190 nm are observed in the UV/Vis spectra of tris(alkoxy)carbenium ions.[11b] In these compounds the HOMO–LUMO gap thus is significantly larger.

The experimental observations are consistent with calculations of the cations $[C(XH)_3]^+$ **7a–d** at the MP2(full)/LANL1DZ+P′ level[12] (Table 2) which establish strict C_{3h} symmetry for all of the trigonal-planar monocations and demonstrate excellent agreement between theoretical and experimental bond lengths and angles (average deviations are < 0.01 Å and < 3°, respectively). Information about the bonding situations and, for example, the size of the atoms in the molecules can be obtained from a topological electron density analysis (TEDA). TEDA is based on properties of the gradient vector field of the electron density distributions in Cartesian space and, in Figure 2, the gradient vector fields are exemplified for **7a** and **7b**.

The corresponding plots for the Se- and Te-containing cations greatly resemble the plot for **7b**. It becomes immediately apparent that the "bond critical points" (BCPs) for the C–X bonds (X = S, Se, Te) are closer to the X atoms than to the C atoms, which is in sharp contrast to the C–O bond in **7a**. The electron densities at the locations of the bond critical points (ρ_b) decrease in the series O > S > Se > Te. These TEDA results clearly demonstrate the umpolung of the C–X bond on going from the second to the third period and allow for an interpretation of the SE values (Table 1). As was previously described by Bernardi et al.,[2c] the stabilization of the RO-substituted carbenium ions can largely be attributed to the high polarity of the $C^{\delta+}$–$O^{\delta-}$

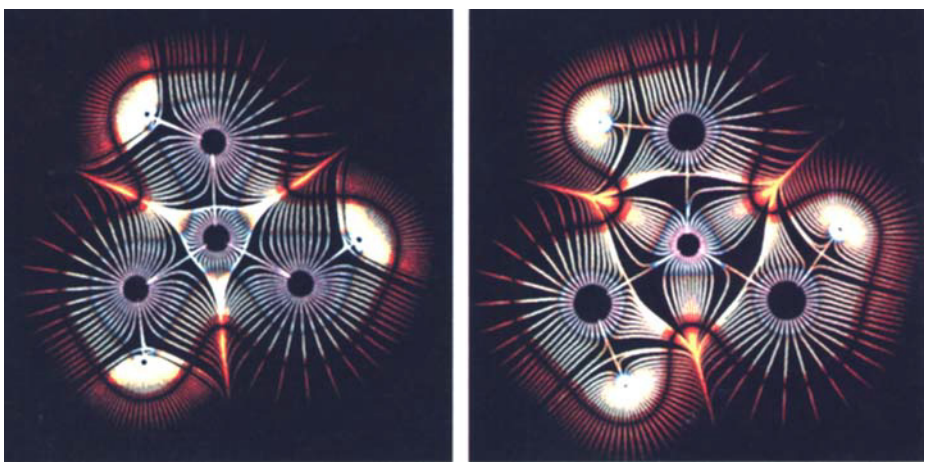

Fig. 2. Graphical representations of the gradient vector fields of the electron density distributions in the ions $[C(OH)_3]^+$ (**7a**, left) and $[C(SH)_3]^+$ (**7b**, right). The color coding reflects the magnitude of the electron density (pink 3–0.7, blue 0.35–0.3, yellow 0.2–0.1, red 0.05–0.01 e a_0^{-3}). The bond paths and the cross sections of the zero-flux surfaces also are shown and the bond critical points occur at their intersections.

bonding in the cations $[H_{3-n}C(OR)_n]^+$. This bond polarity results in spite of significant X→C π-bonding contributions, which, however, do not suffice to compensate the stronger C→X electron density shifts in the σ system. Consequently, instead of the expected charge *dispersal* an increased charge *separation* occurs. This interpretation also is consistent with the particularly large increase of the stabilities of the oxocarbenium ions (X = O) with increasing n in $[H_{3-n}C(XR)_n]^+$ ions because the Coloumb term contributes significantly to the binding energy in this case and increases the stability compared to the neutral compound $HC(XH)_3$. In contrast, the homologous cations $[R_{3-n}C(XR)_n]^+$ are stabilized by σ- and π-dative X→C bonding. Again an increasing electron density shift to the C atom is observed in the series S < Se < Te which goes beyond formal charge dispersal and results in $X^{\delta+}-C^{\delta-}$ bond polarizations that contribute to the stability of the cations. The nearly equal SE values of the $[H_2C(XH)]^+$ cations are fortuitous and result from different mechanisms of charge stabilization, which becomes clear only when the SE values associated with multiple substitution are considered.

Experimental Procedure

6b, c: Cu(XR) (3.35 mmol) (1.00 g **1b** or 1.16 g **1c**) was dissolved in acetonitrile (50 mL) and treated with freshly sublimed 2,2'-bipyridine (3.35 mmol, 523 mg). The deep red solution was cooled to 0 °C and a solution of CBr_4 (372 mg, 1.12 mmol) in acetonitrile (5 mL) was added by syringe over the course of 1 min. The solution was stirred overnight at room temperature. The resulting precipitate was separated by using a filtering crucible (fritted glass disk D4), and the acetonitrile was removed under vacuum. The dark, oily residue was stirred with warm hexane (3 × 10 mL) and after this treatment the yellow crude product **3b, c** was obtained after drying under high vacuum. The crude product was treated with $AgPF_6 \cdot 2CH_3CN$ (for **3b** (211 mg, 0.63 mmol), for **3c** (270 mg, 0.81 mmol)) in THF (20 mL) in the dark. After the mixture had been stirred for 1 h, the THF was removed under high vacuum, the residue was taken up in CH_2Cl_2 (20 mL), and the solution was filtered through silica. CH_2Cl_2 was removed under high vacuum and the remaining solid was washed with hexane and dried. **6b**: Yield 542 mg (56%) (m.p. 211 °C); ^1H NMR ($CDCl_3$): $\delta = 1.19$ (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 1.27 (d, 18H, $J(H,H) = 6.8$ Hz, *p*-CH_3), 1.42 (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 3.03 (m, 9H, $J(H,H) = 6.8$ Hz, *o*- and *p*-CH), 7.27 (s, 6H$_{aryl}$); ^{13}C NMR ($CDCl_3$): $\delta = 23.29$ and 23.57 (*o*-CH_3), 25.04 (*p*-CH_3), 32.97 (*o*-CH), 34.44 (*p*-CH), 117.22 (*p*-C_{aryl}), 124.50 (H-C_{aryl}), 152.73 (*o*-C_{aryl}), 156.52 (*ipso*-C_{aryl}), 239.51 ($C_{central}$); ^{31}P NMR ($CDCl_3$): $\delta = -144.5$ (m, $J(P,F) = 711$ Hz); ^{19}F NMR ($CDCl_3$): $\delta = -74.4$ (d, $J(F,P) = 711$ Hz); UV (Et_2O) λ_{max} (ε): 214 (60810), 256 (59310), 309 (31065), 375 nm (5665) strong offset shoulder. **6c**: Yield 809 mg (72%) (> 185 °C decomp.); ^1H NMR ($CDCl_3$): $\delta = 1.19$ (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 1.28 (d, 18H, $J(H,H) = 6.8$ Hz, *p*-CH_3), 1.39 (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 2.98 (m, 3H, $J(H,H) = 6.8$ Hz, *p*-CH), 2.99 (m, 6H, $J(H,H) = 6.8$ Hz, *o*-CH), 7.29 (s, 6H$_{aryl}$); ^{13}C NMR ($CDCl_3$): $\delta = 22.73$ and 22.83 (*o*-CH_3), 24.01 (*p*-CH_3), 33.43 (*p*-CH), 34.16 (*o*-CH), 123.25 (*p*-C_{aryl}), 123.66 (H-C_{aryl}), 151.26 (*o*-C_{aryl}), 155.03 (*ipso*-C_{aryl}), 253.71 [$C_{central}$, $^1J(^{77}Se, ^{13}C) = 210.5$ Hz]; ^{77}Se NMR ($CDCl_3$): $\delta = -769.5$; ^{31}P NMR ($CDCl_3$): $\delta = -144.4$ (m, $J(P,F) = 712$ Hz); ^{19}F NMR ($CDCl_3$): $\delta = -74.0$ (d, $J(F,P) = 712$ Hz); UV (Et_2O) λ_{max} (ε): 208 (63265), 254 (40490), 343 (9565) shoulder, 388 nm (16835).

6d: $[(thf)_2LiTeR]$ (1.61 g, 3.35 mmol) and $[(bipy)CuBr]_2$ (1.00 g, 1.67 mmol) were mixed and THF (50 mL) was added at −80 °C. The mixture was allowed to warm to −30 °C and stirred until a clear deep red solution was obtained. At 0 °C, half of the THF was removed under high vacuum and replaced by toluene. The solution was further reduced to about 15 mL and toluene (25 mL) was added subsequently. This solution was stored overnight at −70 °C. Precipitated LiBr was separated by filtration (fritted filter D4). The red-brown solution was brought to 0 °C and a solution of CBr_4 (372 mg, 1.12 mmol) in toluene (5 mL) was added by syringe over the course of 1 min. The solution was stirred overnight at room temperature, the resulting solid was separated by filtration (fritted filter D4) and toluene was removed in a high vacuum. The residue was stirred with warm hexane (3 × 10 mL). After drying in high vacuum, crude **3d** was obtained as a pink solid. As with **6b,c**, **6d** was prepared with $AgPF_6 \cdot 2CH_3CN$ (128 mg, 0.38 mmol). **6d**: Yield 437 mg (34%) (m.p. 152 °C); ^1H NMR (C_6D_6): $\delta = 1.16$ (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 1.26 (d, 18H, $J(H,H) = 6.8$ Hz, *p*-CH_3), 1.39 (d, 18H, $J(H,H) = 6.8$ Hz, *o*-CH_3), 2.89 (m, 3H, $J(H,H) = 6.8$ Hz, *p*-CH), 3.11 (m, 6H, $J(H,H) = 6.8$ Hz, *o*-CH), 7.37 (s, 6H$_{aryl}$); ^{13}C NMR (C_6D_6): $\delta = 23.92$ (*p*-CH_3), 24.92 and 25.05 (*o*-CH_3), 34.70 (*p*-CH), 40.08 (*o*-CH), 124.61 (H-C_{aryl}), 129.83 (*p*-C_{aryl}), 154.60 (*o*-C_{aryl}), 155.58 (*ipso*-C_{aryl}), 230.39 [$C_{central}$, $^1J(^{125}Te, ^{13}C) = 535$ Hz]; ^{125}Te NMR (C_6D_6): $\delta = 1278.8$; ^{31}P NMR (C_6D_6): $\delta = -145.0$ (m, $J(P,F) = 714$ Hz); ^{19}F NMR (C_6D_6): $\delta = -75.0$ (d, $J(F,P) = 714$ Hz); UV (Et_2O) λ_{max} (ε): 210 (65415), 275 (34565), 361 (2705), 500 nm (22940).

Conformational Differences of O- and C-Glycosides in the Protein-Bound State: Different Conformations of C-Lactose and Its O-Analogue are Recognized by Ricin B, a Galactose-Binding Protein**

Juan-Félix Espinosa, F. Javier Cañada, Juan Luis Asensio, Hansjörg Dietrich, Manuel Martín-Lomas, Richard R. Schmidt, and Jesús Jiménez-Barbero*

Dedicated to Prof. Dr. Manuel Bernabé on the occasion of his 60th birthday

The interest in the chemistry of C-disaccharides as structural analogues of O-glycosides continues to grow[1] since these carbon-bridged compounds are thought to affect the activity of glycosidases as competitive inhibitors of the natural compounds. Therefore, it is extremely important that both compounds, the natural substrate and its C-glycoside analogue, are recognized by the enzyme in a similar way. The conformation of free C-glycosides has usually been assumed to be the same as that of the corresponding O-analogues.[2] However, we have recently demonstrated that, at least for O- and C-lactoses, this is not the case.[3]

To the best of our knowledge, it is not yet known whether both compounds are recognized by a carbohydrate-binding protein in the same conformation. Apart from the presence of the key interacting groups in the nonnatural substrate, this would be an essential requirement for an important inhibitory activity. On this basis, we report now on the use of 2D transferred NOE (TR-NOESY) and transferred ROE (TR-ROESY) experiments[4] to study the complexation of C-lactose (**1**) by a galactose-binding protein, ricin B.[5] In addition, we compare the obtained results with those reported for the complexation of regular lactose analogues.[6] Taking advantage of the large size of lectins, TR-NOE (TR-ROE) experiments have recently been used to determine the 3D structure of protein-bound carbohydrates[7] by focusing on the easily detected NMR signals of the free ligand.

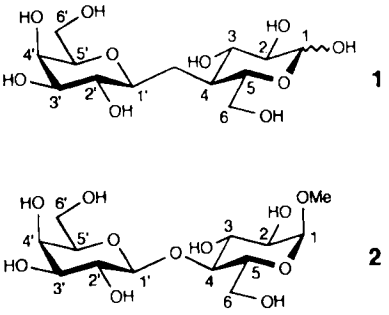

Fig. 1. Views of C-lactose (**1**) and methyl α-lactoside (**2**) showing the atomic numbering.

Figure 1 shows compound **1** and its O-analogue, methyl α-lactoside (**2**), along with their atomic numbering. The glycosidic dihedral angles are defined as Φ (H1'-C1'-O1'(C_x)-C4) and Ψ (C1'-O1'(C_x)-C4-H4). We have recently reported on the conformational study of **1** and **2** using NMR spectroscopy and only the basic features will be presented here.[3, 8] Both compounds adopt the *exo*-anomeric conformation around the glycosidic bonds but the conformation around the aglyconic bonds are rather different. For **2**, about 90% of the population is located in the central low-energy region (minimum A, Φ/Ψ 54/18), while roughly 10% of population presents similar Φ values but has Ψ values around 180° (minimum B, Φ/Ψ 36/180). These two different dispositions around the aglyconic bond are referred to as *syn* and *anti*, respectively.[9a] However, for **1** approximately 55% of the population adopts the *anti* conformation, while about 40% presents the *syn* orientation. The experimental data also indicate that minimum C (Φ/Ψ 180/0) is also populated (ca. 5%). Therefore, C-lactose exhibits much higher flexibility than its O-analogue. Table 1 summarizes the exclusive NOEs[9b] that characterize each region for **1**.

Table 1. Normalized NOESY and TR-NOESY intensities [%] for **1** at 30 °C in D_2O at (Varian, 500 MHz). The mixing times for the NOESY and TR-NOESY experiments were 700 and 300 ms, respectively.

Proton pair	NOE [%] Free	Bound
H^{pro-R}/H3	5.7	0.0
H^{pro-S}/H5	3.0	0.0
H^{pro-S}/H6 [a]	2.7	0.0
H1'/H4	2.1	−1.2
H1'/H3	5.9	−3.1
H^{pro-R}/H6 [a]	5.1	−5.4

[a] These NOEs were obtained by adding the contributions of both H6 protons.

The conformational changes that occur when methyl α-lactoside is bound to ricin B have been studied using TR-NOESY and TR-ROESY experiments.[6a] In summary, the bound conformation deviates slightly from the *exo*-anomeric conformation towards smaller Φ angles, while the orientation around the aglyconic bond is exclusively *syn*. The relevant interproton distances (H1'–H4 ca. 2.2–2.3 Å) are in agreement with those reported previously for the binding of methyl β-lactoside to ricin.[6b]

For C-lactose in the presence of ricin B the observed NOEs are negative, an indication of binding. The NOESY spectra of **1** (Fig. 2) recorded in the absence and in the presence of the lectin show important differences. First, the presence of both H1'/H3 and H^{pro-R}/H6 cross peaks, which define the population around minimum B, indicates that the *anti* conformation is indeed recognized by the protein, in contrast with the results

obtained for methyl α-lactoside (**2**).[6] Moreover, a total of four NOEs, which were observed for free **1**, are not detected in the complex (Table 1, Fig. 3). The H4/H2′ NOE (an exclusive NOE of the region around minimum C) is not present, indicating that this conformation is not bound. In addition, three exclusive NOEs for the *syn* conformation (H^{pro-R}/H3, H^{pro-S}/H5, and H^{pro-S}/H6) are also absent in the TR-NOESY spectrum (Fig. 2) and, thus, the *syn* conformation is not recognized by the lectin. The presence of the H1′/H4 cross peak seems to be a contradiction. However, a careful study of the spectrum shows that, for the complex, the NOE between H1′ and H^{pro-S} NOE (ca. −3%) is much more intense than that between H1′ and H4 (ca. −1%), while, for free **1**, these cross peaks have the same intensity. Since spin diffusion is extremely efficient for a molecular complex of this size,[10] it may be that this H1′/H4 NOE is mediated by an indirect effect in the complex. Indeed, the presence of the two methylene protons in **1** provides important diffusion pathways, and therefore an indirect H1′/H4 cross peak via H^{pro-S} may be expected. To confirm this hypothesis and to differentiate spin diffusion effects from direct NOE enhancements, TR-ROESY experiments are essential,[6a, 10] since under spin-locking conditions direct and three-spin effects are of opposite sign. The major disadvantage of TR-ROESY is that cross relaxation of the free ligand cannot be neglected and must be measured in a separate experiment. The experimental data show that the H1′/H3 ROE is roughly three times more intense in the spectrum recorded in the presence of protein than in the spectra for free **1** at the same mixing time. In contrast, the H1′/H4 NOE has the same magnitude in both cases, hence demonstrating that the corresponding TR-NOESY cross peak detected in the complex between **1** and the lectin is mediated by an indirect effect. The presence of the H1′/H4

Fig. 2. 2D NOESY ^{1}H NMR spectra (Varian, 500 MHz, 30 °C, D_2O) of **1** in the absence (a) and in the presence (b) of protein. Samples of ricin B were concentrated after repeated cycles of exchange with deuterated sodium phosphate and transferred to the NMR tube; the final pH was 6.5, the concentration 0.12 mM, and the molar ratio of C-lactose/ricin B 20:1. Mixing times of 700 and 300 ms were used for free and bound **1**, respectively. TR-NOESY experiments were also carried out with mixing times of 120, 400, and 500 ms.

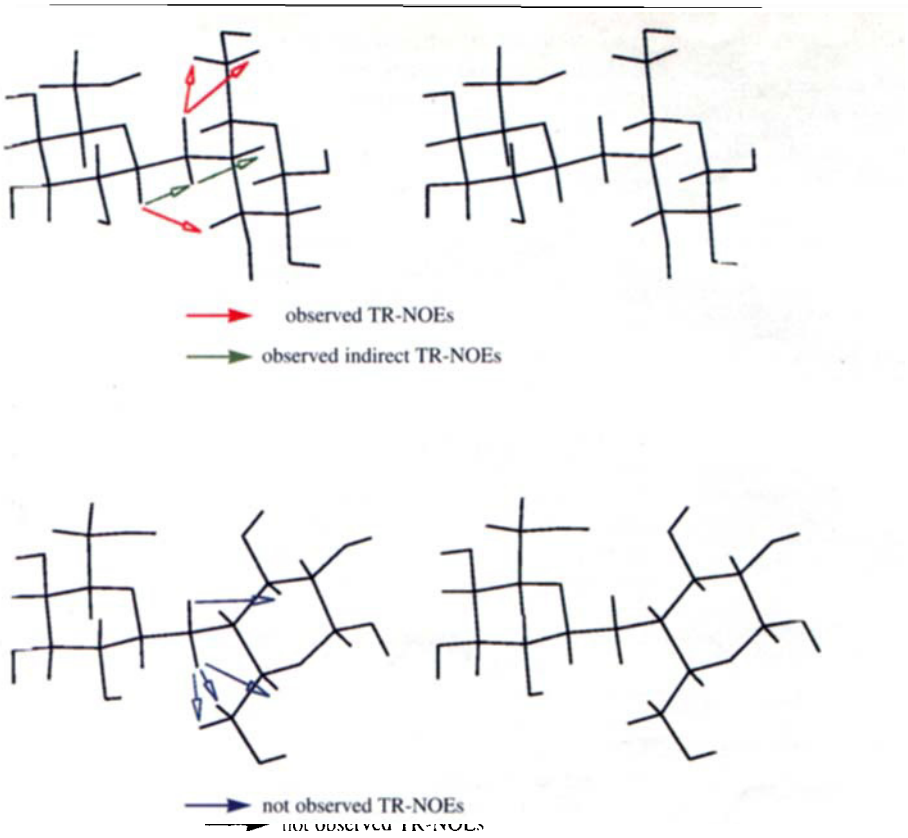

Fig. 3. Stereoscopic views of the *syn* (minimum A, Φ, Ψ 54/18) and *anti* (minimum B, Φ Ψ 36/180) conformations of **1** with the exclusive NOEs in each case.

cross peak in the TR-ROESY experiment is evidently due to the excess of free ligand. Differences between TR-NOESY and TR-ROESY spectra are also found for H1′/H4′, H^{pro-S}/H3′ + H5′, and H^{pro-R}/H3′ + H5′ cross peaks, which disappear in the TR-ROESY spectrum.[11] Our results confirm recent reports that indicate that spin diffusion plays a significant role in transferred NOE experiments.[10] A quantitative analysis of the TR-NOE data obtained for C-lactose/ricin B was attempted by simulation of the TR-NOESY spectrum according to the full relaxation matrix method.[12] However, it was not possible to completely reproduce the experimental data by using a rigid model of the ligand within the binding site.[13] This fact confirms that C-lactose is mobile even in the binding site and that several conformers within the *anti* valley defined by minimum B are still possible.

More importantly, the experimental results indicate (Fig. 2) unequivocally and unexpectedly that ricin B selects differentconformers of **1** (*anti*), and its O-analogue, **2** (*syn*) (Fig. 4).

Crystallographic and binding studies of the ricin B/lactose complex[5c] have shown that the lectin contains two noncooperative β-galactose binding sites.[5d] To estimate the relative binding affinities of **1** and **2**, competitive TR-NOESY experiments were performed with different **1**:**2** ratios. It was observed that the increase in the amount of **2** added to the NMR tube induced a decrease in the negative NOE cross peak intensities of **1**. When a 1:1 ratio was reached, the NOEs of **1** became positive, whereas strong negative NOEs were clearly observed for **2**. These results lead to two conclusions: a) both ligands compete for the same binding sites of the lectin, and b) the affinity constant of **1** is smaller than that of its O-analogue **2**.

The study of the crystal structure of the complex of ricin B with lactose does not give any unambiguous explanation for the change in conformation on going from **1** to **2**. The lack of recognition of the *anti* conformation of **2** by the lectin could be explained by a steric interaction between the hydroxymethyl group of the glucose moiety and the protein.[6a] Although merely speculative, the higher flexibility and the larger distances between the pyranoid rings might allow the recognition of the *anti* conformation of C-lactose. Nevertheless, no obvious reason has been found for the exclusive binding of this conformation to the protein.

In conclusion, we have shown for the first time that not only the 3D structure of a C-glycoside may be different from that of its corresponding O-glycoside in the free state, but also that a carbohydrate-binding protein may select different conformations of these types of compounds. Although the case presented here cannot be generalized, care should be taken in the design of competitive inhibitors of glycosidases based on C-glycosides, since these compounds may have different preferred conformations than their natural substrates.

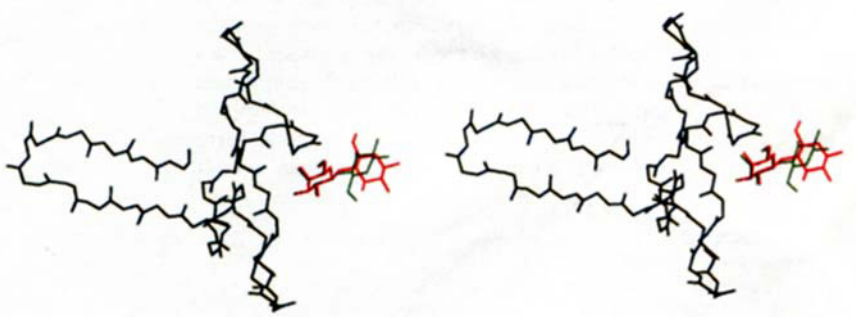

Fig. 4. Stereoscopic view of compounds **1** (red) and **2** (green) docked into the 1α subdomain of ricin B as constructed from the crystallographic coordinates [5c]. Both ligands were docked in the selected conformation into the protein to fit the hydrogen bond pattern observed in the crystal for the galactose moiety. Extensive minimization of each complex with the CVFF program was performed as described [6a]. This figure should be regarded as just a model of the conformation of the ligands within the binding site of ricin B, since protein–carbohydrate contacts have not been detected experimentally.

[13] The correlation times for the bound state and the exchange rate constants that fit all the intragalactose NOEs did not reproduce all the intra- and interglycosidic NOEs involving the glucose unit. In contrast, for **2**/ricin B all the experimental TR-NOEs could be fitted by a simple set of parameters [6a].

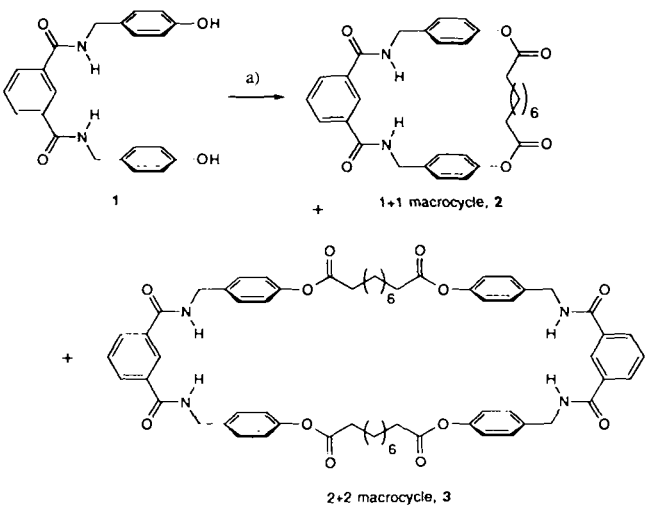
Catenane Chameleons: Environment-Sensitive Translational Isomerism in Amphiphilic Benzylic Amide [2]Catenanes**

David A. Leigh,* Karen Moody, John P. Smart, Karen J. Watson, and Alexandra M. Z. Slawin

The organization of two or more amphiphilic molecules into oligomeric and polymeric ensembles such as micelles, reverse micelles, and lipid bilayers[1, 2] is a spectacular example of molecular self-assembly which gives rise to supramolecular structures with properties exploited by both nature (for example cell membranes[3]) and mankind (for example detergents,[4] drug delivery systems[5, 6]). Here we report the synthesis, structure, and properties of a new class of constitutionally simple, but topologically complex, compounds containing amphiphilic units connected by noncovalent, mechanical linkages to form catenanes.[7–14] These remarkable *unimolecular* species exhibit in solution conformational and dynamic properties reminiscent of the micellar and reverse micellar behavior of classical, *multimolecular* amphiphilic systems. In particular, in polar solvents the amphiphilic units of the catenanes arrange themselves such that the polar groups are at the surface of the supramolecular structure where they can form hydrogen bonds with solvent molecules and the lipophilic chains are on the inside where their interaction with the solvent is minimized. In nonpolar media the situation is reversed, that is the catenanes undergo a chameleon-like translational isomerism, adopting a supramolecular conformation to suit the character of the local environment. The X-ray crystal structure of one of the catenanes is consistent with the preferred conformation in nonpolar solvents: one macrocycle (the "host"[15]) of each catenane adopts a conformation that has convergent hydrogen bonding sites; the other (the "guest") one with divergent hydrogen bonding sites. Extraordinary double bifurcated hydrogen bonding occurs between host and guest in the solid state and, together with polarphobic forces, determines the supramolecular conformations adopted by the amphiphilic catenanes in solution.

We recently described[16, 17] the synthesis of a series of octaamide benzylic amide catenanes that exhibit a range of dynamic behavior, dependent upon both steric and electronic factors,[17] and solvent-controlled rates of macrocyclic ring rotation mediated by the strength of the intermacrocyclic ring hydrogen bonding. The solid-state structure[16] of one catenane revealed six intramolecular, interring hydrogen bonds per catenane and an extensive network of π-stacks composed of four aromatic rings that together were proposed to provide the driving force for the formation of the topologically complex product. We have now investigated the effect on the benzylic amide catenane self-assembly process of removing some of the amide groups and aromatic rings in the catenane precursors.

Initial base-promoted reactions of the diol **1** and sebacoyl chloride (Scheme 1) in various polar solvents (e.g. THF, MeCN, pyridine, DMF; **1** is insoluble in halogenated and less polar solvents) led to the (1 + 1) and (2 + 2) macrocycles **2** and **3**, respectively, in combined yields of up to 80%, but no catenanes could be detected. Since directional hydrogen bonds are weak in these solvents, we sought methods that would allow the use of **1** in less polar media so as to maximize the strength of



Scheme 1. The condensation of the diol **1** with sebacoyl chloride and triethylamine in polar solvents. a) $ClOC(CH_2)_8COCl$, Et_3N, polar solvents (e.g. THF, MeCN, pyridine, DMF).

the hydrogen bonding interactions necessary for benzylic amide catenane assembly.

Stannylation with di- and trialkyltin compounds has been exploited, particularly in carbohydrate chemistry, to modify the reactivity of hydroxyl groups and to solubilize polyols in nonpolar solvents.[18] Although the attempted preparation of the bis(dibutylstannylene ether) derivative of **1** led to an insoluble gum, the analogous bis(tributylstannylene ether) derivative **4** could be prepared quantitatively in toluene by removal of water (Dean–Stark apparatus) and proved highly soluble in common halogenated solvents. In contrast to the results obtained by using the underivatized diol, **4** reacts with sebacoyl chloride in the presence of triethylamine[19] in anhydrous chloroform under high dilution conditions to give the (1 + 1 + 1 + 1) [2]catenane **5** in 18% yield, together with **2** (19%) and **3** (14%, Scheme 2). The different macrocycles were distinguished unambiguously by mass spectrometry and the (1 + 1 + 1 + 1) catenane **5** was discernible from the isomeric (2 + 2) macrocycle **3** by FAB-MS fragmentation patterns, ^{1}H NMR spectroscopy, and X-ray crystallography (see below).

Scheme 2. Preparation of **4** and its condensation with *n*-alkanedicarboxylic acid dichlorides and triethylamine in anhydrous chloroform. a) $(Bu_3Sn)_2O$, toluene, Dean-Stark apparatus; b) $ClOC(CH_2)_nCOCl$, Et_3N, anhydrous $CHCl_3$ [29]. [a] From FAB-MS (MS-MS excludes catenane formation); however, these compounds proved too insoluble to be isolated.

Single crystals of **5** suitable for investigation by X-ray diffraction were obtained from $CHCl_3$/cyclohexane mixtures by vapor diffusion. The crystal structure analysis (Figs. 1a–d) shows that

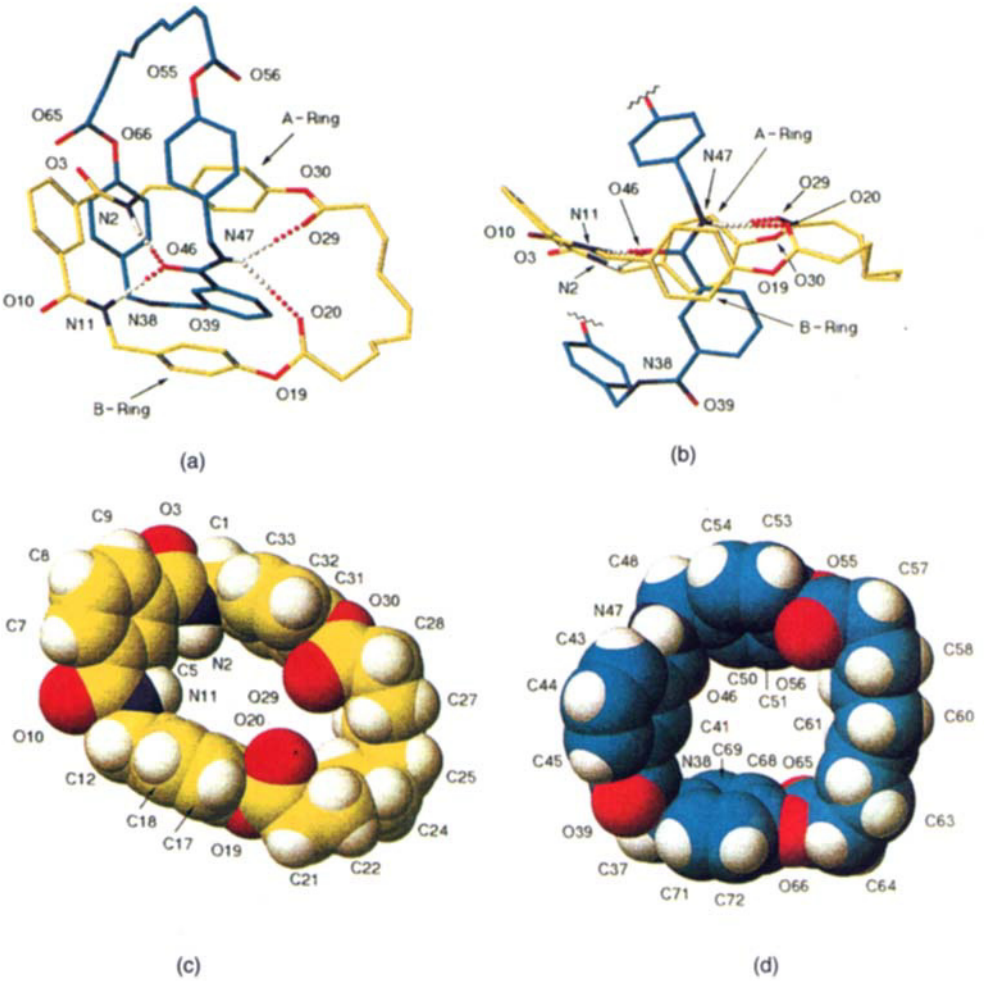

Fig. 1. Solid-state structure of the [2]catenane **5** as determined by X-ray crystallography [26] (for clarity carbon atoms of the "host" macrocyclic ring of the catenane are shown in yellow and those of the guest in blue; oxygen atoms are depicted red, nitrogen atoms purple, and hydrogen atoms white). a) Framework representation of the [2]catenane illustrating the double bifurcated hydrogen bonding. Intramolecular hydrogen bond lengths [Å]: N2···O46 3.232 [2.230 for NH···O]; N11···O46 2.989 [2.610 for NH···O]; O29···N47 3.365 [2.801 for NH···O]; O20···N47 3.483 [3.112 for NH···O]. Intermolecular hydrogen bonding occurs in the packed structure between N38-H and O10 (N···O distance 2.861 Å; 2.569 for NH···O) of adjacent catenanes. b) Framework representation of the [2]catenane illustrating π stacking between two aromatic rings of the host macrocycle and a benzamide unit of the guest. Closest contact distances [Å]: "External" (ring-B, Fig. 1b) host aromatic ring···guest benzamide unit 3.541; "internal" (ring-A, Fig. 1b) host aromatic ring···guest benzamide unit 3.296. c) Space-filling representation of the host macrocycle. Selected bond lengths [Å]: O10–C10 1.228, N11–C10 1.319, N11–C12 1.441, O19–C20 1.343, O20–C20 1.156, O29–C29 1.189, O30–C29 1.327, N2–C1 1.533, N2–C3 1.184, O3–C3 1.332. Selected bond angles [°]: C4-C3-O3 112.11, O3-C3-N2 121.44, C3-N2-C1 117.52, N2-C1-C34 110.53, C31-O30-C29 123, O30-C29-O29 118.81, O29-C29-C28 130.65, C21-C20-O20 131.66, O20-C20-O19 125.64, C20-O19-C16 117.77, C13-C12-N11 112.55, C12-N11-C10 122.20, N11-C10-O10 120.72, O10-C10-C6 120.998. Selected dihedral angles [°]: C5-C4-C3-O3 145.499, C5-C4-C3-N2 −22.600, C4-C3-N2-C1 −170.190, C3-N2-C1-C34 141.808, C36-C31-O30-C29 −112.517, C31-O30-C29-O29 0.557, C15-C16-O19-C20 131.868, C16-O19-C20-C21 −12.378, C5-C6-C10-O10 −155.454, C5-C6-C10-N11 26.886, C10-N11-C12-C13 −167.526. d) Space-filling representation of the guest macrocycle. Selected bond lengths [Å]: O46–C46 1.258, N47–C46 1.324, N47–C48 1.445, O55–C56 1.32, O56–C56 1.498, O65–C65 1.227, O66–C65 1.334, N38–C37 1.472, N38–C39 1.309, O39–C39 1.209. the two chemically identical component macrocycles of the [2]catenane adopt very different conformations in the solid state. One macrocycle (Fig. 1c, carbon atoms shown in yellow) effectively acts as a "host" for the other and binds through four hydrogen bonds in an extraordinary double bifurcated motif to *both* sides of an amide group on the other ("guest") macrocycle (Fig. 1d, carbon atoms shown in blue).

The host macrocycle (Fig. 1c) adopts a flattened chairlike conformation which is almost D_2-symmetric; the cisoid isophthaloyl 1,3-diamide group and the carbonyl groups of the phenolic esters are directed into the cavity to form precisely positioned convergent hydrogen bonding sites. The guest macrocycle (Fig. 1d) has a more open and less regular geometry which allows both the isophthaloyl amides and the phenolic ester groups to adopt their preferred transoid orientations. The O46-C46-N47-H amide group of the guest is accessible by virtue of the open conformation of the macrocycle and acts as the divergent double hydrogen bonding site for the host macrocycle. In addition to the four hydrogen bonding groups, the aromatic A- and B-rings of the host form close noncovalently bonded contacts with the extended π-system of the C42-C46-(-O46)-N47 benzamide group of the guest (closest π-stacking distances 3.541 and 3.296 Å, Fig. 1b). However, in contrast to the amide catenane solid-state structures reported previously,[16, 20, 21] there are no other π-stacking interactions found in the crystal structure of **5**, suggesting that such interactions are, after all, of limited importance in the catenane assembly process.

As seen with both the benzylic amide [2]catenanes[16] and the catenane systems investigated by Hunter and Vögtle,[20, 21] the bifurcated hydrogen bonding to the amide carbonyl group (O46, Fig. 1a and b) does not occur to the lone pairs of the oxygen atom—such an interaction is prevented in these molecules on steric grounds—but rather orthogonal to them. In the absence of the conventional H···lone pair hydrogen bond geometry the thermodynamic driving force for this unusual (but clearly strong since it drives the entire catenane assembly process and has short NH···O bond lengths of 2.23 and 2.61 Å) interaction appears to be either a general, nondirectional electrostatic association between the δ^- oxygen and δ^+ hydrogen atoms, or a specific directional interaction between the two amide hydrogen atoms and the π electrons of the carbonyl group. In contrast, the weaker O···H(N)···O bifurcated hydrogen bonding (2.80 and 3.11 Å) from the ester carbonyl groups (O20 and O29) to the amide (N47) hydrogen atom occurs in a standard fashion to the lone pairs of the sp^2-hybridized oxygen atoms.

A comparison of the ^{1}H NMR spectra (Fig. 2a) of the (1 + 1) macrocycle **2** (the (2 + 2) macrocycle **3** is insoluble in halogenated solvents) and the (1 + 1 + 1 + 1) catenane **5** allows the determination of the "supramolecular conformation" adopted by the [2]catenane in $CDCl_3$ solution.[22] The chemical shifts of the *h*, *i*, *j*, and *k* protons in the sebacoyl chains are virtually identical for **2** and **5**, suggesting that in the catenane the alkyl chains spend little time in close proximity to aromatic rings which would cause shielding or deshielding effects. In contrast, the protons of the benzylic spacer (*e*, *f*, and *g*) show large shielding (up to $\Delta\delta = 0.7$) in the catenane with respect to the analogous protons in the macrocycle. These observations are consistent with the preferred conformation of the catenane in $CDCl_3$ being similar to that determined by X-ray crystallography for the solid state (Fig. 3, conformation **I**). The lipophilic sebacoyl chains are on the surface of the molecule away from the aromatic rings and polar regions, whereas the hydrogen bonding groups are buried in the middle of the supramolecular structure involved in intermacrocycle, intramolecular hydrogen bonding shifting the amide protons (*d*) downfield by $\Delta\delta = -1.5$. The network of hydrogen bonds locks the aromatic rings in close proximity to each

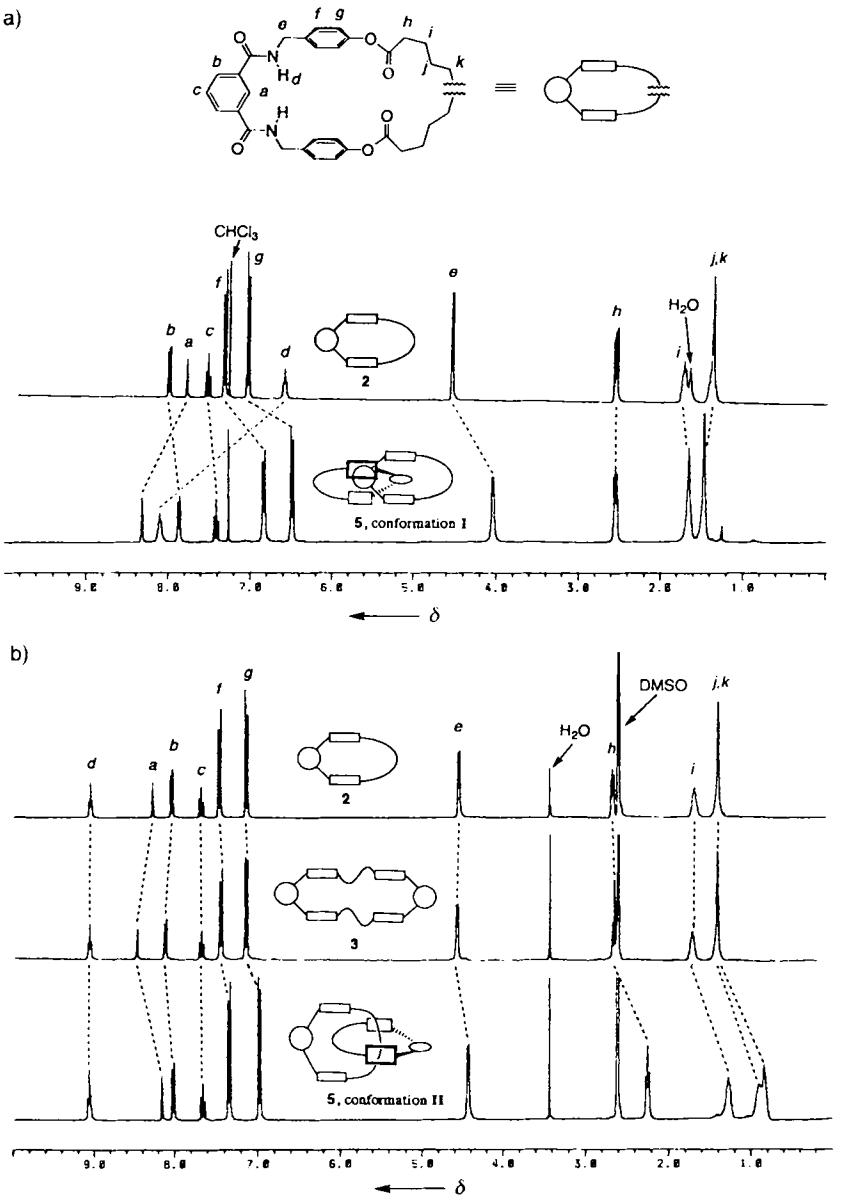

Fig. 2. a) ^{1}H NMR spectra (300 MHz, $CDCl_3$) of **2** and **5**. b) ^{1}H NMR spectra (300 MHz, [D$_6$]DMSO) of **2**, **3**, and **5**.

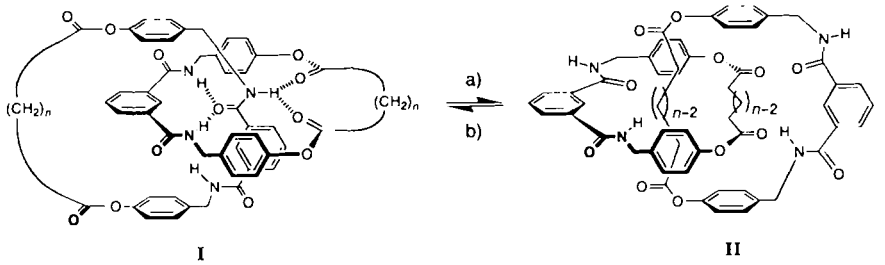

Fig. 3. Translational isomerism of amphiphilic benzylic amide [2]catenanes in nonpolar (conformation **I**) and polar solvents (conformation **II**). The preferred supramolecular conformation in nonpolar solvents is similar to that determined for the solid-state by X-ray crystallography.

other leading to the shielding effects seen in the ^{1}H NMR spectra. Further supporting evidence is found in the relative chemical shift of the isophthaloyl ring protons; the protons *b* and *c* show small shielding shifts, but proton *a* is substantially deshielded ($\Delta\delta = 0.5$) by the cone of the carbonyl group which occurs through the bifurcated hydrogen bonding geometry seen in the X-ray crystal structure (cf. conformation **I**, Fig. 3).

In [D$_6$]DMSO, a hydrogen bond accepting solvent, comparison of the ^{1}H NMR spectra (see Fig. 2b) of the (1 + 1) and (2 + 2) macrocycles and the (1 + 1 + 1 + 1) catenane shows that in this solvent a dramatically different supramolecular conformation is adopted by the catenane. The aromatic protons of the two macrocycles and the catenane occur at similar chemical shifts, indicating that little shielding/deshielding is taking place in the catenane, that is the aromatic rings are spending little time close to one another. However, the protons of the sebacoyl chain of the catenane are heavily shielded with respect to those of the two macrocycles. This is consistent with a structure where the lipophilic chains of the catenane are buried in the center of the catenane (Fig. 3, conformation **II**) and shielded by the aromatic spacer groups that line the cavity, and the hydrogen bonding amide groups are exposed to interact with the polar solvent. The driving force for such a geometry is twofold: the hydrogen bonding of the amide groups with the solvent and the polarphobic benefit of shielding the lipophilic chains from the polar media.[23]

The synthesis of **5** is not unique (see Scheme 2). Variation in the length of the alkyl chain of the dicarboxylic acid dichloride shows that a minimum of six carbon atoms is required to allow catenane formation, in broad agreement with inspection of CPK space-filling models. The yields of (1 + 1) macrocycle and [2]catenane decrease on shortening of the alkyl chain, reflecting the increase in strain and preorganization required for the ring closure reactions. The ^{1}H NMR spectra of each of the [2]catenanes in $CDCl_3$ and [D$_6$]DMSO mirror the trends outlined above for the sebacoyl (C_8) spacer.

The simplicity of the catenane NMR spectra suggest that whichever supramolecular conformation is preferentially adopted the rotation of the macrocyclic rings is rapid on the NMR timescale at room temperature in either type of solvent. Low-temperature ^{1}H NMR studies in $CDCl_3$ give a rate of rotation (circumvolution) of the component macrocyclic rings of the [2]catenane **5** of 8100 s^{-1} at room temperature ($\Delta G^{\ddagger}$ = 11.3 kcal mol^{-1}; T_c = 240, $\Delta\nu$ = 105 Hz, k_c 233 s^{-1}).[24] Although a similar experiment with [D$_6$]DMSO is not possible because of the freezing point of the solvent, in neat [D$_7$]DMF (an alternative hydrogen bond accepting solvent) circumvolution of **5** at room temperature was found to occur at a rate greater than 100000 s^{-1} ($\Delta G^{\ddagger} < 10.2$ kcal mol^{-1}).[25] Initial results suggest that the solvent-mediated rotation frequency is a continuum and that mixing of two or more solvents (e.g. [D$_4$]MeOH and $CDCl_3$) allows regulation of the rate of circumvolution of the macrocyclic rings at a given temperature. Such tunable control over the frequency and mode of translational isomerism is of fundamental importance to the design of nanoscale devices based upon molecular shuttles and switches.

The amphiphilic benzylic amide catenanes described illustrate well how the noncovalent assembly of even the simplest of molecules can result in materials with remarkable and unexpected properties by virtue of their supramolecular architectures. The chameleon-like ability of the catenanes to alter their shape, conformation, and surface properties in accordance with their local environment offers fascinating possibilities in areas where interactions at surfaces or interfaces are important, such as drug delivery systems, surfactants, nanoemulsions, vesicles, interfacial arrays, thin films, and "nanotape". The opportunities for new strategies in organic synthesis will be discussed elsewhere. Finally, the discovery of a double bifurcated binding site for an amide group provides a route to the design of synthetic receptors for amino acids and peptides and serves as a reminder that although hydrogen bonding is considered amongst the best understood of supramolecular forces, the rules regarding its geometrical requirements are, as yet, nowhere near complete.

Experimental Procedure

4: To a stirred suspension of the diol **1** (0.451 g, 1.2 mmol) in toluene (30 mL) was added bis(tributyltin)oxide (0.715 g, 1.2 mmol). The mixture was heated at reflux for 20 h with removal of water by azeotropic distillation (Dean-Stark apparatus). The resulting clear solution was cooled and the toluene removed under reduced pressure. After drying for 2 h in vacuo the product **4** was obtained as a cream gum (1.14 g, 100%) and used immediately.

Preparation of **5**, **2**, and **3**: A solution of sebacoyl chloride (0.32 g, 1.34 mmol) in anhydrous $CHCl_3$ (10 mL) [29] and **4** (1.14 g, 1.2 mmol) in anhydrous $CHCl_3$ (20 mL) [29] were added simultaneously over 2 h, by using motor-driven syringe pumps, to a stirred solution of triethylamine (0.35 mL, 2.53 mmol) in anhydrous $CHCl_3$ (100 mL) [29] at room temperature under argon. After 24 h the reaction mixture was filtered and the combined filtrates washed successively with 0.1 M hydrochloric acid (50 mL), distilled water (3 × 50 mL), 10% aqueous potassium fluoride solution (50 mL), and distilled water (3 × 50 mL). The organic washings were dried over anhydrous $MgSO_4$, filtered, the solvent removed under reduced pressure, and the resulting solid subjected to column chromatography on silica gel (98:2 $CHCl_3$:MeOH as eluent) to give as the first fraction eluted the [2]catenane **5** (0.117 g, 18%); m.p. 309 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.45 (bs, 16H, H-j,k), 1.75 (bs, 8H, H-i), 2.58 (t, J = 6 Hz, 8H, H-h), 4.05 (d, J = 6 Hz, 8H, H-e), 6.45 (AA', J = 8 Hz, 8H, H-g), 6.85 (BB', J = 8 Hz, 8H, H-f), 7.4 (t, J = 8 Hz, 2H, H-c), 7.85 (d, J = 8 Hz, 4H, H-b), 8.10 (bt, 4H, H-d), 8.30 (s, 2H, H-a); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.47 (C-k), 28.12 (C-j), 29.03 (C-i), 33.86 (C-h), 43.82 (C-e), 120.92, 127.46, 127.62, 130.06, 130.12 (C-a,b,c,f,g), 134.95, 135.59 (quaternary C), 149.48 (*C*-OCO), 166.87 (*C*ONH), 172.74 (O*C*=O); FAB-MS: m/z 1085 [M + H], 565 [M/2 + Na], 543 [M/2 + H]; anal. calcd for $C_{64}H_{88}N_4O_{12}$: C 70.8, H 6.3, N 5.2; found C 70.5, H 6.3, N 4.9. The second fraction eluted was characterized as the (1 + 1) macrocycle **2** (0.124 g, 19%): m.p. 262–263 °C; ^{1}H NMR (300 MHz, $CDCl_3$)[22]: δ = 1.40 (bs, 8H, H-j,k), 1.78 (bs, 4H, H-i), 2.60 (t, J = 6 Hz, 4H, H-h), 4.60 (d, J = 6 Hz, 4H, H-e), 6.50 (bt, 2H, H-d), 7.00 (AA', J = 8 Hz, 4H, H-g), 7.35 (BB', J = 8 Hz, 4H, H-f), 7.55 (t, J = 8 Hz, 1H, H-c), 7.80 (s, 1H, H-a), 8.05 (d, J = 8 Hz, 2H, H-b); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.90 (C-k), 28.44 (C-j), 29.25 (C-i), 34.01 (C-h), 43.88 (C-e), 122.01, 123.68, 129.46, 129.52, 130.89 (C-a,b,c,f,g), 134.69, 135.30 (quaternary C), 150.25 (*C*-OCO), 166.59 (*C*ONH), 172.29 (O*C*=O); FAB-MS: m/z 565 [M + Na], 543 [M + H], anal. calcd for $C_{32}H_{34}N_2O_6$: C 70.8, H 6.3, N 5.2; found C 70.5, H 6.0, N 5.1. The third fraction eluted was characterized as the (2 + 2) macrocycle **3** (0.091 g, 14%): m.p. 301–303 °C; ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 1.40 (bs, 16H, H-j,k), 1.85 (bs, 8H, H-i), 2.65 (t, J = 6 Hz, 8H, H-h), 4.56 (d, J = 6 Hz, 8H, H-e), 7.17 (AA', J = 8 Hz, 8H, H-g), 7.43 (BB', J = 8 Hz, 8H, H-f), 7.65 (t, J = 8Hz, 2H, H-c), 8.00 (d, J = 8 Hz, 4H, H-b), 8.39 (s, 2H, H-a), 9.06 (bt, 4H, H-d); ^{13}C NMR (75 MHz, [D$_6$]DMSO): δ = 28.304 (C-k), 32.436 (C-j), 32.573 (C-i), 37.691 (C-h), 46.243 (C-e), 125.666, 130.248, 132.468, 132.550, 134.014 (C-a,b,c,f,g), 138.561, 141.085 (quaternary C),

153.325 (*C*-OCO), 169.879 (CONH), 175.955 (OC-O); FAB-MS: *m/z* 1107 [*M* + Na], 1085 [*M* + H]; anal. calcd for $C_{64}H_{68}N_4O_{12}$: C 70.8, H 6.3, N 5.2; found C 70.3, H 5.9, N 5.1.

[19] The necessity of the triethylamine is at first sight somewhat surprising and was originally included by mistake; however, the reaction does not proceed in the absence of the amine! The phenolic stannylene derivative **4** is less reactive than the alkoxystannylene derivatives used routinely with acid chlorides in carbohydrate chemistry and therefore the role of the triethylamine may be to activate the stannylene acetal derivative either directly, by nucleophilic attack on tin, or indirectly by liberating the stannophilic chloride ion from the acid chloride.

[22] The ^{1}H NMR spectra of the macrocycle **2** in $CDCl_3$ (but not [D_6]DMSO) is slightly concentration dependent due to self-association ($K_a = 0.1\ M^{-1}$); however, the shifts of all non-amide hydrogen atoms are very small ($\Delta\delta < 0.02$). All the NMR spectra reported here were carried out at 5 mM concentration)
[23] A less dramatic, but equally fascinating, example of solvent-dependent translational isomerism occurs with one of the catenanes described by Stoddart et al., and was attributed to ion solvation effects: P. R. Ashton, M. Blower, D. Philp, N. Spencer, J. F. Stoddart, M. S. Tolley, R. Ballardini, M. Ciano, V. Balzani, M. T. Gandolfi, L. Prodi, C. H. McLean, *New J. Chem.* **1993**, *17*, 689.
[24] I. O. Sutherland, *Ann. Rep. NMR Spectrosc.* **1971**, *4*, 71.
[25] Because of the symmetry of conformation **II**, the rate of rotation in [D_7]DMF was calculated by line broadening of protons passing through the macrocycle cavity rather than by the coalescence method [see J. Sandström, *Dynamic NMR Spectroscopy*, Academic Press, London, **1982**].
[26] Crystal data for **5**: $C_{64}H_{68}O_{12}N_4$, $M = 1085.26$, a clear block crystal, dimensions $0.6 \times 0.6 \times 0.58$ mm, was mounted in epoxy resin on a quartz fiber, monoclinic, space group $P2_1/n$ (no. 14), $a = 14.722(2)$, $b = 20.447(2)$, $c = 20.056(3)$ Å, $\beta = 105.17(1)^\circ$, $V = 5826(1)$ Å^3, $\rho_{calcd} = 1.24$ g cm^{-3}, $Z = 4$; 9358 reflections were measured on a Rigaku AFC7S diffractometer by using the ω-scan technique, of which 8968 were unique ($R_{int} = 0.02$), and 5720 observed ($I > 3\sigma I$, $2\theta_{max} = 120.2^\circ$, $Cu_{K\alpha}$ radiation at $T = 293.2$. The data were corrected for Lorentz and polarization effects and for absorption using DIFABS [27] ($\mu = 6.6$ cm^{-1}, min/max transmission 0.60/1.00). The structure was solved and refined on 286 variables [20.0 reflection/parameter ratio] using the teXsan crystallographic package of Molecular Structure Corporation [28]. The crystal decayed by 19.3% during data collection and a linear correction factor was applied to account for this phenomenon. Some disorder was observed in the middle region of the alkyl chains and at O65 and O66, and these could not always be separated into discrete partial occupancy carbon and oxygen atoms. All six-membered rings were refined as rigid isotropic bodies with a common *B* factor. The nitrogen, oxygen, and all other carbon atoms were refined anisotropically. All hydrogen atoms on carbon atoms were placed in idealized fixed geometries. All hydrogen atoms on nitrogen atoms were located from a ΔF map and allowed to refine. The disorder in the alkyl chains and decay leads to a fairly high agreement factor of $R = 0.197$ and $R_w = 0.210$, refined against $|F|$, with a residual electron density of 0.77 e Å^{-3}. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

A Chelating Triscarbene Ligand and Its Hexacarbene Iron Complex**

Ulrich Kernbach, Matthias Ramm, Peter Luger, and Wolf P. Fehlhammer*

Dedicated to Professor Henri Brunner on the occasion of his 60th birthday

Here we report on a triscarbene ligand which has the topology of Trofimenko's tris(pyrazolyl)borate,[1] and thus perfectly meets all requirements for the synthesis of novel chelate-like poly- and percarbene complexes. At the same time we present the first hexacarbene iron complex with this ligand.

The first hexacarbene complexes **1** were synthesized by us in 1985 from simple metal compounds and 2-hydroxyalkyl isocyanides, which proved to be a highly efficient approach to homoleptic carbene complexes.[2] The easy access mainly to tetrakis(oxazolidin-2-ylidene) complexes of the nickel triad[3] and their straightforward handling prompted us to study the reactivity of the coordinated ligand. Here, a particularly attractive goal was the linking together of ligands to form C-porphyrin-type systems and C cages (from hexacarbene moieties), that is, possibly highly stable materials with interesting properties. Unfortu-

[**] Homoleptic Carbene Complexes, Part 7. This work has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Bundesministerium für Bildung und Wissenschaft (Graduiertenkolleg "Synthese und Strukturaufklärung niedermolekularer Verbindungen"). Part 6: ref. [6].

nately, all experiments in this direction were unsuccessful which we attributed to the "wrong" conformation found in all structures of the five-membered heterocycles. These were arranged almost perpendicular with respect to the coordination plane of the metal. It is for the same reason, presumably, that even the precursor complex **2** is unable to react in the desired fashion.[4] As regards functionality and reactivity, **2** appeared particularly predisposed to an eightfold(!) ring closure to give **3**. In contrast, both the classical addition of amines (here of diamines) to isocyanide ligands and the deprotonation of bisimidazolium salts in the presence of palladium iodide turn out to be feasible routes at least to the first chelating percarbene complexes **4** and **5**, respectively.[5, 6]

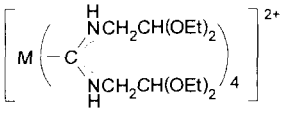
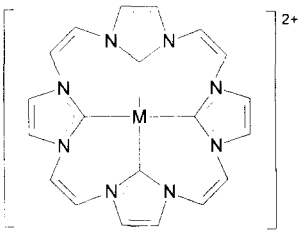
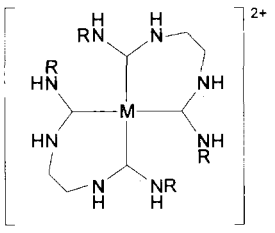
(M = Co^{III}, Rh^{III})



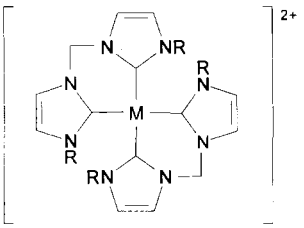
2
(M = Pd^{II}, Pt^{II})



3
(M = Pd^{II}, Pt^{II})

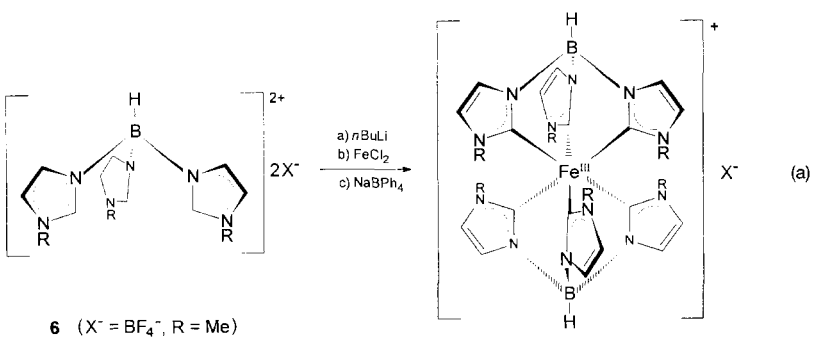


4
(M = Pd^{II}, Pt^{II})



5
(M = Pd^{II}, R = Me, Et)

By an extension of the latter approach, that is by trialkylation of tris(imidazolyl)borate to give **6** followed by deprotonation with *n*BuLi, coordination to Fe^{2+}, and precipitation with tetraphenylborate, we have now obtained the bis(tricarbene)iron complex **7** [Eq. (a)] (see Experimental Procedure). As in the case of complexes **5** no efforts were made to isolate the intermediate free tricarbene.[7]



6 (X^- = BF_4^-, R = Me)

7 (X^- = BPh_4^-)

(a)

Surprisingly, the red solid that crystallized from the red solution is a saltlike substance with a complex cation, thus indicating the presence of an iron(III) compound. This is unequivocally confirmed by the magnetic moment which shows the expected value for a low-spin d^5 system.[8] At present it is still unclear when and how the oxidation occurred. After the reaction an iron(III) content of 2.6 wt% was determined in the iron(II) starting material, an amount which, of course, cannot explain the 25% yield of **7**.

Nevertheless, the stability of the organometallic 17-electron species is really astonishing, particularly in view of the reducing character of the reaction mixture. This might be explained, however, by the extraordinary donor abilities of diheteroatom-stabilized carbene ligands which clearly favor higher valent metals for bonding.[2] Closely related findings are, for example, the isolation of the "purely open-chain" hexakis(2-hydroxyethyl isocyanide)iron(II) complex $[Fe^{II}(CNCH_2CH_2OH)_6][BPh_4]_2$[9] and the noncyclization of the 2-hydroxyethyl isocyanide ligands in the product resulting from $H_4[Fe(CN)_6]$ and ethylene oxide, namely $[Fe^{II}(CN)_2(CNCH_2CH_2OH)_4]$[10], that is the nonexistence of a polycarbene iron(II) species.[11] Though as yet, no corresponding iron(III) complex is known either.

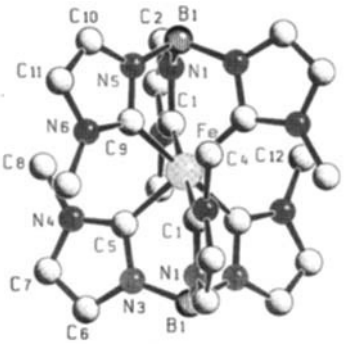


Fig. 1 SCHAKAL drawing of a complex cation of **7** in the crystal. Selected bond lengths [Å] and angles [°]: Fe1–C1 1.987(3), Fe1–C5 1.975(3), Fe1–C9 1.988(4), N1–C1 1.352(3), N1–C2 1.383(4), N1–B1 1.547(4), N2–C1 1.369(3), N2–C3 1.383(4), N2–C4 1.459(4), C2–C3 1.335(4); C5-Fe1-C1 92.22(11), C5-Fe1-C9 87.09(13), C1-Fe1-C9 87.08(14), C1-N1-C2 110.6(2), C1-N1-B1 119.2(3), C2-N1-B1 130.1(3), C1-N2-C3 110.4(2), C1-N2-C4 126.7(3), C3-N2-C4 122.9(3), N1-C1-N2 104.6(2), N1-C1-Fe1 120.4(2), N2-C1-Fe1 135.0(2), C3-C2-N1 107.5(3), C2-C3-N2 106.9(3).

Fig. 2. The highly symmetric (S_6) hexacarbene iron cation of **7** as viewed along the B-Fe-B axis.

The X-ray crystal structure analysis of **7**[12] shows an iron atom which is spherically surrounded by six five-membered heterocycles and is common to six six-membered metallacycles, thereby achieving the same highly symmetric *quasi* cage structure as in numerous bis[hydridotris(pyrazolyl)borato]metal complexes (Figs. 1 and 2).[1] The average Fe–C distance (1.984 Å) as taken from the two crystallographically independent complex cations[13] is greater than the Fe^{III}–N bond lengths of the isomeric bis[hydridotris(3,5-dimethyl-1-pyrazolyl)borato]iron(III) PF_6^- (1.964 Å) and $TCNQ^-$ salts (1.966 Å; TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane)[14] by a little less than the difference between the atomic radii, $r(N_{sp^2}) - r(C_{sp^2})$,[15] which points to very similar bonding situations without metal–ligand multiple bonds. This was certainly to be expected, since

according to the Fe–C(carbene) bond lengths in **8** (2.007(5) Å) and **9** (1.951(10) Å)[16] even in Fe^0-carbene complexes "in case of CO competition" there is no appreciable back donation to the *N,N'*-carbene ligand.

$[Fe(CO)_4\{\overline{CN(Me)CHCHNMe}\}]$ **8**

$[Fe(CO)_3\{\overline{CN(Me)CHCHNMe}\}(PEt_3)]$ **9**

Finally, a comparison of the bonding parameters within the different five-membered heterocycles of the two types of tripod ligands, tris(pyrazolyl)borate and tris(imidazolin-2-ylidene)-borate, is quite informative. While the bond lengths in the pyrazole rings vary very little (1.37 ± 0.02 Å) in spite of the presence of three different combinations of elements (NN, CN, CC), the carbenoid imidazole, as already reported a number of times, exhibits a tendency to break up into two more or less localized π systems that are characterized by short C(carbene)–N bonds (av 1.358 Å) and a C–C double bond (1.332 Å) loosely tied together by two longer C–N bonds (1.383 Å).[5, 6, 17] This structural phenomenon which frequently is even more pronounced has been described by us as "activation of heterocycles"; in fact, recently we have discovered a chemical consequence thereof—the epoxidation of the isolated C–C double bond of carbenoid 4-aminoimidazoles on their oxidative removal from the metal with $KMnO_4/Fe^{3+}$.[18]

The straightforward synthesis, the great similarity to cyclopentadienyl, and the evident stability of its metal complexes are sufficient to predict a brilliant future for the tridentate *C,C',C''* ligand and its organometallic and coordination chemistry. Judging from the recent extremely positive experiences with the "Arduengo carbenes"[19] we are convinced that its application particularly in homogeneous catalysis, for example in the place of triphosphanes, will open new opportunities.

Experimental Procedure

6: Trimethyloxonium tetrafluoroborate (2.25 g, 15.24 mmol) was added to a suspension of potassium hydridotris(imidazolyl)borate (1.28 g, 5.08 mmol) [20] in dichloromethane (50 mL) at 0 °C. The mixture was then stirred for 24 h at 25 °C after which time the solid was filtered off and washed several times with small amounts of ethanol followed by diethyl ether. After the mixture had been dried in high vacuum, **6** (1.55 g, 71%) was obtained as a colorless hygroscopic powder. ^1H NMR (250 MHz, [D$_6$]DMSO, 25 °C, TMS): δ = 3.80 (s, 3H, Me), 7.55 (s, 1H, CH), 7.75 (s, 1H, CH), 8.80 (s, 1H, CH); ^{13}C NMR (62 MHz, [D$_6$]DMSO): δ = 35.3, 123.1, 124.6, 139.4; IR (KBr): $\tilde{\nu}$ = 3075, 2487, 1570, 1271, 1033 cm^{-1}; MS (FAB (positive ion), Xe, DMSO, 3-nitrobenzyl alcohol): *m/z* (%) = 345 (100) [$M^+ - BF_4^-$], 257 (66) [$M^+ - 2BF_4^- - H^+$]; elemental analysis: calcd. (for $C_{12}H_{19}B_3F_8N_6$): C 33.32, H 4.43, N 19.44; found C 31.20, H 4.65, N 18.01%.

7: A solution of *n*BuLi in hexane (1.60 M, 6.02 mL, 9.63 mmol) was added to a suspension of **6** (1.39 g, 3.21 mmol) in THF (100 mL) at −78 °C under argon. After the reaction mixture had been stirred for 30 min at 0 °C, it was again cooled to −78 °C, and anhydrous $FeCl_2$ (0.20 g, 1.60 mmol; Fluka) was added. The suspension was allowed to warm to room temperature and stirred for another 24 h during which time the color changed from a greenish gray to bright red. The red solid was collected on a D4 frit, washed with small portions of THF and diethyl ether, and dissolved in methanol (20 mL). On addition of a saturated solution (5 mL) of sodium tetraphenylborate in methanol, the bordeaux-red complex salt **7** (0.35 g, 25%) precipitated immediately, which was recrystallized from dichloromethane. M.p. 305–307 °C (decomp.); IR (KBr): $\tilde{\nu}$ = 3122, 3053, 2983, 2945, 2463, 1197, 731, 705 cm^{-1}; MS (FAB (positive ion), Xe, DMSO, 3-nitrobenzyl alcohol): *m/z* (%) = 566 (100) [Fe(C-tripod)$_2^+$], 311 (43) [Fe(C-tripod)$^+$]; elemental analysis: calcd. (for $C_{48}H_{52}B_3FeN_{12}$): C 65.05, H 5.92, N 18.98; found C 63.91, H 5.89, N 18.35%. No further defined compound has been obtained from a work-up of the red filtrate by concentration and column chromatography.

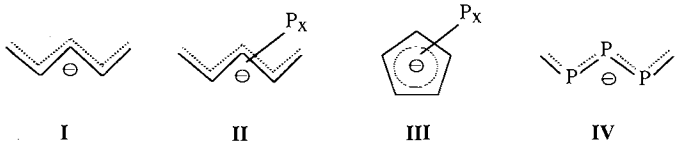
Synthesis, Structure, and Reactivity of a 2,3,4-Triphosphapentadienide**

Vera Thelen, Dietmar Schmidt, Martin Nieger, Edgar Niecke,* and Wolfgang W. Schoeller

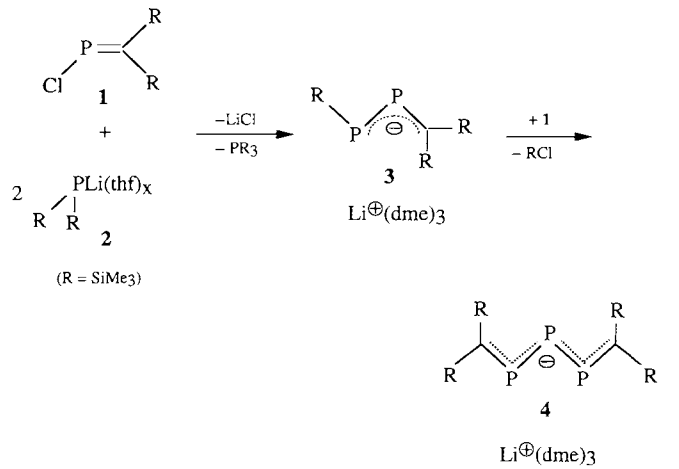
Dedicated to Professor Ralf Appel on the occasion of this 75th birthday

Pentadienides **I**, which, as a result of their different configurations (W, U, S form) and modes of coordination (η^1, η^3, η^5 coordination) have proven to be versatile ligands for d- and f-block metals,[1] have recently attracted interest as π ligands for metals of the s-block.[2] In the context of our work on phosphaallylic anions[3] we became interested in the corresponding vinylogous heteroallylic systems (phospha- and polyphosphapentadienides **II**) about which little is known.[4] Their corresponding cyclic analogues (phospha- and polyphosphacyclopentadienides **III**) are known for their manifold coordination chemistry[6] (σ and π coordination) and are of interest as building blocks for P/C cage compounds.[7] Here we report on the synthesis and structural elucidation of the first lithium salt of a 2,3,4-triphosphapentadienide (**IV**) as well as on the consecutive reactions of this species.



I **II** **III** **IV**

Treatment of the chloromethylenephosphane[8] **1** with two equivalents[9] of lithium bis(trimethylsilyl)phosphanide[10] **2** in DME, led to the lithium salt of the 1,2-diphosphapropenide[11] **3**, which was isolated as a microcrystalline solid. Subsequent reaction of **3** with chloromethylenephosphane **1** proceeded by elimination of trimethylchlorosilane and formation of the lithium salt of the persilylated 2,3,4-triphosphapentadienide **4** · Li(dme)$_3$, suitable crystals of which were obtained for an X-ray structural analysis.[12] The structure determination shows **4** as a discrete anion in the crystal; the shortest contact between the lithium atom, which is coordinated in a distorted octahedral fashion by three dme solvent molecules, and the phosphorus atom P(2) is 620 pm. The anion adopts a W geometry with crystallographic C_s symmetry, as has been established for a variety of pentadienides[1] (Fig. 1). The all-*trans* arrangement of the lone pairs at the phosphorus atoms is energetically most favorable. The atoms of the Si_2C-P-P-P-CSi_2 skeleton are nearly in one plane (average deviation from the best plane: 3.1 pm). Hence, they span a delocalized five-center/six-electron pπ electron system. The large differences in the valence angles at the two-coordinate phosphorus centers are unusual (P(2): 88.3(1)° vs. P(1/3): 113.6(1)°. Associated with this are comparably long P–P distances (213.7(1) pm), which are compensated by a contraction of the P–C bonds (168.7(3) pm).



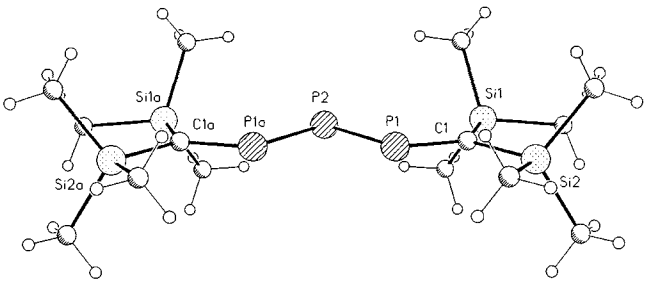


Fig. 1. Structure of the anion **4**. Selected bond lengths [pm] and angles [°]: P1-P2 213.7(1), P1-C1 168.7(3), C1-Si1 185.3(3), C1-Si2 185.8(3); P1-P2-P1a 88.3(1), C1-P1-P2 113.6(1), P1-C1-Si1 126.6(2), P1-C1-Si2 112.6(2), Si1-C1-Si2 120.9(2).

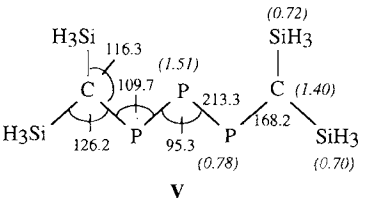
The results of an ab initio calculation[14] on the model system, $[(H_3Si)_2CPPPC(SiH_3)_2]^-$ **V** are in agreement, with respect to the P–C and P–P distances, with those determined experimentally for **4**. On the other hand, the calculated P-P-P angle is wider than the one found in **4** (Fig. 2). According to a vibrational analysis, the structure is highly flexible. On this basis, deviations from the experimentally determined structure can be attributed to steric hindrance. A NBO analysis on the parent system **V**[16] reveals the expected density distribution for the π-space to be most strongly pronounced at the positions 1, 3, and 5. The stabilizing effect of the silyl substituents (Fig. 2) is indicated by the energy of the HOMO (π_3, b_1 in C_{2v}) which is lower than that of the parent system $[H_2CPPPCH_2]^-$.[17]



V

Fig. 2. Calculated [6-31 + G*] π-electron density for 1,1,5,5-tetrasilyl-2,3,4-triphosphapentadienide **V**.

The observed multiplet structure of the resonance signals in the ^{31}P NMR spectrum of **4** (δ = 494.1(d), 295.5(t); J(P, P) = 430 Hz) indicates the preference of the W geometry in solution as well. Diagnostic criteria for the constitution of **3** are the significant ^{31}P and ^{13}C NMR data [^{31}P NMR: δ = 86.1, 510.8; ^1J(P, P) = 487 Hz); ^{13}C NMR: δ = 137.6 (dd, ^1J(C, P) = 97.6 Hz, ^2J(C, P) = 4.6 Hz)]. The *cis* position of the P-bound trimethylsilyl group with respect to the lone pair at the central phosphorus atom is evidenced by the large value of ^3J(P, C) = 18.6 Hz.

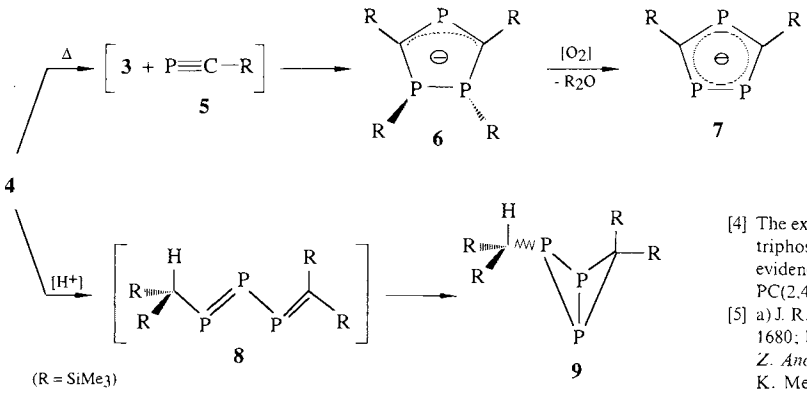
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The lithium salt of the heteropentadienide anion **4** is remarkably stable in DME solution; however, above 100 °C, it rearranges to the corresponding salt of the 1,2,4-triphospholenide **6**, which was characterized by its NMR data [^{31}P NMR: $\delta = -71$ (d), 377 (t), $^2J(P,P) = 15.3$ Hz; ^{13}C NMR: $\delta = 94.1$ (m)]. Decomposition of **4** into the trimethylsilylphosphaalkyne[16] **5** and the 1,2-diphosphaallylanion **3** appeared plausible as a primary step of this "rearrangement". Subsequent [2+3]cycloaddition of **3** and **5**, followed by silyl group migration yields **6**.[18] The formation of **6** from **3** and **5** is comparable to that of the dihydrophospholyl system from 1-phosphaallyl anions and alkynes.[3b] In the presence of air the heterocyclic anion **6** was transformed to the 1,2,4-triphospholide **7**[19] by removal of the two trimethylsilyl groups at the phosphorus atoms. The lithium salt of **7** was isolated as a yellow, crystalline solid. The formation of three two-coordinate phosphorus centers in **7** is evidenced by the low-field shift of all ^{31}P NMR signals [$\delta = 313$ (t), 328 (d), $^2J(P,P) = 31.8$ Hz], a diagnostic tool for polyphospholid ions.[6].

Unexpectedly in the presence of traces of moisture the thermolysis of **4** yields the 1,2,3-triphosphabicyclo[1.1.0]butane **9**, which probably forms from a valence isomerization of the 1,2,3-triphosphabutadiene intermediate **8**. The bicyclic structure of compound **9** follows from the characteristic[20] ^{31}P NMR data of this class of compounds [$\delta = -72.5$ (t), -263.5 (dd), $^1J(P,P) = 179.3$ Hz].



Experimental Procedure

3: A solution of $LiP(SiMe_3)_2 \cdot 1.8$ THF (1.56 g, 5 mmol) in DME (10 mL) was added to a stirred and cooled (−40 °C) solution of $ClP{=}C(SiMe_3)_2$ (0.56 g, 2.5 mmol) in DME (5 mL). After the solution was allowed to warm up to 25 °C the volatiles were removed under vacuum and the residue was taken up in benzene (20 mL). The solution was filtered, the solvent removed, and the residue dried under vacuum. Yield: 76%; m.p. 35–37 °C. $^{31}P\{^1H\}$ NMR (121.5 MHz, DME): $\delta = 86.1$ (d), 510.8 (d, $^1J(P,P) = 487$ Hz). ^{1}H NMR (300 MHz, C_6D_6): $\delta = 0.72$ (s, 9H, $CSiMe_3$-*exo*); 0.76 (s, 9H, $CSiMe_3$-*endo*); 0.95 (s, 9H, $PSiMe_3$). ^{13}C NMR (75.5 MHz, C_6D_6): $\delta = 4.9$ (d, $^3J(C,P) = 13.7$ Hz, $PCSiC_3$-*exo*), 8.7 (d, $^3J(C,P) = 10.3$ Hz, $PCSiC_3$-*endo*), 6.2 (m, $|^2J(C,P) + {}^3J(C,P)| = 18.6$ Hz, $PPSiC_3$). 137.6 (dd, $^1J(C,P) = 97.6$, $^2J(C,P) = 4.6$ Hz, PPC).

4: A solution of **1** (0.62 g, 2.5 mmol) in DME (8 mL) was added dropwise to a solution of **3** (2.5 mmol) in DME (10 mL) at −78 °C. The reaction mixture was allowed to warm up to 20 °C and stirred, the volatiles were removed under vacuum, and the residue was taken up in a small amount of DME. Compound **4** crystallized from the concentrated solution at −25 °C as deep red prismlike crystals. Yield: 58%. Concentration of the mother liquor and crystallization afforded further pure product. $^{31}P\{^1H\}$ NMR (121.5 MHz, DME): $\delta = 494.1$ (d), 295.5 (t, $^1J(P,P) = 430.1$ Hz); ^{1}H NMR (300 MHz, ext. ref., DME): $\delta = 0.4$ (s, 9H, $CSiMe_3$), 0.5 (s, 9H, $CSiMe_3$). ^{13}C NMR (75.5 MHz, ext. ref., DME): $\delta = 2.3$ (d, $^3J(C,P) = 9.9$ Hz, $PCSiC_3$), 3.0 (m), $|^3J(C,P) + {}^4J(C,P)| = 12.5$ Hz, $PPCSiC_3$), 156.8 (m, X part of a ABB'X spin system: $^2J(C,P) = 4.5$ Hz; $|^1J(C,P) + {}^3J(C,P)| = 60.3$ Hz. MS (EI, 70 eV): *m/z* (%): $[M^+ + H]$ 410(3), $[M^+ + H - SiMe_3]$ 377(2.6), $[PPCSiMe_3]^+$ 147 (15), $[SiMe_3]^+$ 73(100).

6: A solution of **4** (2 mmol) in DME was heated to reflux for 2 h at 100 °C, during which the reaction mixture changed color from deep red to violet. The volatiles were removed under vacuum at 25 °C to afford **6** as a red-violet oil. ^{31}P NMR (121.5 MHz, DME): $\delta = -71$ (d); 377 (t) ($^2J(P,P) = 15.3$ Hz). ^{1}H NMR (300 MHz, ext. ref., DME): $\delta = 0.4$ (s), 0.5 (s) ($SiMe_3$). ^{13}C NMR (75.5 MHz, ext. ref., DME): $\delta = 0.1$ (m, $|^2J(C,P) + {}^3J(C,P)| = 15.2$ Hz, $PPCSiC_3$), 5.4 (dd, $^3J_{CP} = 4.6$, 1.5 Hz, $PPCSiC_3$), 94.1 (m, X part of an AMM'X spin system: $^1J(C,P_A) = 70$ Hz, $|^1J(C,P_M) + {}^2J(C,P_{M'})| = 61.8$ Hz). MS (EI, 20 eV): *m/z*: (%): $[M^+ + H]$ 410(4), $[M^+ - 2\,SiMe_3 + H]$ 265(5), $[M^+ - PC(SiMe_3)_2]$ 221(6), $[PPCSiMe_3]^+$ 147(21), $[SiMe_3]^+$ 73(100).

7: A solution of **4** was stirred at room temperature in an open atmosphere under exclusion of moisture for 24 h, during which the solution changed color from red-violet to yellow. The volatiles were removed under vacuum and the residue was washed several times with *n*-pentane. In this way **7** was obtained as a microcrystalline solid. Yield: 72%. $^{31}P\{^1H\}$ NMR (121.5 MHz, DME): $\delta = 313$ (t), 328 (d), ($^2J(P,P) = 31.8$ Hz). ^{13}C NMR (75.5 MHz, C_6D_6): $\delta = 179.1$ (m, X part of an ABB'X spin system: $^1J(C,P_A) = 77.8$ Hz, $|^1J(C,P_B) + {}^2J(C,P_{B'})| = 51.5$ Hz), 5.4 (m, SiC_3). MS (EI, 70 eV): *m/z*: (%): $[M^+ + H]$ 264(2), $[M^+ - PC(SiMe_3)_2]$ 221(2), $[PPCSiMe_3]^+$ 147(52), $[SiMe_3]^+$ 73(100).

9: A solution of **2** in DME, containing traces of moisture, was heated for 2 h at 100 °C, during which time the solution changed color from deep red to pale yellow. After removing the solvent under vacuum **9** remained as a yellow oil. ^{31}P NMR (121.5 MHz, C_6D_6): $\delta = -72.5$ (t), -263.5 (dd); $^1J(P,P) = 179.3$ Hz; $^2J(P,H) = 9$ Hz. MS (EI, 70 eV): *m/z* (%): $[M^+]$ 410(21), $[M^+ - P_2]$ 348(28), $[M^+ - PC(SiMe_3)_2]$ 221 (33), $[PPCSiMe_3]^+$ 147(52), $[SiMe_3]^+$ 73(100).

Reactivity of Tungstenocene with B–B and B–H Bonds versus C–H Bonds**

John F. Hartwig* and Xiaoming He

The oxidative addition of B–H and B–B bonds of borane reagents to transition metals is a crucial step in the mechanism of metal-catalyzed borane additions to carbon–carbon multiple bonds.[1–8] An understanding of the factors controlling these addition reactions will help to determine which metal centers would be effective catalysts for such catalytic hydroboration and diboration reactions. Preferences for additions of C–H bonds rather than C–C bonds are well established and can serve as a benchmark for evaluating additions of main group hydride and element–element bonds.[9] In homogeneous systems, oxidative addition of C–H bonds is preferred over addition of unstrained C–C bonds, except in highly unusual cases.[10]

We report herein that tungstenocene, $[Cp_2W]$, which is known to readily add C–H bonds of arenes,[11] exclusively forms $[Cp_2W(Bcat')_2]$ (Cat' = 4-*t*Bu$C_6H_3O_2$) (**1**) by addition of the B–B bond of Cat'BBCat' in the presence of arene solvent when generated either thermally or photochemically, whereas catecholborane is eliminated from $[Cp_2W(H)(Bcat)]$ (**2**) under photochemical conditions to form $[Cp_2WH(Ph)]$ (**3**) in benzene as solvent. An X-ray structure of the bisboryl complex **1** showed a nondistorted structure with ligand orientations indicative of π bonding.

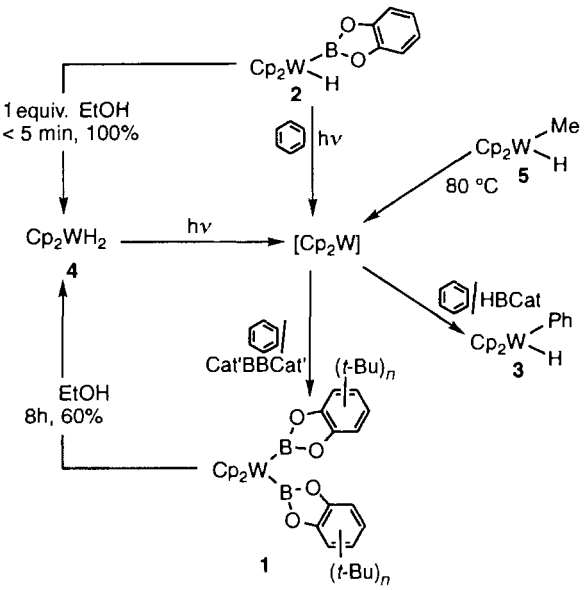
The reactivity of $[Cp_2W]$ with regard to borane additions and eliminations is shown in Scheme 1. Irradiation of $[Cp_2WH_2]$ (**4**) with a medium-pressure mercury arc lamp is known to generate the highly reactive intermediate $[Cp_2W]$ that reacts further to



Scheme 1. Formation and reactivity of $[Cp_2W]$ and tungstenocene–boron compounds.

give the phenyl hydride **3** when benzene is used as solvent.[11] However, irradiation of **4** for 6.5 h in a benzene solution containing just one equivalent of Cat'BBCat' gave the B–B bond oxidative addition product $[Cp_2W(BCat')_2]$ (**1**) in 82% yield by ^{1}H NMR spectroscopy.[12] No phenyl hydride product **3** was formed in this reaction. Product **1** was isolated in 55% yield by concentration of the reaction solution and layering with pentane. The bisboryl compound displayed a ^{11}B NMR spectrum with a signal at $\delta = 59.3$, which is close to but slightly downfield from the $\delta = 57.2$ chemical shift of $[Cp_2WH(BCat)]$ (**2**).[13] Our data indicates that the phenyl hydride **3** is not formed as a kinetic product that would subsequently undergo photochemical conversion to diboron compound **1**, since isolated samples of **3** were stable in the presence of Cat'BBCat' under reaction conditions identical to those employed for the conversion of the **4** to **1**.

An X-ray diffraction study of **1** (Fig. 1) was conducted on a sample obtained from benzene/pentane solvent mixture. Compound **1** crystallized in the space group $P2/n$ and showed well-separated monomeric units with no intermolecular contacts.[14] The unit cell contains one benzene molecule per tungsten complex. The two boryl ligands are oriented in a fashion that allows for π bonding between the basic metal center and each electrophilic boron atom. This orientation is also observed in the boryl compound **2**.[13] Moreover, the metal–boron distances of **1** are similar to that reported for **2**, which appeared to be shortened by π bonding. Finally, the B1-W-B2 angle of 78.0(4)° in **1** is identical to the H-W-B angle in **2** and the calculated ideal angle for d^2 Cp_2ML_2 compounds.[15] A similar B-M-B angle is also found in pseudo square planar and octahedral bis boryl compounds in which the idealized angle would be 90°.[4, 16] In the case of **1**, however, the small B-W-B angle reflects the ideal angle of the metallocene system and does not contain any distortion relative to the geometry of other metallocene compounds that could be attributed to B–B interactions.

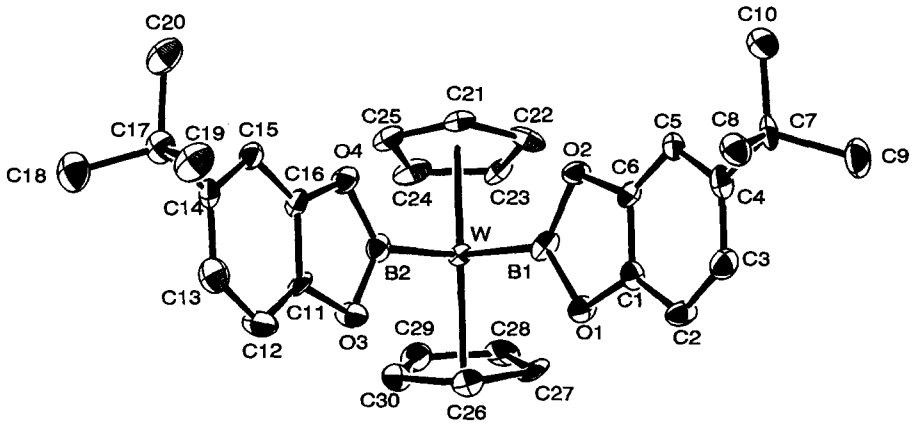

Fig. 1. ORTEP drawing of **1**. Selected bond lengths [Å] and angles [°]: W–B1 2.19(19; W–B2 2.23(1), W-Cp1 1.96, W–Cp2 1.97; B1-W-B2 78.0(4), Cp1-W-Cp2 142.

The selectivity for B–B over C–H bond addition is independent of whether tungstenocene is generated photochemically or thermally. Gentle thermolysis of $[Cp_2W(H)(Me)]$ (**5**) is known to generate $[Cp_2W]$.[17, 18] If a solution of **5** in benzene is heated for 4 h at 80 °C in the presence of 1–2 equivalents of Cat'BBCat', **1** is formed in 70% yield. No phenyl hydride **3** was observed during the course of the reaction; **3** is stable in benzene at 80 °C in the presence of Cat'BBCat'. Therefore, **3** is, again, not even a reaction intermediate in the synthesis of **1**.

The clean oxidative addition chemistry of diboron compounds led us to probe the potential oxidative addition chemistry of catecholborane by $[Cp_2W]$. Irradiation of a solution of dihydride **4** for 6 h in benzene containing HBCat (6 equiv) led to the solvent C–H activation product **3**, rather than the borane addition product **2**. At short reaction times (30 and 60 min), however, we did observe small amounts of the B–H activation product **2** (10–20% relative to **3**). The formation of this product in benzene indicates that catecholborane addition is kinetically preferred over benzene addition. However, at longer reaction times the small amounts of **2** were converted to the phenyl hydride **3**.

Thus, it appeared that isolated **2** should undergo photochemically induced reductive elimination to generate $[Cp_2W]$. Indeed, irradiation of pure **2** in benzene for only 10 min gave **3** in 90% yield. If the reaction was carried out in [D$_6$]benzene, the ^{1}H NMR spectra of final reaction mixtures showed the absence of a hydride resonance, and the ^{11}B NMR spectra showed the presence of a doublet resonance for catecholborane. This suggests that clean reductive elimination of borane to form $[Cp_2W]$ takes place, rather than a photochemically induced C–H activation reaction by intact **2** or a radical generated from it.

Attempts to induce thermal reductive elimination of catecholborane were unsuccessful. Compound **2** was stable for several days at 120 °C. Attempts to induce thermal oxidative addition of catecholborane to $[Cp_2W]$ by warming compound **5** in the presence of catecholborane led to several reaction products, including MeBCat, which was presumably formed from exchange reactions with $[Cp_2W(H)(Me)]$ (**5**), similar to those observed previously in other systems.[19–21]

These studies led to the following series of photochemical stabilities: $[Cp_2W(BCat')_2] > [Cp_2W(Ph)(H)] > [Cp_2W(BCat)(H)]$. These selectivities by $[Cp_2W]$ for B–B over C–H bond activation are precedented by the oxidative addition of diboron compounds with systems that do not undergo intermolecular C–H activation.[3, 4, 16] However, the overall selectivity for C–H over B–H activation with Cp_2W contrasts the selectivities of systems that add the B–H bond of catecholborane but do not add the C–H bond of hydrocarbons.[6–8] Furthermore, the resulting selectivity for B–B over B–H activation is exactly the opposite of the general preference for C–H over C–C bond activation.

We have shown previously with an electron-rich, third row system, albeit an iridium system, that the metal–boron bond is stronger thermodynamically than the corresponding metal–hydrogen bond.[22] The stability of the tungsten bisboryl compound may be derived from a similar high bond dissociation energy of the metal–boron linkage. A kinetic effect that enhances selectivity for the boranes may result from the favorable match-up of the electron-rich d^4 $[Cp_2W]$ with the electrophilic diboron reagent.

Experimental Procedure

1: A solution of $[Cp_2WH_2]$ (42.0 mg, 0.133 mmol) was dissolved in either benzene or toluene (4 mL) and the solution was added to a vial containing (tBu-C$_6$H$_3$O$_2$B)$_2$ (1.0 equiv, 49.5 mg). The solution was divided into four NMR sample tubes, which were irradiated. ^{11}B NMR spectra that were taken periodically showed complete reaction after 3.5 h. The samples were then transferred to the drybox, the solutions were combined, and the volume was reduced to 0.5 mL. This toluene or benzene solution was then layered with pentane to afford yellow crystals of **1**. Samples obtained from a toluene/pentane mixture revealed the presence of one solvent of crystallization by ^{1}H NMR spectroscopy in C_6D_6 and gave satisfactory microanalysis. Crystals suitable for X-ray diffraction analysis were obtained from a benzene/pentane solvent mixture. Yield 52 mg (57%). ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C, TMS): δ = 7.13 (d, ^4J(H·H) = 2.0 Hz, 1H, C-H), 6.93 (d, ^3J(H·H) = 8.2 Hz, 1H), 6.73 (dd, ^3J(H,H) = 8.2 Hz, ^4J(H·H) = 2.0 Hz, 1H), 4.70 (s, 10H, Cp), 1.16 (s, 9H, tBu); ^{11}B NMR (96.38 MHz, [D$_6$]benzene, 25 °C, BF_3-OEt$_2$): δ = 59.3; ^{13}C{^{1}H} NMR (75.48 MHz, [D$_6$]benzene, 25 °C, TMS): δ = 151.19, 149.14, 143.69, 117.2, 109.5, 108.27, 81.59, 34.42, 31.86. Anal. Calcd for $C_{30}H_{34}WB_2O_4 \cdot C_7H_7$: C 58.85, H 5.47. Found: C 58.59, H 5.56.

Specific Protein Docking to Chelator Lipid Monolayers Monitored by FT-IR Spectroscopy at the Air–Water Interface

Lutz Schmitt, Tom M. Bohanon, Steffen Denzinger, Helmut Ringsdorf, and Robert Tampé*

The concept of fusion proteins is widespread in molecular biology for the identification, one-step purification, and characterization of gene products. Among the most prominent examples are histidine-tagged fusion proteins, which can be isolated by immobilized metal ion affinity chromatography.[1, 2] To combine this strategy with the fundamental properties of lipid interfaces such as self-organization, supramolecular assembly, and the interplay of fluidity and rigidity, we have synthesized a novel class of chelator lipids bearing a nitrilotriacetic acid (NTA) head group.[3, 4] Thin films of these lipids are highly sensitive towards nickel ions,[3] forming complexes and thereby generate binding sites for the histidine tag.[5, 6] We describe here how the specific docking of a histidine-tagged protein to a chelator lipid monolayer at the air–water interface was monitored directly by external reflection Fourier transform infrared spectroscopy (FT-IR) at the air–water interface. Evidence for complex formation and specific and reversible binding was obtained.

External reflection FT-IR at the air–water interface can be used to study the physical properties of lipid monolayers,[7] for example configurations of the lipid acyl chain.[8, 9] This technique requires no extrinsic probes like fluorescent dyes, which could perturb the properties of the system under investigation. Until now, the adsorption or even specific binding of proteins to lipid monolayers at the air–water interface was not studied directly. We combined a film balance setup with an FT-IR spectrometer that collected spectra in the external reflection mode (Fig. 1 bottom). The specific binding of imidazole and histidine-tagged biomolecules to these chelator lipids was revealed by film balance techniques, fluorescence spectroscopy, and reflection interference contrast microscopy.[3–6] Complex formation and specific binding of histidine-tagged fusion proteins to the novel chelator lipids used in the IR experiments are illustrated in Figure 1 top.

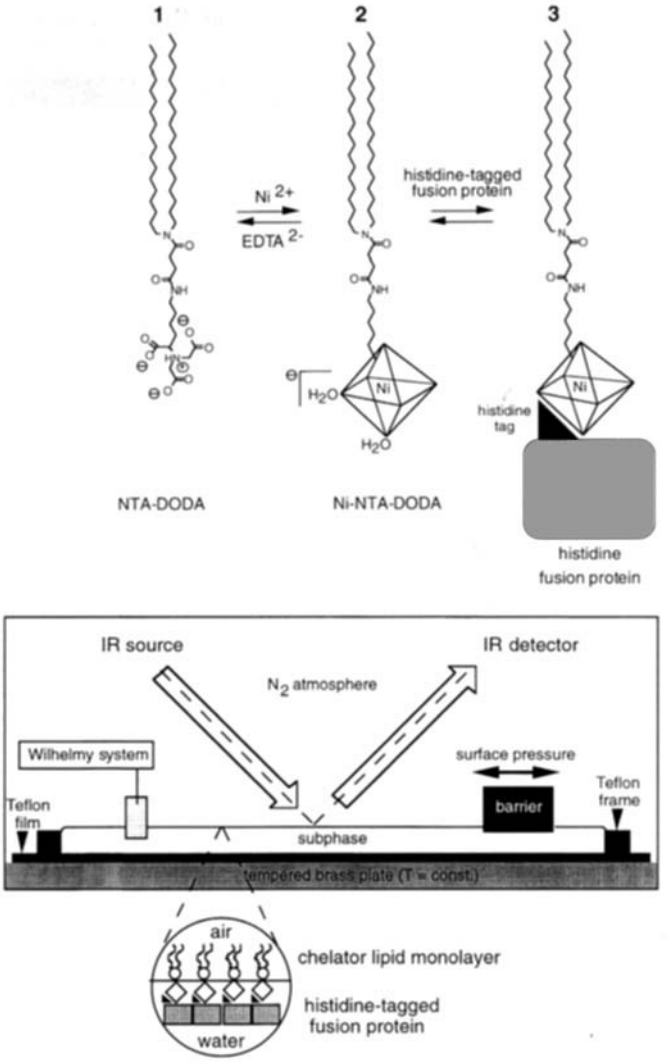

Fig. 1. Top: Compounds used in the experiments: nonloaded (NTA-DODA **1**) and nickel-loaded chelator lipids (Ni-NTA-DODA **2**), and a nickel-loaded chelator lipid with an immobilized histidine-tagged protein (protein/Ni-NTA-DODA **3**). The chelator lipid N^{α},N^{α}-bis(carboxymethyl)-N^{ε}-[(dioctadecylamino)succinyl]-L-lysine (NTA-DODA) was synthesized and used in unloaded and loaded forms as described in ref. [3]. For the IR experiments, 30 nmol of Ni-NTA-DODA or NTA-DODA was spread onto subphase buffer (10 mM HEPES, 140 mM NaCl, pH 8.0). As a model compound for histidine-tagged fusion proteins, a heat shock factor from tomato (HSF24) was used [15], which kindly provided by Oliver Boscheinen and Dr. Klaus-Dieter Scharf (University Frankfurt, Germany). HSF24 was expressed in *E. coli* as fusion protein containing a C-terminal sequence of six histidines [17]. The functionality of this protein is demonstrated by DNA gel retardation assays [15, 17]. Bottom: Experimental setup for external reflection FT-IR spectroscopy at the air–water interface; details are given in ref. [21]. All spectra were recorded with a resolution of 8 cm^{-1} by Fourier transformation of 5000 scans, and analyzed using the software provided by Nicolet. Automatic baseline and automatic smooth corrections were applied for all the spectra.

For reasons of sensitivity and simplicity, pure lipid layers were used for the measurements. First, we were interested in whether we could detect any differences between a nonloaded and a metal-loaded chelator lipid layer. To directly compare the symmetric and asymmetric stretching vibrations of the methylene groups near 2850 and 2920 cm^{-1}, respectively, of a nonloaded (NTA-DODA) and nickel-loaded chelator lipid monolayer (Ni-NTA-DODA), the spectra were recorded at the

same area per molecule. The spectrum of the NTA-DODA monolayer was recorded at 20 mN m^{-1} and that of the Ni-NTA-DODA monolayer at 15 mN m^{-1} in the coexistence region of the liquid expanded (LE) and liquid condensed (LC) phase (Fig. 2a). While changes in the homogenous LC or LE phase are negligible over a large range, changes in the coexistence region drastically influence the IR bands for the CH_2 stretching modes, as was previously determined for similar lipid systems.[8] As expected, complex formation at the lipid head group decreases the repulsive forces between the negatively charged lipid head groups and thereby lowers the pressure for a given area per molecule. For both lipid systems (Fig. 2b,c) the positions of these IR bands were identical (2847 cm^{-1}/2916 cm^{-1}). Complexation of the NTA head group does not affect the conformational order of the alkyl chains within the experimental error.

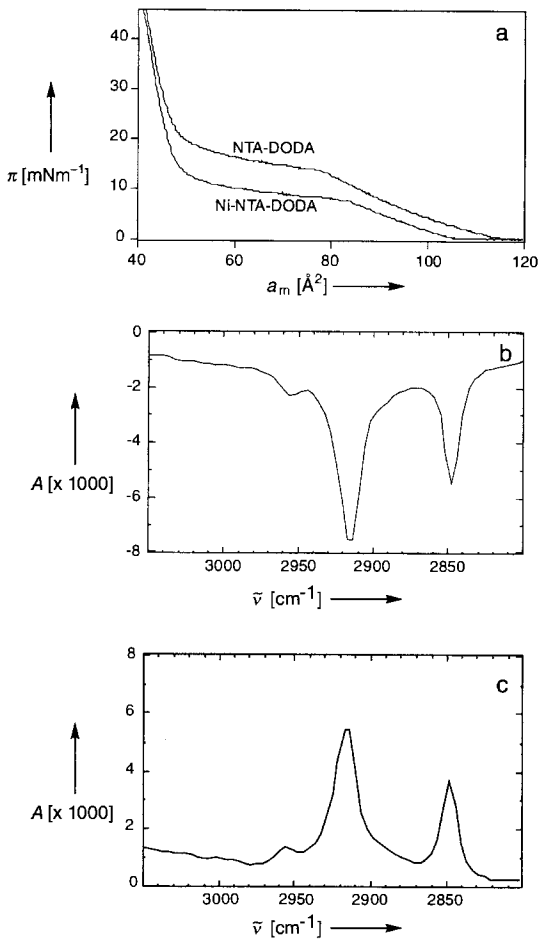

Fig. 2. a) Area–pressure diagram for a nonloaded NTA-DODA monolayer and a loaded Ni-NTA-DODA monolayer. The molar ratio Ni^{2+}:NTA-DODA was 1:1. Compressions were performed at 22 °C (1.8 Å^2 molecule^{-1} min^{-1}) as described in ref. [3]. FT-IR spectra of the NTA-DODA (b) and Ni-NTA-DODA monolayer (c) in the range 3050–2800 cm^{-1}. Spectra were recorded in the coexistence regions at 20 mN m^{-1} (22 °C) for the NTA-DODA system and 15 mN m^{-1} (22 °C) for the Ni-NTA-DODA system. a_m = area per molecule, A = absorption.

IR spectra recorded in the transmission mode are dominated by the attenuation constant (k) of the complex refractive index ($\hat{n} = n + ik$) and are fairly insensitive towards the real part of the refractive index (n). In reflection mode IR spectra the real part (n) of the complex refractive index dominates.[10, 11] In addition, incoming light is reflected at several interfaces with different Fresnel reflection coefficients. The most significant difference between the spectra of an nonloaded NTA lipid (Fig. 2b) and a loaded Ni-NTA lipid monolayer (Fig. 2c) is the inversion of the absorption signal, which can be explained only by the presence of a nickel layer complexed by the lipid interface. In contrast to the expected negative absorption sign of the NTA lipid monolayer,[12, 13] the positive absorption signals of the Ni-NTA lipid monolayer suggests a comparison with lipid monolayers at air–metal interfaces. But the assignment of a macroscopic value, the refractive index $\hat{n}$, to a monoatomic layer of complexed nickel ions is not justified in our case, and one must use caution when comparing peak areas from external reflection IR spectra. Nevertheless, it is interesting to note that the peak areas of the CH_2 stretching bands are nearly identical. Because the peak areas of the IR bands for the alkyl stretching vibration of the Ni-NTA lipid monolayer did not change over 12 h, dissociation of the complexed nickel ions just after spreading or within this time period can be excluded. In accord with the minute concentration of nickel ions, which was calculated to be 200 nM for our subphase volume of a loaded Ni-NTA (1:1) complex, the formation constant for the lipid head group complex seems to be high (10^{-12} M in solution[14]). This concept offers in principle a new perspective for the design of biofunctionalized interfaces by specific docking of histidine-tagged biomolecules to these chelator lipids.

To investigate the specific functionalization of a chelator lipid interface by histidine-tagged fusion proteins, the heat shock factor HSF24 containing a C-terminal histidine tag[15] was injected into the subphase of a Ni-NTA-DODA monolayer at 15 mN m^{-1} to yield a final concentration of 0.5 nM. After 1 h additional IR signals of the immobilized protein were detected. To circumvent any steric interference during protein binding, the monolayer was expanded to 4 mN m^{-1} for 12 h. After recompression to 15 mN m^{-1}, IR spectra were recorded. A new signal was observed at 3014 cm^{-1} (Fig. 3b), not seen in the spectrum of a Ni-NTA-DODA monolayer (Fig. 3a), which corresponds to intramolecular hydrogen bonds of the NH groups or an overtone of the amide II absorption;[16] another new band around 2200 cm^{-1} (Fig. 4a) was also recorded. Because of the overlap with the CO_2 signal, the latter band was taken into account only in qualitative analysis.

To evaluate the amount of unspecific versus specific immobilization, the experiment was repeated with a nonloaded NTA-DODA monolayer (Fig. 3c) under identical conditions (final pressure 15 mN m^{-1}). In this case, only weak protein bands at 3014 cm^{-1} and around 2200 cm^{-1} were found. In these protein binding experiments the positions of the CH_2 stretching modes are identical, indicating that the immobilized protein does not drastically affect the conformational order of the lipid chains. Interestingly, the peak areas of these bands are nearly identical in the presence and absence of immobilized protein. Assuming that the transition dipole moments of the protein bound to both layers are identical, we can estimate the amount of nonspecifically bound protein to be 20%. This unspecific binding is in agreement with the results of film balance and epifluorescence microscopy studies.[17] In these experiments HSF24 was only functionally immobilized if it was bound through the histidine tag and chelator lipid. HSF24 nonspecifically bound to lipid monolayers was not functional in DNA binding. In an additional control experiment the heat shock factor without the histidine tag did not specifically interact with a nickel-loaded chelator lipid layer.

Biotinylated lipids are very useful for immobilizing biotinylated proteins through an additional (strept)avidin layer as docking station.[18, 19] But the orientation of the attached mole-

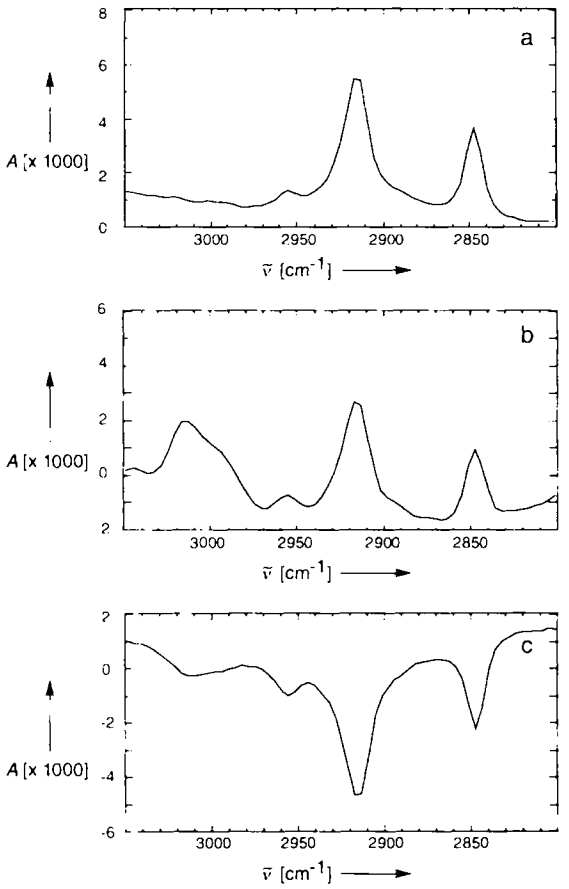

Fig. 3. FT-IR spectra of the Ni-NTA-DODA monolayer in the absence (a) and presence of the HSF24 (b) as well as the NTA-DODA monolayer (c) in the presence of HSF24 in the range 3050–2800 cm^{-1}. The experimental conditions are described in the legend of Fig. 2. For protein binding experiments, 80 pmol of HSF24 was injected into the subphase at 15 mN m^{-1} (22 °C), yielding a final concentration of 0.5 nM (lipid:protein = 380:1 mol mol^{-1}). After 1 h the monolayer was expanded to 4 mN m^{-1} and after 12 h recompressed to 15 mN m^{-1} (22 °C).

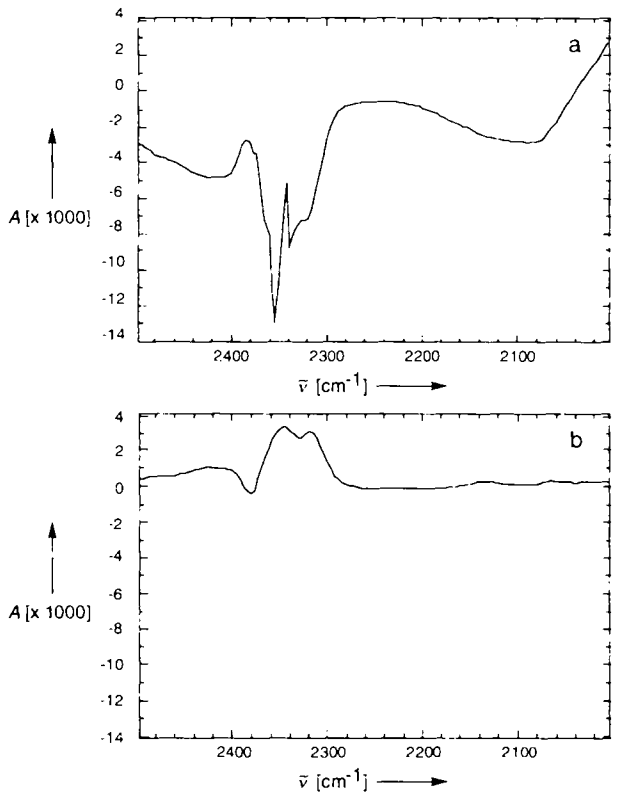

Fig. 4. a) FT IR spectra of the Ni-NTA-DODA monolayer in the presence of the HSF24 as described in the legend of Fig. 3b in the range 2500–2000 cm^{-1}. b) FT IR spectra of the Ni-NTA-DODA monolayer 30 min after the injection of EDTA yielding a final concentration 0.8 mM.

cules is limited by the regioselectivity and stoichiometry of chemical biotinylation. In contrast, the concept of NTA lipids makes use of a vast variety of proteins carrying the affinity tag at well-defined positions. A further advantage is that the binding is reversible. The dissociation of any immobilized protein can be achieved either by competition with imidazole, by complexing the Ni^{2+} ions with stronger chelating agents such as EDTA, or by lowering the pH.[5, 6] To examine this reversibility, EDTA was injected into an immobilized protein monolayer. Because EDTA has strong absorption peaks at 3015 and 2982 cm^{-1},[20] the detected protein absorption at 3014 cm^{-1} could not be used to follow the disassembly of the protein. But within 30 min after EDTA addition, firstly the absorption signal was again inverted, which implies dissociation of the Ni-NTA complex (data not shown), and secondly the protein peak around 2200 cm^{-1} was not detected (Fig. 4b). Note, in the absence of EDTA the Ni-NTA-DODA monolayer gave invariant spectra over 12 h. The peak positions of the CH_2 stretching modes are identical before and after EDTA addition. Comparison of the peak areas of these modes yields a ratio of 3:1 for the unloaded versus loaded chelator lipid layer. This incomplete complexation of the nickel ions by EDTA is not surprising because the dissociation generates a negatively charged surface, depleting EDTA from its interface. An alternative explanation could be that EDTA itself binds to the Ni-NTA head group. In order to achieve complete unloading, EDTA, imidazole, or low pH should be applied in a continuous-flow experiment.

External reflection FT-IR spectroscopy at the air–water interface was used to demonstrate specific and reversible protein docking at chelator lipid interfaces for the first time. This method also permits studies of lipid–protein and lipid–ligand interactions without labels or probes and is restricted by scan time only. Due to the vast variety of histidine-tagged fusion proteins already available, the concept of chelator lipids should make it possible to organize and orient biomolecules in a well-defined way, generating two-dimensional protein arrays for studying molecular mechanisms of membrane recognition, vesicle targeting, docking and fusion, the immune response in the cell, and adhesion processes.

The Crystal Structure of Difluoroamine**

Martin Frank Klapdor, Helge Willner,* Wolfgang Poll, and Dietrich Mootz*

Dedicated to Professor Hans Joachim Seifert on the occasion of his 65th birthday

The structure of difluoroamine, HNF_2, has been well studied by vibrational and microwave spectroscopy and ab initio calculations. The results for the geometry and self-association of this small and prominent molecule of inorganic fluorine chemistry have now been independently confirmed and significantly complemented by a crystal structure analysis at low temperature.

Caution! Difluoroamine (m.p. −117, b.p. −23 °C) is potentially explosive (particularly in the solid state) and should be handled only on a mmol scale and with suitable protective measures.[1] We observed no explosion when working with submmol quantities. For the synthesis of HNF_2, N_2F_4 was treated with excess thiophenol.[2] DNF_2 was prepared by treating 0.5 mmol HNF_2 with an excess of D_2O (ca. 50 mmol, 99.9%, Merck, Sharpe and Dohme) at ambient temperature. After one day the reaction mixture was fractionated by "trap to trap" condensation at −80, −120, −196 °C. The trap at −120 °C contained pure DNF_2. In sealed glass tubes at −20 °C, gaseous HNF_2/DNF_2 could be kept without decomposition for years.

On cooling with liquid nitrogen, small amounts of the compound were condensed into thin-walled quartz-glass capillaries and sealed. A single crystal was grown by miniature zone melting with focused heat radiation[3] in situ on a diffractometer. The structure of HNF_2 was determined at −150 °C in the usual way.[4]

The values obtained for the N–F bond lengths and F–N–F bond angle, of 139.6(2) and 139.2(2) pm and 102.4(1)°, respectively, are quite similar to those determined from the microwave spectrum[5] (N–F: 140.0 pm, F–N–F: 102.9°, N–H: 102.6 pm, F–N–H: 99.8°) and ab initio calculations[6] for the free molecule. As common in X-ray analysis, the H atom is less accurately localized (N–H: 86(3) pm, F–N–H: 99(2) and 106(2)°), but clearly in an ordered position (Fig. 1).

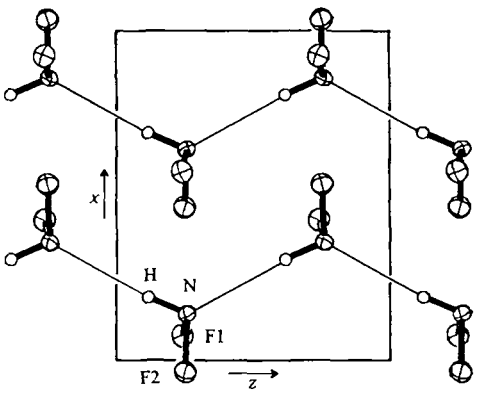

Fig. 1. Crystal structure of difluoroamine. Projection of two chains (see text) at different heights onto the *a,c* plane of the unit cell, with hydrogen bonds as thin lines and with ellipsoids with 25% probability [7].

In the crystal, the molecules are linked by weak hydrogen bonds of the type N–H···N (N···N: 314.9(2) pm, H···N: 230(3) pm, N–H···N: 171(2)°) to form zigzag chains of uniform (parallel) polarity, extending along the crystallographic *c* axis (Fig. 1). The presence of hydrogen bonds N–H···N (as distinguished from N–H···F) in the solid as in the liquid state has already been inferred from IR and Raman spectra.[1] The crystal structure of HNF_2 is hence similar to that previously determined[8] for HOF (hypofluorous acid) with chains (here antiparallel) of hydrogen bonds of the type O–H···O, that is, also not involving the particularly electronegative F atom.

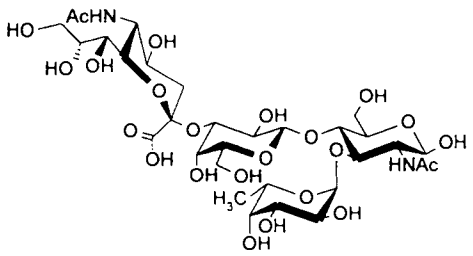
Multiple Sialyl Lewis^X N-Glycopeptides: Effective Ligands for E-Selectin**

Ulrich Sprengard, Manfred Schudok, Wolfgang Schmidt, Gerhard Kretzschmar, and Horst Kunz*

Dedicated to Professor A. Eschenmoser on the occasion of his 70th birthday

Selectins, a special group of transmembrane glycoproteins on platelets and endothelial cells, play a key role in the early stages of leukocyte adhesion.[1] The transient binding of selectins to oligosaccharide ligands like sialyl Lewis^X mediates the so-called rolling of leukocytes on the vascular endothelium. This event is the first in a complex cascade of macromolecular interactions involving other adhesion molecules in the extravasation of leukocytes into the tissue. Complex glycoproteins bearing the sialyl Lewis^X epitope and related saccharide moieties have been identified as efficient ligands for the selectins.[2, 3] Mucins with multiple oligosaccharide moieties at very high surface densities have been identified as endogenous selectin ligands.[4] Multivalent interactions between ligand and protein may increase the efficacy of selectin–glycoprotein binding.



sialyl Lewis^X unit

Simple model compounds have been synthesized, for example diol-bridged bivalent sialyl Lewis^X analogues[5] and trivalent sialyl Lewis^X conjugates[6] derived from a nitromethanetripropionic acid template. Inspired by the endogenous ligands, we designed the trivalent N-glycopeptides **7a** and **7b** based on sialyl Lewis^X. These compounds showed improved inhibitory activity in an E-selectin cell adhesion assay. We prepared the cyclic N-glycopeptides containing three asparagine-linked sialyl Lewis^X tetrasaccharides by a synthetic strategy involving orthogonally stable protective groups for both the peptide and oligosaccharide synthesis. The sequential introduction of glycosylated, presynthesized amino acid building blocks might be an alternative strategy;[7] however, this approach would require the use of a considerable excess of coupling agents and valuable, temporarily protected glycosyl amino acids. In addition, the acid lability of fucose restricts the application of trifluoroacetic acid and other reagents often used in solid-phase synthesis.[8, 9]

The synthesis of trivalent sialyl Lewis^X glycopeptides was achieved by means of a combined strategy utilizing solid-phase peptide synthesis and fragment condensation in solution: a) The cyclic peptides **4a** and **4b** were prepared in high purity as versatile templates in a combined solid-phase and solution synthesis. b) The 4′-lactone of neuraminic acid served as an internal protective group during the synthesis and masked the carboxyl function of the partially blocked sialyl Lewis^X unit **1**.[2,7] c) The threefold condensation of the partially deblocked sialyl Lewis^X unit **1** with the cycloheptapeptides **4a** and **4b** led to the N-glycosidically linked sialyl Lewis^X glycopeptides **5a** and **5b**, respectively. d) The protecting group strategy allowed final deblocking of the glycosylated cyclopeptides by mild catalytic hydrogenolysis of 15 benzyl ether groups.

The linear heptapeptide containing D-alanine for more efficient cyclization was synthesized according to the Fmoc solid-phase strategy on acid-labile Sasrin resin.[10] Detachment of the partially protected heptapeptide **2a** from the resin under mild conditions (1% TFA in CH_2Cl_2) with retention of the orthogonally stable protective groups proceeded in 62% yield.[11] Sub-

[**] The authors thank Dr. Kogler (Pharmaforschung, Hoechst AG) for stimulating discussions and for performing valuable NMR experiments. In this article the following abbreviations are used: Asp = asparagine, COSY = correlated spectroscopy, DIPEA = diisopropylamine, EEDQ = *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline, ESI = electrospray ionization, Fmoc = (9*H*-fluoren-9-ylmethoxy)carbonyl, Fuc = fucosyl, Gal = D-galactose, Glc = D-glucose, Gly = glycine, HATU = *O*-(7-azabenzo-triazol-1-yl)-1,1,3,3,-tetramethyluronium hexafluorophosphate, HMBC = H-detected multiple-bond correlation, HMQC = heteronuclear multiple-quantum coherence (NMR), HOAT = 1-hydroxy-7-azabenzotriazole, HOBt = 1-hydroxy-1*H*-benzotriazol, HSQC = heteronuclear single-quantum coherence (NMR), PHDQF = phase-sensitive double quantum filtered, Ser = serine, TBTU = (1*H*-benzotriazol-1-yloxy)bis(dimethylamino)methylium tetrafluoroborate, TCP = chlortrityl-polystyrene (PepChem, Tübingen), TFA = trifluoroacetic acid, TOCSY = total correlation spectroscopy (2D NMR).

sequent cyclization of the linear peptide, deblocked at the N- and C-termini, using HATU/HOAT/DIPEA[12] in dilute solution ($c_{peptide}$ = 0.001 M) afforded **3a** in 50% yield (Scheme 1). Cyclization with EEDQ via mixed anhydrides generated in situ resulted in complex mixtures of products. This may be due to aspartimide formation through the activation of β-carboxyl groups. The *t*-butyl protecting groups of **3a** were removed with TFA (5% water) leading to **4a** in 96% yield.

The acid- or base-catalyzed formation of aspartimides in asparagine-containing peptides and the subsequent transpeptidation are well-known side reactions.[13] This has been observed in particular in the case of Asp-Gly- and Asp-Ser-containing sequences; however, HSQC- and PHDQF-COSY NMR experiments confirmed the sequential integrity of the conformationally restricted cyclopeptide. The analysis of long-range couplings (^2J, ^3J, and ^4J couplings) obtained by proton-detected multiple-bond coherence (HMBC) experiments made structure determination possible even when the proton spin system is interrupted by heteroatoms and nonprotonated carbonyl groups (Table 1).[14]

Fragment condensation of the sialyl Lewis^X unit **1** with cyclopeptide **4a** using HATU/HOAT/DIPEA produced the partially protected sialyl Lewis^X cyclopeptide **5a** in 48% yield (Scheme 2). The 4'-lactone group of the sialic acid was not affected during this step. Cleavage of the benzyl ether groups by hydrogenolysis over Pd/C in methanol/acetic acid/dioxane (5/1/1) gave **6a** in 88% yield. The lactone was opened by mild, alkaline hydrolysis in 96% yield, and the cyclic sialyl Lewis^X glycopeptide **7a** was purified by gel permeation chromatography on Biogel P2. The structure of **7a** was confirmed by electrospray ionization mass spectrometry (ESI-MS) and HSQC-, HMBC-, HSQC-TOCSY and HMQC-COSY NMR experiments. The PHDQF-COSY NMR spectrum (Table 2) showed almost complete coincidence of the signals for each of the three GlcNAc, Fuc, Gal, and NeuNAc residues.[15] This indicates that the trivalent cyclopeptide barely restricts the flexibility of the three sialyl Lewis^X ligands compared to the monomeric tetrasaccharide.

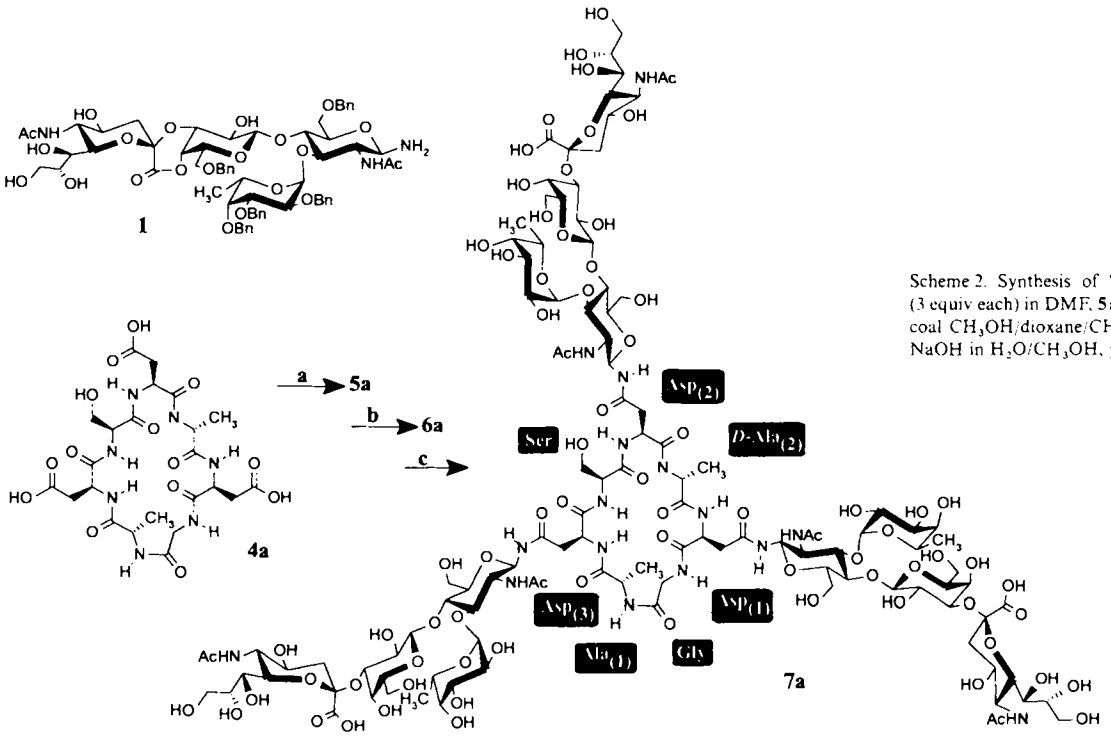
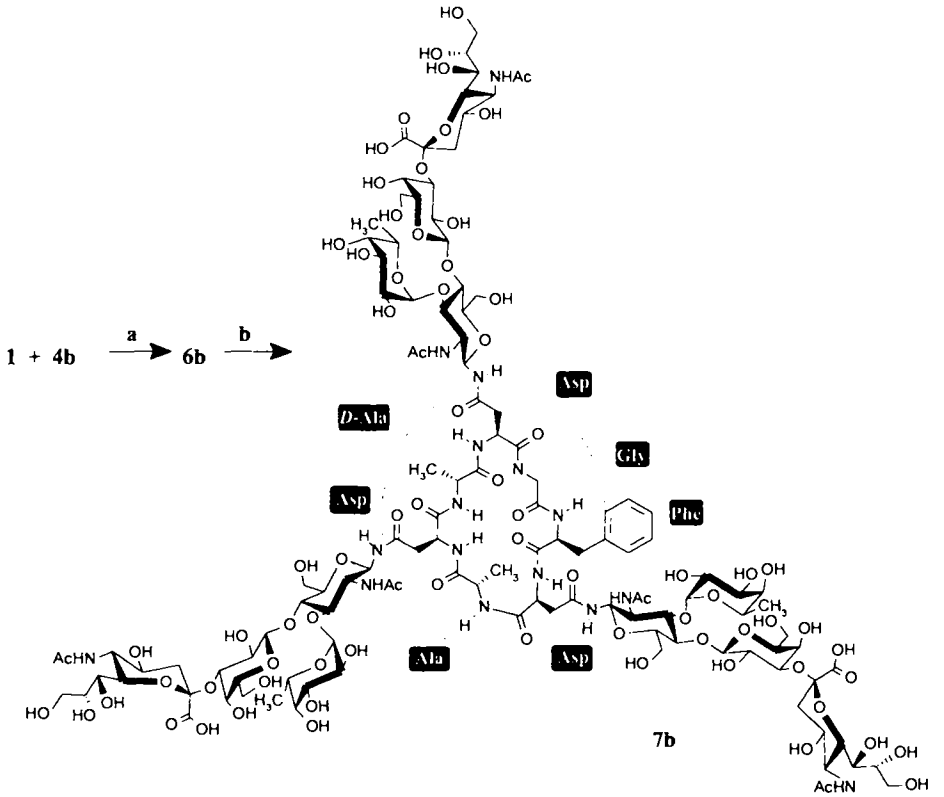


Scheme 2. Synthesis of **7a**. a) HATU/HOAT/DIPEA (3 equiv each) in DMF, **5a**: 48%; b) H_2, Pd active charcoal CH_3OH/dioxane/CH_3COOH (5/1/1), **6a**: 88%; c) NaOH in H_2O/CH_3OH, pH = 10.4, **7a**: 96%.

The partially protected, linear heptapeptide **2b** having a different peptide sequence was synthesized in analogy to **2a** by solid-phase Fmoc methods. Detachment from the extremely acid-labile TCP resin[16] with retention of the *t*-butyl esters could be carried out under substantially milder conditions (acetic acid/methanol/dioxane 5/1/4) than those typically applied in solid-phase synthesis.[17] In principle, these conditions should be compatible with the solid-phase glycopeptide synthesis of fucosylated structures since the loss of acid-labile fucose should not occur.[18] Cyclization of **2b** using HATU/HOAT/DIPEA (**3b**: 83% yield) and cleavage of the *t*-butyl esters with aqueous trifluoroacetic acid furnished **4b** (81% yield). Subsequent fragment condensation using HATU/HOAT/DIPEA gave **5b**, and hydrogenolytic cleavage of the benzyl ether groups and saponification of the lactone afforded the sialyl Lewis^X glycopeptide **7b** in an overall yield of 80%. (Scheme 3).



Scheme 3. Synthesis of **7b**. a) HATU, HOAT, DIPEA (1.5 equiv each) in DMF, after 4 h additional HATU/HOAT/DIPEA (0.5 equiv each) then H_2, Pd active charcoal, CH_3OH/dioxane/CH_3COOH (1:1:1), **6b**: 92%; b) NaOH in H_2O/CH_3OH (4:1), pH = 10.6, **7a**: 87%.

An efficient condensation was required for linking the aspartic acid unit in **4b** with the amine in **1** due to the adjacent bulky phenylalanine residue. The conditions used here permitted a complete N-glycoside formation between the sterically hindered aspartic acid and the sialyl Lewis^X amine **1**.

The synthesis of topologically functionalizable cyclopeptide templates involving an orthogonal protective group strategy allowed access to N-glycosides containing various oligosaccharides. In the past, solid-phase or solution glycopeptide synthesis using presynthesized glycosyl amino acids have been applied to reach this goal.[7] Owing to the good solubility of the partially protected tetrasaccharide unit **1**, a broad spectrum of organic solvents (dichloromethane, DMF, methanol) could be used for N-glycoside formation with lipophilic as well as with hydrophilic components. The partially protected sialyl Lewis^X unit has proven useful for multiple formation of N-glycosides on trivalent templates,[6, 27] and the convergent synthetic strategy has opened up a route to multivalent glycopeptide structures with repetitive oligosaccharide units. Until now, related strategies have been applied only for smaller glycopeptides.[19]

In cell adhesion tests measuring the binding of **7b** to recombinant human E-selectin–immunoglobulin fusion proteins (E-selectin–IgG[20]) in competition to tumour cells carrying sialyl Lewis^X ligands (cell line HL_{60}), **7b** proved to be an active synthetic ligand. The trivalent glycopeptide inhibited the adhesion of HL_{60} cells with an IC_{50} of 0.35–0.6 mM, which is two to three times more efficient than monomeric sialyl Lewis^X. In an extension of the concept, multiple conjugation of sialyl Lewis^X with biocompatible, peptide-derived polymers led to multivalent saccharide clusters which proved to be efficient inhibitors of leukocyte adhesion.[21, 22] Besides highly active, monovalent sialyl Lewis^X mimetics,[23–27] multivalent antagonists seem to be valuable antiinflammatory agents for selectin-mediated leukocyte adhesion.

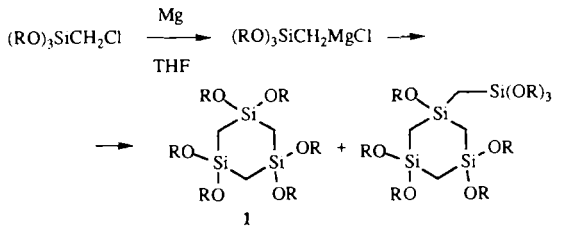
Synthesis and Dynamic Behavior of the Heptafluorotrisilacyclohexane Anion: A New Fluxional Silicate with Rapid Intramolecular Exchange of Fluoride Ligand

Dalci Brondani, Francis H. Carré, Robert J. P. Corriu,* Joel J. E. Moreau,* and Michel Wong Chi Man

The search for new silicon-based polymers and materials[1, 2] led to a growing interest in polyfunctional organosilicon precursors. These molecules are important for the preparation of hypervalent silicon species, which exhibit interesting structural properties and also unusual chemical reactivity.[3] Recent work has also revealed some unique properties of polysilylated hypervalent molecules: new structural and dynamic behaviors involving rapid intramolecular exchange of a fluoride ligand between silicon atoms were observed in disilyl- and hexasilylbenzene derivatives.[4, 5]

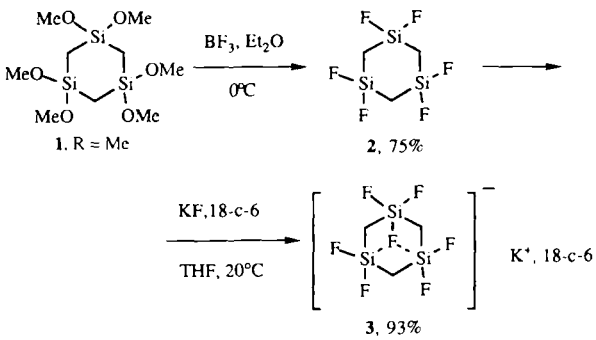
We recently reported that functional Grignard reagents provide a short route to carbosilane oligomers,[6] which are precursors of ceramic and sol–gel materials.[7] We thought that the cyclosilane **1** [Eq. (a), e.g. R = Me, Et] would be an interesting type of precursor for hypervalent species that, owing to the presence of three functionalized silicon atoms, might demonstrate unusual dynamic behavior. We report here the preparation of a new silicate anion which exhibits a rapid intramolecular ligand exchange in solution and in the solid state.



(a)

1

The 1,1,3,3,5,5-hexafluoro-1,3,5-trisilacyclohexane **2** was readily obtained when the hexamethoxy derivative **1** (R = CH_3) was[6b] treated with BF_3 and Et_2O [Eq. (b)].[8a] The reaction



(b)

action of **2** with 1 mol of KF in the presence of [18]crown-6 (18-c-6) led to crystalline derivative **3** in 93% yield. Analysis of compound **3** indicated that it was a heptafluorosilicate derivative; single lines were observed in both the ^{19}F and ^{29}Si NMR spectra.[8b]

Evidence for the fluxional behavior was obtained upon NMR analysis of compound **3**. The observation of a single resonance in the ^{19}F spectrum indicated that rapid intramolecular ligand exchange occurred. Even at low temperature (as low as 183 K), the ^{19}F NMR spectrum of compound **3** in THF contains a single line at δ = −108.8.

More information can be gleaned from the ^{29}Si NMR analysis. At room temperature, the ^{29}Si NMR spectrum consists of a sharp singlet centered at δ = −25.56. This is consistent with a fluoride ligand exchange that is rapid on the NMR time scale; the environment of the three silicon atoms is thus averaged. Moreover, the absence of Si–F coupling suggests rapid intermolecular exchange in solution as well. It is also interesting to note that the ^{29}Si resonance occurs at δ = −25.56, intermediate between the expected chemical shift for a tetracoordinate difluorosilane $(CH_2SiF_2)_3$ (δ = −2.38[8a]) and the chemical shift of a pentacoordinate trifluorosilicate in a related cyclic structure $[CH_2(CH_2)_4SiF_3]$ (δ = −76.9[9]). The value for the ^{29}Si NMR chemical shift observed for **3** indicates that the seventh fluoride ligand is "equally shared" by the three silicon atoms in **3**.

Upon lowering the temperature, the signal broadened, and at 183 K a coupled signal was observed ($J_{Si,F}$ = 85.55 Hz, Fig. 1). The spectrum appeared as an octuplet (1:7:21:35:35:21:7:1), although the intensities of the external

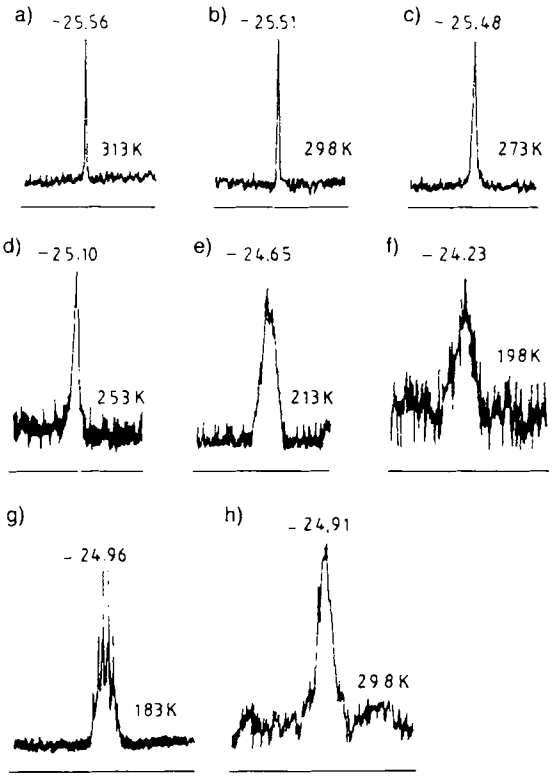

Fig. 1. ^{29}Si NMR spectra of **3** in [D_6]acetone at various temperatures (a–g) and the ^{29}Si CP MAS NMR spectrum of **3** at 298 K (h).

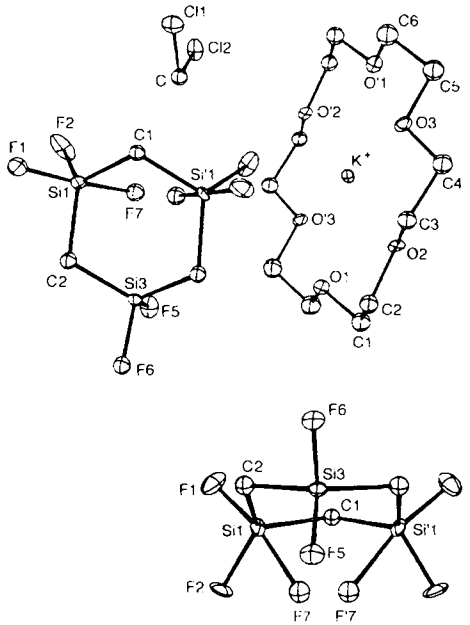

Fig. 2. Top: ORTEP projection of the crystal structure of **3** (hydrogen atoms are omitted for clarity; the ellipsoids and spheres enclose 20% of the electron density). Selected bond lengths [Å] and angles [°]: Si1–F1 1.62(1), Si1–F2 1.57(1), Si3–F5 1.59(2), Si3–F6 1.60(2), Si1–F7 1.86(2), C1-Si1-C2 117.6(9), F1-Si1-F2 95.9(7), F1-Si1-C1 102.7(7), F1-Si1-C2 98.6(7), F1-Si1-F7 169(1), C2-Si3-C2' 116.3(9), F5-Si3-F6 101.2(8); bottom: projection of the trisilacyclohexane anion of **3**. The distance between the two disordered positions F7 and F7' is 1.04(3) Å. An increase in the mean values of the C-Si-C and Si-C-Si angles of as much as 115.5° is observed; this increase results in a flatter trisilacyclohexane ring.

lines is quite low. The multiplicity is confirmed by the relative intensities (1:3:5) observed for the six internal lines (which would be 1:5:10 for a sextuplet). These observations show that even at 183 K a rapid intramolecular exchange occurs and that each silicon atom in **3** is coupled to seven equivalent fluorine atoms.

Interestingly, evidence for a rapid exchange of fluoride within the molecule was obtained even in the solid state. The ^{29}Si CP/MAS NMR spectrum of crystals of **3** revealed a single broad resonance at $\delta = -24.91$ (Fig. 1). The observed chemical shift indicates that even in the solid state, rapid exchange of the fluoride ligand between the three silicon atoms of **3** takes place.

The structure of compound **3** was determined by single-crystal X-ray diffraction analysis.[10] The crystals were unstable. The measurements were therefore made at 178 K by immersing the crystal in a cold stream of dry nitrogen. Two ORTEP diagrams of the heptafluorotrisilacyclohexane anion are shown in Figure 2.

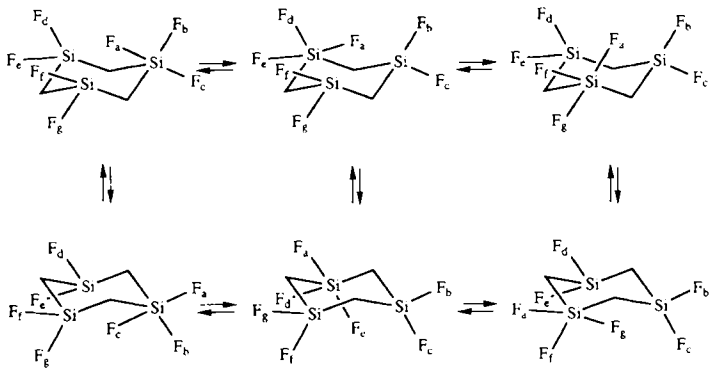
The potassium cation is located at an inversion center of the lattice and is surrounded by six oxygen atoms at a mean distance of 2.79(1) Å and two fluorine atoms. The F2···K^+ distance is 2.68(1) Å. The dominant feature of the crown ether ring is the 1-point geometry in which pairs of atoms correspond to each other through the inversion center.

Figures 1 and 2 depict the hexafluorotrisilacyclohexane moiety in which the two half-occupied positions of the seventh fluorine atom are displaced (F7 and F'7, mirror images). We think that the F7/F'7 disorder induces an additional, corresponding, although smaller, disorder in the F1 and F2 atomic positions. It was not possible to detect such weak displacements. The values for the coordinates reported here for atoms F1 and F2 must be taken as mean values. In other words silicon atom Si1 (or Si1') should have tetrahedral geometry, while atom Si1' (or Si1) should be close to the center of a trigonal bipyramid. The X-ray diffraction methods can lead to only an average view of such disorder. Hence the resulting geometry around Si1 can be compared to either a capped tetrahedron or a distorted trigonal bipyramid in which the fluorines F1 and F7 occupy the axial sites [F1-Si1-F7 is 169(1)°]. In fact, the mean value for the F1-Si-F2, F1-Si1-C1, and F1-Si1-C2 is 99° as opposed to a mean value of only 81° for the angles F7-Si-F2, F7-Si1-C1, and F7-Si1-C2.

A significant difference in bond length is also observed between the axial bonds Si1–F1 [1.62(1) Å and Si1–F7 [1.86(2) Å]. It is noteworthy that, except for the Si1–F7 bond, the Si–F bond lengths are equal within the experimental error; the mean value is 1.60(1) Å. The separation between the two disordered positions F7 and F7' is only 1.04(3) Å in the solid state at 178 K, whereas the distance between F7 and Si3 is as much as 2.75(2) Å. At higher temperatures minor deformations of the six-membered ring are induced. It can be assumed that the fluorine anion moves easily between positions. The trisilacylclohexane moiety is somewhat flattened: the mean value for the bond angles in the ring atoms (both C and Si) is 115.5° (for the cyclohexane ring it is 109.5°). Such a geometry allows the molecule more fluxional character; thus the F7 atom should easily reach its new position on the Si3–F6 bond axis, *opposite* to the F6 atom. Actually, this theoretical position (calculated coordinates: 0.3904, 0.25, and −0.0262) is only 1 Å away from the F7 (or F7') atomic position, which is close to the F7···F7' separation reported above. It is consistent with the observed disorder in the solid state structure of **3** and with the presence of a single resonance in the ^{29}Si CP/MAS NMR spectrum of **3**.

The heptafluorotrisilacyclohexane anion does exhibit a unique dynamic behavior. The structure may be described as a $C_3Si_3F_6$ ring in a chair conformation with a seventh "bridging"

fluoride ion in an averaged position between the three silicon atoms. The presence of bridging fluoride ligand was recently proposed by Tamao et al.[4] and Sakurai et al.[5] to account for rapid exchange processes in ortho(fluorosilyl)benzene derivatives. For silicate **3** the mechanism in Scheme 1 accounts for the



Scheme 1.

facile intramolecular ligand exchange at low temperatures. The mechanism involves a rapid transfer of the fluoride between silicon atoms and a conformational equilibrium of the six-membered ring. As shown in Scheme 1, successive fluoride transfers and chair inversions will shuttle the fluoride ligand from the "bridging" to the equatorial and axial positions. These low-energy processes are probably responsible for the observed dynamic behavior. In particular, the barrier to intramolecular fluoride transfer between silicon atoms is presumably of very low energy.

Residual electron density: 2.25 e Å^{-3}, near the potassium peak; further details of the crystal structure investigation may be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

A Reversible Transition between an α-Helix and a 3_{10}-Helix in a Fluorescence-Labeled Peptide**

Graham Hungerford, Marta Martinez-Insua, David J. S. Birch, and Barry D. Moore*

A key goal of molecular electronics is to synthesize molecular-based systems that can be rapidly and reversibly switched between two or more states in response to specific stimuli.[1] Ideally the switch should include a sensitive transduction mechanism so that changes occurring at a molecular level can be detected at a macroscopic level.[2, 3] Towards this end we have used oligopeptides to develop molecular switches for which different conformational states can be probed optically by monitoring the extent of intramolecular electron transfer quenching of fluorescence of internal labels.[2] Our eventual aim is to develop generic switching systems that can be tuned to respond to a wide range of stimuli by the inclusion of different functionality in the peptide chain. Here we describe a novel peptide that can be switched between two helical states, an α-helix and a 3_{10}-helix. Evidence for this transition has been obtained from circular dichroism (CD), infrared spectroscopy (IR), and photoinduced electron transfer (PET) fluorescence quenching.

Transitions between peptide secondary structures such as α-helix to random coil and α-helix to β-sheet have been very well studied.[4, 5] In contrast much less attention has been paid to the transition between the two most common types of peptide helix, the α- and 3_{10}-helices, although it has been implicated in the function of enzymes.[6, 7] Figure 1 shows schematically the difference between the two forms. The 3_{10}-helix is more highly pitched and has a different hydrogen bonding pattern. It is most often found in short peptides containing α-aminoisobutyric acid (Aib) residues[8] and at the termini of longer α-helical stretches in proteins.[9] Studies of a number of peptide families have shown that the relative stability of the two conformations can be

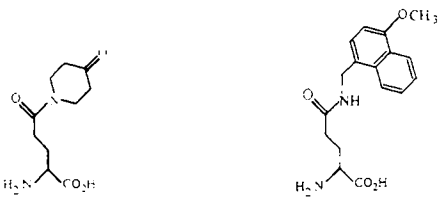
altered by changing the sequence,[10] the length of the peptide,[11, 12] and its environment.[13] Molecular dynamics simulations have shown that there is a well-defined pathway between the two forms[14, 15] and that the transition occurs over 15 picoseconds.[15] It therefore provides an attractive system for the development of a molecular switch.

We synthesized a series of peptides of differing length and sequence in which changes in conformational state can be probed by measuring the rate of PET between specific amino acids.[16] The peptides all include three or more Aib residues to promote helicity[17, 18] and two differently modified glutamic acids (at relative positions i and $i+4$). One glutamic acid is conjugated with a fluorescent methoxynaphthalene electron donor (Don) and the other with a piperidone electron accepting group (Acc) (Fig. 2).



Acc Don

2) Ac-Ala-Ala-Aib-Ala-Phe-Ala-Acc-Leu-Aib-Ala-Don-Ala-Aib-Leu-Ala-NH_2

Fig. 2. Sequences of peptides **1** and **2** and the structures of Don and Acc [16, 30].

The CD spectra in acetonitrile of the shorter members (twelvemers) of the series including **1** are indicative of an incompletely formed helical structure that is nevertheless stable over the temperature range 0 to 60 °C. Intriguingly PET fluorescence quenching studies on **1** suggested that at low temperature (below 0 °C) two different conformations were present in solution.[16]

To obtain more information peptide **2** was synthesized. This had the same central sequence as **1** but was three amino acids longer in order to promote greater helicity. The CD spectrum of **2** in acetonitrile was measured over the temperature range −40 to 60 °C. At lower temperatures it was highly characteristic of an α-helix,[19–22] with two pronounced minima of similar intensity at 208 nm and 222 nm (Fig. 3a). The intensity of the spectrum at −30 °C shows that almost all the peptide is α-helical.[19] On warming above −20 °C the CD spectrum changed rapidly with a large loss in the relative intensity of the 222 nm minimum (Fig. 3b). This continued up to 20 °C. Further heating to 60 °C left the spectrum largely unchanged (Fig. 3c). This data provides convincing evidence for a sharp thermal transition from an α-helical conformation at lower temperatures to another stable conformation at higher temperatures. This is neither a random coil nor a β-sheet structure as evidenced by the constant inter-

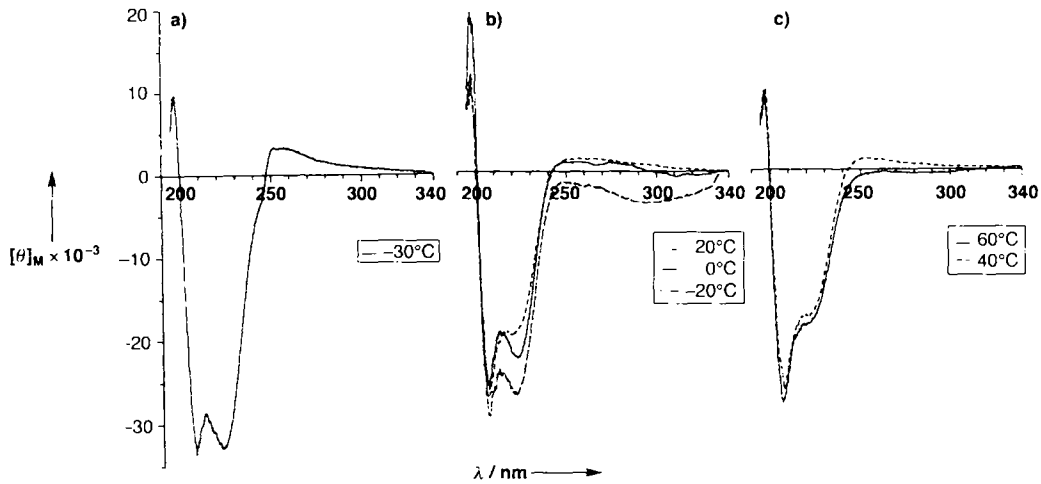

Fig. 3. Circular dichroism spectra of peptide **2** in acetonitrile at −30 °C (a), −20 to 20 °C (b), and 40 and 60 °C (c) [31].

cept of the x axis at 200 nm and the nearly constant intensity of the θ_{208} minimum.[19] Comparisons with other published CD spectra of helical peptides strongly suggest that this conformation is a 3_{10}-helix.[13, 20, 23] These spectra show a minimum at θ_{208} and a shoulder at θ_{222} with an intensity ratio $\theta_{222}:\theta_{208}$ in the range 0.5 to 0.8.[23, 21] This is comparable with the ratio of 0.7 at 20 °C found for peptide **2**.

Further evidence for the formation of a 3_{10}-helix was obtained from the room temperature infrared spectrum of **2** in acetonitrile, which showed a strong amide I band at 1662 cm^{-1}. This lies outside the 1650–1655 cm^{-1} range usually associated with the amide I band for an α-helix,[24] but is within the 1662–1665 cm^{-1} range measured for short $(Aib)_n$ homopeptides, known to form well characterized 3_{10}-helices.[25] It also coincides with the amide I band found for the antibiotic alamethicin in fluid phospholipid membranes and methanol, where it is reported to be a combination of α- and 3_{10}-helices.[24]

Although the CD spectra are consistent with a reversible change in the conformation of the whole peptide, it might be argued that only part of the backbone alters. Both X-ray[26] and NMR[27] measurements of helical peptides have shown stretches of α- and 3_{10}-helices within the same molecule, and α-helical stretches in proteins are often found to terminate with a 3_{10}-turn.[9] We introduced labeled glutamic acid residues within the central segment of the peptide to investigate this possibility further, as the results obtained should reflect changes in this section of the peptide. The fluorescence behavior of the peptide solution was monitored over the same temperature range as that used for

the CD measurements. At all temperatures it was possible to distinguish two species from their different fluorescence lifetimes. The relative amounts of each species varied reversibly with temperature, and the greatest change was observed over the same range as in the CD spectrum. These results show that the peptide exists in two discrete conformations that are in thermal equilibrium. Figure 4 shows the percentage of peptide exhibiting the shorter fluorescence lifetime plotted against temperature, along with the ratio of θ_{222} to θ_{208} for comparison. The latter gives a measure of the interconversion from α- to 3_{10}-helix, and it can be seen that the two data sets are strongly correlated. They both show a sharp transition indicative of a cooperative process. A similar melting range (ΔT) of 44 °C was measured by CD and PET fluorescence quenching, but the melting temperature (T_m) was -8 ± 4 °C by fluorescence and $4 + 10$ °C by circular dichroism. The fluorescence data shows clearly that the conformational changes seen in the CD measurements must also affect the central region of the peptide backbone where the labels are attached. By comparison we can assign the short lifetime component to peptide in the 3_{10} state, which indicates that PET fluorescence quenching is more efficient in this form.

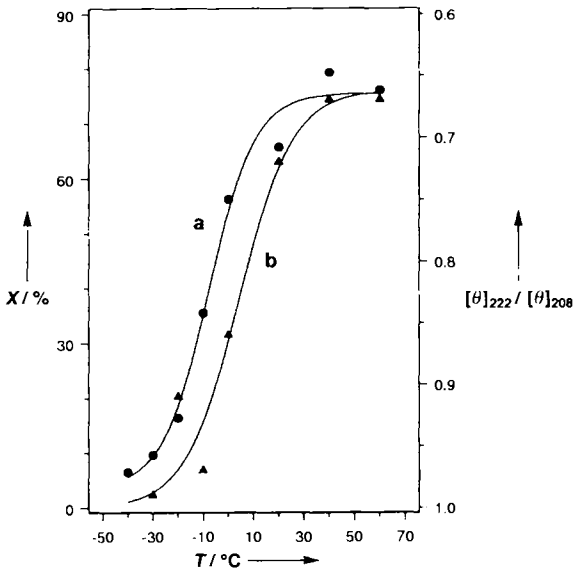

Fig. 4. The percentage X of the short lifetime component [32] (●, curve a) and the ratio of the intensities of the 222 nm and 208 nm CD minima (▲, curve b) against temperature for peptide **2** in acetonitrile.

The observed formation of a stable 3_{10}-helix at higher temperature indicates that there is a favorable entropic term associated with this conformation. Figure 5 shows the average conformations of the peptide in the two helical forms obtained from molecular dynamics simulations. It can be seen that in the 3_{10}-helix the bulky labeled side chains are, on average, further apart. The greater degree of conformational freedom this allows is consistent with a switch to this conformation at higher temperature (see Fig. 5). The lack of any detectable random coil formation in the accessible temperature range could be ascribed to the inclusion of three strongly helix-forming Aib residues and the use of an aprotic solvent, acetonitrile, which promotes strong intramolecular hydrogen bonding. The puzzling question why the fluorescence quenching is more efficient in this form is currently under investigation. Interestingly, de Rege et al. have predicted that distinct secondary structural motifs may modulate donor–acceptor electronic coupling differently.[28]

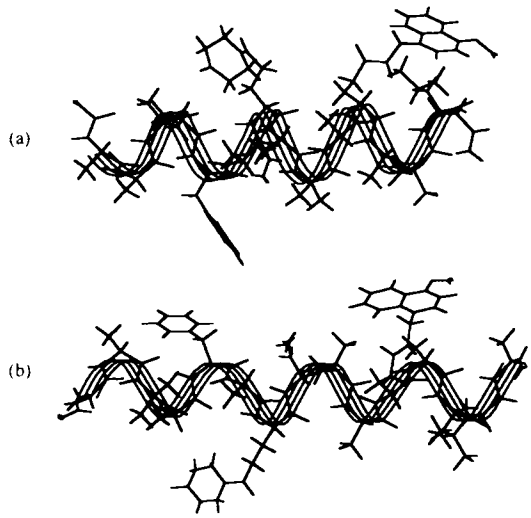

Fig. 5. The average conformation obtained from a 200 ps molecular dynamics simulation on peptide **2** with the peptide constrained in an α-helix (a) and in a 3_{10} helix (b) [33].

These results prove that a well-defined α- to 3_{10}-helical transition is possible in a synthetic peptide. This is the first step towards a molecular switch based on these conformational states. The well-defined transition seen here suggests that it will be possible to synthesize more complex peptides that respond to different stimuli such as the binding of ions or molecules. This will enable the development of the logic functions required for molecular electronics.

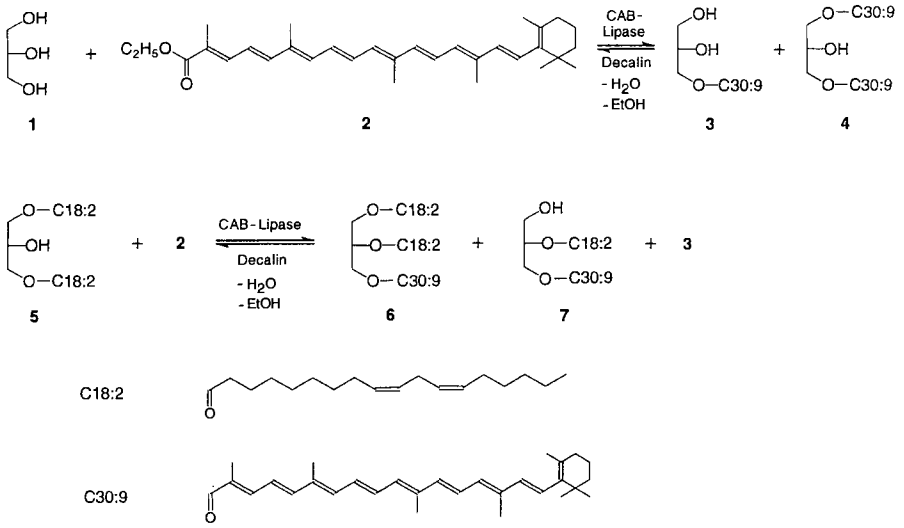
[30] The peptides were synthesized with a NovaSyn Crystal solid phase peptide synthesizer on a modified Rink type resin using 9-fluorenylmethoxycarbonyl (FMOC) protecting group strategies and benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) coupling protocols. Following cleavage with 10% trifluoroacetic acid in dichloromethane, the crude peptide was purified by reversed-phase high-performance liquid chromatography and characterized with electrospray mass spectrometry.
[31] The spectra were recorded at a concentration of about 10^{-5} M with a Jasco J600 spectropolarimeter (1 cm pathlength cell). $[\theta]_M$ is in units of deg cm^2 dmol^{-1}. The experiment was performed by first heating to 60 °C then cooling to −40 °C. Identical spectra were obtained over several cycles.
[32] The fluorescence data were obtained at a peptide concentration of about 5×10^{-5} M in degassed acetonitrile with a time-resolved single-photon counting fluorometer with a coaxial flashlamp excitation source which gives an instrumental response of about 1.2 ns at full width half maximum. The excitation and emission wavelengths of 300 nm and 360 nm, respectively, were selected by monochromators. At 0 °C the lifetimes recovered were 4.14 and 6.32 ns, whilst the lifetime without fluorescence quenching was 7.59 ns. The curve fitted to both sets of data was a logistic sigmoid of the form $F(T) = y_{min} + [(y_{max} - y_{min})/(1 + \exp(-A(T - T_m)))]$, where A is a constant, T is temperature, and T_m is the melting temperature. The melting range ΔT was obtained by taking the center 80% of the curve between the upper and lower y data values. The uncertainty in the T_m value was taken as two standard errors.
[33] Calculations were performed with the software packages InsightII, Discover, and Analysis from BioSym Technologies on a Silicon Graphics Iris Indigo workstation. The force field used was CVFF, dynamics were run at 293 K in a vacuum, and the peptide was constrained in each helical form by fixing the α carbon atoms.

Stable, Highly Unsaturated Glycerides—Enzymatic Synthesis with a Carotenoic Acid**

Vassilia Partali, Lise Kvittingen, Hans-Richard Sliwka,* and Thorleif Anthonsen

The recent interest in highly unsaturated long-chain glycerides has resulted in the development of several synthetic and concentration methods.[1–4] However, glycerols of polyunsaturated fatty acids such as icosapentaenoic acid (C20:5), docosahexaenoic acid (C22:6), and the conjugated ajenonoic acids (C12:5, C14:5) are at least as unstable as the free fatty acids and can therefore only be handled at low temperature under an inert atmosphere or with stabilizers such as carotenoids.[4–6]

Thus, the synthesis of stable, highly unsaturated glycerides has to be based on stable highly unsaturated fatty acids. This requirement is met by the approximately 25 carotenoic acids that occur in low concentrations in nature.[7] One of these acids, 8′-apo-β-carotenoic acid (C30:9), is a stable, vitamin A active carotenoid, which is commercially available as the ethyl ester (C30-ester) **2** (see Scheme 1).[8,9]



Scheme 1. Enzymatic synthesis of carotenoid glycerides.

Glycerides with a carotenoid as fatty acid have not been encountered in nature, although the carotenoic acid **2** can be considered as a dehydrogenated form of the naturally occurring branched fatty acids.[8,10]

We expect the carotenoid glycerides **3**, **4**, **6**, and **7** to combine the many physiological effects of fatty acids with those of carotenoids.[11–13] The carotenoid glycerides will probably be better absorbed and therefore their pharmacological effects might be higher than those of free carotenoids, which, even when esterified with palmitic acid, are not easily absorbed by man and animals.[14–16] The carotenoid fats **6** and **7** are polyfunctional glyceride derivatives in which the antioxidant carotenoid part can function as an intramolecular stabilizer for the fatty acid acyl groups in the molecule, while, simultaneously, the fatty acid acyl groups promote the absorption of the carotenoid.[17] We report here on the synthesis of the first stable highly unsaturated, conjugated glycerides.

The classical syntheses of glycerides (transesterification, direct synthesis) appeared to be less suitable as a route to these compounds, since the carotenoid ester **2**, like most carotenoids, is decomposed under the reaction conditions (high temperature or presence of acids) required.[18,19] Therefore, the conjugated mono-, di-, and trinonaenoylglycerol derivatives **3**, **4**, **6**, and **7** were synthesized with the help of enzymatic catalysis (Scheme 1), a method, which has not often been applied in carotenoid chemistry.[4,20–22]

Compounds **3** and **4** were obtained by esterification, and fats **6** and **7** by transesterification. Glycerol (**1**) was treated with **2** in decalin at 30–37 °C under reduced pressure in the presence of lipase from *Candida Antartica B* (CAB). This gave the mono- and diglycerides **3** and **4**, respectively, in about equal amounts (total yield 43%). The reaction of the diglyceride **5** with **2** produced the triglyceride **6** and the glycerides **3** and **7** in a ratio of 9:2:1 (total yield 38%). The yield of the enzymatic esterification of glycerol (**1**) with unsaturated fatty acids decreases with the

increasing proximity of the double bond to the carbonyl group.[4] Nevertheless, the yield of carotenoyl glycerols in the esterification and the transesterification reaction between the carbonyl conjugated ester **2** and glycerol (**1**) or glyceride **5** can be considered as satisfactory.

The reaction of diglyceride **5** with ester **2** can give, statistically, nine glyceride products, not including possible positional and stereoisomers. In theory the formation of the products depends on an overall equilibrium constant which itself is a function of the three hydrolytic equilibrium constants for the tri-, di-, and monoglycerides. In fact, the product formation is also dependent on the reactant concentration, the solvent, the position specificity of the lipase, and, eventually acyl migration. By reducing the pressure, the products water and ethanol are continuously removed, which has a favorable effect on the formation of higher glycerides. Despite the complexity of the transesterification reaction, the main product was triglyceride **6**, with smaller amounts of mono- and diglycerides **3** and **7**, respectively.

The carotenoid glycerols were separated from the few by-products, unconverted **2**, and colorless glycerides by chromatographic work-up.

The structure of the new fats was confirmed by UV-Vis, ^{1}H, ^{13}C NMR, and IR spectroscopy, and mass spectrometry. After work-up of the reaction mixture, NMR spectroscopy revealed the presence of only the 1,3-derivative **4**, the triglyceride **6**, and the 1,2-isomer **7**, although acyl migration cannot be excluded.[23]

Mono- and diglycerides of medium- and long-chain fatty acids form stable emulsions in water.[24] Thus, compounds **3**, **4**, and **7** may be suitable for preparing easily absorbable carotenoid dispersions without relying on additional emulsifiers.[25]

Experimental Procedure

Esterification: **1** (83 mg, 0,90 mol), **2** (73 mg, 0.16 mmol), and CAB-lipase (350 mg) were stirred in decahydronaphthalene (10 mL) at 35 °C at reduced pressure (10 Torr) for 4 days.

Transesterification: **5** (7.4 mg, 0.012 mmol), **2** (12 mg, 0.026 mmol), and CAB-lipase (60 mg) were stirred in decahydronaphthalene (2 mL) at 35 °C at reduced pressure (10 Torr) for 8 days. After evaporation of the solvent, the yellow-red carotenoid glyceride products from both reactions were separated by column or preparative TLC chromatography on silica gel with hexane/acetone mixtures as eluents. Colorless glycerides were not analyzed. The esterification reaction gave the products **3** and **4** in the ratio 1:1 in 43% yield. The transesterification reaction afforded the products **3**, **6**, and **7** in 38% yield in a ratio of 9:2:1. The VIS spectra of products **3**, **4**, **6**, and **7** (λ_{max} = 456 nm, CH_2Cl_2) were identical with that of the starting material **2**.

Esterification reaction: Recovered **2**: 22 mg. **3**: Obtained: 15 mg. MS (70 eV) *m/z*: 506 [M^+], 414 [$M^+ - 92$]; IR (KBr): $\tilde{\nu}$ = 3428 (OH), 1700 (conj. Synthesis of Tailor-Made Glycoconjugates Showing AT III-Mediated Inhibition of Blood Coagulation Factors Xa and Thrombin**

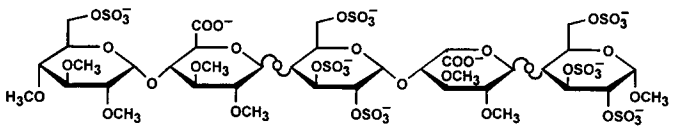
Pieter Westerduin, Jan E. M. Basten, Marc A. Broekhoven, Vera de Kimpe, Will H. A. Kuijpers, and Constant A. A. van Boeckel*

The sulfated glycosaminoglycan heparin binds with high affinity to the plasma protein antithrombin III (AT III), thereby accelerating its inhibitory activity towards factor Xa and thrombin, two serine proteases involved in blood coagulation.[1, 2] The AT III-binding region in heparin consists of a unique pentasaccharide (PS) domain,[3, 4] the synthetic counterpart of which was found to accelerate the AT III-mediated inhibition of factor Xa but not that of thrombin.[5, 6]

In the course of studies on the preparation of PS analogues[7, 8] the molecular requirements for the specific binding of PS to AT III became transparent and a three-dimensional model of the interaction of PS and AT III could be constructed.[9, 10] In addition, easily accessible, highly potent O-sulfated/O-methylated PS analogues such as **1** have been identified.[11–13]



1

The next challenge was to extend the concept of AT III-mediated inhibition of factor Xa by PS towards synthetically feasible derivatives displaying both antifactor Xa and antithrombin activity.

It is now well recognized that for AT III-mediated inhibition of thrombin a heparin fragment comprising at least 18 saccharide units is required,[14] facilitating the binding of AT III and thrombin to the same polysaccharide chain (the so-called "bridge" or "template" mechanism) (Fig. 1).[15] In the formation of the heparin/AT III/thrombin ternary complex the unique PS sequence interacts specifically with AT III, and any sulfated oligosaccharide fragment along the heparin chain interacts in a less specific mode with thrombin.[15, 16] Our recent model of the heparin/AT III/thrombin ternary complex reveals that heparin analogues may be obtained when a thrombin-binding oligosaccharide is tethered to the nonreducing terminus of the AT III-binding pentasaccharide with a spacer about 50 atoms in length (Fig. 1).[17] To this end, glycoconjugate **I** (see Scheme 3) has been synthesized, which comprises the AT III-binding PS **1** (AT III-binding domain, ABD), a linear spacer, and a persulfated maltotrioside moiety (thrombin-binding domain, TBD). For the construction of a pentasaccharide (ABD) containing a functionalized molecular spacer at its nonreducing end, the following key synthetic steps have to be performed (Scheme 1): a) glycosylation of the tetrasaccharide acceptor **3** with 6-*O*-acetyl-4-*O*-(11-azido-3,6,9-trioxaundecane)-2,3-di-*O*-methyl-D-glucopyranosyl trichloroacetimidate (**2**) to give the protected pentasaccharide **4** having a 1-azidotetraethylene glycol moiety[18] and b) linkage of the amino group in compound **5** with the thioacetyl-substituted bifunctional spacer **6**, and subsequent *O*-sulfation.

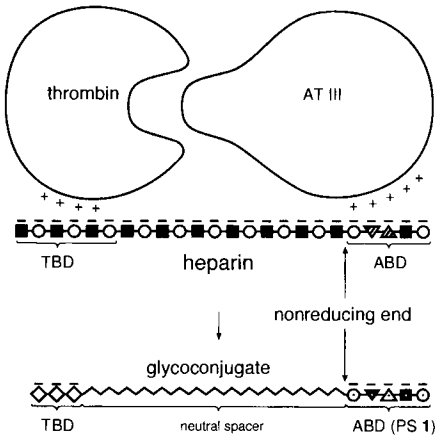


Fig. 1. Schematic representation of the heparin/AT III/thrombin ternary complex, leading to the concept of synthetic heparin analogues such as glycoconjugates **I**–**VI**.

To synthesize donor **2**, methyl 6-*O*-benzyl-2,3-di-*O*-methyl-α-D-glucopyranoside[19] was treated with tetraethylene glycol ditosylate in DMF in the presence of sodium hydride at 40 °C followed by addition of sodium azide to the reaction mixture and elevation of the temperature to 70 °C. Subsequent acetolysis using 1% sulfuric acid in acetic anhydride at −20 °C and treatment with piperidine and trichloroacetonitrile/cesium carbonate afforded the glycosyl donor **2** in 30% overall yield.

Trimethylsilyl trifluoromethanesulfonate (TMSOTf) mediated coupling of **2** with **3** at −20 °C afforded the α-linked pentasaccharide **4** in 65% yield after purification (Scheme 1). Concomitant hydrogenolysis of benzyl esters, benzyl ethers, and the azide group of **4** followed by saponification gave pentasaccharide **5** (75% overall yield), which bears an amino function for attaching the bifunctional spacer **6**. The latter was synthesized by a seven-step procedure starting from tetraethylene glycol: 1) monosilylation (*tert*-butyldimethylsilyl chloride/NaH in DMF), 2) introduction of a methylene carboxylate ester (NaH/*tert*-butylbromoacetate in DMF), 3) desilylation (tetrabutylammonium fluoride), 4) tosylation (tosyl chloride, pyridine, 20 h, room temperature), 5) substitution of tosylate with thioacetate (KSAc/acetone, 18 h, room temperature), 6) cleavage of the *tert*-butyl ester (trifluoroacetic acid in dichloromethane), and 7) activation of the carboxyl group (diisopropylcarbodiimide/*N*-hydroxysuccinimide) to give **6** in 20% overall yield.

Coupling of **5** with **6** afforded, after sulfation with triethylamine/sulfur trioxide complex in DMF at 50 °C, a mixture of **7a** and **7b**. HPLC and mass spectrometry indicated that the amide group in the spacer moiety was partly sulfated (65%) giving derivative **7a**. Nevertheless, this problem could be overcome easily: treatment of the crude mixture with 0.2 N hydrochloric acid at 0 °C for 24 h led to selective desulfation of the amide sulfate group (without any observed cleavage of the $O-SO_3^-$ bond) to give the desired ABD moiety **7b** in quantitative yield.

To equip glycoconjugate **I** with a spacer about 50 atoms in length, the polysulfated maltotrioside (TBD) fragment should bear a spacer about 25 atoms in length. In addition, the latter should carry a thiophilic group to allow coupling with the thiol

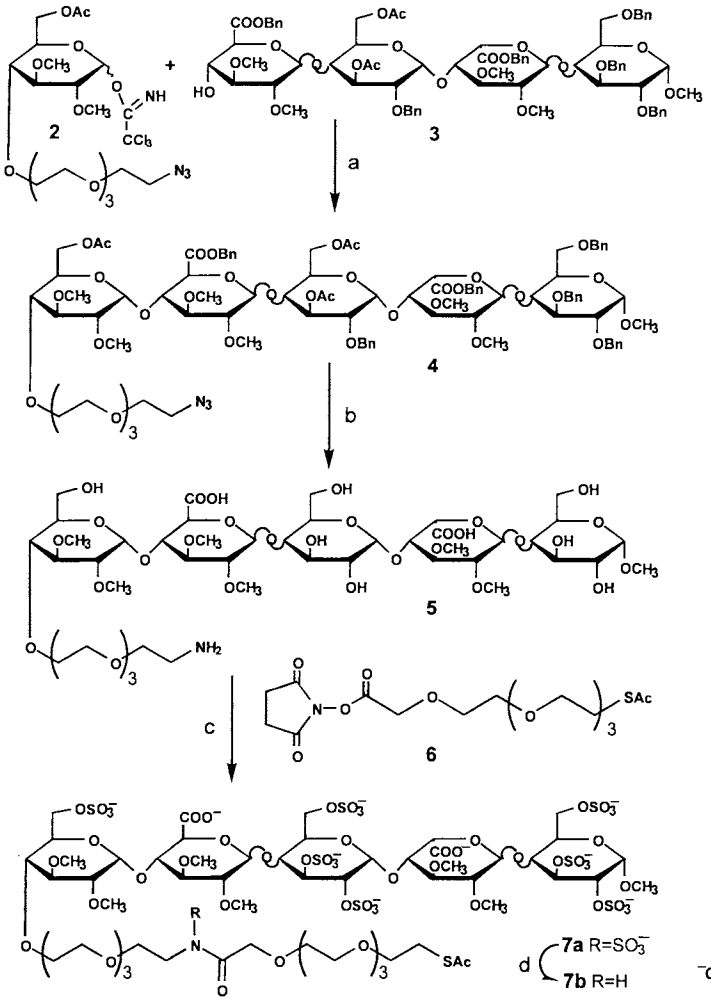
[**] This work was carried out in collaboration with Sanofi Recherche, France. We thank Dr. M. Petitou (Sanofi Recherche, France) for useful discussions, Dr. P. A. van Veelen (N. V. Organon) for the MALDI MS measurements, and T. G. van Dinther and E. van As (N. V. Organon) for determining the in vitro biological activities.



Scheme 1. a) TMSOTf, CH_2Cl_2, 4 Å molecular sieves, 1 h, −20 °C (65%); b) Pd/C, H_2, DMF, H_2O, HOAc, 24 h and 0.3 M NaOH, CH_3OH, H_2O, 1/1, v/v, 4 h (75%); c) H_2O, DMF, *N*-methylmorpholine, 15 min, (80%); $Et_3N{\cdot}SO_3$, DMF, 50 °C, 16 h; d) 0.2 N HCl, 24 h, 0 °C, (100%).

function of deprotected **7b**. Thus, TMSOTf-promoted coupling of peracetylated maltotriose trichloroacetimidate[20] and 1-azido-17-hydroxy-3,6,9,12,15-pentaoxaheptadecane[21] was performed giving 1-azidohexaethylene glycol glycoside **8**. Saponification, subsequent sulfation, and catalytic hydrogenation provided the polysulfated maltotrisaccharide 1-amino-hexaethylene glycol derivative **9** in 55% yield (Scheme 2), which was then condensed with sulfosuccinimidyl (4-iodoacetyl-amino)benzoate (**10**, sulfo-SIAB) to give the TBD moiety **11** in 70% yield after G-15 size exclusion chromatography (Scheme 3). The ABD and TBD units were linked in a one-step procedure. A solution of **7b** (ABD) and **11** (TBD) in 0.1 M sodium hydrogenphosphate buffer (pH 7.5) was treated with 0.05 M hydroxylamine under argon atmosphere to furnish, after G-50 size exclusion chromatography, conjugate **I** in 65% yield and in

excellent purity as revealed by ^1H NMR spectroscopy[22] and reversed UV capillary electrophoresis (**I** $[\alpha]_D^{21}$ 40.1 ($c = 1$ in water)). In addition, the identity of **I** was corroborated unambiguously by matrix-assisted laser desorption ionization (MALDI) mass spectrometry.[23, 24]

The ABD and TBD fragments in glycoconjugate **I** are separated by a 53-atom spacer, and the compound has roughly the same length as a heparin fragment of about 18 saccharide units. Indeed compound **I** displays a substantial antithrombin activity (Table 1), thus demonstrating that the syn-

Table 1. In vitro AT III-mediated anti-Xa and anti-thrombin activities of glycoconjugates **I**–**VI**, PS **1**, and heparin.

Compound	TBD moiety[a]	anti-Xa activity [U mg^{-1}]	anti-thrombin activity [U mg^{-1}]	anti-Xa/ anti-thrombin activity
I	maltotriose (10)	490	64	7.6

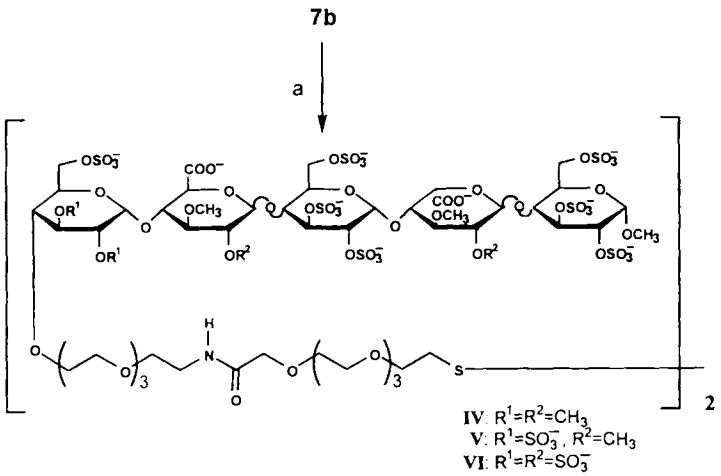
III	maltopentaose (16)	280	330	0.9
IV	TBD = ABD (7)	770	14	55
V	TBD = ABD (9)	640	36	18
VI	TBD = ABD (11)	280	160	1.75
PS 1		1600	–	∞
heparin	oligosaccharide	160	160	1

[a] The number of sulfate groups in the TBD is in parentheses.

thesis of large, complex heparin-like oligosaccharides can be circumvented elegantly and efficiently by the demonstrated spacer strategy.

We also wished to study the requirements for the binding of TBD to thrombin. For this purpose a disaccharide and a pentasaccharide, cellobiose heptasulfate and maltopentaose hexadecasulfate, were prepared and attached to ABD **7b** in a similar fashion as described for conjugate **I**, furnishing ABD–TBD conjugates **II** ($[\alpha]_D^{21} = 24.8$ ($c = 1$ in water)) and **III** ($[\alpha]_D^{21} = 30.6$ ($c = 0.4$ in water)), respectively.

We were anxious to find out if the ATIII-binding pentasaccharide itself may also act as a thrombin-binding domain. These studies would require a symmetric pentasaccharide conjugate such as compound **IV**, which should be accessible by oxidative coupling of a thiol like **7b** after removal of the acetyl protecting group. Indeed, dimerization of functionalized pentasaccharide **7b** was accomplished in a single step by treatment with hydroxylamine in the presence of oxygen; the symmetric conjugate **IV** was isolated in 90% yield after G-50 size exclusion chromatography (Scheme 4). The identity of **IV** ($[\alpha]_D^{21} = 46.9$ ($c = 1$ in water)) was corroborated unambiguously by ^{1}H NMR spectroscopy and MALDI mass spectrometry.[25] Conjugates **V** ($[\alpha]_D^{21} = 42.9$ ($c = 1$ in water)) and **VI** ($[\alpha]_D^{21} = 31.6$ ($c = 0.82$ in water)) were obtained by procedures analogous to those used in the synthesis of **IV**.



Scheme 4. a) 0.1 M aqueous Na_2HPO_4 (pH 7.5), 0.05 M $NH_2OH \cdot HCl$, O_2 stream, 16 h (90%).

The conjugates **I**–**VI** were tested in vitro for ATIII-mediated antifactor Xa and antithrombin activity, and the results were compared to those with heparin and PS **1** (Table 1). The glycoconjugates **I**–**VI** display good to strong ATIII-mediated antifactor Xa and antithrombin activity, while the activities of glycoconjugates **III** and **VI** even exceed that of heparin. It is clearly shown that the increase in charge of the TBD moiety gives rise to higher antithrombin activity. In this way, a chemical basis is provided for imparting a desired antifactor Xa and antithrombin activity to one synthetic glycoconjugate, leading to tailor-made antithrombotics.

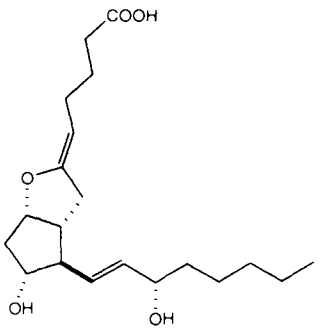
(15*R*)-16-*m*-Tolyl-17,18,19,20-tetranorisocarbacyclin: A Stable Ligand with High Binding Affinity and Selectivity for a Prostacyclin Receptor in the Central Nervous System**

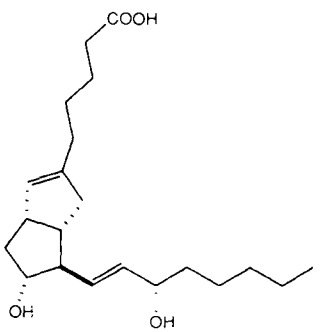
Masaaki Suzuki,* Koichi Kato, Ryoji Noyori, Yumiko Watanabe, Hajime Takechi, Kiyoshi Matsumura, Bengt Långström, and Yasuyoshi Watanabe

Prostaglandins (PGs) are known to exhibit diverse biological activities controlling a wide range of physiological functions in the circulatory, reproductive respiratory, and digestive systems.[1] In recent years there has been strong interest in elucidating the role of PGs in brain function.[2]



1

Prostacyclin (PGI_2, **1**) is a potent vasodilator and plays an important role in the circulatory system through antithrombotic actions.[3] Several lines of evidence suggest that PGI_2 has neuromodulatory actions as well.[4] Quite recently, a quantitative in vitro autoradiographic mapping of a PGI_2 receptor in the rat brain using [^{3}H]iloprost,[5] a stable specific agonist for a PGI_2 receptor, demonstrated a high density distribution in four regions of the lower brain stem including the medial and commissural subnuclei of the nucleus tractus solitarius (NTS).[6] Precise analysis of the role of PGI_2 in the brain requires the development of a specific molecular probe capable of sharply discriminating its action in the central and peripheral nervous systems. In this context, our interest has been directed towards designing a new ligand selectively responsive to a receptor in the central nervous system. We describe here a tolyl-functionalized isocarbacyclin derivative with high binding affinity and selectivity for a PGI_2 receptor in the thalamus.



2

The title compound was devised based on the structural modification of the ω side chain of isocarbacyclin (**2**), a chemically stable PGI_2 agonist,[7] starting from the aldehyde intermediate **3**[8] shown in Scheme 1.[9] Incorporation of the tolyl group at the terminus of the the PG ω side chain in **3** was planned in the hope of later conversion into a $^{11}CH_3$-containing hypersensitive ligand usable for positron emission tomography (PET).[11] Thus the starting methyl *m*-tolylacetate **4**[12] was condensed with the anion of dimethyl methylphosphonate, which was generated by action of *n*-butyllithium in THF at −78 °C, to give the β-keto phosphonate **5** as a Horner–Emmons reagent in 48% yield.

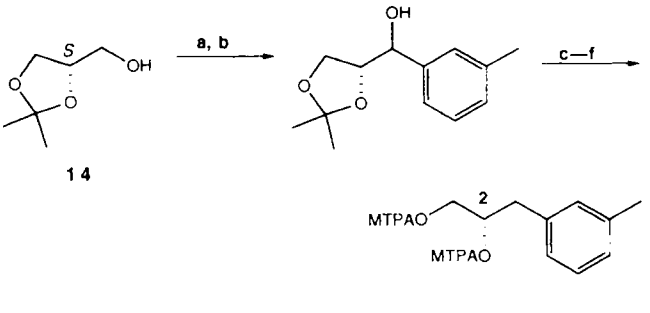
[**] This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science, and Culture of Japan.

Other Horner–Emmons reagents required for the ω side-chain modification were prepared in a similar manner by combining the same phosphonate with the corresponding longer chain ester substrates.[14] The phosphonate **5** was then condensed with the aldehyde **3**[8] in 1,2-dimethoxyethane with sodium hydride as the base to afford the enone **6** in 96% yield, which then reduced with sodium borohydride in the presence of cerium(III) chloride in methanol to give the diol **7** (as a 1:1 mixture of stereoisomers at C-15) in quantitative yield. The stereoisomers were separated by conventional silica gel column chromatography to give the stereochemically pure alcohols **8** and **9** (each in 50% yield) as the less and more polar materials, respectively (TLC on silica gel (ethyl acetate/hexane 1/1) R_f = 0.26 and 0.18, respectively). Finally, alkaline hydrolysis of **8** and **9** led to the corresponding tolylisocarbacyclin derivatives **10** and **11** in quantitative yields.[13] Other tolylisocarbacyclin derivatives subjected to the binding assay were also synthesized by a similar method using the corresponding Horner–Emmons reagents as described above.[14, 15]

The absolute configuration at C-15 of the tolylisocarbacyclin derivatives **10** and **11** was determined unambiguously at the stage of the ester by chemical correlation[8] as outlined in Schemes 2 and 3. Thus selective masking of the double bond in one of the five-membered rings of **9** by transformation to a tricyclic compound followed by esterification of the C-15 hydroxyl group with (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride [(*S*)-MTPA chloride] gave the MTPA ester **12** (Scheme 2). Then, oxidative cleavage of the double bond in the ω side chain, reduction of the resulting aldehyde to give the alcohol, and MTPA esterification provided the tolyl group containing, optically active bis(MTPA) ester **13** and the tricyclic residue. The stereodefined ester (2*S*)-**13** was prepared independently from the optically pure glycerol derivative (2*S*)-**14** by Grignard reaction with an aldehyde and Barton's deoxygenation of the resulting alcohol (Scheme 3).[16] The corresponding diastereomeric mixture of (2*R*)- and (2*S*)-**13** was also prepared via the racemic **14**. HPLC analysis of these authentic samples indicated that the retention time of **13** obtained by degradation of the isocarbacyclin derivative **9** was identical with that of (2*S*)-**13**,[17] thus indicating that the C-15 stereocenter of **11** has the *S* configuration, and thereby the *R* configuration can be assigned to **10**.

The binding assay of the isocarbacyclin derivatives was conducted for PGI_2 receptor proteins in frozen tissue sections containing either the thalamus or the NTS as representative of the central or peripheral nervous systems, respectively, using C-15 tritium-labeled isocarbacyclin ([^{3}H]isocarbacyclin) as a radioligand. The 50% inhibitory concentrations of the binding (IC_{50} values) were determined on the basis of the degree of



Scheme 3. a) PCC, CH_2Cl_2; b) *m*-$CH_3C_6H_4MgCl$, ether; c) NaH, THF, then CS_2, CH_3I, 98%; d) nBu_3SnH, toluene, reflux, 66%; e) CF_3COOH, THF/H_2O (4:1); f) (*S*)-MTPACl, pyridine.

displacement of 10 nM [^{3}H]isocarbacyclin bound to the receptor by its nonradioactive derivatives. We found that (15*R*)-16-*m*-tolyl-17,18,19,20-tetranorisocarbacyclin [**10**, referred to as (15*R*)-TIC], among other tolylisocarbacyclin derivatives, exhibited the highest binding affinity sufficient for a receptor in the thalamus (IC_{50} = 31 nM) but showed very weak binding with a receptor in the NTS (IC_{50} = 1.2 μM). The (15*S*) isomer **11** [referred to as (15*S*)-TIC] showed slightly lower binding (IC_{50} = 38 nM) in the thalamus than **10** and still maintained considerably strong binding affinity (IC_{50} = 32 nM) in the NTS. Other tolylisocarbacyclin derivatives[15] showed weaker thalamus binding affinity. Isocarbacyclin (**2**), the lead compound for this study, exhibited high binding affinity in the thalamus (IC_{50} = 31 nM) and NTS (IC_{50} = 23 nM). The resulting binding profile of (15*R*)-TIC (**10**), as illustrated by plots A and B in Figure 1,

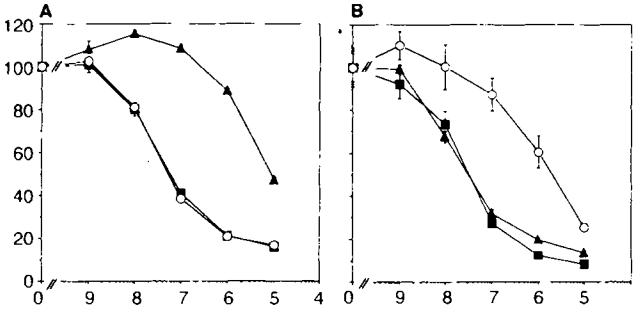


Fig. 1. Displacement of 10 nM [^{3}H]isocarbacyclin binding by nonradioactive (15*R*)-TIC (**10**) (○), isocarbacyclin (**2**) (■), and cicaprost (**15**) (▲) to thalamus (**A**) and the NTS (**B**) of rat brain. The frozen sections of rat brain (10 μm thick) containing thalamus and the NTS of medulla oblongata were incubated with 10 nM [^{3}H]isocarbacyclin in the absence or presence of different concentrations of the above displacers at 4 °C for 120 min. The sections were then washed, air-dried, and exposed to imaging plates (BAS TR2040, Fuji Film Co., Ltd., Tokyo, Japan). After calibration with plastic tritium scales, densitometric analysis of the radioautograms was performed with the image analyzing program NIH image. The quantitated data are expressed as % control of the 10 nM [^{3}H]isocarbacyclin binding without displacer. The plotted data are the means ± standard deviations of four determinations, each determination consisting of 5–8 sections. Some standard deviation bars are too small to be visible. The concentration of the ligands (−log M) is plotted on the x axes.

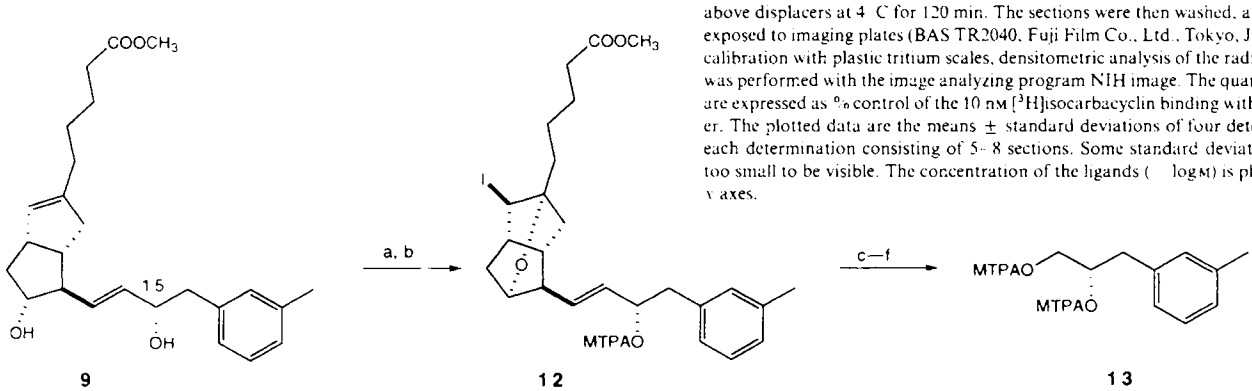
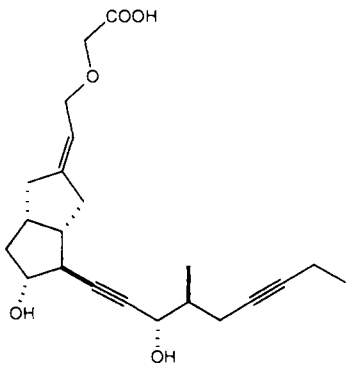


Scheme 2. a) I_2, CH_3OH, H_2O (3:1), 89%; b) (*S*)-MTPACl, pyridine, 92%; c) OsO_4, pyridine; d) $NaIO_4$, THF/ether/H_2O (2:1:1); e) $NaBH_4$, CH_3OH; f) (*S*)-MTPACl, pyridine, 20% overall yield from **12**.

contrasts markedly with that of cicaprost (**15**),[18] a stable PGI_2 agonist belonging to the iloprost family, which shows high binding affinity and selectivity for a PGI_2 receptor in the NTS (IC_{50} – 30 nM). In agreement with these binding experiments, (15*R*)-TIC (**10**) showed a very weak inhibitory effect (IC_{50} > 400 nM)[19] on platelet aggregation, while cicaprost (**15**) and isocarbacyclin (**2**) exhibit potent inhibitory effects (IC_{50} = 3.2 nM[18] and 2.5 nM[19], respectively). Thus we have succeeded in finding a stable PGI_2 analogue based on a structural modification of **2** which acts with high selectivity on the central nervous system.[20] We hope that this ligand will ameliorate the biological problems arising from the instability of PGI_2 and the lack of a stable analogue specific to a PGI_2 receptor expressed in the central nervous system.



15

The fascinating binding characteristics of (15*R*)-TIC (**10**) and its potential usefulness as an efficient molecular probe for a PGI_2 receptor in the central nervous system prompted us to synthesize the corresponding tritium-labeled derivative. Thus radioisotope labeling was achieved at the stage of the enone **6** by reduction using [^{3}H]$NaBH_4$ (60 Ci mmol^{-1}) in the presence of cerium(III) chloride. The tritium-labeled compound [^{3}H]-**7** was obtained as a 1:1 mixture of epimers with a specific activity of roughly 15 Ci mmol^{-1}.[8, 21] Separation of these epimers with reversed-phase HPLC followed by ester hydrolysis gave [^{3}H]-(15*R*)-TIC ([^{3}H]-**10**) and [^{3}H]-(15*S*)-TIC ([^{3}H]-**11**) in pure forms.

The biological study, including the successful quantitative in vitro autoradiographic mapping of a new PGI_2 receptor subtype in the rat brain using [^{3}H]-(15*R*)-TIC, will be reported separately.[22]

[9] In this context, we recently synthesized an azido-functionalized isocarbacyclin derivative, referred to as APNIC[8], from the same aldehyde intermediate **3**. APNIC acts as a specific probe for a PGI_2 receptor in mastocytoma P-815 cells. We succeeded in identifying PGI_2 receptor proteins and determining their molecular weights in these cells and in porcine and human platelets for the first time by photoaffinity labeling with a [^{3}H]APNIC ligand[10].

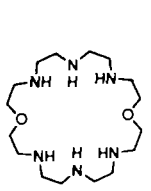
Supramolecular Catalysis of H/D Exchange in Malonate Ions by Macrocyclic Polyamines: A Model Enzyme with Enolase Activity**

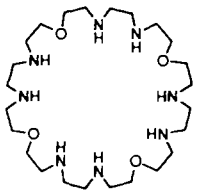
Hicham Fenniri, Jean-Marie Lehn,* and Annie Marquis-Rigault

The enolization of carbonyl compounds such as carboxylic acids and ketones is a crucial event in a wide variety of key reactions in chemical and in biochemical transformations.[1] Examples include enzyme-catalyzed carbon- carbon bond formation,[2] racemization,[3] β-elimination,[4] and isomerization.[5] Model systems have been designed and schemes proposed for elucidating the many steps of this process.[6] Of special interest is the question how a catalytic group of an enzyme whose pK_a is usually less than 8 can efficiently abstract a proton from a substrate with a pK_a greater than 20.[7, 8]

We now report that binding malonate ions to the polyammonium macrocycles **1** and **2** greatly accelerates the H/D exchange at the CH_2 group. This supramolecular catalytic process[9] markedly facilitates enolization and provides information about the mechanistic factors involved.



1 [24]ane N_6O_2



2 [36]ane N_8O_4

Macrocyclic polyamines possess the remarkable property of simultaneously 1) carrying a high positive charge through protonation,[10, 11] 2) presenting unprotonated nucleophilic sites, and 3) serving as a potential proton reservoir in a reaction on a bound substrate. These features come into play in the catalysis of ATP hydrolysis and of phosphorylation reactions by various macrocyclic polyamines, in particular by the [24]ane N_6O_2 macrocycle **1**.[9a, 12] It appeared that they could also provide a pathway for facilitating enolization processes.

Protonated macrocyclic polyamines form stable complexes with polycarboxylate substances.[11, 13] In particular, the protonated compound **1** binds malonate ions,[14] which are geometrically and electrostatically complementary to this receptor.[15] The predominant species around pH $\approx$ 7 is the complex between the tetraprotonated form of **1** and the malonate dianion;[16] it displays a stability constant of 240 M^{-1}.[14] Thus, **1** was a good candidate for investigating the effect of binding on the H/D exchange in malonate ions. The most extensive studies were performed with this more readily available compound **1** and complemented by experiments with macrocycle **2**.

The reaction was followed by ^1H NMR spectroscopy[17] ($D_2O > 98\%$) under different conditions to investigate the effects of pH, ionic strength, and temperature on the enolization process in the presence and absence of macrocycle **1**. It was found to display Michaelis-Menten kinetics with saturation behavior (Fig. 1). The Lineweaver-Burk plot of the same data (Fig. 1, insert) yielded $K_m = 3.8\,10^{-3}$ M and $k_{cat} = 1.75\ 10^{-3}\ s^{-1}$,

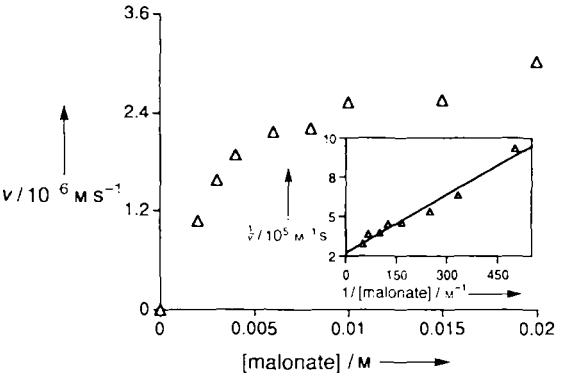


Fig. 1. Michaelis-Menten and Lineweaver-Burk (insert) plots for H/D exchange at the α position in malonate catalyzed by the macrocyclic polyamine **1**; [**1**] = 2 mM, [malonate] = 2, 3, 4, 6, 8, 12, 15, and 20 mM, pD = 7, 25 °C, D_2O; $K_m = 3.8 \times 10^{-3}$ M, $k_{cat} = 1.75 \times 10^{-3}\ s^{-1}$, $v_{max} = 3.5 \times 10^{-6}\ M\,s^{-1}$.

which gave a large rate enhancement ($k_{cat}/k_{uncat} \approx 1.4 \times 10^3$) relative to the uncatalyzed reaction ($k_{uncat} = 1.2 \times 10^{-6}\ s^{-1}$; Table 1).[18] Similar values were obtained from Eadie-Hofstee plots of v versus v/[malonate] (Table 1). In comparison, diethylenetriamine (DET), which is the reactive structural subunit of **1**, gave a rate acceleration of a factor of only about 6 (Table 1). As expected, the H/D exchange at the α position of malonate ions in the absence of **1** is more sensitive to acid catalysis than to base catalysis: the rate is slowest in the pH 7-11 range (Fig. 2).[19]

Table 1. Kinetic data for H/D exchange at the α position in malonate ions in the presence and absence of catalyst (25 °C, pD = 7 in D_2O).

Catalyst	k_{cat} [s^{-1}] [a]	K_m [M] [a]	v_{max} [$M\,s^{-1}$] [a]	k_{cat}/k_{uncat} [a]
-	1.2×10^{-6} [b]	-	-	-
DET	7.2×10^{-6} [c]	-	-	-
1	1.75×10^{-3}	3.8×10^{-3}	3.5×10^{-6}	1.4×10^3
	(1.62×10^{-3})	(4.0×10^{-3})	(3.25×10^{-6})	(1.3×10^3)
2	0.22	7×10^{-2}	2.16×10^{-5}	1.8×10^5
	(0.215)	(6.6×10^{-2})	(2.15×10^{-5})	(2.0×10^5)

[a] Data obtained from Lineweaver-Burk or from Eadie-Hofstee plots (values in parentheses) in a similar fashion for the two catalysts under the conditions given in Fig. 1 for **1** and in Ref. [23] for **2**; the pD was adjusted by addition of small amounts of NaOH or HCl and checked at the end of the reaction (less than $\pm$ 0.1 pD unit variation). [b] k_{uncat} is the slope of the relationship $v = k_{uncat}$ · [malonate] for [malonate] = 2, 5, and 10 mM. [c] k_{obs} obtained for [DET] = 2 mM and [malonate] = 10 mM; under the same conditions **1** gives $k_{obs} = 225 \times 10^{-6}\ s^{-1}$.

In the presence of the macrocycle **1** the rate depends on the protonation state of the polyamine. At low pH (< 2), malonate ions are protonated[16] and hence do not interact with the protonated polyamine; at high pH (> 10) the polyamine is unprotonated and does not bind malonate ions; at neutral pH, malonate is dianionic, and the polyamine is tetraprotonated,[10] allowing the formation of a moderately stable complex.[14] The rate acceleration in this pH domain indicates that the H/D exchange is catalyzed through complex formation, in agreement with the saturation kinetics, which indicates that the reaction proceeds through the formation of a Michaelis-Menten complex.

[**] Communicated in part at the XVIIIth International Symposium on Macrocyclic Chemistry, Enschede, The Netherlands, 1993.

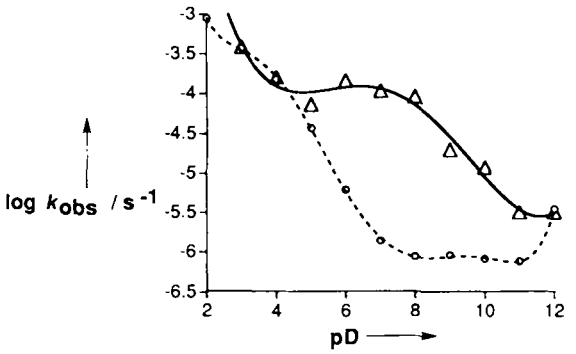

Fig. 2. Dependence of the observed rate constant for H/D exchange at the α position in malonate on pD in the presence (Δ) and absence (○) of the macrocyclic polyamine **1**; [**1**] = 2 mM, [malonate] = 10 mM, [$NaClO_4$] = 100 mM, 25 °C, D_2O.

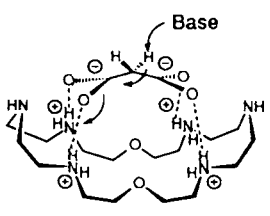
Ionic strength has a negligible effect on the uncatalyzed reaction, whereas in the presence of a large excess of NaCl (500 equiv) the polyamine can be completely inhibited.[20]

The highest rate acceleration was obtained for the octa ammine [36]ane N_8O_4 **2**[21, 22] for which $k_{cat}/k_{uncat} \approx 1.8 \times 10^5$ (Table 1).[18, 23] This result is seemingly at variance with the apparent structural features of **2**, such as its ring size. It may indicate that the protonated polyamine **2** adopts a special conformation responsible for its high activity. Indeed, the crystal structure of the octahydrobromide of **2**[24] displays a pocket-shaped conformation into which a malonate unit would fit quite well.

The complexation of the dianionic substrate by the polyprotonated receptors could accelerate the rate of H/D exchange by activating the enolization through several combined effects: 1) neutralization of the negative charges resulting in a dicationic complex; 2) electrostatic facilitation of the approach of an electron rich base; 3) introduction of acidic proton transfer sites NH^+ and of weakly basic sites (the central N of each triamine subunit, which might participate in proton abstraction)

Electrophilic catalysis in the case of mandelic acid enolization can induce a decrease of the pK_a of the α-CH site by up to 15 units upon protonation of the carbonyl group,[4a, 8b, 8c] and concerted general acid–base catalysis is capable of providing a low-energy route for α-proton exchange.[4a] In the present case, more or less concerted proton abstraction from the CH_2 group and proton transfer to one of the carboxylates of the malonate dianion would yield a dianionic species $^-O_2CCH{\cdot}C(O^-)OH$; the conservation of the dianionic character of the substrate would ensure that it is bound throughout the whole process; such a (strongly) hydrogen-bonded enolate intermediate could be compatible with the requirements for electrophilic catalysis of α-proton exchange.[4a] Transfer of a second proton would lead to a less well (but perhaps sufficiently) bound intermediate $^-O_2CCH{\cdot}C(OH)_2$. Rapid reprotonation of either species at the α-C atom and back-transfer of the OH proton(s) regenerates the (exchanged) malonate ion. Whatever the exact amount of negative charge generated and the timing of the proton transfer processes, it is clear that stabilization of the intermediate and transition states is provided by strong electrostatic interaction between the anionic substrate and the cationic receptor, with respect to the corresponding intermediates for unbound malonate ions. Structure **3** represents schematically one of the possible arrangements of the substrate and the receptor in the reactive supramolecular species with an external base as proton abstraction agent.



3

The present systems provide models for supramolecular electrophilic catalysis in the activation of α-proton exchange in carboxylic acids. High rate accelerations are achieved by structurally very simple macrocyclic polyamine receptors; they compare favorably with those displayed by catalytic antibodies[25] and by hydrogen-bonded supramolecular species that operate in organic solvents[26] (acceleration factors of about 10^4 and 10^3, respectively). It may be possible to obtain even larger rate increases by exploring further structural variations. Extension to H/D exchange in ketoacids (such as pyruvate)[27] and to aldolization reactions may be considered. Such studies give insight into the factors that control the activation of proton transfer and the catalysis of reactions involving this process.

[17] The course of the reaction was monitored at 25 ± 3 °C with the integrated CH_2 signal. The exchange of each proton and the isotope effect of the first exchange on the second one were studied [19]. Since we followed the exchange of both protons, the present values constitute a lower limit for the H/D exchange rate. The spectra were recorded 1–5 min after sample mixing. Concentration, pH, and temperature are given in the legend of each figure. The pH was adjusted by adding very small volumes of concentrated aqueous HCl or NaOH.

[18] It was not possible to perform measurements under saturation conditions, because the rates k_{obs} became too fast for determination by the NMR method. The factor of about 100 between the ratios k_{cat}/k_{uncat} produced by **1** and **2** can also be illustrated by the fact that, at the same malonate concentration (10 mM), k_{obs} for **2** is about the same as that for **1** (about 260×10^{-6} s^{-1}) at a 20-fold lower concentration (10^{-4} M for **1** versus 10^{-3} M for **2**, that is, under conditions much further from saturation for **2** than for **1**.

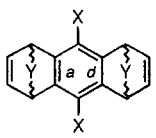
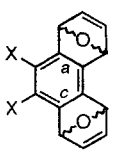
Effects of Strained Bicyclic Annelation on the Benzene Nucleus: The X-Ray Crystal Structures of a Triphenylene and Two Anthracene Derivatives**

Francesca Cardullo, Daniele Giuffrida, Franz H. Kohnke,* Françisco M. Raymo, J. Fraser Stoddart, and David J. Williams

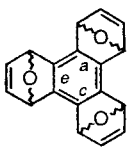
In the course of our studies on the assembly of molecular doughnuts, cages, and ribbons using repetitive Diels–Alder reactions between molecular building blocks containing endocyclic dienophilic double bonds, and exocyclic butadiene units grafted onto either norbornane or 7-oxanorbornane skeletons, we have synthesized the bisdienophiles **1** and **2** and the trisdienophiles **3**.[1] Here we report[2, 3] on the X-ray structural analyses of *anti*-**1b**, *anti*-**1c**, and *anti*-**3**. The structure of *anti*-**3** shows significant bond length alternation within its benzene unit. This feature is not observed in *anti*-**1b** and *anti*-**1c**.



1a: X = H; Y = O
b: X = Me; Y = CH_2
c: X = Br; Y = O

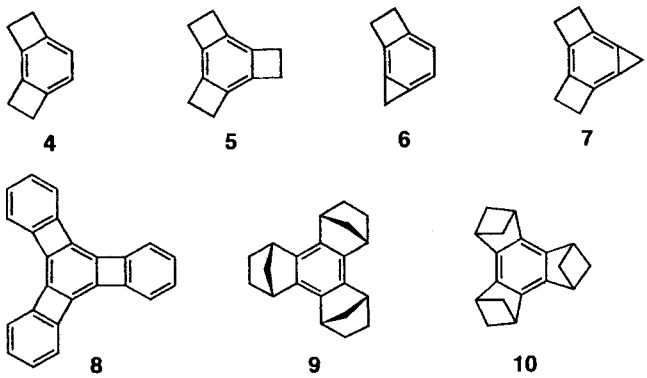


2a: X = H
b: X = Me



3

Bond length alternation within the benzene nucleus as a result of annelation to small rings was first postulated by Mills and Nixon.[4] Although they based their work on the wrong model of benzene, the idea that annelation to small rings could induce bond length alternation has survived up to the currently accepted model of benzene.[5] Multiple angular [*a*,*c*] and [*a*,*c*,*e*] annelation was expected to be more effective at promoting bond length alternation than linear [*a*,*d*] bisannelation because in the former case the strain imposed by each of the small rings on to the benzene nucleus would act cooperatively. However, with the exception of compound **8**,[6] in which electronic factors play a major role, the latest findings indicate that there is no significant bond length alternation in the planar compounds **4**–**7**.[7] In



4 **5** **6** **7**

8 **9** **10**

these compounds angular distorsion appears to lead to the formation of bent bonds instead.[7] Yet the crucial role of strained bicyclic annelation in the induction of bond length alternation in the benzene nucleus has recently been fully confirmed by the results of computational and X-ray structural analysis of **9**[8] and **10**[9], and the interpretation of this effect in terms of the Mills–Nixon theory has finally been rejected.[9]

Besides angular strain, bicyclic annelation such as that in **1**–**3** is recognized to introduce anomalous effects by σ through-bond coupling of the attached framework and additional coupling to the σ-linked π bonding orbitals of the ethylenic group.[10]

In the X-ray crystal structure of *anti*-**3**[2] (Fig. 1) the average lengths of the bonds in the benzene ring *endo* and *exo* to the annelated bicyclic systems are 1.425 and 1.353 Å, respectively.

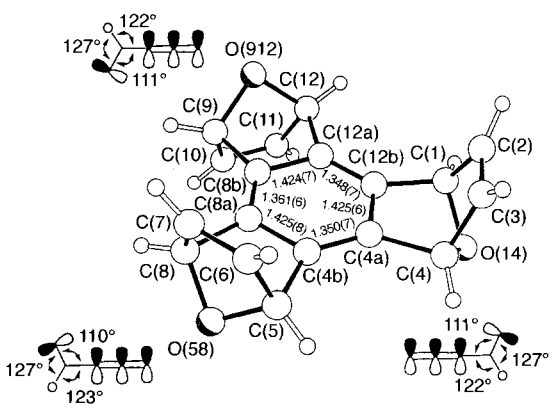


Fig. 1. The X-ray crystal structure of *anti*-**3**. The values of relevant dihedral angles involving the oxygen bridges are indicated beside each associated ring system.

The corresponding values observed for **9** (1.417 and 1.379 Å) and for **10** (1.438 and 1.349 Å) indicate that bond length alternation in *anti*-**3** is intermediate to those in these two hydrocarbons. This is consistent with the increasing angular distortion of the σ bonds between the aromatic and the methine carbon atoms, which subtend with the *endo* bond angles of 106.5, 104, and 102.3° in **9**, *anti*-**3**, and **10**, respectively. In the recently reported structure of **3** calculated at the 6-31G(d) level,[11] the bond lengths are 1.438 Å (*exo*) and 1.340 Å (*endo*); the angles formed by the σ bonds between the arene and the methine carbon atoms and the *endo* annelated bonds are 103.0°.

Accompanying the pronounced bond alternation within the benzene nucleus in *anti*-**3**, there are subtle perturbations in the conformation of the molecule as a whole. The oxymethine carbon atoms all lie slightly out of the plane of the benzene nucleus: the deviations, which are in the range of 0.02–0.05 Å, are consistent with a repulsion between the oxygen lone pairs and the aromatic π system. Thus, C(9) and C(12) lie below the plane of the aromatic ring, while C(1) and C(4), and C(5) and C(8) all lie above this plane (Fig. 1). The dihedral angle between the plane containing the oxygen bridge and the one containing the olefinic double bond is in each case greater than that formed by the plane containing the oxygen bridge and the plane containing the pair of annelated aromatic carbon atoms. Thus, the repulsive interaction of the oxygen lone pairs is more pronounced in the former case than in the latter. A study of the packing of the molecules in the crystal reveals (Fig. 2) an elegant network of weak but cooperative C–H···O hydrogen bonds, involving both olefinic and methine hydrogen atoms. All three oxygen atoms within each molecule are implicated in hydrogen bonding interactions.[12]

The structural evidence obtained previously[13] supports the proposal that when the benzenoid ring is linearly bisannelated with bicyclic units, no significant bond alternation occurs within the aromatic ring. Further direct evidence for the absence of bond alternation is provided by the crystal structures of *anti*-**1b** and *anti*-**1c** (Fig. 3). Both of these structures have molecular C_{2h} and crystallographic C_i symmetry. In *anti*-**1c** the methine carbon atoms lie 0.023 and 0.041 Å out of the aromatic ring plane in a direction opposite to that of the bridging oxygen atoms. In *anti*-**1b** this effect is not observed to any significant extent. In *anti*-**1c** the dihedral angles between the principal planes within the bicyclic residues, that is, those containing the olefinic bond and the oxygen bridge, do not differ significantly from those observed in *anti*-**3**. In *anti*-**1b** the replacement of the oxygen atoms by methylene groups is accompanied by a reduction in the analogous dihedral angle (123.9° in **1b**, cf. 126.2° in **1c**, Fig. 3). An inspection of the packing of the molecules in both these structures does not reveal any notable intermolecular interactions.

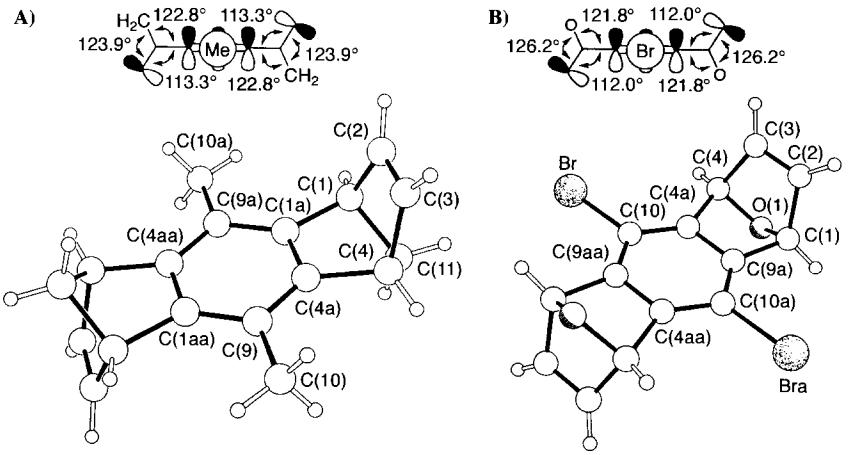

Fig. 3. The X-ray crystal structures of A) *anti*-**1b** and B) *anti*-**1c**. The relevant dihedral angles involving the one-atom bridges are indicated beside each associated ring system.

In contrast with the structures observed for the linear bisdienophiles, the bond length alternations observed for the benzene rings in the crystal structures of the bisdienophiles **2b**[14] confirms that the angular fusion allows the two 2,5-dihydrofuran residues to act upon the aromatic nucleus in a cooperative manner. The relative magnitudes of the effects in **2b** (average lengths of the *endo* and *exo* bonds are 1.422 and 1.367 Å, respectively) and in *anti*-**3** are consistent with this.

The definitive experimental evidence for bond alternation provided by the structure of *anti*-**3** and support for the predicted through-space and through-bond interactions between the aromatic ring and the bicyclic annelated units provides an explanation for the difficulties encountered[1d] in the synthesis of angularly annelated systems.

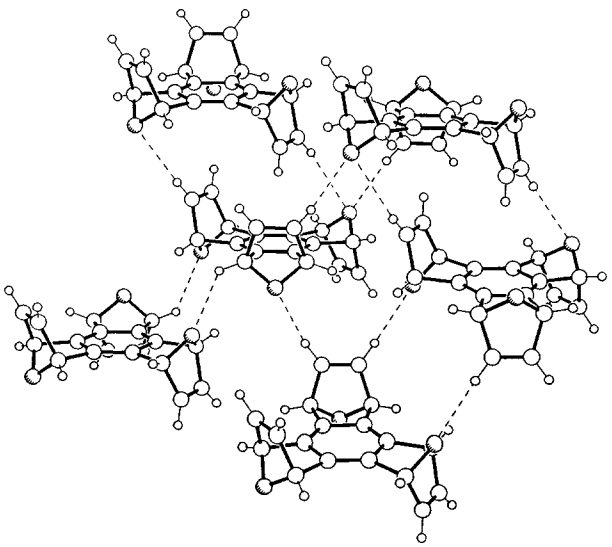

Fig. 2. The packing of *anti*-**3** in the solid state; the elegant network of C–H···O hydrogen bonds is indicated by the dotted lines.

Asymmetric Catalysis in the Complexation of Prochiral Dienes by the Tricarbonyliron Fragment: A Novel Methodology for the Enantioselective Synthesis of Planar Chiral Tricarbonyl(diene)iron Complexes**

Hans-Joachim Knölker* and Holger Hermann

Tricarbonyl(η^4-1,3-diene)iron complexes are important building blocks for organic synthesis.[1] The bulky tricarbonyliron moiety ensures in most cases a complete diastereoselectivity of reactions at these complexes. Applications of tricarbonyl(η^4-1,3-diene)iron complexes to asymmetric synthesis have demonstrated that the metal fragment may also serve as a chiral auxiliary.[2] The methods available for the preparation of enantiopure complexes include the classical separation of racemic complexes through diastereoisomers,[3] the diastereoselective complexation of enantiopure diene ligands,[4] the separation of planar chiral complexes by enzymatic reactions,[5] and the enantioselective complexation of prochiral 1,3-dienes by chiral tricarbonyliron transfer reagents.[6] We recently introduced (η^4-1-aza-1,3-butadiene)tricarbonyliron complexes as highly efficient novel tricarbonyliron transfer reagents.[7–9] The 1-aza-1,3-butadienes serve as catalysts for the complexation of 1,3-dienes with pentacarbonyliron.[7–9]

Based on these findings we investigated the possibility of achieving an asymmetric induction in the complexation of prochiral 1,3-dienes with the tricarbonyliron fragment by using chiral enantiopure 1-aza-1,3-butadienes as catalysts. We describe herein the first asymmetric catalysis of the complexation of a prochiral ligand by a transition metal fragment, in which an optically active, planar chiral transition metal π complex is generated.

The reaction of 1-methoxy-1,3-cyclohexadiene (**1**) with pentacarbonyliron [Eq. (a)], in which the corresponding planar chiral tricarbonyliron complex was generated, was used as a model reaction to optimize the catalytic system with respect to yield and asymmetric induction (Table 1).

Condensation of (*R*)- and (*S*)-1-phenylethylamine with cinnamaldehyde afforded the azadienes (*S*)-**3** and (*R*)-**3** shown in Scheme 1.[10] The fact that stoichiometric complexation of these chiral azadienes by the tricarbonyliron fragment is nonstereoselective is of no consequence for the present investigations, since epimerization of the two diastereoisomers occurs under the reaction conditions.[11] Under standard reaction conditions (2 equiv $Fe(CO)_5$, 0.125 equiv of catalyst, benzene, 80 °C), the catalyst (*S*)-**3** provided complex **2** in 69% yield with 6% *ee* of the *R* enantiomer. Correspondingly, complexation in presence of catalyst (*R*)-**3** gave **2** with 6% *ee* of the *S* enantiomer. The enantiomeric excess in each case was determined by separation of the planar chiral tricarbonyliron complexes **2** on a permethylated β-cyclodextrin column by HPLC.[12]

The axially chiral binaphthyl-substituted azadienes (*S*)-**4** and (*S*)-**5** were prepared by reaction of the enantiopure (*S*)-2-

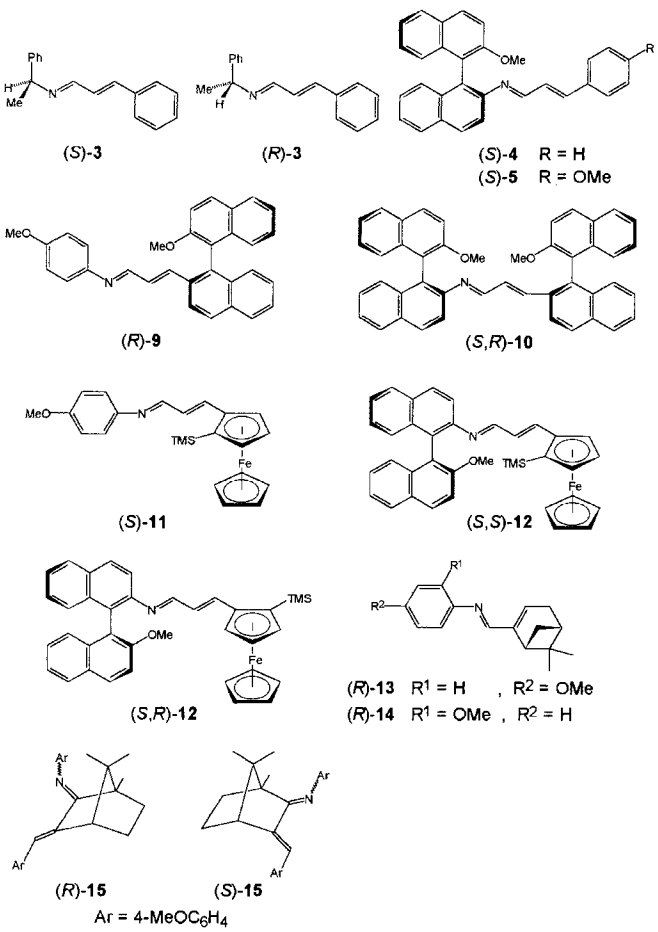
[a] Determined by chiral HPLC on a permethylated β-cyclodextrin column [12]. [b] $[\alpha]_D^{20} = -35.3$, $c = 1.32$ in $CHCl_3$. [c] (*S*,*R*)-**10** is almost insoluble in C_6H_6.

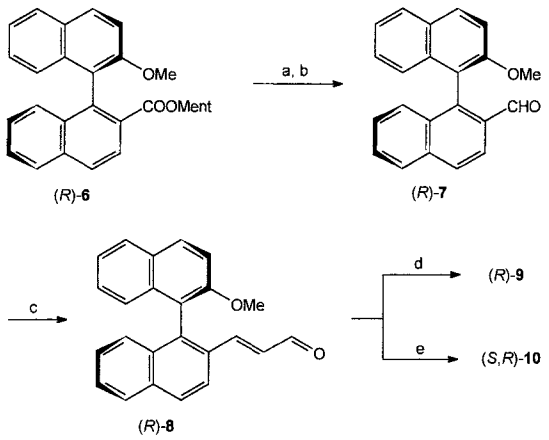


Scheme 1. Formulae of the catalysts employed.

amino-2′-methoxy-1,1′-binaphthyl[13] with cinnamaldehyde and *p*-methoxycinnamaldehyde (yields: 90 and 79%, respectively). Complexation of **1** with pentacarbonyliron in the presence of catalyst (*S*)-**4** afforded after a reaction time of 42 h complex **2** in 87% yield with 25% *ee* of the *R* enantiomer. The determination of the absolute configuration of complex **2** was based on correlation of the value for optical rotation ($[\alpha]_D^{20} = -35.3$, $c = 1.32$ in $CHCl_3$) with data previously published by Birch.[14] By using (*S*)-**5** as catalyst, complex **2** was obtained after 16 h in 20% yield with 28% *ee* of the *R* enantiomer.

In this context, two experimental observations are noteworthy. First, the pure enantiomers of complex **2** are stable under the reaction conditions and no racemization occurs. This has been demonstrated by heating an enantioenriched sample of (*R*)-**2** (18% *ee*) in benzene at reflux for four days without any detectable change of the *ee* value. Second, the asymmetric induction is independent of the concentration of the azadiene catalyst. The use of 0.03 equivalents of (*S*)-**4** in the above reaction afforded complex **2** with the same *ee* value (25% *ee* of the *R* enantiomer). However, as previously reported for the non-chiral catalysts,[7, 8] the best chemical yields were obtained by using 0.125 equivalents of the catalyst. Thus, in the asymmetric catalysis an extension of the reaction time led to higher turnovers and therefore higher yields without causing a decrease in the *ee* value.

We then decided to introduce the axially chiral binaphthyl moiety, which was successfully utilized as chiral auxiliary in the 1-position of 1-aza-1,3-butadiene for the asymmetrically catalyzed complexation, at the 4-position of the 1-aza-1,3-butadiene catalyst. In the mechanism, which we proposed for the 1-aza-1,3-butadiene catalyzed complexation of 1,3-dienes, a [(1-η)-1-aza-1,3-butadiene]tricarbonyliron complex was suggested as the crucial intermediate of the catalytic process.[8] Based on this 16-electron η^1-imine tricarbonyliron complex as the reactive species of the catalytic cycle, the degree of asymmetric induction was expected to be lower by having the chiral auxiliary at C-4, because of the larger distance to the reactive center. The synthesis of the catalyst is depicted in Scheme 2. Reduction of the



Scheme 2. a) 1.5 equiv $LiAlH_4$, Et_2O, 0 °C, 30 min (95%); b) 1.2 equiv $(COCl)_2$, 2.6 equiv DMSO, 5 equiv Et_3N, CH_2Cl_2, −78 °C, 30 min (86%); c) 1.4 equiv $(EtO)_2P(O)CH{=}CHN(t\text{Bu})Li$, THF, −78 °C → room temperature (RT) (47%); d) 1.0 equiv *p*-anisidine, molecular sieves 4 Å, benzene, RT, 6 h (82%); e) 1.0 equiv (*S*)-2-amino-2′-methoxy-1,1′-binaphthyl, molecular sieves 4 Å, benzene, 80 °C, 24 h (95%). Ment = D-(+)-menthyl.

(+)-menthyl ester (*R*)-**6**[13] followed by Swern oxidation afforded the aldehyde (*R*)-**7**, which was transformed to the α,β-unsaturated aldehyde (*R*)-**8** according to the method of Nagata et al. and Meyers et al.[15] Imine condensation of (*R*)-**8** with *p*-anisidine or (*S*)-2-amino-2′-methoxy-1,1′-binaphthyl provided the catalysts (*R*)-**9** and (*S*,*R*)-**10**, respectively. As expected, the asymmetric induction using (*R*)-**9** as the catalyst for the complexation of **1** was disappointing. However, compound (*S*,*R*)-**10**, which contains chiral binaphthyl units at the 1- and 4-posi-

tion, gave better results (16% *ee* of the *S* enantiomer of **2**). Moreover, with the bis(binaphthyl)-substituted 1-aza-1,3-butadiene **10** we realized that we get *matched* and *mismatched* pairs of the two chiral auxiliaries in the catalysts. By using the enantiopure diastereoisomeric compound (*S,S*)-**10**, prepared from (*S*)-**6** as described for (*S,R*)-**10** in Scheme 2, we obtained only 8% *ee* of the *S* enantiomer. Therefore, it is possible to achieve a double stereodifferentiation in this novel asymmetric catalysis by having two different chiral auxiliaries bound to the catalyst.[16] This finding will be of great value for the future design of novel catalysts, particularly with respect to optimization directed towards high asymmetric inductions in the complexation.

Asymmetric induction on complexation of **1** was expected to be even more efficient by using a catalyst with planar chiral auxiliaries. Based on this assumption we prepared complex (*S*)-**11** by condensation of the corresponding enantiopure (*S*)-ferrocenylpropenal[17] with *p*-anisidine (81% yield). Although the chiral center of compound (*S*)-**11** is at the unfavorable 4-position of the 1-aza-1,3-diene (see above), this catalyst led to an asymmetric induction of the complexation of **1** affording 20% *ee* of the *R* enantiomer of **2**. Combination of planar chirality and axial chirality in the catalyst by reaction of the (*S*)-2-amino-2′-methoxy-1,1′-binaphthyl with the (*S*)- and (*R*)-ferrocenylpropenal,[17] provided us with the enantiopure diastereoisomeric catalysts (*S,S*)-**12** (75% yield) and (*S,R*)-**12** (74% yield), respectively. With these catalysts a further impressive example of double stereodifferentiation in the asymmetric catalysis was observed. Catalysis of the complexation of **1** by (*S,S*)-**12** gave 34% *ee* of the *R* enantiomer of **2**, whereas the complexation catalyzed by (*S,R*)-**12** led to a lower *ee* of the opposite enantiomer (14% *ee* of (*S*)-**2**). As mentioned above, increasing the reaction time of the asymmetrically catalyzed complexation leads to higher yields without a decrease of the *ee* value. At this stage of our investigations we were therefore mainly interested in achieving higher asymmetric inductions by optimizing the catalyst.

In this context, we tested several enantiopure 1-aza-1,3-butadienes derived from the chiral pool. Condensation of (1*R*)-( )-myrtenal with *p*-anisidine led to the catalyst (*R*)-**13** (62% yield) which in the catalyzed complexation of **1** provided (*R*)-**2** in 33% *ee* and 29% yield. Catalysis with (*R*)-**14** (obtained from condensation of (1*R*)-(-)-myrtenal with *o*-anisidine, 62% yield) afforded after the same reaction time (*R*)-**2** of the same optical purity in 67% yield. The beneficial effect of an *ortho*-methoxy substituent in the arylamine moiety of the 1-aza-1,3-butadiene was previously reported by us for the achiral catalysts.[8] The catalysts (*R*)-**15** and (*S*)-**15** were easily prepared from (1*R*)-(+)-camphor and (1*S*)-(−)-camphor, respectively, by aldol condensation with *p*-methoxybenzaldehyde and subsequent imine condensation with *p*-anisidine (43% overall yield). Without having attempted to optimize the yields (see above), our initial results indicated that asymmetric catalysis of the complexation of **1** by (*R*)-**15** and (*S*)-**15** afforded (*S*)-**2** in 62% *ee* and (*R*)-**2** 56% *ee*, respectively. This asymmetric induction was accurately determined by HPLC separation of (*R*)-**2** and (*S*)-**2** on a permethylated β-cyclodextrin-bound chiral stationary phase (Figs. 1 and 2).[12]

Finally, we were also able to achieve an asymmetric catalysis in the complexation of the prochiral diene **16** (Scheme 3). The resulting iron complex **17** is an important building block for diastereoselective iron-mediated spiroannulations.[18] Asymmetric complexation of **16** with pentacarbonyliron in presence of the binaphthyl-substituted catalyst (*S*)-**4** provided complex **17** in 26% yield and, as determined by chiral HPLC,[12] with 19% *ee* of the *R* enantiomer.[19]

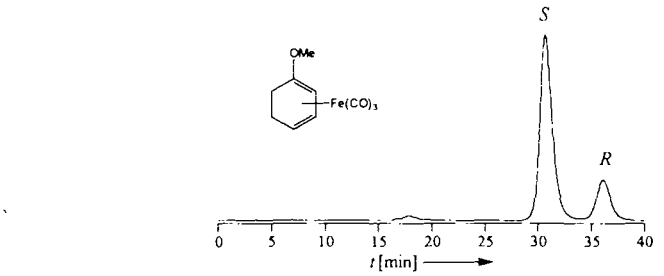


Fig. 1. Chiral HPLC of **2** with 62% *ee* of the (*S*) (+) enantiomer [12]. *t* = retention time.

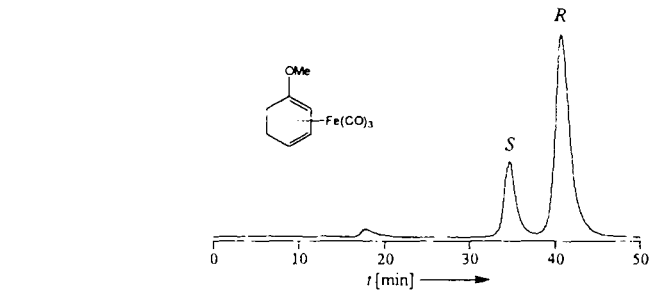

Fig. 2. Chiral HPLC of **2** with 56% *ee* of the (*R*) (−) enantiomer [12]. *t* = retention time.

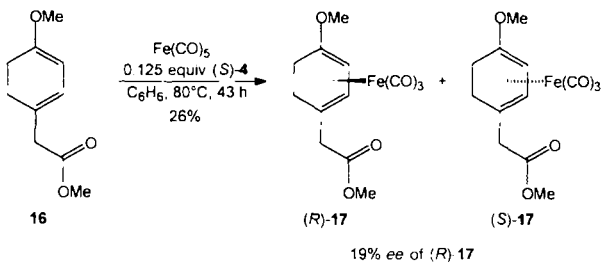

Scheme 3.

In conclusion, we have shown for the first time the feasibility of generating planar chirality by asymmetric catalysis[20] of the complexation of prochiral ligands with transition metal fragments. Therefore, the results described above may have a major impact on the applications of planar chiral transition metal π complexes in synthetic organic chemistry.

Brian Kaye
Chaos & Complexity
Discovering the Surprising Patterns of Science and Technology

1993. XXII, 593 pages with 257 figures, 2 in color
Hardcover. DM 148.-/öS 1154.-/sFr 140.-.
ISBN 3-527-29039-7 (VCH, Weinheim)
Softcover. DM 78.-/öS 608.-/sFr 75.-.
ISBN 3-527-29007-9 (VCH, Weinheim)

The surprising patterns of chaos and complexity are to be found in many areas of nature and science, examples ranging from cabbages to coastlines.

Quite often, those who could benefit most from an understanding of the principles behind chaos and complexity are denied access to the power and wonders of the field by the mathematical and unnecessarily convoluted way the topic is usually presented.

This book makes these sometimes complicated wonders accessible to students and professionals alike. Amusing tales and cartoons are used to explain the concepts and demonstrate the fascinating applications of this powerful technique.

What's in a Gene?

Dictionary of Gene Technology. By *G. Kahl.* VCH Verlagsgesellschaft, Weinheim, 1994. 550 pp., hardcover DM 184.00.—ISBN 3-527-30005-8

It is an undisputed fact that the importance of gene technology was first recognized in the USA, and it was there that its applications were most vigorously pursued. This circumstance has given rise to a whole vocabulary of English terms that have become firmly established in the everyday language of molecular biology. For many of us in the German-speaking world, the difficulty of finding a German equivalent for an English technical term in gene technology or molecular biology is already a familiar problem. Many of the expressions used to describe processes, phenomena, etc. cannot actually be translated, since it is the privilege of the discoverer to invent a name for his brain-child. In many cases the name is an abbreviation.

The *Dictionary of Gene Technology* acknowledges this development and sets out to define and explain, in English, the increasing flood of technical terms, names, and abbreviations used to describe methods, processes, substances, materials, and biological macromolecules. What sort of terms should be included in such a dictionary, and how much detail can be put into the definitions and explanations? In many cases the decisions are not easy. In this compilation the main emphasis is on keywords that are concerned, in the broadest sense, with nucleic acids and their structures, synthesis, analysis, transfer, modification, and processing. Although the dictionary includes many terms belonging to related fields outside gene technology, the author has not aimed at a complete coverage of these peripheral areas.

The result is an impressive compilation of technical terms with explanations that are mostly brief and easily understandable, occasionally rather more detailed but never long-winded, and nearly always absolutely correct. The author has set out to meet the needs of a wide readership, especially scientists working in the relevant disciplines and their students, but also specialists in neighboring areas of science as well as journalists and politicians. The book has not been written for the lay reader, as it assumes an understanding of the language and jargon commonly used by molecular biologists. However, the great majority of the envisaged readership should find the book useful, especially in view of the fact that their educational backgrounds differ widely. The clear and simple diagrams, the practical examples included for illustration, and the more detailed explanations where these are appropriate, all contribute to the usefulness of the work.

Of course one does not actually read through a dictionary, but even on just randomly leafing through it the many cross-references gently lead one to read further. These cross-references are indicated by small arrows which tend to dominate the appearance of the text, so that in many of the entries their effect is at first sight rather irritating. However, on closer examination one discovers that they are very useful, as they serve to form a network linking the various terms and to place each individual term within a wider context. A dictionary cannot be a substitute for a textbook or practical handbook and is certainly not intended as such. It can explain the principle of a technique, remind one of a formula, show the structure of a molecule, or give the meaning of an abbreviation. It is a reference source which can help to call things to mind or to fill gaps in one's knowledge. This book fulfills those aims very well.

It will certainly not be an easy task to update such a book in printed form so as to keep place with future developments. Even now there are a few important and highly topical techniques, such as "two-hybrid system", "interaction trap", and "knock-out animal", that should have been included. These omissions are all the more surprising in view of the fact that in the preface the author emphasizes that new technological developments are included. Other readers will undoubtedly be able to list other omissions. Also a few of the definitions could have been better expressed or expanded, such as those of "gene expression" and "repressor". The explanations of some of the keywords seem too short or too dull.

A dictionary, by its very nature, informs one about matters that are treated more fully and with more explanation elsewhere. Its advantage lies in its convenience, allowing one to look things up very quickly. It seems to me an almost impossible task for a single author to write a book of this kind that is complete and free of mistakes. On the whole, however, that appears to have been achieved in this case. This is a comprehensive, balanced, and useful work of reference, and it will certainly find an assured place on the office desk and in the laboratory.

Integrated Chemical Systems. A Chemical Approach to Nanotechnology. (Baker Lecture Series.) By *A. J. Bard.* Wiley, Chichester, 1994. 324 pp., hardcover £ 41.50.—ISBN 0-471-00733-1

This book contains the text of a course of lectures which the author, who is best known to electrochemists and physical chemists, gave during 1987. The reader will recognize in the title two keywords that are of particular interest: "nanotechnology" and "integrated". Although it is now some time since microelectronics gave birth to the microtechnologies, which are already almost part of the everyday scene, the next stage in this field, the nanotechnology referred to in the title, is still in an exciting and very promising state of development. The word "integrated" is also associated with novel and high-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ly topical advances in technology. Both these concepts are synonymous with very rapid developments, and the delay in producing this book therefore seems unfortunate.

Probably only those few readers who make a pastime of phantasizing about future developments will start off with an idea of what an integrated chemical system might consist of. The rest must wait for several pages before coming to the following definition: "We define these integrated chemical systems (ICSs) as heterogeneous, multiphase systems involving several different components (e.g., semiconductors, polymers, catalysts, membranes) designed and arranged for specific functions or to carry out specific reactions or processes. Often the different components will be organized structurally and will show synergistic effects. Usually it is the interaction of the components of the ICS that determines its properties." Unfortunately many readers will still not have a clear picture of an ICS from this definition. However, some examples follow which should help in making the breakthrough. In the biological field chloroplasts and mitochondria are cited as typical ICSs, while in chemistry a heterogeneous catalyst coupled to a redox system is given as an example, in photography the instant color film is cited, and in chemical analysis various sensor systems are mentioned. In accordance with the author's aim of giving a systematic overview of nanotechnology the following chapters describe methods for constructing and characterizing ICSs, which could perhaps be incorporated into future nanotechnological developments. Many of the methods described will already be familiar to some readers from their acquaintance with microtechnology. Others based on self-organizing structures are common knowledge, while some, such as the use of a scanning electron microscope for fabricating components, are speculative. The methods proposed for characterizing ICSs are mainly drawn from surface and thin film analytical techniques, although some new advances in these will be needed to enable them to be applied to ICSs.

This is followed by chapters on chemically modified electrodes and methods for characterizing these, as well as developments in photoelectrochemistry, both of which are stages on the way to nanostructured systems. The author describes advances towards producing these, which are already well covered in existing review articles. The choice of substrates, reactants, and systems is discussed, with some complicated examples related to the development of sensors and highly selective electrocatalytic films. The description of electrochemical methods used to study such modified electrodes concentrates mainly on potentiodynamic measurements; nonclassical methods are not discussed. This omission is surprising if one assumes that nanostructured surfaces for many of the functions envisaged will need to have a specific well-defined surface topography or other properties that cannot be investigated by electrochemical methods. The following chapter is concerned with semiconductors and their photochemistry; starting with the band model, this gives a thorough and detailed account of current knowledge. This is then related to the development of ICSs by discussing photosemiconducting electrodes with modified surfaces and finely-divided photosemiconductor particles as components for such systems. The final chapter is an appraisal of future prospects and research trends in the areas of microsensors, microreactors, and composite materials. The book is completed by a comprehensive index which provides a useful key to the contents. The numerous figures are mostly successful in illustrating and clarifying even the more complicated discussions. However, many of these are of inferior quality, occasionally making them difficult to understand.

One must now ask who are the readers most likely to benefit from the book. It will be of interest to scientists entering the field of methods for modifying surface properties and for generating surface structures with molecular dimensions. Experienced electrochemists and specialists in microtechnology will gain little new knowledge from the book.

Chemnitz (Germany)

A New Dimension to Quantum Chemistry. Analytic Derivative Methods in Ab-Initio Molecular Electronic Structure Theory. By *Y. Yamaguchi, Y. Osamura, J. D. Goddard* and *H. F. Schaefer*. Oxford University Press, Oxford, 1994. 471 pp., hardcover £ 60.00.— ISBN 0-19-507038-3

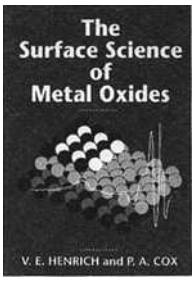
It is probably no exaggeration when, in the title of this book, the development of analytical derivative methods for ab-initio wave-function calculations is described as a new dimension in quantum chemistry. Following on from the pioneering work of P. Pulay in the late 1960s, the standing of ab-initio methods of calculation has been considerably enhanced through the advantages of analytical gradients, especially their use for reliably determining equilibrium structures and saddle points. In addition, however, the development and appropriate implementation of algorithms for analytical calculations of derivatives of the energy function has now made it possible to calculate harmonic vibration frequencies, anharmonic corrections, IR and Raman intensities, and many other properties. There already exist a number of review articles and collections of papers on this topic, but this book by Schaefer and coauthors is the most detailed and thorough retrospective survey to appear so far. Starting from a concise introduction to the LCAO-MO formalism, the authors derive explicit expressions for the first and second derivatives of various Hartree–Fock (HF) SCF wave-functions and of wave-functions of the configurational interaction (CI), two-configurational SCF, and general multiconfigurational SCF (MCSCF) types. This is followed by chapters describing in detail the methods for solving "coupled perturbed" HF, CI, or MCSCF equations. Next there is a discussion of higher derivatives and of the special case of derivatives involving an electric field. The mathematical part of the book ends with a short chapter on the "Z-vector" method recently developed by Handy and Schaefer for calculating analytical derivatives. In the penultimate chapter the authors describe a number of typical applications of analytical derivatives for obtaining answers to chemical problems. The final (20th) chapter offers an optimistic assessment of likely future developments. This is followed by 28 appendices which summarize the key equations from all the chapters. The book ends with a bibliography listing the relevant original papers, which is commendably up-to-date as it extends up to 1993.

The quality of production is up to the same excellent standard as others in this series from the same publisher. However, after even an initial brief glance through the book one is struck by the large proportion of space devoted to mathematical expressions, which is unusual even for a monograph on a theoretical subject. In fact the work is essentially a collection of formulas relieved only by a small amount of explanatory text. The structure of the chapters is rigid and very formalized. Chapters treating related aspects have an almost identical structure, with only small differences in the wording. As a result the book makes arid and heavy reading. Who are the readers most likely to benefit from

this book? Whether it is suitable for the advanced students envisaged in the preface seems rather doubtful, since the style is too condensed and the amount of mathematics too demanding; also the book makes few concessions to the need to show the subject within a wider context. On the other hand, for the specialist it should certainly be useful as a work of reference. Even here, however, it must be said that the authors have concentrated on discussing their own research, with the result that apart from the Hartree - Fock case the main emphasis is on the derivatives of CI and MCSCF energy functions. It is unfortunate that there is no discussion of the popular methods based on perturbation theory, nor of the increasingly important coupled-cluster methods. In conclusion, therefore, the book can be recommended only for a rather restricted circle of theoretical chemists.

Wolfram Koch
Institut für Organische Chemie
der Technischen Universität Berlin
(Germany)

The Surface Science of Metal Oxides. By *V. E. Henrich* and *P. A. Cox*. Cambridge University Press, Cambridge, 1994. 464 pp., hardcover £ 55.00. –ISBN 0-521-44389-X



In the interdisciplinary field of "surface science", which encompasses surface physics and surface chemistry, the physical aspects are at present much more developed than the chemical. This is mainly due to progress in the single crystal physics of metal surfaces and in semiconductor studies. So far as the chemistry is concerned, the investigations have been limited to a relatively small number of reactions and to only a few studies of chemical compounds with well-characterized surfaces (which in this book means single crystal surfaces). This situation applies especially to the large class of solid oxides. Despite their great scientific and technological importance, which far outweighs that of pure metal surfaces, little progress has so far been achieved in oxide studies. The reasons for this are clearly explained in a general context in the introduction to this book, and are illustrated more specifically by the many examples described later.

The work is a critical survey of the most important results achieved by research into the surface physics and chemistry of oxide single crystals. Many examples are discussed, including oxides of the main-group elements magnesium, aluminum, zinc, and tin (silicon oxide is excluded, being an oxide of a nonmetal) and of the sub-group elements titanium, vanadium, and iron. Other oxides are also included where it has been possible to find sufficient published work. Regrettably the alkali metal oxides, which would have fitted appropriately into the subject matter of the book, are not mentioned, presumably due to the lack of examples involving single crystals. Thin films of metal oxides with monocrystalline surfaces are also absent, despite the fact that there is currently much research activity in this area.

Nevertheless, these omissions are outweighed by the thoroughness of the treatment of those oxides that are included. After a short introduction to ideal structures, the electronic properties of the main- and sub-group metal oxides are treated in detail and at a high standard, starting with a chapter on the relevant lattice vibrations, which have a considerable influence on the physical properties of the surfaces. This is followed by two long chapters on the surface chemistry of molecular compounds and reactions at their interfaces with other oxides or metals. However, the sections on heterogeneous catalysis and ceramic superconductors included here can only be rated as a fair attempt at their targets rather than a direct hit.

A noteworthy feature of the book is that the chemical and physical aspects are treated with equal competence and rigor. Consequently the reader needs to have an appropriate background of knowledge in both disciplines; this is certainly not an introductory text. One of the characteristics of interdisciplinary research is that the same terms are sometimes used with different meanings, and wherever appropriate that is pointed out and clarified. The different definitions of hybridization on page 104 are a good example of this.

The value of the exhaustive analysis of the relevant literature, in some cases with information-packed tables summarizing the results, can hardly be overstated. This makes the book a useful work of reference for the scientist engaged in research in this field. In this respect it is far more than a monograph and has the status of a standard work.

This high quality is also evident in the examples, which are illustrated by excellent figures; in some of the more important examples, such as the surface chemistry of titanium oxide (Ch. 6.4), these contain so much detail that one would learn little more by reading the original papers. The book's usefulness as a reference source is further enhanced by around 1000 literature citations, a well arranged contents list, and indexes of keywords and compounds.

A less favorable aspect is the inconsistency in the frequency of references in the text; often one has to search for a long time to find the reference corresponding to a particular topic. Also the claim that this book is the first of its kind is not quite correct. Two other works are in fact mentioned in the introduction, but the main text contains no mention of other monographs on the subject, such as that by Nowottny and Dufour.

Altogether, however, this is an extremely useful book which gives a competent and reliable survey of the field. It can be recommended as a standard work on the subject, and everyone working in this area will find it a reliable source of information. The general observations that are offered should provide many useful ideas when designing one's own research projects in the currently burgeoning field of surface science. The style of presentation, the instructive diagrams, and not least the outstandingly good treatment of the literature also make the book a valuable resource for those engaged in research in related disciplines such as solid state physics, oxides chemistry, materials science, and catalysis. Libraries are strongly recommended to buy it as a comprehensive monograph with a long life expectancy.

Control of the Structure and Functions of Biomaterials by Light

Itamar Willner* and Shai Rubin

Vision and other light-triggered biochemical transformations in plants and living organisms represent a sophisticated biological processes in which optical signals are recorded and transduced as (physico)chemical events. Photoswitchable biomaterials are a new class of substances in which optical signals generate discrete "On" and "Off" states of biological functions, resembling logic gates that flip between 0 and 1 states in response to the changes in electric currents in computers. The (photo)chemistry of photochromic materials has been extensively developed in the past four decades. These materials isomerize reversibly upon light absorption, and the discrete photoisomeric states exhibit distinct spectral and chemical features. Integration of photoisomerizable (or photochromic) units into biomaterials allow their secondary functions such as biocatalysis, binding, and electron transfer to be tailored so that they can be switched on or off. This can be accomplished by chemical modification of the biomaterial by photoisomerizable units and by integration of biomaterials in photoisomerizable microenvironments such as monolayers or polymers. The photoswitchable properties of chemically modified biomaterials originate from the light-induced generation or perturbation of the biologically active site, whereas in photoisomerizable matrices they depend upon the regulation of the physical or chemical features of the photoisomerizable assemblies of polymers, monolayers, or membranes. Light-triggered activation of catalytic biomaterials provides a means of amplifying the recorded optical signal by biochemical transformations, and photostimulated biochemical redox switches allow its electrochemical transduction and amplification. The field of photoswitches based on biomaterials has developed extensively in the past few years within the general context of molecular switching devices and micromachinery. The extensive knowledge on the manipulation of biomaterials through genetic engineering and the fabrication of surfaces modified by biologically active materials enables us to prepare biomaterials with improved optical-switching features. Their application in optoelectronic or bioelectronic devices has been transformed from fantasy to reality. The use of photoswitchable biomaterials in information storage and processing devices (biocomputers), sensors, reversible immunosensors, and biological amplifiers of optical signals has already been demonstrated, but still leaves important future challenges.

Keywords: bioelectronics · enzymes · optoelectronics · photoswitchable systems

1. Introduction

Diverse biological processes are triggered by light signals. Photosynthesis[1, 2] and vision[3, 4] are the most fundamental light-controlled biological mechanisms. Other processes, such as photomovement at various biological levels[5] (movement of motile organisms, dynamics of plant tissues), photomorphogenesis[6, 7] (seed germination, induction of flowering, synthesis of chlorophyll), and conversion of light energy into chemical energy[8, 9] (ATP synthesis, proton pumps, and ion-transport) add important light-triggered biological mechanisms. The common feature of all these systems is the participation of a chromophore (photosensor or photoreceptor) that upon light absorption activates a series of chemical transformations in the chromophore surrounding the biomembrane or protein. Such light-activated biochemical cycles represent reversible photobiological optical switches: the bioevent is switched on upon recording of the optical signal and off in the dark. To identify the fundamental characteristics of biological photoswitches, the functions of the extensively studied bacteriorhodopsin system will be mentioned here briefly.

Bacteriorhodopsin is a retinal-containing protein in *Holobacterium halobium* that converts light energy into chemical energy by synthesizing ATP.[10] The 11-*trans*-retinal chromophore of bacteriorhodopsin is embedded in the bacterium membrane, and upon absorption of light it activates the net transport of protons from the inner (cytoplasm) to the outer (extracellular) side of the cell membrane. The generated potential gradient activates a membrane-bound ATPase for ATP synthesis.[11] Scheme 1 summarizes the interactions of the photoreceptor with its surrounding protein that causes the formation of a potential

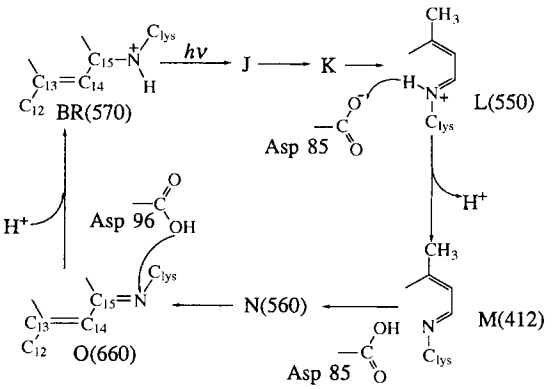

Scheme 1. Interactions of rhodopsin photoisomers with the surrounding membrane, resulting in a proton-pump.

gradient and provides a mode of relaxation for the optical switch. Photoisomerization of the chromophore BR to state L results in deprotonation of the protonated, isomerized Schiff base by a proton transfer to the Asp85 residue. In the subsequent isomerization of state O a proton is translocated from Asp96 to regenerate the initial chromophore and complete the photocycle. The bacteriorhodopsin photocycle illustrates the basic principles of biological photoswitches:

1) The optical signal is recorded by the photosensor site and triggers a structural change in the chromophore.

2) Isomerization of the chromophore is transduced to the surrounding protein. The protein, and thereby an ion-pump, is stimulated.

3) The photosensor–protein assembly provides a relaxation pathway by which the photosensor is recycled for a secondary optical recording event.

The rapid transformation of photobiological switches between different states enables their application as optical memory devices.[12] The photostimulated transitions of bacteriorhodopsin from BR through M back to BR allows repeated "write and erase" cycles.[13] Various optical applications[14] such as holographic pattern recording,[15] dynamic optical filtering,[16] and associative optical memories[17] were developed with bacteriorhodopsin as photosensor. This highlights the broad practical implications of the photochemical control of the functions of biomaterials.

Recent efforts have been directed towards the development of semisynthetic photobiological switches.[18] A photobiological switch is a biological material or a biological environment that is activated to perform its biochemical function upon exposure to light. Two fundamental subclasses of photobiological switches have been developed.

1. Single-cyle photoswitches are a class of biological photoswitches in which the biomaterial is deactivated by attachment of photosensitive chemical protecting groups (Scheme 2). The

Scheme 2. A single-cycle photobiological switch. I = inactive assembly, II = active assembly, S = photosensitive group.

biomaterial is activated by light-stimulated removal of the protective group to restore the biologically active structure.[19, 20] Activation of enzymes,[21–23] photoinduced formation of specific ion-chelators,[24–26] and light-triggered activation of important biological components such as cAMP,[27] cGMP,[28] ATP,[29] and InP_3[30] have been used in this approach. Several review articles summarize the subject of single-cycle photoswitches.[31–33]

2. Multicycle photobiological switches are the results of efforts to transform biomaterials or biological environments into light-activated matrices operating reversibly between a mute bioactive state (switch "Off") and an activated biological function (switch "On") (Fig. 1). Three different methodologies to reversibly photostimulate biomaterials are envisaged:

a) Chemical modification of biomaterials by photoisomerizable units could lead to photoswitchable biological assemblies (Fig. 1a). Synthetic modification of the biomaterial with one photosensor state (state B) could distort the biomaterial or its active site (that is, the protein) and deactivate it. Upon photoisomerization of the photosensor to state A the structural

Itamar Willner was born in 1947. He completed his Ph. D. studies in Chemistry in 1978 at The Hebrew University of Jerusalem. After a postdoctoral stay with M. Calvin at the University of California, Berkeley, he acted as research associate at the Lawrence Berkeley Laboratory until he joined the Institute of Chemistry at the Hebrew University as Senior Lecturer in 1982. In 1986 he accepted a position as Professor there. His research interests encompass light-induced electron transfer processes and artificial photosynthesis, photo- and electroswitchable molecular, macromolecular, and biological assemblies, including their application in optoelectronics and bioelectronics, supramolecular chemistry and photochemistry, and nanoscale chemical and photochemical transformations at monolayer interfaces.

S. Rubin

I. Willner

Shai Rubin finished his B. Sc. studies at The Hebrew University of Jerusalem in 1988 and his Ph. D. studies there in 1994. He is currently a postdoctoral fellow at the Los Alamos National Laboratory, Material Science and Technology Division. His research interests include the photochemical and electrochemical activation of biomaterials, self-assembled monolayers, and the physical characterization of thin-film assemblies.

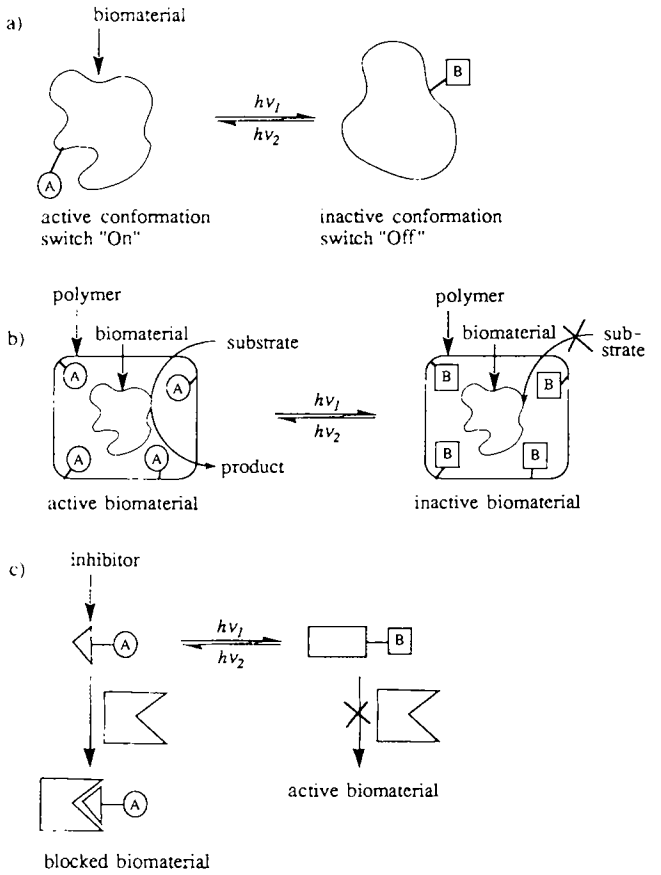

Fig. 1. Methods for tailoring reversible photobiological switches: a) by covalent attachment of photoisomerizable units to the biomaterial; b) by embedding the biomaterial in a photoisomerizable environment; c) by use of a low molecular-weight photoisomerizable inhibitor.

perturbations originally induced on the biomaterial diminish, and the biomaterial restores its active-site structure and is activated to its biochemical function (switch "On"). By reversible photochemical isomerization of the photosensor site, cyclic activation of the biomaterial's functions such as biocatalysis or binding can be switched "On" and "Off".

b) Entrapment of biomaterials in photoisomerizable environments provides a further means to switch "On" and "Off" biochemical functionalities (Fig. 1b). Physicochemical properties of photoisomerizable membrane-mimetic assemblies (for example, polymers, monolayers, and liposomes) are controlled by light.[34-38] The wettability,[39] sol–gel transitions,[40] effective volume viscosity,[41] and permeability[42] of such assemblies are controlled by light. Figure 1b outlines schematically the photostimulation of the biocatalytic functions of an enzyme by a photoisomerizable membrane. In one isomeric state of the environment the membrane is nonpermeable to the substrate, and the membrane-entrapped enzyme is switched off. Upon photoisomerization of the membrane to state B it becomes permeable to the substrate, and the protein can perform its biological function (switch "On").

c) Application of low molecular-weight photoisomerizable compounds that are recognized by biological macromolecules provides a third method to reversibly activate biomaterials (Fig. 1c). Inhibitors or cofactors act as low molecular-weight deactivators or activators of proteins, respectively. Thus, by the application of a photoisomerizable inhibitor the reversible activation of the biomacromolecule is feasible. In one photoisomeric state the inhibitor blocks the protein's active site, and its biological function is switched off. In the complementary photoisomeric state, the low molecular-weight component lacks inhibition properties, and it is released from the active site of the protein.[33,43-49] Similarly, use of a photoisomerizable cofactor that has only one state recognizable by the biomaterial could reversibly switch its biological functions.

The photochemistry of reversibly photoisomerizable compounds has been extensively reviewed in the context of photochromic compounds.[50-53] Various classes of reversibly photoisomerizable substances are available, including isomerization across double bonds (stilbenes, azobenzenes, indigo, and thioindigo derivatives),[54,55] photochemical $(4n+2)\pi$-electron ring closures and openings (fulgides (= dialkylidene butanedioic anhydrides), spiropyrans, spirooxazines),[56,57] photoisomerization of $(4n)\pi$-electron ring systems (oxiranes and aziridines),[58] photoisomerization based on cycloaddition reactions,[59] and photoisomerization by light-induced tautomerism (*N*-salicylidenanilines, anils, *aci*-nitro compounds).[60,61]

These classes of compounds could be coupled to biological substances, membrane mimetic assemblies, and molecular inhibitors (or cofactors) to act as photosensor sites.

Diverse potential applications of photoswitchable biomaterials can be envisaged.[18,62] Fast photobiological switches as interfaces for the recording and readout of optical signals are the basis for optical memory devices and biocomputers.[63,64] Amplification of weak light signals by a photoswitchable catalytic biomacromolecule (enzyme) whose resting state is the mute—"Off"—position represents a further optoelectronic application: absorption of a weak light signal by the photosensor site activates the enzyme, and the chemical transformation driven by the biocatalyst chemically amplifies the light signal by the cyclic formation of the reaction product.[65] Various therapeutic uses and the development of reversible biosensor devices based on photoswitchable biomaterials seem feasible.[33] As many enzymes or their reaction products act as therapeutic agents,[66,67] their reversible light-induced activation and deactivation allows targeting and controlled release of the therapeutic agent by irradiation of the infected organism. The use of photoswitchable biomaterials in the organization of reversible biosensor devices is schematically shown in Figure 2. Numerous biosensors (immunosensors) transduce the binding process between an analyte and the biological sensing receptor into a physical output (color, fluorescence, or electrochemical response).[68-70] However, due to the strong receptor–analyte interactions, many of these biosensors operate as single-cycle (that is, not reusable)

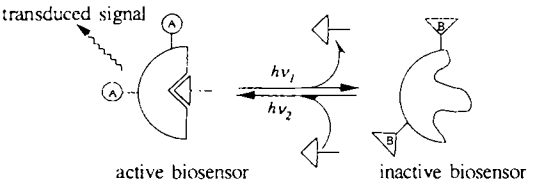

Fig. 2. Scheme illustrating the operation of a reversible biosensor, which utilizes a photoisomerizable biomaterial sensing interface.

analytical devices. Use of a photoisomerizable biomaterial as sensing interface enables the biosensor's active interface to be recycled. The bioreceptor modified by the photosensor in isomeric state A is activated towards the analyte and permits the sensing process. Photoisomerization of the biological interface to state B upon completion of the first sensing cycle yields a biological interface of low affinity for the analyte, which facilitates its release. The analyte is then washed off, and further reisomerization of the biological receptor to state A regenerates the active sensing interface for the subsequent analysis cycle.[33]

The present review summarizes recent advances in the development of photobiological switches based on covalent attachment of photoisomerizable units to biological materials and on immobilization of biomaterials in photoisomerizable environments.

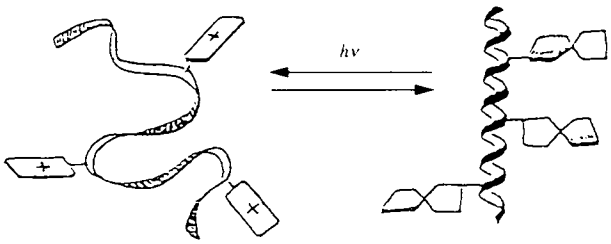
2. Photoregulation of Structures and Functions of Biomaterials and Related Macromolecules by Anchored Photoisomerizable Units

Photochemical isomerization of small molecules attached to macromolecules are known to induce pronounced structural perturbations on the macromolecular matrix; these changes are reflected in the photoswitchable physical properties of the macromolecular assembly.[39, 71–75] Similarly, photoisomerizable units covalently linked to biomaterials provide a means of controlling by light the functions of the biological macromolecules.

2.1. Photochemical Control of the Structure of Polypeptides

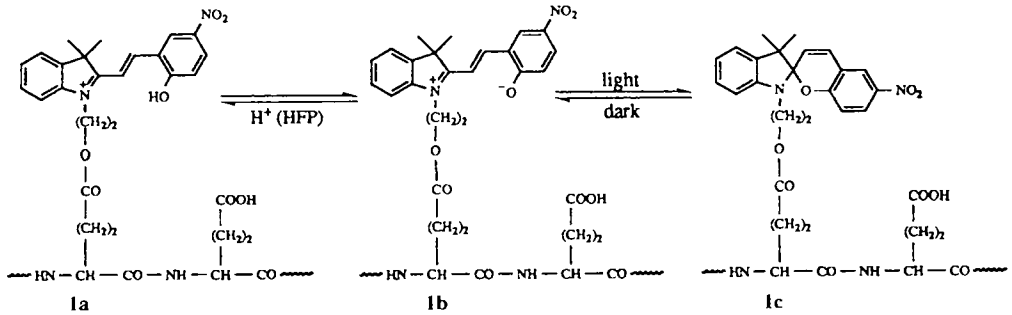
Polypeptides are synthetic analogs of proteins, and they organize as random-coil, β-sheet, and α-helix structures, depending on the reaction medium, pH, and temperature.[76] Photochemical control of polypeptide structures by covalently linked photoisomerizable components[77] represents the junction between photostimulated biomaterials and synthetic photoisomerizable polymers.

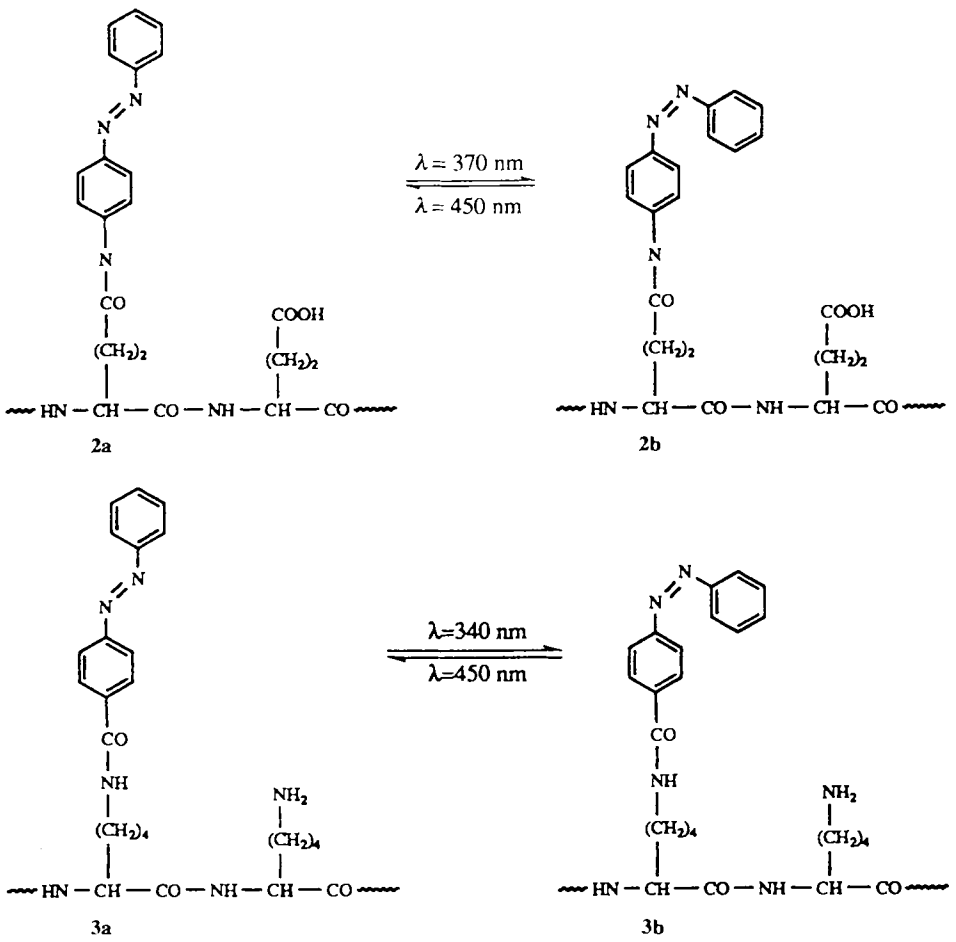
Poly(L-glutamic acid) was modified with nitrospiropyran units, and the resulting polymer was stabilized in hexafluoropropanol (HFP) in the merocyanine isomeric structure **1b**. The basicity of the phenolate group results in protonation by the solvent, and the protonated merocyanine poly(L-glutamic acid) (**1a**) turns the polymer into a positively charged matrix. Illumination of the stable mixture of **1a** and **1b** with visible light induces isomerization to the spiropyran poly(L-glutamic acid) (**1c**) that undergoes thermal relaxation to the merocyanine isomers **1a** and **1b**. Spiropyran poly(L-glutamic acid) (**1c**) has an α-helix structure that is reflected by typical CD curves with two negative bands at λ = 208 and 222 nm. Thermal back-isomerization of **1c** to **1a** and **1b** decreases the intensity of the CD signal, which implies that the peptide is transformed into an extended coil conformation. The reason for the light-stimulated ordering of **1c** was attributed to the hydrophobic apolar state of the isomer that enables the polymer to form intramolecular H-bonds, thus adopting the α-helix structure.[78, 79] Thermal isomerization to **1a**/**1b** results in electrostatic repulsions between the positively charged photoisomer units tagged to the polypeptide that perturb the α-helix structure and an extended coil conformation results (Scheme 3). These light-stimulated α-helix → random coil changes in polymer **1** are reversible.



Scheme 3. Schematic representation of photostimulated random-coil/helix transitions of a spiropyran-modified poly(L-glutamic acid) (**1**).

Closely related photoregulation of polypeptide structures was accomplished with azobenzene-modified poly(L-glutamic acid)[80, 81] (**2**) and azobenzene-modified poly(L-lysine)[82] (**3**) in the presence of appropriate surfactants. *Trans*-azobenzene-poly(L-glutamic acid) (**2a**) undergoes reversible photoisomerization. Upon illumination at λ = 370 nm it transforms into *cis*-azobenene-poly(L-glutamic acid) (**2b**), which reisomerizes to **2a** upon illumination at 450 nm. The pK_a values of the free carboxylic acid functionalities of an azobenzene poly(L-glutamic acid) polymer (35 mol% loading) depend on the isomeric structures of the azobenzene units (pK_a 6.8 for **2a** and 6.3 for **2b**). The difference in the pK_a values of the polymer was attributed to the polarity of *cis*-azobenzene units, which enhances the local dielectric constant of neighboring carboxylic acid functionalities. As a result, photoisomerization in an aqueous solution (pH = 6.5) transforms *trans*-isomer **2a** to the *cis*-isomer **2b**.[83] Not only the acidity of adjacent carboxylic acid functionalities but also the structure of the polymer is influenced by the photochemical isomerization. The *trans*-isomer **2a** (which includes a 20 mol% loading of the photoisomerizable units) was found to exist in the presence of dodecylammonium chloride micelles in a



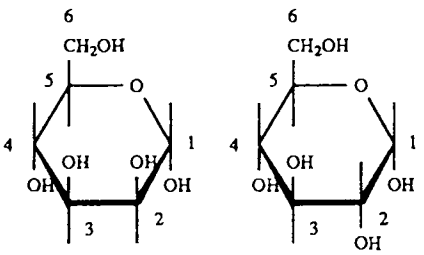


random coil conformation. Photoisomerization to **2b** induces a coil-to-helix transition, which is evident from CD bands at 210 and 228 nm. The existence of the *trans*-isomer **2a** in a disordered coil structure was attributed to the hydrophobic character of the *trans*-azobenzene units: the distortion of the polymer results from the incorporation of the hydrophobic units into the core of micelles. Photoisomerization to **2b** forms the polar *cis*-azobenzene polypeptide units, which leave the micelles, and the stabilized α-helix conformation of the polymer is favored in the aqueous phase.[84] Similar photomodulated structural control of azobenzene poly(L-lysine) (**3**) was observed in a hexafluoropropanol/water/sodium dodecylsulfate system (the polymer contained 43 mol% of azobenzene units). The CD spectrum of the *trans* isomer **3a** was characteristic of a polypeptide in a β-sheet conformation. Upon irradiation at 340 nm and isomerization to **3b** the β-sheet structure was disrupted, and an α-helix polypeptide conformation was promoted (50% α-helix content). Upon further photoisomerization of **3b** to **3a** (illumination at $\lambda = 450$ nm) the β-sheet structure was reconstituted. These photostimulated β-sheet → α-helix transitions were ascribed to the different geometries and polarities of the polymer-anchored azobenzene units. Polypeptide β-sheets are stabilized by hydrophobic interactions of the polymer's side chains. Accordingly, the planar structure of *trans*-azobenzene units and their hydrophobic nature contribute to the stabilization of the β-sheets. Photoisomerization to **3b**, which has polar side-chain chromophoric units, favors the α-helix conformation.[85]

2.2. Photoregulated Binding of Proteins

Intermolecular recognition is a fundamental function of biomaterials. Catalysis within the recognition pair, transport of specific substrates across natural membranes, and storage of materials, specifically small molecular-weight compounds, represent biological processes where recognition and binding play a primary role. Modification of biomaterials with photoisomerizable components provides a general means to control by light the binding affinities of the complementary components. Whereas in one photoisomeric state the biomaterial's binding site is preserved and the formation of the intermolecular complex is facilitated, the second photoisomeric state distorts the biomaterial's recognition site and binding is blocked.

The lectin concanavalin A (Con. A) was modified by photoisomerizable components, and its binding properties towards α-D-mannopyranose and α-D-glucopyranose were regulated by light.[86-89] Con. A is a globular lectin composed of four subunits ($M \approx 26$ kDa). Each subunit includes binding sites for Mn^{2+} and Ca^{2+}, which act cooperatively in the recognition of α-D-mannopyranose (**4**) and α-D-glucopyranose (**5**). Con. A was modified by photoisomerizable



4 **5**

thiophenefulgide[86] and nitrospiropyran[87] components (Scheme 4). The photosensitive proteins undergo reversible photoisomerization: thiophenefulgide-modified Con. A (**6a**) undergoes electrocyclization to **6b** upon irradiation at $\lambda = 300$–400 nm, whereas **6b** is photoisomerized into **6a** upon exposure to visible light ($\lambda > 475$ nm). Spiropyran-modified Con. A (**7a**) undergoes a 6π-electron photochemical ring-opening to the zwitterionic merocyanine-Con. A (**7b**) upon illumination at $\lambda = 300$–400 nm. The latter photoisomer is reversibly electrocyclyzed to **7a** by irradiation with visible light ($\lambda = 475$ nm). Table 1 gives the association constants for the binding between

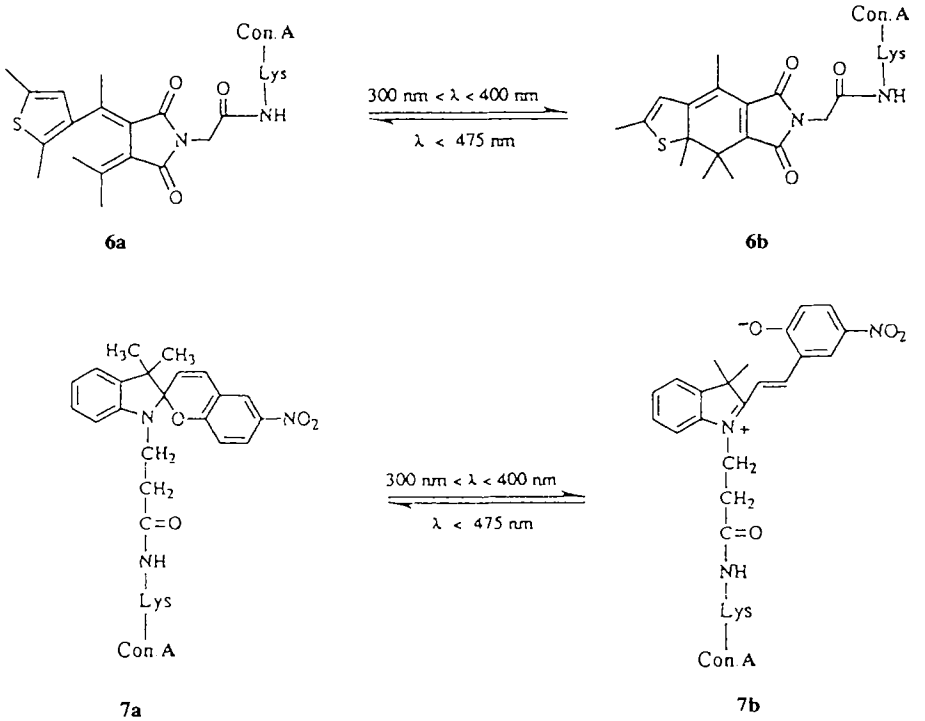
8

state **6b** exhibits higher affinity towards α-D-mannopyranose, while for spiropyran-modified Con. A the photoisomeric state **7a** exhibits enhanced binding properties for the monosaccharide. The difference between the binding properties of the concanavalin A photoisomeric states is very sensitive to the loading degree. While low loadings do not substantially change the binding affinities of the two photoisomeric proteins that recognize the substrate, high loadings result in a significant decrease in the binding properties, presumably due to substantial distortion of the proteins.

Table 1. Association constants K_a for the binding of **8** to the two photochromic states of **6** and **7** as a function of degree of loading by the photochromic substituent.

Degree of loading	K_a [M^{-1}] **6a**	K_a [M^{-1}] **6b**	K_a [M^{-1}] **7a**	K_a [M^{-1}] **7b**
0	22000		24000	
3			23000	23000
6	16400	20000	18000	12000
8			10000	7300
9	7800	12100		
12	6400	6400		



6a **6b**

7a **7b**

The difference in the affinities of **6a** and **6b** for α-D-mannopyranose was utilized for reversible photostimulated association of the host-substrate to the protein (Fig. 3). In this system the concentration of free α-D-mannopyranose in solution is controlled by the photoisomeric state of Con. A. In state **6b** the monosaccharide binds efficiently to the protein, and its free concentration is low. Upon photoisomerization of **6b** to **6a** the binding constant of the substrate to the protein decreases, and the free monosaccharide concentration in the solution increases. This intermolecular complex formation and dissociation is fully reversible upon photoswitching Con. A between states **6b** and **6a**.

The binding process of the monosaccharides to the photoisomerizable Con. A proteins was not only thermodynamically controlled; a kinetic control of the protein–substrate association processes was also revealed.[90] Self-assembled monolayers of the guest monosaccharides

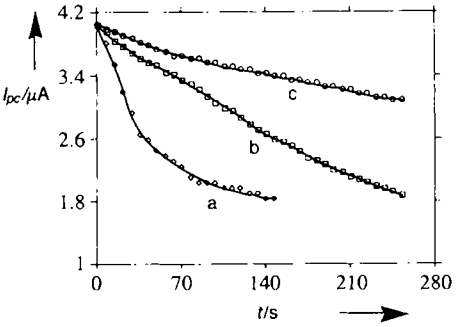

Fig. 5. Decay of current (I_{pc}) of a $[Fe(CN)_6]^{4-}$ redox probe upon interaction of phenyl-α-D-glucopyranose monolayer Au electrode with native Con. A (a), **7a** (b), and **7b** (c). All experiments were performed in a three-electrode cell with Ag/AgCl as reference electrode; electrolyte composition: 1×10^{-3} M $K_4[Fe(CN)_6]$, 1×10^{-3} M KCl in phosphate buffer (0.1 M, pH = 8); concentration of added protein: 0.01 mg mL^{-1}; T: 20 ± 1 °C; scan rate: 200 mV sec^{-1}.

were organized on Au electrodes (Fig. 4). The kinetics of the association of the spiropyran-modified Con. A (**7a**) and merocyanine-derivatized Con. A (**7b**) to the monosaccharide monolayer on the electrode was followed by inspecting the extent of electrode insulation towards a redox probe in solution. Figure 5 depicts the kinetics of insulation by native Con. A, **7a**, and **7b** of an electrode modified by the thiourea-linked phenyl-α-D-glucopyranose monolayer. Native Con. A reveals the highest affinity for the substrate-coated electrode, as reflected by the rapid insulation of this monolayer electrode. The photoisomer **7b** that exhibits a low association constant for α-D-glucopyranose (K_a = 12000 M^{-1}) reveals slow kinetics of interaction with the electrode. In contrast, the photoisomeric protein **7a** (K_a = 18000 M^{-1}) associates faster with the electrode. Table 2 presents the time constants for association of the photoisomers **7a** and **7b** to various monosaccharide monolayer electrodes.

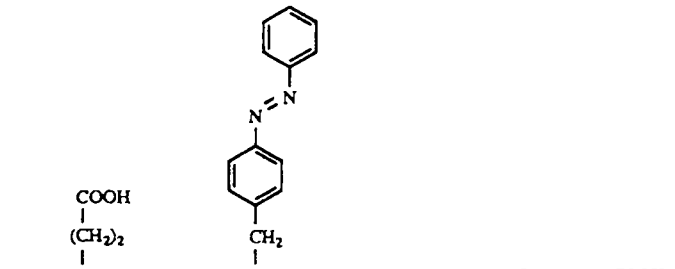
The different association properties of the monosaccharides to photoisomerizable Con. A were attributed to enhanced perturbations by one of the photoisomeric states to the structure of the protein and specifically its binding site. Evidence for the structural distortion of Con. A following the photoisomerization of **7a** to **7b** and the associated dynamics was revealed by time-resolved light-scattering experiments.[91] Photoisomerization of **7a** to **7b** is accompanied by a transient increase in the light-scattered signal by the protein, which implies protein shrinkage upon isomerization. The dynamics of the protein condensation is reflected by the time constants of the intensity of the scattered light. For a protein loaded with six photoisomerizable units the matrix shrank within 60 msec. At a loading of eight units the dynamics of structural perturbation revealed biexponential kinetics, where shrinkage to a metastable protein configuration occurred within 60 msec, and the matrix condensed further on a longer time scale (t = 250 msec).

Table 2. Time constant $\tau_{1/2}$ [sec] [a] for the association of Con A and spiropyran-modified Con A (7) to monosaccharide substrates.

Substrate	$\tau_{1/2}$ (Con. A)	$\tau_{1/2}$ (**7a**)	$\tau_{1/2}$ (**7b**)
phenyl-α-D-mannopyranoside	40	60	160
phenyl-α-D-glucopyranoside	85	220	670
phenyl-β-D-glucopyranoside	100	100	100

[a] $\tau_{1/2}$ is the time required for the cathodic peak current I_{pc} to decay to half of its original value in the cyclic voltammogram of the $[Fe(CN)_6]^{4-}$ redox probe. At this stage the monolayer is half-covered by the protein.

Mutual recognition of antibody and antigen was photostimulated in a photoisomerizable antigen. A monoclonal antibody (Z1H01) for the hapten Glu-(*trans*-azobenzene Ala)-Gly_2 (**9a**)



9a

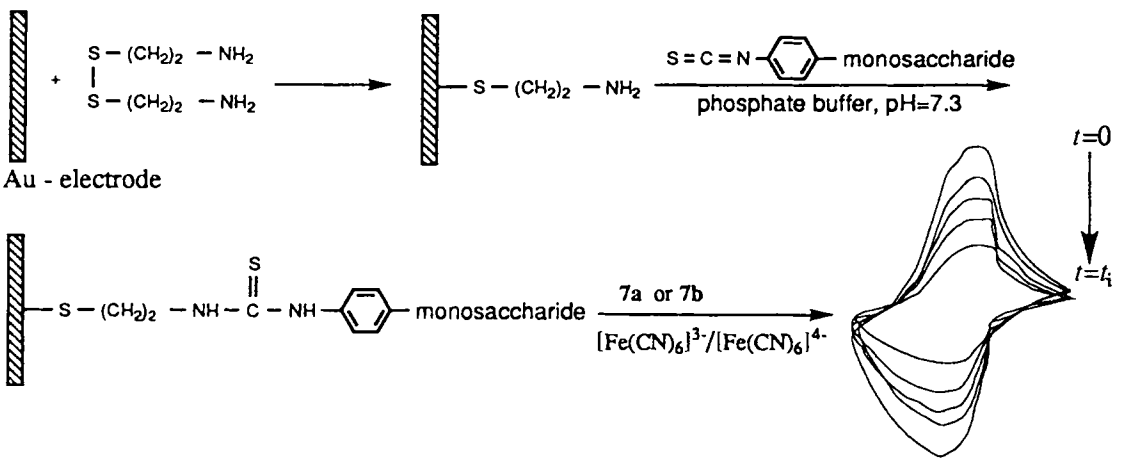


Fig. 4. Construction of monosaccharide monolayers on Au electrodes and cyclic voltammograms of a soluble redox probe at different time intervals as schematic representation of the insulation of the electrodes through association with the photoisomerizable proteins. The monosaccharides used were α-D-manno-, α-D-gluco-, and β-D-glucopyranoside.

was prepared.[92] The *trans*-azobenzene hapten state exhibits high affinity for the antibody. The binding process was followed by quenching of the antibody fluorescence through energy transfer to the associated azobenzene hapten. The value of the derived association constant K_a is $5 \times 10^7\,M^{-1}$. Photoisomerization of **9a** to the *cis*-azobenzene hapten **9b** (λ = 360 nm) resulted in a hapten isomer with poor affinity for the antibody as reflected by inefficient quenching of the antibody fluorescence. Further illumination of the photoisomer **9b** to **9a** by illumination with visible light (λ = 430 nm) restored the active hapten recognized by the antibody. Uptake and release of the hapten to and from the antibody was accomplished reversibly and followed by the fluorescence resulting from the system (Fig. 6). The light-induced association and dissociation of antigen–antibody pairs could provide a general means for the development of reversible immunosensor devices (for a specific example see Section 3.3).

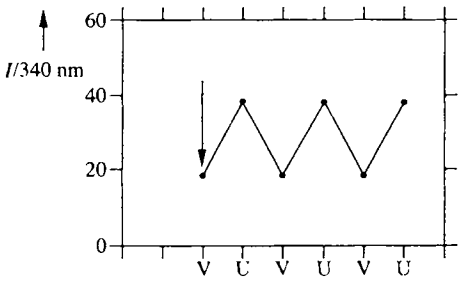

Fig. 6. Reversible photostimulated binding and dissociation of the photoisomerizable hapten **9** to and from the monoclonal antibody Z1HO1. V indicates hapten in the **9a** (*trans*) configuration; U indicates hapten in the **9b** (*cis*) isomeric state. The arrow indicates addition of **9a**; *I* is the intensity of the fluorescence at 340 nm.

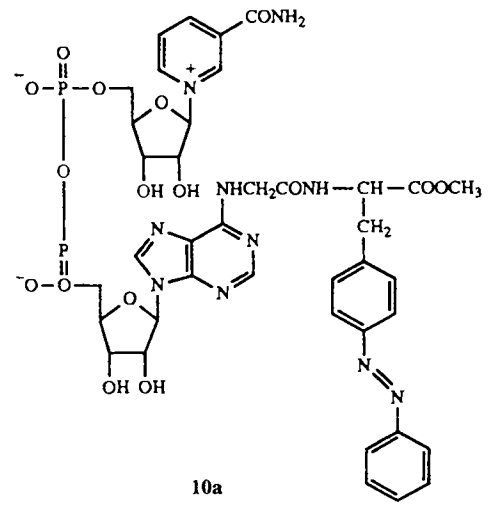
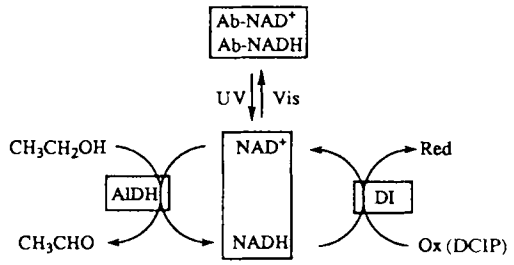
The monoclonal antibody against *trans*-azobenzene units was recently applied in the reversible photostimulation of biocatalytic activities. The *trans*-azobenzene-modified NAD^+-cofactor (**10a**) was prepared.[93] This cofactor exhibits photoisomerizable properties, and upon UV irradiation of **10a** (λ = 320 nm) the *cis*-azobenzene-NAD^+-cofactor (**10b**) is formed. Further illumination of **10b** with visible light ($\lambda > 420$ nm) restores **10a**. While **10a** binds to the corresponding antibody, **10b** is not recognized and is released from it. Accordingly, coupling of NAD^+-dependent enzymes with the *trans*-azobenzene-NAD^+-antibody provides a mechanism for controlling the availability of the cofactor for biocatalyzed transformations: association of the cofactor in state **10a** to the antibody eliminates the free cofactor from solution, and the enzyme activity is inhibited; photoisomerization of **10a** to state **10b** dissociates the antibody–antigen complex, and the cofactor is released to solution and activates the enzyme. In Scheme 5 the photostimulated activation and deactivation of NAD^+-mediated biocatalyzed transformations with the photoisomerizable cofactor **10** and the *trans*-azobenzene antibody is described schematically. The two NAD^+/NADH-dependent enzymes are alcohol dehydrogenase and diaphorase. The cofactor in state **10a** is associated to the antibody, and the activities of the two enzymes are blocked. Photoisomerization of **10a** to *cis*-azobenzene-NAD^+ (**10b**) releases the cofactor from the antibody. The free cofactor is then reduced by ethanol in the presence of alcohol dehydrogenase to form *cis*-azobenzene-NADH, which is oxidized by 2,6-dichlorophenol–indophenol (DCIP) in the presence of diaphorase. The biocatalyzed reduction of DCIP by ethanol in the presence of the two enzymes can be blocked by reisomerization of **10b** to **10a** and entrapment of the cofactor in the antibody matrix. This indirect approach to photomodulating enzyme activities by antibodies specific to the photoisomerizable unit that is linked to a cofactor seems to be generally applicable to the design of reversible photoswitchable biomaterials. Attachment of photoisomerizable units to inhibitors, coenzymes, activating proteins, etc., and utilization of the appropriate antibodies could trigger enzyme activities by selective release of the biocatalyst-dependent co-component.



10a



Scheme 5. Reversible photostimulation of alcohol dehydrogenase (AlDH) by the photoisomerizable azobenzene-modified NAD^+ (**10**) in the presence of the monoclonal antibody Z1HO1 (Ab). Diaphorase (DI) is used to regenerate the oxidized cofactor. The Ab complexes at the top of the scheme are inactive.

2.3. Photostimulation of Enzyme Activities

Attachment of photoisomerizable units to enzymes provides a general means of regulating biocatalytic activities (Fig. 7). In one photoisomeric state the tertiary structure of the protein and the conformation of its active site are preserved, and the enzyme is switched "On" with respect to its native activity. Photoisomerization induces distortion of the protein structure that could originate from electrostatic interactions between the isomeric state and the protein, steric distortions, or disruption of hydro-

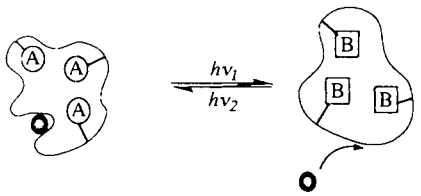


Fig. 7. Schematic representation of the photoswitchable activation and deactivation of an enzyme by covalently linked photoisomerizable components. The binding site is accessible in the undistorted protein (on the left), but not in the distorted protein (on the right).

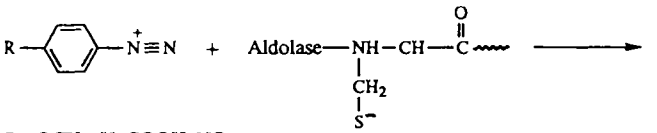
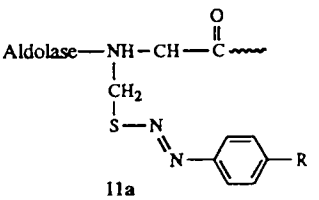
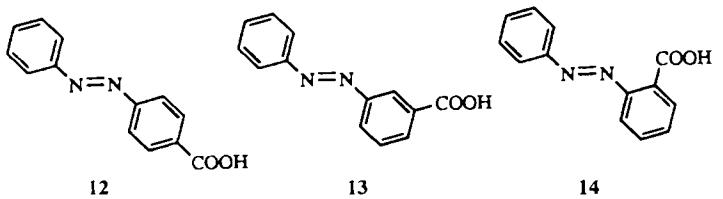
gen bonds associated with the tertiary enzyme structure. The initial attempts at "On–Off" photostimulation of an enzyme by this method were reported by Montagnoli et al., who modified aldolase at Cys 237 and Cys 287 by attaching different diazonium salts.[94, 95] The resulting diazo-modified aldolases (**11a**) exhibited photoisomerizable properties, but the two states **11a** and **11b** exhibited little differences in their biocatalytic proper-



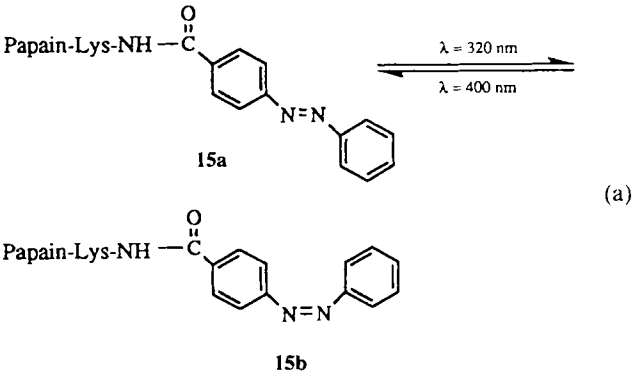


ties. The isomeric states gave different mobilities in gel electrophoresis, which implies that they have different structures, but the protein-embedded active site is not sufficiently distorted to reveal switchable biocatalytic activities.

The approach has been successfully applied to photoregulate the activity of papain.[96] This enzyme was modified by covalent coupling of either *trans*-4-carboxyazobenzene (**12**), *trans*-3-carboxyazobenzene (**13**), or *trans*-2-carboxyazobenzene (**14**) to its

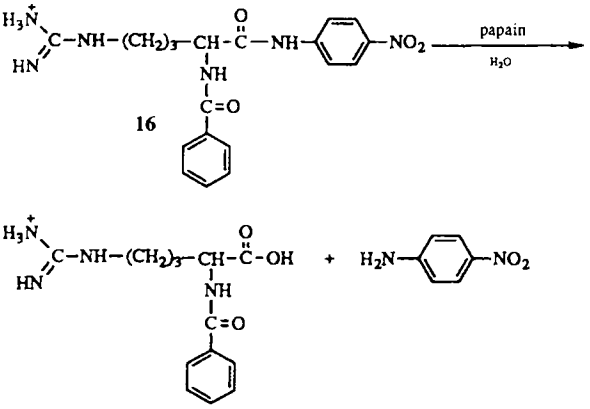


lysine residues. The different azobenzene-modified papains undergo reversible *trans* → *cis* photoisomerization [Eq. (a)]. The activity of the modified enzymes depends on the nature of the azobenzene components. (*Trans*-4-carboxyazobenzene)-papain, (*trans*-3-carboxyazobenzene)-papain, and (*trans*-2-carboxyazobenzene)-papain retain 80%, 36%, and 1%, respectively, of the activity of the native enzyme. The best photostimulated activities were detected with the 4-carboxyazobenzene derivative **15** for a loading corresponding to five photoactive units per enzyme. In this protein assembly, the *trans*-isomer **15a** was



(a)

about 2.75 times more active than the *cis*-isomer **15b** towards the hydrolysis of *N*-benzyl-D,L-arginine-nitroanilide [**16**, Eq. (b)]. Since photoisomerization of **15a** to **15b** yields a photo-



(b)

stationary equilibrium where [**15b**]/[**15a**] = 0.89, even partial transformation into the *cis*-state is sufficient to retard the hydrolytic activity of the enzyme. The different activities of the papain photoisomeric states **15a** and **15b** enabled reversible cyclic photostimulation of the hydrolytic process of Equation (b) (Fig. 8). Kinetic analyses of the biocatalysts in the two

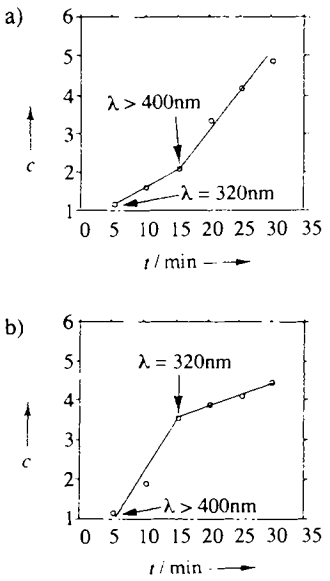


Fig. 8. Photostimulated hydrolysis of **15** by azobenzene-modified papain. a) Hydrolysis is initiated by the *cis*-isomer **15b** and switched on by irradiation (marked by an arrow) that transforms **15b** into the *trans*-derivative **15a**. b) Hydrolysis is initiated with **15a** and switched off by irradiation (marked by an arrow) that transforms **15a** into **15b**. *c* = concentration of product in 10^{-5} M.

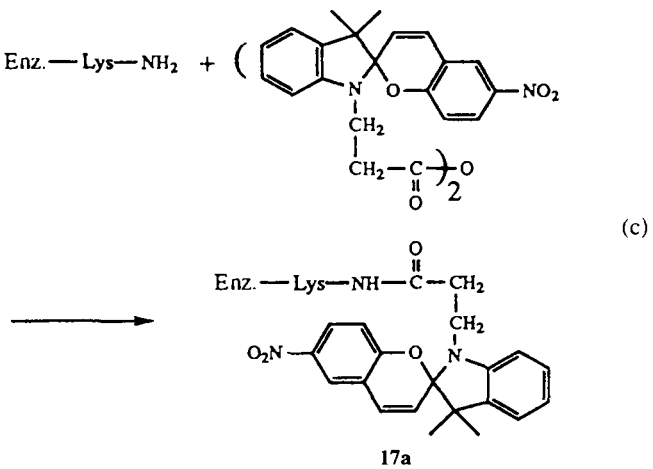
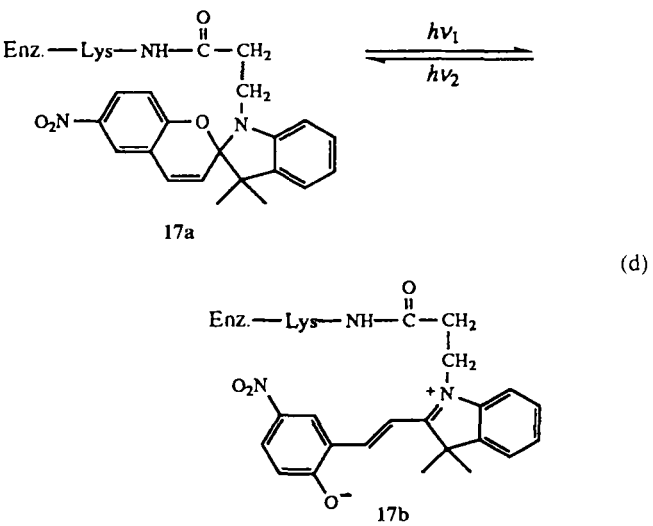
photoisomeric states **15a** and **15b** were conducted to elucidate the mechanism of photoswitchable activity of the enzyme. The two photoisomeric states of papain (**15a** and **15b**) exhibit similar V_{max} values ((1.9 ± 0.2) mM min^{-1}) but differ in their K_m values ($K_m = (2.2 \pm 0.2)$ mM for **15a** and (6.5 ± 0.6) mM for **15b**). These results suggested that the binding of the substrate to the enzyme's active site was inhibited in the "Off" state of papain (**15b**) but the catalytic functions of the active center were not influenced by photoisomerization.

Closely related reversible activation of biocatalysts' functions were reported for a series of spiropyran-modified enzymes.[97, 98] Spiropyran units were covalently linked to a series of enzymes [Eq. (c)], and the resulting enzymes exhibited reversible photoisomerization [Eq. (d)]. Table 3 summarizes the



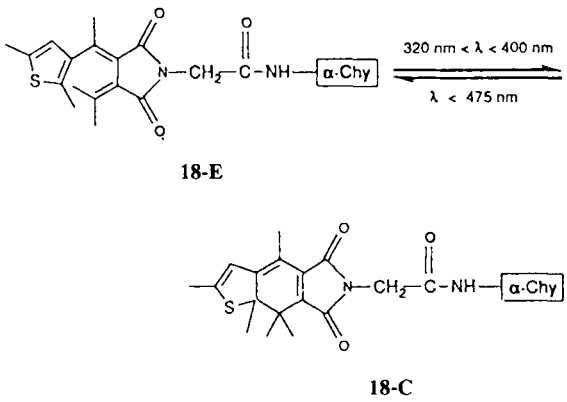


different enzymes used in this study, the substrates used to assay them, and the relative activities of the enzyme's isomeric states **17a** and **17b**. The K_m values of the enzymes' isomeric states are also provided. The highest photoswitchable activation/deactivation is observed for β-amylase, for which the activity in the isomeric state **17b** is only about a tenth of the activity in state **17a**. The substantially higher K_m value of the α-amylase in state **17b** suggests that the binding to the protein's active site is perturbed in this conformation.

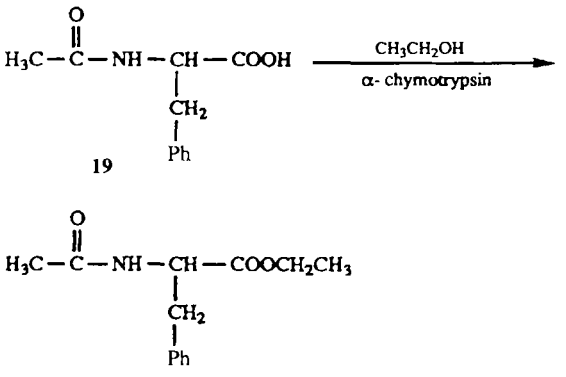
Table 3. Activities and affinity parameters of photoisomerizable spiropyran-modified enzymes **17**.

Enzyme	Substrate	17a		17b	
		Activity	K_m [mM]	Activity	K_m [mM]
α-chymotrypsin	*N*-benzoyl-L-tyrosinethylester	1	15	1.5	4.3
β-glucosidase	*p*-nitrophenyl-β-D-glucoside	1	4.0	1.15	3.3
β-amylase	amylose	1	3.4	0.13	60
α-amylase	amylose	1	12	0.64	15

Modification of enzymes by attaching photoisomerizable units led to incomplete photoswitchable activities of the biocatalysts in aqueous media, as the enzymes in the "Off" states exhibited residual biocatalytic properties. It has been suggested that better light-controlled biocatalysts could be obtained by employing the photoisomerizable enzymes in organic solvents,[99] because proteins should then be more sensitive to structural perturbations induced by the photoactive units due to the limited amount of water that participates in the stabilization of the biopolymer's tertiary structure.[100–102] Accordingly, α-chymotrypsin was modified with thiophenefulgide units to introduce reversible photoisomerizable properties [states **18**-E and **18**-C, Eq. (e)]. The two photoisomeric states have similar



hydrolytic activities in an aqueous solution (assayed by hydrolysis of *N*-acetyl-*N*-phenylalanine ethyl ester or *N*-succinyl-L-phenylalanine-*p*-nitroanilide). However, the photoisomerizable α-chymotrypsin exhibits light-controlled biocatalytic activities in an organic solvent (cyclohexane). Esterification of *N*-acetyl-L-phenylalanine (**19**) by ethanol is slow in the presence of **18**-E, and photoisomerization to **18**-C accelerates the reaction by about a factor of 5 [Fig. 9 and Eq. (f)].



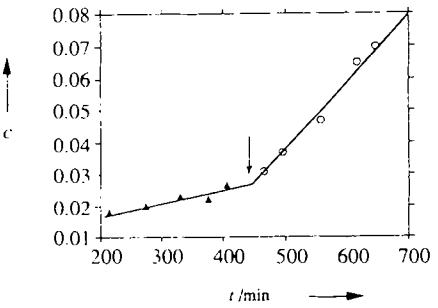


Fig. 9. Photostimulation of the esterification of **19** by ethanol in cyclohexane by using thiophenefulgide-modified α-chymotrypsin (**18**). The biocatalyzed transformation is initiated with **18-E** and switched on by photoisomerization of the biocatalyst to state **18-C** ($320\ nm < \lambda < 400\ nm$, at the time indicated by the arrow). c = concentration of the product in 10^{-3} M.

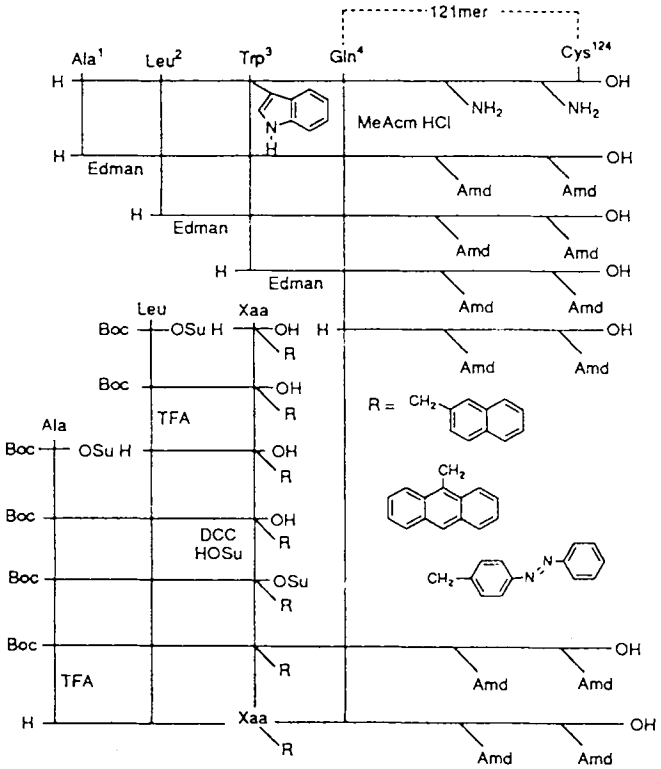
The control of enzyme activities by photoswitchable, covalently linked, isomerizable groups has involved random chemical substitution of the proteins by photoisomerizable groups, and superior switchable activities were observed at high loadings. It has been suggested that at high loadings maximal steric distortions of the proteins are induced, leading to inhibited catalytic or binding properties of the biomaterial's active sites. A significant advance, however, would include the specific mutation of selected amino acid residues by photoisomerizable units. This would allow direct correlation between computational analyses of the tertiary structure of the isomerizable mutants, and specifically their active sites, and the observable photoswitchable properties.

Preliminary studies based on these concepts have recently been reported by the semisynthesis of a photoisomerizable mutant of phospholipase A_2.[103] This lipolytic enzyme cleaves 2-acyl bonds of phosphoglycerides, and its activity is enhanced towards substrates associated with aggregated interfaces such as micelles or vesicles. It was suggested that the N-terminus of phospholipase A_2, composed of Ala-1, Leu-2, Trp-3, Arg-6, Leu-15, Met-20, Leu-31, and Try-69, adopts an α-helical conformation that generates a recognition site at the interface.[104, 105] This site facilitates the association of the enzyme at lipid–water interfaces and thereby enhances the hydrolysis of substrates at such boundaries.[106] Covalent linkage of a photoisomerizable unit to an amino acid residue associated with the recognition site of the interface enables photostimulation of the enzyme activity. A photoisomerizable phospholipase A_2 mutant was prepared by a semisynthetic approach (Scheme 6).[103] The ε-amidinated enzyme was subjected to three consecutive Edman degradations to degrade the terminal amino acids Ala-1, Leu-2, and Trp-3. The protein was then reconstituted by the stepwise synthesis of the tripeptide Boc-Ala-Leu-(*trans*-azobenzene-Phe) (X_{aa} = *trans*-azobenzene-phenylalanine) followed by its coupling to the 121-mer obtained in the initial cleavage step. The procedure specifically substituted the Trp-3-residue with the photoisomerizable azobenzene-Phe.

The activities of the photoisomerizable phospholipase A_2 mutant were assayed towards hydrolysis of the lipids associated with palmitoyl phosphatidylcholine vesicles. (Radio-labeled lipids or vesicle-encapsulated fluorescence probes were used to monitor lipid hydrolyses). The mutant in the *trans*-azobenzene-phenylalanine conformation does not exhibit any hydrolytic activity towards the lipid hydrolysis. Photoisomerization of the mutant to the *cis*-azobenzene-Phe isomer activates it towards hydrolysis. The mutant in the *cis*-conformation retains about 10% of the native enzyme activity. CD spectra of the mutant phospholipase A_2 revealed that the α-helix content of the *cis*-isomer is substantially higher than in the *trans*-mutant. The enzyme recognition site adopts the α-helical conformation and is the active counterpart for the biocatalytic lipid hydrolysis. This suggests that in the *trans*-form of the mutant the recognition site of the interface is perturbed, and the enzyme activity is blocked. Upon photoisomerization to the *cis*-mutant, the recognition site is reconstituted (as evidenced by the α-helical conformation deduced from the CD spectrum), and the enzyme is switched on towards the hydrolytic process.



Scheme 6. Semisynthetic method for cleavage of phospholipase A_2 to constitute azobenzene-modified phospholipase A_2. Acm = acetamidate, Amd = ε-amidinated, DCC = dicyclohexylcarbodiimide, HOSu = *N*-hydroxysuccinimide, TFA = trifluoroacetic acid, Xaa = *trans*-azobenzene phenylalanine.

Photoswitchable biomaterials exhibit the fundamental optical recording feature of an optoelectronic active interface. Recorded optical signals are translated into mute or chemically activated functions. Fast read-out of the recorded optical information, preferably by a different physical signal, is essential for applications of photoswitchable biomaterials as active interfaces in optoelectronics. Amperometric transduction of recorded optical signals was recently demonstrated with a photoisomerizable redox enzyme, which acted as the optical recording and transducing matrix.[107] Glucose oxidase (GOD) was modified by nitrospiropyran photoisomerizable units. The modified enzyme is photoisomerizable between the nitrospiropyran-GOD (SP-GOD, **20a**) and the protonated merocyanine-GOD (MRH^+-GOD, **20b**) states and displays light-controlled activities: **20a** is about twice as active as **20b**. The

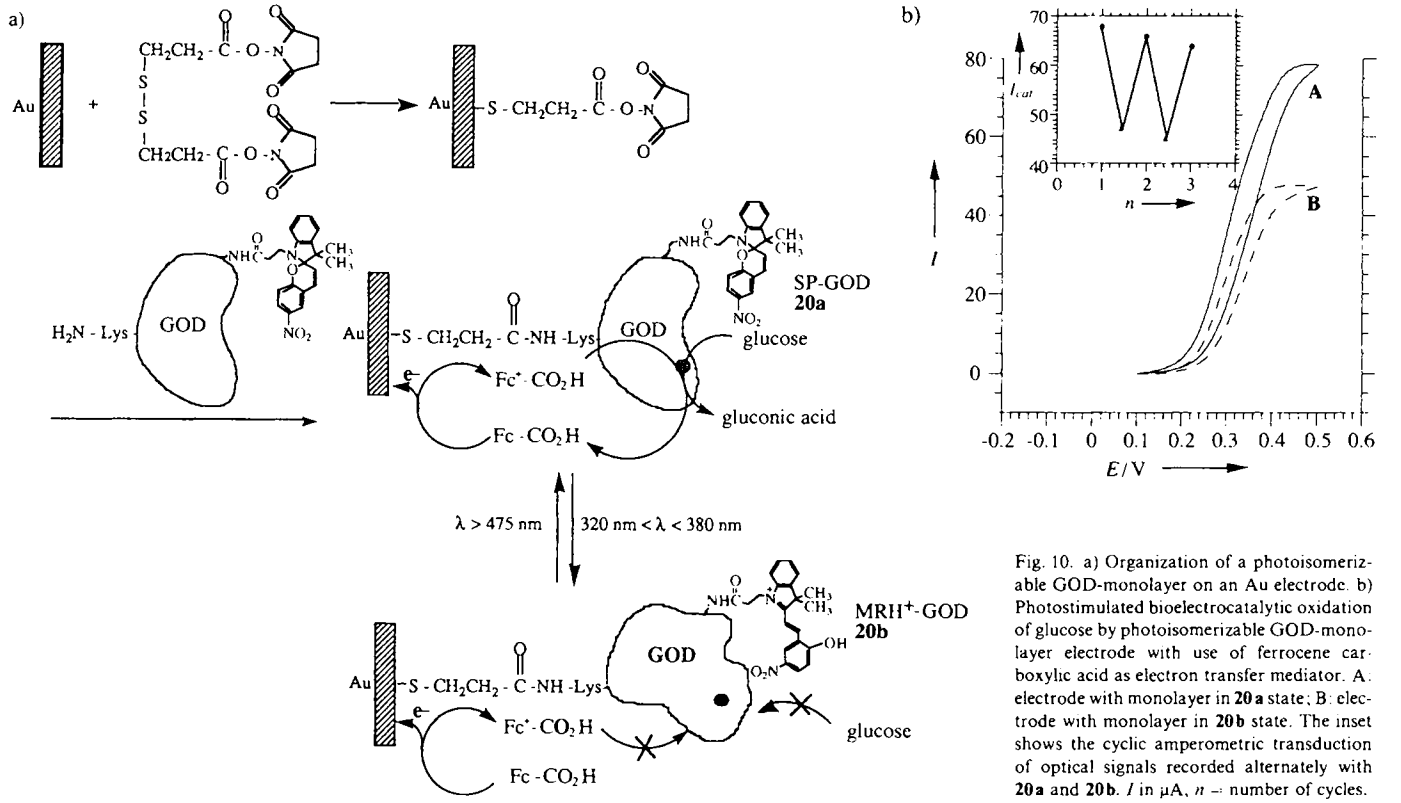


Fig. 10. a) Organization of a photoisomerizable GOD-monolayer on an Au electrode. b) Photostimulated bioelectrocatalytic oxidation of glucose by photoisomerizable GOD-monolayer electrode with use of ferrocene carboxylic acid as electron transfer mediator. A: electrode with monolayer in **20a** state; B: electrode with monolayer in **20b** state. The inset shows the cyclic amperometric transduction of optical signals recorded alternately with **20a** and **20b**. I in μA, n = number of cycles.

photoswitchable amperometric activities of the photoisomerizable GOD were used for the transduction of recorded optical signals. Enzyme **20a** was assembled as a monolayer on an Au electrode (Fig. 10a). The electrode coated with the monolayer in **20a** state exhibits electrobiocatalytic properties: In the presence of ferrocene carboxylic acid as electron transfer mediator, electrocatalyzed oxidation of glucose gives rise to an electrocatalytic anodic current (I_{cat}). Upon photoisomerization of the monolayer to the **20b** state the enzyme is deactivated, and the efficiency of the bioelectrocatalytic oxidation of glucose decreases. This is reflected by a lower amperometric response of the enzyme-electrode. By cyclic photoisomerization of the monolayer between these states, the recorded optical signals are amperometrically transduced (Fig. 10b).

3. Modulation of Biomaterial Functions by Photoisomerizable Environments

The effects of photoisomerizable components on the physical and chemical properties of membrane mimetic assemblies such as micelles, microemulsions, and liposomes are well documented.[108-112] Photochemical control of the organization of liquid crystal phases[113-116] and sol-gel transitions of polymers[117-119] containing appropriate photoisomerizable components exemplifies the regulation by light of the structure and properties of microscopic and macroscopic phases. If biomaterials are incorporated into such photomodulated phases, their functions could be triggered by environmental effects. This is schematically presented in Figure 11, in which the catalytic function (Fig. 11a) or the binding properties (Fig. 11b) of a biomaterial immobilized into a liposome that contains a photoisomerizable component as a part of the membrane boundary are triggered by light. In photoisomeric state B (Fig. 11a) the liposome is nonpermeable towards the substrate, and the enzyme activity is switched off. Upon photoisomerization to state A the liposome becomes permeable towards the substrate, and the catalytic function of the protein is switched on. The permeability of the membrane could be modulated by a phase transition of the hydrophobic boundary or by utilizing the photoisomeric state A as substrate carrier. In Figure 11b the light-stimulated binding of an antibody is illustrated. The environment in isomeric state A does not include any recognition

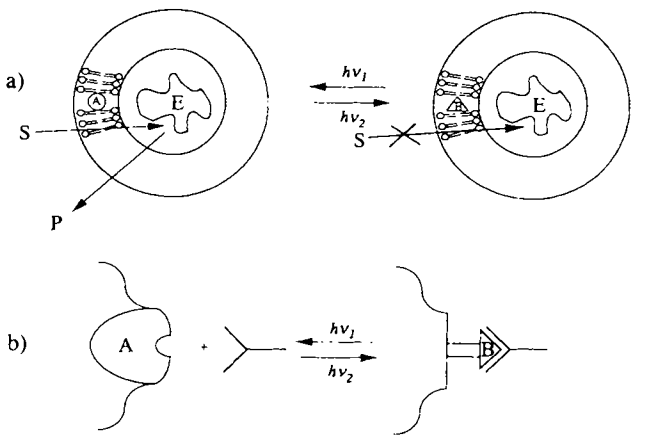

Fig. 11. Principles for photostimulation of a biomaterial's functions by photoisomerizable environments: a) "On-Off" activation of an enzyme by controlling permeability to the substrate (S) of a photoisomerizable liposome. P = product. b) Photoswitchable binding of an antibody to a photoisomerizable antigenic interface.

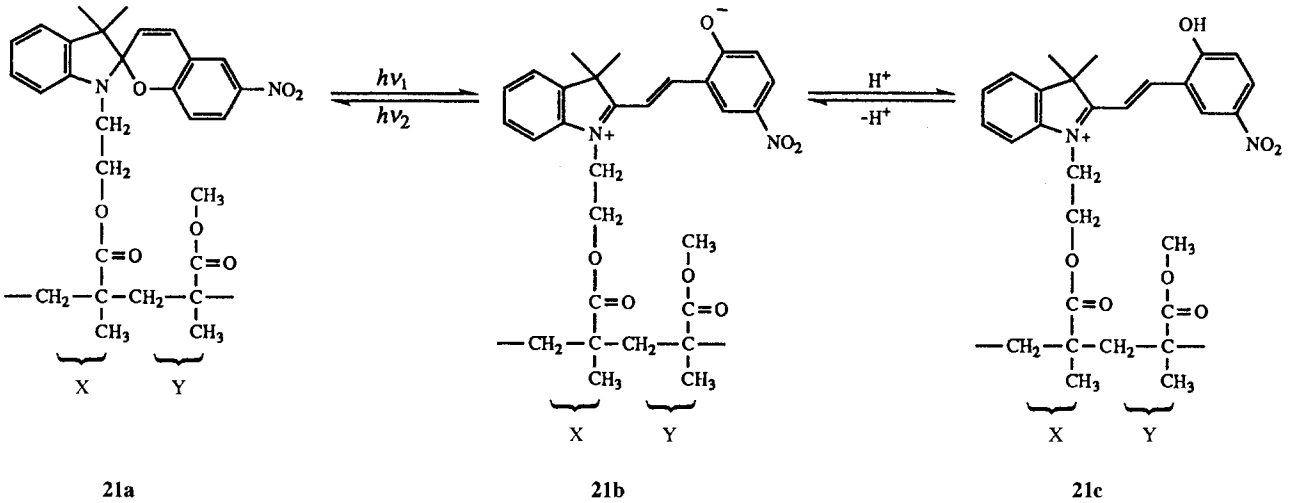
element towards the antibody. As a result, no binding interactions between the antibody and its surroundings exist. Photoisomerization of the environment to state B generates an antigenic interface, and binding of the antibody is switched on. Upon reversible photoisomerization to state A the antigen interface is perturbed, and the complex between antibody and the surrounding phase dissociates. In the following subsections the light-stimulated activation and deactivation of biomaterials by photoisomerizable environments will be discussed with particular emphasis on the practical implications of such systems.

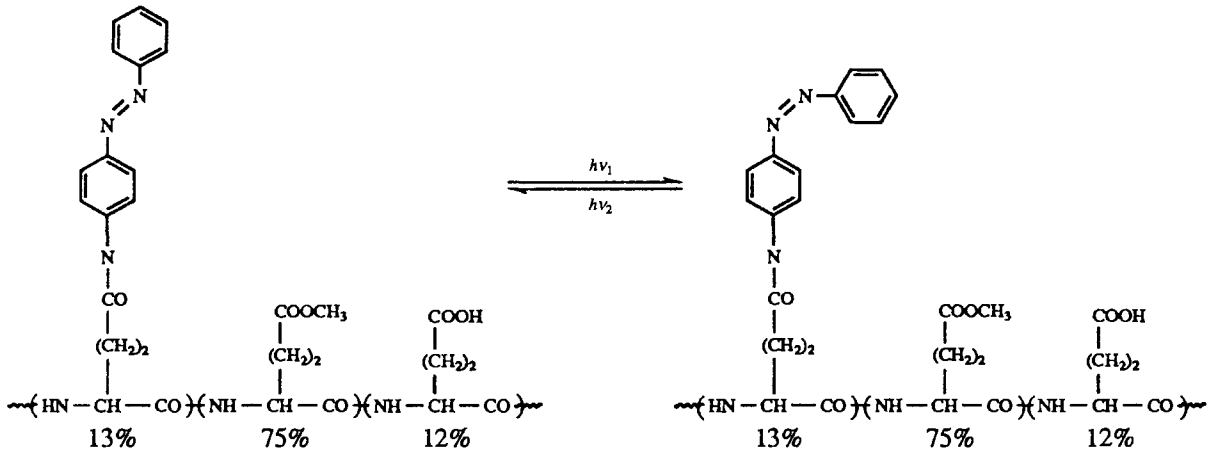
3.1. Light-Controlled Structure and Permeability of Membrane Mimetic Systems

Monolayers provide two-dimensional arrays that mimic membrane assemblies. Monolayers of poly(L-lysine) with 43% loading of azobenzene groups were prepared.[82] Exposure of the *trans*-azobenzene monolayer compressed to a pressure of 7 $mN\,m^{-1}$ to UV irradiation results in isomerization to the *cis*-azobenzene monolayer and a decrease in the monolayer surface pressure corresponding to $(1.8 \pm 0.2)\,mN\,m^{-1}$. On restoration of the *trans*-azobenzene monolayer by illumination with visible light the monolayer surface pressure increased reversibly. These changes in the monolayer surface pressure were attributed to the different structures of the monolayers: the *trans* isomer exhibits an extended structure of higher surface area, and the *cis* isomer exists in an α-helix monolayer configuration. Similar observations were made with spiropyran-modified poly(methyl methacrylate) (**21a**) monolayers.[120] Upon irradiation of this monolayer with UV light and isomerization of the monolayer to the merocyanine isomer, the monolayer surface pressure increases by $10^{-3}\,N\,m^{-1}$ and $0.3 \times 10^{-3}\,N\,m^{-1}$ at pH = 1.5 and pH = 5.5, respectively. Reversible photoisomerization to the spiropyran monolayer is accompanied by a decrease in the surface pressure to its original value. The pH dependence was attributed to the protonation of the photoisomerized spiropyran polymer. While at pH < 3 it exists as a protonated *o*-hydroxystyrylic cation (**21c**), at pH > 4 the zwitterionic merocyanine isomer (**21b**) is formed. It was also concluded that changes in the surface area are influenced by the location of the chromophores in the monolayer assembly. The charged chromophores of the isomer monolayers **21b** and **21c** are located close to aqueous subphase within the formed monolayer at the air–water interface, while the apolar spiropyran isomer (**21a**) is buried in the hydrophobic monolayer and does not contribute significantly to the surface pressure.

Control of the adhesion and the functions of vesicles was possible by the incorporation of a photoisomerizable polypeptide into the bilayer membrane of the vesicle.[121] Azobenzene-modified poly(γ-methyl-L-glutamate–co(L-glutamic acid)) (**22a**) was incorporated into the bilayer of distearyldimethyl-

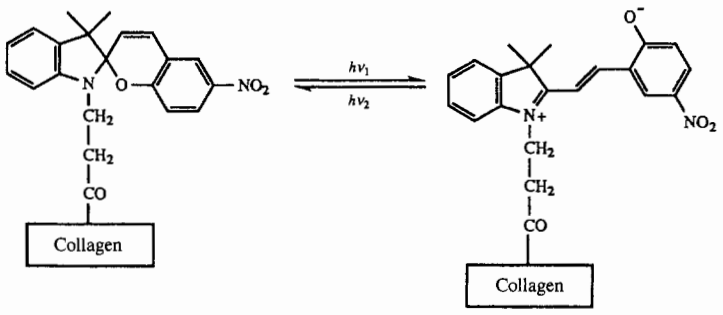


21a **21b** **21c**



22a **22b**

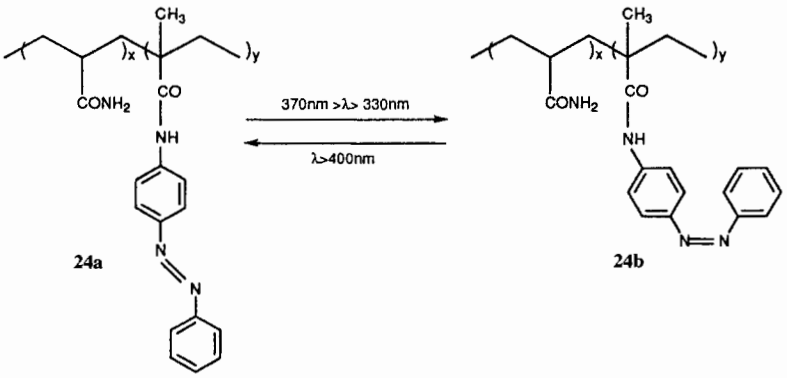
ammonium chloride vesicles. Upon photoisomerization of **22a** to the *cis* isomer **22b** the polypeptide chain translocated to the exterior hydrophilic subphase of the liposome. Upon photoisomerization of the *cis* isomer back to **22a** with visible light, the polypeptide did not reorganize to its interior boundary position, but retained its translocated position. In a vesicle assembly kept above the gel–liquid phase transition temperature, translocation of the *trans*-azobenene polypeptide **22a** into the interior part of the bilayer did occur, and upon cooling the reconstituted vesicles exhibited properties similar to the original vesicles. The positions and translocation of the polypeptide isomers **22a** and **22b** within the vesicles was characterized by following the polarity effects of the microenvironment on the emission of the fluorescence probe linked to copolymer **22** in the *trans*- and *cis*-configurations. Light-stimulated translocation of the cis-azobenzene-modified polypeptide **22b** has important effects on the vesicle's properties and functions. Adhesion between vesicles containing **22b** at the exterior boundary occurred, presumably through intervesicular interactions of the polypeptide chains. Permeation of ions across the vesicle boundary is controlled by the position of the photoisomerizable polypeptide. The vesicle membrane that includes the interlaced *trans*-polypeptide **22a** is permeable to Na^+, and the permeability to the ion decreases approximately fivefold upon photoisomerization to **22b** and translocation of the polypeptide chain to the exterior boundary of the bilayer. Dissociation of the intervesicular aggregates and restoration of the ion permeability properties of the vesicles was accomplished by photoisomerization of the polypeptide to state **22a** followed by heating the vesicle assembly to the gel–liquid phase transition temperature ($T_c = 40\,^{\circ}C$).



23a **23b**

membrane **23a**. The permeability of the membrane states **23a** and **23b** to the urea substrate is similar and cannot account for the different activities of the biocatalyst. It has been suggested that the enhanced activity of urease in the polymer **23b** originates from the faster release of the reaction product (NH_4^+) from the active complex in the polar isomeric state of the collagen membrane.

Control of the permeation of substrates across photoisomerizable polymers provides a general means to photostimulate polymer-entrapped enzymes (see Fig. 11a). The series of polymers **24**–**26** serve as macromolecular matrices for encapsulation



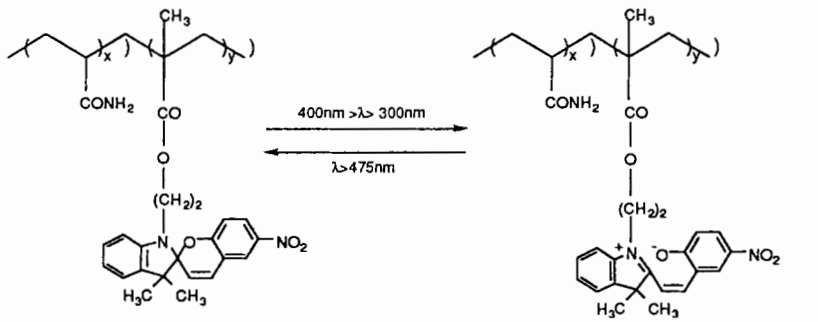
24a **24b**

3.2. Control by Light of Catalytic Functions of Biomaterials by Photoactive Environments

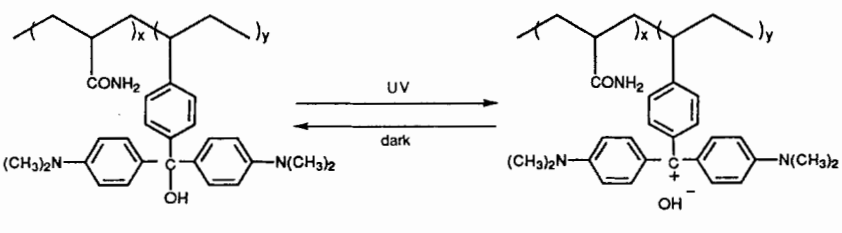
Attempts to affect protein functions by photoisomerizable environments were initiated by Balasurbamanian et al. as early as 1975, who studied the influence of model membrane systems containing photoisomerizable compounds on α-chymotrypsin activity.[122]

These investigations showed that addition of *trans*-4-carboxyazobenzene (**12**) to a microemulsion within a lamellar bilayer structure that contains α-chymotrypsin led to photochemically controllable enzyme activity. The biocatalyst activity was enhanced eightfold in the presence of *cis*-4-carboxyazobenzene. Although the origin of the photostimulation of α-chymotrypsin is not clear, it has been suggested that the photoisomerizable additive affects the lamellar bilayer structure. The photostimulation of α-chymotrypsin was attributed to different interactions of the enzymes with the light-controlled states of the bilayer membrane.

Immobilization of urease in a spiropyran-modified collagen membrane (**23**) led to light-controllable enzyme activity.[123–125] The biocatalyst decomposes urea within the merocyanine collagen membrane **23b** at a rate that is about twice that within the spiropyran

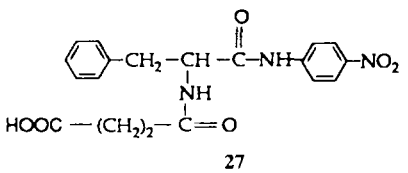


25a **25b**



26a **26b**

of α-chymotrypsin and its reversible photoactivation.[126-128] Figure 12 shows the rate of hydrolysis of *N*-(3-carboxypropionyl)-L-phenylalanine-*p*-nitroanilide (**27**) by α-chymotrypsin immobilized in the azobenzene-acrylamide copolymer **24** or in



27

the spiropyran-acrylamide copolymer **25**. At a polymer loading of 0.5 mol% azobenzene units, the hydrolytic activity of the immobilized enzyme is entirely blocked in the *trans*-azobenzene copolymer **24a** (Fig. 12A). Photochemical isomerization to the

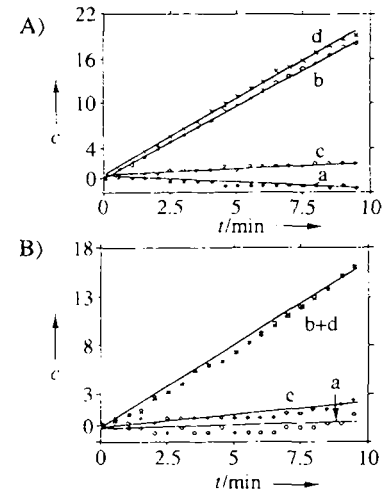


Fig. 12. Reversible photoactivation of α-chymotrypsin towards hydrolysis of **27** by immobilization in photoisomerizable polymers: A) Immobilization in polymer **24**. Curves a and c represent the rates of hydrolysis in **24a** generated by illumination with light of wavelength $\lambda > 400$ nm and curves b and d that in polymer **24b** generated by completing the cycle of illumination with light within the range 330 nm $< \lambda <$ 370 nm. B) Immobilization in polymer **25**. Curves a and c refer to **25a** (illumination at $\lambda > 475$ nm) and curves b and d to **25b** generated by completing a cycle of illumination (300 nm $< \lambda <$ 400 nm). c = concentration of product in 10^{-6} M.

cis-azobenzene copolymer **24** (330 nm $< \lambda <$ 370 nm) switches on the biocatalyst's activity ($V_{max} = 2$ mM min^{-1}). Photoisomerization of **24b** back to **24a** ($\lambda > 400$ nm) switches off the enzyme activity. The biocatalytic transformation is repeatedly switched "On" and "Off" by cyclic isomerization of the polymer between states **24a** and **24b**.

Similar results are observed for the spiropyran-acrylamide copolymer **25** (Fig. 12B). The enzyme activity is almost blocked in the copolymer **25a** that contains 0.12 mol% spiropyran units. In the copolymer state **25b** the activity of α-chymotrypsin is ten times higher ($V = 1.5$ μm min^{-1}). The "On–Off" photostimulated activation of the biocatalyst is fully reversible upon cyclic photoisomerization of the copolymer between states **25a** and **25b**.

Copolymer **26** does not undergo reversible photoisomerization. Upon illumination of **26a** the cationic copolymer state **26b** is formed, which relaxes *thermally* to the copolymer form **26a**. α-Chymotrypsin immobilized in copolymer **26a** loaded by 0.2 mol% of the photoisomerizable units is fully deactivated towards hydrolysis of **27**, whereas it reveals pronounced hydrolytic activity upon photoisomerization (330 nm $< \lambda <$ 370 nm) of the copolymer to state **26b** ($V = 1$ μM min^{-1}). Complementary flow-dialysis experiments, in which the permeability of the two isomeric states of polymers **24**, **25**, and **26** to **27** were examined, revealed that the photostimulated activities of α-chymotrypsin correlate with the permeability of the polymer membranes. That is, polymer states **24a**, **25a**, and **26a** exhibit poor permeability towards the enzyme's substrate, whereas the copolymer membranes in states **24b**, **25b**, and **26b** show effective permeability of the reaction substrates. It was suggested that the high dipole moment of *cis*-azobenzene units linked to copolymer **24b** (3.0 D vs. $\mu = 0$ for *trans*-azobenzene units), and the electrical charges associated with copolymer states **25b** and **26b** yield porous membrane assemblies because of electrical repulsion. Such pores facilitate permeation of the substrate **27** into the polymer and allow its transport to the enzyme's active site.

3.3. Photoswitchable Binding of Biomaterials in Photoisomerizable Environments

Photoisomerizable monolayers associated with surfaces provide organized two-dimensional membrane mimetic microenvironments in which the interactions of biomaterials with the monolayer and the base solid surface are controlled by light. Light-switchable interactions of antibodies with a photoisomerizable, self-assembled monolayers of antigens have been the basis for the development of reversible amperometric immunosensors.[129] Figure 13 shows the organization of a dinitrospiropyran monolayer electrode by self-assembly. The spiropyran monolayer can be reversibly photoisomerized between the monolayer states **28a** and **28b**. In a homogeneous phase, this monolayer exhibits high affinity for the anti-DNP-antibody, while the affinity of the merocyanine isomer **28b** for this antibody is poor. The switchable binding interactions of isomers **28a** and **28b** provide the foundation for an amperometric immunosensor electrode, and specifically a reversible amperometric immunosensor. In an electrochemical cell that includes a redox couple R^+/R (such as $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$) the spiropyran monolayer electrode (**28a**) gives an electrochemical response. Challenging the electrode with the DNP antibody resulted in the antibody's binding to the antigen monolayer and in the electrode's insulation towards the redox couple (Fig. 14). The amount of antibody interacting with the monolayer electrode and the extent of insulation of the electrode is dependent on the concentration of the antibody in solution. By appropriate calibration of the electrode's amperometric response as a function of antibody concentration, quantitative amperometric analysis of the antibody was achieved. In contrast to antigen electrodes that are single-cycle devices, the photoisomerizable properties of the antigen monolayer **28a** provide a means of regenerating the active antigen electrode. Photoisomerization of the antigen monolayer to state **28b** resulted in an interface with poor affinity towards the antibody, which could be washed off. The antibody-free monolayer electrode was then reisomerized to state **28a** and reactivated towards a second immuno-amperometric sensing cycle (Fig. 15, top). Figure 15 (bottom) shows the

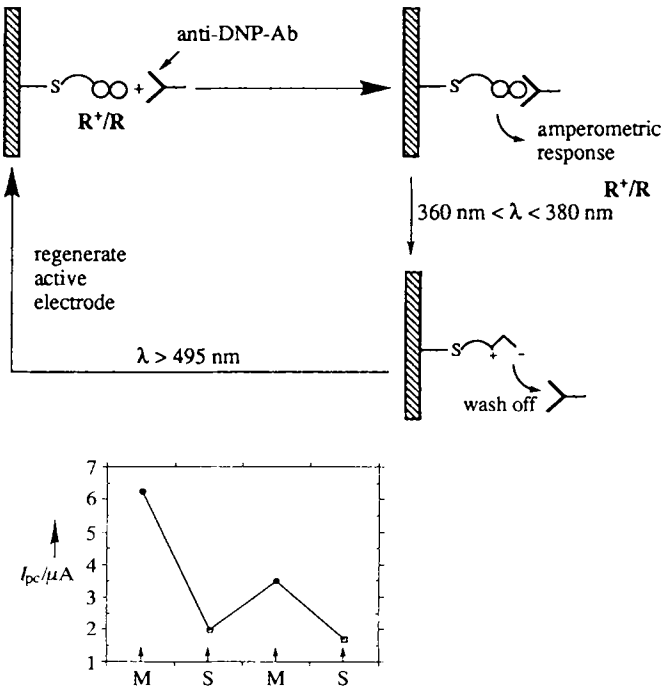

Fig. 15. Top: Principles for the application of the dinitrospiropyran-modified monolayer electrode for reversible amperometric analysis of the antibody anti-DNP-Ab. Bottom: Reversible amperometric response of the monolayer electrode (**28** as monolayer) in the presence of 1.5 mM anti-DNP-Ab. ■ electrode in **28a** state (S, generated by irradiation at $\lambda > 495$ nm); ● electrode in **28b** state (M, generated by irradiation in the range 360 nm $< \lambda <$ 380 nm). Electrodes were washed prior to each measurement.

reversible operation of the dinitrospiropyran/merocyanine monolayer electrode in the amperometric detection of anti-DNP-antibody. Initially, the electrode in state **28b** is challenged with the antibody. Due to poor interaction with the monolayer, the electrode is not insulated and gives rise to a high amperometric response. Photoisomerization to state **28a** yields the active antigen surface that binds the DNP antibody, which insulates the electrode and decreases its amperometric response. Subsequent photoisomerization of the electrode to state **28b** releases the antibody and enhances the electrode's electrochemical response.

The changes in potential at an electrode modified by a photoisomerizable polymer matrix were used to probe antibody–antigen interactions. Carboxyl-substituted polyvinyl chloride was applied as a coating polymer membrane on a glassy-carbon electrode. Into this polymer were incorporated 2,4-dinitrophenyldecylamine and spiro(2*H*-1-benzopyran-2,2'-indoline) (**29a**).[130] The latter component turned the polymer into a photoisomerizable membrane assembly. The electrode potential is sensitive to the photoisomeric state, and upon light-induced isomerization of state **29a** to the merocyanine isomer **29b**, the electrode potential increased by about 120 mV. Figure 16A shows the reversible light-stimulated potential switches of the electrode upon cyclic photoisomerization of **29a** to **29b** and back. Introduction of the anti-dinitrophenyl-BSA antibody to the system consisting of the electrode coated with the polymer membrane in state **29b** (high electrode potential) results in a decrease in the electrode potential (Fig. 16B). At an antibody concentration corresponding to 15 mg ml^{-1} the electrode potential drops by about 100 mV. The decrease in the electrode potential is dependent on the DNP-antibody concentration and hence provides a quantitative measure for the antigen–antibody interactions. The decrease of the electrode potential upon association of the antibody to the antigen membrane-coated elec-

trode was attributed to the perturbation of the electrolyte gradient at the polymer-solution interface as a result of the antibody adsorption. The electrode could be reused by washing off the adsorbed antibody in a pure electrolyte solution.

Light-controlled association of cytochrome c (Cyt. c) to a photoisomerizable monolayer membrane associated with an electrode is of specific relevance to the vision process.[131] A mixed monolayer consisting of pyridine units and nitrospiropyran photoisomerizable components was assembled on an Au electrode surface (Fig. 17). The pyridine units act as promoting site that associates Cyt. c to the monolayer interface. Association of Cyt. c to the monolayer facilitates electrical communication between the redox center of the heme of Cyt. c and the electrode. Photoisomerization of the monolayer results in the protonated nitromerocyanine mixed monolayer. Electrostatic repulsion of the positively charged Cyt. c from the monolayer blocks the electrical communication between Cyt. c and the electrode surface. Recording of cyclic optical signals by the monolayer is transduced into amperometric responses as a result of "On–Off" photostimulated electrical communication between Cyt. c and the electrode (Fig. 18). Amplification of the transduced amperometric signal is observed upon coupling the light-stimulated electrical communication of Cyt. c to an enzymatic

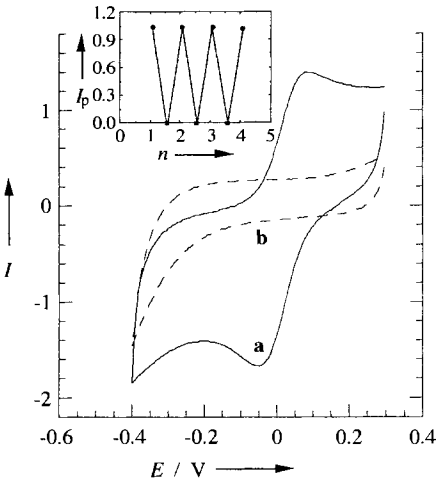

Fig. 18. Photostimulated electrical communication of cytochrome c with the photoisomerizable mixed pyridine monolayer electrode in a) the SP state and b) the MRH^+ state (see Fig. 17). transformation. In the pyridine–nitrospiropyran monolayer electrode state, electrical communication between Cyt. c and the electrode is maintained. Reduced Cyt. c was coupled to the reduction of cytochrome c oxidase (COX) that biocatalyzed the reduction of molecular oxygen. The enzymatic transformation regenerates the electrical interaction of Cyt. c with the electrode, and the optical signal triggering the electron transfer is amplified. The enzymatic cascade is alternately activated and blocked through photoisomerization of the monolayer and control of the primary electrical interactions of Cyt. c with the electrode

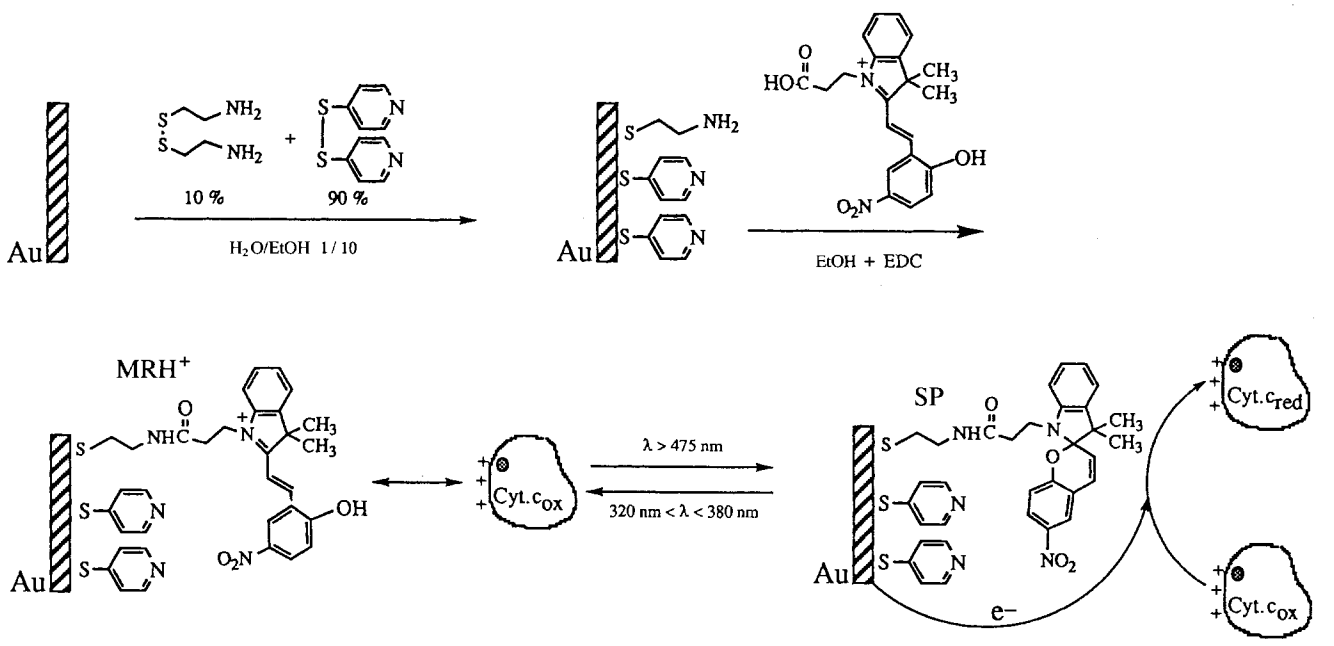

Fig. 17. Organization of a mixed nitrospiropyran/nitromerocyanine–pyridine monolayer on an Au electrode.

(Fig. 19). This system resembles features of the vision process:[132] isomerization of the protein-bound 11-*cis*-retinal transforms the protein into an appropriate conformation that binds the G-protein. The associated G-protein triggers an enzymatic cascade, which ultimately yields c-GMP that activates the neural response. In the example presented above, the mixed monolayer associated with the electrode controls the binding of Cyt. c to the photoisomerizable membrane. Binding of Cyt. c to the monolayer results in electrical communication with the electrode and triggers an enzymatic cascade that reduces oxygen. The optical signal is amplified by the enzymatic cascade and transduced by an electrochemical amperometric output.

The inset shows amperometric transduction of the optical signals recorded by the monolayer. I in μA; n = number of cycles.

4. Summary and Outlook

We have presented an overview on the scientific progress in the development of reversible photobiological switches. Two general methodologies to transform bioactive materials into light-regulated assemblies were discussed. One approach involved the chemical modification of the biomaterial by means of synthetic photoisomerizable components. In this approach the two photoisomeric states of the photoreceptor stimulate "On–Off" activities of the biomaterial. That is, in one photoisomeric state the biomaterial retains its bioactive structure and its biological function switched on, while in the complementary photoisomeric state the biomaterial structure is distorted and consequently switched off towards its bioactivity. The second methodology to photostimulate biomaterials involved its entrapment in a photoisomerizable environment. Control of the physical properties of the photoisomerizable matrix such as membrane permeability, phase viscosity, or local electrical potential, have led to activation and deactivation of the immobilized biomaterial by light. Development of such artificial photobiological switches represents a scientific effort to mimic photoswitchable biological systems in nature, like the process of vision. Photobiological switches can therefore be viewed as the chemist's approach to transforming bioactive materials into "intelligent" new materials whose function responds to external light signals.

Potential applications of photoswitchable biomaterials in the tailoring of targeted light-activated bioactive drugs, the design of reversible biosensors, and the organization of light amplification devices have been discussed. Future goals include the challenge of applying photoswitchable biomaterials as bioelectronic devices. The recording of an optical output by a biochemical transformation is undesirable for practical reasons. Nonetheless, the progress in electrical communication of redox protein with electrodes[133–136] and the novel techniques to organize biomaterials as self-assembled monolayers on electrode surfaces[136–138] imply that optical recording by photoswitchable biomaterials and electrochemical read-out of the information is an attractive path to follow. Indeed, the recently reported amperometric transduction of recorded optical signals by photoisomerizable redox proteins[107] and by photoisomerizable monolayer coupled to redox proteins[131] demonstrated the viability of this approach. It is envisaged that photoswitchable biomaterials will find extensive use in the future for information storage, recording, and transfer. Clearly, photoswitchable biomaterials offer exciting perspectives at the frontiers of chemistry, biology, physics, medicine, and materials science.

The research project on photobiological switches is supported by a grant from the Ministry of Science and Technology, Israel, and the Commission of the European Union.

Nonstabilized Alkyl Complexes and Alkyl-Cyano-Ate Complexes of Iron(II) and Cobalt(II) as New Reagents in Organic Synthesis**

Thomas Kauffmann*

Alkyl transition metal reagents are being increasingly used for alkylations in organic synthesis. They have various advantages over alkyllithium and alkylmagnesium reagents including higher selectivity, lower basicity, and as long as the transition metal is not in its highest oxidation state—their willingness to undergo oxidative addition with electrophiles. Alkyl derivatives of Fe^{II} and Co^{II}, which are not stabilized by special ligands but still can be easily handled, are in many cases superior to the well-known alkyl-Cu^{I} and -Mn^{II} reagents and can also undergo unexpected reactions. The introduction of alkyl-cyano-ate complexes of Fe^{II} and Co^{II}, the cyanide ligands of which (in contrast to neutral π-acidic ligands) do not reduce the reactivity, has led to further advances. Reaction mechanisms will be discussed and comparisons will be made with alkylating reagents containing Cu^{I}, Mn^{II}, Ni^{II}, or Ti^{IV} as well as with Pd-catalyzed coupling reactions. Furthermore, it will be shown that super-ate Fe^{II} complexes are almost certainly the reactive species in highly selective catalytic alkylations.

Keywords: alkylations · catalysis · cobalt compounds · iron compounds

1. Introduction

Collman's reagent $Na_2[Fe(CO)_4]$ and its half-sandwich analog $Na[Fe(C_5H_5)(CO)_2]$ react with alkyl halides by oxidative addition to afford alkyl-Fe^{II} compounds (e.g. $[(C_5H_5)(CO)_2FeEt]$, which are stabilized by π-acidic ligands and are useful reagents for C–C bond formations.[2] Prior to the investigations reported herein little was known about alkyl-Fe^{II} reagents that contain no stabilizing ligands or about analogous Co^{II} compounds. After various unsuccessful or questionable attempts had been made by other authors to obtain "homoleptic" alkyl derivatives of Fe^{II} and Co^{II}, Berthold et al.[3] described the isolation of $[Me_4FeLi_2(Et_2O)_2]$ and $[Me_4FeLi_2(dioxane)_{1.25}]$ in 1973, while in 1975 Wilkinson et al.[4] obtained $[Me_4CoLi_2(tmeda)_2]$ (TMEDA = tetramethylethylenediamine). Some years earlier Corey and Posner[5] had synthesized the complexes R_3FeLi (R = Me, *n*Bu) and Me_3CoLi in situ by transmetalation of FeI_2 and CoI_2 and had established that Me_3FeLi undergoes cross-coupling reactions in good yields with (*E*)-1-iodo-1-nonene, (*E*)-β-bromostyrene, and (*E*)-1-bromocyclohexene but does not react with alkyl halides. As far as Me_3CoLi is concerned, they stated that "the predominant course of reaction with most of the halides was via metal–halogen replacement; a predominance of the cross-coupling was only observed with vinyl bromides and iodides." Perhaps mainly because of the incorrect statement[5] that nBu_3FeLi, which in contrast to Me_3FeLi is potentially able to undergo decomposition by β-elimination, is unsuitable for cross-coupling reactions and the fact that Corey and Posner used their reagent Me_3FeLi in an unnecessary fivefold excess, the synthetic potential of the reagents R_3MLi (M = Fe, Co) was apparently considered to be very low in comparison with that of alkyl cuprates.[6] In contrast to the R_3MnLi reagents, also first introduced by Corey and Posner,[7] they remained unused for many years.

In 1983, as part of a broad comparative study of alkyl transition metal reagents, members of the author's research group commenced their studies of alkyl derivatives of Fe^{II} and Co^{II} that are not stabilized by special ligands. The low thermal stabilities of these reagents were not considered to be a disadvantage, since low temperatures are generally required for selective reactions. Since the stability of the divalent state of the middle and late 3d elements has its minimum at Fe^{II} [Mn^{II} (half-filled 3d shell) > Fe^{II} < Co^{II} < Ni^{II})[8]], it seemed likely that alkyl-Fe^{II} reagents would be particularly tolerable of the oxidative addition of electrophiles and thus offer advantages over other similar reagents.

2. Synthesis and Characterization of Fe and Co Reagents

2.1. Reagents with Simple Alkyl Groups

The Fe and Co reagents that we have used were usually obtained in situ by transmetalation of alkyllithium compounds

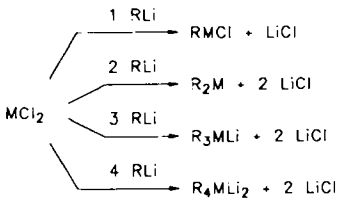
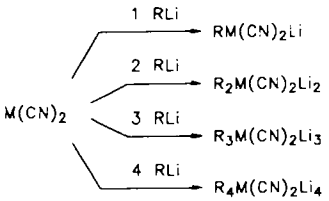
[**] Alkyliron and Alkylcobalt Reagents, Part 11. Part 10: ref. [1].

with $FeCl_2$,[9, 10] $CoCl_2$,[11, 12] $Fe(CN)_2$,[1] or $Co(CN)_2$[1] according to Schemes 1 and 2. In some cases Grignard reagents were also subjected to transmetalations. It was possible to use either pure $[FeCl_2(thf)_{1.5}]$[13] or to prepare $FeCl_2$ in situ by reducing[14] $FeCl_3$ with one equivalent of MeLi at $-78\,^{\circ}C$. Pure $CoCl_2$ is commercially available, while $Fe(CN)_2$ and $Co(CN)_2$ can be obtained preparatively.[1] No methane or ethane is set free in reactions carried out according to Schemes 1 and 2 (in contrast to the reaction of MeLi with $FeCl_3$), so that apparently



Scheme 1. R = Me, *n*Bu, *n*-octyl, cyclopropyl; M = Fe, Co.



Scheme 2. R = Me, *n*Bu; M = Fe, Co, Ni.

reduction to the M^I or M^0 state is not involved. As far as reactivity and selectivity is concerned there is no difference between the isolated complexes $[Me_4FeLi_2(Et_2O)_2]$[3] and $[Me_4CoLi_2(tmeda)]$[4] referred to above and the $[Me_4ML_{i2}(thf)_n]$ (M = Fe, Co) complexes prepared in situ. Thus, there is no advantage in using the isolated complexes. The formulae in Schemes 1 and 2 are based solely on the stoichiometry of the reactants. Since LiCl is formed in the in situ syntheses carried out according to Scheme 1, this salt may possibly form complexes with the alkyl transition metal compounds. Thus, for example the hetero-ate complexes $Me_2Co(Cl)Li$ or $Me_2Co(Cl)_2Li_2$ might be present rather than simply Me_2Co; this must be taken into account in mechanistic discussions. The hetero-ate complexes "$Me_3M(CN)_2Li_3$" and "$Me_4M(CN)_2Li_4$" (M = Fe, Co), obtained according to Scheme 2, are in fact probably compounds of the type $Me_2M(CN)_2Li_2$ containing one or two equivalents of MeLi[1] (see below). Further hetero-ate complexes of Fe^{II} are dealt with in Section 4.5 and Scheme 26.

The *β-bromostyrene–ketone test*[9-11] can be applied to determine whether the organolithium reagent has been completely used up in transmetalation reactions carried out according to Scheme 1: equimolar amounts of β-bromostyrene and a ketone are added, and gas chromatography is used to check whether only the styrene derivative has been alkylated; see Section 3.1.1. The *aldehyde–ketone test*[14] also gives reliable results (equimolar amounts of an aldehyde and a ketone are added, and gas chromatography is used to determine whether only the aldehyde has undergone alkylation). Neither test can be used if the transmetalations are carried out according to Scheme 2, either because free MeLi is present in the reaction mixture or because the cyano-ate complexes formed are strongly nucleophilic towards ketones. In these cases the transmetalation becomes evident from the resulting change in selectivity (see Section 4.1).[11] Schemes 1 and 2 are a considerable simplification of the reaction processes, since in each case only a single product is stated to result from the transmetalation step. In fact several alkyl- or cyano-ate complexes can be formed in each case and can undergo rapid interconversion. Which species in fact actually reacts can be proposed from the stoichiometry but not determined with certainty, since no relevant studies have been carried out.

As in the case of the alkyl–Mn^{II} compounds,[7] the thermal stability of the alkyl derivatives of Fe^{II} and Co^{II} (Scheme 3)[10, 11] decreases in the series $R_3MLi > RMCl > R_2M$. The hypothetical cyano-ate complexes of Fe^{II} (black

MeFeCl	Me_2Fe	Me_3FeLi	Me_4FeLi_2	nBu_4FeLi_2

Scheme 3. Approximate decomposition temperature [°C] of the reagents in THF.

suspension) and Co^{II} (blue suspension) depicted in Scheme 2 do not change color on warming to 0 °C. Since no gases are liberated under these conditions the reagents appear to be stable up to 0 °C. In the case of the *n*-butyl-cyano-ate complexes this indicates an increase in their stability compared to that of nBu_4MLi_2 (M = Fe, Co). Thus cross-coupling reactions can be carried out with $nBu_2Co(CN)_2Li_2$, although not with nBu_4CoLi_2 (see Section 3.3).

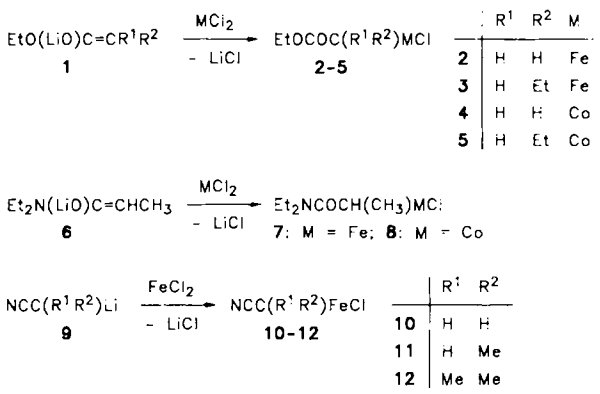
The paramagnetism of the solutions obtained according to Scheme 1 prevented NMR measurements. It was also not possible to obtain crystals of the isolated complex $[Me_4FeLi_2(Et_2O)_2]$[1] that were suitable for X-ray crystallographic analysis. It has been shown, however, that the iron atom

Thomas Kauffmann was born in Reutlingen in 1924, studied at the Universität Würzburg, carried out research and taught at Technische Hochschule Darmstadt, and has been a Professor for Organic Chemistry at the Universität Münster since 1965 (Emeritus Professor in 1990). His main research interests have focused on sodium hydrazide as a reagent in organic synthesis, hetarynes, homocoupling by organocopper compounds, 1,3-anionic cycloaddition, preparative application of the areno-analogy principle, organoelement–lithium reagents and organo transition metal reagents for organic syntheses, chele- and anticheleselectivity, and the additive ARCD reductive carbonyl dimerization (reaction).

in $[(1\text{-naphthyl})_4FeLi_2(Et_2O)_2]$ is in an octahedral environment; the two ether ligands occupy equatorial positions (X-ray structure analysis).[15] The cyano-ate complexes of Fe and Co, which were obtained as paramagnetic suspensions, provided no analyzable NMR and IR spectra. The corresponding Ni compounds, which can be obtained from $Ni(CN)_2$ as diamagnetic solutions according to Scheme 2, exhibit IR spectra with a strong vibration at 2047 cm^{-1}, which is attributed to cyano groups bonded to Ni. ^1H and ^{13}C NMR spectra of solutions of "$Me_4Ni(CN)_2Li_4$" reveal the presence of free MeLi as well as of two different types of methyl group bonded to nickel. This, together with the diamagnetism of the solution, indicates the presence of *cis and trans* isomers of the square-planar anion $[Me_2Ni(CN)_2]^{2-}$.[1]

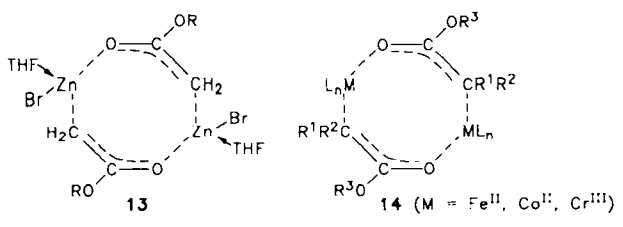
2.2. Reagents with Functionalized Alkyl Groups

The α-transition metalated carboxylates **2**–**5**,[16] *N*,*N*-diethylcarboxamides **7** and **8**,[17o] and cyanides **10**–**12**[18] were synthesized in situ according to Scheme 4. The transmetalation



Scheme 4.

of the lithium enolates **1** cannot be checked by using the Gilman test with Michler's ketone,[19] the aldehyde–ketone test,[14] or the β-bromostyrene–ketone test,[10] but is evident from the anticheleselectivity (see Section 4.1.2) of the transmetalation products **2**–**5** and from a shift of the band at about 1650 cm^{-1} to about 1600 cm^{-1} in the IR spectrum. The carbonyl band of the Reformatsky reagent **13**[20] also lies at about 1600 cm^{-1}, thus suggesting the presence of an analogous dimeric structure (**14**) for **2**–**5**. An additional argument for structure **14** is the appearance of a carbonyl band at about 1600 cm^{-1} observed for the Cr^{III} reagent formed by oxidative addition of ethyl α-bromobutanoate to two equivalents of $CrCl_2$.[16] The transmetalation of **6** and **9** according to Scheme 4 is demonstrated by the change in



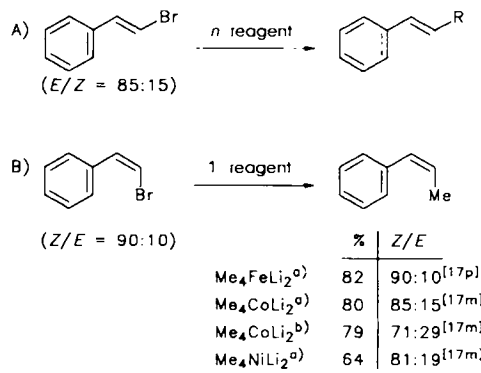
selectivity (see Section 4.1), and in the case of **9** also by the shift of the CN band in the IR spectrum from 2051 to 2190 cm^{-1}. Because of their anticheleselectivity (see Section 4.1.2) it is assumed that the reagents **7**, **8**, and **10**–**12** are aggregated in THF.[17o, 55]

3. Cross-Coupling with Organic Halides and Triflates[*]

3.1. 1-Alkenyl Halides and Triflates

3.1.1. 1-Alkenyl Bromides

Methyl derivatives of Fe^{II} and Co^{II} appear likely to become important reagents for stiochiometric cross-coupling reactions with 1-alkenyl halides. In this respect they are certainly superior to the Gilman reagent Me_2CuLi and the methylmanganates Me_3MnLi and Me_4MnLi_2, since unlike Me_2CuLi they do not need to be used in excess but can be employed in less than stoichiometric amounts, while unlike the methylmanganates they react rapidly at −78 °C. A comparison of the activity of Me_4FeLi_2 in cross-coupling with (*E*)-β-bromostyrene with that of Me_2CuLi and methylmanganates has been reported.[10] Me_4CoLi_2 is as good as Me_4FeLi_2 for the methylation of (*E*)-β-bromostyrene; however, Me_4FeLi_2 is more efficient with respect to functionalized 1-alkenyl bromides (Table 1).[11, 12] The



Scheme 5. A) Conditions and results of reactions from Scheme 5A: see Table 1. B) a) THF, 1 h, −78 °C; b) THF, −78 to 20 °C in 18 h.

Table 1. Cross-coupling with (*E*)-β-bromostyrene (*E*:*Z* = 85:15) according to Scheme 5A [17p] (n.d. = not determined).

n Equiv reagent	Product yield [%]	*E*:*Z*	Substrate recovered [%]
1 Me_4FeLi_2 [a]	92	90:10	0
0.5 Me_4FeLi_2 [b]	80	88:12	10
0.5 Me_4CoLi_2 [b]	91 [c]	85:15	<1

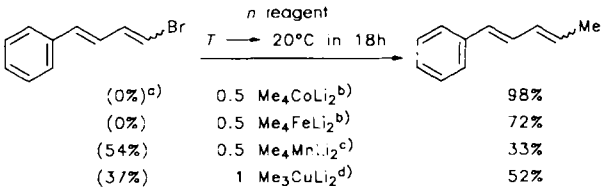
[a] THF; −78 °C (0.5 h). [b] THF, −78 to 20 °C in 18 h. [c] These results: ref. [11]. [d] Et_2O, −40 °C (0.5 h).

[*] Triflate = trifluoromethanesulfonate.

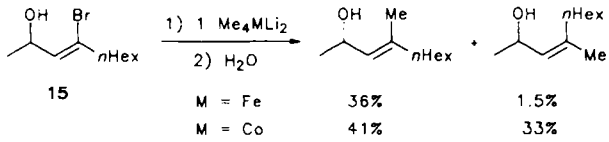
cyano-ate complexes $Me_2Fe(CN)_2Li_2$ and $Me_2Co(CN)_2Li_2$ have comparable methylation activity, as shown in 1:1 reactions with α-bromostyrene[11] (yield of α-methylstyrene with $Me_2Fe(CN)_2Li_2$: 89% in ether and 69% in THF; in comparison, yield with 0.5 equivalents of Me_4FeLi_2: 82% in THF).[17p] The iron complexes also give good results in the *n*- and *s*-butylation of (*E*)-β-bromostyrene (Table 1). In the cross-coupling with (*E*,*Z*)-1-bromo-4-phenyl-1,3-butadiene to give (*E*,*Z*)-1-phenyl-1,3-pentadiene both Me_4FeLi_2 and Me_4CoLi_2 give considerably better results than Me_3CuLi_2 and Me_4MnLi_2[17p] (Scheme 6; reaction conditions optimized in each case), while



Scheme 6. a) Recovery; b) THF, $T = -78$ °C; c) Et_2O, $T = 0$ °C; d) THF, $T = 0$ °C. See also ref. [17p].

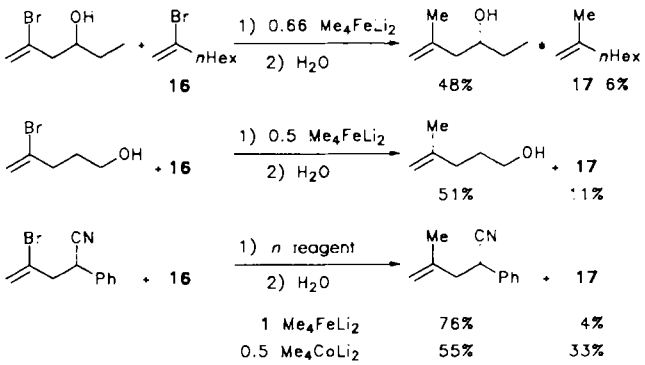
β,β-dibromostyrene reacts with one equivalent of Me_4FeLi_2 (THF, 1 h, −78 °C)[17p] or with Me_2CuLi (Et_2O, 3 h, −80 °C),[21] to give medium yields (43 and 40%, respectively) of β,β-dimethylstyrene (for the probable mechanism see Scheme 22). The *n*-octylation of a 1-alkenyl bromide is shown in Scheme 9. The Fe and Co derivatives of functionalized alkanes obtained according to Scheme 4 are unexpectedly found to be inactive towards 1-alkenyl bromides[17f, 17a] (cf. Section 4.1.4).

Stereoselectivity: As in the case of the cross-couplings with (*E*)-β-bromostyrene (Table 1), those with (*Z*)-β-bromostyrene (Scheme 5B) occur with predominant retention of configuration. One exception is provided by the reaction of Me_4CoLi_2 with (*Z*)-β-bromostyrene in which the reaction mixture was allowed to warm from −78 to 20 °C (Scheme 5). A mechanistic interpretation of the more pronounced reversal of configuration in the reaction of Me_4CoLi_2 with the β-hydroxyalkenyl bromide **15** (Scheme 7) has been reported.[12]



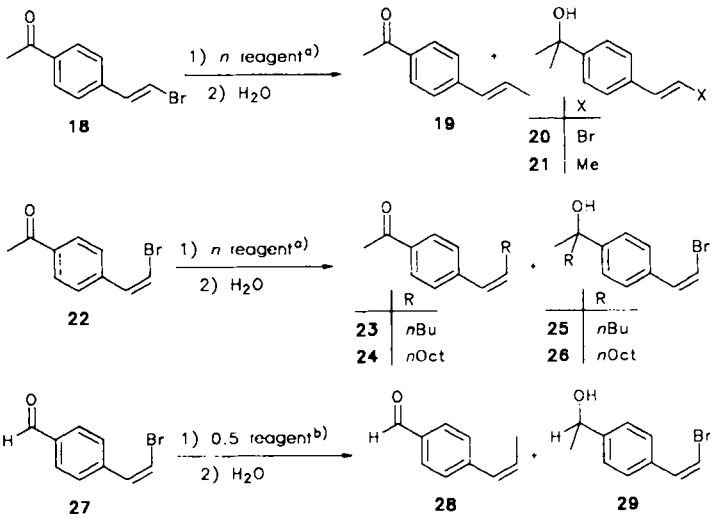
Scheme 7. Different stereoselectivities of Me_4FeLi_2 and Me_4CoLi_2 [12]. Reaction conditions: −78 °C (0.5 h) to 20 °C in 18 h.

Chemoselectivity and Neighboring Group Effects: alkyl-Fe^{II}[9, 10] and methyl-Co^{II} reagents[11] exhibit a high *aldehyde-versus-ketone selectivity* in competition experiments. Since this is also valid for $Me_3Ni(MgBr)$,[17m] this type of selectivity[8, 14] has now been demonstrated for alkyl derivatives of all the 3d metals. At −78 °C the reagents R_4FeLi_2 (R = Me, *n*Bu, *n*-octyl, cyclopropyl) and Me_4CoLi_2 react exclusively or almost exclusively with the bromide when treated with a 1:1 mixture of (*E*)-β-bromostyrene and 4-methyl-2-pentanone, while alkyllithium or alkylmagnesium reagents attack only the ketone. This result enables confirmation of transmetalation reactions carried out according to Scheme 1 with the help of the *β-bromostyrene–ketone test*,[9, 10] although this test cannot be applied to the cyano-ate complexes prepared according to Scheme 2.[1] Me_4CoLi_2, in fact, methylates (*E*)-β-bromostyrene much faster than benzaldehyde in competition experiments: when 0.5 equivalents of the reagent in THF were allowed to react at −78 °C, (*E*)-β-methylstyrene was formed in 97% yield and 1-phenylethanol in only 17% yield.[17m] In alkylation of ketones with transition metal reagents, basic groups α or β to the keto group exert a reaction-promoting neighboring group effect that leads to highly selective alkylations ("*cheleselectivity*").[22] Corresponding effects (for a mechanistic interpretation see reference [23]) of basic groups (OH, OMe, NEt_2, NH-*n*-C_6H_{13}, CN) in the α-, β-, or γ-position to the bromine atoms in 1-alkenyl bromides are observed in intermolecular competition experiments carried out with Me_4FeLi_2 (Scheme 8) and R_4MnLi_2 (R = Me, *n*Bu).[23] Me_4CoLi_2 is much too reactive for highly selective reactions of this type (Scheme 8 bottom), and Me_2CuLi is completely deactivated by the functionalized 1-alkenyl bromides. Thus, the reagents Me_4FeLi_2 and R_4FeLi_2 appear to have an important preparative potential.



Scheme 8. Cheleselective cross-coupling [23]. Reaction conditions: THF, −78 to 20 °C in 1 h. Details of the substrate recovery see ref. [23].

Regioselectivity: As expected from the results of the competition experiments with two substrates, the compounds **18**, **22**, and **27**, which contain two competing reactive groups, are alkylated in cross-coupling reactions with a high degree of regioselectivity and with retention of configuration (Scheme 9, Table 2).



Scheme 9. Regioselective cross-coupling (*n*Oct = *n*-octyl) [17j,m]. Reaction conditions: a) THF, −78 to 20 °C in 18 h; b) THF, −78 °C, 1 h; Yields: Table 2.

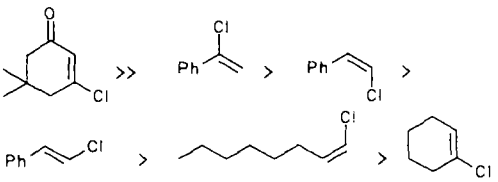
Table 2. Regioselective alkylation of **18**, **22**, and **27** according to Scheme 9 [17j,m].

n Equiv reagent	Yield [%]		Recovered [%]
	19	**20**	**18**
1 $Me_3FeMgBr$	87	3	7
1 Me_2Co	85	0	5
0.5 Me_4CoLi_2	96	0	0
1 $Me_3MnMgBr$	25	20 [a]	15
	23/24	**25/26**	**22**
1 nBu_2Fe	57	0	0
1 $nOct_2Fe$	54	0	30
1 $nOct_4FeLi_2$	78	0	0
	28	**29**	**27**
0.5 Me_4CoLi_2	56	0	17

[a] In this case the dimethylation product **21** is formed in 21% yield. In all other cases no dialkylation product is formed.

3.1.2. 1-Alkenyl Chlorides, Fluorides, and Triflates

Several methods for cross-coupling involving 1-alkenyl chlorides have been described; the more effective of these are catalytic in nature (for a review see ref. [24]). The Pd-catalyzed Stille and Suzuki couplings (see Section 3.8) are apparently not possible for 1-alkenyl chlorides and fluorides; in the other catalytic methods the reaction mixture contains free alkyllithium or alkylmagnesium compounds, which can lead to unselective alkylation if the substrate contains an additional electrophilic group apart from the 1-alkenyl chloride functionality. Me_4FeLi_2, Me_4CoLi_2, and Me_3CoLi, which, in contrast to Me_3CuLi_2,[25] are not in equilibrium with MeLi according to the β-bromostyrene–ketone test (see Section 3.1.1), have shown themselves to be suitable reagents for cross-coupling reactions with *1-alkenyl chlorides* (yields 68–99%).[24] In the case of (*Z*)-1-chloro-1-octene, Me_3CoLi couples with complete retention, Me_4CoLi_2 with partial inversion of configuration, and the higher ate-complex Me_5CoLi_3 with complete inversion of configuration.[17k] In competition experiments Me_4FeLi_2 is able to differentiate better between different 1-alkenyl chlorides than Me_3CoLi or Me_4CoLi_2. The variation in the electrophilic character of 1-alkenyl chlorides towards Me_4FeLi_2, Me_4CoLi_2, and Me_3CoLi is shown in Scheme 10.[24] Me_4FeLi_2 methylates



Scheme 10. Variation in electrophilicity of alkenyl chlorides towards Me_4FeLi_2, Me_4CoLi_2, and Me_3CoLi.

(*E*,*Z*)-4-(2-chlorethenyl)benzyl chloride almost exclusively at the chloroethenyl functionality, while with Me_2CuLi virtually only the chloromethyl group is attacked.[24]

While Me_2CuLi is completely inert towards (*Z*)-β-fluorostyrene,[26] cross-coupling between (*E*,*Z*)-β-fluorostyrene and Me_4CoLi_2 or Me_4FeLi_2 occurs in 92 and 59% yield, respectively.[24] 1-Fluoronaphthalene, which because of the high double-bond character of the α,β-bond of the naphthalene system can be considered as an alkenyl fluoride, can be methylated in good yield by Me_4CoLi_2 (see Section 3.3). In an important alkene synthesis ketones are transformed to 1-alkenyl triflates, followed by a cross-coupling with alkyl cuprates.[27] It is thus of interest that Me_4FeLi_2 gives better yields in cross-coupling with 1-alkenyl triflates than the particularly reactive cuprate Me_3CuLi_2 or Me_4CoLi_2 and Me_4MnLi_2 (Scheme 11).[17p]

		R = Ph	R = *n*Hex
0.5	Me_4FeLi_2 [a]	82%	98%
0.5	Me_4CoLi_2 [a]	75%	78%
0.5	Me_4MnLi_2 [b]	58%	
1	Me_3CuLi_2 [c]	69%	82%

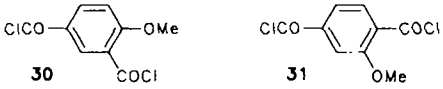
3.2. Acyl Chlorides

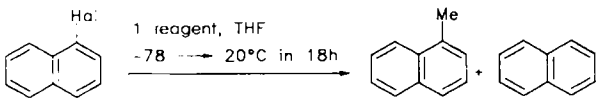
An important application of alkyl transition metal complexes is the transformation of acyl chlorides to ketones without the subsequent reaction to tertiary alcohols. Alkyl–Mn^{II} compounds are regarded as reagents that are particularly suitable for such ketone syntheses.[7] As is shown by the generally high yields obtained in reactions between *monoacyl chlorides* and Me_2Fe, Me_2Co, Me_2Fe, Me_3CoLi, nBu_2Fe, and nBu_3FeLi,[28] these reagents are just as suitable as the Mn reagents. The *bisacyl chlorides* **30** and **31** are converted into the corresponding



diketones by three equivalents of Me_2Fe in 86 and 65% yields, respectively. The acyl chloride group of **30** and **31** without adjacent substituents is methylated when only 1.25 equivalents of Me_2Fe are used, while Me_2CuLi reacts predominantly with the other acyl chloride group (for Fe-catalyzed synthesis of ketones from acyl chlorides see Section 3.7).

3.3. Aryl Halides

Alkyl cuprates of the type R_2CuLi are not particularly suitable for cross-coupling with aryl halides, since a large excess of the reagent must generally be used and the yield of the cross-coupling product is reduced by halogen/hydrogen exchange reactions (see for example reference [29]). The hypothetical hetero-ate complexes $Me_3Fe(CN)_2Li_3$ and $Me_nCo(CN)_2Li_n$ ($n = 2-4$) are excellent reagents for cross-coupling with *1-halogenonaphthalenes* (Scheme 12).[1] Since they give much higher yields of cross-coupling product and cause much less reduction of the halides to naphthalene they are clearly superior to the homo-ate complexes Me_3FeLi, Me_4FeLi_2, and Me_4CoLi_2. In contrast to the behavior of $Me_4Co(CN)_2Li_4$, the reaction between 1-fluoronaphthalene and Me_3CuLi_2 leads



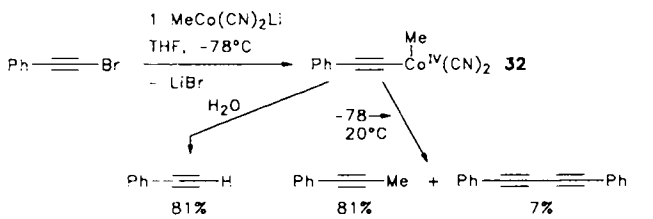
Hal = Br	$Me_3Fe(CN)_2Li_3$	86%	10%
Hal = Br	$Me_2Co(CN)_2Li_2$	89%	5%
Hal = Br	$Me_3Co(CN)_2Li_3$	95%	4%
Hal = Cl	$Me_3Co(CN)_2Li_3$	77%	16%
Hal = F	$Me_4Co(CN)_2Li_4$	67%	1%

Scheme 12. See also ref. [1].

mainly to the cine-substitution product 2-methylnaphthalene.[17k] While nBu$_4$CoLi$_2$ is completely unsuitable for cross-coupling with 1-bromonaphthalene, the reaction proceeds in 28% yield when nBu$_2$Co(CN)$_2$Li$_2$ is used, thus demonstrating the lower tendency of the cyano-ate complex to decompose by β-H-elimination. Up to now *bromobenzene* has only been treated with cobalt cyano-ate complexes: $Me_3Co(CN)_2Li_3$, the most suitable reagent, affords toluene (70%), benzene (14%), and biphenyl (7%) under the conditions in Scheme 12.[1]

3.4. 1-Alkynyl Halides

Although 1-alkynyl halides are more strongly electrophilic towards organometallic reagents than are 1-alkenyl halides, no good method for *alkylating* cross-coupling with these substrates has been reported. [nBuCu·MgBr$_2$] is relatively useful for this purpose, since it reacts with 1-iodo-, 1-bromo-, and 1-chloro-1-heptyne to give the cross-coupling products in 71, 33, and 19%, respectively.[30, 31] Me_4FeLi_2 has shown itself to be a good reagent for methylating cross-coupling reactions with 1-bromo- and 1-chloro-2-phenylethyne and with 1-chloro-3-phenoxypropyne (yields 46,[17p] 70,[17k] and 80%,[17l] respectively), while Me_4CoLi_2, Me_4MnLi_2, Me_2Cu, and Me_3CuLi_2 gave disappointing results.[24] Ether is not a suitable solvent for these reactions, and 1,2-dimethoxyethane is better than THF. $MeCo(CN)_2Li$, the optimum reagent for cross-coupling with 1-bromo-2-phenylethyne, gives the methylation product via **32** in 81% yield; 1,4-diphenyl-1,3-butadiyne (7%) and phenylethyne (3%) are also formed (Scheme 13; for the reaction mechanism see Section 3.6).[1] There was no evidence for the formation of a vinylidene complex by methyl migration in the acetylide complex. Substitution of the Cl atom in 1-chloro-2-phenylethyne by n-butyl, n-octyl, or phenyl groups is carried out more effectively by using the catalytic system [RMgBr + 2.5 mol% $FeCl_3$] (R = nBu, nOct, Ph; yields 75, 63, and 96%, respectively) than by nBu$_4$FeLi$_2$ or R$_4$Fe(MgBr)$_2$ with R = nBu, nOct, Ph; yields 18–28%.[24, 17l] It appears possible that the active catalysts in the catalytic system are super-ate



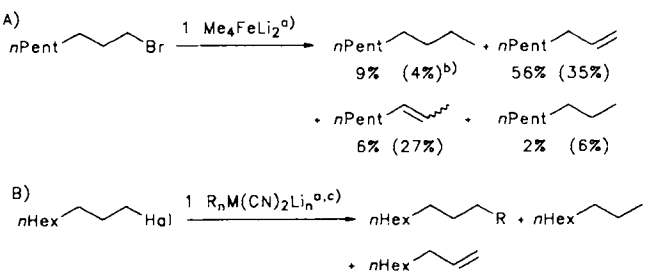
Scheme 13. Products formed from 1-bromo-2-phenylethyne and a rationalization of their formation [1].

complexes of the type [R$_4$Fe(MgBr)$_2$·(RMgBr)$_n$] (see Section 3.7). Competition experiments, in which the reagent was given the choice of two reaction partners (reagent:substrate ratio 1:1:1), gave the following order of the electrophilic behavior towards Me_4FeLi_2: benzoyl chloride > 1-bromo-2-phenylethyne > (*E*)-β-bromostyrene.

3.5. Alkyl Halides

3.5.1. *Monohalides*

Cross-coupling with alkyl halides is well known to be a domain of the organocuprates and organoheterocuprates (e.g. R$_2$Cu(CN)Li$_2$[25]). It was recognized in the study by Corey and Posner mentioned above[5] that Me_3FeLi is not suitable for cross-coupling with 1-iododecane and iodocyclohexane (3 and 1% of methylation product, respectively). Co-workers of the author also obtained very low yields of coupling product in the reactions of 1-bromooctane and 1-bromo-3-phenylpropane in THF with Me_4MLi_2 (M = Fe, Co, −78 °C, in 18 h) or Me_4MnLi_2 (0 to 20 °C, in 18 h). The identification of all the products (for the results of the reaction of Me_4FeLi_2 or Me_4CoLi_2 with 1-bromooctane see Scheme 14 A; similar results



Scheme 14. The reactivity of Me_4FeLi_2 and alkyl-cyano-ate complexes towards alkyl halides [1,17p] (nPent = n-pentyl; nHex = n-Hexyl). a) THF, −78 °C to 20 °C in 18 h; b) yields in parentheses: corresponding reactions with Me_4CoLi_2; c) results for Scheme 14 B: Table 3.

were obtained in reactions with 1-bromo-3-phenylpropane or by using Me_4MnLi_2) showed that the predominant reaction involved dehydrobromination and led to the formation of the terminal alkene and an alkene in which the double bond is shifted by one C atom.[17p] Cyano-ate complexes of Fe^{II} and Ni^{II} are, however, very good reagents for cross-coupling with monohalogenoalkanes[1, 17q] (Scheme 14 B and Table 3). A compari-

Table 3. Cross-coupling of n-nonyl halides with alkyl-cyano-ate complexes in THF (−78 °C to 20 °C in 18 h) in a molar ratio of 1:1 according to Scheme 14B.

Reagent	Hal	Yield [%] Decane	Nonane	1-Nonene	Halide recovered [%]

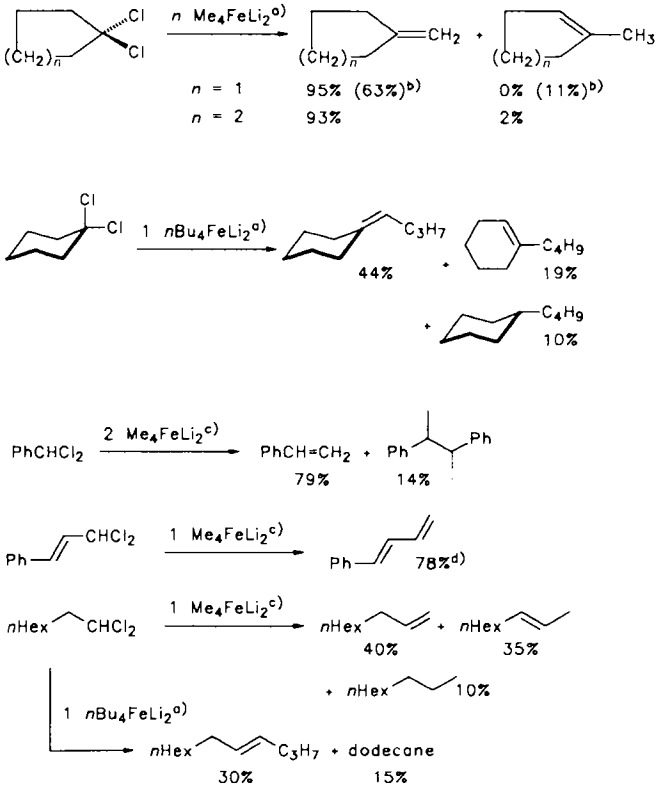
son of the reactivity of $Me_2Fe(CN)_2Li_2$ and Me_4FeLi_2 towards such substrates shows that the cyano ligands alter the course of the reaction (for a mechanistic interpretation see Section 3.6). The use of $Fe(CN)_2$ as a source of iron in the preparation of the reagent thus represents an important advance in the area of iron reagents.

3.5.2. *Geminal Dihalides*

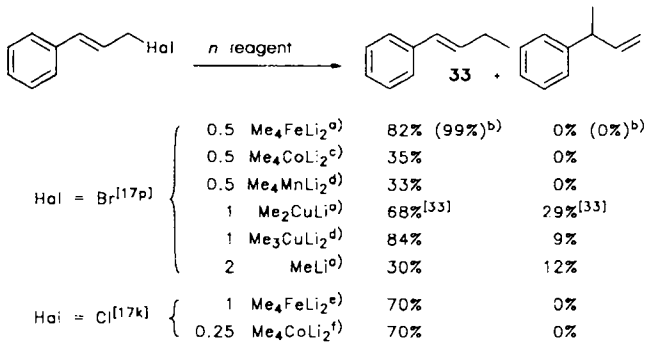
The main reaction that occurs when geminal dihaloalkanes are allowed to react with an excess of Me_2CuLi is the exchange of both halogen atoms by methyl groups.[32] In contrast, Me_4FeLi_2, Me_4CoLi_2, and nBu_4FeLi_2 convert such halides into alkenes.[17k, p] When Me_4FeLi_2, which in this case is a better choice than Me_4CoLi_2, is allowed to react with 1,1-dichlorocyclopentane and 1,1-dichlorocyclohexane, the predominant or sole product is the corresponding methylenecycloalkane (for the probable mechanism see Section 3.6), while in the reaction of nBu_4FeLi_2 with 1,1-dichlorocyclohexane the double bond formed initially is shifted to a large extent into the ring. This and analogous olefinations are shown in Scheme 15.



Scheme 15. Olefination of geminal alkyl dichlorides [17k,q]. a) THF, −78 °C (1 h) to 20 °C in 1 h; b) yields in parentheses: corresponding reactions with Me_4CoLi_2; c) Et_2O, −78 °C (1 h); d) THF, −78 °C; d) sole product.

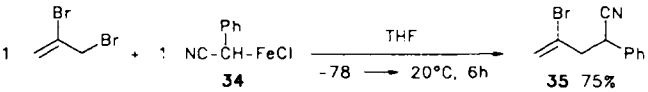
3.5.3. *Allyl Halides, 3-Chloro-1-octyne, and Benzyl Bromide*

"In general, substitution reactions of allylic substrates without (or with) complete allylic rearrangement via organometallics are still unpredictable processes." This statement made in 1980[33] is still valid today (with few exceptions). Substitution reactions involving alkyl–Cu complexes and primary allyl bromides occur in high yield, but often give two regioisomers[6, 33, 34] (for an example see Scheme 16). In contrast, the reactions of Me_4FeLi_2 and Me_4CoLi_2 with 3-chloro- and 3-bromo-1-propene lead exclusively to the unrearranged substitution product **33** (Scheme 16). Me_4FeLi_2 reacts in an analogous manner with 3-chloro-1-octyne to give only 1-methyl-3-pentylallene (58%, THF, −55 °C).[17k]



Scheme 16. Regiospecific cross-coupling reactions with allyl halides. a) Et_2O, −78 °C, 1 h; b) 1 molar equivalent of the reagent rather than 0.5; c) THF, −78 °C, 1 h; d) Et_2O, 0 °C, 1 h; e) THF, −40 to 20 °C in 0.5 h; f) THF, −78 to 20 °C in 0.5 h.

The Fe and Co derivatives of *functionalized alkanes* obtained according to Scheme 4, which are inert towards (*E*)-β-bromostyrene and the S_N1-inactive alkyl halide 1-bromocyclohexane, are found to be reactive towards S_N1-active bromides. They react with allyl bromides in good yields to give unrearranged cross-coupling products.[17f, i, n] Cross-coupling also occurs readily with benzyl bromide and 2-methoxybenzyl bromide.[17f, n] The reagent **34**, obtained in a manner analogous to **11**, does not react with vinylic bromine but well with allylic bromine; this enables the regiospecific cross-coupling to give **35**[12, 17i] (Scheme 17).

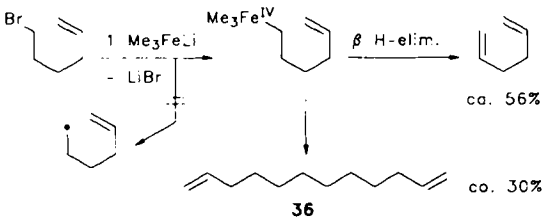


Scheme 17. See also ref. [12].

3.6. Discussion of the Reaction Mechanism of Stoichiometric Cross-Coupling

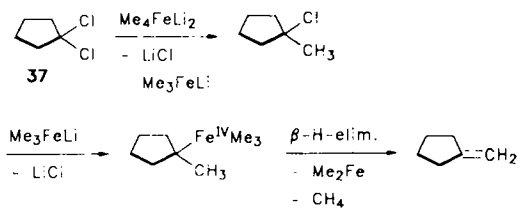
The reactions of alkyl derivatives of Fe^{II} and Co^{II} with organic substrates often resemble the well-studied reactions of dialkyl cuprates with such substrates. Although the mechanistic rationales devised for dialkyl cuprates are in part controversial, they do provide valuable guidelines for attempts to determine the mechanisms of cross-coupling reactions involving alkyl derivatives of Fe^{II} and Co^{II}. The following features are characteristic of cross-couplings of Me_2CuLi with *alkyl halides*:[35] complete inversion of configuration as in classical S_N2 reactions, second-order kinetics, and the structure–reactivity pattern methyl halide > primary > secondary > tertiary alkyl halide and I > Br > Cl ≫ F. The following mechanisms have been

discussed:[36] 1) normal S_N2 process (methyl "anion" attacks the halide), 2) S_N2 process in which the Cu attacks the alkyl halide (= two-electron transfer process via Cu^{III} species), and 3) one-electron transfer process in which both Cu atoms of the dimeric Me_2CuLi are temporarily oxidized to Cu^{II}. It has been suggested that the second mechanism is not compatible with the highly selective formation of the coupling products R–Me; however, this argument can be countered by the observation that larger alkyl residues are generally more rapidly eliminated than methyl groups because of the release of steric strain. The reaction of Me_2CuLi with 6-iodo-1-heptene leads to the initial generation of a free radical, as can be seen from the formation of a cyclopentane derivative.[37] In contrast, the analogous reaction of Me_3FeLi with 6-bromo-1-hexene[17a] (Scheme 18) is a nonradical process, as is shown by the absence of a cyclization product; the same is true for Me_3MnLi.[17d] The presence of the coupling product **36** indicates that the main product, 1,5-hexadiene, is not formed by the classical E1cB-mechanism[38] (E1 at the carbanion) but by Br/Fe exchange with subsequent β-H-elimination (Scheme 18). The initial reaction step is thus most probably a two-electron oxidative addition.



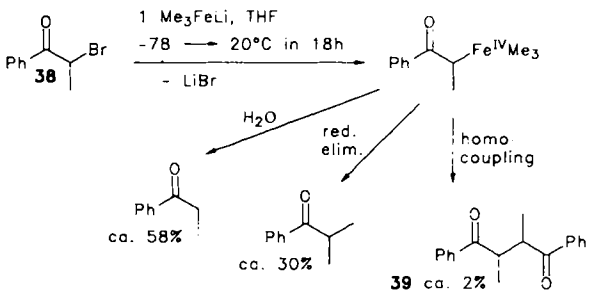
Scheme 18. Study of the mechanism of the reaction between Me_3FeLi and an alkyl bromide [17a]. Reaction conditions: THF, −78 to 20 °C in 18 h.

Halogen/Fe exchange must also be assumed for the second phase of the reaction of 1,1-dichlorocyclopentane (**37**) with Me_4FeLi_2 and Me_4CoLi_2 (see Scheme 15 and Scheme 19) and



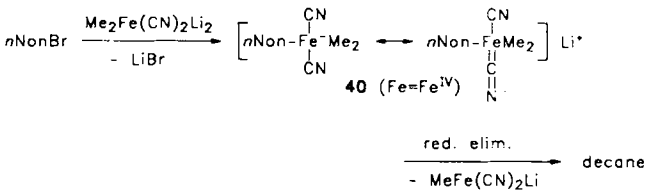
Scheme 19. Mechanistic rationale for the methylenation of a geminal dichloride [17q].

for the initial phase of the reaction of 2-bromopropiophenone (**38**) with Me_3FeLi[17a] (Scheme 20). In the former case this provides a simple explanation for the formation of the olefinic double bond (Scheme 19) and in the latter for the three reaction products (Scheme 20). The 1,4-diketone **39** could also be formed by radical dimerization subsequent to a one-electron transfer process, rather than by homocoupling. While Me_4FeLi_2 reacts with 1-octyl bromide to give 1-octene as the main product (see Scheme 14), the analogous reaction of $Me_2Fe(CN)_2Li_2$ with 1-nonyl bromide gives no olefins but only



Scheme 20. Mechanistic rationale for the product formation in the reaction of 2-bromopropiophenone with Me_3FeLi [17a].

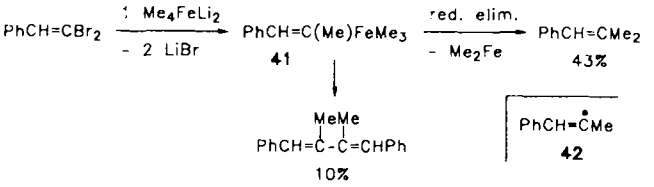
the coupling product decane in 83% yield[1] (Table 3; Scheme 21). The increase in the length of the carbon chain by one carbon atom in the bromide is hardly likely to play an important role here. Thus the cyano ligands apparently prevent the β-H-elimination that leads to the formation of olefins. It appears likely that because of delocalization of the negative charge, as shown in **40**, the basicity of the Fe atom is reduced to such an extent that it is no longer able to carry out the proton abstraction necessary for β-elimination to occur.



Scheme 21. Control of the course of the reaction by cyanide ligands (*n*Non = *n*-nonyl).

In the reaction of one equivalent of $MeCo(CN)_2Li$ with 1-bromo-2-phenylethyne,[1] the Co^{IV} intermediate **32** (see Scheme 13) and thus a two-electron oxidative addition of the bromide as the initial step, appears almost certain, since there is no other plausible explanation for the formation of the two products (each in 81% yield) when different reaction conditions are used. A one-electron oxidative addition to form 1-methyl-2-phenylethyne (81%) via a Co^{III} intermediate would require two equivalents of the reagent. Homocoupling of **32** (see Scheme 13) gives 1,4-diphenyl-1,3-butadiyne in 7% yield. Little can be said with certainty about the mechanism of the cross-coupling of alkyl derivatives of Fe^{II} and Co^{II} with *1-alkenyl bromides*, which occurs with retention of configuration, and also about the corresponding reactions with Me_2CuLi.[6] A process analogous to that shown in Scheme 13 appears most likely. In the same way the formation of 2,3-dimethyl-1,4-diphenyl-1,3-butadiene (10%) in the reaction referred to in Section 3.1.1 (Scheme 22) of β,β-dibromostyrene with Me_4FeLi_2 to give β,β-dimethylstyrene indicates that an electron-transfer step is involved in the second methylation step; the butadiene derivative is formed either by homocoupling of **41** or by the dimerization of the radical **42** formed in a one-electron transfer process.

The reagents $MeTiCl_3$, $MeNbCl_4$, Me_2NbCl_3, and $MeTi(OiPr)_3$, in which the metals are in their highest possible oxidation states, are not suited for the transformation of *acyl chlorides* into methyl ketones: the three chlorides are inert or



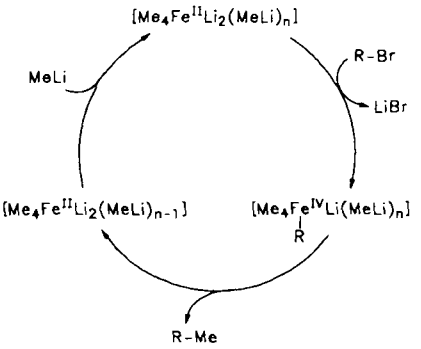
Scheme 22. Mechanistic rationale of product formation in the reaction of β,β-dibromostyrene with Me_4FeLi_2 [17p].

almost inert towards such substrates,[39] while $MeTi(OiPr)_3$ transfers an *O*iPr group instead of its methyl group.[40] In contrast, methyl derivatives of Fe^{II} and Co^{II}, like those of other low-valent transition metals, react readily with acyl chlorides to give cross-coupling products (see Section 3.2). It is thus almost certain that these methyl transfer reactions proceed by oxidative addition followed by reductive elimination; the reaction proposed by Hegedus et al.[41] for the cross-coupling of benzoyl chloride with alkyl-Rh^I complexes (initial formation of an η^1-acyl-M(Cl) complex by oxidative addition of the C-Cl bond) appears most probable. Because of the complete agreement between the observations made for the methylation of acyl chlorides on the one hand and of phenyl isocyanate on the other (with respect to Ti^{IV} reagents, see Section 4.4), there is a slight possibility that cross-coupling reactions of acyl chlorides proceed by *oxidative addition of the CO double bond* (in analogy to Scheme 34) followed by reductive elimination and subsequent β-elimination with renewed formation of the carbonyl function.

3.7. Catalytic Cross-Coupling: Highly Selective Super-Ate Complexes as Catalysts

In the period 1971-1975 Kochi et al.[42] described Fe-catalyzed cross-coupling reactions of *1-alkenyl bromides* with Grignard reagents and catalytic amounts of $FeCl_3$ or Fe^{III} complexes carried out at 25 °C in THF (yields 25 99%) and surmised that labile Fe^I species could well be the active catalytic species. Analogous catalytic cross-coupling reactions of *acyl chlorides at* $-65\,^{\circ}C$ with $FeCl_3$ as the iron source afford ketones in high yields.[43] These ketone syntheses were postulated to involve Fe^{III} catalysts;[44,45] this is extremely unlikely, since $FeCl_3$ is reduced very rapidly to Fe^{II} by MeMgBr or *n*BuMgBr in THF or Et_2O even at $-78\,^{\circ}C$.[28,17l,p]

On the basis of the idea that Me_4FeLi_2 is converted into Me_3FeLi in the reaction with 1-alkenyl bromides and that Me_4FeLi_2 can be regenerated by adding MeLi to Me_3FeLi, the author's group studied Fe-catalyzed cross-couplings of *1-alkenyl bromides* with MeLi or *n*BuLi as well as of *acyl chlorides* with MeMgBr in THF at about $-78\,^{\circ}C$.[28] Use of the systems [RLi +5 mol% $FeCl_3$] or [MeMgBr +2.5 mol% $FeCl_3$] led in each case to high yields of cross-coupling products; in both cases the catalytic species was most probably an Fe^{II} compound.[28,46] Competition reactions with α-bromostyrene/(*E*)-β-bromostyrene showed that the selectivity increases in the series Me_3FeLi, Me_4FeLi_2, and [MeLi +5 mol% $FeCl_3$] (competition constants $K_k = 3.0$, 3.6, 11.1, respectively). In corresponding experiments with benzoyl chloride and 2-methoxybenzoyl chloride the selectivity increased in the analogous series MeFeCl, Me_2Fe, $Me_3Fe(MgBr)$, $Me_4Fe(MgBr)_2$, and [MeMgBr +2.5 mol% $FeCl_3$] ($K_k = 9.9$, 10.7, 10.9, 15.0, and about 110, respectively). These results for the "competition constant method"[47] indicate the presence of "super-ate complexes" [$Me_4FeLi_2 \cdot n$MeLi] and [$Me_4Fe(MgBr)_2 \cdot n$MeMgBr].[28,46] The high selectivity of these catalysts is explained on the basis that their outer sphere, which consists of MeLi or MeMgBr and solvent molecules, hinders the attack of relatively large organic halides at the Fe atom.[28] The catalytic cycle proposed for [$Me_4FeLi_2 \cdot n$MeLi] is shown in Scheme 23.



Scheme 23. Postulated catalytic cycle for catalytic cross-coupling of 1-alkenyl bromides with the system [MeLi +5 mol% $FeCl_3$].

The main advantage of catalytic cross-coupling over the stoichiometric procedure is its high chemoselectivity. Its disadvantage is that, because of the presence of MeLi or MeMgBr in the mixtures, catalytic systems cannot be used when the halide contains a functional group that is strongly electrophilic towards MeLi or MeMgBr (e.g. **18**, **22**, **27**). The catalytic rearrangement of terminal epoxides in the presence of [MeLi +2.5 mol% $FeCl_3$] to give methyl ketones (see Section 5.3) is also assumed to involve a super-ate complex as the active catalyst.[46]

3.8. A Comparison with Pd-Catalyzed Cross-Coupling

The cross-coupling reactions discussed in Sections 3.1-3.5 and 3.7 must also be compared with the Pd-catalyzed cross-coupling processes of Stille[48] and Suzuki.[49] The alkylating *Stille coupling*[48] (alkyl-Sn^{IV} compound +Pd catalyst; substrates: allyl, benzyl, aryl, and acyl halides, 1-alkenyl iodides, bromides, and triflates; mild conditions, high stereo- and regioselectivity) has the clear advantage over the *catalytic* cross-couplings described in Section 3.7 that the electrophilic groups >C=O, -COOR, $-CONR_2$, -CN, and even -CHO are tolerated. Nothing is, however, known as to whether these couplings permit a good differentiation between similar substrates, as is the case for the Fe-catalyzed couplings. As far as the comparison with the *stoichiometric* cross-couplings discussed in Sections 3.1-3.5 is concerned, there is the important limitation that in contrast to the couplings with the methylcyanoferrates and alkylcyanonickelates listed in Table 3 (as well as with organocuprates and organocyanocuprates), substrates which bear a hydrogen atom at the sp^3-C atom β to the leaving group (such as RCH_2CH_2Hal, where the intermediate species $RCH_2CH_2Pd(L)_2Hal$ rapidly eliminates alkene) are not suitable

for Stille coupling. (This limitation does not apply to the organotin reagent). In addition the Stille coupling cannot be applied to 1-alkenyl chlorides and fluorides or to aryl chlorides and fluorides. In many cases it will, however, be a useful alternative to the couplings described in Sections 3.1–3.5.

In the case of the alkylating *Suzuki coupling*[49] (β-alkyl-9-borabicyclo[3.3.1]nonane derivative + Pd catalyst + base; substrates aryl and 1-alkenyl halides (Hal = I, Br)), the limitations with respect to the substrate are much more severe; this reaction, which differs mainly from the much more widely studied Stille coupling in that the Pd catalyst is alkylated by a boron compound rather than a tin compound, requires the presence of a strong base; thus, base-sensitive substrates cannot be used. In addition the reaction temperatures are relatively high (generally reflux temperature in THF + H_2O).

4. Reactions with Carbonyl Compounds, Azomethines, and Nitriles

The cyano-ate complexes of Fe, Co, and Ni which have been referred to several times in Section 3 will not be discussed in this section, since relevant studies have not yet been carried out.

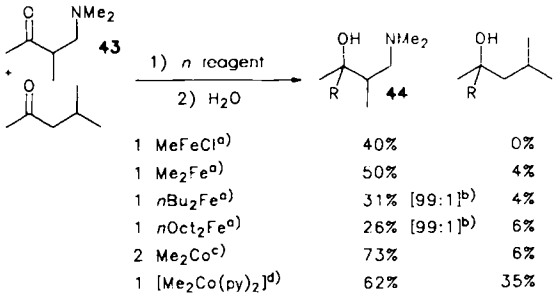
4.1. Chemoselective Alkylation of Aldehydes and Ketones

4.1.1. Aldehyde versus Ketone Selectivity

Alkyl derivatives of Cu, Mn, Ti, Cr, and other transition metals have been shown to exhibit a high chemoselectivity in competition reactions with aldehyde/ketone pairs ("aldehyde selectivity"): for a survey see reference [10]. Alkyl derivatives[8a, 9, 11] and functionalized alkyl derivatives[16, 18] of Fe and Co, obtained according to Schemes 1 and 4, are also highly aldehyde-selective. In this respect the *α-cyanoalkyl–Fe complexes* **10–12** are either as good as the corresponding Ti^{IV} complexes or even superior.[18]

4.1.2. Chele- and Anticheleselectivity

Alkyl derivatives of certain transition metals alkylate ketones that contain a basic group in the α-position ("1,2-chelator ketones")[22] or in the β-position ("1,3-chelator ketones")[22] much faster than normal ketones.[22, 50, 51] Me_2Mg methylates α-alkoxy ketones more rapidly than α-siloxy ketones,[52] and Grignard reagents alkylate β-dimethylamino ketones somewhat more rapidly than normal ketones.[50] This "cheleselectivity",[22] which is due to chelate formation in a reaction intermediate, has also been observed for alkyl derivatives of Fe^{II}[9, 17h] and (in a much less pronounced form) for methyl derivatives of Co^{II}[17f, 53d] and Ni[17m]. Alkyl derivatives of Ti^{IV}, Cr^{III}, Mn^{II}, Fe^{II}, and Ag^{I} are probably the best choice for preparative cheleselective alkylation reactions.[22] The preferential alkylation of the β-dimethylamino ketone **43** by Fe and Co reagents in the presence of a normal ketone is shown in Scheme 24.[17h, m, 53d] The *n*-butylation and *n*-octylation of **43** results in almost complete formation of the *S,R/R,S*-diastereoisomer of **44**. This corresponds to an alkylation according to the

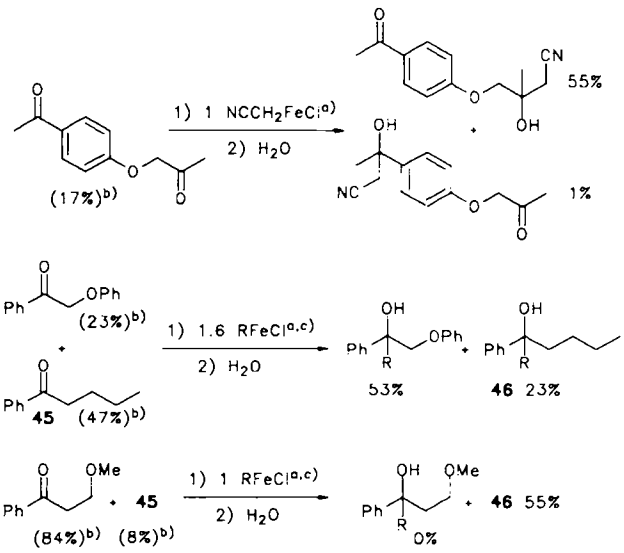


1	MeFeCl[a]	40%	0%
1	Me_2Fe[a]	50%	4%
1	nBu_2Fe[a]	31% [99:1][b]	4%
1	$nOct_2Fe$[a]	26% [99:1][b]	6%
2	Me_2Co[c]	73%	6%
1	$[Me_2Co(py)_2]$[d]	62%	35%

Scheme 24. Cheleselective carbonyl alkylations. a) THF, −78 to 20 °C in 18 h, reagents prepared from RLi [17h]; b) ratio of *S,R/R,S* to *S,S/R,R* diastereoisomers; c) THF, −78 to 20 °C in 18 h, reagent prepared from MeMgBr [53d]; d) Et_2O, −50 to 20 °C in 18 h, reagents prepared from MeLi [53d].

cyclic model proposed by Cram and Kopecky;[54] thus, the formation of an iron chelate intermediate is extremely likely. The decrease in the cheleselectivity in the series Me_2Fe, nBu_2Fe, and $nOct_2Fe$ (as shown in Scheme 24) can easily be explained on the basis of the decreasing tendency to chelation because of the increasing size of the alkyl groups. In contrast to the situation when Ti or Cr reagents are used,[22] the reaction-accelerating effect of a methoxy group in reactions of methyl–Fe reagents only becomes apparent (see Scheme 4 in reference [9]) when the very weakly basic CH_2Cl_2 is used as the solvent and when the Fe reagents (e.g. Me_2Fe) are prepared from MeMgBr rather than from MeLi. This indicates that Mg chelates may be responsible for the cheleselectivity.

Cheleselectivity is also observed when the Fe and Co reagents **2–5**, **7**, **8**, and **10–12** (prepared according to Scheme 4) containing functionalized alkyl groups are allowed to react with *1,2-chelator ketone/ketone competition systems* (for examples see reference [16] and Scheme 25[17o, f]). However, in reactions involving *1,3-chelator ketone/ketone competition systems* the transfer of the functionalized alkyl group occurs in an anticheleselective manner (for examples see references [16,22] and Scheme 25[17o]). The reason for the anticheleselectivity, which in stereochemically relevant cases is always accompanied by low

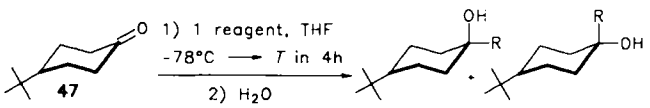


Scheme 25. Chele- and anticheleselectivity of Fe derivatives of functionalized alkanes [17f,o]. a) THF, −78 to 20 °C in 18 h; b) recovery; c) R = $Et_2NCOCH(Me)$.

or even zero diastereoselectivity, is likely to lie in aggregation of the transition-metalated functionalized alkanes[16, 55] (see Section 2.2). The above-mentioned change from chele- to anticheleselectivity, which is also observed for titanated functionalized alkanes,[22] is probably due to the fact that for entropy reasons the formation of a five-membered chelate occurs more readily than that of a six-membered one. Kinetic studies of cheleselective reactions, such as those on alkyl derivatives of Ti^{IV}[51] and Mg^{II}[52], remain to be carried out for the alkyl derivatives of Fe^{II}, Co^{II}, and Ni^{II}.

4.1.3. 99:1 Equatorial-Diastereoselective Addition to Substituted Cyclohexanones

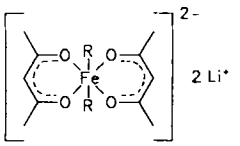
The competition between equatorial and axial attack in nucleophilic additions to substituted cyclohexanones is of both theoretical and synthetic interest. Small nucleophiles such as the hydride ion attack in an axial manner, while organometallic compounds tend towards equatorial attack (for a survey see reference [56]). The degree of selectivity observed is often unsatisfactory. The alkyl–Fe complexes (prepared according to or in analogy to Scheme 1) and Ph_2Fe, as well as the hetero-ate complexes $R_2Fe(acac)_2Li_2$ (R = Me, Ph; Hacac = pentane-1,3-dione) obtained from in situ transmetalation of RLi with Fe $(acac)_2$, were allowed to react with **47** and a second alkylated cyclohexanone by Reetz et al.[56] The results (for examples see Scheme 26) show that the methyl-, *n*-butyl-, and phenyl–Fe



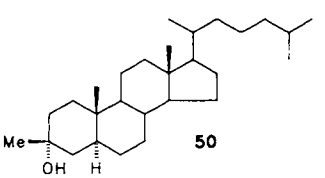
Me_2Fe[a]	99:1 (98%)[b]
Me_3FeLi[a]	98:2 (99%)
$Me_2Fe(acac)_2Li_2$[a,c]	99:1 (85%)
nBu_2Fe[d]	99:1 (60%)
Ph_2Fe[e]	93:7 (64%)
$Ph_2Fe(acac)_2Li_2$[a,c]	97:3 (76%)

Scheme 26. Highly equatorial-selective alkylation and phenylation of a cyclohexanone derivative [56]. a) $T = -22$ °C; b) total yield; c) Hacac = pentane-2,4-dione; d) $T = -15$ °C; e) $T = 0$ °C.

reagents alkylate in an equatorial manner with a diastereoselectivity superior to any achieved previously; thus, the axial alcohols are virtually the sole products. Even the planar phenyl group, which is normally very problematic in such reactions,[57] can be attached to **47** with an equatorial diastereoselectivity of 97:3. For the two hetero-ate complexes, which have been suggested to have the structures **48** and **49**,[56] the methyl derivative is not as good as Me_2Fe, while the phenyl derivative is better than Ph_2Fe. Cholestanone reacts with Me_2Fe to give the axial



48: R = Me
49: R = Ph



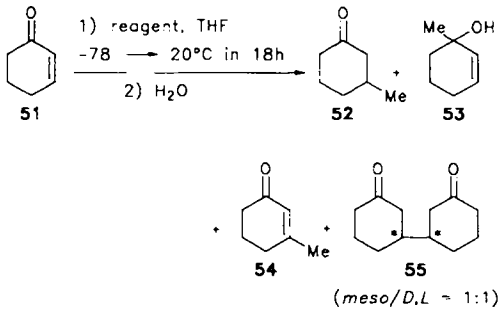
50

alcohol **50** (78%) with a diastereoselectivity of 99:1 (**48**: yield 36%, diastereoselectivity 98:2). A possible explanation of the extreme equatorial selectivity is given in Section 4.4.

4.1.4. Regioselective Addition to Conjugated Enones

Not only organocuprates but also homoleptic alkyl complexes of Mn^{II},[58, 59, 17d] Fe^{II},[60, 17h] Co^{II}[11, 17m] as well as of some later 4d metals[60] react with conjugated enones under 1,4-addition. Nevertheless, organocuprates remain the reagents of choice for 1,4-addition, since in difficult cases (transfer of large residues, open-chain enones) they react in a highly selective manner and give high yields.

In the reactions of the methyl–Fe complexes shown in Table 4 with *2-cyclohexenone* (**51**) (Scheme 27) an increase in the number of methyl groups bonded to the Fe atom correlates with



Scheme 27. Reagents and yields: Table 4.

decrease in the yield of the 1,4-addition product **52**, while the opposite is true for methyl–Co and methyl–Mn complexes (Table 4); this indicates the presence of different mechanisms (a possible explanation is given in Section 4.4). The dihydrodimers formed as by-products, *meso*-**55** (m.p. 97 °C and D,L-**55** (m.p. 63–65 °C), are already known,[61] and their structure has been determined by proton NMR spectroscopy.[17h] In contrast to the methyl reagents listed in Table 4 and the hetero-ate complexes nBuFe(OtBu)$_2$Li and nBuFe(SPh)$_2$Li referred to in Section 4.5, the reagents **3** and **5** (Scheme 4), which contain functionalized alkyl groups, react with **51** to give almost exclu-

Table 4. Reactions of Fe [17h,60] and Co reagents [11,17m] and for comparison of Mn reagents [17d] with 2-cyclohexenone (**51**) in a molar ratio of 1:1 according to Scheme 27 (n.d. = not determined).

Reagent [a]	Yield [%]				Recovered [%]
	52	**53**	**54**	**55**	**51**
Me_2Fe	87	3	0	0	3
Me_3FeLi	64	10	0	3 [c]	0
Me_4FeLi_2 [b]	0	35	0	54 [c]	0
$Me_4Co(MgBr)_2$	69	3	0	n.d. [d]	0
Me_3CoLi_4	64	5	6	n.d. [d]	1
Me_3CoLi	44	13	19	n.d. [d]	1
Me_3Co	15	27	17	n.d. [d]	8
Me_3MnLi	60	2	0	19	2
Me_2Mn	57	9	0	4	1
MeMnCl	43	2	0	21	5

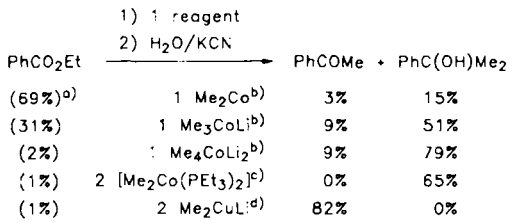
[a] Prepared (with the exception of $Me_4Co(MgBr)_2$) from MeLi according to Scheme 1. [b] Almost identical results are obtained by using isolated Me_4FeLi_2. [c] 1:1 mixture of *meso*- and D,L-**55**. [d] Up to four dihydromers $C_{12}H_{18}O_2$ of unknown structure are formed.

sively products derived from 1,2-addition.[17n] Since these aggregated reagents also differ clearly from those obtained according to Scheme 1 in that they do not react with 1-alkenyl bromides, it appears likely that they are not able to undergo oxidative addition of organic substrates because of stabilization of the oxidation states of their metal atoms.

By using *methyl vinyl ketone*[17m,h] as the open-chain substrate, the addition of Me_2Fe, Me_3FeLi, and Me_4CoLi_2 occurs highly selectively in a 1,4-manner (in 1:1 reactions 2-pentanone is formed in 32, 39, and 32% yield, respectively), while Me_4FeLi_2 again gives only the 1,2-addition product (26%). In all cases the dihydrodimers $C_8H_{14}O_2$ are formed in high yields (27–50%).

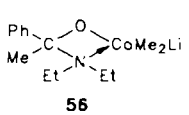
4.2. Reactions with Esters of Carboxylic Acids and *N,N*-Diethylbenzamide

While the Fe reagents prepared according to Scheme 1 are virtually inert towards esters of carboxylic acids, the methyl–Co reagents listed in Scheme 28 react under mild conditions with ethyl benzoate to give predominantly 2-phenyl-2-propanol,[11,17m] while Me_2CuLi yields only acetophenone.[17c]



Scheme 28. a) Recovery; b) Et_2O, −78 to 20 °C in 18 h [17m]; c) Et_2O, −78 to 20 °C in 30 min [53b]; d) Et_2O, −50 to 20 °C in 18 h [17c].

In the former case the second methylation step is apparently faster than the first, indicating the intermediate formation of free acetophenone. This is, however, not the case when *N,N*-diethylbenzamide is allowed to react with Me_3CoLi (Scheme 28): acetophenone is almost the sole product obtained when the reaction mixture is treated with an aqueous solution of KCN, suggesting that the initial product is a complex of acetophenone that is stable in nonaqueous media, possibly complex **56**. Me_3CoLi also methylates the ethoxycarbonyl group of ethyl valerate. A 1:1 reaction in Et_2O (−78 to 20 °C in 18 h) affords hexanone (8%) and 2-methyl-2-hexanol (44%).[17m] Me_3CoLi is unable to differentiate between ethyl valerate and *N,N*-diethylbenzamide in 1:1 competition experiments carried out in THF. The reagent is deactivated to such an extent by the two substrates that almost no methyl transfer is observed. However, an analogous experiment with (*E*)-β-bromostyrene and *N,N*-diethylbenzamide leads to the chemospecific formation of (*E*)-β-methylstyrene in 95% yield.[17m]



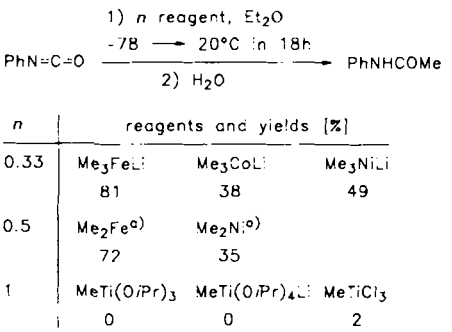
56

4.3. Reactions with Compounds Containing a C–N Multiple Bond

4.3.1. Addition and Substitution Reactions

The reactions described here are of considerable mechanistic interest, since a series of observations indicate that the organic substrates undergo oxidative addition to the reagents (see Section 4.4). It is of interest with regard to synthesis that methyl–Fe and methyl–Co reagents can replace the strongly basic alkyllithium reagents in nucleophilic substitution reactions at heteroarenes; apart from their lower basicity, the former have the further advantage that the addition step is followed by β-H-elimination, which leads to spontaneous rearomatization.

Me_3MnLi reacts with *phenyl isocyanate* in the molar ratio 0.33:1 (THF at −50 to 20 °C) to afford acetanilide in 98% yield.[62] This requires that all three methyl groups are transferred, though this could not be confirmed in attempts[53c] to repeat the work (yield 63%). In contrast to reactions of methyl–Ti^{IV} reagents or $MeNbCl_4$, reactions carried out according to Scheme 29 with the methyl derivatives of Fe, Co, and Ni listed

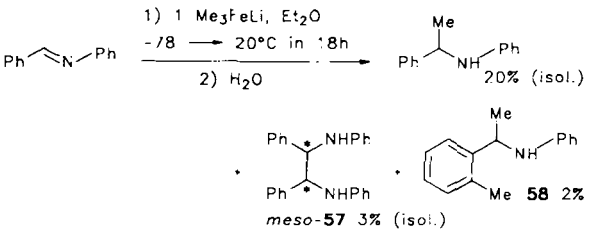


n	reagents and yields [%]		
0.33	Me_3FeLi	Me_3CoLi	Me_3NiLi
	81	38	49
0.5	Me_2Fe[a]	Me_2Ni[a]	
	72	35	
1	$MeTi(OiPr)_3$	$MeTi(OiPr)_4Li$	$MeTiCl_3$
	0	0	2

Scheme 29. See also ref. [53e]. a) These reagents were prepared from MeMgBr in analogy to Scheme 1.

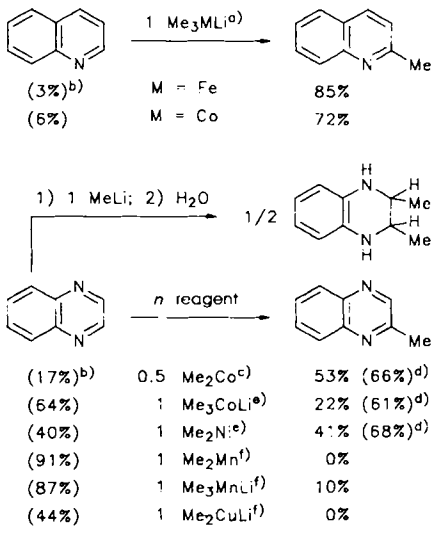
there also gave acetanilide; the best yields are obtained with Me_3FeLi and Me_2Fe.[53e] The mechanism of these methylations is discussed in Section 4.4. 1:1:1 Competition experiments carried out in analogy to Scheme 8 (Et_2O, −78 to 20 °C in 18 h) suggest the following variation of the electrophilic character towards Me_3FeLi:[53e] PhCHO > PhN=C=O > PhCOMe. Me_2CuLi reacts faster with PhN=C=O than with PhCHO.[53e] No studies have yet been carried out to establish whether (as expected) methyl derivatives of Fe^{II} or Co^{II} will methylate carbon dioxide.

In terms of the mechanism, the reaction of Me_3FeLi with *benzalaniline*[17a] (Scheme 30) is remarkable, since the coupling



Scheme 30.

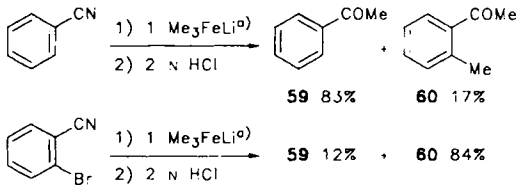
product *meso*-**57** indicates the presence of an electron transfer process (see Section 4.4). The assignment of the configuration of *meso*-**57** was determined by ^{1}H NMR spectroscopy: δ(PhC*H*) − 5.01;[63] *meso*-**57** δ = 4.95, D,L-**57** δ = 4.55. The *ortho*-methylation product **58** is discussed in Section 5.1. Under the conditions shown in Scheme 31, the reactions of Me_3FeLi[17a]



Scheme 31. a) THF, −78 to 20 °C in 18 h [17a,63]; b) recovery; c) Et_2O, −70 °C, 5 days [53d]; d) yields based on unconverted quinoxaline; e) Et_2O, −78 to 20 °C in 18 h [17m]; f) 1 h, −30 °C, 18 h, 20 °C.

or Me_3CoLi[64] with *quinoline* gave 2-methylquinoline in high yield. This product is certainly not formed via MeLi, since neither of the reagents used splits off MeLi in THF (see the β-bromostyrene test in Section 3.1.1); in addition, MeLi would give predominantly 1,2-dihydro-2-methylquinoline under the reaction conditions used which would have to undergo oxidation to form 2-methylquinoline. The products also differ when a transition metal reagent or MeLi is allowed to react with *quinoxaline* (Scheme 31): MeLi does not lead to 2-methylquinoxaline but (in high yield) to 2,3-dimethyl-1,2,3,4-tetrahydroquinoxaline.[17e, 53d] In contrast, the reactions with 0.5 equivalents of Me_3Co[53b, 53d] or Me_2Ni[17m] (Scheme 31) lead to the formation of medium yields of 2-methylquinoxaline as the sole low-molecular weight product, while Me_2Fe[17h] and Me_2Mn[17e] are almost inert towards this heteroarene. The reason for the spontaneous rearomatization that occurs prior to the addition of the transition metal reagents to quinoline and quinoxaline is discussed in Section 4.4.

Nitriles are normally resistant or rather unreactive towards alkyl transition metal reagents. In the case of the well-studied dialkylcuprates this is documented by their position in the "Posner series"[65] RCOCl > RCHO > epoxides > RI > RR'CO > RCO_2R' > RCN. Alkyl-Ti^{IV} derivatives, the second most intensively studied class of alkyl transition metal reagents,[14, 66] are inert towards nitriles, and both $MeHfCl_3$[17b] and Me_3MnLi[17a, d] do not react with benzonitrile. It is thus surprising that the CN group of benzonitrile undergoes quantitative addition with Me_3FeLi under the mild conditions of Scheme 32; subsequent hydrolysis with 2N HCl leads to acetophenone (**59**; 83%) and 2-methylacetophenone (**60**; 17%; due to *ortho*-

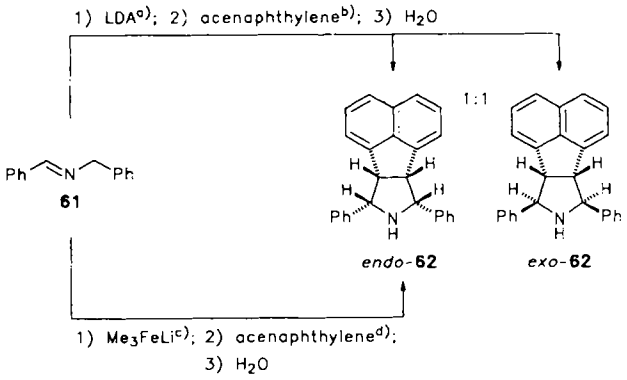


Scheme 32. a) THF, −78 to 20 °C in 18 h.

methylation, see Section 5.1). This attack occurs very rapidly: the yield of acetophenone was 54% after one equivalent of Me_3FeLi was allowed to react for two minutes in THF at −20 °C.[17a] The high reactivity of Me_3FeLi towards the cyano group is confirmed by the reaction with 2-bromobenzonitrile to give **59** and **60**[17a] (Scheme 32). The reactions shown in Scheme 32 could theoretically be caused by MeLi formed by dissociation of Me_3FeLi; apart from the results of the β-bromostyrene-ketone test when carried out with Me_3FeLi (the ketone is not attacked), the formation of the *ortho*-methylation product **60** is also not consistent with such a postulate, since it is not formed when MeLi is allowed to react with benzonitrile.

4.3.2. Stereocontrol of a 1,3-Anionic Cycloaddition by Interactions with Fe Orbitals

The reaction of 1,3-diphenyl-2-azaallyllithium, which can be obtained by lithiation of *N*-benzylidenebenzylamine (**61**) by lithium diisopropylamide (LDA), with acenaphthylene leads to a 1:1 mixture of *endo*-**62** and the thermodynamically more stable *exo*-**62**.[67, 68] If, however, **61** is allowed to react with one molar equivalent of Me_3FeLi (THF, −78 to 20 °C in 18 h) and then treated with acenaphthylene (−78 °C, 18 h) the sole product is *endo*-**62** (55%)[17a] (Scheme 33). The kinetically controlled formation of *endo*-**62** is of more general interest, as it demonstrates that 1,3-anionic cycloadditions[67] are subject to steric control by a transition metal.



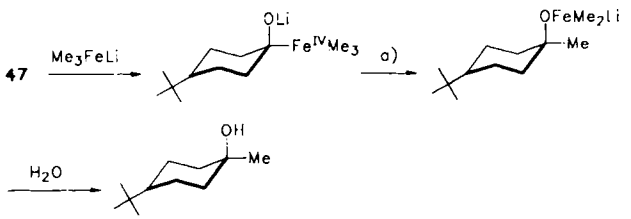
Scheme 33. 1,3-Anionic cycloaddition directed by Fe orbitals. a) THF, −60 to 20 °C; b) 0 °C [67]; c) −78 to 20 °C in 18 h; d) 20 °C [17a].

4.4. Discussion of Reaction Mechanisms

Two classes of methyl reagents containing 3d metals can presently be distinguished: in *category A reagents*, for example $MeTiCl_3$, $MeTi(OiPr)_3$, $MeTi(OiPr)_4Li$, $MeHfCl_3$, $MeV(O)Cl_2$, Me_2NbCl_3, and $MeTaCl_4$, the transition metal is

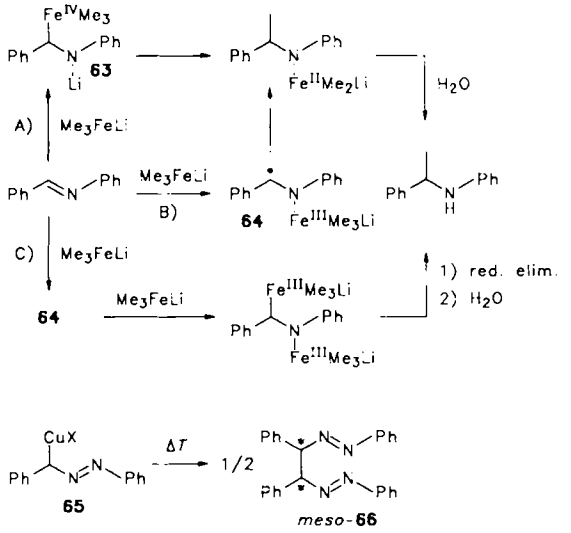
in its highest possible oxidation state; the reagent is characterized by low basicities, as well as reactivity towards aldehydes, ketones, epoxides, and S_N1-active alkyl halides such as allyl and benzyl halides and α-halogenated carboxylates). In *category B reagents*, for example $MeCrCl_2$, Me_3MnLi, Me_2Fe, Me_4CoLi_2, and Me_2CuLi, the transition metal is not in its highest oxidation state; apart from typical substrates for reactions of category A reagents these can also attack S_N1-inactive alkyl halides, 1-alkenyl, aryl, and 1-alkynyl halides, phenyl isocyanate and azomethines as well as (to some extent) electrophilic heteroarenes, nitriles, esters, amides, and CO_2.[69] In their reactions with alkyl halides the category B reagents make use of their ability to undergo oxidative additions (see Section 3.6). They employ this potential in reactions with substrates containing a CO double or CN multiple bond when other modes of reaction are unfavorable. Comparative studies carried out in the author's research group have demonstrated that the nucleophilicity of methyl derivatives of the following metals towards (*E*)-β-bromostyrene and the heteroarene quinoxaline follows the same order in each case: $Mn^{II} < Co^{II} > Cu^{I}$.

It is not clear whether ketones react with category B reagents by the addition mechanism normally found for carbanions or whether the reagent attacks by an oxidative addition. The surprisingly high equatorial selectivity[56] of the methylation of 4-*tert*-butylcyclohexanone (**47**) by Me_3FeLi discussed in Section 4.1.3 could be due to oxidative addition in which the trimethyliron residue (increased in size due to the presence of coordinated THF molecules) is forced to attack from the equatorial side; thus, after reductive elimination the methyl group is located solely in this position (Scheme 34). However, no trace of a dihydrodimerization product of **47** (of the pinacol type) was found; the presence of such a product would also have indicated an oxidative addition step.



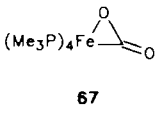
Scheme 34. Possible mechanism for the highly equatorial-selective methylation of 4-*tert*-butylcyclohexanone (**47**) with Me_3FeLi (see also Scheme 26). a) Reductive elimination and complexation of the liberated Me_2Fe to the alkoxide group.

There are several indications that an electron transfer process may be involved in the reactions of category B reagents with CN multiple bonds. When Me_3FeLi is allowed to react with *benzalaniline* (Scheme 30) the formation of a dihydrodimerization product indicates the presence of an oxidative addition step. Assuming that Me_3FeLi reacts as a monomer, the mechanisms A, B, and C shown in Scheme 35 may be involved. The dihydrodimerization product could be formed via the radical **64** or via a species (e.g. **63**) in which the benzylic carbon atom is linked to iron. In the former case D,L-**57** should be formed as well as *meso*-**57** (compare the formation of *meso*-**55** and D,L-**55** in Scheme 27). Since only *meso*-**57** is detected (see Scheme 30), the second possibility (analogous to the homocoupling **65** → *meso*-**66**[70] in Scheme 35) is much more likely.

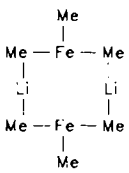


Scheme 35. Possible electron-transfer processes A–C in the methylation of benzalaniline according to Scheme 30 and an interesting stereospecific homocoupling which is of interest in this context [70].

In analogy to the behavior of category A reagents towards acyl chlorides (see Section 3.6) the reagents $MeTiCl_3$, $MeTi(OiPr)_3$, $MeTi(OiPr)_4Li$, $MeTi(OiPr)_4MgBr$, $MeHfCl_3$ and Me_2NbCl_4, which are reactive towards aldehydes and generally also towards ketones, methylate *phenyl isocyanate* only to a very small extent if at all;[53e] the same is true for the behavior of $Me_2V(O)Cl$ towards *methyl isocyanate*[53c] (when the above-mentioned isopropoxytitanium reagents are allowed to react with phenyl isocyanate they instead form PhNHCOO*i*Pr in 40–80% yield[53e]). Phenyl isocyanate is, however, methylated in medium to good yields by $MeCrCl_2$,[53c] Me_3MnLi,[62] $Me_3MnMgBr$,[62] and the derivatives of Fe, Co, and Ni shown in Scheme 29.[53e] Thus, it is likely that these reactions also involve an oxidative addition; in this context it is worth mentioning the two-electron oxidative addition of CO_2 to $(Me_3P)_4Fe$ which leads to the ferraoxirane **67**.[71]

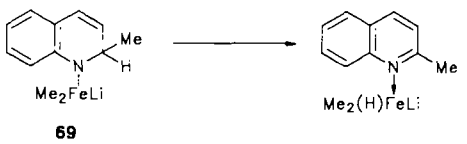


67



68

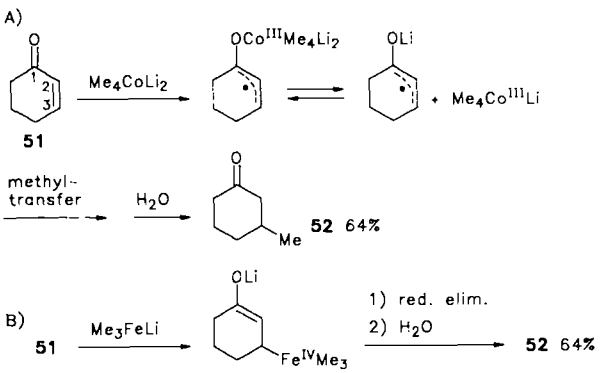
In the methylation of the heteroarenes *quinoline* and *quinoxaline* according to Scheme 31, as well as of *nitriles* according to Scheme 32, the surprisingly high nucleophilicity of the reagents towards these substrates provides evidence for the occurrence of an oxidative addition. Analogous mechanisms to those formulated in Scheme 35 for benzalaniline thus appear likely for the addition step. A synchronous *cis*-addition (insertion) of a Me–Fe or Me–Co bond is also possible. Since in each case these reactions lead to a single species in which the transition metal is bound to the N atom, the spontaneous rearomatization that occurs in the case of quinoline and quinoxaline can readily be explained on the basis of a transition metal induced β-H-elimination, as formulated for compound **69** in Scheme 36. As in the case of all the other mechanistically discussed reactions of Me_3FeLi, the possibility must also be taken into account that this reagent, analogous to Me_2CuLi, can perhaps exist and react in the dimeric form **68**.



69

Scheme 36.

Two processes have been discussed for the often-studied "1,4-addition" of Me_2CuLi to *2-cyclohexenone* (**51**): an initial one-electron transfer step to give a radical anion and alternatively an attack of the dimeric Me_2CuLi at the enone in analogy to the Michael addition at position C-3.[72] When **51** is methylated by methyl–Fe reagents, the ratio of 1,4- to 1,2-addition product (**52**:**53**) decreases with increasing degree of methylation of the transition metal, while the opposite is true for methylation with Co reagents (Table 4). This clearly suggests that two different mechanisms are involved; these could differ in that (as formulated for Me_4CoLi_2 and Me_3FeLi in Scheme 37) the transition



Scheme 37. Possible mechanisms for the methylation reactions **51** → **52** (see also Scheme 27 and Table 4).

metal attacks at either the O atom or at C-3 of **51**. The increase in the ratio **52**:**53** as the degree of methylation at the cobalt atom increases (Table 4) can be explained (assuming a mechanism of type A in Scheme 37) on the basis of increasing steric hindrance to methyl transfer to C-1. The dihydrodimer **55** obtained when Me_3FeLi or, in particular, Me_4FeLi_2 is used (Scheme 27) indicates a one-electron transfer process; compound **55** is probably formed by radical dimerization and not by homocoupling, since a 1:1 mixture of the *meso*- and D,L-forms is obtained.
